There is an 8- to 12-hour delay in the action of warfarin. Its anticoagulant effect results from a balance between partially inhibited synthesis and unaltered degradation of the four vitamin K-dependent clotting factors. The resulting inhibition of coagulation is dependent on their degradation rate in the circulation. These half-lives are 6, 24, 40, and 60 hours for factors VII, IX, X, and II, respectively. Larger initial doses of warfarin—up to about 0.75 mg/kg—hasten the onset of the anticoagulant effect. Beyond this dosage, the speed of onset is independent of the dose size. The only effect of a larger loading dose is to prolong the time that the plasma concentration of drug remains above that required for suppression of clotting factor synthesis. The only difference among oral anticoagulants in producing and maintaining hypoprothrombinemia is the half-life of each drug.

Toxicity

Warfarin crosses the placenta readily and can cause a hemorrhagic disorder in the fetus. Furthermore, fetal proteins with γ -carboxyglutamate residues found in bone and blood may be affected by warfarin; the drug can cause a serious birth defect characterized by abnormal bone formation. Thus, warfarin should never be administered during pregnancy. Cutaneous necrosis with reduced activity of protein C sometimes occurs during the first weeks of therapy. Rarely, the same process causes frank infarction of breast, fatty tissues, intestine, and extremities. The pathologic lesion associated with the hemorrhagic infarction is venous thrombosis, suggesting that it is caused by warfarin-induced depression of protein C synthesis.

Administration & Dosage

Treatment with warfarin should be initiated with standard doses of 5–10 mg rather than the large loading doses formerly used. The initial adjustment of the prothrombin time takes about 1 week, which usually results in a maintenance dose of 5–7 mg/d. The prothrombin time should be increased to a level representing a reduction of prothrombin activity to 25% of normal and maintained there for long-term therapy. When the activity is less than 20%, the warfarin dosage should be reduced or omitted until the activity rises above 20%.

The therapeutic range for oral anticoagulant therapy is now defined in terms of an international normalized ratio (INR). The INR is the prothrombin time ratio (test/control) obtained if the more sensitive international reference thromboplastin made from human brain is used rather than the less sensitive rabbit brain thromboplastin used in North America. Randomized prospective studies with the INR system have resulted in use of lower doses of anticoagulant drug and less bleeding, yet the efficacy is equal to that of the regimens with higher doses. These less intensive and lower dose regimens are efficacious for many therapeutic indications. Analysis of several clinical trials in patients with artificial heart valves has led to the recommendation that dosage be adjusted to achieve an INR of 2.5–3.5.

Drug Interactions

The oral anticoagulants often interact with other drugs and with disease states. These interactions can be broadly divided into **pharmacokinetic** and **pharmacodynamic** effects (Table 34–2). Pharmacokinetic mechanisms for drug interaction with oral anticoagulants are mainly **enzyme induction, enzyme inhibition, and reduced plasma protein binding**. Pharmacodynamic mechanisms for interactions with warfarin are **synergism** (impaired hemostasis, reduced clotting factor synthesis, as in hepatic disease), **competitive antagonism** (vitamin K), and an **altered physiologic control loop for vitamin K** (hereditary resistance to oral anticoagulants).

Table 34–2. Pharmacokinetic and Pharmacodynamic Drug and Body Interactions with Oral Anticoagulants.

Increased Prothrombin Time		Decreased Prothrombin Time	
Pharmacokinetic	Pharmacodynamic	Pharmacokinetic	Pharmacodynamic
Amiodarone	Drugs	Barbiturates	Drugs
Cimetidine	Aspirin (high doses)	Cholestyramine	Diuretics
Disulfiram	Cephalosporins, third-generation	Rifampin	Vitamin K
Metronidazole ¹	Heparin		Body factors
Fluconazole ¹			Hereditary resistance
Phenylbutazone ¹	Body factors		Hypothyroidism
Sulfinpyrazone ¹	Hepatic disease		

Trimethoprim-sulfamethoxazole	Hyperthyroidism		
¹ Stereoselectively inhibits the oxidative metabolism of the (<i>S</i>)-warfarin enantiomorph of racemic warfarin.			

The most serious interactions with warfarin are those that increase the anticoagulant effect and the risk of bleeding. The most dangerous of these interactions are the pharmacokinetic interactions with the pyrazolones phenylbutazone and sulfinpyrazone. These drugs not only augment the hypoprothrombinemia but also inhibit platelet function and may induce peptic ulcer disease (see Chapter 36: Nonsteroidal Anti-Inflammatory Drugs, Disease-Modifying Antirheumatic Drugs, Nonopioid Analgesics, & Drugs Used in Gout). The mechanisms for their hypoprothrombinemic interaction are a stereoselective inhibition of oxidative metabolic transformation of *S*-warfarin (the more potent isomer) and displacement of albumin-bound warfarin, increasing the free fraction. For this and other reasons, neither phenylbutazone nor sulfinpyrazone is in common use in the USA. Metronidazole, fluconazole, and trimethoprim-sulfamethoxazole also stereoselectively inhibit the metabolic transformation of *S*-warfarin, whereas amiodarone, disulfiram, and cimetidine inhibit metabolism of both enantiomorphs of warfarin. Aspirin, hepatic disease, and hyperthyroidism augment warfarin pharmacodynamically— aspirin by its effect on platelet function and the latter two by increasing the turnover rate of clotting factors. The third-generation cephalosporins eliminate the bacteria in the intestinal tract that produce vitamin K and, like warfarin, also directly inhibit vitamin K epoxide reductase. Heparin directly prolongs the prothrombin time by inhibiting the activity of several clotting factors.

Barbiturates and rifampin cause a marked *decrease* of the anticoagulant effect by induction of the hepatic enzymes that transform racemic warfarin. Cholestyramine binds warfarin in the intestine and reduces its absorption and bioavailability.

Pharmacodynamic reductions of anticoagulant effect occur with vitamin K (increased synthesis of clotting factors), the diuretics chlorthalidone and spironolactone (clotting factor concentration), hereditary resistance (mutation of vitamin K reactivation cycle molecules), and hypothyroidism (decreased turnover rate of clotting factors).

Drugs with *no* significant effect on anticoagulant therapy include ethanol, phenothiazines, benzodiazepines, acetaminophen, opioids, indomethacin, and most antibiotics.

Reversal of Action

Excessive anticoagulant effect and bleeding from warfarin can be reversed by stopping the drug and administering vitamin K1 (phytonadione), fresh-frozen plasma, prothrombin complex concentrates (PCC) such as Bebulin and Proplex T, and recombinant factor VIIa (rFVIIa). The disappearance of excessive effect is not correlated with plasma warfarin concentrations but rather with reestablishment of normal activity of the clotting factors. A modest excess of anticoagulant effect without bleeding may require no more than cessation of the drug. The warfarin effect can be rapidly reversed in the setting of severe bleeding with the administration of a prothrombin complex or recombinant factor VIIa coupled with intravenous vitamin K.

Analogs & Variants

Vitamin K antagonists other than warfarin are seldom used, because they have less favorable

pharmacologic properties or greater toxicity. **Dicumarol** is incompletely absorbed and frequently causes gastrointestinal symptoms. **Phenprocoumon** has a long half-life of 6 days—a disadvantage should toxicity occur. The indanedione group, which includes phenindione and diphenadione, has potentially serious adverse effects in the kidney and liver and is of little clinical use.

Basic Pharmacology of the Fibrinolytic Drugs

Fibrinolytic drugs rapidly lyse thrombi by catalyzing the formation of the serine protease **plasmin** from its precursor zymogen, plasminogen (Figure 34–3). These drugs (**streptokinase, alteplase, anistreplase, tissue plasminogen activator, reteplase, tenecteplase, and urokinase**) create a generalized lytic state when administered intravenously. Thus, both protective hemostatic thrombi and target thromboemboli are broken down. The section Thrombolytic Drugs for Acute Myocardial Infarction describes the use of these drugs in one major application.

Pharmacology

Streptokinase is a protein (but not an enzyme in itself) synthesized by streptococci that combines with the proactivator plasminogen. This enzymatic complex catalyzes the conversion of inactive plasminogen to active plasmin. **Urokinase** is a human enzyme synthesized by the kidney that directly converts plasminogen to active plasmin. Plasmin itself cannot be used because naturally occurring inhibitors in plasma prevent its effects. However, the absence of inhibitors for urokinase and the streptokinase-proactivator complex permit their use clinically. Plasmin formed inside a thrombus by these activators is protected from plasma antiplasmins, which allows it to lyse the thrombus from within.

Anistreplase (anisoylated plasminogen streptokinase activator complex; APSAC) consists of a complex of purified human plasminogen and bacterial streptokinase that has been acylated to protect the enzyme's active site. When administered, the acyl group spontaneously hydrolyzes, freeing the activated streptokinase-proactivator complex. This product (recently discontinued in the USA) allows for rapid intravenous injection, greater clot selectivity (ie, more activity on plasminogen associated with clots than on free plasminogen in the blood), and more thrombolytic activity.

Plasminogen can also be activated endogenously by **tissue plasminogen activators (t-PA)**. These activators preferentially activate plasminogen that is bound to fibrin, which (in theory) confines fibrinolysis to the formed thrombus and avoids systemic activation. Human t-PA is manufactured as alteplase by means of recombinant DNA technology.

Reteplase is another recombinant human t-PA from which several amino acid sequences have been deleted. Reteplase is less expensive to produce than t-PA. Because it lacks the major fibrin-binding domain, reteplase is less fibrin-specific than t-PA. **Tenecteplase** is a mutant form of t-PA that has a longer half-life, and it can be given as an intravenous bolus. Tenecteplase is slightly more fibrin-specific than t-PA.

Indications & Dosage

Use of fibrinolytic drugs by the intravenous route is indicated in cases of **multiple pulmonary emboli** that are not massive enough to require surgical management. Intravenous fibrinolytic drugs

are also indicated in cases of **central deep venous thrombosis** such as the superior vena caval syndrome and ascending thrombophlebitis of the iliofemoral vein. They have also been used intrarterially, especially for peripheral vascular disease.

Thrombolytic therapy in the management of **acute myocardial infarction** requires careful patient selection, the use of a specific thrombolytic agent, and the benefit of adjuvant therapy. Considerable controversy surrounds the question of greater safety or efficacy of t-PA compared with the other thrombolytic agents (see Thrombolytic Drugs for Acute Myocardial Infarction).

Streptokinase is administered by intravenous infusion of a loading dose of 250,000 units, followed by 100,000 units/h for 24–72 hours. Patients with antistreptococcal antibodies can develop fever, allergic reactions, and therapeutic resistance. Urokinase requires a loading dose of 300,000 units given over 10 minutes and a maintenance dose of 300,000 units/h for 12 hours. Alteplase (t-PA) is given by intravenous infusion of 60 mg over the first hour and then 40 mg at a rate of 20 mg/h. Reteplase is given as two intravenous bolus injections of 10 units each, separated by 30 minutes. Tenecteplase is given as a single intravenous bolus of 0.5 mg/kg. Anistreplase is given as a single intravenous injection of 30 units over 3–5 minutes. A single course of fibrinolytic drugs is expensive: hundreds of dollars for streptokinase and thousands for urokinase and t-PA.

Recombinant tissue plasminogen activator has increasingly been used for patients presenting with acute stroke symptoms. A recent outcomes study demonstrated an advantage with respect to neurologic disability at 1 year in those patients with acute ischemic stroke who received intravenous t-PA within 3 hours after onset of symptoms.

Thrombolytic Drugs for Acute Myocardial Infarction

Background: The paradigm shift in 1980 on the causation of acute myocardial infarction to acute coronary occlusion by a thrombus created the rationale for thrombolytic therapy of this common lethal disease. At that time—and for the first time—intravenous thrombolytic therapy for acute myocardial infarction in the European Cooperative Study Group trial was found to reduce mortality significantly. Later studies, with thousands of patients in each trial, provided enough statistical power for the 20% reduction in mortality to be considered statistically significant. Although the standard of care in areas with adequate facilities and experience in percutaneous coronary intervention (PCI) now favors catheterization and placement of a stent, thrombolytic therapy is still very important where PCI is not readily available.

Patients: The selection of patients for thrombolytic therapy is critical. The diagnosis of acute myocardial infarction is made clinically and is confirmed by electrocardiography. Patients with ST segment elevation and bundle branch block on electrocardiography do best; those with ST segment depression or a normal ECG do less well; and those with non-Q-wave acute myocardial infarction may even be harmed. All trials to date show the greatest benefit for thrombolytic therapy when it is given early, within 6 hours after symptomatic onset of acute myocardial infarction.

Clinical trials: One of the trials (ISIS-3) showed that streptokinase plus aspirin performed as well as recombinant tissue-type plasminogen activator (rt-PA) or complex formulations of streptokinase such as anistreplase (APSAC). The GUSTO trial showed a small advantage for the much more expensive t-PA over streptokinase, but with a significantly higher risk of hemorrhagic stroke. Nine clinical trials—each containing over 1000 patients with suspected acute myocardial infarction—

reported 11.6% mortality at 35 days in the control group and 9.5% in the treatment group, an 18% reduction in mortality.

Adjunctive drugs: The best results occur with thrombolytic drugs supplemented by other drugs. β -Blocker drugs reduced myocardial ischemia and infarct size, prevented arrhythmias, decreased reinfarction, and improved survival in ISIS-1 and GISSI-1. Aspirin alone and with streptokinase reduced mortality in ISIS-2. Nitroglycerin, given early in acute myocardial infarction for pain relief, had no beneficial effect on mortality in GISSI-3 and ISIS-4. Oral anticoagulants are best used in patients with depressed left ventricular function or systemic embolization. Heparin was a necessary adjunct for t-PA in GUSTO but was less useful with streptokinase plus aspirin because of the increased risk of bleeding. ACE inhibitors reduced infarct expansion and arrhythmias and improved survival in GISSI-3. Direct thrombin inhibitors like hirudin and bivalirudin are undergoing clinical trials to better determine their efficacy in conjunction with thrombolytic therapy (TIMI-9B, GUSTO-2A, OASIS, HERO).

Summary: Thrombolytic drugs reduce the mortality of acute myocardial infarction. The early and appropriate use of any thrombolytic drug probably transcends individual advantages. Adjunctive drugs like aspirin, β -blockers, and ACE inhibitors reduce mortality even further. The principles of management are outlined in part 7 of the American Heart Association Guidelines, 2000.

Katzung PHARMACOLOGY, 9e > Section VI. Drugs Used to Treat Disease of the Blood, Inflammation, & Gout > Chapter 34. Drugs Used in Disorders of Coagulation >

Basic Pharmacology of Antiplatelet Agents

Platelet function is regulated by three categories of substances. The first group consists of agents generated outside the platelet that interact with platelet membrane receptors, eg, catecholamines, collagen, thrombin, and prostacyclin. The second category contains agents generated within the platelet that interact with membrane receptors, eg, ADP, prostaglandin D₂, prostaglandin E₂, and serotonin. The third group comprises agents generated within the platelet that act within the platelet, eg, prostaglandin endoperoxides and thromboxane A₂, the cyclic nucleotides cAMP and cGMP, and calcium ion. From this list of agents, several targets for platelet inhibitory drugs have been identified (Figure 34–1): inhibition of prostaglandin metabolism (aspirin), inhibition of ADP-induced platelet aggregation (clopidogrel, ticlopidine), and blockade of GP IIb/IIIa receptors on platelets (abciximab, tirofiban, and eptifibatid). Dipyridamole and cilostazol are additional antiplatelet drugs.

Aspirin

The prostaglandin **thromboxane A₂** is an arachidonate product that causes platelets to change shape, to release their granules, and to aggregate (see Chapter 18: The Eicosanoids: Prostaglandins, Thromboxanes, Leukotrienes, & Related Compounds). Drugs that antagonize this pathway interfere with platelet aggregation in vitro and prolong the bleeding time in vivo. **Aspirin** is the prototype of this class of drugs. Drugs that modulate the intraplatelet concentration of cAMP do not prolong the bleeding time. However, dietary therapy can be useful in the prophylaxis of thrombosis. Ingestion of the unsaturated fatty acid **eicosapentaenoic acid**, which is high in cold water fish, generates prostaglandin I₃, an effective antiaggregating substance like prostacyclin, and thromboxane A₃, which is much less active than TXA₂ (Chapter 18: The Eicosanoids: Prostaglandins, Thromboxanes, Leukotrienes, & Related Compounds).

As described in Chapter 18: The Eicosanoids: Prostaglandins, Thromboxanes, Leukotrienes, &

Related Compounds, aspirin inhibits the synthesis of thromboxane A₂ by irreversible acetylation of the enzyme cyclooxygenase. Other salicylates and nonsteroidal anti-inflammatory drugs also inhibit cyclooxygenase but have a shorter duration of inhibitory action because they cannot acetylate cyclooxygenase, ie, their action is reversible.

The FDA has approved the use of 325 mg/d for *primary* prophylaxis of myocardial infarction but urges caution in this use of aspirin by the general population except when prescribed as an adjunct to risk factor management by smoking cessation and lowering of blood cholesterol and blood pressure. Meta-analysis of many published trials of aspirin and other antiplatelet agents confirms the value of this intervention in the *secondary* prevention of vascular events among patients with a history of vascular events.

Clopidogrel & Ticlopidine

Clopidogrel and ticlopidine reduce platelet aggregation by inhibiting the ADP pathway of platelets. These drugs are thienopyridine derivatives that achieve their antiplatelet effects by irreversibly blocking the ADP receptor on platelets. Unlike aspirin, these drugs have no effect on prostaglandin metabolism. Randomized clinical trials with both drugs report efficacy in the prevention of vascular events among patients with transient ischemic attacks, completed strokes, and unstable angina pectoris. Use of clopidogrel or ticlopidine to prevent thrombosis is now considered standard practice in patients undergoing placement of a coronary stent.

Adverse effects of ticlopidine include nausea, dyspepsia, and diarrhea in up to 20% of patients, hemorrhage in 5%, and, most seriously, leukopenia in 1%. The leukopenia is detected by regular monitoring of the white blood cell count during the first 3 months of treatment. Development of thrombotic thrombocytopenic purpura (TTP) has also been associated with the ingestion of ticlopidine. The dosage of ticlopidine is 250 mg twice daily. It is particularly useful in patients who cannot tolerate aspirin. Doses of ticlopidine less than 500 mg/d may be efficacious with fewer adverse effects.

Clopidogrel has fewer adverse effects than ticlopidine and is rarely associated with neutropenia. Thrombotic thrombocytopenic purpura associated with clopidogrel has recently been reported. Because of its superior side effect profile and dosing requirements, clopidogrel is preferred over ticlopidine. The antithrombotic effects of clopidogrel are dose-dependent; within 5 hours after an oral loading dose of 300 mg, 80% of platelet activity will be inhibited. The maintenance dose of clopidogrel is 75 mg/d, which achieves maximum platelet inhibition. The duration of the antiplatelet effect is 7–10 days.

Blockade of Platelet Gp IIb/IIIa Receptors

The glycoprotein IIb/IIIa inhibitors are used in patients with acute coronary syndromes. These drugs target the platelet IIb/IIIa receptor complex (Figure 34–1). The IIb/IIIa complex functions as a receptor mainly for fibrinogen and vitronectin but also for fibronectin and von Willebrand factor. Activation of this receptor complex is the "final common pathway" for platelet aggregation. There are approximately 50,000 copies of this complex on the platelet surface. Persons lacking this receptor have a bleeding disorder called Glanzmann's thrombasthenia.

Abciximab, a humanized monoclonal antibody directed against the IIb/IIIa complex including the vitronectin receptor, was the first agent approved in this class of drugs. It has been approved for use in percutaneous coronary intervention and in acute coronary syndromes. **Eptifibatide** is an analog of the sequence at the extreme carboxyl terminal of the delta chain of fi-brinogen, which mediates

the binding of fibrinogen to the receptor. **Tirofiban** is a smaller molecule with similar properties. Eptifibatide and tirofiban inhibit ligand binding to the IIb/IIIa receptor by their occupancy of the receptor but do not block the vitronectin receptor.

The three agents described above are administered parenterally. Oral formulations of IIb/IIIa antagonists have been developed and are in various stages of development. Thus far, however, lack of efficacy and significant thrombocytopenia have prevented progress with the oral analogs.

Additional Antiplatelet-Directed Drugs

Dipyridamole is a vasodilator that inhibits platelet function by inhibiting adenosine uptake and cyclic GMP phosphodiesterase activity. Dipyridamole by itself has little or no beneficial effect. Therefore, therapeutic use of this agent is primarily in combination with aspirin to prevent cerebrovascular ischemia. It may also be used in combination with warfarin for primary prophylaxis of thromboemboli in patients with prosthetic heart valves. A combination of dipyridamole complexed with 25 mg of aspirin is now available for secondary prophylaxis of cerebrovascular disease.

Cilostazol is a newer phosphodiesterase inhibitor that promotes vasodilation and inhibition of platelet aggregation. Cilostazol is used primarily to treat intermittent claudication.

Katzung PHARMACOLOGY, 9e > Section VI. Drugs Used to Treat Disease of the Blood, Inflammation, & Gout > Chapter 34. Drugs Used in Disorders of Coagulation >

Clinical Pharmacology of Drugs Used to Prevent Clotting

Venous Thrombosis

Risk Factors

Inherited Disorders

The inherited disorders characterized by an tendency to form thrombi (thrombophilia) derive from either quantitative or qualitative abnormalities of the natural anticoagulant system. Deficiencies in the natural anticoagulants antithrombin, protein C, and protein S account for approximately 15% of selected patients with juvenile or recurrent thrombosis and 5–10% of unselected cases of acute venous thrombosis. Additional causes of thrombophilia include the factor V Leiden mutation, hyperhomocystinemia, and the prothrombin 20210 mutation that together account for the greater number of hypercoagulable patients.

Acquired Disease

The increased risk of thromboembolism associated with arrhythmia, primarily atrial fibrillation, and the placement of mechanical heart valves has long been recognized. Similarly, prolonged bed rest, high-risk surgical procedures, and the presence of cancer are clearly associated with an increased incidence of deep venous thrombosis and embolism.

Antithrombotic Management

Prevention

Primary prevention of venous thrombosis reduces the incidence of and mortality rate from pulmonary emboli. Heparin and warfarin may be used to prevent venous thrombosis. Subcutaneous administration of low-dose unfractionated heparin, low-molecular-weight heparin, or fondaparinux provides effective prophylaxis. Warfarin is also effective but requires laboratory monitoring of the prothrombin time.

Treatment of Established Disease

Treatment for established venous thrombosis is initiated with unfractionated or low-molecular-weight heparin for the first 5–7 days, with an overlap with warfarin. Once therapeutic effects of warfarin have been established, therapy with warfarin is continued for a minimum of 3–6 months. Patients with recurrent disease or identifiable, nonreversible risk factors may be treated indefinitely. Small thrombi confined to the calf veins may be managed without anticoagulants if there is documentation over time that the thrombus is not extending.

Warfarin readily crosses the placenta. It can cause hemorrhage at any time during pregnancy as well as developmental defects when administered during the first trimester. Therefore, venous thromboembolic disease in pregnant women is generally treated with heparin, best administered by subcutaneous injection.

Arterial Thrombosis

Activation of platelets is considered an essential process for arterial thrombosis. Thus, treatment with platelet-inhibiting drugs such as aspirin and ticlopidine or clopidogrel is indicated in patients with transient ischemic attacks and strokes or unstable angina and acute myocardial infarction. In angina and infarction, these drugs are often used in conjunction with β -blockers, calcium channel blockers, and fibrinolytic drugs.

Katzung PHARMACOLOGY, 9e > Section VI. Drugs Used to Treat Disease of the Blood, Inflammation, & Gout > Chapter 34. Drugs Used in Disorders of Coagulation >

Drugs Used in Bleeding Disorders

Vitamin K

Vitamin K confers biologic activity upon prothrombin and factors VII, IX, and X by participating in their postribosomal modification. Vitamin K is a fat-soluble substance found primarily in leafy green vegetables. The dietary requirement is low, because the vitamin is additionally synthesized by bacteria that colonize the human intestine. Two natural forms exist: vitamins K₁ and K₂. Vitamin K₁ (phytonadione; Figure 34–5) is found in food. Vitamin K₂ (menaquinone) is found in human tissues and is synthesized by intestinal bacteria.

Vitamins K₁ and K₂ require bile salts for absorption from the intestinal tract. Vitamin K₁ is available clinically in 5 mg tablets and 50 mg ampules. Onset of effect is delayed for 6 hours but the effect is complete by 24 hours when treating depression of prothrombin activity by excess warfarin or vitamin K deficiency. Intravenous administration of vitamin K₁ should be slow, because rapid infusion can produce dyspnea, chest and back pain, and even death. Vitamin K repletion is best achieved with intravenous or oral administration, because its bioavailability after subcutaneous administration is erratic. Vitamin K₁ is currently administered to all newborns to prevent the

hemorrhagic disease of vitamin K deficiency, which is especially common in premature infants. The water-soluble salt of vitamin K₃ (menadione) should never be used in therapeutics. It is particularly ineffective in the treatment of warfarin overdose. Vitamin K deficiency frequently occurs in hospitalized patients in intensive care units because of poor diet, parenteral nutrition, recent surgery, multiple antibiotic therapy, and uremia. Severe hepatic failure results in diminished protein synthesis and a hemorrhagic diathesis that is unresponsive to vitamin K.

Plasma Fractions

Sources & Preparations

Deficiencies in plasma coagulation factors can cause bleeding (Table 34–3). Spontaneous bleeding occurs when factor activity is less than 5–10% of normal. Factor VIII deficiency (classic hemophilia, or hemophilia A) and factor IX deficiency (Christmas disease, or hemophilia B) account for most of the heritable coagulation defects. Concentrated plasma fractions are available for the treatment of these deficiencies. Administration of plasma-derived, heat- or detergent-treated factor concentrates and recombinant factor concentrates are the standard treatments for bleeding associated with hemophilia. Lyophilized factor VIII concentrates are prepared from large pools of plasma. Transmission of viral diseases such as hepatitis B and C and AIDS is reduced or eliminated by pasteurization and by extraction of plasma with solvents and detergents. The best use of these therapeutic materials requires diagnostic specificity of the deficient factor and quantitation of its activity in plasma. Intermediate purity factor VIII concentrates (as opposed to recombinant or high-purity concentrates) contain significant amounts of von Willebrand factor. Humate-P is a factor VIII concentrate that is approved by the FDA for the treatment of bleeding associated with von Willebrand disease.

Table 34–3. Therapeutic Products for the Treatment of Coagulation Disorders.

Factor	Deficiency State	Hemostatic Levels	Half-Life of Infused Factor	Replacement Source
I	Hypofibrinogenemia	1 g/dL	4 days	Cryoprecipitate FFP
II	Prothrombin deficiency	30–40%	3 days	Prothrombin complex concentrates (intermediate purity factor IX concentrates)
V	Factor V deficiency	20%	1 day	FFP
VII	Factor VII deficiency	30%	4–6 hours	FFP Prothrombin complex concentrates (intermediate purity factor IX concentrates) rFVIIa

VIII	Hemophilia A	30–50% 100% for major bleeding or trauma	12 hours	Recombinant factor VIII products Plasma-derived high purity concentrates ¹ Cryoprecipitate Some patients with mild deficiency will respond to DDAVP
IX	Hemophilia B Christmas disease	30–50% 100% for major bleeding or trauma	24 hours	Recombinant F IX products Plasma-derived high purity concentrates
X	Stuart-Prower defect	25%	36 hours	FFP Prothrombin complex concentrates
XI	Hemophilia C	30–50%	3 days	FFP
XII	Hageman defect	Not required		Treatment not necessary
Von Willebrand	Von Willebrand disease	30%	Approximately 10 hours	Intermediate purity factor VIII concentrates that contain von Willebrand factor Some patients respond to DDAVP ¹ Cryoprecipitate
XIII	Factor XIII deficiency	5%	6 days	FFP Cryoprecipitate

FFP, fresh frozen plasma.

Antithrombin and activated protein C concentrates are available for the appropriate indications that include thrombosis in the setting of antithrombin deficiency and sepsis respectively.

¹Cryoprecipitate should be used to treat bleeding in the setting of factor VIII deficiency and von Willebrand disease only in an emergency in which pathogen-inactivated products are not available.

Clinical Uses

An uncomplicated hemorrhage into a joint should be treated with sufficient factor VIII or factor IX replacement to maintain a level of at least 30–50% of the normal concentration for 24 hours. Soft

tissue hematomas require a minimum of 100% activity for 7 days. Hematuria requires at least 10% activity for 3 days. Surgery and major trauma require a minimum of 100% activity for 10 days. The initial loading dose for factor VIII is 50 units/kg of body weight to achieve 100% activity of factor VIII from a baseline of $\leq 1\%$, assuming a normal hemoglobin. Each unit of factor VIII per kilogram of body weight raises its activity in plasma 2%. Replacement should be administered every 12 hours. Factor IX therapy requires twice the dose of factor VIII, but with an administration of about every 24 hours because of its longer half-life. Recombinant factor IX has only 80% recovery compared to plasma-derived factor IX products. Therefore, dosing with recombinant factor IX requires 120% of the dose used with the plasma-derived product.

Desmopressin acetate (arginine vasopressin) increases the factor VIII activity of patients with mild hemophilia A or von Willebrand disease. It can be used in preparation for minor surgery such as tooth extraction without any requirement for infusion of clotting factors if the patient has a documented adequate response. High-dose intranasal desmopressin (see Chapter 17: Vasoactive Peptides) is available and has been shown to be efficacious and well tolerated by patients.

Freeze-dried concentrates of plasma containing prothrombin, factors IX and X, and varied amounts of factor VII (Proplex, etc) are commercially available for treating deficiencies of these factors (Table 34–3). Each unit of factor IX per kilogram of body weight raises its activity in plasma 1.5%. Heparin is often added to inhibit coagulation factors activated by the manufacturing process. However, addition of heparin does not eliminate all thromboembolic events.

Some preparations of factor IX concentrate contain *activated* clotting factors, which has led to their use in treating patients with inhibitors or antibodies to factor VIII or factor IX. Two products are available expressly for this purpose: **Autoplex** (with factor VIII correctional activity) and **Feiba** (with factor VIII inhibitor bypassing activity). These products are not uniformly successful in arresting hemorrhage, and the factor IX inhibitor titers often rise after treatment with them. Acquired inhibitors of coagulation factors may also be treated with porcine factor VIII (for factor VIII inhibitors) and recombinant activated factor VII. Recombinant activated factor VII (**NovoSeven**) is being increasingly used to treat coagulopathy associated with liver disease and major blood loss in trauma and surgery. These recombinant and plasma-derived factor concentrates are very expensive, and the indications for them are very precise. Therefore, close consultation with a hematologist knowledgeable in this area is essential.

Cryoprecipitate is a plasma protein fraction obtainable from whole blood. It is used to treat deficiencies or qualitative abnormalities of fibrinogen, such as that which occurs with disseminated intravascular coagulation and liver disease. A single unit of cryoprecipitate contains 300 mg of fibrinogen.

Cryoprecipitate may also be used for patients with factor VIII deficiency and von Willebrand disease if desmopressin is not indicated and a pathogen-inactivated recombinant or plasma-derived product is not available. The concentration of factor VIII and von Willebrand factor in cryoprecipitate is not as great as that found in the concentrated plasma fractions. Moreover, cryoprecipitate is not treated in any manner to decrease the risk of viral exposure. For infusion, the frozen cryoprecipitate unit is thawed and dissolved in a small volume of sterile citrate-saline solution and pooled with other units. Rh-negative women with potential for childbearing should receive only Rh-negative cryoprecipitate because of possible contamination of the product with Rh-positive blood cells.

Fibrinolytic Inhibitors: Aminocaproic Acid

Aminocaproic acid (EACA), which is chemically similar to the amino acid lysine, is a synthetic inhibitor of fibrinolysis. It competitively inhibits plasminogen activation (Figure 34–3). It is rapidly absorbed orally and is cleared from the body by the kidney. The usual oral dosage of EACA is 6 g four times a day. When the drug is administered intravenously, a 5 g loading dose should be infused over 30 minutes to avoid hypotension. **Tranexamic acid** is an analog of aminocaproic acid and has the same properties. It is administered orally with a 15 mg/kg loading dose followed by 30 mg/kg every 6 hours, but the drug is not currently available in the United States.

Clinical uses of aminocaproic acid are as adjunctive therapy in hemophilia, as therapy for bleeding from fibrinolytic therapy, and as prophylaxis for rebleeding from intracranial aneurysms. Treatment success has also been reported in patients with postsurgical gastrointestinal bleeding and postprostatectomy bleeding and bladder hemorrhage secondary to radiation- and drug-induced cystitis. Adverse effects of the drug include intravascular thrombosis from inhibition of plasminogen activator, hypotension, myopathy, abdominal discomfort, diarrhea, and nasal stuffiness. The drug should not be used in patients with disseminated intravascular coagulation or genitourinary bleeding of the upper tract, eg, kidney and ureters, because of the potential for excessive clotting.

Serine Protease Inhibitors: Aprotinin

Aprotinin is a serine protease inhibitor ("serpin") that inhibits fibrinolysis by free plasmin and may have other antihemorrhagic effects as well. It also inhibits the plasmin-streptokinase complex in patients who have received that thrombolytic agent. Aprotinin will reduce bleeding—by as much as 50%—from many types of surgery, especially that involving extracorporeal circulation for open heart procedures and liver transplantation. It is currently approved for use in patients undergoing coronary artery bypass grafting who are at high risk of excessive blood loss. In placebo-controlled trials, adverse effects of aprotinin were little different from those reported in patients in the placebo group. In larger studies, a possible association with anaphylaxis has been reported in < 0.5% of cases. Therefore, a small test dose is recommended before the full therapeutic dose is given.

Preparations Available

Abciximab (ReoPro)

Parenteral: 2 mg/mL for IV injection

Alteplase recombinant [t-PA] (Activase*)

Parenteral: 50, 100 mg lyophilized powder to reconstitute for IV injection

Aminocaproic acid (generic, Amicar)

Oral: 500 mg tablets; 250 mg/mL syrup

Parenteral: 250 mg/mL for IV injection

Anisindione (Miradon)

Oral: 50 mg tablets

Antihemophilic factor [factor VIII, AHF] (Alphanate, Bioclote*, Helixate*, Hemofil M, Koate-HP, Kogenate*, Monoclate, Recombinate,* others)* Recombinant product.

Parenteral: in vials

Anti-inhibitor coagulant complex (Autoplex T, Feiba VH Immuno)

Parenteral: in vials

Antithrombin III (Thrombate III)

Parenteral: 500, 1000 IU powder to reconstitute for IV injection

Aprotinin (Trasylol)

Parenteral: 10,000 units/mL in 100 and 200 mL vials

Argatroban

Parenteral: 100 mg/ml in 2.5 mL vials

Bivalirudin (Angiomax)

Parenteral: 250 mg per vial

Cilostazol (Pletal)

Oral: 50, 100 mg tablets

Clopidogrel (Plavix)

Oral: 75 mg tablets

Coagulation factor VIIa recombinant (Novo- Seven*)

Parenteral: 1.2, 4.8 mg powder/vial for IV injection

Dalteparin (Fragmin)

Parenteral: 2500, 5000, 10,000 anti-factor Xa units/0.2 mL for SC injection only

Danaparoid (Orgaran)

Parenteral: 750 anti-Xa units/vial

Dipyridamole (Persantine)

Oral: 25, 50, 75 mg tablets

Oral combination product (Aggrenox): 200 mg extended-release dipyridamole plus 25 mg aspirin

Enoxaparin (low-molecular-weight heparin, Lovenox)

Parenteral: pre-filled, multiple-dose syringes for SC injection only

Eptifibatid (Integrilin)

Parenteral: 0.75, 2 mg/mL for IV infusion

Factor VIIa: see Coagulation factor VIIa recombinant

Factor VIII: see Antihemophilic factor

Factor IX complex, human (AlphaNine SD, Bebulin VH, BeneFix*, Konyne 80, Mononine, Profilnine SD, Proplex T, Proplex SX-T)

Parenteral: in vials

Fondaparinux (Arixtra)

Parenteral: 2.5 mg in 0.5 mL single-dose prefilled syringes

Heparin sodium (generic, Liquaemin)

Parenteral: 1000, 2000, 2500, 5000, 10,000, 20,000, 40,000 units/mL for injection

Lepirudin (Refludan*)

Parenteral: 50 mg powder for IV injection

Phytonadione [K₁] (generic, Mephyton, AquaMephyton)

Oral: 5 mg tablets

Parenteral: 2, 10 mg/mL aqueous colloidal solution or suspension for injection

Protamine (generic)

Parenteral: 10 mg/mL for injection

Retepase (Retavase*)

Parenteral: 10.8 IU powder for injection

Streptokinase (Streptase)

Parenteral: 250,000, 750,000, 1,500,000 IU per vial powders to reconstitute for injection

Tenecteplase (TNKase)

Parenteral: 50 mg powder for injection

Ticlopidine (Ticlid)

Oral: 250 mg tablets

Tinzaparin (Innohep)

Parenteral: 20,000 anti-Xa units/mL for subcutaneous injection only

Tirofiban (Aggrastat)

Parenteral: 50, 250 µg/mL for IV infusion

Tranexamic acid (Cyklokapron)

Oral: 500 mg tablets

Parenteral: 100 mg/mL for IV infusion

Urokinase (Abbokinase)

Parenteral: 250,000 IU per vial for systemic use

Warfarin (generic, Coumadin)

Oral: 1, 2, 2.5, 3, 4, 5, 6, 7.5, 10 mg tablets

Chapter 35. Agents Used in Hyperlipidemia

Katzung PHARMACOLOGY, 9e > Section VI. Drugs Used to Treat Disease of the Blood, Inflammation, & Gout > Chapter 35. Agents Used in Hyperlipidemia >

Acronyms

ACAT: Acyl-CoA:cholesterol acyltransferase

Apo: Apolipoprotein

CETP: Cholesteryl ester transfer protein

HDL: High-density lipoproteins

HMG-CoA: 3-Hydroxy-3-methylglutaryl-coenzyme A

IDL: Intermediate-density lipoproteins

LCAT: Lecithin:cholesterol acyltransferase

LDL: Low-density lipoproteins

Lp(a): Lipoprotein(a)

LPL: Lipoprotein lipase

PPAR-α: Peroxisome proliferator-activated receptor-alpha

VLDL: Very low density lipoproteins

Agents Used in Hyperlipidemia: Introduction

The lipids of human plasma are transported in macromolecular complexes termed **lipoproteins**. A number of metabolic disorders that involve elevations in levels of any of the lipoprotein species are thus termed **hyperlipoproteinemias** or **hyperlipidemias**. The term **hyperlipemia** denotes increased levels of triglycerides in plasma.

The two major clinical sequelae of the hyperlipoproteinemias are acute pancreatitis and atherosclerosis. The former occurs in patients with marked hyperlipemia. Control of triglycerides can prevent recurrent attacks of this life-threatening disease.

Atherosclerosis is the leading cause of death for both sexes in the USA and other Western countries. Lipoproteins that contain **apolipoprotein (apo) B100** convey lipids into the artery wall. These are the **low-density (LDL)**, **intermediate-density (IDL)**, **very low density (VLDL)**, and **lipoprotein(a) (Lp[a]) lipoproteins**.

The characteristic cellular components in atherosclerotic plaques are foam cells, which are transformed macrophages and smooth muscle cells filled with **cholesteryl esters**. This is the result of endocytosis of chemically modified lipoproteins via at least four species of **scavenger receptors**. Chemical modification of lipoproteins by free radicals creates ligands for scavenger receptors. The atheroma grows with the accumulation of foam cells, collagen, fibrin, and frequently calcium. Whereas lesions can slowly occlude coronary vessels, clinical symptoms are more frequently precipitated by rupture of unstable plaques, leading to activation of platelets and formation of occlusive thrombi. These acute events are thought to reflect inflammatory activities of macrophages.

Although treatment of hyperlipidemia can cause slow physical regression of plaques, the well-documented reduction in acute coronary events that follows vigorous treatment is attributable chiefly to mitigation of the inflammatory activity of macrophages and is evident within 2–3 months after starting therapy.

High-density lipoproteins (HDL) exert several antiatherogenic effects. They participate in pathways that retrieve cholesterol from the artery wall and inhibit the oxidation of atherogenic lipoproteins. Low levels of HDL (hypoalphalipoproteinemia) are an independent risk factor for coronary disease. The use of drugs that increase levels of HDL is indicated in patients with hypoalphalipoproteinemia.

Cigarette smoking is a major risk factor for coronary disease. It is associated with reduced levels of HDL, impairment of cholesterol retrieval, cytotoxic effects on the endothelium, increased oxidation of lipoproteins, and stimulation of thrombogenesis.

Normal coronary arteries can dilate in response to ischemia, increasing delivery of oxygen to the myocardium. This is mediated by nitric oxide, which acts upon smooth muscle cells of the arterial media. This function is impaired by atherogenic lipoproteins in several phenotypes of hyperlipidemia, aggravating ischemic manifestations of atherosclerosis. Reducing levels of atherogenic lipoproteins and inhibition of their oxidation helps restore endothelial function.

Because atherogenesis is multifactorial, therapy should be directed toward all the modifiable risk

factors. Atherosclerosis is a dynamic process. Quantitative angiographic measurements in clinical trials have demonstrated that net regression of plaques can occur during aggressive lipid-lowering therapy. Large primary and secondary prevention trials have shown significant reduction in mortality from new coronary events and in all-cause mortality. Therefore, the timely diagnosis and treatment of lipoprotein disorders can be expected to decrease morbidity and mortality due to coronary disease.

Many of the hyperlipidemic states are associated with the development of xanthomas. These lesions, which are produced by deposition of lipid in tendons or skin, may be painful or cosmetically unacceptable to the patient. Because xanthomas regress with lipid-lowering therapy, this provides another indication for treatment.

Pathophysiology of Hyperlipoproteinemia

Normal Lipoprotein Metabolism

Structure

Lipoproteins are particles with hydrophobic core regions containing cholesteryl esters and triglycerides. Unesterified cholesterol, phospholipids, and apoproteins surround the core. Certain lipoproteins contain very high-molecular-weight B proteins that exist in two forms: **B48**, which is formed in the intestine and found in chylomicrons and their remnants; and **B100**, synthesized in liver and found in **VLDL**, **VLDL remnants** (intermediate-density lipoproteins; **IDL**), **LDL** (formed from VLDL), and the **Lp(a) lipoproteins**.

Synthesis & Catabolism

Chylomicrons

Chylomicrons are formed in the intestine and carry **triglycerides** of dietary origin, **unesterified cholesterol**, and **cholesteryl esters**. They transit the thoracic duct to the bloodstream.

Triglycerides are removed from chylomicrons in extrahepatic tissues through a pathway shared with VLDL that involves hydrolysis by the **lipoprotein lipase (LPL)** system. A progressive decrease in particle diameter occurs as triglycerides in the core are depleted. Surface lipids and small apoproteins are transferred to HDL. The resultant chylomicron remnants are taken up by receptor-mediated endocytosis into hepatocytes.

Very Low Density Lipoproteins (VLDL)

VLDL are secreted by the liver and provide a means for export of triglycerides to peripheral tissues (Figure 35–1). VLDL triglycerides are hydrolyzed by LPL, yielding free fatty acids for storage in adipose tissue and for oxidation in tissues such as cardiac and skeletal muscle. Depletion of triglycerides produces remnants (IDL). Some IDL are endocytosed directly by liver. The remainder are converted to LDL by further removal of triglycerides mediated by hepatic lipase. This process explains the clinical phenomenon of the "beta shift," the increase of LDL (beta-lipoprotein) in serum as a hypertriglyceridemic state subsides. Increased levels of LDL can also result from

increased secretion of its precursor VLDL as well as from decreased LDL catabolism.

Figure 35-1.

Metabolism of lipoproteins of hepatic origin. The heavy arrows show the primary pathways. Nascent VLDL are secreted via the Golgi apparatus. They acquire additional C lipoproteins and apo E from HDL. VLDL are converted to VLDL remnants (IDL) by lipolysis via lipoprotein lipase in the vessels of peripheral tissues. In the process, C apolipoproteins and a portion of the apo E are given back to HDL. Some of the VLDL remnants are converted to LDL by further loss of triglycerides and loss of apo E. A major pathway for LDL degradation involves the endocytosis of LDL by LDL receptors in the liver and the peripheral tissues, for which apo B100 is the ligand. (Dark color denotes cholesteryl esters; light color, triglycerides; the asterisk denotes a functional ligand for LDL receptors; triangles indicate apolipoprotein E; circles and squares represent C apolipoproteins; RER denotes rough endoplasmic reticulum.) (Modified and redrawn, with permission, from Kane J, Malloy M: Disorders of lipoproteins. In: Rosenberg RN et al (editors). *The Molecular and Genetic Basis of Neurological Disease*. Butterworth-Heinemann, 1993.)

Low-Density Lipoproteins (LDL)

A major pathway by which LDL are catabolized in hepatocytes and other cells involves receptor-mediated endocytosis. Cholesteryl esters from the LDL core are hydrolyzed, yielding free cholesterol for the synthesis of cell membranes. Cells also obtain cholesterol by de novo synthesis via a pathway involving the formation of mevalonic acid by HMG-CoA reductase. Production of this enzyme and of LDL receptors is transcriptionally regulated by the content of cholesterol in the cell. Normally, about 70% of LDL is removed from plasma by hepatocytes. Even more cholesterol is delivered to the liver via remnants of VLDL and chylomicrons. Thus, the liver plays a major role in the cholesterol economy. Unlike other cells, hepatocytes are capable of eliminating cholesterol by secretion of cholesterol in bile and by conversion of cholesterol to bile acids.

LP(A) Lipoprotein

Lp(a) lipoprotein is formed from LDL and the Lp(a) protein linked by a disulfide bridge. Lp(a) protein is highly homologous with plasminogen but is not activated by tissue plasminogen activator. It occurs in a number of isoforms of different molecular weights. Levels of Lp(a) in serum vary from nil to over 200 mg/dL and are determined chiefly by genetic factors. Lp(a) can be found in atherosclerotic plaques and may also contribute to coronary disease by inhibiting thrombolysis. Levels are elevated in nephrosis.

High-Density Lipoproteins (HDL)

The apoproteins of HDL are secreted by the liver and intestine. Much of the lipid comes from the surface monolayers of chylomicrons and VLDL during lipolysis. HDL also acquire cholesterol from peripheral tissues in a pathway that protects the cholesterol homeostasis of cells. In this process, free cholesterol is transported from the cell membrane by a transporter protein, ABCA1, acquired by a small particle termed prebeta-1 HDL, and then esterified by lecithin:cholesterol acyltransferase (LCAT), leading to the formation of larger HDL species. The cholesteryl esters are transferred to VLDL, IDL, LDL, and chylomicron remnants with the aid of cholesteryl ester transfer protein (CETP). Much of the cholesteryl ester thus transferred is ultimately delivered to the liver by endocytosis of the acceptor lipoproteins. HDL can also deliver cholesteryl esters directly to the liver via a docking receptor (scavenger receptor, SR-BI) that does not endocytose the lipoproteins.

Lipoprotein Disorders

Lipoprotein disorders are detected by measuring lipids in serum after a 10-hour fast. Risk of atherosclerotic heart disease increases with concentrations of the atherogenic lipoproteins, is inversely related to levels of HDL, and is modified by other risk factors (Table 35–1). Evidence from clinical trials suggests that LDL cholesterol levels of 60–70 mg/dL may be optimal for patients with coronary disease. Ideally, triglyceride levels should be below 150 mg/dL. Differentiation requires identification of the lipoproteins involved (Table 35–2). Diagnosis of a primary lipoprotein disorder usually requires further clinical and genetic data as well as ruling out secondary hyperlipidemias (Table 35–3).

Table 35–1. National Cholesterol Education Program: Adult Treatment Guidelines (2001).

	Desirable	Borderline to High¹	High
Total cholesterol	< 200 (5.2) ²	200–239 ² (5.2–6.2)	> 240 (6.2) ²
LDL cholesterol	< 130 (3.4) ³	130–159 (3.4–4.1)	> 160 (4.1)
HDL cholesterol			> 60 (1.55)
Men	> 40 (1.04)		
Women	> 50 (1.30)		
Triglycerides	< 150 (1.7)	150–199 (1.7–2.3)	> 200 (2.3)

¹ Consider as high if coronary disease or more than 2 risk factors are present

² mg/dL (mmol/L)

³ Optimal level is < 100 (2.6)

Table 35–2. The Primary Hyperlipoproteinemias and Their Drug Treatment.

Disorder	Manifestations	Single Drug¹	Drug Combination
Primary chylomicronemia (familial lipoprotein lipase or cofactor deficiency)	Chylomicrons, VLDL increased	Dietary management (niacin, fibrate)	Niacin plus fibrate
Familial hypertriglyceridemia			
Severe	VLDL, chylomicrons increased	Niacin, fibrate	Niacin plus fibrate
Moderate	VLDL increased; chylomicrons may be increased	Niacin, fibrate	
Familial combined hyperlipoproteinemia	VLDL increased	Niacin, fibrate	
	LDL increased	Niacin, reductase inhibitor, ezetimibe	Two or three of the individual drugs
	VLDL, LDL increased	Niacin, reductase inhibitor	Niacin plus resin or reductase inhibitor or ezetimibe
Familial dysbetalipoproteinemia	VLDL remnants, chylomicron remnants increased	Fibrate, niacin	Fibrate plus niacin, or niacin plus reductase inhibitor

Familial hypercholesterolemia			
Heterozygous	LDL increased	Reductase inhibitor, resin, niacin, ezetimibe	Two or three of the individual drugs
Homozygous	LDL increased	Niacin, atorvastatin, ezetimibe, rosuvastatin	Niacin plus reductase inhibitor plus ezetimibe
Familial ligand-defective apoB	LDL increased	Niacin, reductase inhibitor, ezetimibe	Niacin plus reductase inhibitor or ezetimibe
Lp(a) hyperlipoproteinemia	Lp(a) increased	Niacin	

¹Single-drug therapy should be evaluated before drug combinations are used.

Phenotypes of abnormal lipoprotein distribution are described in this section. Drugs mentioned for use in these conditions are described in the following section on basic and clinical pharmacology.

The Primary Hypertriglyceridemias

Hypertriglyceridemia is linked epidemiologically with increased risk of coronary disease. VLDL and its remnants have been found in atherosclerotic plaques. In some kindreds, hypertriglyceridemia may be the only evident risk factor. These patients tend to have cholesterol-rich VLDL of small particle diameter. Hypertriglyceridemic patients with coronary disease or a family history of premature coronary disease should be treated aggressively. In others, treatment decisions should be based on the aggregate of risk factors. Because clearance of triglycerides by the LPL system is saturated at about 800 mg/dL of triglycerides, patients with higher levels should be treated to prevent acute pancreatitis.

Primary Chylomicronemia

Chylomicrons are not present in the serum of normal individuals who have fasted 10 hours. The recessive traits of lipoprotein lipase deficiency and cofactor deficiency are usually associated with severe lipemia (2000–2500 mg/dL triglycerides when the patient is consuming a typical American diet). These disorders might not be diagnosed until an attack of acute pancreatitis occurs. Patients may have eruptive xanthomas, hepatosplenomegaly, hypersplenism, and lipid-laden foam cells in bone marrow, liver, and spleen. The lipemia is aggravated by estrogens because they stimulate VLDL production, and pregnancy may cause marked increases in triglycerides despite strict dietary control. Although these patients have a predominant chylomicronemia, they may also have moderately elevated VLDL, presenting with a pattern of mixed lipemia (fasting chylomicronemia and elevated VLDL). LPL deficiency is diagnosed by assay of lipolytic activity after intravenous injection of heparin; cofactor deficiency is diagnosed by isoelectric focusing of the VLDL proteins. A presumptive diagnosis of these disorders is made by demonstrating a pronounced decrease in levels of triglycerides a few days after sharp restriction of oral fat intake. Marked restriction of the total fat content in the diet provides effective long-term treatment. Niacin or a fibrate may be of some benefit.

Familial Hypertriglyceridemia

Severe (Usually Mixed Lipemia)

A pattern of mixed lipemia usually results from impaired removal of triglyceride-rich lipoproteins. Factors that increase VLDL production aggravate the lipemia because VLDL and chylomicrons are competing substrates for LPL. The primary mixed lipemias probably represent a variety of modes of inheritance. Most patients have the centripetal pattern of obesity with insulin resistance. Other factors that lead to an increased rate of secretion of VLDL also worsen the lipemia. Eruptive xanthomas, lipemia retinalis, epigastric pain, and pancreatitis are variably present depending on the severity of the lipemia. Treatment is primarily dietary, with restriction of total fat, avoidance of alcohol and exogenous estrogens, and weight reduction. Some patients may require treatment with a fibrate or niacin.

Moderate (Endogenous Lipemia)

Primary increases of VLDL probably reflect a number of genetic determinants and are worsened by factors that increase the rate of VLDL secretion from liver, ie, obesity, alcohol, diabetes, and estrogens. A major indication for treatment is the presence of atherosclerosis in the patient or the patient's family. Treatment includes weight reduction, restriction of all types of dietary fat, and avoidance of alcohol. Fibrates or niacin usually produce further reduction in triglyceride levels if dietary measures are not sufficient. Marine omega fatty acids may also be of value.

Familial Combined Hyperlipoproteinemia

In kindreds with this disorder, individuals may have elevated levels of VLDL, LDL, or both, and the pattern may change with time. Familial combined hyperlipoproteinemia involves an approximate doubling in VLDL secretion. It seems to be transmitted as a semidominant trait. Triglycerides can be increased by the factors noted above. Elevations of cholesterol and triglycerides are generally moderate, and xanthomas are usually absent. Drug treatment is warranted because the risk of coronary atherosclerosis is increased and diet alone does not normalize lipid levels. A reductase inhibitor or ezetimibe in combination with niacin is usually required to treat these patients.

Familial Dysbetalipoproteinemia

In this disorder, remnants of chylomicrons and VLDL accumulate. Levels of LDL are usually decreased. Because remnants are rich in cholesteryl esters, the level of cholesterol may be as high as that of triglycerides. Diagnosis is confirmed by the absence of the E3 and E4 isoforms of apo E. Patients often develop tuberous or tuberoeruptive xanthomas, or characteristic planar xanthomas of the palmar creases. They tend to be obese, and some have impaired glucose tolerance. These factors, as well as hypothyroidism, can aggravate the lipemia. Coronary and peripheral atherosclerosis occur with increased frequency. Weight loss, together with decreased fat, cholesterol, and alcohol consumption, may be sufficient treatment, but a fibrate or niacin is needed in most cases. These agents can be given together in more resistant cases, or a reductase inhibitor may be added.

The Primary Hypercholesterolemias

Familial Hypercholesterolemia

Familial hypercholesterolemia is an autosomal dominant trait. Although levels of LDL tend to increase throughout childhood, the diagnosis can often be made on the basis of elevated umbilical

cord blood cholesterol. In most heterozygotes, cholesterol levels commonly range from 260 to 500 mg/dL. Triglycerides are usually normal, tendinous xanthomatosis is often present, and arcus corneae and xanthelasma may appear in the third decade. Coronary atherosclerosis tends to occur prematurely. Homozygous familial hypercholesterolemia, which can lead to coronary disease in childhood, is characterized by levels of cholesterol often exceeding 1000 mg/dL and early tuberous and tendinous xanthomatosis. These patients may also develop elevated plaque-like xanthomas of the aortic valve, digital webs, buttocks, and extremities.

Defects of LDL receptors underlie this disorder. Some individuals have combined heterozygosity for alleles producing nonfunctional and kinetically impaired receptors. Levels of LDL in compliant heterozygous patients can be normalized with combined drug regimens (Figure 35–2). Those whose receptors retain even minimal function may partially respond to resins or reductase inhibitors. Niacin and atorvastatin may benefit patients with no receptor function.

Figure 35–2.

Sites of action of HMG-CoA reductase inhibitors, niacin, ezetimibe, and resins used in treating hyperlipidemias. LDL receptors (R) are increased by treatment with resins and HMG-CoA reductase inhibitors.

Familial Ligand-Defective Apolipoprotein B

Defects in the ligand domain of apo B100 (the region that binds to the LDL receptor) impair the

endocytosis of LDL, leading to hypercholesterolemia of moderate severity. Tendon xanthomas may occur. These disorders are as prevalent as familial hypercholesterolemia. Response to reductase inhibitors is variable. Up-regulation of LDL receptors in liver increases endocytosis of LDL precursors but does not increase uptake of ligand-defective LDL particles. Niacin often has beneficial effects by reducing VLDL production.

Familial Combined Hyperlipoproteinemia (FCH)

As described above, some persons in kindreds with this disorder have only an elevation in LDL. Serum cholesterol is usually less than 350 mg/dL. Premature coronary disease is common. Dietary and drug treatment, usually with niacin or a reductase inhibitor, is indicated. It is frequently necessary to add niacin to normalize LDL or to reduce triglycerides if treatment is initiated with a resin.

Lp(a) Hyperlipoproteinemia

This familial disorder, which is associated with increased atherogenesis, is determined chiefly by alleles that dictate increased production of the Lp(a) lipoprotein. Niacin reduces levels of Lp(a) in many patients.

Other Disorders

Deficiency of cholesterol 7 α -hydroxylase can cause elevated LDL in the heterozygous state. Homozygotes can also have elevated triglycerides, resistance to reductase inhibitors, and premature gallstones. Autosomal recessive hypercholesterolemia is due to mutations in a protein that assists in endocytosis of LDL. Niacin and ezetimibe may be useful in these disorders.

HDL Deficiency

Certain rare genetic disorders are associated with extremely low levels of HDL in serum. These include Tangier disease and disorders of LCAT. Familial hypoalphalipoproteinemia is a more common disorder in which levels of HDL cholesterol are usually below 35 mg/dL, with apparent codominant transmission. These patients tend to have premature atherosclerosis, and the low HDL may be the only identified risk factor. Treatment should include special attention to avoidance of other risk factors. Niacin increases HDL cholesterol in many of these patients. Reductase inhibitors and fibric acid derivatives exert lesser effects.

In the presence of hypertriglyceridemia, HDL cholesterol is low because of exchange of cholesteryl esters from HDL into triglyceride-rich lipoproteins. This may contribute to the atherogenic effect of hypertriglyceridemia. In most, treatment of the hypertriglyceridemia will result in normalization of HDL.

Secondary Hyperlipoproteinemia

Before primary disorders can be diagnosed, secondary causes of the phenotype must be considered. The more common conditions are summarized in Table 35–3. The lipoprotein abnormality usually resolves if the underlying disorder can be treated successfully.

Table 35–3. Secondary Causes of Hyperlipoproteinemia.

Hypertriglyceridemia	Hypercholesterolemia
Diabetes mellitus	Hypothyroidism
Alcohol ingestion	Early nephrosis
Severe nephrosis	Resolving lipemia
Estrogens	Immunoglobulin-lipoprotein complex disorders
Uremia	Anorexia nervosa
Corticosteroid excess	Cholestasis
Myxedema	Hypopituitarism
Glycogen storage disease	Corticosteroid excess
Hypopituitarism	
Acromegaly	
Immunoglobulin-lipoprotein complex disorders	
Lipodystrophy	
Isotretinoin	
Protease inhibitors	

Katzung PHARMACOLOGY, 9e > Section VI. Drugs Used to Treat Disease of the Blood, Inflammation, & Gout > Chapter 35. Agents Used in Hyperlipidemia >

Dietary Management of Hyperlipoproteinemia

Dietary measures are always initiated first and may obviate the need for drugs. Exceptions are patients with familial hypercholesterolemia or familial combined hyperlipidemia in whom diet and drug therapy should be started simultaneously. Cholesterol, saturated fats, and trans fats are the principal factors that influence LDL levels, whereas total fat and calorie restriction is important in management of triglycerides.

Lipoprotein levels are also affected—but to a lesser extent—by other dietary factors. Increases in VLDL occur when carbohydrate intake is increased but tend to normalize after several months. Sucrose and other simple sugars raise VLDL levels in hypertriglyceridemic patients. Some forms of dietary fiber reduce LDL modestly. Alcohol can cause significant hypertriglyceridemia by increasing hepatic secretion of VLDL. Synthesis and secretion of VLDL are increased by excess calories. Caloric restriction, especially in obese subjects, reduces VLDL and often LDL as well. During weight loss, LDL and VLDL levels may be much lower than can be maintained during neutral caloric balance. The conclusion that diet suffices for management can only be arrived at after weight has stabilized for at least 1 month.

Most patients with elevated LDL can be managed with a diet restricted in cholesterol and saturated fat but with sufficient calories to achieve and maintain ideal body weight. Total fat calories should be 20–25%, with saturated fats less than 8% and cholesterol less than 200 mg/d. Reductions in serum cholesterol range from 10% to 20% on this regimen. Use of complex carbohydrates and fiber is recommended, and monounsaturated fats should predominate within the fat allowance. Weight reduction and caloric restriction are especially important for patients with elevated VLDL and IDL. Those with hypertriglyceridemia should avoid alcohol.

The effect of dietary fats on hypertriglyceridemia is dependent upon the disposition of double bonds in the fatty acid. Omega-3 fatty acids found in fish oils—but not those from plant sources—can induce profound lowering of triglycerides in some patients with endogenous or mixed lipemia. In contrast, the omega-6 fatty acids present in vegetable oils may cause triglycerides to increase.

Patients with primary chylomicronemia and some with mixed lipemia must consume a diet severely restricted in total fat—10–15 g/d, of which 5 g should be vegetable oils rich in essential fatty acids. Supplementation of fat-soluble vitamins should be given.

Supplementation with the antioxidant vitamins ascorbic acid (250 mg) and mixed natural tocopherols (50 IU on alternate days) may be beneficial. Higher doses may vitiate the impact of lipid lowering therapy. Other naturally occurring antioxidants such as resveratrol, E-catechin, selenium, and various carotenoids found in a variety of fruits and vegetables may provide additional antioxidant defense. Homocysteine, which initiates proatherogenic changes in endothelium, can be reduced in many patients by restriction of total protein intake to the amount required for amino acid replacement. Daily supplementation with up to 2 mg of folic acid plus other B vitamins is also recommended.

Katzung PHARMACOLOGY, 9e > Section VI. Drugs Used to Treat Disease of the Blood, Inflammation, & Gout > Chapter 35. Agents Used in Hyperlipidemia >

Basic & Clinical Pharmacology of Drugs Used in Hyperlipidemia

The decision to use drug therapy is based on the specific metabolic defect and its potential for causing atherosclerosis or pancreatitis. Suggested regimens for the principal lipoprotein disorders are presented in Table 35–2. Diet should be continued for achievement of the full potential of the drug regimen. Drugs should be avoided in pregnant and lactating women and those likely to become pregnant. All drugs that alter plasma lipoprotein concentrations may require adjustment of doses of warfarin and indandione anticoagulants. Children with heterozygous familial hypercholesterolemia may be treated with a resin or reductase inhibitor, usually after 7 or 8 years of age, when myelination of the central nervous system is essentially complete. The decision to treat a child should be based on the level of LDL, other risk factors, the family history, and the child's age. Drugs are rarely indicated before age 18.

Competitive Inhibitors of HMG-CoA Reductase (Reductase Inhibitors; "Statins")

These compounds are structural analogs of HMG-CoA (3-hydroxy-3-methylglutaryl-coenzyme A). (Figure 35–3). **Lovastatin, atorvastatin, fluvastatin, pravastatin, simvastatin, and rosuvastatin** belong to this class. They are most effective in reducing LDL. Other effects include decreased oxidative stress and vascular inflammation with increased stability of atherosclerotic lesions. It has become standard practice to initiate reductase inhibitor therapy immediately after myocardial infarction, irrespective of lipid levels.

Figure 35–3.

Chemistry & Pharmacokinetics

Lovastatin and simvastatin are inactive lactone prodrugs that are hydrolyzed in the gastrointestinal tract to the active β -hydroxyl derivatives, whereas pravastatin has an open, active lactone ring. Atorvastatin, fluvastatin, and rosuvastatin are fluorine-containing congeners that are active as given. Absorption of the ingested doses of the reductase inhibitors varies from 40% to 75% with the exception of fluvastatin, which is almost completely absorbed. All have high first-pass extraction by the liver. Most of the absorbed dose is excreted in the bile; about 5–20% is excreted in the urine. Plasma half-lives of these drugs range from 1 hour to 3 hours except for atorvastatin, which has a half-life of 14 hours, and rosuvastatin, 19 hours.

Mechanism of Action

HMG-CoA reductase mediates the first committed step in sterol biosynthesis. The active forms of the reductase inhibitors are structural analogs of the HMG-CoA intermediate (Figure 35–3) that is formed by HMG-CoA reductase in the synthesis of mevalonate. These analogs cause partial inhibition of the enzyme and thus may impair the synthesis of isoprenoids such as ubiquinone and dolichol and the prenylation of proteins. It is not known whether this has biologic significance.

However, the reductase inhibitors clearly induce an increase in high-affinity LDL receptors. This effect increases both the fractional catabolic rate of LDL and the liver's extraction of LDL precursors (VLDL remnants), thus reducing plasma LDL (Figure 35–2). Because of marked first-pass hepatic extraction, the major effect is on liver. Preferential activity in liver of some congeners appears to be attributable to tissue-specific differences in uptake. Limited reduction of LDL levels in patients who lack functional LDL receptors indicates that decreases in de novo cholesterologenesis also contribute to cholesterol reduction. Modest decreases in plasma triglycerides and small increases in HDL also occur.

Therapeutic Uses & Dosage

Reductase inhibitors are useful alone or with resins, niacin, or ezetimibe in reducing levels of LDL. Women who are pregnant, lactating, or likely to become pregnant should not be given these agents. Use in children is restricted to those with homozygous familial hypercholesterolemia and selected patients with heterozygous familial hypercholesterolemia.

Because cholesterol biosynthesis occurs predominantly at night, reductase inhibitors—except atorvastatin and rosuvastatin—should be given in the evening if a single daily dose is used. Absorption generally (with the exception of pravastatin) is enhanced by taking the dose with food. Daily doses of lovastatin vary from 10 mg to 80 mg. Pravastatin is nearly as potent on a mass basis as lovastatin up to the maximum recommended daily dose, 80 mg. Simvastatin is twice as potent and is given in doses of 5–80 mg daily. Fluvastatin appears to be about half as potent as lovastatin on a mass basis and is given in doses of 10–80 mg daily. Atorvastatin is given in doses of 10–80 mg/d, and rosuvastatin, the most efficacious agent for severe hypercholesterolemia, at 10–40 mg/d. The dose-response curves of pravastatin and especially of fluvastatin tend to level off in the upper part of the dosage range in patients with moderate to severe hypercholesterolemia. Those of lovastatin, simvastatin, and atorvastatin are more nearly linear.

Toxicity

Elevations of serum aminotransferase activity (up to three times the normal level) occur in some patients. These increases are often intermittent and usually not associated with other evidence of hepatic toxicity. Therapy may be continued in such patients in the absence of symptoms if aminotransferase levels are measured frequently. In about 2% of patients, some of whom have underlying liver disease or a history of alcohol abuse, aminotransferase levels may exceed three times the normal limit. This effect, which can occur at any time, portends more severe hepatic toxicity. These patients may present with malaise, anorexia, and precipitous decreases in LDL. Medication should be discontinued immediately in these patients and in asymptomatic patients whose aminotransferase activity is persistently elevated to more than three times the upper limit of normal. These agents should be used with caution and in reduced dosage in patients with hepatic parenchymal disease. In general, aminotransferase activity should be measured at baseline, at 1–2 months, and then every 6 months (if stable).

Minor increases in creatine kinase activity in plasma are observed in some patients receiving reductase inhibitors, frequently associated with heavy physical activity. Rarely, patients may have marked elevations in kinase activity, often accompanied by generalized pain or weakness in skeletal muscles. If the drug is not discontinued, rhabdomyolysis may cause myoglobinuria, which may lead to renal shutdown. Myopathy may occur with monotherapy, but there is an increased incidence in patients receiving a reductase inhibitor concurrently with certain other drugs. The catabolism of lovastatin, simvastatin, and atorvastatin proceeds chiefly through cytochrome P450 3A4, whereas that of fluvastatin and rosuvastatin is mediated by CYP2C9. Pravastatin is catabolized through other

pathways, including sulfation. The 3A4-dependent reductase inhibitors tend to accumulate in plasma in the presence of drugs that inhibit or compete for the 3A4 cytochrome. These include the macrolide antibiotics, cyclosporine, ketoconazole and its congeners, HIV protease inhibitors, tacrolimus, nefazodone, fibrates, and others (see Chapter 4: Drug Biotransformation). Concomitant use of reductase inhibitors with amiodarone or verapamil also causes an increased risk of myopathy. Conversely, drugs such as phenytoin, griseofulvin, barbiturates, rifampin, and thiazolidinediones increase expression of CYP3A4 and can reduce the plasma concentrations of the 3A4-dependent reductase inhibitors. Inhibitors of CYP2C9 such as ketoconazole and its congeners, metronidazole, sulfinpyrazone, amiodarone, and cimetidine may increase plasma levels of fluvastatin and rosuvastatin. Pravastatin appears to be the drug of choice for use with verapamil, the ketoconazole group of antifungal agents, macrolides, and cyclosporine. Plasma levels of lovastatin, simvastatin, and atorvastatin may be elevated in patients ingesting more than 1 liter of grapefruit juice daily.

Creatine kinase activity should be measured frequently in patients receiving potentially interacting drug combinations. In all patients, creatine kinase levels should be measured before treatment and then every 6–12 months (depending on the dose). If significant muscle pain, tenderness, or weakness appears, creatine kinase activity should be measured immediately and the drug discontinued if activity is elevated over baseline. The myopathy usually reverses promptly upon cessation of therapy. If the association is unclear, the patient can be rechallenged under close surveillance. Myopathy in the absence of elevated creatine kinase activity has been reported. Rarely, hypersensitivity syndromes have been reported that include a lupus-like disorder and peripheral neuropathy.

These drugs should be temporarily discontinued in the event of serious illness, trauma, or major surgery.

Niacin (Nicotinic Acid)

Niacin (but not niacinamide) decreases VLDL and LDL levels—and Lp(a) in most patients. It often increases HDL levels significantly.

Chemistry & Pharmacokinetics

Niacin (vitamin B₃) is converted in the body to the amide, which is incorporated into niacinamide adenine dinucleotide (NAD). It is excreted in the urine unmodified and as several metabolites.

Mechanism of Action

Niacin inhibits VLDL secretion, in turn decreasing production of LDL (Figure 35–2). Increased clearance of VLDL via the LPL pathway contributes to triglyceride reduction. Niacin has no effect on bile acid production. Excretion of neutral sterols in the stool is increased acutely as cholesterol is mobilized from tissue pools and a new steady state is reached. The catabolic rate for HDL is decreased. Fibrinogen levels are reduced, and levels of tissue plasminogen activator appear to increase. Niacin inhibits the intracellular lipase of adipose tissue via receptor-mediated signaling, possibly reducing VLDL production by decreasing the flux of free fatty acids to liver. Sustained inhibition of lipolysis has not been established, however.

Therapeutic Uses & Dosage

In combination with a resin or reductase inhibitor, niacin normalizes LDL in most patients with heterozygous familial hypercholesterolemia and other forms of hypercholesterolemia. These

combinations are also indicated in some cases of nephrosis. In severe mixed lipemia that is incompletely responsive to diet, niacin often produces marked reduction of triglycerides, an effect enhanced by marine omega-3 fatty acids. It is useful in patients with combined hyperlipoproteinemia and in those with familial dysbetalipoproteinemia. Niacin reduces levels of Lp(a) in many subjects. It is clearly the most effective agent for increasing levels of HDL.

For treatment of heterozygous familial hypercholesterolemia, most patients require 2–6 g of niacin daily; more than this should not be given. For other types of hypercholesterolemia and for hypertriglyceridemia, 1.5–3.5 g daily is often sufficient. The drug should be given in divided doses with meals, starting with 100 mg two or three times daily and increasing gradually.

Toxicity

Most persons experience a harmless cutaneous vasodilation and sensation of warmth after each dose when the drug is started or the dose is increased. Taking 0.3 g of aspirin one half hour beforehand blunts this prostaglandin-mediated effect. Ibuprofen, once daily, also mitigates the flush. Tachyphylaxis to flushing usually occurs within a few days at doses above 1.5–3 g daily. Care providers should warn patients to expect the flush and explain that it is a harmless side effect. Pruritus, rashes, dry skin or mucous membranes, and acanthosis nigricans have been reported. The latter contraindicates use of niacin because of its association with insulin resistance. Some patients experience nausea and abdominal discomfort. Many can continue the drug at reduced dosage, with inhibitors of gastric acid secretion, or use of antacids not containing aluminum. Niacin should be avoided in patients with severe peptic disease.

Reversible elevations in aminotransferases up to twice normal may occur, usually not associated with liver toxicity. However, liver function should be monitored regularly. Rarely, true hepatotoxicity may occur and is an indication for discontinuing the drug. The association of severe hepatic dysfunction, including acute necrosis, with the use of sustained-release preparations of niacin has been reported. Experience to date with one of these, given at bedtime in doses of 2 g or less, suggests that acute liver failure may be avoided. Carbohydrate tolerance may be moderately impaired, but this is also reversible. In some patients with latent diabetes, however, this effect may be incompletely reversible. Niacin may be given to diabetics who are receiving insulin and to some receiving oral agents if insulin resistance is not increased. Hyperuricemia occurs in some patients and occasionally precipitates gout. Allopurinol can be given with niacin if needed. Rarely, niacin is associated with arrhythmias, mostly atrial, and a reversible toxic amblyopia. Patients should be instructed to report blurring of distance vision. Niacin may potentiate the action of antihypertensive agents, requiring adjustment of their dosages. Dryness of mucous membranes is occasionally reported.

Fibric Acid Derivatives

Gemfibrozil and **fenofibrate** decrease levels of VLDL and, in some patients, LDL as well. Another fibrate, **bezafibrate**, is not yet available in the USA.

Chemistry & Pharmacokinetics

Gemfibrozil is absorbed quantitatively from the intestine and is tightly bound to plasma proteins. It undergoes enterohepatic circulation and readily passes the placenta. The plasma half-life is 1.5 hours. Seventy percent is eliminated through the kidneys, mostly unmodified. The liver modifies some of the drug to hydroxymethyl, carboxyl, or quinol derivatives. Fenofibrate is a methylethyl ester that is hydrolyzed completely in the intestine. Its plasma half-life is 20 hours. Sixty percent is

excreted in the urine as the glucuronide, and about 25% in feces.

Gemfibrozil

Fenofibrate

Mechanism of Action

These agents function primarily as ligands for the nuclear transcription receptor, peroxisome proliferator-activated receptor- α (PPAR- α). They increase lipo-lysis of lipoprotein triglyceride via LPL. Intracellular lipolysis in adipose tissue is decreased. Levels of VLDL decrease, in part as a result of decreased secretion by the liver. Only modest reductions of LDL occur in most patients. In others, especially those with combined hyperlipidemia, LDL often increases as triglycerides are reduced. HDL cholesterol increases moderately. Part of this apparent increase is a consequence of decreasing triglycerides in plasma, with reduction in exchange of triglycerides into HDL in place of cholesteryl esters. Some increase in HDL protein has been reported.

Therapeutic Uses & Dosage

These drugs are useful in hypertriglyceridemias in which VLDL predominate and in dysbetalipoproteinemia. They also may be of benefit in treating the hypertriglyceridemia that results from treatment with viral protease inhibitors. The usual dose of gemfibrozil is 600 mg orally once or twice daily. The dosage of fenofibrate is one to three 54 mg tablets (or a single 160 mg tablet) daily. Absorption of both drugs is improved when they are taken with food.

Toxicity

Rare adverse effects include rashes, gastrointestinal symptoms, myopathy, arrhythmias, hypokalemia, and high blood levels of aminotransferases or alkaline phosphatase. A few patients show decreases in white blood count or hematocrit. Both agents potentiate the action of coumarin and indanedione anticoagulants, and doses of these agents should be adjusted. Rhabdomyolysis has occurred rarely. Risk of myopathy increases when fibrates are given with reductase inhibitors. These drugs should be avoided in patients with hepatic or renal dysfunction. There appears to be a modest increase in the risk of cholesterol gallstones, reflecting an increase in the cholesterol content of bile. Therefore, fibrates should be used with caution in patients with biliary tract disease or in those at high risk such as women, obese patients, and Native Americans.

Bile Acid-Binding Resins

Colestipol, cholestyramine, and colesevelam are useful only for isolated increases in LDL. In patients who also have hypertriglyceridemia, VLDL levels may be further increased during treatment with resins.

Chemistry & Pharmacokinetics

These agents are large polymeric cationic exchange resins that are insoluble in water. They bind bile acids in the intestinal lumen and prevent their reabsorption. The resin itself is not absorbed.

Mechanism of Action

The bile acids, metabolites of cholesterol, are normally efficiently reabsorbed in the jejunum and ileum (Figure 35–2). Excretion is increased up to tenfold when resins are given, resulting in enhanced conversion of cholesterol to bile acids in liver via 7 α -hydroxylation, normally controlled by negative feedback by bile acids. Increased uptake of LDL and IDL from plasma results from up-regulation of LDL receptors, particularly in liver. Therefore, the resins are without effect in patients with homozygous familial hypercholesterolemia who have no functioning receptors but may be useful in patients with receptor-defective combined heterozygous states.

Therapeutic Uses & Dosage

The resins are used in treatment of patients with primary hypercholesterolemia, producing approximately 20% reduction in LDL cholesterol in maximal dosage. If resins are used to treat LDL elevations in persons with combined hyperlipidemia, they may cause an increase in VLDL requiring the addition of a second agent such as niacin. Resins are also used in combination with other drugs to achieve further hypocholesterolemic effect (see below). They may be helpful in relieving pruritus in patients who have cholestasis and bile salt accumulation. Because they bind digitalis glycosides, the resins may be useful in digitalis toxicity.

Colestipol and cholestyramine are available as granular preparations. Colestipol is also available in 1 g tablets that must be swallowed whole. The maximum dose is 16 g daily. A gradual increase of dosage of granules from 4 or 5 g/d to 20 g/d is recommended. Total dosages of 30–32 g/d may be needed for maximum effect. The usual dosage for a child is 10–20 g/d. Granular resins are mixed with juice or water and allowed to hydrate for 1 minute. Colesevelam is available in 625 mg tablets. The maximum dose is six tablets daily. Resins should be taken in two or three doses with meals, and they lack effect when taken between meals.

Toxicity

Common complaints are constipation and bloating, usually relieved by increasing dietary fiber or mixing psyllium seed with the resin. Resins should be avoided in patients with diverticulitis. Heartburn and diarrhea are occasionally reported. In patients who have preexisting bowel disease or cholestasis, steatorrhea may occur. Malabsorption of vitamin K occurs rarely, leading to hypoprothrombinemia. Prothrombin time should be measured frequently in patients who are taking resins and anticoagulants. Malabsorption of folic acid has been reported rarely. Increased formation of gallstones, particularly in obese persons, was an anticipated adverse effect but has rarely occurred in practice. An occasional problem is dry flaking skin, relieved by application of lanolin.

Absorption of certain drugs, including those with neutral or cationic charge as well as anions, may be impaired by the resins. These include digitalis glycosides, thiazides, warfarin, tetracycline, thyroxine, iron salts, pravastatin, fluvastatin, folic acid, phenylbutazone, aspirin, and ascorbic acid.

Any additional medication (except niacin) should be given 1 hour before or at least 2 hours after the resin to ensure adequate absorption. Colesevelam does not bind digoxin, warfarin, or reductase inhibitors.

Inhibitors of Intestinal Sterol Absorption

Ezetimibe is the first member of a new group of drugs that inhibit intestinal absorption of phytosterols and cholesterol. Its primary clinical effect is reduction of LDL levels.

Chemistry & Pharmacokinetics

Ezetimibe is readily absorbed and conjugated in the intestine to an active glucuronide, reaching peak blood levels in 12–14 hours. It undergoes enterohepatic circulation. Its half-life is 22 hours. Approximately 80% of the drug is excreted in feces. Plasma ezetimibe concentrations are substantially increased when it is administered with fibrates and reduced when it is given with cholestyramine. Other resins may also decrease its absorption. There are no significant interactions with warfarin or digoxin.

Mechanism of Action

Ezetimibe is a selective inhibitor of intestinal absorption of cholesterol and phytosterols. It is effective even in the absence of dietary cholesterol because it inhibits reabsorption of cholesterol excreted in the bile.

Therapeutic Uses & Dosage

The effect on cholesterol absorption is constant over the dosage range of 5–20 mg/d. Therefore, a single daily dose of 10 mg is used. Average reduction in LDL cholesterol with ezetimibe alone in patients with primary hypercholesterolemia is about 18%, with minimal increases in HDL cholesterol. It is also effective in patients with phytosterolemia. Ezetimibe is apparently synergistic with reductase inhibitors, producing decrements as great as 25% in LDL cholesterol beyond that achieved with the reductase inhibitor alone.

Toxicity

Ezetimibe does not appear to be a substrate for cytochrome P450 enzymes. Preliminary data reveal a low incidence of reversible impaired hepatic function with a small increase in incidence when given with a reductase inhibitor. Liver function tests should be done before starting the drug and then at intervals of 2–4 months.

Treatment with Drug Combinations

Combined drug therapy is useful (1) when VLDL levels are significantly increased during treatment of hyper-cholesterolemia with a resin; (2) when LDL and VLDL levels are both elevated initially; (3) when LDL or VLDL levels are not normalized with a single agent, or (4) when elevated levels of Lp(a) or HDL deficiency coexist with other hyperlipidemias.

Fibric Acid Derivatives & Bile Acid-Binding Resins

This combination is sometimes useful in treating patients with familial combined hyperlipidemia who are intolerant of niacin. However, it may increase the risk of cholelithiasis.

HMG-CoA Reductase Inhibitors & Bile Acid-Binding Resins

This highly synergistic combination is useful for treatment of familial hypercholesterolemia but may not control levels of VLDL in some patients with familial combined hyperlipoproteinemia. Pravastatin, atorvastatin, and fluvastatin should be given at least 1 hour before or 4 hours after the resin to ensure their absorption.

Niacin & Bile Acid-Binding Resins

This combination effectively controls VLDL levels during resin therapy of familial combined hyperlipoproteinemia or other disorders involving both increased VLDL and LDL levels. When VLDL and LDL levels are both initially increased, doses of niacin as low as 1–3 g/d may be sufficient in combination with a resin. The niacin-resin combination is effective for treating heterozygous familial hypercholesterolemia. Niacin also significantly elevates levels of HDL cholesterol and frequently decreases levels of Lp(a).

Quantitative evidence of reversal of coronary disease was demonstrated with this regimen in three major clinical trials. Effects on lipoprotein levels are sustained, and no additional adverse effects have developed other than those encountered when the drugs are used singly. The drugs may be taken together, because niacin does not bind to the resins. LDL levels in patients with heterozygous familial hypercholesterolemia are usually normalized with daily doses of up to 6.5 g of niacin with 24–30 g of resin.

Niacin & Reductase Inhibitors

This regimen is more effective than either agent alone in treating familial hypercholesterolemia. Experience indicates that it is the most efficacious and practical combination for treatment of familial combined hyperlipoproteinemia.

Reductase Inhibitors & Ezetimibe

This combination is synergistic in treating primary hypercholesterolemia and has some use in the treatment of homozygous familial hypercholesterolemia.

Ternary Combination of Resins, Niacin, & Reductase Inhibitors

These agents act in a complementary fashion to normalize cholesterol in patients with severe disorders involving elevated LDL. The effects are sustained, and little compound toxicity has been observed. Effective doses of the individual drugs may be lower than when each is used alone—eg,

as little as 1–2 g of niacin may substantially increase the effects of the other agents.

Katzung PHARMACOLOGY, 9e > Section VI. Drugs Used to Treat Disease of the Blood, Inflammation, & Gout > Chapter 35. Agents Used in Hyperlipidemia >

Preparations Available

Atorvastatin (Lipitor)

Oral: 10, 20, 40, 80 mg tablets

Cholestyramine (generic, Questran, Questran Light)

Oral: 4 g packets anhydrous granules cholestyramine resin; 210 g (Questran Light), 378 g (Questran) cans

Colesevelam (Welchol)

Oral: 625 mg tablets

Colestipol (Colestid)

Oral: 5 g packets granules; 300, 500 g bottles; 1 g tablets

Ezetimibe (Zetia)

Oral: 10 mg tablets

Fenofibrate (Tricor)

Oral: 54, 160 mg tablets

Fluvastatin (Lescol)

Oral: 20, 40 mg capsules; extended release (Lescol XL): 80 mg capsules

Gemfibrozil (generic, Lopid)

Oral: 600 mg tablets

Lovastatin (generic, Mevacor)

Oral: 10, 20, 40, 80 mg tablets; extended release tablets (Altocar) 10, 20, 40, 60 mg

Niacin, nicotinic acid, vitamin B₃ (generic, others)

Oral: 100, 250, 500, 1000 mg tablets

Pravastatin (Pravachol)

Oral: 10, 20, 40, 80 mg tablets

Rosuvastatin (Crestor)

Oral: 5, 10, 20, 40 mg tablets

Simvastatin (Zocor)

Oral: 5, 10, 20, 40, 80 mg tablets

Chapter 36. Nonsteroidal Anti-Inflammatory Drugs, Disease-Modifying Antirheumatic Drugs, Nonopioid Analgesics, & Drugs Used in Gout

Katzung PHARMACOLOGY, 9e > Section VI. Drugs Used to Treat Disease of the Blood, Inflammation, & Gout > Chapter 36. Nonsteroidal Anti-Inflammatory Drugs, Disease-Modifying Antirheumatic Drugs, Nonopioid Analgesics, & Drugs Used in Gout >

The Immune Response

The immune response occurs when immunologically competent cells are activated in response to foreign organisms or antigenic substances liberated during the acute or chronic inflammatory response. The outcome of the immune response for the host may be beneficial, as when it causes invading organisms to be phagocytosed or neutralized. On the other hand, the outcome may be deleterious if it leads to chronic inflammation without resolution of the underlying injurious process (see Chapter 56: Immunopharmacology). Chronic inflammation involves the release of a number of mediators that are not prominent in the acute response. One of the most important conditions involving these mediators is rheumatoid arthritis, in which chronic inflammation results in pain and destruction of bone and cartilage that can lead to severe disability and in which systemic changes occur that can result in shortening of life.

The cell damage associated with inflammation acts on cell membranes to cause leukocytes to release lysosomal enzymes; arachidonic acid is then liberated from precursor compounds, and various eicosanoids are synthesized. As discussed in Chapter 18: The Eicosanoids: Prostaglandins, Thromboxanes, Leukotrienes, & Related Compounds, the cyclooxygenase pathway of arachidonate metabolism produces prostaglandins, which have a variety of effects on blood vessels, on nerve endings, and on cells involved in inflammation. The discovery of cyclooxygenase (COX) isoforms (COX-1 and COX-2) led to the concepts that the constitutive COX-1 isoform tends to be homeostatic in function, while COX-2 is induced during inflammation and tends to facilitate the inflammatory response. On this basis, highly selective COX-2 inhibitors have been developed and marketed on the assumption that such selective inhibitors would be safer than nonselective COX-1 inhibitors but without loss of efficacy. The lipoxygenase pathway of arachidonate metabolism yields leukotrienes, which have a powerful chemotactic effect on eosinophils, neutrophils, and macrophages and promote bronchoconstriction and alterations in vascular permeability.

Kinins, neuropeptides, and histamine are also released at the site of tissue injury, as are complement components, cytokines, and other products of leukocytes and platelets. Stimulation of the neutrophil

membranes produces oxygen-derived free radicals. Superoxide anion is formed by the reduction of molecular oxygen, which may stimulate the production of other reactive molecules such as hydrogen peroxide and hydroxyl radicals. The interaction of these substances with arachidonic acid results in the generation of chemotactic substances, thus perpetuating the inflammatory process.

Katzung PHARMACOLOGY, 9e > Section VI. Drugs Used to Treat Disease of the Blood, Inflammation, & Gout > Chapter 36. Nonsteroidal Anti-Inflammatory Drugs, Disease-Modifying Antirheumatic Drugs, Nonopioid Analgesics, & Drugs Used in Gout >

Therapeutic Strategies

The treatment of patients with inflammation involves two primary goals: first, the relief of pain, which is often the presenting symptom and the major continuing complaint of the patient; and second, the slowing or—in theory—arrest of the tissue-damaging process. In rheumatoid arthritis, response to therapy can be quantitated by means of the American College of Rheumatology scoring system values ACR20, ACR50, and ACR70, which denote the percentage of patients showing an improvement of 20%, 50%, or 70% in a global assessment of signs and symptoms.

Reduction of inflammation with **nonsteroidal anti-inflammatory drugs (NSAIDs)** often results in relief of pain for significant periods. Furthermore, most of the nonopioid analgesics (aspirin, etc) also have anti-inflammatory effects, so they are appropriate for the treatment of both acute and chronic inflammatory conditions.

The **glucocorticoids** also have powerful anti-inflammatory effects and when first introduced were considered to be the ultimate answer to the treatment of inflammatory arthritis. Unfortunately, the toxicity associated with chronic corticosteroid therapy limits their use except in the control of acute flare-ups of joint disease. Therefore, the nonsteroidal anti-inflammatory drugs have assumed a major role in the long-term treatment of arthritis.

Another important group of agents are characterized as **slow-acting antirheumatic drugs (SAARDs)** or **disease-modifying antirheumatic drugs (DMARDs)**. They may slow the bone damage associated with rheumatoid arthritis and are thought to affect more basic inflammatory mechanisms than do the NSAIDs. Unfortunately, they may also be more toxic than the nonsteroidal anti-inflammatory agents.

Katzung PHARMACOLOGY, 9e > Section VI. Drugs Used to Treat Disease of the Blood, Inflammation, & Gout > Chapter 36. Nonsteroidal Anti-Inflammatory Drugs, Disease-Modifying Antirheumatic Drugs, Nonopioid Analgesics, & Drugs Used in Gout >

Nonsteroidal Anti-Inflammatory Drugs

Salicylates and other similar agents used to treat rheumatic disease share the capacity to suppress the signs and symptoms of inflammation. These drugs also exert antipyretic and analgesic effects, but it is their anti-inflammatory properties that make them most useful in the management of disorders in which pain is related to the intensity of the inflammatory process.

Although all NSAIDs are not FDA-approved for the whole range of rheumatic diseases, all are probably effective in rheumatoid arthritis, seronegative spondyloarthropathies (eg, psoriatic arthritis and arthritis associated with inflammatory bowel disease), osteoarthritis, localized musculoskeletal syndromes (eg, sprains and strains, low back pain), and gout (except tolmetin, which appears to be

ineffective in gout). Since aspirin, the original NSAID, has a number of adverse effects, many other NSAIDs have been developed in attempts to improve upon aspirin's efficacy and decrease its toxicity.

Chemistry & Pharmacokinetics

The NSAIDs are grouped in several chemical classes, some of which are shown in Figure 36–1. This chemical diversity yields a broad range of pharmacokinetic characteristics (Table 36–1). Although there are many differences in the kinetics of NSAIDs, they have some general properties in common. All but one of the NSAIDs are weak organic acids as given; the exception, nabumetone, is a ketone prodrug that is metabolized to the acidic active drug. Most of these drugs are well absorbed, and food does not substantially change their bioavailability. Most of the NSAIDs are highly metabolized, some by phase I followed by phase II mechanisms and others by direct glucuronidation (phase II) alone. Metabolism of most NSAIDs proceeds, in part, by way of the CYP3A or CYP2C families of P450 enzymes in the liver. While renal excretion is the most important route for final elimination, nearly all undergo varying degrees of biliary excretion and reabsorption (enterohepatic circulation). In fact, the degree of lower gastrointestinal tract irritation correlates with the amount of enterohepatic circulation. Most of the NSAIDs are highly protein-bound ($\approx 98\%$), usually to albumin. Some of the NSAIDs (eg, ibuprofen) are racemic mixtures, while one, naproxen, is provided as a single enantiomer and a few have no chiral center (eg, diclofenac).

Figure 36–1.

Chemical structures of some NSAIDs.

Table 36–1. Properties of Aspirin and Some Nonsteroidal Anti-Inflammatory Drugs.

Drug	Half-life (hours)	Urinary Excretion of Unchanged Drug	Recommended Anti-inflammatory Dosage
Aspirin	0.25	< 2%	1200–1500 mg tid
Salicylate ¹	2–19	2–30%	See footnote 2
Apazone	15	62%	600 mg bid
Celecoxib	11	27% ³	100–200 mg bid
Diclofenac	1.1	< 1%	50–75 mg qid
Diflunisal	13	3–9%	500 mg bid

Etodolac	6.5	< 1%	200–300 mg qid
Fenoprofen	2.5	30%	600 mg qid
Flurbiprofen	3.8	< 1%	300 mg tid
Ibuprofen	2	< 1%	600 mg qid
Indomethacin	4–5	16%	50–70 mg tid
Ketoprofen	1.8	< 1%	70 mg tid
Ketorolac	4–10	58%	10 mg qid ⁴
Meclofenamate	3	2–4%	100 mg qid
Meloxicam	20	Data not found	7.5–15 mg qd
Nabumetone ⁵	26	1%	1000–2000 mg qd ⁶
Naproxen	14	< 1%	375 mg bid
Oxaprozin	58	1–4%	1200–1800 mg qd ⁶
Piroxicam	57	4–10%	20 mg qd ⁶
Rofecoxib	17	72% ³	12.5–50 mg qd
Sulindac	8	7%	200 mg bid
Tolmetin	1	7%	400 mg qid
Valdecoxib	8–11	90 ³	10 mg qd

¹Major anti-inflammatory metabolite of aspirin.

²Salicylate is usually given in the form of aspirin.

³Total urinary excretion including metabolites.

⁴Recommended for treatment of acute (eg, surgical) pain only.

⁵Nabumetone is a prodrug; the half-life and urinary excretion are for its active metabolite.

⁶A single daily dose is sufficient because of the long half-life.

All NSAIDs can be found in synovial fluid after repeated dosing. Drugs with short half-lives remain in the joints longer than would be predicted from their half-lives, while drugs with longer half-lives disappear from the synovial fluid at a rate proportionate to their half-lives.

Pharmacodynamics

The anti-inflammatory activity of the NSAIDs is mediated chiefly through inhibition of biosynthesis of prostaglandins. Various NSAIDs have additional possible mechanisms of action,

including inhibition of chemotaxis, down-regulation of interleukin-1 production, decreased production of free radicals and superoxide, and interference with calcium-mediated intracellular events. Aspirin irreversibly acetylates and blocks platelet cyclooxygenase, while most non-COX-selective NSAIDs are reversible inhibitors. Selectivity for COX-1 versus COX-2 is variable and incomplete for the older members, but highly selective COX-2 inhibitors (celecoxib, rofecoxib, and valdecoxib) are now available and other highly selective coxibs are being developed. The highly selective COX-2 inhibitors do not affect platelet function at their usual doses. In testing using human whole blood, aspirin, indomethacin, piroxicam, and sulindac were somewhat more effective in inhibiting COX-1; ibuprofen and meclufenamate inhibited the two isozymes about equally. The efficacy of COX-2-selective drugs equals that of the older NSAIDs, while gastrointestinal safety may be improved. On the other hand, highly selective COX-2 inhibitors may increase the incidence of edema and hypertension.

The NSAIDs decrease the sensitivity of vessels to bradykinin and histamine, affect lymphokine production from T lymphocytes, and reverse vasodilation. To varying degrees, all newer NSAIDs are analgesic, anti-inflammatory, and antipyretic, and all (except the COX-2-selective agents and the nonacetylated salicylates) inhibit platelet aggregation. NSAIDs are all gastric irritants as well, though as a group the newer agents tend to cause less gastric irritation than aspirin. Nephrotoxicity has been observed for all of the drugs for which extensive experience has been reported, and hepatotoxicity can also occur with any NSAID.

Although these drugs effectively inhibit inflammation, there is no evidence that—in contrast to drugs such as methotrexate and gold—they alter the course of an arthritic disorder.

Aspirin

Aspirin's long use and availability without prescription diminishes its glamour compared to that of the newer NSAIDs. Aspirin is now rarely used as an anti-inflammatory medication; it has been replaced by ibuprofen and naproxen, since they are effective, are also available over the counter, and have good to excellent safety records.

Pharmacokinetics

Salicylic acid is a simple organic acid with a pK_a of 3.0. Aspirin (acetylsalicylic acid; ASA) has a pK_a of 3.5 (see Table 1–1). Sodium salicylate and aspirin (Figure 36–2) are equally effective anti-inflammatory drugs, though aspirin may be more effective as an analgesic. The salicylates are rapidly absorbed from the stomach and upper small intestine, yielding a peak plasma salicylate level within 1–2 hours. Aspirin is absorbed as such and is rapidly hydrolyzed (serum half-life 15 minutes) to acetic acid and salicylate by esterases in tissue and blood. Salicylate is bound to albumin, but the binding is saturable so that the unbound fraction increases as total concentration increases. Ingested salicylate and that generated by the hydrolysis of aspirin may be excreted unchanged, but the metabolic pathways for salicylate disposition become saturated when the total body load of salicylate exceeds 600 mg. Beyond this amount, increases in salicylate dosage increase salicylate concentration disproportionately. As doses of aspirin increase, salicylate elimination half-life increases from 3–5 hours (for 600 mg/d dosage) to 12–16 hours (dosage > 3.6 g/d). Alkalinization of the urine increases the rate of excretion of free salicylate and its water-soluble conjugates.

Figure 36–2.

Structure and metabolism of the salicylates. (Modified and reproduced, with permission, from Meyers FH, Jawetz E, Goldfien A: *Review of Medical Pharmacology*, 7th ed. McGraw-Hill, 1980.)

Mechanisms of Action

Anti-Inflammatory Effects

Aspirin is a nonselective inhibitor of both COX isoforms (Figure 36–3), but salicylate is much less effective in inhibiting either isoform. Nonacetylated salicylates may work as oxygen radical scavengers. Aspirin irreversibly inhibits COX and inhibits platelet aggregation, while nonacetylated salicylates do not.

Figure 36–3.

Aspirin also interferes with the chemical mediators of the kallikrein system (see Chapter 17: Vasoactive Peptides), thus inhibiting granulocyte adherence to damaged vasculature, stabilizing lysosomes, and inhibiting the chemotaxis of polymorphonuclear leukocytes and macrophages.

Analgesic Effects

Aspirin is most effective in reducing pain of mild to moderate intensity through its effects on inflammation and because it probably inhibits pain stimuli at a subcortical site.

Antipyretic Effects

Aspirin reduces elevated temperature, whereas normal body temperature is only slightly affected. Aspirin's antipyretic effect is probably mediated by both COX inhibition in the central nervous system and inhibition of IL-1 (which is released from macrophages during episodes of inflammation).

Antiplatelet Effects

Single low doses of aspirin (81 mg daily) produce a slightly prolonged bleeding time, which doubles if administration is continued for a week (see Chapter 34: Drugs Used in Disorders of Coagulation). The change is due to irreversible inhibition of platelet COX, so that aspirin's antiplatelet effect lasts 8–10 days (the life of the platelet).

Clinical Uses

Analgesia, Antipyresis, and Anti-Inflammatory Effects

Aspirin is employed for mild to moderate pain of varied origin but is not effective for severe visceral pain. Aspirin and other NSAIDs have been combined with opioid analgesics for treatment of cancer pain, where their anti-inflammatory effects act synergistically with the opioids to enhance analgesia. High-dose salicylates are effective for treatment of rheumatic fever, rheumatoid arthritis, and other inflammatory joint conditions.

Other Effects

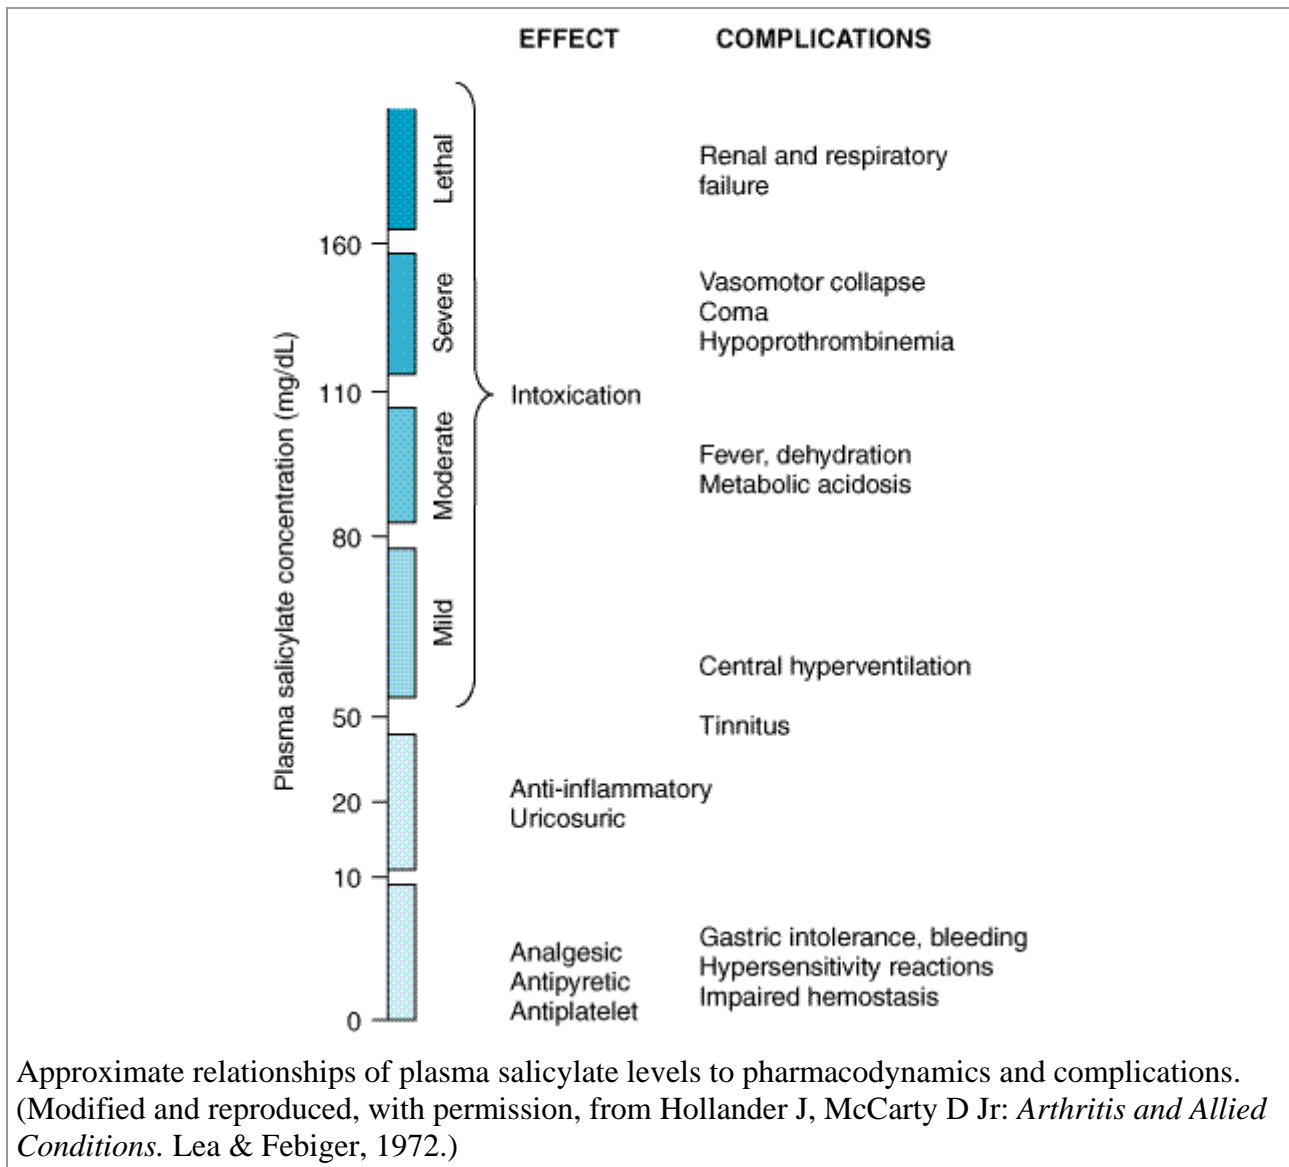

Aspirin decreases the incidence of transient ischemic attacks, unstable angina, coronary artery thrombosis with myocardial infarction, and thrombosis after coronary artery bypass grafting (see Chapter 34: Drugs Used in Disorders of Coagulation).

Epidemiologic studies suggest that long-term use of aspirin at low dosage is associated with a lower incidence of colon cancer, possibly related to its COX-inhibiting effects.

Dosage

The optimal analgesic or antipyretic dose of aspirin is less than the 0.6–0.65 g oral dose commonly used. Larger doses may prolong the effect. The usual dose may be repeated every 4 hours. The anti-inflammatory dose for children is 50–75 mg/kg/d in divided doses and the average starting anti-inflammatory dose for adults is 45 mg/kg/d in divided doses (Table 36–1). The relationship of salicylate blood levels to therapeutic effect and toxicity is illustrated in Figure 36–4.

Figure 36–4.

Adverse Effects

At the usual dosage, aspirin's main adverse effects are gastric upset (intolerance) and gastric and duodenal ulcers, while hepatotoxicity, asthma, rashes, and renal toxicity occur less frequently. Upper gastrointestinal bleeding associated with aspirin use is usually related to erosive gastritis. A 3 mL increase in fecal blood loss is routinely associated with aspirin administration; the blood loss is greater for higher doses. On the other hand, some mucosal adaptation occurs in many patients, so that blood loss declines back to baseline over 4–6 weeks; ulcers have been shown to heal while aspirin was taken concomitantly.

With higher doses, patients may experience "salicylism"—vomiting, tinnitus, decreased hearing, and vertigo—reversible by reducing the dosage. Still larger doses of salicylates cause hyperpnea through a direct effect on the medulla. At toxic salicylate levels, respiratory alkalosis followed by metabolic acidosis (salicylate accumulation), respiratory depression, and even cardiotoxicity and glucose intolerance can occur (Figure 36–4). Two grams or less of aspirin daily usually increases serum uric acid levels, whereas doses exceeding 4 g daily decrease urate levels (see *Drugs Used in Gout*, below). Like other NSAIDs, aspirin can cause elevation of liver enzymes (a frequent but mild effect), hepatitis (rare), decreased renal function, bleeding, rashes, and asthma.

The antiplatelet action of aspirin contraindicates its use by patients with hemophilia. Although previously not recommended during pregnancy, aspirin may be valuable in treating preeclampsia-eclampsia.

When overdosing occurs, gastric lavage is advised and an alkaline, high urine output state should be maintained (see Chapter 59: Management of the Poisoned Patient). Hyperthermia and electrolyte abnormalities should be treated. In severe toxic reactions, ventilatory assistance may be required. Sodium bicarbonate infusions may be employed to alkalinize the urine, which will increase the amount of salicylate excreted.

Nonacetylated Salicylates

These drugs include magnesium choline salicylate, sodium salicylate, and salicylsalicylate. All nonacetylated salicylates are effective anti-inflammatory drugs, though they may be less effective analgesics than aspirin. Because they are much less effective than aspirin as cyclooxygenase inhibitors, they may be preferable when cyclooxygenase inhibition is undesirable, such as in patients with asthma, those with bleeding tendencies, and even (under close supervision) those with renal dysfunction.

The nonacetylated salicylates are administered in the same dosage as aspirin and can be monitored using serum salicylate measurements.

COX-2 Selective Inhibitors

COX-2 selective inhibitors, or coxibs, were developed in an attempt to inhibit prostacyclin synthesis by the COX-2 isoenzyme induced at sites of inflammation without affecting the action of the constitutively active "housekeeping" COX-1 isoenzyme found in the gastrointestinal tract, kidneys, and platelets. Coxibs selectively bind to and block the active site of the COX-2 enzyme much more effectively than that of COX-1. COX-2 inhibitors have analgesic, antipyretic, and anti-inflammatory effects similar to those of nonselective NSAIDs but with fewer gastrointestinal side effects. Likewise, COX-2 inhibitors have been shown to have no impact on platelet aggregation, which is mediated by the COX-1 isoenzyme. As a result, COX-2 inhibitors do not offer the cardioprotective effects of traditional nonselective NSAIDs, which has resulted in some patients taking low-dose aspirin in addition to a coxib regimen to maintain this effect. Unfortunately, because COX-2 is constitutively active within the kidney, recommended doses of COX-2 inhibitors cause renal toxicities similar to those associated with traditional NSAIDs. They are not recommended for patients with severe renal insufficiency. Furthermore, some clinical data have suggested a higher incidence of cardiovascular thrombotic events associated with COX-2 inhibitors such as rofecoxib, but this issue has not yet been settled. Data from animal studies have also pointed to the role of the COX-2 enzyme in bone repair, resulting in a recommendation for short-term use of different drugs in postoperative patients and those undergoing bone repair. COX-2 inhibitors have been recommended mainly for treatment of osteoarthritis and rheumatoid arthritis, but other indications include primary familial adenomatous polyposis, dysmenorrhea, acute gouty arthritis, acute musculoskeletal pain, and perhaps ankylosing spondylitis.

Celecoxib

Celecoxib is a highly selective COX-2 inhibitor—about 10–20 times more selective for COX-2 than for COX-1. Pharmacokinetic and dosage considerations are given in Table 36–1.

Celecoxib

Celecoxib is as effective as other NSAIDs in rheumatoid arthritis and osteoarthritis, and in trials it has caused fewer endoscopic ulcers than most other NSAIDs. Because it is a sulfonamide, celecoxib may cause rashes. It does not affect platelet aggregation. It interacts occasionally with warfarin—as would be expected of a drug metabolized via CYP2C9.

The coxibs continue to be investigated to determine whether their effect on prostacyclin production could lead to a prothrombotic state. The frequency of other adverse effects approximates that of other NSAIDs. Celecoxib causes no more edema or renal effects than other members of the NSAID group, but edema and hypertension have been documented.

Etoricoxib

Etoricoxib, a bipyridine derivative, is a second-generation COX-2-selective inhibitor with the highest selectivity ratio of any coxib for inhibition of COX-2 relative to COX-1. It is extensively metabolized by hepatic P450 enzymes followed by renal excretion and has an elimination half-life of 22 hours. Etoricoxib is approved in the United Kingdom for acute treatment of the signs and symptoms of osteoarthritis (60 mg once daily) and rheumatoid arthritis (90 mg once daily), for treatment of acute gouty arthritis (120 mg once daily), and for relief of acute musculoskeletal pain (60 mg once daily). Approval in the United States is pending. Clinical data have demonstrated that 90 mg of etoricoxib once daily has superior efficacy compared with 500 mg of naproxen twice daily for treatment of patients with rheumatoid arthritis over 12 weeks. Other studies have shown etoricoxib to have similar efficacy to traditional NSAIDs for treatment of osteoarthritis, acute gouty arthritis, and primary dysmenorrhea and a gastrointestinal safety profile similar to that of other coxibs. Since etoricoxib has structural similarities to diclofenac, it is appropriate to monitor hepatic function carefully in patients using this drug.

Meloxicam

Meloxicam is an enolcarboxamide related to piroxicam that has been shown to preferentially inhibit COX-2 over COX-1, particularly at its lowest therapeutic dose of 7.5 mg/d. It is not as selective as the other coxibs. The drug is popular in Europe and many other countries for most rheumatic diseases and has recently been approved for treatment of osteoarthritis in the USA. Its efficacy in this condition and rheumatoid arthritis is comparable to that of other NSAIDs. It is associated with fewer clinical gastrointestinal symptoms and complications than piroxicam, diclofenac, and naproxen. Similarly, while meloxicam is known to inhibit synthesis of thromboxane A₂, it appears that even at supratherapeutic doses its blockade of thromboxane A₂ does not reach levels that result

in decreased in vivo platelet function. Other toxicities are similar to those of other NSAIDs.

Rofecoxib

Rofecoxib, a furanose derivative, is a potent, selective COX-2 inhibitor (Table 36–1). In the USA, rofecoxib is approved for osteoarthritis and rheumatoid arthritis, and it also appears to be analgesic and antipyretic—in common with other NSAIDs. This drug does not inhibit platelet aggregation and appears to have little effect on gastric mucosal prostaglandins or lower gastrointestinal tract permeability. At high doses it is associated with occasional edema and hypertension. Other toxicities are similar to those of other coxibs.

Rofecoxib

Valdecoxib

Valdecoxib, a diaryl-substituted isoxazole, is a new highly selective COX-2 inhibitor. Pharmacokinetic characteristics and dosage in arthritis are set forth in Table 36–1. In primary dysmenorrhea, dosage is 20 mg twice daily, and the drug is as effective as nonselective NSAIDs for this indication. Gastrointestinal and other toxicities are similar to those of the other coxibs. Valdecoxib has no effect on platelet aggregation or bleeding time. Serious reactions have been reported in sulfonamide-sensitive individuals.

Valdecoxib

Nonselective COX Inhibitors

Diclofenac

Diclofenac is a phenylacetic acid derivative that is relatively nonselective as a cyclooxygenase inhibitor. Pharmacokinetic and dosage characteristics are set forth in Table 36–1.

Adverse effects occur in approximately 20% of patients and include gastrointestinal distress, occult gastrointestinal bleeding, and gastric ulceration, though ulceration may occur less frequently than with some other NSAIDs. A preparation combining diclofenac and misoprostol decreases upper gastrointestinal ulceration but may result in diarrhea. Another combination of diclofenac and omeprazole was also effective with respect to the prevention of recurrent bleeding, but renal adverse effects were common in high-risk patients. Diclofenac at a dosage of 150 mg/d appears to impair renal blood flow and glomerular filtration rate. Elevation of serum aminotransferases may occur more commonly with this drug than with other NSAIDs.

A 0.1% ophthalmic preparation is recommended for prevention of postoperative ophthalmic inflammation and can be used after intraocular lens implantation and strabismus surgery. A topical gel containing 3% diclofenac is effective for solar keratoses. Diclofenac in rectal suppository form can be considered a drug of choice for preemptive analgesia and postoperative nausea. In Europe, diclofenac is also available as an oral mouthwash and for intramuscular administration.

Diflunisal

Although diflunisal is derived from salicylic acid, it is not metabolized to salicylic acid or salicylate. It undergoes an enterohepatic cycle with reabsorption of its glucuronide metabolite followed by cleavage of the glucuronide to again release the active moiety. Diflunisal is subject to capacity-limited metabolism, with serum half-lives at various dosages approximating that of salicylates (Table 36–1). It is claimed to be particularly effective for cancer pain with bone metastases and for pain control in dental (third molar) surgery. A 2% diflunisal oral ointment is a clinically useful analgesic for painful oral lesions.

Because its clearance depends on renal function as well as hepatic metabolism, diflunisal's dosage should be limited in patients with significant renal impairment. Its adverse event profile is similar to those of other NSAIDs; pseudoporphyria has also been reported.

Etodolac

Etodolac is a racemic acetic acid derivative with an intermediate half-life (Table 36–1). It is slightly more COX-2-selective than most other NSAIDs, with a COX-2:COX-1 activity ratio of about 10. Unlike many other racemic NSAIDs, etodolac does not undergo chiral inversion in the body. Etodolac produces good postoperative pain relief after coronary artery bypass operations, although transient impairment of renal function has been reported. There are no data to suggest that etodolac differs significantly from other NSAIDs except in its pharmacokinetic parameters, though it has been claimed to cause less gastric toxicity in terms of ulcer disease than other nonselective NSAIDs.

Fenoprofen

Fenoprofen, a propionic acid derivative, is the NSAID most closely associated with the toxic effect of interstitial nephritis. This rare toxicity may be associated with a local T cell response in renal tissue.

Other adverse effects of fenoprofen include nausea, dyspepsia, peripheral edema, rash, pruritus, central nervous system and cardiovascular effects, tinnitus, and drug interactions. However, the latter effects are less common than with aspirin.

Flurbiprofen

Flurbiprofen is a propionic acid derivative with a possibly more complex mechanism of action than other NSAIDs. Its (*S*)(-) enantiomer inhibits COX nonselectively, but it has been shown in rat tissue to also affect TNF- α and nitric oxide synthesis. Hepatic metabolism is extensive; its (*R*)(+) and (*S*)(-) enantiomers are metabolized differently, and it does not undergo chiral conversion. It does demonstrate enterohepatic circulation.

The efficacy of flurbiprofen at dosages of 200–400 mg/d is comparable to that of aspirin and other NSAIDs in clinical trials for patients with rheumatoid arthritis, ankylosing spondylitis, gout, and osteoarthritis. It is also available in a topical ophthalmic formulation for inhibition of intraoperative miosis. Flurbiprofen intravenously has been found to be effective for perioperative analgesia in minor ear, neck, and nose surgery and in lozenge form for sore throat.

Although its adverse effect profile is similar to that of other NSAIDs in most ways, flurbiprofen is also associated rarely with cogwheel rigidity, ataxia, tremor, and myoclonus.

Ibuprofen

Ibuprofen is a simple derivative of phenylpropionic acid. In doses of about 2400 mg daily, ibuprofen is equivalent to 4 g of aspirin in anti-inflammatory effect. Pharmacokinetic characteristics are given in table 36–1.

Oral ibuprofen is often prescribed in lower doses (< 2400 mg/d), at which it has analgesic but not anti-inflammatory efficacy. It is available over the counter in low-dose forms under several trade names. A topical cream preparation appears to be absorbed into fascia and muscle; an (*S*)(-) formulation has been tested. Ibuprofen cream was more effective than placebo cream for the treatment of primary knee osteoarthritis. A liquid gel preparation of ibuprofen 400 mg provided faster relief and superior overall efficacy in postsurgical dental pain. In comparison with indomethacin, ibuprofen decreases urine output less and also causes less fluid retention than indomethacin. Ibuprofen has been shown to be effective in closing patent ductus arteriosus in preterm infants, with much the same efficacy and safety as indomethacin. Oral ibuprofen is as effective as intravenous administration in this condition.

Gastrointestinal irritation and bleeding occur, though less frequently than with aspirin. The use of ibuprofen concomitantly with aspirin may *decrease* the total anti-inflammatory effect. The drug is relatively contraindicated in individuals with nasal polyps, angioedema, and bronchospastic reactivity to aspirin. In addition to the gastrointestinal symptoms (which can be modified by ingestion with meals), rash, pruritus, tinnitus, dizziness, headache, aseptic meningitis (particularly in patients with systemic lupus erythematosus), and fluid retention have been reported. Interaction with anticoagulants is uncommon.

The concomitant administration of ibuprofen antagonizes the irreversible platelet inhibition induced by aspirin. Thus, treatment with ibuprofen in patients with increased cardiovascular risk may limit the cardioprotective effects of aspirin. Rare hematologic effects include agranulocytosis and aplastic anemia. Effects on the kidney (as with all NSAIDs) include acute renal failure, interstitial nephritis, and nephrotic syndrome, but these occur very rarely. Finally, hepatitis has been reported.

Indomethacin

Indomethacin, introduced in 1963, is an indole derivative (Figure 36–1). It is a potent nonselective COX inhibitor and may also inhibit phospholipase A and C, reduce neutrophil migration, and decrease T cell and B cell proliferation. Probenecid prolongs indomethacin's half-life by inhibiting both renal and biliary clearance.

Clinical Uses

Indomethacin enjoys the usual indications for use in rheumatic conditions and is particularly popular for gout and ankylosing spondylitis. In addition, it has been used to treat patent ductus arteriosus. Indomethacin has been tried in numerous small or uncontrolled trials for many conditions, including Sweet's syndrome, juvenile rheumatoid arthritis, pleurisy, nephrotic syndrome, diabetes insipidus, urticarial vasculitis, postepisiotomy pain, and prophylaxis of heterotopic ossification in arthroplasty, and many others. An ophthalmic preparation seems to be efficacious for conjunctival inflammation (alone and in combination with gentamicin) to reduce pain after traumatic corneal abrasion. Gingival inflammation is reduced after administration of indomethacin oral rinse. Epidural injections produce a degree of pain relief similar to that achieved with methylprednisolone in postlaminectomy syndrome.

Adverse Effects

At higher dosages, at least a third of patients have reactions to indomethacin requiring discontinuance. The gastrointestinal effects may include abdominal pain, diarrhea, gastrointestinal hemorrhage, and pancreatitis. Headache is experienced by 15–25% of patients and may be associated with dizziness, confusion, and depression. Rarely, psychosis with hallucinations has been reported. Hepatic abnormalities are rare. Serious hematologic reactions have been noted, including thrombocytopenia and aplastic anemia. Hyperkalemia has been reported and is related to inhibition of the synthesis of prostaglandins in the kidney. Renal papillary necrosis has also been observed. Bolus injections decrease organ blood flow and impair urinary output, although continuous infusion does not. A number of interactions with other drugs have been reported (see Appendix II). As is true for other potent cyclooxygenase inhibitors also, use of indomethacin should be avoided in patients with nasal polyps or angioedema, in whom asthma may be precipitated.

Ketoprofen

Ketoprofen is a propionic acid derivative that inhibits both cyclooxygenase (nonselectively) and lipoxygenase. Its pharmacokinetic characteristics are given in Table 36–1. Concurrent administration of probenecid elevates ketoprofen levels and prolongs its plasma half-life.

The effectiveness of ketoprofen at dosages of 100–300 mg/d is equivalent to that of other NSAIDs in the treatment of rheumatoid arthritis, osteoarthritis, gout, dysmenorrhea, and other painful conditions. In spite of its dual effect on prostaglandins and leukotrienes, ketoprofen is not superior to other NSAIDs. Its major adverse effects are on the gastrointestinal tract and the central nervous system.

Ketorolac

Ketorolac is an NSAID promoted for systemic use mainly as an analgesic, not as an anti-inflammatory drug (though it has typical NSAID properties). Pharmacokinetics are presented in Table 36–1. The drug does appear to have significant analgesic efficacy and has been used

successfully to replace morphine in some situations involving mild to moderate postsurgical pain. It is most often given intramuscularly or intravenously, but an oral dose formulation is available. When used with an opioid, it may decrease the opioid requirement by 25–50%. An ophthalmic preparation is available for anti-inflammatory applications. Toxicities are similar to those of other NSAIDs, although renal toxicity may be more common with chronic use.

Meclofenamate & Mefenamic Acid

Meclofenamate and mefenamic acid (Table 36–1) inhibit both COX and phospholipase A₂. Meclofenamate appears to have adverse effects similar to those of other NSAIDs, though diarrhea and abdominal pain may be more common; it has no advantages over other NSAIDs. This drug enhances the effect of oral anticoagulants. Meclofenamate is contraindicated in pregnancy; its efficacy and safety have not been established for young children.

Mefenamic acid is probably less effective than aspirin as an anti-inflammatory agent and is clearly more toxic. It should not be used for longer than 1 week and should not be given to children.

Nabumetone

Nabumetone is the only nonacid NSAID in current use; it is converted to the active acetic acid derivative in the body. It is given as a ketone prodrug that resembles naproxen in structure (Figure 36–1). Its half-life of more than 24 hours (Table 36–1) permits once-daily dosing, and the drug does not appear to undergo enterohepatic circulation. Renal impairment results in a doubling of its half-life and a 30% increase in area under the curve. Its properties are very similar to those of other NSAIDs, though it may be less damaging to the stomach than some other NSAIDs when given at a dosage of 1000 mg/d. Unfortunately, higher doses (eg, 1500–2000 mg/d) are often needed, and this is a very expensive NSAID. Like naproxen, nabumetone has been reported to cause pseudoporphyria and photosensitivity in some patients. Other adverse effects mirror those of other NSAIDs.

Naproxen

Naproxen is a naphthylpropionic acid derivative. It is the only NSAID presently marketed as a single enantiomer, and it is a nonselective COX inhibitor. Naproxen's free fraction is 41% higher in women than in men, though albumin binding is very high in both sexes (Table 36–1). Naproxen is effective for the usual rheumatologic indications and is available both in a slow-release formulation and as an oral suspension. A topical preparation and an ophthalmic solution are also available.

The incidence of upper gastrointestinal bleeding in OTC use is low but still double that of OTC ibuprofen (perhaps due to a dose effect). Rare cases of allergic pneumonitis, leukocytoclastic vasculitis, and pseudoporphyria as well as the more common NSAID-associated adverse effects have been noted.

Oxaprozin

Oxaprozin is another propionic acid derivative NSAID. As noted in Table 36–1, its major difference from the other members of this subgroup is a very long half-life (50–60 hours), though oxaprozin does not undergo enterohepatic circulation. Because of its long half-life, oxaprozin can be given once a day, and dosage adjustments should be made at intervals no shorter than 5 days. The drug appears to have the same benefits and risks that are associated with other NSAIDs. It is mildly uricosuric, making it potentially more useful in gout than some other NSAIDs.

Phenylbutazone

Phenylbutazone, a pyrazolone derivative, rapidly gained favor after its introduction in 1949 for the treatment of rheumatic syndromes, but its toxicities—particularly the hematologic effects (including aplastic anemia)—have resulted in its withdrawal from the North American and most European markets. It is rarely used today.

Piroxicam

Piroxicam, an oxicam (Figure 36–1), is a nonselective COX inhibitor but at high concentrations also inhibits polymorphonuclear leukocyte migration, decreases oxygen radical production, and inhibits lymphocyte function. Its long half-life (Table 36–1) permits once-daily dosing.

Piroxicam can be used for the usual rheumatic indications. Toxicity includes gastrointestinal symptoms (20% of patients), dizziness, tinnitus, headache, and rash. When piroxicam is used in dosages higher than 20 mg/d, an increased incidence of peptic ulcer and bleeding is encountered. Epidemiologic studies suggest that this risk is as much as 9.5 times higher with piroxicam than with other NSAIDs.

Sulindac

Sulindac is a sulfoxide prodrug. It is reversibly metabolized to the active sulfide metabolite, which is excreted in bile and then reabsorbed from the intestine. The enterohepatic cycling prolongs the duration of action to 12–16 hours.

The indications and adverse reactions of sulindac are similar to those of other NSAIDs. In addition to its rheumatic disease indications, sulindac suppresses familial intestinal polyposis; it may inhibit the development of colon, breast, and prostate cancer in humans. It appears to inhibit the occurrence of gastrointestinal cancer in rats. The latter effect may be caused by the sulfone rather than the sulfide.

Because the sulfide may be reoxidized to the inactive prodrug in the kidney, sulindac may inhibit renal COX less than other NSAIDs, though reversible renal failure and nephrotic syndrome have been observed with this drug. Among the more severe reactions, Stevens-Johnson epidermal necrolysis syndrome, thrombocytopenia, agranulocytosis, and nephrotic syndrome have all been observed. Like diclofenac, sulindac may have some propensity to cause elevation of serum aminotransferases; it is also sometimes associated with cholestatic liver damage, which disappears or becomes quiescent when the drug is stopped.

Tenoxicam

Tenoxicam is an oxicam similar to piroxicam and shares its nonselective COX inhibition, long half-life (72 hours), efficacy, and toxicity profile. It is available abroad but not in the USA.

Tiaprofen

Tiaprofen is a racemic propionic acid derivative but does not undergo stereoconversion. It has a short serum half-life (1–2 hours) with an increase to 2–4 hours in the elderly. This drug inhibits renal uric acid reabsorption and thus decreases serum uric acid slightly. It is available for oral and intramuscular administration. Its efficacy and adverse event profiles mirror those of other NSAIDs, but tiaprofen is not available in the USA.

Tolmetin

Tolmetin is a nonselective COX inhibitor. Its short half-life means that it must be given frequently, and it is therefore not often used. It is similar to other NSAIDs in efficacy except in gout, in which it is ineffective (for unknown reasons). Its toxicity profile is also similar to those of other NSAIDs, with the rare additional problem of allergic IgM-related thrombocytopenic purpura.

Azapropazone & Carprofen

These drugs are available in many other countries but are not sold in the USA. Azapropazone (apazone), a pyrazolone derivative, is structurally related to phenylbutazone but appears less likely to cause agranulocytosis. Its half-life of 12–16 hours may be doubled in patients with decreased renal function. Carprofen is a propionic acid derivative with a half-life of 10–16 hours. The indications and adverse effects of azapropazone and carprofen are similar to those of other NSAIDs.

Clinical Pharmacology of the NSAIDs

All NSAIDs, including aspirin, are about equally efficacious with a few exceptions—tolmetin seems not to be effective for gout, and aspirin is less effective than other NSAIDs (eg, indomethacin) for ankylosing spondylitis. Thus, NSAIDs tend to be differentiated on the basis of toxicity and cost-effectiveness. For example, the gastrointestinal and renal side effects of ketorolac limit its use. Fries et al (1993), using a toxicity index, estimated that indomethacin, tolmetin, and meclofenamate were associated with the greatest toxicity, while salsalate, aspirin, and ibuprofen were least toxic. The selective COX-2 inhibitors were not included in this analysis.

For patients with renal insufficiency, nonacetylated salicylates may be best. Fenoprofen is less used because of its rare association with interstitial nephritis. Diclofenac and sulindac are associated with more liver function test abnormalities than other NSAIDs. The relatively expensive and selective COX-2 inhibitors are probably safest for patients at high risk for gastrointestinal bleeding. These drugs or a nonselective NSAID plus omeprazole or misoprostol may be appropriate in those patients at highest risk for gastrointestinal bleeding; in this subpopulation of patients, they are cost-effective despite their high acquisition costs.

The choice of an NSAID thus requires a balance of efficacy, cost-effectiveness, safety, and numerous personal factors (eg, other drugs also being used, concurrent illness, compliance, medical insurance coverage), so that there is no "best" NSAID for all patients. There may, however, be one or two best NSAIDs for a specific person.

Katzung PHARMACOLOGY, 9e > Section VI. Drugs Used to Treat Disease of the Blood, Inflammation, & Gout > Chapter 36. Nonsteroidal Anti-Inflammatory Drugs, Disease-Modifying Antirheumatic Drugs, Nonopioid Analgesics, & Drugs Used in Gout >

Disease-Modifying Antirheumatic Drugs (DMARDs)

Careful clinical and epidemiologic studies have shown that rheumatoid arthritis is an immunologic disease that causes significant systemic effects which shorten life in addition to the joint disease that reduces mobility and quality of life. NSAIDs offer mainly symptomatic relief; they reduce inflammation and the pain it causes and often preserve function, but they have little effect on the progression of bone and cartilage destruction. Interest has therefore centered on finding treatments that might arrest—or at least slow—this progression by modifying the disease itself. The effects of disease-modifying therapies may take 6 weeks to 6 months to become evident, ie, they are slow-

acting compared with NSAIDs. These therapies include methotrexate, azathioprine, penicillamine, hydroxychloroquine and chloroquine, organic gold compounds, sulfasalazine, leflunomide, tumor necrosis factor (TNF)-blocking agents, and immunoadsorption apheresis. Considerable controversy surrounds the long-term efficacy of many of these therapies.

Methotrexate

Methotrexate is now considered the first DMARD of choice in the treatment of rheumatoid arthritis and is used in up to 60% of patients. It is active in this condition at much lower doses than those needed in cancer chemotherapy (see Chapter 55: Cancer Chemotherapy).

Mechanism of Action

Methotrexate's principal mechanism of action at the low doses used in the rheumatic diseases probably relates to inhibition of aminoimidazolecarboxamide (AICAR) transformylase and thymidylate synthetase, with secondary effects on polymorphonuclear chemotaxis. While there is some effect on dihydrofolate reductase—and this effects lymphocyte and macrophage function—it is more likely its effect on AICAR transformylase that accounts for the major portion of its action in autoimmune disease.

Pharmacokinetics

The drug is approximately 70% absorbed after oral administration (see Chapter 55: Cancer Chemotherapy). It is metabolized to a less active hydroxylated metabolite, and both the parent compound and the metabolite are polyglutamated within cells, where they stay for prolonged periods. Methotrexate's serum half-life is usually only 6–9 hours, although it may be as long as 24 hours in some individuals. Methotrexate's concentration is increased in the presence of hydroxychloroquine. This drug is excreted principally in the urine, but up to 30% may be excreted in bile.

Indications

Although the most common methotrexate dosing regimens for the treatment of rheumatoid arthritis are 15 or 17.5 mg weekly, there is an increased effect up to 30 or 35 mg weekly. The drug decreases the rate of appearance of new erosions. Evidence supports its use in juvenile chronic arthritis, and it has been used in psoriasis, psoriatic arthritis, polymyositis, dermatomyositis, Wegener's granulomatosis, giant cell arteritis, subacute lupus erythematosus, and vasculitis.

Adverse Effects

Nausea and mucosal ulcers are the most common toxicities. Progressive dose-related hepatotoxicity in the form of enzyme elevation occurs frequently, but cirrhosis is rare (< 1%). Liver toxicity is not related to methotrexate concentrations, and liver biopsy follow-up is only recommended every 5 years. A rare "hypersensitivity" lung reaction with acute shortness of breath is documented, as are pseudolymphomatous reactions. The incidence of gastrointestinal and liver function test abnormalities can be reduced by the use of leucovorin 24 hours after each weekly dose or by the use of daily folic acid. This drug is contraindicated in pregnancy.

Chlorambucil

Mechanism of Action & Pharmacokinetics

Chlorambucil, probably through its metabolite phenylacetic acid mustard, cross-links DNA, thereby preventing cell replication. Its bioavailability is about 70% and it is completely metabolized, with excretion completed within 24 hours.

Indications

One controlled, double-blind trial plus anecdotal evidence attest to the efficacy of chlorambucil in rheumatoid arthritis. Chlorambucil has also been used in Behçet's disease, systemic lupus erythematosus, vasculitis, and other autoimmune disorders.

Adverse Effects

The most common toxicity is dose-related bone marrow suppression. Infertility with azoospermia and amenorrhea also occurs. The risk of neoplasia is increased, with the relative risk of leukemia increased about tenfold compared with the general population, especially after more than 3 years of use.

Cyclophosphamide

Mechanism of Action

Cyclophosphamide's major active metabolite is phosphoramidate mustard, which cross-links DNA to prevent cell replication. It suppresses T cell and B cell function by 30–40%; the T cell suppression correlates with clinical response in the rheumatic diseases.

Pharmacokinetics

See Chapter 55: Cancer Chemotherapy.

Indications

Cyclophosphamide is active against rheumatoid arthritis when given orally at dosages of 2 mg/kg/d but not when given intravenously. It is used regularly to treat systemic lupus erythematosus, vasculitis, Wegener's granulomatosis, and other severe rheumatic diseases.

Adverse Effects

Cyclophosphamide causes significant dose-related infertility in both men and women as well as bone marrow suppression, alopecia, hemorrhagic cystitis, and, rarely, bladder carcinoma (see Chapter 55: Cancer Chemotherapy).

Cyclosporine

Mechanism of Action

Through regulation of gene transcription, cyclosporine inhibits IL-1 and IL-2 receptor production and secondarily inhibits macrophage-T cell interaction and T cell responsiveness (see Chapter 56: Immunopharmacology). T cell-dependent B cell function is also affected.

Pharmacokinetics

Cyclosporine absorption is incomplete and somewhat erratic, although a new microemulsion formulation improves its consistency and provides 20 to 30% bioavailability. Grapefruit juice increases cyclosporine bioavailability up to 62%. Cyclosporine is metabolized by CYP3A and consequently is subject to a large number of drug interactions (see Chapter 56:

Immunopharmacology and Appendix II: Important Drug Interactions & Their Mechanisms).

Indications

Cyclosporine is approved for use in rheumatoid arthritis and retards the appearance of new bony erosions. Its usual dosage is 3–5 mg/kg/d divided into two doses. Anecdotal reports suggest that it may be useful in systemic lupus erythematosus, polymyositis and dermatomyositis, Wegener's granulomatosis, and juvenile chronic arthritis.

Adverse Effects

Cyclosporine has significant nephrotoxicity, and its toxicity can be increased by drug interactions with diltiazem, potassium-sparing diuretics, and other drugs inhibiting CYP3A. Serum creatinine should be closely monitored. Other toxicities include hypertension, hyperkalemia, hepatotoxicity, gingival hyperplasia, and hirsutism.

Azathioprine

Mechanism of Action

Azathioprine acts through its major metabolite, 6-thioguanine. 6-Thioguanine suppresses inosinic acid synthesis, B cell and T cell function, immunoglobulin production, and IL-2 secretion (see Chapter 56: Immunopharmacology).

Pharmacokinetics

The metabolism of azathioprine is bimodal, with rapid metabolizers clearing the drug four times more rapidly than slow metabolizers. Production of 6-thioguanine is dependent on thiopurine methyltransferase (TPMT), and patients with low or absent TPMT activity (0.3% of the population) are at particularly high risk of myelosuppression by excess concentrations of the parent drug if dosage is not adjusted.

Indications

Azathioprine is approved for use in rheumatoid arthritis and is used at a dosage of 2 mg/kg/d. Controlled trials show efficacy in psoriatic arthritis, reactive arthritis, polymyositis, systemic lupus erythematosus, and Behçet's disease

Adverse Effects

Azathioprine's toxicity includes bone marrow suppression, gastrointestinal disturbances, and some increase in infection risk. As noted in Chapter 56: Immunopharmacology, lymphomas may be increased with azathioprine use. Rarely, fever, rash, and hepatotoxicity signal acute allergic reactions.

Mycophenolate Mofetil

Mechanism of Action

Mycophenolate mofetil (MMF) is converted to myco-phenolic acid, the active form of the drug. The active product inhibits cytosine monophosphate dehydrogenase and secondarily, inhibits T cell lymphocyte proliferation; downstream, it interferes with leukocyte adhesion to endothelial cells through inhibition of E-selectin, P-selectin, and intercellular adhesion molecule 1.

Pharmacokinetics

See Chapter 56: Immunopharmacology.

Indications

MMF has been shown to be effective for the treatment of renal disease due to systemic lupus erythematosus and may be useful in vasculitis and Wegener's granulomatosis. While occasionally used at a dosage of 2 g/d to treat rheumatoid arthritis, there are few controlled data regarding its efficacy in this disease.

Adverse Effects

Comparisons with azathioprine in the renal transplantation literature show that MMF and azathioprine have similar gastrointestinal, hematopoietic, and hepatic toxicity profiles, with a possibly decreased incidence of fungal infections among patients treated with MMF. Hepatic toxicities are infrequent but must be monitored.

Chloroquine & Hydroxychloroquine

Mechanism of Action

Chloroquine and hydroxychloroquine are used mainly in malaria (see Chapter 53: Antiprotozoal Drugs). The mechanism of the anti-inflammatory action of these drugs in rheumatic diseases is unclear. The following mechanisms have been proposed: suppression of T lymphocyte responses to mitogens, decreased leukocyte chemotaxis, stabilization of lysosomal enzymes, inhibition of DNA and RNA synthesis, and the trapping of free radicals.

Pharmacokinetics

Antimalarials are rapidly absorbed but only 50% protein-bound in the plasma. They are very extensively tissue-bound, particularly in melanin-containing tissues such as the eyes. The drugs are deaminated in the liver and have blood elimination half-lives of up to 45 days.

Indications

Antimalarials are approved for rheumatoid arthritis, but they are not considered very efficacious DMARDs. Dose-response and serum concentration-response relationships have been documented for hydroxychloroquine. While antimalarials improve symptoms, there is no evidence that these compounds alter bony damage in rheumatoid arthritis at their usual dosages (up to 6.4 mg/kg/d hydroxychloroquine or 200 mg/d chloroquine). It usually takes 3–6 months to obtain a response. Antimalarials are often used for the treatment of the skin manifestations, serositis, and joint pains of

systemic lupus erythematosus, and they have been used in Sjögren's syndrome.

Adverse Effects

Although ocular toxicity may occur at dosages greater than 250 mg/d chloroquine and greater than 6.4 mg/kg/d hydroxychloroquine, it rarely occurs at lower doses. Nevertheless, ophthalmologic monitoring every 6–12 months is advised. Other toxicities include dyspepsia, nausea, vomiting, abdominal pain, rashes, and nightmares. These drugs appear to be relatively safe in pregnancy.

Gold

Gold compounds were first proved to be effective in a large double-blind trial in 1960. Because of their toxicity, they are used infrequently today. Their intramuscular formulations (**aurothiomalate** and **aurothioglucose**) contain 50% elemental gold. The oral formulation (**auranofin**) contains 29% elemental gold.

Mechanism of Action

Gold alters the morphology and functional capabilities of human macrophages—possibly its major mode of action. As a result, monocyte chemotactic factor-1, interleukin-8, interleukin-1 β production, and vascular endothelial growth factor are all inhibited. Intramuscular gold compounds also alter lysosomal enzyme activity, reduce histamine release from mast cells, inactivate the first component of complement, and suppress the phagocytic activities of polymorphonuclear leukocytes. Auranofin also inhibits release of prostaglandin E₂ and leukotriene B₄.

Pharmacokinetics

These compounds have high bioavailability after intramuscular administration and tend to concentrate in synovial membranes, liver, kidney, spleen, lymph nodes, and bone marrow. One month after an intramuscular injection, 75–80% of the drug is eliminated from the serum, but intramuscular gold's total body half-life is approximately 1 year. Auranofin is only about 25% bioavailable. Gold compounds are excreted approximately 66% in the urine and 33% via the feces. There has generally been no correlation found between serum gold concentration and either efficacy or toxicity.

Indications

Gold is effective for active rheumatoid arthritis and has been shown to slow radiologic progression of the disease. It has also been used in Sjögren's syndrome and juvenile rheumatoid arthritis, while use in psoriatic arthritis is controversial. In Japan, gold is used to treat asthma. The oral form of gold is effective in rheumatoid arthritis, but it appears less effective than the intramuscular formulation and is generally felt to have only modest effects.

Clinical Use

Intramuscular gold is given as a test dose of 5–25 mg and then as 50 mg intramuscular doses weekly for 20 weeks. Continued treatment, with maintained response, frequently allows lengthening of the dosing interval to 2, 3, or 4 weeks. Oral gold is generally given as 6 mg doses daily.

Adverse Effects

Pruritic skin rashes occur in 15–20% of patients, sometimes associated with eosinophilia. Stomatitis and a metallic taste in the mouth are common. Hematologic abnormalities, including thrombocytopenia, leukopenia, and even pancytopenia occur in 1–10% of patients. Aplastic anemia, while very rare, may be fatal. Eight to 10 percent of patients develop proteinuria that may progress to nephrotic syndrome. Other rare toxicities include enterocolitis, cholestatic jaundice, peripheral neuropathy, and pulmonary infiltrates. Corneal deposition of gold occurs but has little clinical import. Nitritoid reactions (sweating, flushing, and headaches) can occur, especially with gold thiomalate, and are presumably due to the vehicle rather than the gold salts. Adverse effects cause 30–40% of patients to discontinue gold therapy within a year.

Penicillamine

Penicillamine, a metabolite of penicillin, is an analog of amino acid cystine. The D isomer has been used in rheumatoid arthritis. Penicillamine is rarely used today because of toxicity.

Penicillamine

Sulfasalazine

Mechanism of Action

Sulfasalazine is metabolized to sulfapyridine and 5-aminosalicylic acid, and it is thought that the sulfapyridine is probably the active moiety when treating rheumatoid arthritis (unlike inflammatory bowel disease; see Chapter 63: Drugs Used in the Treatment of Gastrointestinal Diseases). Some authorities believe that the parent compound, sulfasalazine, also has an effect. In treated arthritis patients, IgA and IgM rheumatoid factor production are decreased. Suppression of T cell responses to concanavalin and inhibition of in vitro B cell proliferation have also been documented. It is not clear how these findings relate to the clinical efficacy of sulfasalazine in rheumatoid arthritis.

Pharmacokinetics

Only 10–20% of orally administered sulfasalazine is absorbed, although a fraction undergoes enterohepatic recirculation into the bowel, where sulfasalazine is reduced by intestinal bacteria to liberate sulfapyridine and 5-aminosalicylic acid. Sulfapyridine is well absorbed while 5-aminosalicylic acid remains unabsorbed. Some sulfasalazine is excreted unchanged in the urine whereas sulfapyridine is excreted after hepatic acetylation and hydroxylation. Sulfasalazine's half-life is 6–17 hours.

Indications

Sulfasalazine is effective in rheumatoid arthritis and reduces the rate of appearance of new joint damage. It has been used in juvenile chronic arthritis and ankylosing spondylitis and its associated uveitis. The usual regimen is 2–3 g/d.

Adverse Effects

Approximately 30% of patients using sulfasalazine discontinue the drug because of toxicity. Common adverse effects include nausea, vomiting, headache, and rash. Hemolytic anemia and methemoglobinemia also occur, but rarely. Neutropenia occurs in 1.4–4.4% of patients, while thrombocytopenia is very rare. Pulmonary toxicity and positive double-stranded DNA are occasionally seen, but drug-induced lupus is rare. Reversible infertility occurs in men, but sulfasalazine does not affect fertility in women. The drug does not appear to be teratogenic.

TNF- α Blocking Agents

Cytokines play a central role in the immune response (see Chapter 56: Immunopharmacology) and in rheumatoid arthritis. Although a wide range of cytokines are expressed in the joints of rheumatoid arthritis patients, TNF- α appears to be at the heart of the inflammatory process.

TNF- α effects cellular function via activation of specific membrane-bound TNF receptors (TNFR₁, TNFR₂). Administered soluble TNF receptors, by combining with soluble TNF- α , can inhibit the effects of the endogenous cytokine. Monoclonal anti-TNF antibodies can, in theory, cross-link TNF receptors on the cell surface and inhibit T cell and macrophage function. Three drugs interfering with TNF- α have been approved for the treatment of rheumatoid arthritis.

Adalimumab

Mechanism of Action

Adalimumab is a recombinant human anti-TNF monoclonal antibody. This compound complexes with soluble TNF- α and prevents its interaction with p55 and p75 cell surface receptors. This results in down-regulation of macrophage and T cell function.

Pharmacokinetics

Adalimumab is given subcutaneously and has a half-life of 9–14 days. Its clearance is decreased by approximately 30% in the presence of methotrexate, and the formation of human antimonoal antibody is decreased from 12% to 4% when methotrexate is given at the same time.

Indications

The compound is indicated for the treatment of rheumatoid arthritis and decreases the rate of formation of new erosions. It is effective both as monotherapy and in combination with methotrexate. The usual dose is 40 mg every other week, though increased responses may be evident at higher dosages. Adalimumab is presently being tested in psoriasis, psoriatic arthritis, ankylosing spondylitis, and juvenile chronic arthritis.

Adverse Effects

In common with the other TNF- α blocking agents, the risk of macrophage-dependent infection (including tuberculosis and other opportunistic infections) must be considered when using adalimumab, and screening for latent tuberculosis or active tuberculosis is recommended before starting adalimumab or other TNF- α blocking agents. There is no evidence of an increased incidence of solid malignancies when adalimumab is used. It is not clear if the incidence of lymphomas is increased by adalimumab. A low incidence of newly formed double-stranded (ds) DNA antibodies and antinuclear antibodies (ANAs) has been documented when using adalimumab, but clinical lupus is extremely rare. Rare leukopenias and vasculitis, apparently associated with

adalimumab, have been documented.

Infliximab

Mechanism of Action

Infliximab is a chimeric (25% mouse, 75% human) monoclonal antibody that binds with high affinity to soluble and possibly membrane-bound TNF- α . Its mechanism of action probably is the same as that of adalimumab.

Pharmacokinetics

Infliximab is given as an intravenous infusion at doses ranging from 3 mg/kg to 10 mg/kg, although the usual dose is 3–5 mg/kg. While most studies used an every-8-week regimen, a number of patients require dosing every 6–7 weeks. There is a relationship between serum concentration and effect, though individual clearances vary markedly. The terminal half-life is 9–12 days without accumulation after repeated dosing at the recommended interval of 8 weeks. After intermittent therapy, infliximab elicits up to a 62% incidence of human antichimeric antibodies. Concurrent therapy with methotrexate markedly decreases the prevalence of human antichimeric antibodies.

Indications

Infliximab is effective in rheumatoid arthritis and ulcerative colitis and is being used in other diseases, including psoriasis, psoriatic arthritis, juvenile chronic arthritis, Wegener's granulomatosis, giant cell arteritis, and sarcoidosis. In rheumatoid arthritis, a regimen of infliximab plus methotrexate decreases the rate of formation of new erosions more than methotrexate alone over 52–104 weeks. While it is recommended that methotrexate be used in conjunction with infliximab, a number of other DMARDs, including antimalarials, azathioprine, and cyclosporine, can be used as background therapy for this drug.

Adverse Effects

Upper respiratory tract infections, nausea, headache, sinusitis, rash, and cough are common when using infliximab, although their incidence does not appear to be very different from that of methotrexate. As a potent macrophage inhibitor, infliximab can be associated with activation of latent tuberculosis, and screening for latent tuberculosis is recommended prior to starting this therapy. Other opportunistic infections have been documented, although rarely. There is no evidence for an increased incidence of solid malignancies or lymphoma, but as with adalimumab, lymphomas should be looked for. It is not clear whether there is an increased incidence of demyelinating syndromes associated with infliximab. Rare cases of leukopenia and vasculitis have been documented. The incidence of positive ANA and double-stranded DNA is increased, although clinical lupus erythematosus remains an extremely rare occurrence and the presence of ANA and dsDNA does not contraindicate the use of infliximab. Infusion site reactions occur in approximately 3–11% of patients, and the combined use of antihistamines and H₂ blocking agents apparently prevents some of these reactions.

Etanercept

Mechanism of Action

Etanercept is a recombinant fusion protein consisting of two soluble TNF p75 receptor moieties

linked to the Fc portion of human IgG1; it binds TNF- α molecules and also inhibits lymphotoxin- α .

Pharmacokinetics

Etanercept is given subcutaneously in a dosage of 25 mg twice weekly. The drug is slowly absorbed, with peak concentration 72 hours after drug administration. Etanercept has a mean serum elimination half-life of 4.5 days. Fifty milligrams given once weekly gives the same area under the curve and minimum serum concentrations as 25 mg twice weekly.

Indications

Etanercept is approved for the treatment of rheumatoid arthritis, juvenile chronic arthritis, and psoriatic arthritis and ankylosing spondylitis. It is used both as monotherapy and with methotrexate background; over 70% of patients taking etanercept are also using methotrexate. Etanercept decreases the rate of formation of new erosions relative to methotrexate alone. While etanercept is ineffective for treatment of ulcerative colitis, it is being used in many rheumatic syndromes such as scleroderma, Wegener's granulomatosis, giant cell arteritis, and sarcoidosis.

Adverse Effects

The incidence of activation of latent tuberculosis in patients treated with etanercept may be lower than that caused by other TNF blocking agents, but this difference is not statistically significant and it is appropriate to screen patients for latent or active tuberculosis prior to starting this medication. Similarly, opportunistic infections can occur when using etanercept. The incidence of solid malignancies is not increased, but as with other TNF-blocking agents one must be alert for lymphomas (although their incidence may not be increased compared with other DMARDs or active rheumatoid arthritis itself). While positive ANAs and double-stranded DNAs may be found in patients receiving this drug, these findings do not contraindicate continued use if clinical lupus symptoms do not occur. Injection site reactions occur in 20–40% of patients, although they rarely result in discontinuation of therapy. Although anti-etanercept antibodies appear sporadically in up to 16% of patients, the presence of the antibodies does not appear to interfere with efficacy or to presage toxicity.

Leflunomide

Mechanism of Action

Leflunomide undergoes rapid conversion, both in the intestine and in the plasma, to its active metabolite, A77-1726. This metabolite inhibits dihydroorotate dehydrogenase, leading to a decrease in ribonucleotide synthesis and the arrest of stimulated cells in the G1 phase of cell growth. Consequently, leflunomide inhibits T cell proliferation and production of autoantibodies by B cells. Secondary effects include increases of interleukin-10 receptor mRNA, decreased interleukin-8 receptor type A mRNA, and decreased TNF- α -dependent NF- κ B activation.

Pharmacokinetics

Leflunomide is completely absorbed and has a mean plasma half-life of 19 days. A77-1726 is subject to enterohepatic recirculation and is efficiently reabsorbed. Cholestyramine can enhance leflunomide excretion and increases total clearance by approximately 50%.

Indications

Leflunomide is as effective as methotrexate in rheumatoid arthritis, including inhibition of bony damage. In one study, combined treatment with methotrexate and leflunomide resulted in a 46.2% ACR20 response compared with 19.5% in patients receiving methotrexate alone.

Adverse Effects

Diarrhea or loose bowels occur in approximately 25% of patients given leflunomide, although only about 3–5% discontinue drug because of this effect. Elevation in liver enzymes also occurs. Both effects can be reduced by decreasing the dose of leflunomide. Other adverse effects associated with leflunomide are mild alopecia, weight gain, and increased blood pressure. Leukopenia and thrombocytopenia occur rarely. This drug is contraindicated in pregnancy.

Combination Therapy with DMARDs

In a 1998 study, approximately half of North American rheumatologists treated moderately aggressive rheumatoid arthritis with combination therapy. Combinations of DMARDs can be designed rationally on the basis of complementary mechanisms of action, nonoverlapping pharmacokinetics, and nonoverlapping toxicity.

When added to methotrexate background therapy, cyclosporine, chloroquine, leflunomide, infliximab, adalimumab, and etanercept have all shown improved efficacy. In contrast, azathioprine, auranofin, or sulfasalazine plus methotrexate results in no additional therapeutic benefit. Other combinations have occasionally been used, including the combination of intramuscular gold with hydroxychloroquine. A triple-therapy regimen (methotrexate, sulfasalazine, and hydroxychloroquine) was recently tested and compared with methotrexate plus sulfasalazine or methotrexate plus hydroxychloroquine. Seventy-eight percent of the triple therapy group achieved an ACR20 response at 2 years, compared with 60% of those treated with methotrexate plus hydroxychloroquine and 49% of those treated with methotrexate plus sulfasalazine.

While it might be anticipated that combination therapy might result in more toxicity, this is often not the case. Combination therapy for patients not responding adequately to monotherapy is becoming the rule in the treatment of rheumatoid arthritis.

Immunoabsorption Apheresis

Extracorporeal immunoabsorption of plasma over columns containing an inert silica matrix and covalently attached highly purified staphylococcal protein A (Proisorba column) involves apheresis of about 1200 mL plasma weekly for 3 months.

Mechanism of Action

Although this treatment has been available for idiopathic thrombocytopenic purpura for several years, its mechanism of action is not understood. Removal of IgG and IgG-containing immune complexes does not explain its effects in rheumatoid arthritis. The most recent hypothesis for this treatment's mechanism of action is down-regulation of B cell function through the release of small amounts of staphylococcal protein A complexed with immunoglobulins.

Indications

This treatment has generally been used in patients who have failed numerous other therapies, so its low efficacy in rheumatoid arthritis is better than it appears. The study establishing efficacy in rheumatoid arthritis showed a 41.7% ACR20 response among ProSORBA-treated patients compared with 15.6% in the sham-treated group. Further testing is clearly indicated.

Adverse Effects

Common adverse events include joint pain, joint swelling, and hypotension. Central intravenous line usage may be associated with pulmonary emboli and sepsis. Other events, such as nausea, rash, pruritus, flushing, and fever occurred in 1–6% of treatments in both sham and treatment groups in the double-blind trial. Rare leukocytoclastic vasculitis has been documented.

Glucocorticoid Drugs

The general pharmacology of corticosteroids, including mechanism of action, pharmacokinetics, and other applications, is discussed in Chapter 39: Adrenocorticosteroids & Adrenocortical Antagonists.

Indications

Corticosteroids have been used in 60–70% of rheumatoid arthritis patients. Their effects are prompt and dramatic, and they are capable of slowing the appearance of new bone erosions. Corticosteroids may be administered for certain serious extra-articular manifestations such as pericarditis or eye involvement or during periods of exacerbation. When prednisone is required for long-term therapy, the dosage should not exceed 7.5 mg daily, and gradual reduction of the dose should be encouraged. Alternate-day corticosteroid therapy is usually unsuccessful in rheumatoid arthritis.

Other rheumatic diseases in which the corticosteroids' potent anti-inflammatory effects may be useful include vasculitis, systemic lupus erythematosus, Wegener's granulomatosis, psoriatic arthritis, giant cell arteritis, sarcoidosis, and even gout.

Intra-articular corticosteroids are often helpful to alleviate painful symptoms and, when successful, are preferable to increasing the dosage of systemic medication.

Adverse Effects

Prolonged use of these drugs leads to serious and disabling toxic effects as described in Chapter 39: Adrenocorticosteroids & Adrenocortical Antagonists. There is controversy over whether many of these side effects occur at doses below 7.5 mg prednisone equivalent daily, although many experts believe that even 5 mg/d can cause these effects in susceptible individuals.

Dietary Manipulation of Inflammation

Arachidonic acid is an eicosatetraenoic acid that is metabolized by the cyclooxygenase and lipoxygenase pathways, yielding several mediators (see Chapter 18: The Eicosanoids: Prostaglandins, Thromboxanes, Leukotrienes, & Related Compounds). These mediators have potent effects on many systems, including the immune system. It has been demonstrated that dietary manipulation which substitutes unsaturated fatty acids (such as eicosapentaenoic acid, found in marine fish) causes the alternative fatty acids to be metabolized, changing the final prostaglandin and leukotriene products of the process. The products of eicosapentaenoic acid metabolism are less potent than the corresponding mediators derived from arachidonic acid (sometimes by several

orders of magnitude), and they diminish the activities of the eicosatetraenoic mediators by competing with them for shared target-cell receptors.

The results of clinical studies suggest that therapy with dietary eicosapentaenoic acid decreases both morning stiffness and the number of tender joints in patients with rheumatoid arthritis and erythema associated with psoriasis. The efficacy of dietary eicosapentaenoic acid approximates that of the NSAIDs. These preliminary results and the near absence of significant adverse effects suggest that dietary alteration or supplementation to provide 1–4 g/d of eicosapentaenoic acid may be a beneficial addition to conventional treatment of rheumatoid arthritis.

Katzung PHARMACOLOGY, 9e > Section VI. Drugs Used to Treat Disease of the Blood, Inflammation, & Gout > Chapter 36. Nonsteroidal Anti-Inflammatory Drugs, Disease-Modifying Antirheumatic Drugs, Nonopioid Analgesics, & Drugs Used in Gout >

Other Analgesics

Acetaminophen is one of the most important drugs used for the treatment of mild to moderate pain when an anti-inflammatory effect is not necessary. Phenacetin, a prodrug that is metabolized to acetaminophen, is more toxic than its active metabolite and has no rational indications.

Acetaminophen

Acetaminophen is the active metabolite of phenacetin and is responsible for its analgesic effect. It is a weak COX-1 and COX-2 inhibitor in peripheral tissues and possesses no significant anti-inflammatory effects. Recent evidence suggests that acetaminophen may inhibit a third enzyme, COX-3, in the central nervous system. COX-3 appears to be a splice variant product of the COX-1 gene.

Pharmacokinetics

Acetaminophen is administered orally. Absorption is related to the rate of gastric emptying, and peak blood concentrations are usually reached in 30–60 minutes. Acetaminophen is slightly bound to plasma proteins and is partially metabolized by hepatic microsomal enzymes and converted to acetaminophen sulfate and glucuronide, which are pharmacologically inactive (Figure 4–4). Less than 5% is excreted unchanged. A minor but highly active metabolite (*N*-acetyl-*p*-benzoquinone) is important in large doses because of its toxicity to both liver and kidney. The half-life of acetaminophen is 2–3 hours and is relatively unaffected by renal function. With toxic doses or liver disease, the half-life may be increased twofold or more.

Indications

Although equivalent to aspirin as an effective analgesic and antipyretic agent, acetaminophen differs in that it lacks anti-inflammatory properties. It does not affect uric acid levels and lacks

platelet-inhibiting properties. The drug is useful in mild to moderate pain such as headache, myalgia, postpartum pain, and other circumstances in which aspirin is an effective analgesic. Acetaminophen alone is inadequate therapy for inflammatory conditions such as rheumatoid arthritis, though it may be used as an analgesic adjunct to anti-inflammatory therapy. For mild analgesia, acetaminophen is the preferred drug in patients allergic to aspirin or when salicylates are poorly tolerated. It is preferable to aspirin in patients with hemophilia or a history of peptic ulcer and in those in whom bronchospasm is precipitated by aspirin. Unlike aspirin, acetaminophen does not antagonize the effects of uricosuric agents; it may be used concomitantly with probenecid in the treatment of gout. It is preferred to aspirin in children with viral infections.

Adverse Effects

In therapeutic doses, a mild increase in hepatic enzymes may occasionally occur in the absence of jaundice; this is reversible when the drug is withdrawn. With larger doses, dizziness, excitement, and disorientation are seen. Ingestion of 15 g of acetaminophen may be fatal, death being caused by severe hepatotoxicity with centrilobular necrosis, sometimes associated with acute renal tubular necrosis (see Chapter 4: Drug Biotransformation and Chapter 59: Management of the Poisoned Patient). Early symptoms of hepatic damage include nausea, vomiting, diarrhea, and abdominal pain. Recent data also implicate acetaminophen in rare cases of renal damage without hepatic damage. This damage has occurred even after usual doses of acetaminophen. Therapy is much less satisfactory than for aspirin overdose. In addition to supportive therapy, the measure that has proved most useful is the provision of sulfhydryl groups in the form of acetylcysteine to neutralize the toxic metabolites (see Chapter 59: Management of the Poisoned Patient).

Hemolytic anemia and methemoglobinemia, reported with the use of phenacetin, are rarely noted with acetaminophen. Interstitial nephritis and papillary necrosis—serious complications of phenacetin—although anticipated with widespread chronic use of acetaminophen, have not occurred. Gastrointestinal bleeding does not occur. Caution should be exercised in patients with liver disease.

Dosage

Acute pain and fever may be effectively treated with 325–500 mg four times daily and proportionately less for children. Steady state conditions are attained within a day.

Phenacetin

Phenacetin is no longer prescribed in the USA and has been removed from many over-the-counter analgesic combinations. However, it is still present in a number of proprietary analgesics in this country and is in common use in many other parts of the world. The association between the excessive use of analgesic combinations—especially those that contain phenacetin—and the development of renal failure has been recognized for almost 30 years.

Katzung PHARMACOLOGY, 9e > Section VI. Drugs Used to Treat Disease of the Blood, Inflammation, & Gout > Chapter 36. Nonsteroidal Anti-Inflammatory Drugs, Disease-Modifying Antirheumatic Drugs, Nonopioid Analgesics, & Drugs Used in Gout >

Drugs Used in Gout

Gout is a familial metabolic disease characterized by recurrent episodes of acute arthritis due to deposits of monosodium urate in joints and cartilage. Formation of uric acid calculi in the kidneys

may also occur. Gout is usually associated with high serum levels of uric acid, a poorly soluble substance that is the major end product of purine metabolism. In most mammals, uricase converts uric acid to the more soluble allantoin; this enzyme is absent in humans.

The treatment of gout is aimed at relieving the acute gouty attack and preventing recurrent gouty episodes and urate lithiasis. Therapy for an attack of acute gouty arthritis is based on our current understanding of the pathophysiologic events that occur in this disease (Figure 36–5). Urate crystals are initially phagocytosed by synoviocytes, which then release prostaglandins, lysosomal enzymes, and interleukin-1. Attracted by these chemotactic mediators, polymorphonuclear leukocytes migrate into the joint space and amplify the ongoing inflammatory process. In the later phases of the attack, increased numbers of mononuclear phagocytes (macrophages) appear, ingest the urate crystals, and release more inflammatory mediators. This sequence of events suggests that the most effective agents for the management of acute urate crystal-induced inflammation are those that suppress different phases of leukocyte activation.

Figure 36–5.

Pathophysiologic events in a gouty joint. Synoviocytes phagocytose urate crystals and then secrete inflammatory mediators, which attract and activate polymorphonuclear leukocytes (PMN) and mononuclear phagocytes (MNP) (macrophages). Drugs active in gout inhibit crystal phagocytosis and polymorphonuclear leukocyte and macrophage release of inflammatory mediators. (PG, prostaglandin; IL-1, interleukin-1; LTB₄, leukotriene B₄.)

Before starting chronic therapy for gout, patients in whom hyperuricemia is associated with gout and urate lithiasis must be clearly distinguished from those who have only hyperuricemia. In an asymptomatic person with hyperuricemia, the efficacy of long-term drug treatment is unproved. In some individuals, uric acid levels may be elevated up to 2 SD above the mean for a lifetime without adverse consequences.

Colchicine

Colchicine is an alkaloid isolated from the autumn crocus, *Colchicum autumnale*. Its structure is shown in Figure 36–6.

Figure 36–6.

Colchicine

Probenecid

Sulfapyrazone

Colchicine and uricosuric drugs.

Pharmacokinetics

Colchicine is absorbed readily after oral administration and reaches peak plasma levels within 2 hours. Metabolites of the drug are excreted in the intestinal tract and urine.

Pharmacodynamics

Colchicine dramatically relieves the pain and inflammation of gouty arthritis in 12–24 hours without altering the metabolism or excretion of urates and without other analgesic effects. Colchicine produces its anti-inflammatory effects by binding to the intracellular protein tubulin, thereby preventing its polymerization into microtubules and leading to the inhibition of leukocyte migration and phagocytosis. It also inhibits the formation of leukotriene B₄. Several of colchicine's

adverse effects are produced by its inhibition of tubulin polymerization and cell mitosis.

Indications

Colchicine was the traditional drug used for alleviating the inflammation of acute gouty arthritis. Although colchicine is more specific in gout than the NSAIDs, other agents (eg, indomethacin and other NSAIDs [except aspirin]) have replaced it in the treatment of acute gout because of the troublesome diarrhea associated with colchicine therapy. Colchicine is now used for the prophylaxis of recurrent episodes of gouty arthritis, is effective in preventing attacks of acute Mediterranean fever, and may have a mild beneficial effect in sarcoid arthritis and in hepatic cirrhosis.

Adverse Effects

Colchicine often causes diarrhea and may occasionally cause nausea, vomiting, and abdominal pain. Colchicine may rarely cause hair loss and bone marrow depression as well as peripheral neuritis and myopathy.

Acute intoxication after ingestion of large (nontherapeutic) doses of the alkaloid is characterized by burning throat pain, bloody diarrhea, shock, hematuria, and oliguria. Fatal ascending central nervous system depression has been reported. Treatment is supportive.

Dosage

The prophylactic dose of colchicine is 0.6 mg one to three times daily. For terminating an attack of gout, the traditional initial dose of colchicine is usually 0.6 or 1.2 mg, followed by 0.6 mg every 2 hours until pain is relieved or nausea and diarrhea appear. The total dose can be given intravenously if necessary, but it should be remembered that as little as 8 mg in 24 hours may be fatal.

NSAIDs in Gout

In addition to inhibiting prostaglandin synthase, indomethacin and other NSAIDs also inhibit urate crystal phagocytosis. Indomethacin is commonly used as initial treatment of gout as the replacement for colchicine. Three or four doses of 50 mg every 6 hours are given; when a response occurs, the dosage is reduced to 25 mg three or four times daily for about 5 days.

All other NSAIDs except aspirin, salicylates, and tolmetin have been successfully used to treat acute gouty episodes. Oxaprozin, which lowers serum uric acid, is theoretically a good NSAID though it should not be given to patients with uric acid stones because it increases uric acid excretion in the urine. These agents appear to be as effective and safe as the older drugs.

Uricosuric Agents

Probenecid and sulfinpyrazone are uricosuric drugs employed to decrease the body pool of urate in patients with tophaceous gout or in those with increasingly frequent gouty attacks. In a patient who excretes large amounts of uric acid, the uricosuric agents should be avoided so as not to precipitate the formation of uric acid calculi.

Chemistry

Uricosuric drugs are organic acids (Figure 36–6) and, as such, act at the anionic transport sites of the renal tubule (see Chapter 15: Diuretic Agents). Sulfinpyrazone is a metabolite of an analog of

phenylbutazone.

Pharmacokinetics

Probenecid is completely reabsorbed by the renal tubules and is metabolized very slowly. Sulfipyrazone or its active hydroxylated derivative is rapidly excreted by the kidneys. Even so, the duration of its effect after oral administration is almost as long as that of probenecid.

Pharmacodynamics

Uric acid is freely filtered at the glomerulus. Like many other weak acids, it is also both reabsorbed and secreted in the middle segment of the proximal tubule. Uricosuric drugs—probenecid, sulfipyrazone, and large doses of aspirin—affect these active transport sites so that net reabsorption of uric acid in the proximal tubule is decreased. Because aspirin in small (analgesic or antipyretic) doses causes net retention of uric acid by inhibiting the secretory transporter, it should not be used for analgesia in patients with gout. The secretion of other weak acids (eg, penicillin) is also reduced by uricosuric agents. Probenecid was originally developed to prolong penicillin blood levels.

As the urinary excretion of uric acid increases, the size of the urate pool decreases, although the plasma concentration may not be greatly reduced. In patients who respond favorably, tophaceous deposits of urate are reabsorbed, with relief of arthritis and remineralization of bone. With the ensuing increase in uric acid excretion, a predisposition to the formation of renal stones is augmented rather than decreased; therefore, the urine volume should be maintained at a high level, and at least early in treatment the urine pH should be kept above 6.0 by the administration of alkali.

Indications

Uricosuric therapy should be initiated if several acute attacks of gouty arthritis have occurred, when evidence of tophi appears, or when plasma levels of uric acid in patients with gout are so high that tissue damage is almost inevitable. Therapy should not be started until 2–3 weeks after an acute attack.

Adverse Effects

Adverse effects do not provide a basis for preferring one or the other of the uricosuric agents. Both of these organic acids cause gastrointestinal irritation, but sulfipyrazone is more active in this regard. Probenecid is more likely to cause allergic dermatitis, but a rash may appear after the use of either compound. Nephrotic syndrome has resulted from the use of probenecid. Both sulfipyrazone and probenecid may rarely cause aplastic anemia.

Contraindications & Cautions

It is essential to maintain a large urine volume to minimize the possibility of stone formation.

Dosage

Probenecid is usually started at a dosage of 0.5 g orally daily in divided doses, progressing to 1 g daily after 1 week. Sulfipyrazone is started at a dosage of 200 mg orally daily, progressing to 400–800 mg daily. It should be given in divided doses with food to reduce adverse gastrointestinal effects.

Allopurinol

An alternative to increasing uric acid excretion in the treatment of gout is to reduce its synthesis by inhibiting xanthine oxidase with allopurinol.

Chemistry

The structure of allopurinol, an isomer of hypoxanthine, is shown in Figure 36–7.

Figure 36–7.

Inhibition of uric acid synthesis by allopurinol. (Modified and reproduced, with permission, from Meyers FH, Jawetz E, Goldfien A: *Review of Medical Pharmacology*, 7th ed. McGraw-Hill, 1980.)

Pharmacokinetics

Allopurinol is approximately 80% absorbed after oral administration. Like uric acid, allopurinol is itself metabolized by xanthine oxidase. The resulting compound, alloxanthine, retains the capacity to inhibit xanthine oxidase and has a long enough duration of action so that allopurinol need be given only once a day.

Pharmacodynamics

Dietary purines are not an important source of uric acid. The quantitatively important amounts of purine are formed from amino acids, formate, and carbon dioxide in the body. Those purine ribonucleotides not incorporated into nucleic acids and those derived from the degradation of nucleic acids are converted to xanthine or hypoxanthine and oxidized to uric acid (Figure 36–7). When this last step is inhibited by allopurinol, there is a fall in the plasma urate level and a decrease in the size of the urate pool with a concurrent rise in the more soluble xanthine and hypoxanthine.

Indications

Treatment of gout with allopurinol, as with uricosuric agents, is begun with the expectation that it will be continued for years if not for life. Although allopurinol is often the first urate-lowering drug used, its most rational indications are as follows: (1) in chronic tophaceous gout, in which reabsorption of tophi is more rapid than with uricosuric agents; (2) in patients with gout whose 24-hour urinary uric acid on purine-free diet exceeds 600–700 mg; (3) when probenecid or sulfinpyrazone cannot be used because of adverse effects or allergic reactions, or when they are providing less than optimal therapeutic effect; (4) for recurrent renal stones; (5) in patients with renal functional impairment; or (6) when serum urate levels are grossly elevated. One should attempt to lower serum urate levels to less than 6.5 mg/dL. Aside from gout, allopurinol is used as an antiprotozoal agent (see Chapter 52: Basic Principles of Antiparasitic Chemotherapy) and is indicated to prevent the massive uricosuria following therapy of blood dyscrasias that could otherwise lead to renal calculi.

Adverse Effects

Acute attacks of gouty arthritis occur early in treatment with allopurinol, when urate crystals are being withdrawn from the tissues and plasma levels are below normal. To prevent acute attacks, colchicine or indomethacin should be given during the initial period of therapy with allopurinol unless allopurinol is being used in combination with probenecid or sulfinpyrazone. Gastrointestinal intolerance, including nausea, vomiting, and diarrhea, may occur. Peripheral neuritis and necrotizing vasculitis, depression of bone marrow elements, and, rarely, aplastic anemia may also occur. Hepatic toxicity and interstitial nephritis have been reported. An allergic skin reaction characterized by pruritic maculopapular lesions occurs in 3% of patients. Isolated cases of exfoliative dermatitis have been reported. In very rare cases, allopurinol has become bound to the lens, resulting in cataracts.

Interactions & Cautions

When chemotherapeutic mercaptopurines are being given concomitantly with allopurinol, their dosage must be reduced by about 75%. Allopurinol may also increase the effect of cyclophosphamide. Allopurinol inhibits the metabolism of probenecid and oral anticoagulants and may increase hepatic iron concentration. Safety in children and during pregnancy has not been established.

Dosage

The initial dosage of allopurinol is 100 mg/d. It may be titrated to 300 mg/d depending on the serum uric acid response.

Colchicine or an NSAID should be given during the first weeks of allopurinol therapy to prevent the gouty arthritis episodes that sometimes occur.

Katzung PHARMACOLOGY, 9e > Section VI. Drugs Used to Treat Disease of the Blood, Inflammation, & Gout > Chapter 36. Nonsteroidal Anti-Inflammatory Drugs, Disease-Modifying Antirheumatic Drugs, Nonopioid Analgesics, & Drugs Used in Gout >

Preparations Available

NSAIDs

Aspirin, acetylsalicylic acid (generic, Easprin, others)

Oral (regular, enteric-coated, buffered): 81, 165, 325, 500, 650, 800, 975 mg tablets; 81, 650, 800 mg timed- or extended-release tablets

Rectal: 120, 200, 300, 600 mg suppositories

Celecoxib (Celebrex)

Oral: 100, 200 mg capsules

Choline salicylate (Arthropan)

Oral: 870 mg/5 mL liquid

Diclofenac (generic, Cataflam, Voltaren)

Oral: 50 mg tablets; 25, 50, 75 mg delayed-release tablets; 100 mg extended-release tablets

Ophthalmic: 0.1% solution

Diflunisal (generic, Dolobid)

Oral: 250, 500 mg tablets

Etodolac (generic, Lodine)

Oral: 200, 300 mg capsules; 400, 500 mg tablets; 400, 500, 600 mg extended-release tablets

Fenoprofen (generic, Nalfon)

Oral: 200, 300 mg capsules; 600 mg tablets

Flurbiprofen (generic, Ansaid)

Oral: 50, 100 mg tablets

Ophthalmic (generic, Ocufen): 0.03% solution

Ibuprofen (generic, Motrin, Rufen, Advil [OTC], Nuprin [OTC], others)

Oral: 100, 200, 400, 600, 800 mg tablets; 50, 100 mg chewable tablets; 200 mg capsules; 100 mg/2.5 mL suspension, 100 mg/5 mL suspension; 40 mg/mL drops

Indomethacin (generic, Indocin, others)

Oral: 25, 50 mg capsules; 75 mg sustained-release capsules; 25 mg/5 mL suspension

Rectal: 50 mg suppositories

Ketoprofen (generic, Orudis, others)

Oral: 12.5 mg tablets; 25, 50, 75 mg capsules; 100, 150, 200 mg extended-release capsules

Ketorolac tromethamine (generic, Toradol)

Oral: 10 mg tablets

Parenteral: 15, 30 mg/mL for IM injection

Ophthalmic: 0.5% solution

Magnesium salicylate (Doan's Pills, Magan, Mobidin)

Oral: 545, 600 mg tablets; 467, 500, 580 mg caplets

Meclofenamate sodium (generic)

Oral: 50, 100 mg capsules

Mefenamic acid (Ponstel)

Oral: 250 mg capsules

Meloxicam (Mobic)

Oral: 7.5 mg tablets

Nabumetone (Relafen)

Oral: 500, 750 mg tablets

Naproxen (generic, Naprosyn, Anaprox, Aleve [otc])

Oral: 200, 250, 375, 500 mg tablets; 375, 550 mg sustained-release tablets; 375, 500 mg delayed-release tablets; 125 mg/5 mL suspension

Oxaprozin (Daypro)

Oral: 600 mg tablets

Piroxicam (generic, Feldene)

Oral: 10, 20 mg capsules

Rofecoxib (Vioxx)

Oral: 12.5, 25, 50 mg tablets; 12.5, 25 mg/5 mL suspension

Salsalate, salicylsalicylic acid (generic, Disalcid)

Oral: 500, 750 mg tablets; 500 mg capsules

Sodium salicylate (generic)

Oral: 325, 650 mg enteric-coated tablets

Sodium thiosalicylate (generic, Rexolate)

Parenteral: 50 mg/mL for IM injection

Sulindac (generic, Clinoril)

Oral: 150, 200 mg tablets

Suprofen (Profenal)

Topical: 1% ophthalmic solution

Tolmetin (Tolectin, generic [400 mg only])

Oral: 200, 600 mg tablets; 400 mg capsules

Valdecoxib (Bextra)

Oral: 10, 20 mg tablets

Disease-Modifying Antirheumatic Drugs

Anakinra (Kineret)

Parenteral: 100 mg solution for SC injection

Adalimumab (Humira)

Parenteral: 40 mg/0.8 mL for SC injection

Auranofin (Ridaura)

Oral: 3 mg capsules

Aurothioglucose (Solganal)

Parenteral: 50 mg/mL suspension for injection

Etanercept (Enbrel)

Parenteral: 25 mg powder for subcutaneous injection

Gold sodium thiomalate (generic, Aurolate)

Parenteral: 50 mg/mL for injection

Hydroxychloroquine (Plaquenil)

Oral: 200 mg tablets

Infliximab (Remicade)

Parenteral: 100 mg powder for IV infusion

Leflunomide (Arava)

Oral: 10, 20, 100 mg tablets

Methotrexate (generic, Rheumatrex)

Oral: 2.5 mg tablets

Penicillamine (Cuprimine, Depen)

Oral: 125, 250 mg capsules; 250 mg tablets

Sulfasalazine (Azulfidine)

Oral: 500 mg tablets; 500 mg delayed-release tablets

Acetaminophen

Acetaminophen (generic, Tylenol, Tempra, Panadol, Acephen, others)

Oral: 160, 325, 500, 650 mg tablets; 80 mg chewable tablets; 160, 500, 650 mg caplets; 325, 500 mg capsules; 80, 120, 160 mg/5 mL elixir; 500 mg/15 mL elixir; 100 mg/mL solution

Rectal: 80, 120, 125, 300, 325, 650 mg suppositories

Drugs Used in Gout

Allopurinol (generic, Zyloprim, others)

Oral: 100, 300 mg tablets

Colchicine (generic)

Oral: 0.5 and 0.6 mg tablets

Parenteral: 0.5 mg/mL for injection

Probenecid (generic)

Oral: 500 mg tablets

Sulfinpyrazone (generic, Anturane)

Oral: 100 mg tablets; 200 mg capsules

- TSH:** Thyroid-stimulating hormone (thyrotropin)

Katzung PHARMACOLOGY, 9e > Section VII. Endocrine Drugs > Chapter 37. Hypothalamic & Pituitary Hormones >

Hypothalamic & Pituitary Hormones: Introduction

The control of metabolism, growth, and reproduction is mediated by a combination of neural and endocrine systems located in the hypothalamus and pituitary gland. The pituitary weighs about 0.6 g and rests in the bony sella turcica under a layer of dura mater and is bordered by the cavernous sinuses. It consists of an anterior lobe (adenohypophysis) and a posterior lobe (neurohypophysis). The pituitary is connected to the overlying hypothalamus by a stalk of neurosecretory fibers and blood vessels, including a portal venous system that drains the hypothalamus and perfuses the anterior pituitary. The portal venous system carries small regulatory peptide hormones (Table 37–1) from the hypothalamus to the anterior pituitary.

Table 37–1. Links between Hypothalamic, Pituitary, and Target Gland Hormones.

Hypothalamic Hormone	Pituitary Hormone	Target Organ	Target Organ Hormone
----------------------	-------------------	--------------	----------------------

Growth hormone-releasing hormone (GHRH) (+) Somatotropin release-inhibiting hormone (SRIH, somatostatin) (-)	Growth hormone (somatotropin, GH)	Liver	Insulin-like growth factors (IGF, somatomedins)
Corticotropin-releasing hormone (CRH) (+)	Adrenocorticotropin (ACTH)	Adrenal cortex	Glucocorticoids, mineralocorticoids, androgens
Thyrotropin-releasing hormone (TRH) (+)	Thyroid-stimulating hormone (TSH)	Thyroid	Thyroxine, triiodothyronine
Gonadotropin-releasing hormone (GnRH)	Follicle-stimulating hormone (FSH) Luteinizing hormone (LH)	Gonads	Estrogen, progesterone, testosterone
Dopamine (-)	Prolactin (PRL)	Breast	—

(+), stimulant; (-), inhibitor.

The posterior lobe hormones are synthesized in the hypothalamus and transported via the neurosecretory fibers in the stalk of the pituitary to the posterior lobe, from which they are released into the circulation.

Hypothalamic and pituitary hormones (and their synthetic analogs) have pharmacologic applications in three areas: (1) as replacement therapy for hormone deficiency states; (2) as drug therapy and (3) as diagnostic tools for performing stimulation tests.

Katzung PHARMACOLOGY, 9e > Section VII. Endocrine Drugs > Chapter 37. Hypothalamic & Pituitary Hormones >

Hypothalamic & Anterior Pituitary Hormones

Hypothalamic regulatory hormones include growth hormone-releasing hormone (GHRH); a growth hormone-inhibiting hormone (somatostatin); thyrotropin-releasing hormone (TRH); corticotropin-releasing hormone (CRH); gonadotropin-releasing hormone (GnRH), also called luteinizing hormone-releasing hormone (LHRH); and prolactin-inhibiting hormone (dopamine).

Anterior pituitary hormones include growth hormone (GH), thyrotropin (TSH), follicle-stimulating hormone (FSH), luteinizing hormone (LH), prolactin (PRL), and adrenocorticotropin (ACTH). Another peptide, β -lipotropin (β -LPH), is derived from the same prohormone, pro-opiomelanocortin, as ACTH. β -LPH is secreted from the pituitary (along with ACTH), and is a precursor of the opioid peptide β -endorphin (see Chapter 31: Opioid Analgesics & Antagonists).

Mechanisms of Hormone Action

The hypothalamic and pituitary hormones are all peptides that exert their effects by binding to target cell surface membrane receptors with high specificity and affinity.

GHRH, Somatostatin, TRH, TSH, CRH, ACTH, GnRH, FSH, LH, & Dopamine

The receptors for these hormones are typical seven-transmembrane-domain serpentine peptides (see Chapter 2: Drug Receptors & Pharmacodynamics). Each hormone acts as a ligand within a receptor pocket, inducing conformational activating changes in the receptor. The conformational changes in the receptor's intracellular third loop and carboxyl terminal tail activate an adjacent intracellular G protein. The G_{14} protein is associated with the receptors for GnRH and TRH, G_i with the dopamine receptor, and G_s protein with the receptors for the other hormones listed above.

GHRH, CRH, GnRH, TSH, ACTH, FSH, LH, and Dopamine

The G protein-GTP complexes related to receptors for these hormones activate adenylyl cyclase, which synthesizes the second messenger cAMP. Cyclic AMP activates protein kinases, which phosphorylate certain intracellular proteins (eg, enzymes), thus producing the hormonal effect. Conversely, dopamine binding to lactotroph receptors causes conformational changes in its G_i protein that reduce the activity of adenylyl cyclase and inhibit the secretion of prolactin.

Somatostatin

The α -GTP complexes related to somatostatin receptors exert effects on potassium channels, thereby inhibiting GH secretion.

Thyrotropin-Releasing Hormone

The G protein complexes related to thyrotrophs' TRH receptors affect phosphoinositide-specific phospholipase C, which increases intracellular cytoplasmic free calcium, thereby stimulating TSH secretion.

Growth Hormone & Prolactin

The receptors for both GH and PRL consist of similar single peptides. The two types of receptors have extracellular amino terminal hormone-binding domains. Both receptors pass through the cell membrane, where an intracellular carboxyl terminal sequence activates a tyrosine kinase, JAK2, causing phosphorylation on tyrosines of intracellular proteins and gene regulation. Fragments of GH receptors circulate in plasma (GH binding protein, GHBP), binding about 50% of the circulating growth hormone.

Growth Hormone-Releasing Hormone (GHRH) & Growth Hormone-Releasing Peptides (GHRPS)

Growth hormone-releasing hormone is a peptide hormone found in the hypothalamus that stimulates synthesis and release of growth hormone (GH) from the pituitary. It is sometimes abbreviated GRH and was originally named growth hormone-releasing factor (GRF). It was first isolated from rare pancreatic tumors that caused acromegaly by stimulating excessive GH secretion by pituitary somatotroph cells (an unusual cause—almost all cases of acromegaly are caused by pituitary tumors). In the hypothalamus, cells in the arcuate nuclei secrete GHRH into the hypophysial-pituitary portal venous system.

Chemistry & Pharmacokinetics

Structure

Naturally occurring GHRH has been isolated as both 40 and 44 amino acid peptides (GHRH₄₀, GHRH₄₄), which are derived from precursor molecules of 107 and 108 amino acids. GHRH bears distinct structural homologies to certain gastrointestinal peptide hormones such as gastrin, gastric inhibitory peptide, secretin, and vasoactive intestinal polypeptide. Full biologic activity of GHRH lies in the 1–29 amino terminal segment.

Growth hormone-releasing peptides comprise several groups of small synthetic peptide analogs of GHRH that can stimulate GH secretion. **Sermorelin** is the commercially available acetate salt of a synthetic 29-amino-acid peptide that is the amino terminal segment of GHRH. It has also been called GRH_{1–29} and GHRH_{1–29}. Sermorelin is similar to native GHRH in its ability to stimulate GH secretion. Similar peptides (GHRP-2, GHRP-6, and **hexarelin**, an analog of GHRP-6) also have clinical activity.

Absorption, Metabolism, and Excretion

GHRH is not currently available commercially; in research use it may be administered intravenously, subcutaneously, or intranasally, and the relative potencies (defined as incremental growth hormone release) by these three routes are 300, 10, and 1, respectively. Intravenous GHRH (1 $\mu\text{g}/\text{kg}$) has a distribution half-life of 4 minutes and an elimination half-life of 53 minutes. Subcutaneous GHRH has a similar elimination half-life but a distribution half-life of about 10 minutes. Peak serum levels of GHRH (1 $\mu\text{g}/\text{kg}$) are 37 times higher after intravenous administration compared with subcutaneous injection. Sermorelin, 2 $\mu\text{g}/\text{kg}$ subcutaneously, reaches peak serum concentrations in 5–20 minutes; its bioavailability is 6%. The half-life of sermorelin is about 12 minutes after either subcutaneous or intravenous injection.

Clinical Pharmacology

Diagnostic Uses

GHRH is not currently available commercially. GHRH or GHRPs such as sermorelin may be given intravenously to test pituitary GH secretory capacity as part of the clinical evaluation of childhood short stature. It is used after GH deficiency has already been established by clinical criteria, including testing with conventional stimuli for GH secretion, ie, exercise, insulin-induced hypoglycemia, intravenous arginine, oral carbidopa/levodopa, and oral clonidine. In such children, a normal GH response to GHRH indicates that GH deficiency is due to hypothalamic dysfunction. A subnormal response is not diagnostic. A rise in the serum growth hormone level demonstrates the somatotrophs' ability to produce GH and predicts a favorable response to GHRH therapy.

The response of GH to GHRH can be blunted by prior treatment with octreotide, glucocorticoids, and cyclooxygenase inhibitors such as aspirin or indomethacin. GH response to GHRH is also blunted in hypothyroidism, in obesity, and in adults over 40 years of age. Exogenous growth hormone therapy should be discontinued for at least a week prior to GHRH testing.

Therapeutic Uses

Synthetic human growth hormone is now usually used for treatment of growth hormone deficiency (see below).

Sermorelin is commercially available (see above). It and other GHRH analogs, given subcutaneously, can also stimulate GH (and thereby growth) in certain GH-deficient children with short stature. Sermorelin is given only to children who have had a positive growth hormone

response to the diagnostic test and who have a bone age of less than 7.5 years (girls) or 8 years (boys). A physician experienced in its use must carefully monitor treatment. If successful in promoting growth, treatment is continued until the desired height is reached or the epiphyses have fused, whichever comes first. Children who have an inadequate response are evaluated for hypothyroidism and considered for growth hormone therapy.

Dosage

Diagnostic Use

Sermorelin may be used as a diagnostic test for pituitary GH reserve according to the following protocol: After an overnight fast, the patient has blood drawn for GH at -15 and 0 minutes; sermorelin 1 $\mu\text{g}/\text{kg}$ is injected intravenously, followed by a 3 mL normal saline flush of the infusion line. Blood for GH is then drawn at 15, 30, 45, and 60 minutes following the injection. Serum GH levels must reach a peak of over 2 ng/mL to be considered a positive response.

Therapeutic Use

Sermorelin is usually given subcutaneously at a dosage of 0.03 mg/kg body weight once daily at bedtime. Alternative regimens include GHRH, 2–5 $\mu\text{g}/\text{kg}$ subcutaneously every 6–12 hours. GHRP-2 has been administered intranasally in doses of 5–20 $\mu\text{g}/\text{kg}$. Hexarelin has clinical activity in doses of 20 $\mu\text{g}/\text{kg}$ intranasally.

Toxicity

Intravenous GHRH usually causes acute but transient adverse effects lasting several minutes. These effects include flushing, injection site pain and erythema, nausea, headache, metallic taste, pallor, and chest tightness.

Chronic subcutaneous GHRH therapy causes injection site reactions (pain, swelling, erythema) in about 20% of patients. Other reported adverse reactions have included headaches, flushing, dysphagia, dizziness, hyperactivity, somnolence, and urticaria.

GHRH analogs are not known to cause or stimulate malignancies, and long-term carcinogenic potential has not been studied. It is recommended that GHRH treatment be terminated if a malignancy is detected. GHRH treatment is not recommended for patients with GH deficiency due to an intracranial neoplasm.

Somatostatin (Growth Hormone-Inhibiting Hormone, Somato-Tropin Release-Inhibiting Hormone)

Somatostatin, a 14-amino-acid peptide, is found in the hypothalamus and other parts of the central nervous system. It has been sequenced (Figure 37–1) and synthesized. It inhibits growth hormone release in normal individuals. Somatostatin has also been identified in the pancreas and other sites in the gastrointestinal tract. It has been shown to inhibit the release of glucagon, insulin, and gastrin.

Figure 37–1.

Above: Amino acid sequence of somatostatin. **Below:** Sequence of the synthetic analog, octreotide (SMS 201-995).

Exogenously administered somatostatin is rapidly cleared from the circulation, with an initial half-life of 1–3 minutes. The kidney appears to play an important role in its metabolism and excretion.

Peptides have been synthesized that partially separate the various properties of somatostatin. A 7-aminoheptanoic acid derivative containing only four of the 14 amino acids of somatostatin has been found to block the effect of somatostatin.

Clinical Pharmacology of Octreotide (Somatostatin Analog)

Somatostatin has limited therapeutic usefulness because of its short duration of action and its multiple effects on many secretory systems. Octreotide is 45 times more potent than somatostatin in inhibiting growth hormone release but only twice as potent in reducing insulin secretion. Because of this relatively reduced effect on pancreatic B cells, hyperglycemia rarely occurs during treatment. The greater potency of octreotide as compared with somatostatin is not due to differences in affinity for somatostatin receptors. Rather, it appears to be due to octreotide's much lower clearance and longer half-life. The plasma elimination half-life of octreotide is about 80 minutes, 30 times longer in humans than the half-life of somatostatin.

Octreotide, in doses of 50–200 μ g given subcutaneously every 8 hours, reduces symptoms caused by a variety of hormone-secreting tumors: acromegaly; the carcinoid syndrome; gastrinoma; glucagonoma; nesidioblastosis; the watery diarrhea, hypokalemia, and achlorhydria (WDHA) syndrome; and "diabetic diarrhea." Somatostatin receptor scintigraphy, using radiolabeled octreotide, is useful in localizing neuroendocrine tumors having somatostatin receptors and helps predict the response to octreotide therapy. Octreotide is also useful for the acute control of bleeding from esophageal varices.

Octreotide acetate injectable suspension (octreotide long-acting release; Sandostatin LAR) is a slow-release formulation in which octreotide is incorporated into microspheres. It is instituted only after a brief course of shorter-acting octreotide has been demonstrated to be effective and tolerated. The microspheres must be carefully put into suspension and immediately injected into a gluteal muscle. Injections into alternate gluteal muscles are repeated at 4-week intervals in doses of 20–40 mg. Octreotide is extremely costly.

Adverse effects of therapy include nausea with or without vomiting, abdominal cramps, flatulence, and steatorrhea with bulky bowel movements. Biliary sludge and gallstones may occur after 6

months of use in 20–30% of patients. However, the yearly incidence of symptomatic gallstones is about 1%. Cardiac effects include sinus bradycardia (25%) and conduction disturbances (10%). Pain at the site of injection is common, especially with the long-acting octreotide suspension. Vitamin B12 deficiency may occur with long-term use of octreotide.

Pegvisomant (Growth Hormone Receptor Antagonist)

Pegvisomant is a new GH receptor antagonist that is proving useful for the treatment of acromegaly. Pegvisomant is the polyethylene glycol (PEG) derivative of a mutant growth hormone (B2036) that has increased affinity for one site of the GH receptor but a reduced affinity at its second binding site. This allows dimerization of the receptor but blocks the conformational changes required for signal transduction. Pegvisomant has less GH receptor antagonism than does B2036, but pegylation reduces its clearance rate and improves its overall clinical effectiveness. When pegvisomant was administered to 160 acromegalic patients subcutaneously daily for 12 months or more, serum levels of IGF-I fell into the normal range in 97% while serum levels of GH rose during treatment; two patients experienced growth of their GH-secreting pituitary tumors, and two patients developed increases in liver enzymes.

Growth Hormone (Somatotropin, GH)

Growth hormone is a peptide hormone produced by the anterior pituitary. It produces growth at open epiphyses via stimulation of insulin-like growth factor I (IGF-I, somatomedin C). It also causes lipolysis in adipose tissue and growth of skeletal muscle.

Chemistry & Pharmacokinetics

Structure

Human pituitary GH (**somatotropin**) is a 191-amino-acid peptide with two sulfhydryl bridges. Its structure closely resembles that of prolactin and the placental hormone human chorionic somatomammotropin. Pituitary-derived GH is no longer used (see below). Animal GH is not completely homologous to human GH and is ineffective in humans.

Recombinant human growth hormone (rhGH) is the growth hormone preparation in widespread use. It is synthesized by introducing plasmids containing the gene for human growth hormone into a strain of microorganisms that synthesize rhGH, which is purified for pharmacologic use.

Somatropin has a 191-amino-acid sequence that is identical with human growth hormone.

Somatrem has 192 amino acids consisting of the 191 amino acids of growth hormone plus an extra methionine residue at the amino terminal end. These preparations all appear to be equipotent.

Absorption, Metabolism, and Excretion

Circulating endogenous growth hormone has a half-life of 20–25 minutes and is predominantly cleared by the liver. Human growth hormone can be administered subcutaneously, with peak levels occurring in 2–4 hours and active blood levels persisting for 36 hours.

Somatropin injectable suspension (Nutropin Depot) is a long-acting preparation of rhGH enclosed within biodegradable microspheres. These microspheres degrade slowly after subcutaneous injection such that the rhGH is released over about 1 month.

Pharmacodynamics

Recombinant human growth hormone is equipotent with native pituitary growth hormone. The metabolic consequence of a pharmacologic dose of growth hormone is an initial insulin-like effect with increased tissue uptake of both glucose and amino acids and decreased lipolysis. Within a few hours, there is a peripheral insulin-antagonistic effect with impaired glucose uptake and increased lipolysis.

Pharmacologic doses of growth hormone cause longitudinal growth indirectly via another class of peptide hormones, the somatomedins, or insulin-like growth factors (IGFs). Growth hormone stimulates synthesis of somatomedins IGF-I and IGF-II (predominantly in growth plate cartilage and the liver); somatomedins promote uptake of sulfate into cartilage and are probably the actual mediators of the cellular processes associated with bone growth. This growth can be traced back to the molecular level, where increased incorporation of thymidine into DNA and uridine into RNA occurs (indicating cellular proliferation) along with increased conversion of proline to hydroxyproline (indicating cartilage synthesis).

Growth hormone deficiency leads to inadequate somatomedin production and short stature. Rarely, short stature may be caused by IGF-I deficiency despite high growth hormone levels (Laron dwarfism) or a lack of a pubertal surge of IGF-I (pygmies).

Clinical Pharmacology

Growth Hormone Deficiency

Genetic GH deficiency may present in the newborn with hypoglycemic seizures. Acquired GH deficiency is caused by damage to the pituitary or hypothalamus. In childhood, GH deficiency presents as short stature and adiposity. Criteria for diagnosis of growth hormone deficiency usually include (1) a growth rate below 4 cm per year and (2) the absence of a serum growth hormone response to two growth hormone secretagogues. The prevalence of congenital growth hormone deficiency is approximately 1:4000 live births.

Therapy with rhGH permits many children with short stature to achieve normal adult height.

Adults with GH deficiency tend to have generalized obesity, reduced muscle mass, asthenia, and reduced cardiac output. Adult-onset GH deficiency is usually found in the presence of other pituitary hormone deficiencies, and is usually due to damage to the hypothalamus or pituitary caused by tumor, infection, surgery, or radiation therapy.

The precise testing required to diagnose GH deficiency is controversial. Treatment of GH-deficient adults can cause increased lean body mass and bone density, decreased fat mass, increased exercise tolerance, and an improved sense of well-being. Adverse effects often include arthralgias and fluid retention.

Growth Hormone-Responsive States

Some non-growth hormone-deficient short children with a delayed bone age and a slow growth rate achieve increased growth with short-term growth hormone therapy. Selected "normal variant short stature" children can be offered a trial of growth hormone following a baseline period of measurement to confirm a subnormal growth rate. During the first 6 months of treatment, the height velocity must increase by 2 cm per year for treatment to continue. Girls with Turner's syndrome frequently respond to high-dose growth hormone therapy with increased growth velocity and increased height as adults.

In 1993, the FDA approved the use of recombinant bovine growth hormone (rbGH) in dairy cattle to increase milk production. Although milk and meat from rbGH-treated cows appears to be safe, these cows have a higher frequency of mastitis, which could increase antibiotic use and result in greater antibiotic residues in milk and meat.

Experimental Uses

Therapy with rhGH appears to be effective for infants with intrauterine growth retardation. Children with growth retardation following renal transplantation also appear to respond to rhGH therapy. Hypophosphatemia due to hyperphosphaturia (eg, X-linked hypophosphatemic vitamin D-resistant rickets) has been improved by adding rhGH to the treatment regimen.

Serum levels of growth hormone normally decline with aging. Elderly men treated with rhGH for 6 months had an increase in muscle mass and bone density and a drop of 13% in fat mass, but functional abilities remained unchanged. Available data do not support the use of rhGH to reverse the manifestations of normal aging.

Dosage

The therapeutic dosage of recombinant human growth hormone must be individualized. It is usually given in the evening by subcutaneous injection in the thighs, rotating the sites of injections. One milligram of standard rhGH preparations is equivalent to 3 units.

Children

Treatment is begun with 0.025 mg/kg daily and may be increased to a maximum of 0.045 mg/kg daily. Somatropin injectable suspension (Nutropin Depot) is a long-acting preparation of rhGH that is administered subcutaneously in doses of 1.5 mg/kg monthly or 0.75 mg/kg twice monthly. Children must be observed closely for slowing of growth velocity, which could indicate a need to increase the dosage or the possibility of epiphyseal fusion or intercurrent problems such as hypothyroidism or malnutrition. Children with Turner's syndrome or chronic renal insufficiency require somewhat higher doses. The injection should be given at least 3 hours after dialysis to reduce the risk of hematoma formation due to residual heparin effect.

Adults

The required dosage for adults is lower than that for children. Treatment is begun at about 0.2 mg three times weekly and titrated upward gradually at intervals of 2–4 weeks to a maximum of 0.025 mg/kg/d (adults under age 35) or 0.0125 mg/kg/d (adults over age 35) given three to seven times weekly according to clinical response. Somatropin injectable suspension is administered subcutaneously to adult men in doses of 0.2–0.4 mg/kg every 2 weeks; it is administered to adult women taking oral estrogen in doses of 0.4–0.6 mg/kg every 2 weeks. Women usually require higher dosages than men, perhaps because of concomitant use of oral estrogens. Clinical response and adverse effects best determine the final therapeutic dosage. Serum IGF-I levels (age- and sex-adjusted) can also be used.

Toxicity & Contraindications

Before 1985, GH was obtained from human cadaver pituitary glands. A small number of individuals who received cadaver-derived pooled growth hormone preparations developed Creutzfeldt-Jakob disease, a fatal neurodegenerative disease that presented many years after GH treatment. (This

disease is caused by prions, infectious proteins containing no DNA or RNA, which escaped the usual purification processes.) Distribution of pituitary-derived GH ceased in 1985. Recombinant human growth hormone carries no such risk.

Children generally tolerate GH treatment well. A rarely reported side effect is intracranial hypertension, which may present with vision changes, headache, nausea, or vomiting. Some children develop scoliosis during rapid growth. Patients with Turner's syndrome have an increased risk of otitis media while taking GH. Hypothyroidism is commonly discovered during GH treatment, so periodic assessment of thyroid function is indicated. Pancreatitis, gynecomastia, and nevus growth have occurred in patients receiving GH. Adults tend to have more adverse effects from GH therapy. Peripheral edema, myalgias, and arthralgias (especially in the hands and wrists) occur commonly but remit with dosage reduction. Carpal tunnel syndrome can occur. GH treatment increases the activity of cytochrome P450 isoforms, which could reduce the serum levels of drugs metabolized by that enzyme system (see Chapter 4: Drug Biotransformation). There has been no increased incidence of malignancy among patients receiving GH therapy, but GH treatment is contraindicated in a patient with a known malignancy. Proliferative retinopathy may rarely occur. GH treatment of critically ill patients appears to increase mortality.

Side effects of the long-acting somatotropin injectable suspension have included injection-site nodules that persist for 5–7 days (96%), edema, arthralgias, transient fatigue (24%), mild-moderate nausea (24%), and headache (36%).

Thyrotropin-Releasing Hormone (Protirelin, TRH)

Thyrotropin-releasing hormone, or protirelin, is a tripeptide hormone found in the paraventricular nuclei of the hypothalamus as well as in other parts of the brain. TRH is secreted into the portal venous system and stimulates the pituitary to produce thyroid-stimulating hormone (TSH, thyrotropin), which in turn stimulates the thyroid to produce thyroxine (T_4) and triiodothyronine (T_3). TRH stimulation of thyrotropin is blocked by thyroxine and potentiated by lack of thyroxine.

Chemistry & Pharmacokinetics

TRH is (pyro)Glu-His-Pro-NH₂. It is administered intravenously over 1 minute. Rapid plasma inactivation occurs, with a half-life of 4–5 minutes.

Pharmacodynamics

Peak serum thyrotropin levels occur 20–30 seconds after intravenous TRH injection in healthy individuals. In hyperthyroidism, the serum thyrotropin level is suppressed. In primary hypothyroidism, thyrotropin levels are high and the thyrotropin response to TRH may be accentuated. In secondary (pituitary) hypothyroidism, serum thyrotropin levels are "inappropriately" normal or low (using a sensitive TSH assay); TSH often fails to rise after TRH administration. In tertiary (hypothalamic) hypothyroidism, the baseline serum thyrotropin level may be normal or low and the thyrotropin response to TRH may be normal or blunted.

TRH infusion leads to stimulation of prolactin release by the pituitary in healthy individuals but has no effect on cells producing growth hormone or ACTH. In certain types of pituitary tumors, however, the neoplastic cells may respond abnormally to TRH by releasing growth hormone (in acromegaly), by releasing ACTH (in Cushing's disease), or by failing to release prolactin (in most prolactinomas). Infusion of TRH or TRH analogs has been reported to improve the outcome of partial spinal cord injuries.

Clinical Pharmacology

TRH testing (see above) is now rarely used to diagnose hyperthyroidism or hypothyroidism, having been supplanted by sensitive assays for serum thyrotropin (see below).

Dosage

The dose of protirelin for diagnostic use is 500 μg for adults and 7 $\mu\text{g}/\text{kg}$ for children aged 6 years or older but not to exceed the adult dose. A baseline thyrotropin level should be obtained, followed by three further determinations at 15, 30, and 60 minutes postinfusion. The test is performed with the patient supine while blood pressure is monitored.

Toxicity

Most patients given intravenous TRH note adverse effects lasting for a few minutes: an urge to urinate, a metallic taste, nausea, flushing, or light-headedness. Transient hypertension or hypotension may occur, and marked blood pressure fluctuations have been reported in a few patients.

Thyroid-Stimulating Hormone (Thyrotropin, TSH) & Thyrotropin Alpha (rhTSH)

Thyrotropin is an anterior pituitary hormone that stimulates the thyroid to produce and synthesize thyroxine (T_4), triiodothyronine (T_3), and thyroglobulin. Thyrotropin alpha is a commercially available analog of TSH that is used to help detection of metastatic differentiated thyroid carcinoma; it is also known as recombinant human TSH (rhTSH).

Chemistry & Pharmacokinetics

Structure

Thyrotropin is a glycoprotein consisting of two peptide (alpha and beta) subunits joined noncovalently. The TSH-alpha subunit in humans has 89 amino acids and is virtually identical to that of the alpha subunit of FSH, LH, and hCG. The TSH-beta subunit has 112 amino acids and confers thyroid specificity. Carbohydrate side chains glycosylate each subunit prior to secretion and are important for hormone action. Native TSH is actually secreted as a mixture of glycosylation variants, having both sialylated and sulfated forms.

Thyrotropin alpha is a purified synthetic analog of native pituitary TSH that is produced in a Chinese hamster ovary cell line cotransfected with recombinant plasmids containing DNA sequences that encode the alpha and beta subunits of TSH. Like native TSH, thyrotropin alpha is a heterodimeric glycoprotein containing an alpha subunit of 92 amino acids with two glycosylation sites and a beta subunit of 118 amino acids with one glycosylation site. These subunits are slightly longer than those of pituitary TSH but contain amino acid sequences identical to those of native TSH. Like pituitary TSH, synthetic thyrotropin alpha is a mixture of glycosylated variants, but with only sialylated forms.

Absorption, Metabolism, and Excretion

Following an intramuscular injection of thyrotropin alpha (0.9 mg), the peak rhTSH concentration is reached in about 10 hours (range, 3–24 hours). The mean elimination half-life of thyrotropin alpha is 22 hours. Pituitary TSH is cleared by the kidneys and liver. Little unchanged thyrotropin is

found in the urine.

Pharmacodynamics

Thyrotropin alpha has the biologic properties of pituitary TSH. It binds to TSH receptors on both normal thyroid and differentiated thyroid cancer cells. The TSH-activated receptor stimulates intracellular adenylyl cyclase activity. Increased cAMP production causes increased iodine uptake and increased production of thyroid hormones and thyroglobulin.

Clinical Pharmacology

Diagnostic Uses

Patients with well-differentiated (papillary or follicular) thyroid carcinoma are treated with surgical resection of the cancer along with total or near-total thyroidectomy. Total thyroidectomy normally reduces the serum levels of thyroid hormones and thyroglobulin to undetectable levels. Postoperatively, these patients must take oral thyroid hormone in order to maintain clinical euthyroidism and to suppress pituitary TSH secretion, thereby preventing any stimulation of tumor growth by TSH. Since thyroid cancer can recur years after apparent cure, such patients should have follow-up TSH-stimulated whole-body ^{131}I scans and serum thyroglobulin determinations. However, the aggressiveness of follow-up surveillance must be individualized according to each patient's risk of recurrence. Traditionally, patients have had to endure prolonged withdrawal of thyroid hormone replacement for many weeks before these tests in order to allow their TSH levels to rise high enough to stimulate any remaining tumor cells to resume their uptake of ^{131}I and their secretion of thyroglobulin. The use of thyrotropin alpha can obviate the need for cessation of thyroid hormone replacement prior to the diagnostic whole-body ^{131}I scan and serum thyroglobulin determination.

Therapeutic Uses

Treatment of metastatic differentiated thyroid cancer requires the administration of large doses of ^{131}I (30–200 mCi) in the presence of persistently high serum levels of TSH (see Chapter 38: Thyroid & Antithyroid Drugs). Patients must withdraw from thyroid hormone replacement in order to achieve this. For treatment purposes, thyrotropin alpha administration cannot substitute for thyroid hormone withdrawal.

Dosage

Thyrotropin alpha injections can stimulate uptake of ^{131}I by thyroid cancer or residual thyroid. The preparation is stored as a lyophilized powder that must be reconstituted before use. The dosage is 0.9 mg intragluteally (not intravenously) every 24 hours for two doses (eg, Monday and Tuesday). Twenty-four hours after the final thyrotropin injection (eg, Wednesday), ^{131}I is administered in a dosage of at least 4 mCi (a larger dose than in hypothyroid patients, since iodine clearance is faster in euthyroid patients). Then, 48 hours after the ^{131}I administration (eg, Friday), a serum thyroglobulin is drawn and a scan is obtained using a gamma camera, with neck, anterior whole body, and posterior whole-body imaging. If the scan shows probable metastases or if the serum thyroglobulin level (using a sensitive assay) is > 2.5 ng/mL, further evaluation and treatment are indicated.

Toxicity

Side effects of thyrotropin injections include nausea (11%), headache (7%), and asthenia (3%). Hyperthyroidism can occur in patients with significant metastases or residual normal thyroid. Thyrotropin has caused neurologic deterioration in 7% of patients with brain metastases.

Corticotropin-Releasing Hormone (CRH)

CRH is a hypothalamic hormone that stimulates release of ACTH and β -endorphin from the pituitary.

Chemistry & Pharmacokinetics

Structure

Human CRH is a 41-amino-acid peptide. An analog of human CRH is sheep (ovine) CRH, which also contains 41 amino acids. These molecules differ in seven amino acids.

Absorption, Metabolism, and Excretion

CRH is administered intravenously. The first-phase half-lives of human and sheep CRH are 9 minutes and 18 minutes, respectively. The peptide is metabolized in various tissues, and less than 1% is excreted in the urine.

Pharmacodynamics

ACTH released by CRH stimulation of the pituitary subsequently stimulates the adrenal cortex to produce cortisol and androgens. Ovine CRH is more potent than human CRH.

Clinical Pharmacology

CRH is used only for diagnostic purposes. In Cushing's syndrome, CRH has been used to distinguish Cushing's disease from ectopic ACTH secretion. CRH generally elicits an increase in ACTH and cortisol secretion in Cushing's disease but usually not in the ectopic ACTH syndrome. However, exceptions occur frequently, making this test unreliable. A more reliable test depends on differential concentrations of ACTH. In patients with Cushing's disease, ACTH levels in blood drawn from the inferior petrosal sinuses draining the pituitary are more than 2.5 times higher than levels in simultaneously drawn peripheral venous blood. When tumors are associated with ectopic ACTH production, no such difference is observed. Concurrent administration of CRH (ovine) further improves the distinction between blood levels of ACTH when Cushing's disease is present.

Preparations & Dosage

Synthetic human and ovine CRH are available. Sheep CRH is used more frequently because of its longer half-life and slightly greater potency. CRH may be dissolved in water or dilute acid but not in saline. A dose of 1 mg/kg is used for diagnostic testing.

Toxicity

Intravenous bolus doses of 1 mg/kg produce transient facial flushing and, rarely, dyspnea.

Adrenocorticotropin (Corticotropin, ACTH, ACTH₁₋₂₄)

Adrenocorticotropin is a peptide hormone produced in the anterior pituitary. Its primary endocrine function is to stimulate synthesis and release of cortisol by the adrenal cortex. Corticotropin can be used therapeutically, but a synthetic derivative is more commonly—and almost exclusively—used to assess adrenocortical responsiveness. A substandard adrenocortical response to exogenous corticotropin administration indicates adrenocortical insufficiency.

Chemistry & Pharmacokinetics

Structure

Human ACTH is a single peptide chain of 39 amino acids. The amino terminal portion containing amino acids 1–24 is necessary for full biologic activity. The remaining amino acids (25–39) confer species specificity. Synthetic human ACTH_{1–24} is known as cosyntropin. The amino terminal amino acids 1–13 are identical to melanocyte-stimulating hormone (α -MSH), which has been found in animals but not in humans. In states of excessive pituitary ACTH secretion (Addison's disease or an ACTH-secreting pituitary tumor), hyperpigmentation—caused by the α -MSH activity intrinsic to ACTH—may be noted.

ACTH from animal sources is assayed biologically by measuring the depletion of adrenocortical ascorbic acid that follows subcutaneous administration of the ACTH.

Absorption, Metabolism, and Excretion

Both porcine and synthetic corticotropin are given parenterally. Corticotropin cannot be administered orally because of gastrointestinal proteolysis.

The biologic half-lives of ACTH_{1–39} and ACTH_{1–24} are under 20 minutes. Tissue uptake occurs in the liver and kidneys. ACTH_{1–39} is transformed into a biologically inactive substance, probably by modification of a side chain. ACTH is not excreted in the urine in significant amounts. The effects of long-acting repository forms of porcine corticotropin persist for up to 18 hours with a gelatin complex of the peptide and up to several days with a zinc hydroxide complex.

Pharmacodynamics

ACTH stimulates the adrenal cortex to produce glucocorticoids, mineralocorticoids, and androgens. ACTH increases the activity of cholesterol esterase, the enzyme that catalyzes the rate-limiting step of steroid hormone production: cholesterol \rightarrow pregnenolone. ACTH also stimulates adrenal hypertrophy and hyperplasia. When given chronically in pharmacologic doses, corticotropin causes increased skin pigmentation.

Clinical Pharmacology

Diagnostic Uses

ACTH stimulation of the adrenals will fail to elicit an appropriate response in states of adrenal insufficiency. A rapid test for ruling out adrenal insufficiency employs cosyntropin (see below). Plasma cortisol levels are measured before and either 30 minutes or 60 minutes following an intramuscular or intravenous injection of 0.25 mg of cosyntropin. A normal plasma cortisol response is a stimulated peak level exceeding 20 μ g/dL. A subnormal response indicates primary or secondary adrenocortical insufficiency that can be differentiated using endogenous plasma ACTH levels (which are increased in primary adrenal insufficiency and decreased in the secondary form).

An incremental rise in plasma aldosterone generally occurs in secondary but not primary adrenal insufficiency after cosyntropin stimulation.

ACTH stimulation may distinguish three forms of "late-onset" (nonclassic) congenital adrenal hyperplasia from states of ovarian hyperandrogenism, all of which may be associated with hirsutism. In patients with deficiency of 21-hydroxylase, ACTH stimulation results in an incremental rise in plasma 17-hydroxyprogesterone, the substrate for the deficient enzyme. Patients with 11-hydroxylase deficiency manifest a rise in 11-deoxycortisol, while those with 3 β -hydroxy- δ -5 steroid dehydrogenase deficiency show an increase of 17-hydroxypregnenolone in response to ACTH stimulation.

Therapeutic Uses

Corticotropin therapy has been virtually abandoned since it has no therapeutic advantage over direct administration of glucocorticoids.

Dosage

Cosyntropin is the preferred preparation for diagnostic use. The standard diagnostic test dose of 0.25 mg is equivalent to 25 units of porcine corticotropin. ACTH is rarely indicated but is available for use in doses of 10–20 units four times daily. Repository ACTH, 40–80 units, may be administered every 24–72 hours.

Toxicity & Contraindications

The toxicity of therapeutic doses of ACTH resembles that of the glucocorticoids (see Chapter 39: Adrenocorticosteroids & Adrenocortical Antagonists), with the added adverse effect of hyperandrogenism in women. The occasional development of antibodies to animal ACTH or to depot cosyntropin (a preparation not currently available in the USA) has produced anaphylactic reactions or refractoriness to ACTH therapy in a few individuals. Painful swelling occurs at the injection site more often with the zinc hydroxide depot preparation than with the gelatin preparation. Contraindications are similar to those of glucocorticoids. When immediate effects are desired, glucocorticoids are preferable.

There are virtually no adverse effects from diagnostic doses of cosyntropin.

Gonadotropin-Releasing Hormone (GnRH; Luteinizing Hormone-Releasing Hormone [LHRH]; Gonadorelin Hydrochloride)

GnRH is produced in the arcuate nucleus of the hypothalamus. GnRH is secreted into the hypothalamic-pituitary venous plexus and binds to cell surface receptors of the anterior pituitary gonadotroph cells. Pulsatile GnRH secretion is required to stimulate the gonadotroph cell to produce and release luteinizing hormone (LH) and follicle stimulating hormone (FSH).

Divergent production of the two gonadotropins is controlled by the frequency of GnRH pulses. In women, increasing levels of estradiol at midcycle have a positive feedback upon the hypothalamus that increases GnRH secretion, resulting in a sudden increase in LH secretion. This LH-surge induces the ovulation of the dominant ovarian follicle, with subsequent luteinization in the ovary that secretes progesterone; this changes the uterine proliferative endometrium to a secretory endometrium that is receptive to a fertilized ovum.

Ironically, sustained non-pulsatile administration of GnRH or GnRH analogs *inhibits* the release of FSH and LH by the pituitary in both women and men, resulting in hypogonadism.

Chemistry & Pharmacokinetics

Structure

GnRH is a decapeptide found in all mammals. It is derived from a precursor (proGnRH) with 92 amino acids. Pharmaceutical GnRH is synthetic. Analogs (eg, leuprolide, nafarelin, buserelin, goserelin, and histrelin) with D-amino acids at position 6 and with ethylamide substituted for glycine at position 10 are more potent and longer-lasting than native GnRH.

GnRH (gonadorelin)

Leuprolide

Nafarelin

Goserelin

Histrelin

*D-Nal = D-3-(2-naphthyl)-alanine.

Absorption, Metabolism, and Excretion

GnRH may be administered intravenously or subcutaneously. GnRH analogs may be administered subcutaneously, intramuscularly, or via nasal spray. The half-life of intravenous GnRH is 4 minutes, and the half-lives of subcutaneous and intranasal GnRH analogs are 3 hours. Degradation occurs in the hypothalamus and pituitary. GnRH analogs have increased affinity for GnRH receptors and reduced susceptibility to degradation.

Pharmacodynamics

GnRH binds to receptors on pituitary gonadotrophs. Pulsatile intravenous administration of GnRH every 1–4 hours stimulates FSH and LH secretion. As noted above, GnRH administered continuously or GnRH analogs administered in depot formulations inhibit gonadotropin release.

Clinical Pharmacology

Diagnostic Uses

Delayed puberty in a hypogonadotropic adolescent may be due to a constitutional delay or to hypogonadotropic hypogonadism. The LH response (but not the FSH response) to GnRH can distinguish between these two conditions. Serum LH levels are measured before and then 15, 30, 45, 60, and 120 minutes after a 100 mg intravenous or subcutaneous bolus of GnRH. A peak LH response exceeding 15.6 mIU/mL is normal and suggests impending puberty, whereas an impaired LH response suggests hypogonadotropic hypogonadism due to either pituitary or hypothalamic disease (but may also be seen in constitutional delay of adolescence).

Therapeutic Uses

Stimulation

GnRH can stimulate pituitary function and is used to treat infertility caused by hypothalamic hypogonadotropic hypogonadism in both sexes. A portable battery-powered programmable pump and intravenous tubing allows pulsatile GnRH therapy every 90 minutes.

Suppression

Leuprolide, nafarelin, goserelin, and histrelin are GnRH analog agonists that induce hypogonadism when given continuously. Such GnRH agonists are used to treat prostate cancer, uterine fibroids, endometriosis, polycystic ovary syndrome, and precocious puberty. Many in vitro fertilization programs sequentially use a GnRH analog to suppress endogenous gonadotropin release, along with exogenous gonadotropins to achieve synchronous follicular development.

GnRH analog therapy for the purpose of producing pituitary suppression leads to a transient rise in sex hormone concentration during the first 2 weeks of treatment. This can be deleterious during treatment of prostate cancer, precocious puberty, and infertility.

Dosage: Gonadorelin (GnRH, Factrel)

Gonadorelin hydrochloride is available in a lyophilized powder that is reconstituted and injected either subcutaneously or intravenously.

Diagnostic Use

Gonadorelin has been used to test pituitary luteinizing hormone (LH) responsiveness. Administered as a 100 µg test dose, the average times to peak LH levels are 34 minutes (men) or 72 minutes (women) following subcutaneous gonadorelin and 27 minutes (men) or 36 minutes (women) following intravenous gonadorelin. There is considerable individual variation in response.

Female Infertility

Gonadorelin is administered intravenously, 5 µg every 90 minutes from a portable pump. The woman is followed carefully with serum estradiol levels, and an ovarian ultrasound examination is done weekly before refilling the GnRH pump. When an ovarian follicle reaches 14 mm in diameter, ovulation is induced with hCG, 5000 units subcutaneously, and the luteal phase is maintained with hCG, 1500 units every 3 days for 12 days.

Male Infertility

For male infertility caused by hypothalamic GnRH deficiency, gonadorelin treatment is begun only

after preparatory hCG injections continued for up to 1 year in men with prepubertal hypogonadotropic hypogonadism. A portable pump infuses gonadorelin intravenously every 90 minutes. Serum testosterone levels and semen analyses must be done regularly. At least 3–6 months of bolus infusions are required before significant numbers of sperm are seen. The preferable alternative to intravenous gonadorelin treatment is subcutaneously administered gonadotropins.

Dosage: Leuprolide (GnRH Analog, Lupron)

Leuprolide is available in solution for daily subcutaneous injection and in slow-release depot preparations in which leuprolide is lyophilized in microspheres given by intramuscular injection.

Endometriosis and Uterine Fibroids

Women with endometriosis receive treatment courses of 6 months' duration. Concomitant low-dose hormone replacement therapy has been reported to diminish bone loss without significantly decreasing clinical effectiveness. Women with uterine fibroids that are symptomatic (menorrhagia, anemia, pain) receive treatment courses of 3 months, by which time women have amenorrhea or reduced menorrhagia; uterine fibroids are reduced in size an average of 37%. Intramuscular depot preparations containing 3.75 mg (monthly) or 11.5 mg (every 3 months) are used.

Prostate Cancer

Leuprolide is usually used in depot form, 7.5 mg intramuscularly monthly, 22.5 mg intramuscularly at 84-day intervals, or 30 mg intramuscularly at 4-month intervals.

Central Precocious Puberty

Leuprolide aqueous solution is started at a dosage of 0.05 mg/kg body weight injected subcutaneously daily. If the clinical response is inadequate, the dose can be increased by increments of 0.01 mg/kg body weight. Pediatric depot preparations are also available. The dose can be titrated upward according to the endocrine response.

Leuprolide is indicated for treatment of central precocious puberty (onset of secondary sex characteristics before 8 years in girls or 9 years in boys). Prior to use, central precocious puberty must be confirmed by a puberty gonadotropin response to GnRH and a bone age at least 1 year beyond chronologic age. Pretreatment evaluation must also include sex steroid levels compatible with precocious puberty and not congenital adrenal hyperplasia; a β hCG level to exclude a chronic gonadotropin-secreting tumor; an MRI of the brain to exclude an intracranial tumor; and an ultrasound examination of the adrenals and ovaries or testes to exclude a steroid-secreting tumor.

Dosage: Nafarelin (GnRH Analog, Synarel) Nasal Solution

Nafarelin is available as Synarel, a nasal preparation. The head should be tilted back and 30 seconds allowed to elapse between each spray. Nafarelin is rapidly absorbed by the nasal mucosa. Maximum serum levels occur in 10–40 minutes. Rhinitis is a common side effect. Sneezing should be avoided after administration. Nasal decongestants must not be used for 2 hours following each dose.

Endometriosis

Treatment is begun between days 2 and 4 of the menstrual cycle. The initial dose is one spray (0.1 mL, 0.2 mg) into one nostril in the morning and another spray into the opposite nostril in the

evening. Amenorrhea occurs in about 65%, 80%, and 90% of women at 2, 3, and 4 months of treatment, respectively. About 60% of women become symptom-free by the end of treatment, and of these, about 50% remain symptom-free 6 months after cessation of treatment. Withdrawal menstrual bleeding occurs commonly during the first 2 months of nafarelin therapy. If bleeding persists despite good patient compliance, the dosage may be increased to one spray into each nostril twice daily.

Central Precocious Puberty

The recommended initial daily dose of nafarelin for central precocious puberty is 1.6 mg/d. This is achieved with two unit dose sprays (each spray contains 0.1 mL, 0.2 mg) into each nostril twice daily. If adequate suppression of puberty is not achieved, the dose may be increased to 1.8 mg/d, given as 3 sprays (total) three times daily. Pretreatment evaluation and follow-up are the same as for leuprolide.

Uterine Fibroids

Nafarelin nasal spray has been used to shrink uterine fibroids and reduce menometrorrhagia, dysmenorrhea, and pelvic discomfort. Required doses range from 50 μ g to 400 μ g intranasally twice daily for 3–6 months.

Dosage: Goserelin (GnRH Analog, Zoladex) Implants

Goserelin acetate is available in the form of implantable cylinders, 1–1.5 mm in diameter, that are placed subcutaneously in the upper abdominal area. Goserelin is metabolized in the liver and excreted in the urine. Clearance is greater in women than in men. Stimulation of gonadotropins occurs in the first weeks of therapy, followed by suppression.

Endometriosis, Breast Cancer, and Dysfunctional Uterine Bleeding

Implants containing 3.6 mg of goserelin are injected subcutaneously every 28 days.

Prostate Cancer

Implants containing 10.8 mg goserelin are injected subcutaneously every 12 weeks.

Toxicity

GnRH (gonadorelin) may cause headache, light-headedness, nausea, and flushing. Local swelling often occurs at subcutaneous injection sites. Generalized hypersensitivity dermatitis has occurred after long-term subcutaneous administration. Rare acute hypersensitivity reactions include bronchospasm and anaphylaxis. Sudden pituitary apoplexy and blindness has been reported following administration of GnRH to a patient with a gonadotropin-secreting pituitary tumor.

GnRH analog (leuprolide, nafarelin, goserelin) treatment of women may cause hot flushes and sweats (89%) and headaches (29%). Depression, diminished libido, generalized pain, vaginal dryness, and breast atrophy may also occur. Ovarian cysts may develop within the first 2 months of therapy and generally resolve by 6 weeks, but may persist and require discontinuation of therapy. Osteoporosis may occur with prolonged use, so patients may be monitored with bone densitometry prior to repeated treatment courses. Cholesterol and triglyceride levels may rise. Contraindications include pregnancy and breast-feeding.

GnRH analog (leuprolide, goserelin) treatment in men causes serum testosterone levels to rise for about 1 week; this can precipitate pain in men with bone metastases. In men with vertebral metastases, initial growth of tumor can produce neurologic symptoms. It can also temporarily worsen symptoms of urinary obstruction. Within about 2 weeks, serum testosterone levels fall to the hypogonadal range. Other adverse effects in men include hot flushes and sweats (59%), edema (13%), gynecomastia, decreased libido, decreased hematocrit, and asthenia. For men with prostate cancer, GnRH agonists are often given together with an antiandrogen (see Chapter 40: The Gonadal Hormones & Inhibitors), which may exacerbate hypogonadal symptoms while reducing the risk of exacerbation of bone pain.

GnRH analog (leuprolide, nafarelin) treatment of children is generally well tolerated. However, temporary exacerbation of precocious puberty may occur during the first few weeks of therapy. Injection site reactions occur in about 5%. Nafarelin nasal spray may cause or aggravate sinusitis.

Dosage: Cetrorelix Acetate for Injection (GnRH Antagonist)

Cetrorelix is a synthetic decapeptide that reversibly binds to pituitary GnRH receptors without activating them. Cetrorelix thus inhibits the secretion of FSH and LH in a dose-dependent manner by competing with natural hypothalamic GnRH for pituitary cell surface receptors. At the doses used for in vitro fertilization, cetrorelix produces an immediate suppression of LH; this delays the LH surge and thus delays ovulation. At higher doses, cetrorelix also suppresses FSH secretion, thus inhibiting the secretion of estradiol from the ovaries.

Cetrorelix is absorbed rapidly following subcutaneous injection, with maximum plasma concentrations occurring 1–2 hours after administration. Following a subcutaneous dose of 3 mg, the duration of action is at least 4 days; daily administration of 0.25 mg maintains GnRH antagonism.

in Vitro Fertilization (IVF)

GnRH antagonists produce less ovarian hyperstimulation during IVF than do GnRH analogs. Cetrorelix suppresses endogenous FSH and LH while recombinant FSH (rFSH) is being given to prepare the ova for ovulation-induction by hCG administration. Ovarian stimulation is commenced with rFSH on the second or third day of the menstrual cycle. When serum estradiol rises to levels that indicate sufficient ovarian stimulation (requiring 5–9 days), cetrorelix is administered subcutaneously in order to prevent a natural LH that could cause premature spontaneous ovulation, obviating laparoscopic harvest of the ova. Cetrorelix may be administered subcutaneously in a dose of 3 mg, followed by 0.25 mg daily if hCG stimulation has not been given within the next 4 days. Alternatively, cetrorelix may be given subcutaneously in doses of 0.25 mg subcutaneously daily, beginning on the fifth or sixth day of FSH stimulation and continued daily until hCG is administered.

Endometriosis

Cetrorelix has been given in doses of 3 mg by subcutaneous injection of a depot preparation once weekly for 8 weeks.

Uterine Fibroids

Cetrorelix has been given in doses of 3 mg by subcutaneous injection every 4 days for 2–4 weeks prior to surgery. Therapy is commenced on the first day of the menstrual cycle.

Follicle-Stimulating Hormone (FSH)

Follicle-stimulating hormone is a glycoprotein hormone consisting of two chains and, like LH, is produced by gonadotroph cells in the anterior pituitary. FSH and LH regulate gonadal function by increasing cAMP in the target gonadal tissue. FSH, like other pituitary glycoproteins, is composed of a common alpha subunit that promotes hormone action and a unique beta subunit that confers specificity. The principal function of FSH is to stimulate gametogenesis and follicular development in women and spermatogenesis in men. FSH acts on the immature follicular cells of the ovary and induces development of the mature follicle and oocyte. Both LH and FSH are needed for proper ovarian steroidogenesis. LH stimulates androgen production by these cells, and FSH stimulates androgen conversion into estrogens by the granulosa cells. In the testes, FSH acts on the Sertoli cells and stimulates their production of androgen-binding protein.

FSH has been commercially available since the 1960s. It was first extracted from the urine of postmenopausal women, which contains a substance with FSH-like properties (but with 4% of the potency) and an LH-like substance. This purified extract of FSH and LH, derived from the urine of postmenopausal women, remains available and is known as menotropins, or human menopausal gonadotropins (hMG). A purified preparation of human FSH, also extracted from the urine of postmenopausal women, contains virtually no LH and is known as urofollitropin, or urinary FSH (uFSH). In 1996, a synthetic modified form of FSH became available, known as follitropin alpha, or recombinant FSH (rFSH). Preparations of rFSH have batch-to-batch consistency and are free from possible urinary contaminants. The cost of rFSH is about three times that of hMG. It is controversial whether in vitro fertilization protocols using rFSH are significantly more successful than protocols using uFSH or hMG.

These preparations are used in states of infertility to stimulate ovarian follicle development in women and spermatogenesis in men. In both sexes, they must be used in conjunction with a luteinizing hormone, ie, human chorionic gonadotropin (hCG), to permit ovulation and implantation in women and testosterone production and full masculinization in men.

Pharmacokinetics

Over a 7- to 12-day course of daily hMG or urofollitropin administration (intended to mimic the follicular phase of the ovarian cycle in women with hypothalamic amenorrhea), FSH levels gradually rise to twice their baseline level. LH levels increase to 1.5 times their baseline with hMG, but they do not rise with urofollitropin.

Pharmacodynamics

Ovarian follicular growth and maturation will occur during hMG or FSH treatment of gonadotropin-deficient women. Ovulation requires administration of chorionic gonadotropin when adequate follicular maturation has occurred.

In men with gonadotropin deficiencies, pretreatment with chorionic gonadotropin produces external sexual maturation; addition of a subsequent course of hMG (or rFSH plus hCG) will stimulate spermatogenesis and lead to fertility.

Clinical Pharmacology

FSH or hMG are indicated for pituitary or hypothalamic hypogonadism with infertility. Anovulatory women with the following conditions may benefit from hMG: primary amenorrhea,

secondary amenorrhea, polycystic ovary syndrome, and anovulatory cycles. Both hMG and FSH are used by in vitro fertilization programs for controlled ovarian hyperstimulation.

Over 50% of men with hypogonadotropic hypogonadism become fertile after hMG or hCG/FSH administration.

Dosage

An ampule of menotropins contains 75 IU or 150 IU of FSH and an equal amount of LH. One international unit of LH is approximately equivalent to 0.5 IU of hCG. An ampule of urofollitropin contains 75 IU of FSH and less than 1 IU of LH. Human menopausal gonadotropins, FSH, and hCG are administered intramuscularly.

Women

In hypothalamic hypogonadism and for in vitro fertilization, one or two ampules are administered daily for 5–12 days until evidence of adequate follicular maturation is present. Serum estradiol levels should be measured and a cervical examination performed every 1 or 2 days. When appropriate follicular maturation has occurred, hMG or FSH is discontinued; the following day, hCG (5000–10,000 IU) is administered intramuscularly to induce ovulation.

Men

Following pretreatment with 5000 IU of hCG three times weekly for up to 12 months to achieve masculinization and a normal serum testosterone level, menotropins is administered as one ampule (75 units) three times weekly in combination with hCG, 2000 IU twice weekly. At least 4 months of combined treatment are usually necessary before spermatozoa appear in the ejaculate. If there is no response, the menotropins dose may be doubled. When adding menotropins to hCG therapy, the dose of hCG must be reduced to keep serum testosterone in the high normal range and avoid hyperandrogenism.

Toxicity & Contraindications

Overstimulation of the ovary with hMG can lead to uncomplicated ovarian enlargement in approximately 20% of patients. This usually resolves spontaneously. A more serious complication, the "hyperstimulation syndrome," occurs in 0.5–4% of patients. It is characterized by hMG-induced ovarian enlargement, ascites, hydrothorax, and hypovolemia, sometimes to the point of shock. Hemoperitoneum (from a ruptured ovarian cyst), fever, or arterial thromboembolism can occur. The frequency of multiple births is approximately 20%. A reported 25% incidence of spontaneous abortions may be due to earlier diagnosis of pregnancy in treated than in untreated patients, with recognition of very early abortion. There may, however, be abnormal development and premature degeneration of corpus luteum in some treated patients. Gynecomastia occasionally occurs in men. An association between ovarian cancer and fertility drugs has been reported (Spirtas et al, 1993). However, it is not known which, if any, fertility drugs are causally related to cancer.

Human menopausal gonadotropin, uFSH or rFSH should be administered only by a physician experienced in treating infertility. Before treatment of women, a thorough gynecologic evaluation must be performed to rule out uterine, tubal, or ovarian diseases as well as pregnancy. In cases of irregular bleeding, uterine cancer should be ruled out.

Luteinizing Hormone (LH) & Human Chorionic Gonadotropin (hCG)

Luteinizing hormone is a glycoprotein hormone consisting of two chains and, like FSH, is produced by gonadotroph cells in the anterior pituitary. LH is primarily responsible for regulation of gonadal steroid hormone production. In men, LH acts on testicular Leydig cells to stimulate testosterone production. In the ovary, LH acts in concert with FSH to stimulate follicular development. LH acts on the mature follicle to induce ovulation, and it stimulates the corpus luteum in the luteal phase of the menstrual cycle to produce progesterone and androgens.

There is no LH preparation presently available for clinical use. **Human chorionic gonadotropin**—with an almost identical structure—is available and can be used as a luteinizing hormone substitute.

Human chorionic gonadotropin is a hormone produced by the human placenta and excreted into the urine, whence it can be extracted and purified. Human chorionic gonadotropin is a glycoprotein consisting of a 92-amino-acid alpha chain virtually identical to that of FSH, LH, and TSH and a beta chain of 145 amino acids that resembles that of LH except for the presence of a carboxyl terminal sequence of 30 amino acids not present in LH.

The function of hCG is to stimulate the ovarian corpus luteum to produce progesterone and maintain the placenta. It is very similar to LH in structure and is used to treat both men and women with LH deficiency.

Pharmacokinetics

Human chorionic gonadotropin is well absorbed after intramuscular administration and has a biologic half-life of 8 hours, compared with 30 minutes for LH. The difference may lie in the high sialic acid content of hCG compared with that of LH. It is apparently modified in the body prior to urinary excretion, because the half-life measured by immunoassay far exceeds that measured by bioassay.

Pharmacodynamics

Human chorionic gonadotropin stimulates production of gonadal steroid hormones. The interstitial and corpus luteal cells of the female produce progesterone, and the Leydig cells of the male produce testosterone. hCG can be used to mimic a midcycle LH surge and trigger ovulation in a hypogonadotropic woman.

Clinical Pharmacology

Diagnostic Uses

In prepubertal boys with undescended gonads, hCG can be used to distinguish a truly retained (cryptorchid) testis from a retracted (pseudocryptorchid) one. Testicular descent during a course of hCG administration usually foretells permanent testicular descent at puberty, when circulating LH levels rise. Lack of descent usually means that orchiopexy will be necessary to preserve spermatogenesis.

Patients with constitutional delay in onset of puberty can be distinguished from those with hypogonadotropic hypogonadism using repeated hCG stimulation. Serum testosterone and estradiol levels rise in the former but not in the latter group.

Therapeutic Uses

As described above, hCG can be used in combination with hMG, uFSH, or rFSH to induce ovulation in women with hypogonadotropic hypogonadism or as part of an in vitro fertilization program. hCG stimulates testosterone secretion by the testes of men with hypogonadotropic hypogonadism. In such men, the increased intratesticular testosterone levels promote spermatogenesis, but FSH is often needed for fertility.

In patients with AIDS-related Kaposi's sarcoma, injection of hCG into the lesions has been reported to cause regression in a dose-related manner.

Dosage

The dosages for female and male infertility are described under hMG dosage. For prepubertal cryptorchidism, a dosage of 500–4000 units three times weekly for up to 6 weeks has been advocated.

Toxicity & Contraindications

Reported adverse effects include headache, depression, edema, precocious puberty, gynecomastia, or (rarely) production of antibodies to hCG. Human chorionic gonadotropin should be administered for infertility only by a physician with experience in this field. Androgen-dependent neoplasia and precocious puberty are contraindications to its use.

Prolactin

Prolactin is a 198-amino-acid peptide hormone produced in the anterior pituitary. Its structure resembles that of growth hormone. Prolactin is the principal hormone responsible for lactation. Milk production is stimulated by prolactin when appropriate circulating levels of estrogens, progestins, corticosteroids, and insulin are present. A deficiency of prolactin—which can occur in states of pituitary deficiency—is manifested by failure to lactate or by a luteal phase defect. In hypothalamic destruction, prolactin levels may be elevated as a result of impaired transport of prolactin-inhibiting hormone (dopamine) to the pituitary. Hyperprolactinemia can produce galactorrhea and hypogonadism and may be associated with symptoms of a pituitary mass. No preparation is available for use in prolactin-deficient patients. For patients with symptomatic hyperprolactinemia, inhibition of prolactin secretion can be achieved with cabergoline and other dopamine agonists.

Dopamine Agonists

Dopamine is released by the hypothalamus to inhibit prolactin release from the anterior pituitary. **Bromocriptine**, **cabergoline**, and **pergolide** are ergot derivatives with a very high affinity for dopamine D₂ receptors in the pituitary. **Quinagolide** is a nonergot drug with similar D₂ receptor affinity. These drugs lower circulating prolactin levels and shrink pituitary prolactin-secreting tumors. The chemical structure and pharmacokinetic features of bromocriptine are presented in Chapter 16: Histamine, Serotonin, & the Ergot Alkaloids.

Dopamine agonists decrease pituitary prolactin secretion through a dopamine-mimetic action on the pituitary at two central nervous system loci: (1) they decrease dopamine turnover in the tuberoinfundibular neurons of the arcuate nucleus, generating increased hypothalamic dopamine; and (2) they act directly on pituitary dopamine receptors to inhibit prolactin release.

These agents, like L-dopa, stimulate pituitary growth hormone release in normal subjects and—

paradoxically—suppress growth hormone release in acromegalics.

Pharmacokinetics

Cabergoline reaches peak plasma levels within 2–3 hours after a 1 mg oral dose. It has a half-life of 63–69 hours. Metabolites are excreted mostly in feces. Bromocriptine is metabolized more quickly.

All dopamine agonists may be administered orally. Additionally, bromocriptine and cabergoline are absorbed systemically after intravaginal insertion of tablets. Following intravaginal administration, serum levels peak more gradually.

Clinical Pharmacology

Prolactin-Secreting Adenomas

A dopamine agonist is the usual initial treatment for prolactinomas. Significant reduction in both tumor size and serum prolactin levels occurs in about 85% of those receiving these drugs for 6 months or longer.

Amenorrhea-Galactorrhea

Dopamine agonists are useful for treating problems induced by hyperprolactinemia: amenorrhea, galactorrhea, breast tenderness (mastodynia), infertility, and hypogonadism.

Physiologic Lactation

Dopamine agonists can prevent breast engorgement when breast feeding is not desired. Their use for this purpose has been discouraged because of toxicity (see below).

Acromegaly

A dopamine agonist alone or in combination with pituitary surgery, irradiation, or octreotide may be used to treat acromegaly. Acromegalic patients seldom respond adequately to bromocriptine unless the pituitary tumor secretes prolactin as well as growth hormone.

Parkinson's Disease and Restless Legs Syndrome

Cabergoline, bromocriptine, and pergolide have been used in Parkinson's disease to improve motor function and reduce levodopa requirements as discussed in Chapter 28: Pharmacologic Management of Parkinsonism & Other Movement Disorders. Cabergoline has also been effective in restless legs syndrome.

Preparations & Dosage

Cabergoline is initiated at 0.25 mg orally or vaginally twice weekly. It may be increased gradually according to serum prolactin determinations, up to a maximum of 1 mg twice weekly.

Bromocriptine is generally taken after the evening meal at the initial dose of 1.25 mg; the dose is then increased as tolerated. Most patients require 2.5–7.5 mg daily; acromegalics require higher doses, up to 20 mg/d. Bromocriptine tablets may be administered intravaginally to reduce nausea. Long-acting oral bromocriptine formulations (Parlodel SRO) and intramuscular formulations

(Parlodel L.A.R.) are available outside the USA.

Quinagolide (CV 205-502, Norprolac) in doses of 0.15–0.6 mg/d orally, suppresses prolactin and shrinks most prolactinomas. It also decreases cyclic mastodynia. Quinagolide is sometimes better tolerated than ergot-derived dopamine agonists. It is not available in the USA.

Toxicity & Contraindications

Dopamine agonists may cause nausea, headache, lightheadedness, orthostatic hypotension, and fatigue. Psychiatric manifestations occasionally occur even at lower doses and may take months to resolve. Erythromelalgia occurs rarely. High dosages of ergot-derived preparations may cause cold-induced peripheral digital vasospasm. Pulmonary infiltrates may occur with chronic high-dosage therapy. Cabergoline appears to cause nausea less often than bromocriptine. Vaginal administration of cabergoline or bromocriptine also tends to reduce nausea, but may cause vaginal irritation.

Dopamine agonist therapy during the early weeks of pregnancy has not been associated with an increased risk of spontaneous abortion or congenital malformations. Although there has been a longer experience with the safety of bromocriptine during early pregnancy, there is growing evidence that cabergoline is also safe to use in women with macroprolactinomas who must continue a dopamine agonist during pregnancy. In patients with small pituitary adenomas, dopamine agonist therapy is discontinued upon conception since there is usually no growth of microadenomas during pregnancy. Patients with very large adenomas require vigilance for tumor progression and often require a dopamine agonist throughout pregnancy. There have been rare reports of stroke or coronary thrombosis in postpartum women taking bromocriptine to suppress postpartum lactation.

If a woman who is receiving a dopamine agonist is late in having her menses, a pregnancy test is necessary; if she is amenorrheic, pregnancy tests should be performed regularly because ovulation may occur before menstruation resumes.

Katzung PHARMACOLOGY, 9e > Section VII. Endocrine Drugs > Chapter 37. Hypothalamic & Pituitary Hormones >

Posterior Pituitary Hormones

Two posterior pituitary hormones are known: vasopressin and oxytocin. Their structures are very similar. Posterior pituitary hormones are synthesized in the hypothalamus and then transported to the posterior pituitary, where they are stored and then released into the circulation.

Oxytocin

Oxytocin is a peptide hormone secreted by the posterior pituitary that elicits milk ejection in lactating women. It may contribute to the initiation of labor. Oxytocin is released during sexual orgasm.

Chemistry & Pharmacokinetics

Structure

Oxytocin is a nine-amino-acid peptide composed of a six-amino-acid disulfide ring and a three-membered tail (Figure 37–2). Oxytocin and vasopressin differ from vasotocin—the only posterior

pituitary hormone found in nonmammalian vertebrates—by only one amino acid residue each.

Figure 37–2.

Posterior pituitary hormones. (Modified and reproduced, with permission, from Ganong WF: *Review of Medical Physiology*, 21st ed. McGraw-Hill, 2003.)

Absorption, Metabolism, and Excretion

Oxytocin is usually administered intravenously for stimulation of labor. It is also available as a nasal spray to induce lactation postpartum. It is inactive if swallowed, because it is destroyed in the stomach and intestine. Oxytocin is not bound to plasma proteins and is catabolized by the kidneys and liver, with a circulating half-life of 5 minutes.

Pharmacodynamics

Oxytocin alters transmembrane ionic currents in myometrial smooth muscle cells to produce sustained uterine contraction. The sensitivity of the uterus to oxytocin increases during pregnancy. Oxytocin-induced myometrial contractions can be inhibited by β -adrenoceptor agonists, magnesium sulfate, or inhalation anesthetics. Oxytocin also causes contraction of myoepithelial cells surrounding mammary alveoli, which leads to milk ejection. Without oxytocin-induced contraction, normal lactation cannot occur. Oxytocin has weak antidiuretic and pressor activity.

Clinical Pharmacology

Diagnostic Uses

Oxytocin infusion near term will produce uterine contractions that decrease the fetal blood supply. The fetal heart rate response to a standardized oxytocin challenge test provides information about placental circulatory reserve. An abnormal response suggests intrauterine growth retardation and may warrant immediate cesarean delivery.

Therapeutic Uses

Oxytocin is used to induce labor and augment dysfunctional labor for (1) conditions requiring early vaginal delivery (eg, Rh problems, maternal diabetes, or preeclampsia), (2) uterine inertia, and (3) incomplete abortion. Oxytocin can also be used for control of postpartum uterine hemorrhage.

Impaired milk ejection may respond to nasal oxytocin. Synthetic peptide and nonpeptide oxytocin antagonists that can prevent premature labor are being investigated.

Dosage

Oxytocin is frequently given to induce and maintain labor after the cervix has ripened naturally or with the aid of misoprostol. For induction of labor, oxytocin should be administered intravenously via an infusion pump with appropriate fetal and maternal monitoring. An initial infusion rate of 1 mU/min is increased every 15–30 minutes until a physiologic contraction pattern is established. The maximum infusion rate is 20 mU/min. For postpartum uterine bleeding, 10–40 units is added to 1 L of 5% dextrose, and the infusion rate is titrated to control uterine atony. Alternatively, 10 units can be given intramuscularly after delivery of the placenta. To induce milk let-down, one puff is sprayed into each nostril in the sitting position 2–3 minutes before nursing.

Toxicity & Contraindications

When oxytocin is used properly, serious toxicity is rare. Among the reported adverse reactions are maternal deaths due to hypertensive episodes, uterine rupture, water intoxication, and fetal deaths. Afibrinogenemia has also been reported.

Contraindications include fetal distress, prematurity, abnormal fetal presentation, cephalopelvic disproportion, and other predispositions for uterine rupture.

Vasopressin (Antidiuretic Hormone, ADH)

Vasopressin is a peptide hormone released by the posterior pituitary in response to rising plasma tonicity or falling blood pressure. Vasopressin possesses antidiuretic and vasopressor properties. A deficiency of this hormone results in diabetes insipidus (see Chapters 15 and 17).

Chemistry & Pharmacokinetics

Structure

Vasopressin is a nonapeptide with a six-amino-acid ring and a three-amino-acid side chain. The residue at position 8 is arginine in humans and in most other mammals except pigs and related species, whose vasopressin contains lysine at position 8 (Figure 37–2).

Absorption, Metabolism, and Excretion

Vasopressin is administered by intravenous, intramuscular, or intranasal routes; oral absorption is slight. The half-life of circulating ADH is approximately 20 minutes, with renal and hepatic catabolism via reduction of the disulfide bond and peptide cleavage. A small amount of vasopressin is excreted as such in the urine.

Pharmacodynamics

Vasopressin interacts with two types of receptors. V_1 receptors are found on vascular smooth muscle cells and mediate vasoconstriction (see Chapter 17: Vasoactive Peptides). V_2 receptors are found on renal tubule cells and mediate antidiuresis through increased water permeability and water resorption in the collecting tubules. Extrarenal V_2 -like receptors mediate release of coagulation

factor VIII_c and von Willebrand factor.

Desmopressin acetate (DDAVP, 1-desamino-8-D-arginine vasopressin) is a long-acting synthetic analog of vasopressin with minimal V₁ activity and an antidiuretic-to-pressor ratio 4000 times that of vasopressin.

Clinical Pharmacology

Vasopressin and desmopressin are the alternative treatments of choice for pituitary diabetes insipidus. Bedtime desmopressin therapy ameliorates nocturnal enuresis by decreasing nocturnal urine production. Vasopressin infusion is effective in some cases of esophageal variceal bleeding and colonic diverticular bleeding.

Dosage

Aqueous Vasopressin

Synthetic aqueous vasopressin is a short-acting preparation for intramuscular, subcutaneous, or intravenous administration. The dose is 5–10 units subcutaneously or intramuscularly every 3–6 hours for transient diabetes insipidus and 0.1–0.5 units/min intravenously for gastrointestinal bleeding.

Desmopressin Acetate

This is the preferred treatment for most patients with central diabetes insipidus. Desmopressin may be administered intranasally, intravenously, subcutaneously, or orally. The typical nasal dosage is 10–40 µg (0.1–0.4 mL) daily in one to three divided doses. Nasal desmopressin is available as a unit dose spray that delivers 0.1 mL per spray; it is also available with a calibrated nasal tube that can be made to deliver a more precise dose. Injectable desmopressin is approximately ten times more bioavailable than intranasal desmopressin. The dosage by injection is 1–4 µg (0.25–1 mL) daily every 12–24 hours as needed for polyuria, polydipsia, or hyponatremia.

For nocturnal enuresis, desmopressin, 10–20 µg (0.1–0.2 mL) intranasally at bedtime, is used.

Desmopressin is also available as an oral preparation. The usual dose is 0.1–0.2 mg every 12–24 hours.

Desmopressin is also used for the treatment of coagulopathy in hemophilia A and von Willebrand's disease (see Chapter 34: Drugs Used in Disorders of Coagulation).

Toxicity & Contraindications

Headache, nausea, abdominal cramps, agitation, and allergic reactions occur rarely. Therapy can result in hyponatremic convulsions.

Vasopressin (but not desmopressin) can cause vasoconstriction and should be used cautiously in patients with coronary artery disease. Nasal insufflation of desmopressin may be less effective when nasal congestion is present.

Preparations Available

Bromocriptine (Parlodel)

Oral: 2.5 mg tablets, 5 mg capsules

Cabergoline (Dostinex)

Oral: 0.5 mg scored tablets

Cetrorelix (Cetrotide)

Parenteral: 0.25, 3.0 mg/vial with diluent for subcutaneous injection

Chorionic gonadotropin [hCG] (generic, Profasi, A.P.L., Pregnyl, others)

Parenteral: powder to reconstitute 500, 1000, 2000 units/mL for injection

Corticotropin ovine (Acthrel)

Parenteral: 100 µg for IV injection

Corticotropin (H.P. Acthar Gel)

Parenteral: 80 units/mL

Cosyntropin (Cortrosyn)

Parenteral: 0.25 mg/vial with diluent for IV or IM injection

Desmopressin (DDAVP, Stimate)

Nasal: 0.1, 1.5 mg/mL solution

Nasal: 100 µg/mL spray pump and rhinal tube delivery system

Parenteral: 4 µg/mL solution for injection

Oral: 0.1, 0.2 mg tablets

Follitropin alfa (Gonal-F)

Parenteral: 37.5, 150 IU powder for injection

Follitropin beta [FSH] (Follistim)

Parenteral: 75 IU powder for injection

Ganirelix (Antagon)

Parenteral: 500 µg/mL for injection

Gonadorelin acetate [GnRH] (Lutrepulse)

Parenteral: powder to reconstitute for injection via Lutrepulse pump (0.8, 3.2 mg/vial)

Gonadorelin hydrochloride [GnRH] (Factrel)

Parenteral: 100, 500 mg for injection

Goserelin acetate (Zoladex)

Parenteral: 3.6, 10.8 mg subcutaneous implant

Histrelin (Supprelin)

Parenteral: 120, 300, 600 mg for subcutaneous injection

Leuprolide (generic, Lupron)

Parenteral: 5 mg/mL for subcutaneous injection

Parenteral depot suspension (Lupron Depot, Depot-Ped, Depot-3, Depot-4): lyophilized microspheres to reconstitute for IM injection (3.75, 7.5, 11.25, 15, 22.5, 30 mg/vial)

Parenteral implant: 72 mg

Menotropins [hMG] (Pergonal, Repronex)

Parenteral: 75 IU FSH and 75 IU LH activity, 150 IU FSH and 150 IU LH activity, each with diluent

Nafarelin (Synarel)

Nasal: 2 mg/mL (200 µg/spray)

Octreotide (Sandostatin)

Parenteral: 0.05, 0.1, 0.2, 0.5, 1.0 mg/mL for subcutaneous or IV administration

Parenteral depot injection (Sandostatin LAR Depot): 10, 20, 30 mg for IM injection only

Oxytocin (generic, Pitocin, Syntocinon)

Parenteral: 10 units/mL for injection

Nasal: 40 units/mL spray

Pergolide (Permax)

Oral: 0.05, 0.25, 1.0 mg tablets

Protirelin (Thybinone, Relefact TRH, Thyrel TRH)

Parenteral: 500 mg/mL for injection

Sermorelin (Geref)

Parenteral: 0.5, 1.0 mg for subcutaneous injection; 50 µg powder to reconstitute for intravenous injection

Somatrem (Protropin)

Parenteral: 5, 10 mg/vial with diluent for subcutaneous or IM injection

Somatropin (Genotropin, Humatrope, Nutropin, Nutropin AQ, Norditropin, Serostim, Saizen)

Parenteral: 0.2, 0.4, 0.6, 0.8, 1.0, 1.2, 1.4, 1.5, 1.6, 1.8, 2, 4, 5, 5.8, 6, 8, 10, 12, 13.5, 13.8, 15, 18, 22.5, 24 mg/vial with diluent for subcutaneous or IM injection

Thyrotropin alpha (Thyrogen)

Parenteral: 1.1 mg (> 4 IU)/vial with diluent for IM injection

Triptorelin (Trelstar)

Parenteral: 3.75, 11.25 mg for IM injection

Urofollitropin (Fertinex, Bravelle)

Parenteral: powder to reconstitute for injection, 75, 150 IU FSH activity per ampule

Vasopressin (generic, Pitressin)

Parenteral: 20 pressor units/mL for IM or subcutaneous administration

Chapter 38. Thyroid & Antithyroid Drugs

Katzung PHARMACOLOGY, 9e > Section VII. Endocrine Drugs > Chapter 38. Thyroid & Antithyroid Drugs >

Thyroid & Antithyroid Drugs: Introduction

Because of its anatomic prominence, the thyroid was one of the first of the endocrine glands to be associated with the clinical conditions caused by its malfunction.

Thyroid Physiology

The normal thyroid gland secretes sufficient amounts of the thyroid hormones—triiodothyronine (T_3) and tetraiodothyronine (T_4 , thyroxine)—to normalize growth and development, body temperature, and energy levels. These hormones contain 59% and 65% (respectively) of iodine as an essential part of the molecule. Calcitonin, the second type of thyroid hormone, is important in the regulation of calcium metabolism and is discussed in Chapter 42: Agents That Affect Bone Mineral Homeostasis.

Iodide Metabolism

The recommended daily adult iodide (I^-)* intake is 150 μg (200 μg during pregnancy).

* In this chapter, the term "iodine" denotes all forms of the element; the term "iodide" denotes only the ionic form, I^- .

Iodide, ingested from food, water, or medication, is rapidly absorbed and enters an extracellular fluid pool. The thyroid gland removes about 75 μg a day from this pool for hormone secretion, and the balance is excreted in the urine. If iodide intake is increased, the fractional iodine uptake by the thyroid is diminished.

Biosynthesis of Thyroid Hormones

Once taken up by the thyroid gland, iodide undergoes a series of enzymatic reactions that convert it into active thyroid hormone (Figure 38–1). The first step is the transport of iodide into the thyroid gland by an intrinsic follicle cell basement membrane protein called the sodium/iodide symporter (NIS). This can be inhibited by such anions as SCN^- , TcO_4^- , and ClO_4^- . Iodide is then oxidized by thyroidal peroxidase to iodine, in which form it rapidly iodates tyrosine residues within the thyroglobulin molecule to form monoiodotyrosine (MIT) and diiodotyrosine (DIT). This process is called **iodide organification**. Thyroidal peroxidase is transiently blocked by high levels of intrathyroidal iodide and blocked more persistently by thioamide drugs. Two molecules of DIT combine within the thyroglobulin molecule to form L-thyroxine (T_4). One molecule of MIT and one molecule of DIT combine to form T_3 . In addition to thyroglobulin, other proteins within the gland may be iodinated, but these iodoproteins do not have hormonal activity. Thyroxine, T_3 , MIT, and DIT are released from thyroglobulin by **exocytosis** and **proteolysis** of thyroglobulin at the apical colloid border. The MIT and DIT are deiodinated within the gland, and the iodine is reutilized. This process of proteolysis is also blocked by high levels of intrathyroidal iodide. The ratio of T_4 to T_3 within thyroglobulin is approximately 5:1, so that most of the hormone released is thyroxine. Most of the T_3 circulating in the blood is derived from peripheral metabolism of thyroxine (see below).

Figure 38–1.

Biosynthesis of thyroid hormones. The sites of action of various drugs that interfere with thyroid hormone biosynthesis are shown.

Transport of Thyroid Hormones

T_4 and T_3 in plasma are reversibly bound to protein, primarily thyroxine-binding globulin (TBG). Only about 0.04% of total T_4 and 0.4% of T_3 exist in the free form. Many physiologic and pathologic states and drugs affect T_4 , T_3 , and thyroid transport. However, the actual levels of free hormone generally remain normal, reflecting feedback control.

Peripheral Metabolism of Thyroid Hormones

The primary pathway for the peripheral metabolism of thyroxine is deiodination. Deiodination of T_4 may occur by monodeiodination of the outer ring, producing 3,5,3'-triiodothyronine (T_3), which is three to four times more potent than T_4 . Alternatively, deiodination may occur in the inner ring, producing 3,3',5'-triiodothyronine (reverse T_3 , or rT_3), which is metabolically inactive (Figure 38–2). Drugs such as ipodate, β -blockers, and corticosteroids, and severe illness or starvation inhibit the 5'-deiodinase necessary for the conversion of T_4 to T_3 , resulting in low T_3 and high rT_3 levels in the serum. Normal levels of thyroid hormone in the serum are listed in Table 38–1. The low serum levels of T_3 and rT_3 in normal individuals are due to the high metabolic clearances of these two compounds.

Figure 38–2.

Peripheral metabolism of thyroxine. (Modified from Greenspan FS: The Thyroid Gland. In: Greenspan FS, Gardner D [editors]: *Basic & Clinical Endocrinology*, 6th ed. McGraw-Hill, 2001.)

Table 38–1. Summary of Thyroid Hormone Kinetics.

Variable	T ₄	T ₃
Volume of distribution	10 L	40 L
Extrathyroidal pool	800 µg	54 µg
Daily production	75 µg	25 µg
Fractional turnover per day	10%	60%
Metabolic clearance per day	1.1 L	24 L
Half-life (biologic)	7 days	1 day
Serum levels		
Total	5–11 µg/dL (64–132 nmol/L)	95–190 ng/dL (1.5–2.9 nmol/L)
Free	0.7–1.86 ng/dL (9–24 pmol/L)	0.2–0.52 ng/dL (3–8 pmol/L)
Amount bound	99.96%	99.6%
Biologic potency	1	4

Oral absorption	80%	95%
-----------------	-----	-----

Control of Thyroid Function

The tests used to evaluate thyroid function are listed in Table 38–2.

Name of Test	Normal Value ¹	Results in Hypothyroidism	Results in Hyperthyroidism
Total thyroxine by RIA (T ₄ [RIA])	5–12 µg/dL (64–154 nmol/L)	Low	High
Total triiodothyronine by RIA (T ₃ [RIA])	70–132 ng/dL (1.1–2.0 nmol/L)	Normal or low	High
Resin T ₃ uptake (RT ₃ U)	25–35%	Low	High
Free thyroxine index (FT ₄ I) ¹	1.3–4.2	Low	High
Free T ₃ index (FT ₃ I)	17.5–46	Normal or low	High
Free FT ₄ (FT ₄)	0.7–1.86 (9–24 pmol/L)	Low	High
Free T ₃ (FT ₃)	0.2–0.42 ng/dL (3–8 pmol/L)	Low	High
Thyrotropic hormone (TSH)	0.5–5.0 µIU/mL (0.5–5.0 mIU/L)	High ²	Low
¹²³ I uptake at 24 hours	5–35%	Low	High
Thyroglobulin autoantibodies (Tg-ab)	< 1 IU/mL	Often present	Usually present
Thyroid peroxidase antibodies (TPA)	< 1 IU/mL	Often present	Usually present
Isotope scan with ¹²³ I or ^{99m} TcO ₄	Normal pattern	Test not indicated	Diffusely enlarged gland
Fine-needle aspiration biopsy (FNA)	Normal pattern	Test not indicated	Test not indicated
Serum thyroglobulin	< 40 ng/mL	Test not indicated	Test not indicated
Serum calcitonin	Male: < 8 ng/L (< 2.3	Test not indicated	Test not indicated

pmol/L); female: < 4 ng/L
(< 1.17 pmol/L)

¹Results may vary with different laboratories.

²Exception is central hypothyroidism

Thyroid-Pituitary Relationships

Control of thyroid function via thyroid-pituitary feedback is also discussed in Chapter 37: Hypothalamic & Pituitary Hormones. Briefly, hypothalamic cells secrete thyrotropin-releasing hormone (TRH) (Figure 38–3). TRH is secreted into capillaries of the pituitary portal venous system, and in the pituitary gland, TRH stimulates the synthesis and release of thyroid-stimulating hormone (TSH). TSH in turn stimulates an adenylyl cyclase–mediated mechanism in the thyroid cell to increase the synthesis and release of T_4 and T_3 . These thyroid hormones act in a negative feedback fashion in the pituitary to block the action of TRH and in the hypothalamus to inhibit the synthesis and secretion of TRH. Other hormones or drugs may also affect the release of TRH or TSH.

Figure 38–3.

The hypothalamic-pituitary-thyroid axis. Acute psychosis or prolonged exposure to cold may activate the axis. Hypothalamic TRH stimulates pituitary TSH release, while somatostatin and dopamine inhibit it. TSH stimulates T_4 and T_3 synthesis and release from the thyroid, and they in turn inhibit both TRH and TSH synthesis and release. Small amounts of iodide are necessary for hormone production, but large amounts inhibit T_3 and T_4 production and release. (Solid arrows, stimulatory influence; dashed arrows, inhibitory influence. H, hypothalamus, HP, anterior pituitary.)

Autoregulation of the Thyroid Gland

The thyroid gland also regulates its uptake of iodide and thyroid hormone synthesis by intrathyroidal mechanisms that are independent of TSH. These mechanisms are primarily related to the level of iodine in the blood. Large doses of iodine inhibit iodide organification (Figure 38–1). In certain disease states (eg, Hashimoto's thyroiditis), this can result in inhibition of thyroid hormone synthesis and hypothyroidism.

Abnormal Thyroid Stimulators

In Graves' disease (see below), lymphocytes secrete a TSH receptor-stimulating antibody (TSH-R Ab [stim]), also known as thyroid-stimulating immunoglobulin (TSI). This immunoglobulin binds to the TSH receptor and turns on the gland in the same fashion as TSH itself. The duration of its effect, however, is much longer than that of TSH. TSH receptors are also found in orbital fibrocytes, which may be stimulated by high levels of TSH-R Ab [stim].

Basic Pharmacology of Thyroid & Antithyroid Drugs

Thyroid Hormones

Chemistry

The structural formulas of thyroxine and triiodothyronine as well as reverse triiodothyronine (rT_3) are shown in Figure 38–2. All of these naturally occurring molecules are levo (L) isomers. The synthetic dextro (D) isomer of thyroxine, dextrothyroxine, has approximately 4% of the biologic activity of the L isomer as evidenced by its lesser ability to suppress TSH secretion and correct hypothyroidism.

Pharmacokinetics

Thyroxine is absorbed best in the duodenum and ileum; absorption is modified by intraluminal factors such as food, drugs, and intestinal flora. Oral bioavailability of current preparations of L-thyroxine averages 80% (Table 38–1). In contrast, T_3 is almost completely absorbed (95%). T_4 and T_3 absorption appears not to be affected by mild hypothyroidism but may be impaired in severe myxedema with ileus. These factors are important in switching from oral to parenteral therapy. For parenteral use, the intravenous route is preferred for both hormones.

In patients with hyperthyroidism, the metabolic clearances of T_4 and T_3 are increased and the half-lives decreased; the opposite is true in patients with hypothyroidism. Drugs that induce hepatic

microsomal enzymes (eg, rifampin, phenobarbital, carbamazepine, phenytoin) increase the metabolism of both T₄ and T₃ (Table 38–3). Despite this change in clearance, the normal hormone concentration is maintained in euthyroid patients as a result of compensatory hyperfunction of the thyroid. However, patients receiving T₄ replacement medication may require increased dosages to maintain clinical effectiveness. A similar compensation occurs if binding sites are altered. If TBG sites are increased by pregnancy, estrogens, or oral contraceptives, there is an initial shift of hormone from the free to the bound state and a decrease in its rate of elimination until the normal hormone concentration is restored. Thus, the concentration of total and bound hormone will increase, but the concentration of free hormone and the steady state elimination will remain normal. The reverse occurs when thyroid binding sites are decreased.

Table 38–3. Drug Effects and Thyroid Function.	
Drug Effect	Drugs
Change in thyroid hormone synthesis	
Inhibition of TRH or TSH secretion without induction of hypothyroidism	Dopamine, levodopa, corticosteroids, somatostatin
Inhibition of thyroid hormone synthesis or release with the induction of hypothyroidism (or occasionally hyperthyroidism)	Iodides (including amiodarone), lithium, aminoglutethimide
Alteration of thyroid hormone transport and serum total T₃ and T₄ levels, but usually no modification of FT₄ or TSH	
Increased TBG	Estrogens, tamoxifen, heroin, methadone, mitotane
Decreased TBG	Androgens, glucocorticoids
Displacement of T ₃ and T ₄ from TBG with transient hyperthyroxinemia	Salicylates, fenclofenac, mefenamic acid, furosemide
Alteration of T₄ and T₃ metabolism with modified serum T₃ and T₄ levels but not FT₄ or TSH levels	
Induction of increased hepatic enzyme activity	Phenytoin, carbamazepine, phenobarbital, rifampin, rifabutin
Inhibition of 5'-deiodinase with decreased T ₃ , increased rT ₃	Iopanoic acid, ipodate, amiodarone, β-blockers, corticosteroids, propylthiouracil
Other interactions	
Interference with T ₄ absorption	Cholestyramine, colestipol, aluminum hydroxide, sucralfate, reloxifene, ferrous sulfate, some calcium preparations, bran
Induction of autoimmune thyroid disease with hypothyroidism or hyperthyroidism	Interferon-α, interleukin-2

Mechanism of Action

A model of thyroid hormone action is depicted in Figure 38–4, which shows the free forms of thyroid hormones, T_4 and T_3 , dissociated from thyroid-binding proteins, entering the cell by diffusion or possibly by active transport. Within the cell, T_4 is converted to T_3 by 5'-deiodinase, and the T_3 enters the nucleus, where T_3 binds to a specific T_3 receptor protein, a member of the *c-erb* oncogene family, which also includes the steroid hormone receptors and receptors for vitamins A and D. The T_3 receptor exists in two forms, α and β . Differing concentrations of receptor forms in different tissues may account for variations in T_3 effect on different tissues.

Figure 38–4.

Regulation of transcription by thyroid hormones. T_3 and T_4 are triiodothyronine and thyroxine, respectively. PB, plasma binding protein; F, transcription factor; R, receptor; PP, proteins that bind at the proximal promoter. (Reproduced, with permission, from Baxter JD: General concepts of endocrinology. In: Greenspan FS, Baxter JD (editors). *Basic & Clinical Endocrinology*, 4th ed. Originally published by Appleton & Lange. Copyright © 1994 by The McGraw-Hill Companies, Inc.)

Most of the effects of thyroid on metabolic processes appear to be mediated by activation of nuclear receptors that lead to increased formation of RNA and subsequent protein synthesis, eg, increased formation of Na^+/K^+ ATPase. This is consistent with the observation that the action of thyroid is manifested *in vivo* with a time lag of hours or days after its administration.

Large numbers of thyroid hormone receptors are found in the most hormone-responsive tissues

(pituitary, liver, kidney, heart, skeletal muscle, lung, and intestine), while few receptor sites occur in hormone-unresponsive tissues (spleen, testes). The brain, which lacks an anabolic response to T₃, contains an intermediate number of receptors. In congruence with their biologic potencies, the affinity of the receptor site for T₄ is about ten times lower than that for T₃. The number of nuclear receptors may be altered to preserve body homeostasis. For example, starvation lowers both circulating T₃ hormone and cellular T₃ receptors.

Effects of Thyroid Hormones

The thyroid hormones are responsible for optimal growth, development, function, and maintenance of all body tissues. Excess or inadequate amounts result in the signs and symptoms of thyrotoxicosis or hypothyroidism (Table 38–4). Since T₃ and T₄ are qualitatively similar, they may be considered as one hormone in the discussion that follows.

System	Thyrotoxicosis	Hypothyroidism
Skin and appendages	Warm, moist skin; sweating; heat intolerance; fine, thin hair; Plummer's nails; pretibial dermopathy (Graves' disease)	Pale, cool, puffy skin; dry and brittle hair; brittle nails
Eyes, face	Retraction of upper lid with wide stare; periorbital edema; exophthalmos; diplopia (Graves' disease)	Drooping of eyelids; periorbital edema; loss of temporal aspects of eyebrows; puffy, nonpitting facies; large tongue
Cardiovascular system	Decreased peripheral vascular resistance, increased heart rate, stroke volume, cardiac output, pulse pressure; high-output heart failure; increased inotropic and chronotropic effects; arrhythmias; angina	Increased peripheral vascular resistance; decreased heart rate, stroke volume, cardiac output, pulse pressure; low-output heart failure; ECG: bradycardia, prolonged PR interval, flat T wave, low voltage; pericardial effusion
Respiratory system	Dyspnea; decreased vital capacity	Pleural effusions; hypoventilation and CO ₂ retention
Gastrointestinal system	Increased appetite; increased frequency of bowel movements; hypoproteinemia	Decreased appetite; decreased frequency of bowel movements; ascites
Central nervous system	Nervousness; hyperkinesia; emotional lability	Lethargy; general slowing of mental processes; neuropathies
Musculoskeletal system	Weakness and muscle fatigue; increased deep tendon reflexes; hypercalcemia; osteoporosis	Stiffness and muscle fatigue; decreased deep tendon reflexes; increased alkaline phosphatase, LDH, AST
Renal system	Mild polyuria; increased renal blood flow; increased glomerular filtration rate	Impaired water excretion; decreased renal blood flow; decreased glomerular filtration rate
Hematopoietic	Increased erythropoiesis; anemia ¹	Decreased erythropoiesis; anemia ¹

system		
Reproductive system	Menstrual irregularities; decreased fertility; increased gonadal steroid metabolism	Hypermenorrhea; infertility; decreased libido; impotence; oligospermia; decreased gonadal steroid metabolism
Metabolic system	Increased basal metabolic rate; negative nitrogen balance; hyperglycemia; increased free fatty acids; decreased cholesterol and triglycerides; increased hormone degradation; increased requirements for fat- and water-soluble vitamins; increased drug metabolism	Decreased basal metabolic rate; slight positive nitrogen balance; delayed degradation of insulin, with increased sensitivity; increased cholesterol and triglycerides; decreased hormone degradation; decreased requirements for fat- and water-soluble vitamins; decreased drug metabolism

¹The anemia of hyperthyroidism is usually normochromic and caused by increased red blood cell turnover. The anemia of hypothyroidism may be normochromic, hyperchromic, or hypochromic and may be due to decreased production rate, decreased iron absorption, decreased folic acid absorption, or to autoimmune pernicious anemia.

Thyroid hormone is critical for nervous, skeletal, and reproductive tissues. Its effects depend on protein synthesis as well as potentiation of the secretion and action of growth hormone. Thyroid deprivation in early life results in irreversible mental retardation and dwarfism—symptoms typical of congenital cretinism.

Effects on growth and calorogenesis are accompanied by a pervasive influence on metabolism of drugs as well as carbohydrates, fats, proteins, and vitamins. Many of these changes are dependent upon or modified by activity of other hormones. Conversely, the secretion and degradation rates of virtually all other hormones, including catecholamines, cortisol, estrogens, testosterone, and insulin, are affected by thyroid status.

Many of the manifestations of thyroid hyperactivity resemble sympathetic nervous system overactivity (especially in the cardiovascular system), although catecholamine levels are not increased. Changes in catecholamine-stimulated adenylyl cyclase activity as measured by cAMP are found with changes in thyroid activity. Possible explanations include increased numbers of β receptors or enhanced amplification of the β receptor signal. Other clinical symptoms reminiscent of excessive epinephrine activity (and partially alleviated by adrenoceptor antagonists) include lid lag and retraction, tremor, excessive sweating, anxiety, and nervousness. The opposite constellation of symptoms is seen in hypothyroidism (Table 38–4).

Thyroid Preparations

See the Preparations Available section at the end of this chapter for a list of available preparations. These preparations may be synthetic (levothyroxine, liothyronine, liotrix) or of animal origin (desiccated thyroid).

Synthetic levothyroxine is the preparation of choice for thyroid replacement and suppression therapy because of its stability, content uniformity, low cost, lack of allergenic foreign protein, easy laboratory measurement of serum levels, and long half-life (7 days), which permits once-daily administration. In addition, T_4 is converted to T_3 intracellularly; thus, administration of T_4 produces both hormones. Generic levothyroxine preparations can be used because they provide comparable

efficacy and are more cost-effective than branded preparations.

Although liothyronine is three to four times more potent than levothyroxine, it is not recommended for routine replacement therapy because of its shorter half-life (24 hours), which requires multiple daily doses; its higher cost; and the greater difficulty of monitoring its adequacy of replacement by conventional laboratory tests. Furthermore, because of its greater hormone activity and consequent greater risk of cardiotoxicity, T_3 should be avoided in patients with cardiac disease. It is best used for short-term suppression of TSH. Because oral administration of T_3 is unnecessary, use of the more expensive mixture of thyroxine and liothyronine (liotrix) instead of levothyroxine is never required.

The use of desiccated thyroid rather than synthetic preparations is never justified, since the disadvantages of protein antigenicity, product instability, variable hormone concentrations, and difficulty in laboratory monitoring far outweigh the advantage of low cost. Significant amounts of T_3 found in some thyroid extracts and liotrix may produce significant elevations in T_3 levels and toxicity. Equivalent doses are 100 mg (1.5 g) of desiccated thyroid, 100 μ g of levothyroxine, and 37.5 μ g of liothyronine.

The shelf life of synthetic hormone preparations is about 2 years, particularly if they are stored in dark bottles to minimize spontaneous deiodination. The shelf life of desiccated thyroid is not certainly known, but its potency is better preserved if it is kept dry.

Antithyroid Agents

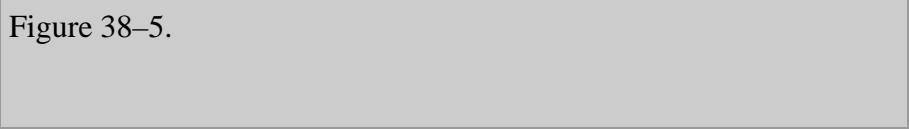

Reduction of thyroid activity and hormone effects can be accomplished by agents that interfere with the production of thyroid hormones; by agents that modify the tissue response to thyroid hormones; or by glandular destruction with radiation or surgery. "Goitrogens" are agents that suppress secretion of T_3 and T_4 to subnormal levels and thereby increase TSH, which in turn produces glandular enlargement (goiter). The antithyroid compounds used clinically include the thioamides, iodides, and radioactive iodine.

Thioamides

The thioamides methimazole and propylthiouracil are major drugs for treatment of thyrotoxicosis. In the United Kingdom, carbimazole, which is converted to methimazole in vivo, is widely used. Methimazole is about ten times more potent than propylthiouracil.

The chemical structures of these compounds are shown in Figure 38–5. The thiocarbamide group is essential for antithyroid activity.

Figure 38–5.

Pharmacokinetics

Propylthiouracil is rapidly absorbed, reaching peak serum levels after 1 hour. The bioavailability of 50–80% may be due to incomplete absorption or a large first-pass effect in the liver. The volume of distribution approximates total body water with accumulation in the thyroid gland. Most of an ingested dose of propylthiouracil is excreted by the kidney as the inactive glucuronide within 24 hours.

In contrast, methimazole is completely absorbed but at variable rates. It is readily accumulated by the thyroid gland and has a volume of distribution similar to that of propylthiouracil. Excretion is slower than with propylthiouracil; 65–70% of a dose is recovered in the urine in 48 hours.

The short plasma half-life of these agents (1.5 hours for propylthiouracil and 6 hours for methimazole) has little influence on the duration of the antithyroid action or the dosing interval because both agents are accumulated by the thyroid gland. For propylthiouracil, giving the drug every 6–8 hours is reasonable since a single 100 mg dose can inhibit 60% of iodine organification for 7 hours. Since a single 30 mg dose of methimazole exerts an antithyroid effect for longer than 24 hours, a single daily dose is effective in the management of mild to moderate hyperthyroidism.

Both thioamides cross the placental barrier and are concentrated by the fetal thyroid, so that caution must be employed when using these drugs in pregnancy. Of the two, propylthiouracil is preferable in pregnancy because it is more strongly protein-bound and therefore crosses the placenta less readily. In addition, it is not secreted in sufficient quantity in breast milk to preclude breast-feeding.

Pharmacodynamics

The thioamides act by multiple mechanisms. The major action is to prevent hormone synthesis by

inhibiting the thyroid peroxidase-catalyzed reactions and blocking iodine organification. In addition, they block coupling of the iodotyrosines. They do not block uptake of iodide by the gland. Propylthiouracil and (to a much lesser extent) methimazole inhibit the peripheral deiodination of T_4 and T_3 (Figure 38–1). Since the synthesis rather than the release of hormones is affected, the onset of these agents is slow, often requiring 3–4 weeks before stores of T_4 are depleted.

Toxicity

Adverse reactions to the thioamides occur in 3–12% of treated patients. Most reactions occur early. The most common adverse effect is a maculopapular pruritic rash, at times accompanied by systemic signs such as fever. Rare adverse effects include an urticarial rash, vasculitis, arthralgia, a lupus-like reaction, cholestatic jaundice, hepatitis, lymphadenopathy, hypoprothrombinemia, exfoliative dermatitis, polyserositis, and acute arthralgia.

The most dangerous complication is agranulocytosis, an infrequent but potentially fatal adverse reaction. It occurs in 0.3–0.6% of patients taking thioamides, but the risk may be increased in older patients and in those receiving high-dose methimazole therapy (over 40 mg/d). The reaction is usually rapidly reversible when the drug is discontinued, but antibiotic therapy may be necessary for complicating infections. Colony-stimulating factors (eg, G-CSF; see Chapter 33: Agents Used in Anemias; Hematopoietic Growth Factors) may hasten recovery of the granulocytes. The cross-sensitivity between propylthiouracil and methimazole is about 50%; therefore, switching drugs in patients with severe reactions is not recommended.

Anion Inhibitors

Monovalent anions such as perchlorate (ClO_4^-), pertechnetate (TcO_4^-), and thiocyanate (SCN^-) can block uptake of iodide by the gland through competitive inhibition of the iodide transport mechanism. Since these effects can be overcome by large doses of iodides, their effectiveness is somewhat unpredictable.

The major clinical use for potassium perchlorate is to block thyroidal reuptake of I^- in patients with iodide-induced hyperthyroidism (eg, amiodarone-induced hyperthyroidism). However, potassium perchlorate is rarely used clinically because it has been shown to cause aplastic anemia.

Iodides

Prior to the introduction of the thioamides in the 1940s, iodides were the major antithyroid agents; today they are rarely used as sole therapy.

Pharmacodynamics

Iodides have several actions on the thyroid. They inhibit organification and hormone release and decrease the size and vascularity of the hyperplastic gland. In susceptible individuals, iodides can induce hyperthyroidism (Jod-Basedow phenomenon) or precipitate hypothyroidism.

In pharmacologic doses (> 6 mg daily), the major action of iodides is to inhibit hormone release, possibly through inhibition of thyroglobulin proteolysis. Rapid improvement in thyrotoxic symptoms occurs within 2–7 days—hence the value of iodide therapy in thyroid storm. In addition, iodides decrease the vascularity, size, and fragility of a hyperplastic gland, making the drugs valuable as preoperative preparation for surgery.

Clinical Use of Iodide

Disadvantages of iodide therapy include an increase in intraglandular stores of iodine, which may delay onset of thioamide therapy or prevent use of radioactive iodine therapy for several weeks. Thus, iodides should be initiated after onset of thioamide therapy and avoided if treatment with radioactive iodine seems likely. Iodide should not be used alone, because the gland will escape from the iodide block in 2–8 weeks, and its withdrawal may produce severe exacerbation of thyrotoxicosis in an iodine-enriched gland. Chronic use of iodides in pregnancy should be avoided, since they cross the placenta and can cause fetal goiter. In radiation emergencies, the thyroid-blocking effects of potassium iodide can protect the gland from subsequent damage if administered before radiation exposure.

Toxicity

Adverse reactions to iodine (iodism) are uncommon and in most cases reversible upon discontinuance. They include acneiform rash (similar to that of bromism), swollen salivary glands, mucous membrane ulcerations, conjunctivitis, rhinorrhea, drug fever, metallic taste, bleeding disorders and, rarely, anaphylactoid reactions.

Iodinated Contrast Media

The iodinated contrast agents—ipodate and iopanoic acid by mouth, or diatrizoate intravenously—are valuable in the treatment of hyperthyroidism, although they are not labeled for this indication. These drugs rapidly inhibit the conversion of T_4 to T_3 in the liver, kidney, pituitary gland, and brain. This accounts for the dramatic improvement in both subjective and objective parameters. For example, a decrease in heart rate is seen after only 3 days of oral administration of 0.5–1 g/d. T_3 levels often return to normal during this time. The prolonged effect of suppressing T_4 as well as T_3 suggests that inhibition of hormone release due to the iodine released may be an additional mechanism of action. Fortunately, these agents are relatively nontoxic. They provide useful adjunctive therapy in the treatment of thyroid storm and offer valuable alternatives when iodides or thioamides are contraindicated. Surprisingly, these agents may not interfere with ^{131}I retention as much as iodides despite their large iodine content. Their toxicity is similar to that of the iodides, and their safety in pregnancy is undocumented.

Radioactive Iodine

^{131}I is the only isotope used for treatment of thyrotoxicosis (others are used in diagnosis). Administered orally in solution as sodium ^{131}I , it is rapidly absorbed, concentrated by the thyroid, and incorporated into storage follicles. Its therapeutic effect depends on emission of β rays with an effective half-life of 5 days and a penetration range of 400–2000 μm . Within a few weeks after administration, destruction of the thyroid parenchyma is evidenced by epithelial swelling and necrosis, follicular disruption, edema, and leukocyte infiltration. Advantages of radioiodine include easy administration, effectiveness, low expense, and absence of pain. Fears of radiation-induced genetic damage, leukemia, and neoplasia have not been realized after more than 30 years of clinical experience with radioiodine. Radioactive iodine should not be administered to pregnant women or nursing mothers, since it crosses the placenta and is excreted in breast milk.

Adrenoceptor-Blocking Agents

Beta blockers without intrinsic sympathomimetic activity are effective therapeutic adjuncts in the management of thyrotoxicosis since many of these symptoms mimic those associated with

sympathetic stimulation. Propranolol has been the β -blocker most widely studied and used in the therapy of thyrotoxicosis.

Clinical Pharmacology of Thyroid & Antithyroid Drugs

Hypothyroidism

Hypothyroidism is a syndrome resulting from deficiency of thyroid hormones and is manifested largely by a reversible slowing down of all body functions (Table 38–4). In infants and children, there is striking retardation of growth and development that results in dwarfism and irreversible mental retardation.

The etiology and pathogenesis of hypothyroidism are outlined in Table 38–5. Hypothyroidism can occur with or without thyroid enlargement (goiter). The laboratory diagnosis of hypothyroidism in the adult is easily made by the combination of a low free thyroxine (or low free thyroxine index) and elevated serum TSH (Table 38–2).

Cause	Pathogenesis	Goiter	Degree of Hypothyroidism
Hashimoto's thyroiditis	Autoimmune destruction of thyroid	Present early, absent later	Mild to severe
Drug-induced ¹	Blocked hormone formation	Present	Mild to moderate
Dyshormonogenesis	Impaired synthesis of T ₄ due to enzyme deficiency	Present	Mild to severe
Radiation, ¹³¹ I, x-ray, thyroidectomy	Destruction or removal of gland	Absent	Severe
Congenital (cretinism)	Athyreosis or ectopic thyroid, iodine deficiency; TSH receptor-blocking antibodies	Absent or present	Severe
Secondary (TSH deficit)	Pituitary or hypothalamic disease	Absent	Mild

¹Iodides, lithium, fluoride, thioamides, aminosalicic acid, phenylbutazone, amiodarone, etc.

The most common cause of hypothyroidism in the USA at this time is probably Hashimoto's thyroiditis, an immunologic disorder in genetically predisposed individuals. In this condition, there is evidence of humoral immunity in the presence of antithyroid antibodies and lymphocyte sensitization to thyroid antigens.

Management of Hypothyroidism

Except for hypothyroidism caused by drugs (Table 38–5), which can be treated by simply removing the depressant agent, the general strategy of replacement therapy is appropriate. The most satisfactory preparation is levothyroxine. Infants and children require more T_4 per kilogram of body weight than adults. The average dosage for an infant 1–6 months of age is 10–15 $\mu\text{g}/\text{kg}/\text{d}$, whereas the average dosage for an adult is about 1.7 $\mu\text{g}/\text{kg}/\text{d}$. There is some variability in the absorption of thyroxine, so this dosage may vary from patient to patient. Because of the long half-life of thyroxine, the dose can be given once daily. Children should be monitored for normal growth and development. Serum TSH and free thyroxine should be measured at regular intervals and maintained within the normal range. It takes 6–8 weeks after starting a given dose of thyroxine to reach steady state levels in the bloodstream. Thus, dosage changes should be made slowly.

In long-standing hypothyroidism, in older patients, and in patients with underlying cardiac disease, it is imperative to start treatment with reduced dosage. In such adult patients, levothyroxine is given in a dosage of 12.5–25 $\mu\text{g}/\text{d}$ for 2 weeks, increasing the daily dose by 25 μg every 2 weeks until euthyroidism or drug toxicity is observed. In older patients, the heart is very sensitive to the level of circulating thyroxine, and if angina pectoris or cardiac arrhythmia develops, it is essential to stop or reduce the dose of thyroxine immediately. In younger patients or those with very mild disease, full replacement therapy may be started immediately.

The toxicity of thyroxine is directly related to the hormone level. In children, restlessness, insomnia, and accelerated bone maturation and growth may be signs of thyroxine toxicity. In adults, increased nervousness, heat intolerance, episodes of palpitation and tachycardia, or unexplained weight loss may be the presenting symptoms. If these symptoms are present, it is important to monitor serum TSH (Table 38–2), which will determine whether the symptoms are due to excess thyroxine blood levels. Chronic overtreatment with T_4 , particularly in elderly patients, can increase the risk of atrial fibrillation and accelerated osteoporosis.

Special Problems in Management of Hypothyroidism

Myxedema and Coronary Artery Disease

Since myxedema frequently occurs in older persons, it is often associated with underlying coronary artery disease. In this situation, the low levels of circulating thyroid hormone actually protect the heart against increasing demands that could result in angina pectoris or myocardial infarction. Correction of myxedema must be done cautiously to avoid provoking arrhythmia, angina, or acute myocardial infarction.

Myxedema Coma

Myxedema coma is an end state of untreated hypothyroidism. It is associated with progressive weakness, stupor, hypothermia, hypoventilation, hypoglycemia, hyponatremia, water intoxication, shock, and death.

Management of myxedema coma is a medical emergency. The patient should be treated in the intensive care unit, since tracheal intubation and mechanical ventilation may be required. Associated illnesses such as infection or heart failure must be treated by appropriate therapy. It is important to give all preparations intravenously, because patients with myxedema coma absorb drugs poorly from other routes. Intravenous fluids should be administered with caution to avoid excessive water intake. These patients have large pools of empty T_3 and T_4 binding sites that must

be filled before there is adequate free thyroxine to affect tissue metabolism. Accordingly, the treatment of choice in myxedema coma is to give a loading dose of levothyroxine intravenously—usually 300–400 μg initially, followed by 50 μg daily. Intravenous T_3 can also be used but may be more cardiotoxic and more difficult to monitor. Intravenous hydrocortisone is indicated if the patient has associated adrenal or pituitary insufficiency but is probably not necessary in most patients with primary myxedema. Opioids and sedatives must be used with extreme caution.

Hypothyroidism and Pregnancy

Hypothyroid women frequently have anovulatory cycles and are therefore relatively infertile until restoration of the euthyroid state. This has led to the widespread use of thyroid hormone for infertility, although there is no evidence for its usefulness in infertile euthyroid patients. In a pregnant hypothyroid patient receiving thyroxine, it is extremely important that the daily dose of thyroxine be adequate because early development of the fetal brain depends on maternal thyroxine. In many hypothyroid patients, a modest increase in the thyroxine dose (about 20–30%) is required to normalize the serum TSH level during pregnancy. Because of the elevated maternal TBG, the free thyroxine index (FT_4I) or free thyroxine (FT_4) and TSH (Table 38–2) must be used to monitor maternal thyroxine dosages.

Hyperthyroidism

Hyperthyroidism (thyrotoxicosis) is the clinical syndrome that results when tissues are exposed to high levels of thyroid hormone (Table 38–4).

Graves' Disease

The most common form of hyperthyroidism is Graves' disease, or diffuse toxic goiter. The presenting signs and symptoms of Graves' disease are set forth in Table 38–4.

Pathophysiology

Graves' disease is considered to be an autoimmune disorder in which there is a genetic defect in suppressor T lymphocytes, and helper T lymphocytes stimulate B lymphocytes to synthesize antibodies to thyroidal antigens. The antibody described previously (TSH-R Ab [stim]) is directed against the TSH receptor site in the thyroid cell membrane and has the capacity to stimulate the thyroid cell. Spontaneous remission occurs but may require 1 to 15 years.

Laboratory Diagnosis

In most patients with hyperthyroidism, T_3 , T_4 , RT_3U , FT_4 , and FT_4I will all be elevated and TSH is suppressed (Table 38–2). Radioiodine uptake is usually markedly elevated as well. Antithyroglobulin antibodies, thyroid peroxidase, and TSH-R Ab [stim] are often present.

Management of Graves' Disease

The three primary methods for controlling hyperthyroidism are antithyroid drug therapy, surgical thyroidectomy, and destruction of the gland with radioactive iodine.

Antithyroid Drug Therapy

Drug therapy is most useful in young patients with small glands and mild disease. Methimazole or

propylthiouracil is administered until the disease undergoes spontaneous remission. This is the only therapy that leaves an intact thyroid gland, but it does require a long period of treatment and observation (1–2 years), and there is a 60–70% incidence of relapse.

Antithyroid drug therapy is usually begun with large divided doses, shifting to maintenance therapy with single daily doses when the patient becomes clinically euthyroid. However, mild to moderately severe thyrotoxicosis can often be controlled with methimazole given in a single morning dose of 30–40 mg; once-daily dosing may enhance adherence. Maintenance therapy requires 5–15 mg once daily. Alternatively, therapy is started with propylthiouracil, 100–150 mg every 6 or 8 hours, followed after 4–8 weeks by gradual reduction of the dose to the maintenance level of 50–150 mg once daily. In addition to inhibiting iodine organification, propylthiouracil also inhibits the conversion of T_4 to T_3 , so it brings the level of activated thyroid hormone down more quickly than does methimazole. The best clinical guide to remission is reduction in the size of the goiter. Laboratory tests most useful in monitoring the course of therapy are serum T_3 by RIA, FT_4 or FT_4I , and serum TSH.

Reactivation of the autoimmune process may occur when the dosage of antithyroid drug is lowered during maintenance therapy and TSH begins to drive the gland. TSH release can be prevented by the daily administration of 50–150 μ g of levothyroxine with 5–15 mg of methimazole or 50–150 mg of propylthiouracil for the second year of therapy. The relapse rate with this program is probably comparable to the rate with antithyroid therapy alone, but the risk of hypothyroidism and overtreatment is avoided.

Reactions to antithyroid drugs have been described above. A minor rash can often be controlled by antihistamine therapy. Because the more severe reaction of agranulocytosis is often heralded by sore throat or high fever, patients receiving antithyroid drugs must be instructed to discontinue the drug and seek immediate medical attention if these symptoms develop. White cell and differential counts and a throat culture are indicated in such cases, followed by appropriate antibiotic therapy.

Thyroidectomy

A near-total thyroidectomy is the treatment of choice for patients with very large glands or multinodular goiters. Patients are treated with antithyroid drugs until euthyroid (about 6 weeks). In addition, for 2 weeks prior to surgery, they receive saturated solution of potassium iodide, 5 drops twice daily, to diminish vascularity of the gland and simplify surgery. About 80–90% of patients will require thyroid supplementation following near-total thyroidectomy.

Radioactive Iodine

Radioiodine therapy utilizing ^{131}I is the preferred treatment for most patients over 21 years of age. In patients without heart disease, the therapeutic dose may be given immediately in a range of 80–120 μ Ci/g of estimated thyroid weight corrected for uptake. In patients with underlying heart disease or severe thyrotoxicosis and in elderly patients, it is desirable to treat with antithyroid drugs (preferably methimazole) until the patient is euthyroid. The medication is then stopped for 5–7 days before the appropriate dose of ^{131}I is administered. Iodides should be avoided to ensure maximal ^{131}I uptake. Six to 12 weeks following the administration of radioiodine, the gland will shrink in size and the patient will usually become euthyroid or hypothyroid. A second dose may be required in some patients. Hypothyroidism occurs in about 80% of patients following radioiodine therapy. Serum FT_4 and TSH levels should be monitored. When hypothyroidism develops, prompt replacement with oral levothyroxine, 50–150 μ g daily, should be instituted.

Adjuncts to Antithyroid Therapy

During the acute phase of thyrotoxicosis, β -adrenoceptor-blocking agents without intrinsic sympathomimetic activity are extremely helpful. Propranolol, 20–40 mg orally every 6 hours, will control tachycardia, hypertension, and atrial fibrillation. Propranolol is gradually withdrawn as serum thyroxine levels return to normal. Diltiazem, 90–120 mg three or four times daily, can be used to control tachycardia in patients in whom β -blockers are contraindicated, eg, those with asthma. Other calcium channel blockers may not be as effective as diltiazem. Adequate nutrition and vitamin supplements are essential. Barbiturates accelerate T_4 breakdown (by hepatic enzyme induction) and may be helpful both as sedatives and to lower T_4 levels.

Toxic Uninodular Goiter & Toxic Multinodular Goiter

These forms of hyperthyroidism occur often in older women with nodular goiters. FT_4 is moderately elevated or occasionally normal, but T_3 by RIA is strikingly elevated. Single toxic adenomas can be managed with either surgical excision of the adenoma or with radioiodine therapy. Toxic multinodular goiter is usually associated with a large goiter and is best treated by preparation with methimazole or propylthiouracil followed by subtotal thyroidectomy.

Subacute Thyroiditis

During the acute phase of a viral infection of the thyroid gland, there is destruction of thyroid parenchyma with transient release of stored thyroid hormones. A similar state may occur in patients with Hashimoto's thyroiditis. These episodes of transient thyrotoxicosis have been termed "spontaneously resolving hyperthyroidism." Supportive therapy is usually all that is necessary, such as propranolol for tachycardia and aspirin or nonsteroidal anti-inflammatory drugs to control local pain and fever. Corticosteroids may be necessary in severe cases to control the inflammation.

Special Problems

Thyroid Storm

Thyroid storm, or thyrotoxic crisis, is sudden acute exacerbation of all of the symptoms of thyrotoxicosis, presenting as a life-threatening syndrome. Vigorous management is mandatory. Propranolol, 1–2 mg slowly intravenously or 40–80 mg orally every 6 hours, is helpful to control the severe cardiovascular manifestations. If propranolol is contraindicated by the presence of severe heart failure or asthma, hypertension and tachycardia may be controlled with diltiazem, 90–120 mg orally three or four times daily or 5–10 mg/h by intravenous infusion (asthmatic patients only). Release of thyroid hormones from the gland is retarded by the administration of saturated solution of potassium iodide, 10 drops orally daily, or iodinated contrast media (eg, sodium ipodate, 1 g orally daily). The latter medication will also block peripheral conversion of T_4 to T_3 . Hormone synthesis is blocked by the administration of propylthiouracil, 250 mg orally every 6 hours. If the patient is unable to take propylthiouracil by mouth, a rectal formulation can be prepared and administered in a dosage of 400 mg every 6 hours as a retention enema. Methimazole may also be prepared for rectal administration in a dose of 60 mg daily. Hydrocortisone, 50 mg intravenously every 6 hours, will protect the patient against shock and will block the conversion of T_4 to T_3 , rapidly bringing down the level of thyroactive material in the blood.

Supportive therapy is essential to control fever, heart failure, and any underlying disease process that may have precipitated the acute storm. In rare situations, where the above methods are not adequate to control the problem, plasmapheresis or peritoneal dialysis has been used to lower the

levels of circulating thyroxine.

Ophthalmopathy

Although severe ophthalmopathy is rare, it is difficult to treat. Management requires effective treatment of the thyroid disease, usually by total surgical excision or ^{131}I ablation of the gland plus oral prednisone therapy (see below). In addition, local therapy may be necessary, eg, elevation of the head to diminish periorbital edema and artificial tears to relieve corneal drying. Smoking cessation should be advised to prevent progression of the ophthalmopathy. For the severe, acute inflammatory reaction, a short course of prednisone, 60–100 mg orally daily for about a week and then 60–100 mg every other day, tapering the dose over a period of 6–12 weeks, may be effective. If steroid therapy fails or is contraindicated, irradiation of the posterior orbit, using well-collimated high-energy x-ray therapy, will frequently result in marked improvement of the acute process. Threatened loss of vision is an indication for surgical decompression of the orbit. Eyelid or eye muscle surgery may be necessary to correct residual problems after the acute process has subsided.

Dermopathy

Dermopathy or pretibial myxedema will often respond to topical corticosteroids applied to the involved area and covered with an occlusive dressing.

Thyrotoxicosis during Pregnancy

Ideally, women in the childbearing period with severe disease should have definitive therapy with ^{131}I or subtotal thyroidectomy *prior* to pregnancy in order to avoid an acute exacerbation of the disease during pregnancy or following delivery. If thyrotoxicosis does develop during pregnancy, radioiodine is contraindicated because it crosses the placenta and may injure the fetal thyroid. In the first trimester, the patient can be prepared with propylthiouracil and a subtotal thyroidectomy performed safely during the mid trimester. It is essential to give the patient a thyroid supplement during the balance of the pregnancy. However, most patients are treated with propylthiouracil during the pregnancy, and the decision regarding long-term management can be made after delivery. The dosage of propylthiouracil must be kept to the minimum necessary for control of the disease (ie, < 300 mg daily), because it may affect the function of the fetal thyroid gland. Methimazole is a potential alternative, although there is concern about a possible risk of fetal scalp defects.

Neonatal Graves' Disease

Graves' disease may occur in the newborn infant, either due to passage of TSH-R Ab [stim] through the placenta, stimulating the thyroid gland of the neonate, or to genetic transmission of the trait to the fetus. Laboratory studies reveal an elevated free thyroxine, a markedly elevated T_3 , and a low TSH—in contrast to the normal infant, in whom TSH is elevated at birth. TSH-R Ab [stim] is usually found in the serum of both the child and the mother.

If caused by maternal TSH-R Ab [stim], the disease is usually self-limited and subsides over a period of 4–12 weeks, coinciding with the fall in the infant's TSH-R Ab [stim] level. However, treatment is necessary because of the severe metabolic stress the infant experiences. Therapy includes propylthiouracil in a dose of 5–10 mg/kg/d in divided doses at 8-hour intervals; Lugol's solution (8 mg of iodide per drop), 1 drop every 8 hours; and propranolol, 2 mg/kg/d in divided doses. Careful supportive therapy is essential. If the infant is very ill, oral prednisone, 2 mg/kg/d in divided doses, will help block conversion of T_4 to T_3 . These medications are gradually reduced as

the clinical picture improves and can be discontinued by 6–12 weeks.

Nontoxic Goiter

Nontoxic goiter is a syndrome of thyroid enlargement without excessive thyroid hormone production. Enlargement of the thyroid gland is usually due to TSH stimulation from inadequate thyroid hormone synthesis. The most common cause of nontoxic goiter worldwide is iodide deficiency, but in the USA, it is Hashimoto's thyroiditis. Less common causes include dietary goitrogens, dysmorphogenesis, and neoplasms (see below).

Goiter due to iodide deficiency is best managed by prophylactic administration of iodide. The optimal daily iodide intake is 150–200 μg . Iodized salt and iodate used as preservatives in flour and bread are excellent sources of iodine in the diet. In areas where it is difficult to introduce iodized salt or iodate preservatives, a solution of iodized poppyseed oil has been administered intramuscularly to provide a long-term source of inorganic iodine.

Goiter due to ingestion of goitrogens in the diet is managed by elimination of the goitrogen or by adding sufficient thyroxine to shut off TSH stimulation. Similarly, in Hashimoto's thyroiditis and dysmorphogenesis, adequate thyroxine therapy—150–200 $\mu\text{g}/\text{d}$ orally—will suppress pituitary TSH and result in slow regression of the goiter as well as correction of hypothyroidism.

Thyroid Neoplasms

Neoplasms of the thyroid gland may be benign (adenomas) or malignant. Some adenomas will regress following thyroxine therapy; those that do not should be rebiopsied or surgically removed. Management of thyroid carcinoma requires a total thyroidectomy, postoperative radioiodine therapy in selected instances, and lifetime replacement with levothyroxine. The evaluation for recurrence of some thyroid malignancies requires withdrawal of thyroxine replacement for 4–6 weeks—accompanied by the development of hypothyroidism. Tumor recurrence is likely if there is a rise in serum thyroglobulin (ie, a tumor marker) or a positive ^{131}I scan when TSH is elevated. Alternatively, administration of recombinant human TSH (Thyrogen) can produce comparable TSH elevations without discontinuing thyroxine and avoiding hypothyroidism. Recombinant human TSH is administered intramuscularly once daily for 2 days. A rise in serum thyroglobulin or a positive ^{131}I scan will indicate a recurrence of the thyroid cancer.

Katzung PHARMACOLOGY, 9e > Section VII. Endocrine Drugs > Chapter 38. Thyroid & Antithyroid Drugs >

Preparations Available

Thyroid Agents

Levothyroxine [T_4] (generic, Levoxyl, Levo-T, Synthroid, Unithroid)

Oral: 0.025, 0.05, 0.075, 0.088, 0.1, 0.112, 0.125, 0.137, 0.15, 0.175, 0.2, 0.3 mg tablets

Parenteral: 200, 500 μg per vial (100 $\mu\text{g}/\text{mL}$ when reconstituted) for injection

Liothyronine [T_3] (generic, Cytomel, Triostat)

Oral: 5, 25, 50 µg tablets

Parenteral: 10 µg/mL

Liotrix [a 4:1 ratio of T₄:T₃] (Thyrolar)

Oral: tablets containing 12.5, 25, 30, 50, 60, 100, 120, 150, 180 µg T₄ and one fourth as much T₃

Thyroid desiccated [USP] (generic, Armour Thyroid, Thyroid Strong, Thyrar, S-P-T)

Oral: tablets containing 15, 30, 60, 90, 120, 180, 240, 300 mg; capsules (S-P-T) containing 120, 180, 300 mg

Antithyroid Agents

Diatrizoate sodium (Hypaque)

Parenteral: 25% (150 mg iodine/mL); 50% (300 mg iodine/mL) (unlabeled use)

Iodide (¹³¹I) sodium (Iodotope, Sodium Iodide I 131 Therapeutic)

Oral: available as capsules and solution

Iopanoic acid (Telepaque)

Oral: 500 mg tablets (unlabeled use)

Ipodate sodium (Oragrafin Sodium, Bilivist)

Oral: 500 mg capsules (unlabeled use)

Methimazole (Tapazole)

Oral: 5, 10 mg tablets

Potassium iodide

Oral solution (generic, SSKI): 1 g/mL

Oral solution (Lugol's solution): 100 mg/mL potassium iodide plus 50 mg/mL iodine

Oral syrup (Pima): 325 mg/5 mL

Oral controlled action tablets (Iodo-Niacin): 135 mg potassium iodide plus 25 mg niacinamide hydroiodide

Oral potassium iodide tablets (generic, IOSAT, RAD-Block, Thyro-Block): 65, 130 mg

Propylthiouracil [PTU] (generic)

Oral: 50 mg tablets

Thyrotropin; recombinant human TSH (Thyrogen)

Parenteral: 0.9 mg per vial

Chapter 39. Adrenocorticosteroids & Adrenocortical Antagonists

Katzung PHARMACOLOGY, 9e > Section VII. Endocrine Drugs > Chapter 39.

Adrenocorticosteroids & Adrenocortical Antagonists >

Adrenocorticosteroids & Adrenocortical Antagonists: Introduction

The natural adrenocortical hormones are steroid molecules produced and released by the adrenal cortex. Both natural and synthetic corticosteroids are used for diagnosis and treatment of disorders of adrenal function. They are also used—more often and in much larger doses—for treatment of a variety of inflammatory and immunologic disorders.

Secretion of adrenocortical steroids is controlled by the pituitary release of corticotropin (ACTH). Secretion of the salt-retaining hormone aldosterone is primarily under the influence of angiotensin. Corticotropin has some actions that do not depend upon its effect on adrenocortical secretion. However, its pharmacologic value as an anti-inflammatory agent and its use in testing adrenal function depend on its secretory action. Its pharmacology is discussed in Chapter 37: Hypothalamic & Pituitary Hormones and will be reviewed only briefly here.

Inhibitors of the synthesis or antagonists of the action of the adrenocortical steroids are important in the treatment of several conditions. These agents are described at the end of this chapter.

Katzung PHARMACOLOGY, 9e > Section VII. Endocrine Drugs > Chapter 39.

Adrenocorticosteroids & Adrenocortical Antagonists >

Adrenocorticosteroids

The adrenal cortex releases a large number of steroids into the circulation. Some have minimal biologic activity and function primarily as precursors, and there are some for which no function has been established. The hormonal steroids may be classified as those having important effects on intermediary metabolism (glucocorticoids), those having principally salt-retaining activity (mineralocorticoids), and those having androgenic or estrogenic activity (see Chapter 40: The Gonadal Hormones & Inhibitors). In humans, the major glucocorticoid is cortisol and the most important mineralocorticoid is aldosterone. Quantitatively, dehydroepiandrosterone (DHEA) in its sulfated form (DHEAS) is the major adrenal androgen, since about 20 mg is secreted daily. However, DHEA and two other adrenal androgens, androstenediol and androstenedione, are weak androgens or estrogens, mostly by peripheral conversion to testosterone and dehydrotestosterone or estradiol and estrone. Adrenal androgens constitute the major endogenous precursors of estrogen in women after menopause and in younger patients in whom ovarian function is deficient or absent.

The Naturally Occurring Glucocorticoids; Cortisol (Hydrocortisone)

Pharmacokinetics

Cortisol (also called hydrocortisone, compound F) exerts a wide range of physiologic effects, including regulation of intermediary metabolism, cardiovascular function, growth, and immunity. Its synthesis and secretion are tightly regulated by the central nervous system, which is very sensitive to negative feedback by the circulating cortisol and exogenous (synthetic) glucocorticoids. Cortisol is synthesized from cholesterol (as shown in Figure 39–1). The mechanisms controlling its secretion are discussed in Chapter 37: Hypothalamic & Pituitary Hormones.

Figure 39–1.

Outline of major pathways in adrenocortical hormone biosynthesis. The major secretory products are underlined. Pregnenolone is the major precursor of corticosterone and aldosterone, and 17-

hydroxypregnenolone is the major precursor of cortisol. The enzymes and cofactors for the reactions progressing down each column are shown on the left and across columns at the top of the figure. When a particular enzyme is deficient, hormone production is blocked at the points indicated by the shaded bars. (Modified after Welikey et al; reproduced, with permission, from Ganong WF: *Review of Medical Physiology*, 17th ed. Originally published by Appleton & Lange. Copyright © 1995 by The McGraw-Hill Companies, Inc.)

In the normal adult, in the absence of stress, 10–20 mg of cortisol is secreted daily. The rate of secretion follows a circadian rhythm governed by pulses of ACTH that peak in the early morning hours and after meals (Figure 39–2). In plasma, cortisol is bound to circulating proteins. Corticosteroid-binding globulin (CBG), an α_2 -globulin synthesized by the liver, binds 90% of the circulating hormone under normal circumstances. The remainder is free (about 5–10%) or loosely bound to albumin (about 5%) and is available to exert its effect on target cells. When plasma cortisol levels exceed 20–30 $\mu\text{g}/\text{dL}$, CBG is saturated, and the concentration of free cortisol rises rapidly. CBG is increased in pregnancy and with estrogen administration and in hyperthyroidism. It is decreased by hypothyroidism, genetic defects in synthesis, and protein deficiency states. Albumin has a large capacity but low affinity for cortisol, and for practical purposes albumin-bound cortisol should be considered free. Synthetic corticosteroids such as dexamethasone are largely bound to albumin rather than CBG.

Figure 39–2.

Fluctuations in plasma ACTH and glucocorticoids throughout the day in a normal girl (age 16). The ACTH was measured by immunoassay and the glucocorticoids as 11-oxysteroids (*11-OHCS*). Note the greater ACTH and glucocorticoid rises in the morning, before awakening from sleep. (Reproduced, with permission, from Krieger DT et al: Characterization of the normal temporal pattern of plasma corticosteroid levels. *J Clin Endocrinol Metab* 1971;32:266.)

The half-life of cortisol in the circulation is normally about 60–90 minutes; half-life may be increased when hydrocortisone (the pharmaceutical preparation of cortisol) is administered in large amounts or when stress, hypothyroidism, or liver disease is present. Only 1% of cortisol is excreted unchanged in the urine as free cortisol; about 20% of cortisol is converted to cortisone by 11-hydroxysteroid dehydrogenase in the kidney and other tissues with mineralocorticoid receptors (see below) before reaching the liver. Most cortisol is inactivated in the liver by reduction of the 4,5 double bond in the A ring and subsequent conversion to tetrahydrocortisol and tetrahydrocortisone by 3-hydroxysteroid dehydrogenase. (See Figure 39–4 for carbon numbering.) Some is converted to cortol and cortolone by reduction of the C₂₀ ketone. There are small amounts of other metabolites. About one third of the cortisol produced daily is excreted in the urine as dihydroxy ketone metabolites and is measured as 17-hydroxysteroids. Many cortisol metabolites are conjugated with glucuronic acid or sulfate at the C₃ and C₂₁ hydroxyls, respectively, in the liver; they then reenter the circulation and are excreted in the urine.

In some species (eg, the rat), corticosterone is the major glucocorticoid. It is less firmly bound to protein and therefore metabolized more rapidly. The pathways of its degradation are similar to those

of cortisol.

Pharmacodynamics

Mechanism of Action

Most of the known effects of the glucocorticoids are mediated by widely distributed glucocorticoid receptors. These proteins are members of the superfamily of nuclear receptors that includes steroid, sterol (vitamin D), thyroid, retinoic acid, and many other receptors with unknown or nonexistent ligands (orphan receptors). All these receptors interact with the promoters of—and regulate the transcription of—target genes (Figure 39–3). In the absence of the hormonal ligand, glucocorticoid receptors are primarily cytoplasmic, in oligomeric complexes with heat shock proteins (Hsp). The most important of these are two molecules of Hsp90, though other proteins are certainly involved. Free hormone from the plasma and interstitial fluid enters the cell and binds to the receptor, inducing conformational changes that allow it to dissociate from the heat shock proteins. The ligand-bound receptor complex then is actively transported into the nucleus, where it interacts with DNA and nuclear proteins. As a homodimer, it binds to glucocorticoid receptor elements (GRE) in the promoters of responsive genes. The GRE is composed of two palindromic sequences that bind to the hormone receptor dimer.

Figure 39–3.

A model of the interaction of a steroid, S (eg, cortisol), and its receptor, R, and the subsequent events in a target cell. The steroid is present in the blood in bound form on the corticosteroid-binding globulin, CBG, but enters the cell as the free molecule. The intracellular receptor is bound to stabilizing proteins, including two molecules of heat shock protein 90 (Hsp90) and several others, denoted as "X" in the figure. This receptor complex is incapable of activating transcription. When the complex binds a molecule of cortisol, an unstable complex is created and the Hsp90 and associated molecules are released. The steroid-receptor complex is able to enter the nucleus, bind to the glucocorticoid response element (GRE) on the gene, and regulate transcription by RNA polymerase II and associated transcription factors. A variety of regulatory factors (not shown) may participate in facilitating (coactivators) or inhibiting (corepressors) the steroid response. The resulting mRNA is edited and exported to the cytoplasm for the production of protein that brings about the final hormone response.

In addition to binding to GREs, the ligand-bound receptor also forms complexes with and influences the function of other transcription factors, such as AP1 and NF- κ B, which act on non-GRE-containing promoters, to contribute to the regulation of transcription of their responsive genes. These transcription factors have broad actions on the regulation of growth factors, proinflammatory cytokines, etc, and to a great extent mediate the anti-growth, anti-inflammatory, and immunosuppressive effects of glucocorticoids. These factors represent new targets in the development of a new generation of glucocorticoid agonists or antagonists with response selectivity or tissue selectivity.

Two genes for the corticoid receptor have been identified, one encoding the classic glucocorticoid receptor and the other the mineralocorticoid receptor. Alternative splicing of human glucocorticoid receptor pre-mRNA generates two highly homologous isoforms, termed hGR alpha and hGR beta. hGR alpha is the classic ligand-activated glucocorticoid receptor which, in the hormone-bound state, modulates the expression of glucocorticoid-responsive genes. In contrast, hGR beta does not bind glucocorticoids and is transcriptionally inactive. However, hGR beta is able to inhibit the effects of hormone-activated hGR alpha on glucocorticoid-responsive genes, playing the role of a physiologically relevant endogenous inhibitor of glucocorticoid action.

The glucocorticoid receptor is composed of about 800 amino acids and can be divided into three functional domains (Figure 2–6). The glucocorticoid-binding domain is located at the carboxyl terminal of the molecule and is the area where free glucocorticoids bind. The DNA-binding domain is located in the middle of the protein and contains nine cysteine residues. This region folds into a "two-finger" structure stabilized by zinc ions connected to cysteines to form two tetrahedrons. This part of the molecule binds to the GREs that regulate glucocorticoid action on glucocorticoid-regulated genes. The zinc-fingers represent the basic structure by which the DNA-binding domain recognizes specific nucleic acid sequences. The amino-terminal domain is highly antigenic. It is involved in the transactivational activity of the receptor and increases its specificity.

The interaction of glucocorticoid receptors with GREs or other transcription factors is facilitated or inhibited by several families of proteins called steroid receptor "coregulators" divided respectively into "coactivators" and "corepressors." They do this by serving as bridges between the receptors and other nuclear proteins and by expressing enzymatic activities such as histone acetylase or deacetylase that alter the conformation of nucleosomes and the transcribability of genes.

Between 10% and 20% of expressed genes in a cell are regulated by glucocorticoids. The number and affinity of receptors for the hormone, the complement of transcription factors and coregulators, and posttranscription events determine the relative specificity of these hormones' actions in various cells. The effects of glucocorticoids are mainly due to proteins synthesized from mRNA transcribed

by their target genes.

Some of the effects of glucocorticoids can be attributed to their binding to aldosterone receptors (AR). Indeed, ARs bind aldosterone and cortisol with similar affinity. A mineralocorticoid effect of cortisol is avoided in some tissues by expression of 11 β -hydroxysteroid dehydrogenase type 2, the enzyme responsible for biotransformation to its 11-keto derivative (cortisone), which has minimal affinity for aldosterone receptors.

Prompt effects such as initial feedback suppression of pituitary ACTH occur in minutes and are too rapid to be explained on the basis of gene transcription and protein synthesis. It is not known how these effects are mediated. Among the proposed mechanisms are direct effects on cell membrane receptors for the hormone or nongenomic effects of the classic hormone-bound glucocorticoid receptor. The putative membrane receptors might be entirely different from the known intracellular receptors.

Physiologic Effects

The glucocorticoids have widespread effects because they influence the function of most cells in the body. The major metabolic consequences of glucocorticoid secretion or administration are due to direct actions of these hormones in the cell. However, some important effects are the result of homeostatic responses by insulin and glucagon. Although many of the effects of glucocorticoids are dose-related and become magnified when large amounts are administered for therapeutic purposes, there are also other effects—called "permissive" effects—in the absence of which many normal functions become deficient. For example, the response of vascular and bronchial smooth muscle to catecholamines is diminished in the absence of cortisol and restored by physiologic amounts of this glucocorticoid. Furthermore, the lipolytic responses of fat cells to catecholamines, ACTH, and growth hormone are attenuated in the absence of glucocorticoids.

Metabolic Effects

The glucocorticoids have important dose-related effects on carbohydrate, protein, and fat metabolism. The same effects are responsible for some of the serious adverse effects associated with their use in therapeutic doses. Glucocorticoids stimulate and are required for gluconeogenesis and glycogen synthesis in the fasting state. They stimulate phosphoenolpyruvate carboxykinase, glucose-6-phosphatase, and glycogen synthase and the release of amino acids in the course of muscle catabolism.

Glucocorticoids increase serum glucose levels and thus stimulate insulin release and inhibit the uptake of glucose by muscle cells, while they stimulate hormone-sensitive lipase and thus lipolysis. The increased insulin secretion stimulates lipogenesis and to a lesser degree inhibits lipolysis, leading to a net increase in fat deposition combined with increased release of fatty acids and glycerol into the circulation.

The net results of these actions are most apparent in the fasting state, when the supply of glucose from gluconeogenesis, the release of amino acids from muscle catabolism, the inhibition of peripheral glucose uptake, and the stimulation of lipolysis all contribute to maintenance of an adequate glucose supply to the brain.

Catabolic and Antianabolic Effects

Although glucocorticoids stimulate protein and RNA synthesis in the liver, they have catabolic and

antianabolic effects in lymphoid and connective tissue, muscle, fat, and skin. Supraphysiologic amounts of glucocorticoids lead to decreased muscle mass and weakness and thinning of the skin. Catabolic and antianabolic effects on bone are the cause of osteoporosis in Cushing's syndrome and impose a major limitation in the long-term therapeutic use of glucocorticoids. In children, glucocorticoids reduce growth. This effect may be partially prevented by administration of growth hormone in high doses.

Anti-Inflammatory and Immunosuppressive Effects

Glucocorticoids dramatically reduce the manifestations of inflammation. This is due to their profound effects on the concentration, distribution, and function of peripheral leukocytes and to their suppressive effects on the inflammatory cytokines and chemokines and on other lipid and glucolipid mediators of inflammation. Inflammation, regardless of its cause, is characterized by the extravasation and infiltration of leukocytes into the affected tissue. These events are mediated by a complex series of interactions of white cell adhesion molecules with those on endothelial cells and are inhibited by glucocorticoids. After a single dose of a short-acting glucocorticoid, the circulating concentration of neutrophils increases while the lymphocytes (T and B cells), monocytes, eosinophils, and basophils in the circulation decrease in number. The changes are maximal at 6 hours and are dissipated in 24 hours. The increase in neutrophils is due both to the increased influx into the blood from the bone marrow and decreased migration from the blood vessels, leading to a reduction in the number of cells at the site of inflammation. The reduction in circulating lymphocytes, monocytes, eosinophils, and basophils is primarily the result of their movement from the vascular bed to lymphoid tissue.

Glucocorticoids also inhibit the functions of tissue macrophages and other antigen-presenting cells. The ability of these cells to respond to antigens and mitogens is reduced. The effect on macrophages is particularly marked and limits their ability to phagocytose and kill microorganisms and to produce tumor necrosis factor- α , interleukin-1, metalloproteinases, and plasminogen activator. Both macrophages and lymphocytes produce less interleukin-12 and interferon- γ , important inducers of TH1 cell activity, and cellular immunity.

In addition to their effects on leukocyte function, glucocorticoids influence the inflammatory response by reducing the prostaglandin, leukotriene, and platelet-activating factor synthesis that results from activation of phospholipase A₂. Finally, glucocorticoids reduce expression of cyclooxygenase II, the inducible form of this enzyme, in inflammatory cells, thus reducing the amount of enzyme available to produce prostaglandins (Chapter 18: The Eicosanoids: Prostaglandins, Thromboxanes, Leukotrienes, & Related Compounds and Chapter 36: Nonsteroidal Anti-Inflammatory Drugs, Disease-Modifying Antirheumatic Drugs, Nonopioid Analgesics, & Drugs Used in Gout).

Glucocorticoids cause vasoconstriction when applied directly to the skin, possibly by suppressing mast cell degranulation. They also decrease capillary permeability by reducing the amount of histamine released by basophils and mast cells.

The anti-inflammatory and immunosuppressive effects of glucocorticoids are largely due to the actions described above. In humans, complement activation is unaltered, but its effects are inhibited. Antibody production can be reduced by large doses of steroids, though it is unaffected by moderate dosages (eg, 20 mg/d of prednisone). The efficacy of glucocorticoids in the control of transplant rejection is augmented by their ability to reduce antigen expression from the grafted tissue, delay revascularization, and interfere with the sensitization of cytotoxic T lymphocytes and the generation of primary antibody-forming cells.

The anti-inflammatory and immunosuppressive effects of these agents are widely useful therapeutically but are also responsible for some of their most serious adverse effects (see below).

Other Effects

Glucocorticoids have important effects on the nervous system. Adrenal insufficiency causes marked slowing of the alpha rhythm of the EEG and is associated with depression. Increased amounts of glucocorticoids often produce behavioral disturbances in humans: initially insomnia and euphoria and subsequently depression. Large doses of glucocorticoids may increase intracranial pressure (pseudotumor cerebri).

Glucocorticoids given chronically suppress the pituitary release of ACTH, GH, TSH, and LH.

Large doses of glucocorticoids have been associated with the development of peptic ulcer, possibly by suppressing the local immune response against *Helicobacter pylori*. They also promote fat redistribution in the body, with increase of visceral, facial, nuchal, and supraclavicular fat, and they appear to antagonize the effect of vitamin D on calcium absorption. The glucocorticoids also have important effects on the hematopoietic system. In addition to their effects on leukocytes described above, they increase the number of platelets and red blood cells.

In the absence of physiologic amounts of cortisol, renal function (particularly glomerular filtration) is impaired, vasopressin secretion is augmented, and there is an inability to excrete a water load normally.

Glucocorticoids have important effects on the development of the fetal lungs. Indeed, the structural and functional changes in the lungs near term, including the production of pulmonary surface-active material required for air breathing (surfactant), are stimulated by glucocorticoids.

Synthetic Corticosteroids

Glucocorticoids have become important agents for use in the treatment of many inflammatory, allergic, hematologic, and other disorders. This has stimulated the development of many synthetic steroids with anti-inflammatory and immunosuppressive activity.

Pharmacokinetics

Source

Pharmaceutical steroids are usually synthesized from cholic acid (obtained from cattle) or steroid saponin, in particular diosgenin and hecopenin, found in plants of the Liliaceae and Dioscoreaceae families. Further modifications of these steroids have led to the marketing of a large group of synthetic steroids with special characteristics that are pharmacologically and therapeutically important (Table 39–1; Figure 39–4).

Table 39–1. Some Commonly Used Natural and Synthetic Corticosteroids for General Use.			
	Activity¹		

Agent	Anti-inflammatory	Topical	Salt-Retaining	Equivalent Oral Dose (mg)	Forms Available
Short- to medium-acting glucocorticoids					
Hydrocortisone (cortisol)	1	1	1	20	Oral, injectable, topical
Cortisone	0.8	0	0.8	25	Oral, injectable, topical
Prednisone	4	0	0.3	5	Oral
Prednisolone	5	4	0.3	5	Oral, injectable, topical
Methylprednisolone	5	5	0	4	Oral, injectable, topical
Meprednisone ²	5		0	4	Oral, injectable
Intermediate-acting glucocorticoids					
Triamcinolone	5	5 ³	0	4	Oral, injectable, topical
Paramethasone ²	10		0	2	Oral, injectable
Fluprednisolone	15	7	0	1.5	Oral
Long-acting glucocorticoids					
Betamethasone	25–40	10	0	0.6	Oral, injectable, topical
Dexamethasone	30	10	0	0.75	Oral, injectable, topical
Mineralocorticoids					
Fludrocortisone	10	10	250	2	Oral, injectable, topical
Desoxycorticosterone acetate	0	0	20		Injectable, pellets

³Acetonide: Up to 100.

Figure 39–4.

Chemical structures of several glucocorticoids. The acetonide-substituted derivatives (eg, triamcin-olone acetonide) have increased surface activity and are useful in dermatology. Dexamethasone is identical to betamethasone except for the configuration of the methyl group at C₁₆: in betamethasone it is beta (projecting *up* from the plane of the rings); in dexamethasone it is alpha.

Disposition

The metabolism of the naturally occurring adrenal steroids has been discussed above. The synthetic cortico-steroids (Table 39–1) are in most cases rapidly and completely absorbed when given by mouth. Although they are transported and metabolized in a fashion similar to that of the endogenous steroids, important differences exist.

Alterations in the glucocorticoid molecule influence its affinity for glucocorticoid and mineralocorticoid receptors as well as its protein-binding avidity, side chain stability, rate of reduction, and metabolic products. Halogenation at the 9 position, unsaturation of the Δ^{1-2} bond of

the A ring, and methylation at the 2 or 16 position prolong the half-life by more than 50%. The Δ^1 compounds are excreted in the free form. In some cases, the agent given is a prodrug—eg, prednisone is rapidly converted to the active product prednisolone in the body.

Pharmacodynamics

The actions of the synthetic steroids are similar to those of cortisol (see above). They bind to the specific intracellular receptor proteins and produce the same effects but have different ratios of glucocorticoid to mineralocorticoid potency (Table 39–1).

Clinical Pharmacology

Diagnosis and Treatment of Disturbed Adrenal Function

Adrenocortical Insufficiency

Chronic (Addison's Disease)

Chronic adrenocortical insufficiency is characterized by weakness, fatigue, weight loss, hypotension, hyperpigmentation, and inability to maintain the blood glucose level during fasting. In such individuals, minor noxious, traumatic, or infectious stimuli may produce acute adrenal insufficiency with circulatory shock and even death.

In primary adrenal insufficiency, about 20–30 mg of hydrocortisone must be given daily, with increased amounts during periods of stress. Although hydrocortisone has some mineralocorticoid activity, this must be supplemented by an appropriate amount of a salt-retaining hormone such as fludrocortisone. Synthetic glucocorticoids that are long-acting and devoid of salt-retaining activity should not be administered to these patients.

Acute

When acute adrenocortical insufficiency is suspected, treatment must be instituted immediately. Therapy consists of correction of fluid and electrolyte abnormalities and treatment of precipitating factors in addition to large amounts of parenteral hydrocortisone.

Hydrocortisone sodium succinate or phosphate in doses of 100 mg intravenously is given every 8 hours until the patient is stable. The dose is then gradually reduced, achieving maintenance dosage within 5 days. The administration of salt-retaining hormone is resumed when the total hydrocortisone dosage has been reduced to 50 mg/d.

Adrenocortical Hypo- and Hyperfunction

Congenital Adrenal Hyperplasia

This group of disorders is characterized by specific defects in the synthesis of cortisol. In pregnancies at high risk for congenital adrenal hyperplasia, fetuses can be protected from genital abnormalities by administration of dexamethasone to the mother. The most common defect is a decrease in or lack of P450c21 (21 β -hydroxylase) activity.*

* Names for the adrenal steroid synthetic enzymes include the following: P450c11 (11 β -hydroxylase) P450c17 (17 α -hydroxylase) P450c21 (21 β -hydroxylase)

As can be seen in Figure 39–1, this would lead to a reduction in cortisol synthesis and produce a compensatory increase in ACTH release. The gland becomes hyperplastic and produces abnormally large amounts of precursors such as 17-hydroxyprogesterone that can be diverted to the androgen pathway, leading to virilization. Metabolism of this compound in the liver leads to pregnanetriol, which is characteristically excreted into the urine in large amounts in this disorder and can be used to make the diagnosis and to monitor efficacy of glucocorticoid substitution. However, the most reliable method of detecting this disorder is the increased response of plasma 17-hydroxyprogesterone to ACTH stimulation.

If the defect is in 11-hydroxylation, large amounts of deoxycorticosterone are produced, and because this steroid has mineralocorticoid activity, hypertension with or without hypokalemic alkalosis ensues. When 17-hydroxylation is defective in the adrenals and gonads, hypogonadism is also present. However, increased amounts of 11-deoxycorticosterone (DOC; see Mineralocorticoids [Aldosterone, Deoxycorticosterone, Fludrocortisone]) are formed, and the signs and symptoms associated with mineralocorticoid excess—such as hypertension and hypokalemia—are also observed.

When first seen, the infant with congenital adrenal hyperplasia may be in acute adrenal crisis and should be treated as described above, using appropriate electrolyte solutions and an intravenous preparation of hydrocortisone in stress doses.

Once the patient is stabilized, oral hydrocortisone, 12–18 mg/m²/d in two unequally divided doses (two thirds in the morning, one third in late afternoon) is begun. The dosage is adjusted to allow normal growth and bone maturation and to prevent androgen excess. Alternate-day therapy with prednisone has also been used to achieve greater ACTH suppression without increasing growth inhibition. Fludrocortisone, 0.05–0.2 mg/d, should also be administered by mouth, with added salt to maintain normal blood pressure, plasma renin activity, and electrolytes.

Cushing's Syndrome

Cushing's syndrome is usually the result of bilateral adrenal hyperplasia secondary to an ACTH-secreting pituitary adenoma (Cushing's disease) but occasionally is due to tumors or nodular hyperplasia of the adrenal gland or ectopic production of ACTH by other tumors. The manifestations are those associated with the chronic presence of excessive glucocorticoids. When glucocorticoid hypersecretion is marked and prolonged, a rounded, plethoric face and trunk obesity are striking in appearance. The manifestations of protein loss are often found and include muscle wasting, thinning, purple color striae and easy bruising of the skin, poor wound healing, and osteoporosis. Other serious disturbances include mental disorders, hypertension, and diabetes. This disorder is treated by surgical removal of the tumor producing ACTH or cortisol, irradiation of the pituitary tumor, or resection of one or both adrenals. These patients must receive large doses of cortisol during and following the surgical procedure. Doses of up to 300 mg of soluble hydrocortisone may be given as a continuous intravenous infusion on the day of surgery. The dose must be reduced slowly to normal replacement levels, since rapid reduction in dose may produce withdrawal symptoms, including fever and joint pain. If adrenalectomy has been performed, long-term maintenance is similar to that outlined above for adrenal insufficiency.

Aldosteronism

Primary aldosteronism usually results from the excessive production of aldosterone by an adrenal adenoma. However, it may also result from abnormal secretion by hyperplastic glands or from a malignant tumor. The clinical findings of hypertension, weakness, and tetany are related to the

continued renal loss of potassium, which leads to hypokalemia, alkalosis, and elevation of serum sodium concentrations. This syndrome can also be produced in disorders of adrenal steroid biosynthesis by excessive secretion of deoxycorticosterone, corticosterone, or 18-hydroxycorticosterone—all compounds with inherent mineralocorticoid activity.

In contrast to patients with secondary aldosteronism (see below), these patients have low (suppressed) levels of plasma renin activity and angiotensin II. When treated with deoxycorticosterone acetate (20 mg/d intramuscularly for 3 days—no longer available in the USA) or fludrocortisone (0.2 mg twice daily orally for 3 days), they fail to retain sodium and their secretion of aldosterone is not significantly reduced. When the disorder is mild, it may escape detection when serum potassium levels are used for screening. However, it may be detected by an increased ratio of plasma aldosterone to renin. Patients are generally improved when treated with spironolactone, and the response to this agent is of diagnostic and therapeutic value.

Use of Glucocorticoids for Diagnostic Purposes

It is sometimes necessary to suppress the production of ACTH in order to identify the source of a particular hormone or to establish whether its production is influenced by the secretion of ACTH. In these circumstances, it is advantageous to employ a very potent substance such as dexamethasone because the use of small quantities reduces the possibility of confusion in the interpretation of hormone assays in blood or urine. For example, if complete suppression is achieved by the use of 50 mg of cortisol, the urinary 17-hydroxycorticosteroids will be 15–18 mg/24 h, since one third of the dose given will be recovered in urine as 17-hydroxycorticosteroid. If an equivalent dose of 1.5 mg of dexamethasone is employed, the urinary excretion will be only 0.5 mg/24 h and blood levels will be low.

The **dexamethasone suppression test** is used for the diagnosis of Cushing's syndrome and has also been used in the differential diagnosis of depressive psychiatric states. As a screening test, dexamethasone, 1 mg, is given orally at 11 PM, and a plasma sample is obtained in the morning. In normal individuals, the morning cortisol concentration is usually less than 3 $\mu\text{g/dL}$, whereas in Cushing's syndrome the level is usually greater than 5 $\mu\text{g/dL}$. The results are not reliable in the presence of depression, anxiety, concurrent illness, and other stressful conditions or if the patient receives a medication that enhances the catabolism of dexamethasone in the liver. To distinguish between hypercortisolism due to anxiety, depression, and alcoholism (pseudo-Cushing syndrome) and bona fide Cushing's syndrome, a combined test is carried out, consisting of dexamethasone (0.5 mg orally every 6 hours for 2 days) followed by a standard corticotropin-releasing hormone (CRH) test (1 mg/kg given as a bolus intravenous infusion 2 hours after the last dose of dexamethasone).

In patients in whom the diagnosis of Cushing's syndrome has been established clinically and confirmed by a finding of elevated free cortisol in the urine, suppression with large doses of dexamethasone will help to distinguish patients with Cushing's disease from those with steroid-producing tumors of the adrenal cortex or with the ectopic ACTH syndrome. Dexamethasone is given in a dosage of 0.5 mg orally every 6 hours for 2 days, followed by 2 mg orally every 6 hours for 2 days, and the urine is then assayed for cortisol or its metabolites (Liddle's test); or dexamethasone is given as a single dose of 8 mg at 11 PM and the plasma cortisol is measured at 8 AM the following day. In patients with Cushing's disease, the suppressant effect of dexamethasone will usually produce a 50% reduction in hormone levels. In patients in whom suppression does not occur, the ACTH level will be low in the presence of a cortisol-producing adrenal tumor and elevated in patients with an ectopic ACTH-producing tumor.

Corticosteroids and Stimulation of Lung Maturation in the Fetus

Lung maturation in the fetus is regulated by the fetal secretion of cortisol. Treatment of the mother with large doses of glucocorticoid reduces the incidence of respiratory distress syndrome in infants delivered prematurely. When delivery is anticipated before 34 weeks of gestation, intramuscular betamethasone, 12 mg, followed by an additional dose of 12 mg 18–24 hours later, is commonly used. Betamethasone is chosen because maternal protein binding and placental metabolism of this corticosteroid is less than that of cortisol, allowing increased transfer across the placenta to the fetus.

Corticosteroids and Nonadrenal Disorders

The synthetic analogs of cortisol are useful in the treatment of a diverse group of diseases unrelated to any known disturbance of adrenal function (Table 39–2). The usefulness of corticosteroids in these disorders is a function of their ability to suppress inflammatory and immune responses, as described above. In disorders in which host response is the cause of the major manifestations of the disease, these agents are useful. In instances where the inflammatory or immune response is important in controlling the pathologic process, therapy with corticosteroids may be dangerous but justified to prevent irreparable damage from an inflammatory response—if used in conjunction with specific therapy for the disease process.

Table 39–2. Some Therapeutic Indications for the Use of Glucocorticoids in Nonadrenal Disorders.

Disorder	Examples
Allergic reactions	Angioneurotic edema, asthma, bee stings, contact dermatitis, drug reactions, allergic rhinitis, serum sickness, urticaria
Collagen-vascular disorders	Giant cell arteritis, lupus erythematosus, mixed connective tissue syndromes, polymyositis, polymyalgia rheumatica, rheumatoid arthritis, temporal arteritis
Eye diseases	Acute uveitis, allergic conjunctivitis, choroiditis, optic neuritis
Gastrointestinal diseases	Inflammatory bowel disease, nontropical sprue, subacute hepatic necrosis
Hematologic disorders	Acquired hemolytic anemia, acute allergic purpura, leukemia, autoimmune hemolytic anemia, idiopathic thrombocytopenic purpura, multiple myeloma
Systemic inflammation	Acute respiratory distress syndrome; (sustained therapy with moderate dosage accelerates recovery and decreases mortality)
Infections	Gram-negative septicemia; (occasionally helpful to suppress excessive inflammation)
Inflammatory conditions of bones and joints	Arthritis, bursitis, tenosynovitis
Neurologic disorders	Cerebral edema (large doses of dexamethasone are given to patients following brain surgery to minimize cerebral edema in the postoperative period), multiple sclerosis
Organ transplants	Prevention and treatment of rejection (immunosuppression)

Pulmonary diseases	Aspiration pneumonia, bronchial asthma, prevention of infant respiratory distress syndrome, sarcoidosis
Renal disorders	Nephrotic syndrome
Skin diseases	Atopic dermatitis, dermatoses, lichen simplex chronicus (localized neurodermatitis), mycosis fungoides, pemphigus, seborrheic dermatitis, xerosis
Thyroid diseases	Malignant exophthalmos, subacute thyroiditis
Miscellaneous	Hypercalcemia, mountain sickness

Since the corticosteroids are not usually curative, the pathologic process may progress while clinical manifestations are suppressed. Therefore, chronic therapy with these drugs should be undertaken with great care and only when the seriousness of the disorder warrants their use and less hazardous measures have been exhausted.

In general, attempts should be made to bring the disease process under control using medium- to intermediate-acting glucocorticoids such as prednisone and prednisolone (Table 39–1), as well as all ancillary measures possible to keep the dose low. Where possible, alternate-day therapy should be utilized (see below). Therapy should not be decreased or stopped abruptly. When prolonged therapy is anticipated, it is helpful to obtain chest x-rays and a tuberculin test, since glucocorticoid therapy can reactivate dormant disease. The presence of diabetes, peptic ulcer, osteoporosis, and psychologic disturbances should be taken into consideration, and cardiovascular function should be assessed.

Toxicity

The benefits obtained from use of the glucocorticoids vary considerably. Use of these drugs must be carefully weighed in each patient against their widespread effects on every part of the organism. The major undesirable effects of the glucocorticoids are the result of their hormonal actions (see above), which lead to the clinical picture of iatrogenic Cushing's syndrome (see below).

When the glucocorticoids are used for short periods (less than 2 weeks), it is unusual to see serious adverse effects even with moderately large doses. However, insomnia, behavioral changes (primarily hypomania), and acute peptic ulcers are occasionally observed even after only a few days of treatment. Acute pancreatitis is a rare but serious acute adverse effect of high-dose glucocorticoids.

Metabolic Effects

Most patients who are given daily doses of 100 mg of hydrocortisone or more (or the equivalent amount of synthetic steroid) for longer than 2 weeks undergo a series of changes that have been termed iatrogenic Cushing's syndrome. The rate of development is a function of the dose and the genetic background of the patient. In the face, rounding, puffiness, fat deposition, and plethora usually appear (moon facies). Similarly, fat tends to be redistributed from the extremities to the trunk, the back of the neck, and the supraclavicular fossae. There is an increased growth of fine hair over the face, thighs and trunk. Steroid-induced punctate acne may appear, and insomnia and increased appetite are noted. In the treatment of dangerous or disabling disorders, these changes may not require cessation of therapy. However, the underlying metabolic changes accompanying them can be very serious by the time they become obvious. The continuing breakdown of protein

and diversion of amino acids to glucose production increase the need for insulin and over a period of time result in weight gain; visceral fat deposition; myopathy and muscle wasting; thinning of the skin, with striae and bruising; hyperglycemia; and eventually the development of osteoporosis, diabetes, and aseptic necrosis of the hip. Wound healing is also impaired under these circumstances. When diabetes occurs, it is treated by diet and insulin. These patients are often resistant to insulin but rarely develop ketoacidosis. In general, patients treated with corticosteroids should be on high-protein and potassium-enriched diets.

Other Complications

Other serious side effects include peptic ulcers and their consequences. The clinical findings associated with certain disorders, particularly bacterial and mycotic infections, may be masked by the corticosteroids, and patients must be carefully watched to avoid serious mishap when large doses are used. The frequency of severe myopathy is greater in patients treated with long-acting glucocorticoids. The administration of such compounds has been associated with nausea, dizziness, and weight loss in some patients. It is treated by changing drugs, reducing dosage, and increasing potassium and protein intake.

Hypomania or acute psychosis may occur, particularly in patients receiving very large doses of cortico-steroids. Long-term therapy with intermediate- and long-acting steroids is associated with depression and the development of posterior subcapsular cataracts. Psychiatric follow-up and periodic slit lamp examination is indicated in such patients. Increased intraocular pressure is common, and glaucoma may be induced. Benign intracranial hypertension also occurs. In dosages of 45 mg/m²/d or more of hydrocortisone or its equivalent, growth retardation occurs in children. Medium-, intermediate-, and long-acting glucocorticoids have greater growth-suppressing potency than the natural steroid at equivalent doses.

When given in greater than physiologic amounts, steroids such as cortisone and hydrocortisone, which have mineralocorticoid effects in addition to glucocorticoid effects, cause some sodium and fluid retention and loss of potassium. In patients with normal cardiovascular and renal function, this leads to a hypokalemic, hypochloremic alkalosis and eventually a rise in blood pressure. In patients with hypoproteinemia, renal disease, or liver disease, edema may also occur. In patients with heart disease, even small degrees of sodium retention may lead to heart failure. These effects can be minimized by using synthetic non-salt-retaining steroids, sodium restriction, and judicious amounts of potassium supplements.

Adrenal Suppression

When corticosteroids are administered for more than 2 weeks, adrenal suppression may occur. If treatment extends over weeks to months, the patient should be given appropriate supplementary therapy at times of minor stress (twofold dose increases for 24–48 hours) or severe stress (up to tenfold dose increases for 48–72 hours) such as accidental trauma or major surgery. If corticosteroid dosage is to be reduced, it should be tapered slowly. If therapy is to be stopped, the reduction process should be quite slow when the dose reaches replacement levels. It may take 2–12 months for the hypothalamic-pituitary-adrenal axis to function acceptably, and cortisol levels may not return to normal for another 6–9 months. The glucocorticoid-induced suppression is not a pituitary problem, and treatment with ACTH does not reduce the time required for the return of normal function.

If the dose is reduced too rapidly in patients receiving glucocorticoids for a certain disorder, the symptoms of the disorder may reappear or increase in intensity. However, patients without an

underlying disorder (eg, patients cured surgically of Cushing's disease) will also develop symptoms with rapid reductions in cortico-steroid levels. These symptoms include anorexia, nausea or vomiting, weight loss, lethargy, headache, fever, joint or muscle pain, and postural hypotension. Although many of these symptoms may reflect true glucocorticoid deficiency, they may also occur in the presence of normal or even elevated plasma cortisol levels, suggesting glucocorticoid dependence.

Contraindications & Cautions

Special Precautions

Patients receiving these drugs must be monitored carefully for the development of hyperglycemia, glycosuria, sodium retention with edema or hypertension, hypokalemia, peptic ulcer, osteoporosis, and hidden infections.

The dosage should be kept as low as possible, and intermittent administration (eg, alternate-day) should be employed when satisfactory therapeutic results can be obtained on this schedule. Even patients maintained on relatively low doses of corticosteroids may require supplementary therapy at times of stress, such as when surgical procedures are performed or intercurrent illness or accidents occur.

Contraindications

These agents must be used with great caution in patients with peptic ulcer, heart disease or hypertension with heart failure, certain infectious illnesses such as varicella and tuberculosis, psychoses, diabetes, osteoporosis, or glaucoma.

Selection of Drug & Dosage Schedule

Since these preparations differ with respect to relative anti-inflammatory and mineralocorticoid effect, duration of action, cost, and dosage forms available (Table 39-1), these factors should be taken into account in selecting the drug to be used.

ACTH Versus Adrenocortical Steroids

In patients with normal adrenals, ACTH was used to induce the endogenous production of cortisol to obtain similar effects. However, except when the increase in androgens is desirable, the use of ACTH as a therapeutic agent has been abandoned. Instances in which ACTH was claimed to be more effective than glucocorticoids were probably due to the administration of smaller amounts of corticosteroids than were produced by the dosage of ACTH.

Dosage

In determining the dosage regimen to be used, the physician must consider the seriousness of the disease, the amount of drug likely to be required to obtain the desired effect, and the duration of therapy. In some diseases, the amount required for maintenance of the desired therapeutic effect is less than the dose needed to obtain the initial effect, and the lowest possible dosage for the needed effect should be determined by gradually lowering the dose until a small increase in signs or symptoms is noted.

When it is necessary to maintain continuously elevated plasma corticosteroid levels in order to

suppress ACTH, a slowly absorbed parenteral preparation or small oral doses at frequent intervals are required. The opposite situation exists with respect to the use of corticosteroids in the treatment of inflammatory and allergic disorders. The same total quantity given in a few doses may be more effective than when given in many smaller doses or in a slowly absorbed parenteral form.

Severe autoimmune conditions involving vital organs must be treated aggressively, and undertreatment is as dangerous as overtreatment. In order to minimize the deposition of immune complexes and the influx of leukocytes and macrophages, 1 mg/kg/d of prednisone in divided doses is required initially. This dose is maintained until the serious manifestations respond. The dose can then be gradually reduced.

When large doses are required for prolonged periods of time, **alternate-day** administration of the compound may be tried after control is achieved. When used in this manner, very large amounts (eg, 100 mg of prednisone) can sometimes be administered with less marked adverse effects because there is a recovery period between each dose. The transition to an alternate-day schedule can be made after the disease process is under control. It should be done gradually and with additional supportive measures between doses. A typical schedule for a patient previously maintained on 50 mg of prednisone daily could be as follows:

Day 1: 50 mg
Day 2: 40 mg
Day 3: 60 mg
Day 4: 30 mg
Day 5: 70 mg
Day 6: 10 mg
Day 7: 75 mg
Day 8: 5 mg
Day 9: 70 mg
Day 10: 5 mg
Day 11: 65 mg
Day 12: 5 mg, etc

When selecting a drug for use in large doses, a medium- or intermediate-acting synthetic steroid with little mineralocorticoid effect is advisable. If possible, it should be given as a single morning dose.

Special Dosage Forms

The use of local therapy, such as topical preparations for skin disease, ophthalmic forms for eye disease, intra-articular injections for joint disease, inhaled steroids for asthma, and hydrocortisone enemas for ulcerative colitis, provides a means of delivering large amounts of steroid to the diseased tissue with reduced systemic effects.

Beclomethasone dipropionate and several other glucocorticoids—primarily budesonide and flunisolide and mometasone furoate, administered as aerosols—have been found to be effective in the treatment of asthma (see Chapter 20: Drugs Used in Asthma). The switch from therapy with systemic glucocorticoids to aerosol therapy must be undertaken with caution, since manifestations of glucocorticoid deficiency will appear if adrenal function has been suppressed. In such patients, a slow, graded reduction of systemic therapy and monitoring of endogenous adrenal function should accompany the institution of aerosol administration.

Beclomethasone dipropionate, triamcinolone acetonide, budesonide, flunisolide, and mometasone furoate are available as nasal sprays for the topical treatment of allergic rhinitis. They are effective at doses (one or two sprays one, two, or three times daily) that in most patients result in plasma levels too low to influence adrenal function or have any other systemic effects.

Corticosteroids incorporated in ointments, creams, lotions, and sprays are used extensively in dermatology. These preparations are discussed in more detail in Chapter 62: Dermatologic Pharmacology.

Mineralocorticoids (Aldosterone, Deoxycorticosterone, Fludrocortisone)

The most important mineralocorticoid in humans is aldosterone. However, small amounts of deoxycorticosterone (DOC) are also formed and released. Although the amount is normally insignificant, DOC was of some importance therapeutically in the past. Its actions, effects, and metabolism are qualitatively similar to those described below for aldosterone.

Fludrocortisone, a synthetic corticosteroid, is the most commonly prescribed salt-retaining hormone.

Aldosterone

Aldosterone is synthesized mainly in the zona glomerulosa of the adrenal cortex. Its structure and synthesis are illustrated in Figure 39–1.

The rate of aldosterone secretion is subject to several influences. ACTH produces a moderate stimulation of its release, but this effect is not sustained for more than a few days in the normal individual. Although aldosterone is no less than one third as effective as cortisol in suppressing ACTH, the quantities of aldosterone produced by the adrenal cortex and its plasma concentrations are insufficient to participate in any significant feedback control of ACTH secretion.

In the absence of ACTH, aldosterone secretion falls to about half the normal rate, indicating that other factors, eg, angiotensin, are able to maintain and perhaps regulate its secretion (see Chapter 17: Vasoactive Peptides). Independent variations between cortisol and aldosterone secretion can also be demonstrated by means of lesions in the nervous system such as decerebration, which decreases the secretion of cortisol while increasing the secretion of aldosterone.

Physiologic & Pharmacologic Effects

Aldosterone and other steroids with mineralocorticoid properties promote the reabsorption of sodium from the distal convoluted and cortical collecting renal tubules, loosely coupled to the excretion of potassium and hydrogen ion. Sodium reabsorption in the sweat and salivary glands, gastrointestinal mucosa, and across cell membranes in general is also increased. Excessive levels of aldosterone produced by tumors or overdosage with synthetic mineralocorticoids lead to hypernatremia, hypokalemia, metabolic alkalosis, increased plasma volume, and hypertension.

Mineralocorticoids act by binding to the mineralocorticoid receptor in the cytoplasm of target cells, especially principal cells of the distal convoluted and collecting tubules of the kidney. The drug-receptor complex activates a series of events similar to those described above for the glucocorticoids and illustrated in Figure 39–3. It is of interest that this receptor has the same affinity for cortisol, which is present in much higher concentrations in the extracellular fluid. The specificity for mineralocorticoids at this site appears to be conferred, at least in part, by the presence of the

enzyme 11 β -hydroxysteroid dehydrogenase, which converts cortisol to cortisone. The latter has low affinity for the receptor and is inactive as a mineralocorticoid or glucocorticoid.

Metabolism

Aldosterone is secreted at the rate of 100–200 $\mu\text{g}/\text{d}$ in normal individuals with a moderate dietary salt intake. The plasma level in men (resting supine) is about 0.007 $\mu\text{g}/\text{dL}$. The half-life of aldosterone injected in tracer quantities is 15–20 minutes, and it does not appear to be firmly bound to serum proteins.

The metabolism of aldosterone is similar to that of cortisol, about 50 $\mu\text{g}/24\text{ h}$ appearing in the urine as conjugated tetrahydroaldosterone. Approximately 5–15 $\mu\text{g}/24\text{ h}$ is excreted free or as the 3-oxo glucuronide.

Deoxycorticosterone (DOC)

DOC, which also serves as a precursor of aldosterone (Figure 39–1), is normally secreted in amounts of about 200 $\mu\text{g}/\text{d}$. Its half-life when injected into the human circulation is about 70 minutes. Preliminary estimates of its concentration in plasma are approximately 0.03 $\mu\text{g}/\text{dL}$. The control of its secretion differs from that of aldosterone in that the secretion of DOC is primarily under the control of ACTH. Although the response to ACTH is enhanced by dietary sodium restriction, a low-salt diet does not increase DOC secretion. The secretion of DOC may be markedly increased in abnormal conditions such as adrenocortical carcinoma and congenital adrenal hyperplasia with reduced P450c11 or P450c17 activity.

Fludrocortisone

This compound, a potent steroid with both glucocorticoid and mineralocorticoid activity, is the most widely used mineralocorticoid. Doses of 0.1 mg two to seven times weekly have potent salt-retaining activity and are used in the treatment of adrenocortical insufficiency associated with mineralocorticoid deficiency. These dosages are too small to have important anti-inflammatory or antigrowth effects.

Adrenal Androgens

The adrenal cortex secretes large amounts of dehydroepiandrosterone (DHEA) and smaller amounts of androstenedione and testosterone. Although these androgens are thought to contribute to the normal maturation process, they do not stimulate or support major androgen-dependent pubertal changes in humans. Recent studies suggest that DHEA and its sulfate (DHEAS) may have other important physiologic actions (see also Chapter 65: Botanicals ("Herbal Medications") & Nutritional Supplements). If that is correct, these results are probably due to the peripheral conversion of DHEA to more potent androgens or to estrogens and interaction with androgen and estrogen receptors, respectively. Additional effects may be exerted through an interaction with the GABA_A and glutamate receptors in the brain or with a newly discovered nuclear receptor in several central and peripheral sites. The therapeutic use of DHEA in humans is being explored, but the substance has already been adopted with uncritical enthusiasm by members of the sports drug culture and the vitamin and food supplement culture. The results of a placebo-controlled trial of DHEA in patients with systemic lupus erythematosus were recently reported as well as those of a study of DHEA replacement in women with adrenal insufficiency. In both studies a beneficial effect was seen, with significant improvement of the disease in the former and a clearly added sense of well-being in the latter. The androgenic or estrogenic actions of DHEA could explain the effects of

the compound in both situations.

Adrenocorticosteroids & Adrenocortical Antagonists >

Antagonists of Adrenocortical Agents

Synthesis Inhibitors & Glucocorticoid Antagonists

Metyrapone

Metyrapone (Figure 39–5) is a relatively selective inhibitor of steroid synthesis. It inhibits 11-hydroxylation, interfering with cortisol and corticosterone synthesis. In the presence of a normal pituitary gland, there is a compensatory increase in 11-deoxycortisol secretion. This response is a measure of the capacity of the anterior pituitary to produce ACTH and has been adapted for clinical use as a diagnostic test. Although the toxicity of metyrapone is much lower than that of mitotane (see below), the drug may produce transient dizziness and gastrointestinal disturbances. This agent has not been widely used for the treatment of Cushing's syndrome. However, in doses of 0.25 g twice daily to 1 g four times daily, metyrapone can reduce cortisol production to normal levels in some patients with endogenous Cushing's syndrome. Thus, it may be useful in the management of severe manifestations of cortisol excess while the cause of this condition is being determined or in conjunction with radiation or surgical treatment. It is the only adrenal-inhibiting medication that can be administered to pregnant women with Cushing's syndrome. The major adverse effects observed are salt and water retention and hirsutism resulting from diversion of the 11-deoxycortisol precursor to DOC and androgen synthesis.

Figure 39–5.

Amphenone B

Metyrapone

Mitotane

Aminoglutethimide

Ketoconazole

Some adrenocortical antagonists. Because of their toxicity, several of these compounds are no longer available in the USA.

Metyrapone is commonly used in tests of adrenal function. The blood levels of 11-deoxycortisol and the urinary excretion of 17-hydroxycorticoids are measured before and after administration of the compound. Normally, there is a twofold or greater increase in the urinary 17-hydroxycorticoid excretion. A dose of 300–500 mg every 4 hours for six doses is often used, and urine collections are made on the day before and the day after treatment. In patients with Cushing's syndrome, a normal response to metyrapone indicates that the cortisol excess is not the result of a cortisol-secreting adrenal carcinoma or adenoma, since secretion by such tumors produces suppression of ACTH and atrophy of normal adrenal cortex.

Adrenal function may also be tested by administering metyrapone, 2–3 g orally at midnight, and measuring the level of ACTH or 11-deoxycortisol in blood drawn at 8 AM, or by comparing the excretion of 17-hydroxycorticosteroids in the urine during the 24-hour periods preceding and following administration of the drug. In patients with suspected or known lesions of the pituitary, this procedure is a means of estimating the ability of the gland to produce ACTH. The drug has been withdrawn from the market in the USA but is available on a compassionate basis.

Aminoglutethimide

Aminoglutethimide (Figure 39–5) blocks the conversion of cholesterol to pregnenolone and causes a reduction in the synthesis of all hormonally active steroids (Figure 39–1). It has been used in conjunction with dexamethasone or hydrocortisone to reduce or eliminate estrogen production in patients with carcinoma of the breast. In a dosage of 1 g/d it was well tolerated; however, with higher dosages, lethargy and skin rash was a common effect. The use of aminoglutethimide in breast cancer patients has now been supplanted by the use of tamoxifen, an estrogen antagonist or another class of drugs, the aromatase inhibitors (see Chapter 40: The Gonadal Hormones & Inhibitors). Aminoglutethimide can be used in conjunction with metyrapone or ketoconazole to reduce steroid secretion in patients with Cushing's syndrome due to adrenocortical cancer who do not respond to mitotane.

Aminoglutethimide also apparently increases the clearance of some steroids. It has been shown to enhance the metabolism of dexamethasone, reducing its half-life from 4–5 hours to 2 hours.

Ketoconazole

Ketoconazole, an antifungal imidazole derivative (see Chapter 48: Antifungal Agents), is a potent and rather nonselective inhibitor of adrenal and gonadal steroid synthesis. This compound inhibits the cholesterol side chain cleavage, P450c17, C17,20-lyase, 3 β -hydroxysteroid dehydrogenase, and P450c11 enzymes required for steroid hormone synthesis. The sensitivity of the P450 enzymes to this compound in mammalian tissues is much lower than that needed to treat fungal infections, so that its inhibitory effects on steroid biosynthesis are seen only at high doses.

Ketoconazole has been used for the treatment of patients with Cushing's syndrome due to several causes. Dosages of 200–1200 mg/d have produced a reduction in hormone levels and impressive clinical improvement. This drug has some hepatotoxicity and should be started at 200 mg/d and slowly increased by 200 mg/d every 2–3 days up to a total daily dose of 1000 mg.

Mifepristone (RU 486)

The search for a glucocorticoid receptor antagonist finally succeeded in the early 1980s with the development of the 11 β -aminophenyl-substituted 19-norsteroid called RU 486, later named mifepristone. This compound has strong antiprogestin activity and initially was proposed as a contraceptive-contragestive agent. High doses of mifepristone exert antiglucocorticoid activity by blocking the glucocorticoid receptor, since mifepristone binds to it with high affinity, causing (1) some stabilization of the Hsp-glucocorticoid receptor complex and, thus, inhibition of the dissociation of the RU 486-bound glucocorticoid receptor from the Hsp chaperone proteins; and (2) alteration of the interaction of the glucocorticoid receptor with coregulators, favoring the formation of a transcriptionally inactive complex in the cell nucleus. The result is inhibition of glucocorticoid receptor activation.

The mean half-life of mifepristone is 20 hours. This is longer than that of many natural and synthetic glucocorticoid agonists (dexamethasone has a half-life of 4–5 hours). Less than 1% of the daily dose is excreted in the urine, suggesting a minor role of kidneys in the clearance of the compound. The long plasma half-life of mifepristone results from extensive and strong binding to plasma proteins. Less than 5% of the compound is found in the free form when plasma is analyzed by equilibrium dialysis. Mifepristone can bind to albumin and α_1 -acid glycoprotein, but it has no affinity for CBG.

In humans, mifepristone causes generalized glucocorticoid resistance. Given orally to several patients with Cushing's syndrome due to ectopic ACTH production or adrenal carcinoma, it was

able to reverse the cushingoid phenotype, to eliminate carbohydrate intolerance, normalize blood pressure, correct thyroid and gonadal hormone suppression, and ameliorate the psychologic sequelae of hypercortisolism in these patients. To date, the application of mifepristone can only be recommended for inoperable patients with ectopic ACTH secretion or adrenal carcinoma who have failed to respond to other therapeutic manipulations. Its pharmacology and use in women as a progesterone antagonist are discussed in Chapter 40: The Gonadal Hormones & Inhibitors.

Mitotane

Mitotane (Figure 39–5) has adrenolytic properties in dogs and to a lesser extent in humans. This drug is administered orally in divided doses up to 12 g daily. About one-third of patients with adrenal carcinoma show a reduction in tumor mass. In 80% of patients, the toxic effects are sufficiently severe to require dose reduction. These include diarrhea, nausea, vomiting, depression, somnolence, and skin rashes. The drug has been withdrawn from the market in the USA but is available on a compassionate basis.

Trilostane

Trilostane is a 3 β -17 hydroxysteroid dehydrogenase inhibitor that interferes with the synthesis of adrenal and gonadal hormones and is comparable to aminoglutethimide. Its side effects are predominantly gastrointestinal; adverse effects occur in about 50% of patients with both agents. There is no cross-resistance or crossover of side effects between these compounds.

Mineralocorticoid Antagonists

In addition to agents that interfere with aldosterone synthesis (see above), there are steroids that compete with aldosterone for binding sites and decrease its effect peripherally. Progesterone is mildly active in this respect.

Spirolactone is a 7 α -acetylthiospirolactone. Its onset of action is slow, and the effects last for 2–3 days after the drug is discontinued. It is used in the treatment of primary aldosteronism in dosages of 50–100 mg/d. This agent reverses many of the manifestations of aldosteronism. It has been useful in establishing the diagnosis in some patients and in ameliorating the signs and symptoms when surgical removal of an adenoma is delayed. When used diagnostically for the detection of aldosteronism in hypokalemic patients with hypertension, dosages of 400–500 mg/d for 4–8 days—with an adequate intake of sodium and potassium—will restore potassium levels to or toward normal. This agent is also useful in preparing these patients for surgery. Dosages of 300–400 mg/d for 2 weeks are used for this purpose and may reduce the incidence of cardiac arrhythmias.

Spirolactone is also an androgen antagonist and as such is used in treatment of hirsutism in women. Dosages of 50–200 mg/d cause a reduction in the density, diameter, and rate of growth of facial hair in patients with idiopathic hirsutism or hirsutism secondary to androgen excess. The effect can usually be seen in 2 months and becomes maximal in about 6 months.

The use of spironolactone as a diuretic is discussed in Chapter 15: Diuretic Agents. The drug has benefits in heart failure greater than those predicted from its diuretic effects alone (see Chapter 13: Drugs Used in Heart Failure). Adverse effects reported for spironolactone include hyperkalemia, cardiac arrhythmia, menstrual abnormalities, gynecomastia, sedation, headache, gastrointestinal disturbances, and skin rashes.

Eplerenone, a new aldosterone antagonist, has been approved for the treatment of hypertension (see Chapter 11: Antihypertensive Agents). This aldosterone receptor antagonist is somewhat more selective than spironolactone and has no reported effects on androgen receptors. The standard dosage in hypertension is 50–100 mg/d. The most common toxicity is hyperkalemia but this is usually mild.

Drospirenone, a progestin in a new oral contraceptive, also antagonizes the effects of aldosterone.

Katzung PHARMACOLOGY, 9e > Section VII. Endocrine Drugs > Chapter 39.
Adrenocorticosteroids & Adrenocortical Antagonists >

Preparations Available¹

Glucocorticoids for Oral & Parenteral Use

Betamethasone (Celestone)

Oral: 0.6 mg tablets; 0.6 mg/5 mL syrup

Betamethasone sodium phosphate (Celestone Phosphate)

Parenteral: 4 mg/mL for IV, IM, intralesional, or intra-articular injection

Cortisone (generic, Cortone Acetate)

Oral: 5, 10, 25 mg tablets

Parenteral: 50 mg/mL solution

Dexamethasone (generic, Decadron, others)

Oral: 0.25, 0.5, 0.75, 1, 1.5, 2, 4, 6 mg tablets; 0.5 mg/5 mL elixir; 0.5 mg/5 mL, 0.5 mg/0.5 mL solution

Dexamethasone acetate (generic, Decadron-LA, others)

Parenteral: 8 mg/mL suspension for IM, intralesional, or intra-articular injection; 16 mg/mL suspension for intralesional injection

Dexamethasone sodium phosphate (generic, Decadron Phosphate, others)

Parenteral: 4, 10, 20 mg/mL for IV, IM, intralesional, or intra-articular injection; 24 mg/mL for IV use only

Hydrocortisone [cortisol] (generic, Cortef)

Oral: 5, 10, 20 mg tablets

Hydrocortisone acetate (generic)

Parenteral: 25, 50 mg/mL suspension for intralesional, soft tissue, or intra-articular injection

Hydrocortisone cypionate (Cortef)

Oral: 10 mg/5 mL suspension

Hydrocortisone sodium phosphate (Hydrocortone)

Parenteral: 50 mg/mL for IV, IM, or SC injection

Hydrocortisone sodium succinate (generic, Solu- Cortef)

Parenteral: 100, 250, 500, 1000 mg/vial for IV, IM injection

Methylprednisolone (generic, Medrol)

Oral: 2, 4, 8, 16, 24, 32 mg tablets

Methylprednisolone acetate (generic, Depo- Medrol)

Parenteral: 20, 40, 80 mg/mL for IM, intralesional, or intra-articular injection

Methylprednisolone sodium succinate (generic, Solu-Medrol)

Parenteral: 40, 125, 500, 1000, 2000 mg/vial for injection

Prednisolone (generic, Delta-Cortef, Prelone)

Oral: 5 mg tablets; 5, 15 mg/5 mL syrup

Prednisolone acetate (generic)

Parenteral: 25, 50 mg/mL for soft tissue or intra-articular injection

Prednisolone sodium phosphate (Hydeltrasol, others)

Oral: 5 mg/5 mL solution

Parenteral: 20 mg/mL for IV, IM, intra-articular, or intralesional injection

Prednisolone tebutate (generic)

Oral: 5 mg/5 mL liquid

Parenteral: 20 mg/mL for intra-articular or intralesional injection

Prednisone (generic, Meticorten)

Oral: 1, 2.5, 5, 10, 20, 50 mg tablets; 1, 5 mg/mL solution and syrup

Triamcinolone (generic, Aristocort, Kenacort)

Oral: 4, 8 mg tablets; 4 mg/5 mL syrup

Triamcinolone acetonide (generic, Kenalog)

Parenteral: 3, 10, 40 mg/mL for IM, intra-articular, or intralesional injection

Triamcinolone diacetate (generic)

Parenteral: 25, 40 mg/mL for IM, intra-articular, or intralesional injection

Triamcinolone hexacetonide (Aristospan)

Parenteral: 5, 20 mg/mL for intra-articular, intralesional, or sublesional injection

Mineralocorticoids

Fludrocortisone acetate (generic, Florinef Acetate)

Oral: 0.1 mg tablets

Adrenal Steroid Inhibitors

Aminoglutethimide (Cytadren)

Oral: 250 mg tablets

Ketoconazole (generic, Nizoral)

Oral: 200 mg tablets (unlabeled use)

Mitotane (Lysodren)

Oral: 500 mg tablets

¹ Glucocorticoids for Aerosol Use: See Chapter 20: Drugs Used in Asthma. Glucocorticoids for Dermatologic Use: See Chapter 62: Dermatologic Pharmacology. Glucocorticoids for Gastrointestinal Use: See Chapter 63: Drugs Used in the Treatment of Gastrointestinal Diseases.

Chapter 40. The Gonadal Hormones & Inhibitors

Acronyms

ACTH: Adrenocorticotrophic hormone

AST: Aspartate aminotransferase

CBG: Corticosteroid-binding globulin (transcortin)

DHEA: Dehydroepiandrosterone

DHEAS: Dehydroepiandrosterone sulfate

ERE: Estrogen response element

FSH: Follicle-stimulating hormone

GnRH: Gonadotropin-releasing hormone

hCG: Human chorionic gonadotropin

hMG: Human menopausal gonadotropin

HRT: Hormone replacement therapy

LH: Luteinizing hormone

LHRH: Luteinizing hormone-releasing hormone (synonym of GnRH)

PRE: Progesterone response element

SERM: Selective estrogen receptor modulator

SHBG: Sex hormone-binding globulin

TBG: Thyroxine-binding globulin

The Ovary (Estrogens, Progestins, Other Ovarian Hormones, Oral Contraceptives, Inhibitors & Antagonists, & Ovulation-Inducing Agents)

The ovary has important gametogenic functions that are integrated with its hormonal activity. In the human female, the gonad is relatively quiescent during childhood, the period of rapid growth and maturation. At puberty, the ovary begins a 30- to 40-year period of cyclic function called the **menstrual cycle** because of the regular episodes of bleeding that are its most obvious manifestation. It then fails to respond to gonadotropins secreted by the anterior pituitary gland, and the cessation of cyclic bleeding that occurs is called the **menopause**.

The mechanism responsible for the onset of ovarian function at the time of puberty is thought to be neural in origin, because the immature gonad can be stimulated by gonadotropins already present in the pituitary and because the pituitary is responsive to exogenous hypothalamic gonadotropin-releasing hormone. The maturation of centers in the brain may withdraw a childhood-related inhibitory effect upon hypothalamic arcuate nucleus neurons, allowing them to produce **gonadotropin-releasing hormone (GnRH)** in pulses with the appropriate amplitude, which stimulates the release of **follicle-stimulating hormone (FSH)** and **luteinizing hormone (LH)** (see

Chapter 37: Hypothalamic & Pituitary Hormones). At first, small amounts of the latter two hormones are released during the night, and the limited quantities of ovarian estrogen secreted in response start to cause breast development. Subsequently, FSH and LH are secreted throughout the day and night, causing secretion of higher amounts of estrogen and leading to further breast enlargement, alterations in fat distribution, and a growth spurt that culminates in epiphyseal closure in the long bones. The beginning of ovarian function at puberty is called **gonadarche**.

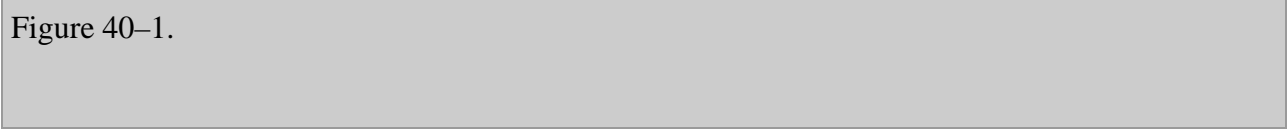

A year or so after gonadarche, sufficient estrogen is produced to induce endometrial changes and periodic bleeding. After the first few irregular cycles, which may be anovulatory, normal cyclic function is established.

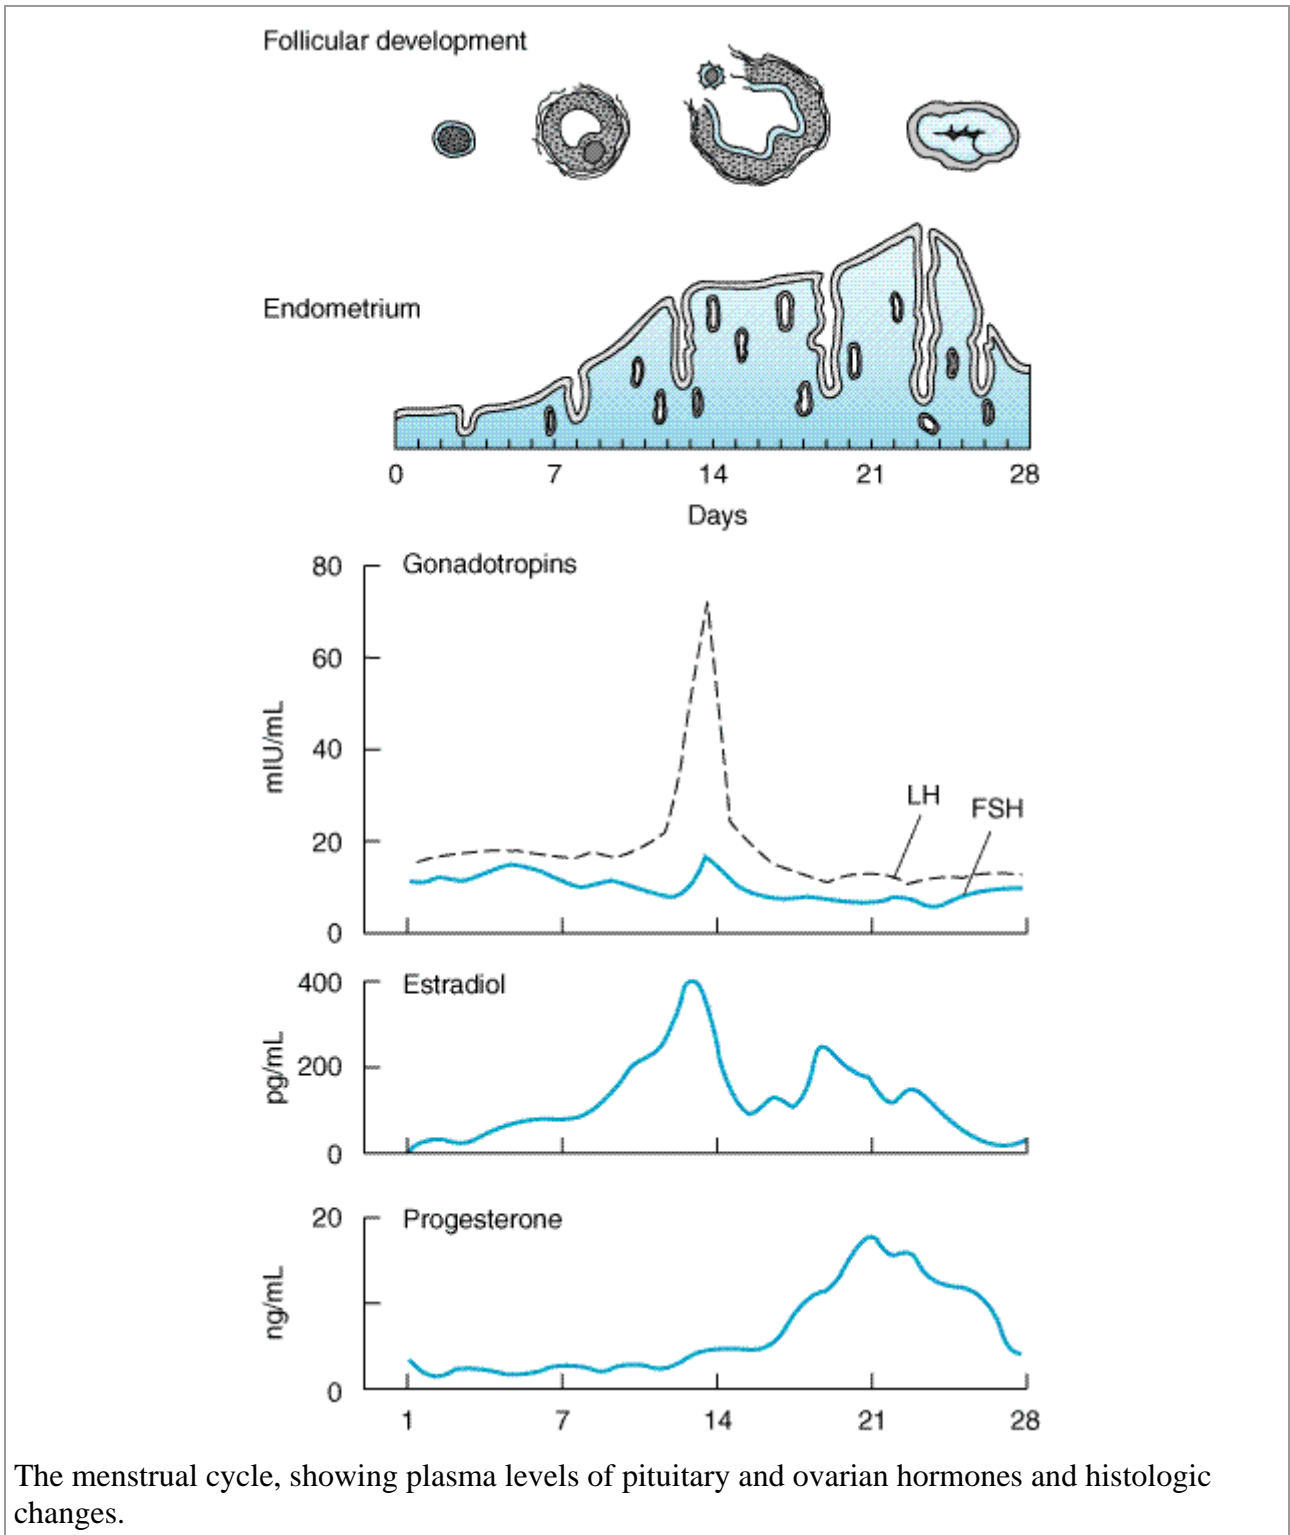

At the beginning of each cycle, a variable number of follicles (vesicular follicles), each containing an ovum, begin to enlarge in response to FSH. After 5 or 6 days, one follicle, called the dominant follicle, begins to develop more rapidly. The outer theca and inner granulosa cells of this follicle multiply and, under the influence of LH, synthesize and release estrogens at an increasing rate. The estrogens appear to inhibit FSH release and may lead to regression of the smaller, less mature follicles. The mature dominant ovarian follicle consists of an ovum surrounded by a fluid-filled antrum lined by granulosa and theca cells. The estrogen secretion reaches a peak just before midcycle, and the granulosa cells begin to secrete progesterone. These changes stimulate the brief surge in LH and FSH release that precedes and causes ovulation. When the follicle ruptures, the ovum is released into the abdominal cavity near the opening of the uterine tube.

Following the above events, the cavity of the ruptured follicle fills with blood (corpus hemorrhagicum), and the luteinized theca and granulosa cells proliferate and replace the blood to form the corpus luteum. The cells of this structure produce estrogens and progesterone for the remainder of the cycle, or longer if pregnancy occurs.

If pregnancy does not occur, the corpus luteum begins to degenerate and ceases hormone production, eventually becoming a corpus albicans. The endometrium, which proliferated during the follicular phase and developed its glandular function during the luteal phase, is shed in the process of menstruation. These events are summarized in Figure 40–1.

Figure 40–1.

The menstrual cycle, showing plasma levels of pituitary and ovarian hormones and histologic changes.

The ovary normally ceases its gametogenic and endocrine function with time. This change is accompanied by a cessation in uterine bleeding (menopause) and occurs at a mean age of 52 years in the USA. Although the ovary ceases to secrete estrogen, significant levels of estrogen persist in many women as a result of conversion of adrenal and ovarian steroids such as androstenedione to estrone and estradiol in adipose and possibly other nonendocrine tissues.

Disturbances in Ovarian Function

Disturbances of cyclic function are common even during the peak years of reproduction. A minority

of these result from inflammatory or neoplastic processes that influence the functions of the uterus, ovaries, or pituitary. Many of the minor disturbances leading to periods of amenorrhea or anovulatory cycles are self-limited. They are often associated with emotional or physical stress and represent temporary alterations in the stress centers in the brain that control the secretion of gonadotropin-releasing hormone. Anovulatory cycles are also associated with eating disorders (bulimia, anorexia nervosa) and with severe exercise such as distance running and swimming. Among the more common organic causes of persistent ovulatory disturbances are pituitary prolactinomas and syndromes and tumors characterized by excessive ovarian or adrenal androgen production. Normal ovarian function can be modified by androgens produced by the adrenal cortex or tumors arising from it. The ovary also gives rise to androgen-producing neoplasms such as arrhenoblastomas, as well as to estrogen-producing granulosa cell tumors.

The Estrogens

Estrogenic activity is shared by a large number of chemical substances. In addition to the variety of steroidal estrogens derived from animal sources, numerous nonsteroidal estrogens have been synthesized. Many phenols are estrogenic, and estrogenic activity has been identified in such diverse forms of life as those found in ocean sediments. Estrogen-mimetic compounds (flavonoids) are found in many plants, including saw palmetto, and soybeans and other foods. Studies have shown that eating these plant products may produce slight estrogenic effects. Additionally, some compounds used in the manufacture of plastics (bisphenols, alkylphenols, phthalate phenols) have been found to be estrogenic. It has been proposed that these agents are associated with an increased breast cancer incidence in both women and men in the industrialized world.

Natural Estrogens

The major estrogens produced by women are estradiol (estradiol-17 β , E₂), estrone (E₁), and estriol (E₃) (Figure 40–2). Estradiol is the major secretory product of the ovary. Although some estrone is produced in the ovary, most estrone and estriol are formed in the liver from estradiol or in peripheral tissues from androstenedione and other androgens. As noted above, during the first part of the menstrual cycle estrogens are produced in the ovarian follicle by the theca and granulosa cells. After ovulation, the estrogens as well as progesterone are synthesized by the luteinized granulosa and theca cells of the corpus luteum, and the pathways of biosynthesis are slightly different.

Figure 40–2.

During pregnancy, a large amount of estrogen is synthesized by the fetoplacental unit—consisting of the fetal adrenal zone, secreting androgen precursor, and the placenta, which aromatizes it into estrogen. The estriol synthesized by the fetoplacental unit is released into the maternal circulation and excreted into the urine. Repeated assay of maternal urinary estriol excretion has been used in the assessment of fetal well-being.

One of the most prolific natural sources of estrogenic substances is the stallion, which liberates more of these hormones than the pregnant mare or pregnant woman. The equine estrogens—equilenin and equilin—and their congeners are unsaturated in the B as well as the A ring and are

excreted in large quantities in urine, from which they can be recovered and used for medicinal purposes.

In normal women, estradiol is produced at a rate that varies during the menstrual cycle, resulting in plasma levels as low as 50 pg/mL in the early follicular phase to as high as 350–850 pg/mL at the time of the preovulatory peak (Figure 40–1).

Synthetic Estrogens

A variety of chemical alterations have been produced in the natural estrogens. The most important effect of these alterations has been to increase the oral effectiveness of the estrogens. Some structures are shown in Figure 40–3. Those with therapeutic use are listed in Table 40–1.

Figure 40–3.

Compounds with estrogenic activity.

Table 40–1. Commonly Used Estrogens.

	Average Replacement Dosage
Ethinyl estradiol	0.005–0.02 mg/d
Micronized estradiol	1–2 mg/d
Estradiol cypionate	2–5 mg every 3–4 weeks
Estradiol valerate	2–20 mg every other week
Estropipate	1.25–2.5 mg/d
Conjugated, esterified, or mixed estrogenic substances:	
Oral	0.3–1.25 mg/d
Injectable	0.2–2 mg/d
Transdermal	Patch
Diethylstilbestrol	0.1–0.5 mg/d
Quinestrol	0.1–0.2 mg/week
Chlorotrianisene	12–25 mg/d
Methallenestril	3–9 mg/d

In addition to the steroidal estrogens, a variety of nonsteroidal compounds with estrogenic activity have been synthesized and used clinically. These include dienestrol, diethylstilbestrol, benzestrol, hexestrol, methestrol, methallenestril, and chlorotrianisene (Figure 40–3).

Pharmacokinetics

When released into the circulation, estradiol binds strongly to an α_2 -globulin (sex hormone-binding globulin [SHBG]) and to albumin with lower affinity. Bound estrogen is relatively unavailable for diffusion into cells, so it is the free fraction that is physiologically active. Estradiol is converted by the liver and other tissues to estrone and estriol (which have low affinity for the estrogen receptor) and their 2-hydroxylated derivatives and conjugated metabolites (which are too insoluble in lipid to cross the cell membrane readily) and excreted in the bile (Figure 40–2). However, the conjugates may be hydrolyzed in the intestine to active, reabsorbable compounds. Estrogens are also excreted in small amounts in the breast milk of nursing mothers.

Because significant amounts of estrogens and their active metabolites are excreted in the bile and reabsorbed from the intestine, the resulting enterohepatic circulation ensures that orally administered estrogens will have a high ratio of hepatic to peripheral effects. As noted below, the hepatic effects are thought to be responsible for some undesirable actions such as synthesis of increased clotting factors and plasma renin substrate. The hepatic effects of estrogen can be minimized by routes that avoid first-pass liver exposure, ie, vaginal, transdermal, or by injection.

Physiologic Effects

Mechanism

Plasma estrogens in the blood and interstitial fluid are bound to sex hormone-binding globulin, from which they dissociate to enter the cell and bind to their receptor. Two genes code for two estrogen receptor isoforms, α and β , which are members of the superfamily of steroid, sterol, retinoic acid, and thyroid receptors. The estrogen receptors are found predominantly in the nucleus bound to heat shock proteins that stabilize them (Figure 39–3).

Binding of the hormone to its receptor alters its conformation and releases it from the stabilizing proteins (predominantly Hsp90). The receptor-hormone complex forms homodimers that bind to a specific sequence of nucleotides called estrogen response elements (EREs) in the promoters of various genes and regulate their transcription. The ERE is composed of two half-sites arranged as a palindrome separated by a small group of nucleotides called the spacer. The interaction of a receptor dimer with the ERE also involves a number of nuclear proteins, the coregulators, as well as components of the transcription machinery. The receptor may also bind to other transcription factors to influence the effects of these factors on their responsive genes.

The relative concentrations and types of receptors, receptor coregulators, and transcription factors confer the cell specificity of the hormone's actions. The genomic effects of estrogens are mainly due to proteins synthesized by translation of RNA transcribed from a responsive gene. Some of the effects of estrogens are indirect, mediated by the autocrine and paracrine actions of autacoids such as growth factors, lipids, glycolipids, and cytokines produced by the target cells in response to estrogen.

Rapid estrogen-induced effects such as granulosa cell Ca^{2+} uptake and increased uterine blood flow do not require gene activation. These appear to be mediated by nongenomic effects of the classic estrogen receptor-estrogen complex, influencing several intracellular signaling pathways.

Female Maturation

Estrogens are required for the normal sexual maturation and growth of the female. They stimulate the development of the vagina, uterus, and uterine tubes as well as the secondary sex characteristics. They stimulate stromal development and ductal growth in the breast and are responsible for the accelerated growth phase and the closing of the epiphyses of the long bones that occur at puberty. They contribute to the growth of axillary and pubic hair and alter the distribution of body fat to produce typical female body contours. Larger quantities also stimulate development of pigmentation in the skin, most prominent in the region of the nipples and areolae and in the genital region.

Endometrial Effects

In addition to its growth effects on uterine muscle, estrogen also plays an important role in the development of the endometrial lining. When estrogen production is properly coordinated with the production of progesterone during the normal human menstrual cycle, regular periodic bleeding and shedding of the endometrial lining occur. Continuous exposure to estrogens for prolonged periods leads to hyperplasia of the endometrium that is usually associated with abnormal bleeding patterns.

Metabolic and Cardiovascular Effects

Estrogens have a number of important metabolic and cardiovascular effects. They seem to be partially responsible for maintenance of the normal structure and function of the skin and blood vessels in women. Estrogens also decrease the rate of resorption of bone by promoting the apoptosis of osteoclasts and by antagonizing the osteoclastogenic and pro-osteoclastic effects of parathyroid

hormone and interleukin-6. Estrogens also stimulate adipose tissue production of leptin and are in part responsible for the higher levels of this hormone in women than in men.

In addition to stimulating the synthesis of enzymes and growth factors leading to uterine and breast growth and differentiation, estrogens alter the production and activity of many other proteins in the body. Metabolic alterations in the liver are especially important, so that there is a higher circulating level of proteins such as transcortin (CBG), thyroxine-binding globulin (TBG), sex hormone-binding globulin (SHBG), transferrin, renin substrate, and fibrinogen. This leads to increased circulating levels of thyroxine, estrogen, testosterone, iron, copper, and other substances.

Alterations in the composition of the plasma lipids caused by estrogens are characterized by an increase in the high-density lipoproteins, a slight reduction in the low-density lipoproteins, and a reduction in plasma cholesterol levels. Plasma triglyceride levels are increased. Estrogens decrease hepatic oxidation of adipose tissue lipid to ketones and increase synthesis of triglycerides.

Effects on Blood Coagulation

Estrogens enhance the coagulability of blood. Many changes in factors influencing coagulation have been reported, including increased circulating levels of factors II, VII, IX, and X and decreased antithrombin III, partially as a result of the hepatic effects mentioned above. Increased plasminogen levels and decreased platelet adhesiveness have also been found (see Hormonal Contraception).

Other Effects

Estrogens induce the synthesis of progesterone receptors. They are responsible for estrous behavior in animals and may influence behavior and libido in humans. Administration of estrogens stimulates central components of the stress system, including the production of corticotropin-releasing hormone and the activity of the sympathetic system, and promotes a sense of well-being in women who are estrogen-deficient. They also facilitate the loss of intravascular fluid into the extracellular space, producing edema. The resulting decrease in plasma volume causes a compensatory retention of sodium and water by the kidney. Estrogens also modulate sympathetic nervous system control of smooth muscle function.

Clinical Uses*

* The use of estrogens in contraception is discussed below.

Primary Hypogonadism

Estrogens have been used extensively for replacement therapy in estrogen-deficient patients. The estrogen deficiency may be due to primary failure of development of the ovaries, premature menopause, castration, or menopause.

Treatment of primary hypogonadism is usually begun at 11–13 years of age in order to stimulate the development of secondary sex characteristics and menses, to stimulate optimal growth, to prevent osteoporosis and to avoid the psychologic consequences of delayed puberty and estrogen deficiency. Treatment attempts to mimic the physiology of puberty. It is initiated with small doses of estrogen (0.3 mg conjugated estrogens or 5–10 μ g ethinyl estradiol) on days 1–21 each month and is slowly increased to adult doses and maintained until the age of menopause (approximately 51 years of age). A progestin is added after the first uterine bleeding. When growth is completed,

chronic therapy consists mainly of the administration of adult doses of both estrogens and progestins, as described below.

Postmenopausal Hormonal Therapy

In addition to the signs and symptoms that follow closely upon the cessation of normal ovarian function—such as loss of periods, vasomotor symptoms, sleep disturbances, and genital atrophy—there are longer-lasting changes that influence the health and well-being of postmenopausal women. These include an acceleration of bone loss, which in susceptible women may lead to vertebral, hip, and wrist fractures; and lipid changes, which may contribute to the acceleration of atherosclerotic cardiovascular disease noted in postmenopausal women. The effects of estrogens on bone have been extensively studied, and the effects of hormone withdrawal have been well-characterized. However, the role of estrogens and progestins in the cause and prevention of cardiovascular disease, which is responsible for 350,000 deaths per year, and breast cancer, which causes 35,000 deaths per year, is less well understood.

When normal ovulatory function ceases and the estrogen levels fall after menopause, oophorectomy, or premature ovarian failure, there is an accelerated rise in plasma cholesterol and LDL concentrations, while LDL receptors decline. HDL is not much affected, and levels remain higher than in men. VLDL and triglyceride levels are also relatively unaffected. Since cardiovascular disorders account for most deaths in this age group, the risk for these disorders constitutes a major consideration in deciding whether or not hormonal replacement therapy (HRT) is indicated and influences the selection of hormones to be administered. Estrogen replacement therapy has a beneficial effect on circulating lipids and lipoproteins, and this was earlier thought to be accompanied by a reduction in myocardial infarction by about 50% and of fatal strokes by as much as 40%. These findings, however, have been recently disputed by the results of a large controlled study from the Womens' Health Initiative project showing no cardiovascular benefit from estrogen plus progestin replacement therapy in perimenopausal or postmenopausal patients. In fact, there may be a small increase in cardiovascular problems as well as breast cancer in women who received the replacement therapy. Interestingly, a small protective effect against colon cancer was observed. In other recent studies, a protective effect of estrogen replacement therapy against Alzheimer's disease was observed.

Progestins antagonize estrogen's effects on LDL and HDL to a variable extent. However, a large study has recently shown that the addition of a progestin to estrogen replacement therapy does not influence the cardiovascular risk.

Optimal management of the postmenopausal patient requires careful assessment of her symptoms as well as consideration of her age and the presence of (or risks for) cardiovascular disease, osteoporosis, breast cancer, and endometrial cancer. Bearing in mind the effects of the gonadal hormones on each of these disorders, the goals of therapy can then be defined and the risks of therapy assessed and discussed with the patient.

If the main indication for therapy is hot flushes and sleep disturbances, therapy with the lowest dose of estrogen required for symptomatic relief is recommended. Treatment may be required for only a limited period of time and the possible increased risk for breast cancer avoided. In women who have undergone hysterectomy, estrogens alone can be given 5 days per week or continuously, since progestins are not required to reduce the risk for endometrial hyperplasia and cancer. Hot flushes, sweating, insomnia, and atrophic vaginitis are generally relieved by estrogens; many patients experience some increased sense of well-being; and climacteric depression and other psychopathologic states are improved.

The role of estrogens in the prevention and treatment of osteoporosis has been carefully studied (see Chapter 42: Agents That Affect Bone Mineral Homeostasis). The amount of bone present in the body is maximal in the young active adult in the third decade of life and begins to decline more rapidly in middle age in both men and women. The development of osteoporosis also depends on the amount of bone present at the start of this process, on vitamin D and calcium intake, and on the degree of physical activity. The risk of osteoporosis is highest in smokers who are thin, Caucasian, and inactive and have a low calcium intake and a strong family history of osteoporosis. Depression also is a major risk factor for development of osteoporosis in women.

Estrogens should be used in the smallest dosage consistent with relief of symptoms. In women who have not undergone hysterectomy, it is most convenient to prescribe estrogen on the first 21–25 days of each month. The recommended dosages of estrogen are 0.3–1.25 mg/d of conjugated estrogen or 0.01–0.02 mg/d of ethinyl estradiol. Dosages in the middle of these ranges have been shown to be maximally effective in preventing the decrease in bone density occurring at menopause. From this point of view, it is important to begin therapy as soon as possible after the menopause for maximum effect. In these patients and others not taking estrogen, calcium supplements that bring the total daily calcium intake up to 1500 mg are useful.

Patients at low risk of developing osteoporosis who manifest only mild atrophic vaginitis can be treated with topical preparations. The vaginal route of application is also useful in the treatment of urinary tract symptoms in these patients. It is important to realize, however, that although locally administered estrogens escape the first-pass effect (so that some undesirable hepatic effects are reduced), they are almost completely absorbed into the circulation, and these preparations should be given cyclically.

As noted below, the administration of estrogen is associated with an increased risk of endometrial carcinoma. The administration of a progestational agent with the estrogen prevents endometrial hyperplasia and markedly reduces the risk of this cancer. When estrogen is given for the first 25 days of the month and the progestin medroxyprogesterone (10 mg/d) is added during the last 10–14 days, the risk is only half of that in women not receiving hormone replacement therapy. On this regimen, some women will experience a return of symptoms during the period off estrogen administration. In these patients, the estrogen can be given continuously. If the progestin produces sedation or other undesirable effects, its dose can be reduced to 2.5–5 mg for the last 10 days of the cycle with a slight increase in the risk for endometrial hyperplasia. These regimens are usually accompanied by bleeding at the end of each cycle. Some women experience migraine headaches during the last few days of the cycle. The use of a continuous estrogen regimen will often prevent their occurrence. Women who object to the cyclic bleeding associated with sequential therapy can also consider continuous therapy. Daily therapy with 0.625 mg of conjugated equine estrogens and 2.5–5 mg of medroxy-progesterone will eliminate cyclic bleeding, control vasomotor symptoms, prevent genital atrophy, maintain bone density, and show a favorable lipid profile with a small decrease in LDL and an increase in HDL concentrations. These women have endometrial atrophy on biopsy. About half of these patients experience breakthrough bleeding during the first few months of therapy. Seventy to 80 percent become amenorrheic after the first 4 months, and most remain so. The main disadvantage of continuous therapy is the need for uterine biopsy when bleeding occurs after the first few months.

As noted above, estrogens may also be administered vaginally or transdermally. When estrogens are given by these routes, the liver is bypassed on the first circulation, and the ratio of the liver effects to peripheral effects is reduced.

In patients in whom estrogen replacement therapy is contraindicated, such as those with estrogen-

sensitive tumors, relief of vasomotor symptoms may be obtained by the use of clonidine.

Other Uses

Estrogens combined with progestins can be used to suppress ovulation in patients with intractable dysmenorrhea or when suppression of ovarian function is used in the treatment of hirsutism and amenorrhea due to excessive secretion of androgens by the ovary. Under these circumstances, greater suppression may be needed, and oral contraceptives containing 50 μ g of estrogen or a combination of a low estrogen pill with GnRH suppression may be required.

Adverse Effects

Adverse effects of variable severity have been reported with the therapeutic use of estrogens. Many other effects reported in conjunction with hormonal contraceptives may be related to their estrogen content. These are discussed below.

Uterine Bleeding

Estrogen therapy is a major cause of postmenopausal uterine bleeding. Unfortunately, vaginal bleeding at this time of life may also be due to carcinoma of the endometrium. In order to avoid confusion, patients should be treated with the smallest amount of estrogen possible. It should be given cyclically so that bleeding, if it occurs, will be more likely to occur during the withdrawal period. As noted above, endometrial hyperplasia can be prevented by administration of a progestational agent with estrogen in each cycle.

Cancer

The relation of estrogen therapy to cancer continues to be the subject of active investigation. Although no adverse effect of short-term estrogen therapy on the incidence of breast cancer has been demonstrated, a small increase in the incidence of this tumor may occur with prolonged therapy. Although the risk factor is small (1.25), the impact may be great since this tumor occurs in 10% of women, and addition of progesterone does not confer a protective effect. Studies indicate that following unilateral excision of breast cancer, women receiving tamoxifen (an estrogen partial agonist, see below) show a 35% decrease in contralateral breast cancer compared with controls. These studies also demonstrate that tamoxifen is well tolerated by most patients, produces estrogen-like alterations in plasma lipid levels, and stabilizes bone mineral loss. Studies bearing on the possible efficacy of tamoxifen in postmenopausal women at high risk for breast cancer are under way. A recent study shows that postmenopausal hormone replacement therapy with estrogens plus progestins was associated with greater breast epithelial cell proliferation and breast epithelial cell density than estrogens alone or no replacement therapy. Furthermore, with estrogens plus progestins, breast proliferation was localized to the terminal duct-lobular unit of the breast, which is the main site of development of breast cancer. Thus, further studies are needed to conclusively assess the possible association between progestins and breast cancer risk.

Many studies show an increased risk of endometrial carcinoma in patients taking estrogens alone. The risk seems to vary with the dose and duration of treatment: 15 times as great in patients taking large doses of estrogen for 5 or more years, in contrast with two to four times greater in patients receiving lower doses for short periods. However, as noted above, the concomitant use of a progestin prevents this increased risk and may in fact reduce the incidence of endometrial cancer to less than that in the general population.

There have been a number of reports of adenocarcinoma of the vagina in young women whose mothers were treated with large doses of diethylstilbestrol early in pregnancy. These cancers are most common in young women (ages 14–44). The incidence is less than 1 per 1000 women exposed—too low to establish a cause-and-effect relationship with certainty. However, the risks for infertility, ectopic pregnancy, and premature delivery are also increased. It is now recognized that there is no indication for the use of diethylstilbestrol during pregnancy, and it should be avoided. It is not known whether other estrogens have a similar effect or whether the observed phenomena are peculiar to diethylstilbestrol. This agent should be used only for the treatment of cancer (eg, of the prostate) or as a "morning after" contraceptive (see below).

Other Effects

Nausea and breast tenderness are common and can be minimized by using the smallest effective dose of estrogen. Hyperpigmentation also occurs. Estrogen therapy is associated with an increase in frequency of migraine headaches as well as cholestasis, gallbladder disease, and hypertension.

Contraindications

Estrogens should not be used in patients with estrogen-dependent neoplasms such as carcinoma of the endometrium or in those with—or at high risk for—carcinoma of the breast. They should be avoided in patients with undiagnosed genital bleeding, liver disease, or a history of thromboembolic disorder. In addition, the use of estrogens should be avoided by heavy smokers.

Preparations & Dosages

The dosages of commonly used natural and synthetic preparations are listed in Table 40–1. Although all of the estrogens produce almost the same hormonal effects, their potencies vary both between agents and depending on the route of administration. As noted above, estradiol is the most active endogenous estrogen, and it has the highest affinity for the estrogen receptor. However, its metabolites estrone and estriol have weak uterine effects.

For a given level of gonadotropin suppression, oral estrogen preparations have more effect on the circulating levels of CBG, SHBG, and a host of other liver proteins, including angiotensinogen, than do transdermal preparations. The oral route of administration allows greater concentrations of hormone to reach the liver, thus increasing the synthesis of these proteins. Transdermal preparations were developed to avoid this effect. When administered transdermally, 50–100 μ g of estradiol has effects similar to those of 0.625–1.25 mg of conjugated oral estrogens on gonadotropin concentrations, endometrium, and vaginal epithelium. Furthermore, the transdermal estrogen preparations do not significantly increase the concentrations of renin substrate, CBG, and TBG and do not produce the characteristic changes in serum lipids. Combined oral preparations containing 0.625 mg of conjugated estrogens and 2.5 mg of medroxyprogesterone acetate are available for menopausal replacement therapy. Tablets containing 0.625 of conjugated estrogens and 5 mg of medroxy-progesterone acetate are available to be used in conjunction with conjugated estrogens in a sequential fashion. Estrogens alone are taken on days 1–14 and the combination on days 15–28.

The Progestins

Natural Progestins: Progesterone

Progesterone is the most important progestin in humans. In addition to having important hormonal effects, it serves as a precursor to the estrogens, androgens, and adrenocortical steroids. It is

synthesized in the ovary, testis, and adrenal from circulating cholesterol. Large amounts are also synthesized and released by the placenta during pregnancy.

In the ovary, progesterone is produced primarily by the corpus luteum. Normal males appear to secrete 1–5 mg of progesterone daily, resulting in plasma levels of about 0.03 µg/dL. The level is only slightly higher in the female during the follicular phase of the cycle, when only a few milligrams per day of progesterone are secreted. During the luteal phase, plasma levels range from 0.5 µg/dL to more than 2 µg/dL (Figure 40–1). Plasma levels of progesterone are further elevated and reach their peak levels in the third trimester of pregnancy.

Synthetic Progestins

A variety of progestational compounds have been synthesized. Some are active when given by mouth. They are not a uniform group of compounds, and all of them differ from progesterone in one or more respects. Table 40–2 lists some of these compounds and their effects. In general, the 21-carbon compounds (hydroxyprogesterone, medroxyprogesterone, megestrol, and dimethisterone) are the most closely related, pharmacologically as well as chemically, to progesterone. A new group of third-generation synthetic progestins has been introduced, principally as components of oral contraceptives. These "19-nor, 13-ethyl" steroid compounds include desogestrel (Figure 40–4), gestodene, and norgestimate. They are claimed to have lower androgenic activity than older synthetic progestins.

Table 40–2. Activities of Progestational Agents.

Table 40–2. Activities of Progestational Agents.							
			Activities ¹				
	Route	Duration of Action	Estrogenic	Androgenic	Antiandrogenic	Antiandrogenic	Anabolic
Progesterone and derivatives							
Progesterone	IM	1 day	–	–	+	–	–
Hydroxyprogesterone caproate	IM	8–14 days	sl	sl	–	–	–

Ethinodiol diacetate ²	PO	1–3 days	sl	+	+	–	–
L-Norgestrel ²	PO	1–3 days	–	+	+	–	+

¹**Interpretation:** + = active; – = inactive; sl = slightly active. Activities have been reported in various species using various end points and may not apply to humans.

²See Table 40–3.

³Not available in USA.

Pharmacokinetics

Progesterone is rapidly absorbed following administration by any route. Its half-life in the plasma is approximately 5 minutes, and small amounts are stored temporarily in body fat. It is almost completely metabolized in one passage through the liver, and for that reason it is quite ineffective when the usual formulation is administered orally. However, high-dose oral micronized progesterone preparations have been developed that provide adequate progestational effect.

In the liver, progesterone is metabolized to pregnanediol and conjugated with glucuronic acid. It is excreted into the urine as pregnanediol glucuronide. The amount of pregnanediol in the urine has been used as an index of progesterone secretion. This measure has been very useful in spite of the fact that the proportion of secreted progesterone converted to this compound varies from day to day and from individual to individual. In addition to progesterone, 20 α - and 20 β -hydroxyprogesterone (20 α - and 20 β -hydroxy-4-pregnene-3-one) are also found. These compounds have about one fifth the progestational activity of progesterone in humans and other species. Little is known of their physiologic role, but 20 α -hydroxyprogesterone is produced in large amounts in some species and may be of some importance biologically.

The usual routes of administration and durations of action of the synthetic progestins are listed in

Table 40–2. Most of these agents are extensively metabolized to inactive products that are excreted mainly in the urine.

Physiologic Effects

Mechanism

The mechanism of action of progesterone—described in more detail above—is similar to that of other steroid hormones. Progestins enter the cell and bind to progesterone receptors that are distributed between the nucleus and the cytoplasm. The ligand-receptor complex binds to a progesterone response element (PRE) to activate gene transcription. The response element for progesterone appears to be similar to the corticosteroid response element, and the specificity of the response depends upon which receptor is present in the cell as well as upon other cell-specific receptor coregulators and interacting transcription factors. The progesterone-receptor complex forms a dimer before binding to DNA. Like the estrogen receptor, it can form heterodimers as well as homodimers between two isoforms: A and B. These isoforms are produced by alternative splicing of the same gene.

Effects of Progesterone

Progesterone has little effect on protein metabolism. It stimulates lipoprotein lipase activity and seems to favor fat deposition. The effects on carbohydrate metabolism are more marked. Progesterone increases basal insulin levels and the insulin response to glucose. There is usually no manifest change in carbohydrate tolerance. In the liver, progesterone promotes glycogen storage, possibly by facilitating the effect of insulin. Progesterone also promotes ketogenesis.

Progesterone can compete with aldosterone for the mineralocorticoid receptor of the renal tubule, causing a decrease in Na^+ reabsorption. This leads to an increased secretion of aldosterone by the adrenal cortex (eg, in pregnancy). Progesterone increases body temperature in humans. The mechanism of this effect is not known, but an alteration of the temperature-regulating centers in the hypothalamus has been suggested. Progesterone also alters the function of the respiratory centers. The ventilatory response to CO_2 is increased (synthetic progestins with an ethinyl group do not have respiratory effects). This leads to a measurable reduction in arterial and alveolar PCO_2 during pregnancy and in the luteal phase of the menstrual cycle. Progesterone and related steroids also have depressant and hypnotic effects on the brain.

Progesterone is responsible for the alveolobular development of the secretory apparatus in the breast. It also participates in the preovulatory LH surge and causes the maturation and secretory changes in the endometrium that are seen following ovulation (Figure 40–1).

Progesterone decreases the plasma levels of many amino acids and leads to increased urinary nitrogen excretion. It induces changes in the structure and function of smooth endoplasmic reticulum in experimental animals.

Other effects of progesterone and its analogs are noted in the section on Hormonal Contraception.

Synthetic Progestins

The 21-carbon progesterone analogs antagonize aldosterone-induced sodium retention (see above). The remaining compounds ("19-nortestosterone" third-generation agents) produce a decidual change in the endometrial stroma, do not support pregnancy in test animals, are more effective

gonadotropin inhibitors, and may have minimal estrogenic and androgenic or anabolic activity (Table 40–2, Figure 40–4). They are sometimes referred to as "impeded androgens." Progestins without androgenic activity include desogestrel, norgestimate, and gestodene. The first two of these compounds are dispensed in combination with ethinyl estradiol for oral contraception (Table 40–3) in the USA. Oral contraceptives containing the progestins cyproterone acetate (also an antiandrogen) in combination with ethinyl estradiol are investigational in the USA.

Figure 40–4.

Progesterone and some progestational agents in clinical use. See Table 40–2.

Table 40–3. Some Oral and Implantable Contraceptive Agents in Use. The Estrogen-Containing Compounds Are Arranged in Order of Increasing Content of Estrogen. (Ethinyl Estradiol and Mestranol Have Similar Potencies.)

	Estrogen (mg)		Progestin (mg)	
Monophasic combination tablets				
Loestrin 21 1/20	Ethinyl estradiol	0.02	Norethindrone acetate	1.0
Desogen, Apri, Ortho-Cept	Ethinyl estradiol	0.03	Desogestrel	0.15
Brevicon, Modicon, Necon 0.5/35	Ethinyl estradiol	0.035	Norethindrone	0.5

Ovrette	. . .		D,L-Norgestrel	0.075
Implantable progestin preparation				
Norplant System	. . .		L-Norgestrel (six tubes of 36 mg each)	

Clinical Uses of Progestins

Therapeutic Applications

The major uses of progestational hormones are for hormone replacement therapy (see above) and hormonal contraception (see below). In addition, they are useful in producing long-term ovarian suppression for other purposes. When used alone in large doses parenterally (eg, medroxyprogesterone acetate, 150 mg intramuscularly every 90 days), prolonged anovulation and amenorrhea result. This therapy has been employed in the treatment of dysmenorrhea, endometriosis, and bleeding disorders when estrogens are contraindicated, and for contraception. The major problem with this regimen is the prolonged time required in some patients for ovulatory function to return after cessation of therapy. It should not be used for patients planning a pregnancy in the near future. Similar regimens will relieve hot flashes in some menopausal women and can be used if estrogen therapy is contraindicated.

Medroxyprogesterone acetate, 10–20 mg orally twice weekly—or intramuscularly in doses of 100 mg/m² every 1–2 weeks—will prevent menstruation, but it will not arrest accelerated bone maturation in children with precocious puberty.

Progestins do not appear to have any place in the therapy of threatened or habitual abortion. Early reports of the usefulness of these agents resulted from the unwarranted assumption that after several abortions the likelihood of repeated abortions was over 90%. When progestational agents were administered to patients with previous abortions, a salvage rate of 80% was achieved. It is now recognized that similar patients abort only 20% of the time even when untreated. On the other hand, progesterone was experimentally given recently to delay premature labor with encouraging results.

Progesterone and medroxyprogesterone have been used in the treatment of women who have difficulty in conceiving and who demonstrate a slow rise in basal body temperature. There is no convincing evidence that this treatment is effective.

Preparations of progesterone and medroxyprogesterone have been used to treat premenstrual syndrome. Controlled studies have not confirmed the effectiveness of such therapy except when

doses sufficient to suppress ovulation have been used.

Diagnostic Uses

Progesterone can be used as a test of estrogen secretion. The administration of progesterone, 150 mg/d, or medroxyprogesterone, 10 mg/d, for 5–7 days, is followed by withdrawal bleeding in amenorrheic patients only when the endometrium has been stimulated by estrogens. A combination of estrogen and progestin can be given to test the responsiveness of the endometrium in patients with amenorrhea.

Contraindications, Cautions, & Adverse Effects

Studies of progestational compounds alone and with combination oral contraceptives indicate that the progestin in these agents may increase blood pressure in some patients. The more androgenic progestins also reduce plasma HDL levels in women. (See Hormonal Contraception, below.) Two recent studies suggest that combined progestin plus estrogen replacement therapy in postmenopausal women may increase breast cancer risk significantly compared with the risk in women taking estrogen alone. These findings require careful examination and if confirmed will lead to important changes in postmenopausal hormone replacement practice.

Other Ovarian Hormones

The normal ovary produces small amounts of **androgens**, including testosterone, androstenedione, and dehydroepiandrosterone. Of these, only testosterone has a significant amount of biologic activity, though androstenedione can be converted to testosterone or estrone in peripheral tissues. The normal woman produces less than 200 μ g of testosterone in 24 hours, and about one third of this is probably formed in the ovary directly. The physiologic significance of these small amounts of androgens is not established, but they may be partly responsible for normal hair growth at puberty, for stimulation of female libido, and, possibly, for other important metabolic effects. Androgen production by the ovary may be markedly increased in some abnormal states, usually in association with hirsutism and amenorrhea as noted above.

The ovary also produces **inhibin** and **activin**. These peptides consist of several combinations of α and β subunits. The $\alpha\beta$ dimer (inhibin) inhibits FSH secretion while the $\beta\beta$ dimer (activin) increases FSH secretion. Studies in primates indicate that inhibin has no direct effect on ovarian steroidogenesis but that activin modulates the response to LH and FSH. For example, simultaneous treatment with activin and human FSH enhances FSH stimulation of progesterone synthesis and aromatase activity in granulosa cells. When combined with LH, activin suppressed the LH-induced progesterone response by 50% but markedly enhanced basal and LH-stimulated aromatase activity. Activin may also act as a growth factor in other tissues. The physiologic roles of these modulators are not fully understood.

Relaxin is another peptide that can be extracted from the ovary. The three-dimensional structure of relaxin is related to that of growth-promoting peptides and is similar to that of insulin. Although the amino acid sequence differs from that of insulin, this hormone, like insulin, consists of two chains linked by disulfide bonds, cleaved from a prohormone. It is found in the ovary, placenta, uterus, and blood. Relaxin synthesis has been demonstrated in luteinized granulosa cells of the corpus luteum. It has been shown to increase glycogen synthesis and water uptake by the myometrium and decreases uterine contractility. In some species, it changes the mechanical properties of the cervix and pubic ligaments, facilitating delivery.

In women, relaxin has been measured by immunoassay. Levels were highest immediately after the LH surge and during menstruation. A physiologic role for this hormone has not been established.

Clinical trials with relaxin have been conducted in patients with dysmenorrhea. Relaxin has also been administered to patients in premature labor and during prolonged labor. When applied to the cervix of a woman at term, it facilitates dilation and shortens labor.

Several other nonsteroidal substances such as corticotropin-releasing hormone, follistatin, and prostaglandins are produced by the ovary. These probably have paracrine effects within the ovary.

Hormonal Contraception (Oral, Parenteral, & Implanted Contraceptives)

A large number of oral contraceptives containing estrogens or progestins (or both) are now available for clinical use (Table 40–3). These preparations vary chemically and pharmacologically and have many properties in common as well as definite differences important for the correct selection of the right agent.

Two types of preparations are used for oral contraception: (1) combinations of estrogens and progestins and (2) continuous progestin therapy without concomitant administration of estrogens. The combination agents are further divided into monophasic forms (constant dosage of both components during the cycle) and biphasic or triphasic forms (dosage of one or both components is changed once or twice during the cycle). The preparations for oral use are all adequately absorbed, and in combination preparations the pharmacokinetics of neither drug is significantly altered by the other.

Only one implantable contraceptive preparation is available at present. Norgestrel, also utilized as the progestin component of some oral contraceptive preparations, is an effective suppressant of ovulation when it is released from subcutaneous implants. Intramuscular injection of large doses of medroxyprogesterone also provides contraceptive action of long duration.

Pharmacologic Effects

Mechanism of Action

The combinations of estrogens and progestins exert their contraceptive effect largely through selective inhibition of pituitary function that results in inhibition of ovulation. The combination agents also produce a change in the cervical mucus, in the uterine endometrium, and in motility and secretion in the uterine tubes, all of which decrease the likelihood of conception and implantation. The continuous use of progestins alone does not always inhibit ovulation. The other factors mentioned, therefore, play a major role in the prevention of pregnancy when these agents are used.

Effects on the Ovary

Chronic use of combination agents depresses ovarian function. Follicular development is minimal, and corpora lutea, larger follicles, stromal edema, and other morphologic features normally seen in ovulating women are absent. The ovaries usually become smaller even when enlarged before therapy.

The great majority of patients return to normal menstrual patterns when these drugs are discontinued. About 75% will ovulate in the first posttreatment cycle and 97% by the third posttreatment cycle. About 2% of patients remain amenorrheic for periods of up to several years

after administration is stopped.

The cytologic findings on vaginal smears vary depending on the preparation used. However, with almost all of the combined drugs, a low maturation index is found because of the presence of progestational agents.

Effects on the Uterus

After prolonged use, the cervix may show some hypertrophy and polyp formation. There are also important effects on the cervical mucus, making it more like postovulation mucus, ie, thicker and less copious.

Agents containing both estrogens and progestins produce further morphologic and biochemical changes of the endometrial stroma under the influence of the progestin, which also stimulates glandular secretion throughout the luteal phase. The agents containing "19-nor" progestins—particularly those with the smaller amounts of estrogen—tend to produce more glandular atrophy and usually less bleeding.

Effects on the Breast

Stimulation of the breasts occurs in most patients receiving estrogen-containing agents. Some enlargement is generally noted. The administration of estrogens and combinations of estrogens and progestins tends to suppress lactation. When the doses are small, the effects on breast feeding are not appreciable. Studies of the transport of the oral contraceptives into breast milk suggest that only small amounts of these compounds cross into the milk, and they have not been considered to be of importance.

Other Effects of Oral Contraceptives

Effects on the Central Nervous System

The central nervous system effects of the oral contraceptives have not been well studied in humans. A variety of effects of estrogen and progesterone have been noted in animals. Estrogens tend to increase excitability in the brain, whereas progesterone tends to decrease it. The thermogenic action of progesterone and some of the synthetic progestins is also thought to occur in the central nervous system.

It is very difficult to evaluate any behavioral or emotional effects of these compounds in humans. Although the incidence of pronounced changes in mood, affect, and behavior appears to be low, milder changes are commonly reported, and estrogens are being successfully employed in the therapy of premenstrual tension syndrome, postpartum depression, and climacteric depression.

Effects on Endocrine Function

The inhibition of pituitary gonadotropin secretion has been mentioned. Estrogens also alter adrenal structure and function. Estrogens given orally or at high doses increase the plasma concentration of the α_2 -globulin that binds cortisol (corticosteroid-binding globulin). Plasma concentrations may be more than double the levels found in untreated individuals, and urinary excretion of free cortisol is elevated.

These preparations cause alterations in the renin-angiotensin-aldosterone system. Plasma renin

activity has been found to increase, and there is an increase in aldosterone secretion.

Thyroxine-binding globulin is increased. As a result, total plasma thyroxine (T_4) levels are increased to those commonly seen during pregnancy. Since more of the thyroxine is bound, the free thyroxine level in these patients is normal. Estrogens also increase the plasma level of SHBG and decrease plasma levels of free androgens by increasing their binding; large amounts of estrogen may decrease androgens by gonadotropin suppression.

Effects on Blood

Serious thromboembolic phenomena occurring in women taking oral contraceptives have given rise to a great many studies of the effects of these compounds on blood coagulation. A clear picture of such effects has not yet emerged. The oral contraceptives do not consistently alter bleeding or clotting times. The changes that have been observed are similar to those reported in pregnancy. There is an increase in factors VII, VIII, IX, and X and a decrease in antithrombin III. Increased amounts of coumarin anticoagulants may be required to prolong prothrombin time in patients taking oral contraceptives.

There is an increase in serum iron and total iron-binding capacity similar to that reported in patients with hepatitis.

Significant alterations in the cellular components of blood have not been reported with any consistency. A number of patients have been reported to develop folic acid deficiency anemias.

Effects on the Liver

These hormones also have profound effects on the function of the liver. Some of these effects are deleterious and will be considered below in the section on adverse effects.

The effects on serum proteins result from the effects of the estrogens on the synthesis of the various α_2 -globulins and fibrinogen. Serum haptoglobins that also arise from the liver are depressed rather than increased by estrogen.

Some of the effects on carbohydrate and lipid metabolism are probably influenced by changes in liver metabolism (see below).

Important alterations in hepatic drug excretion and metabolism also occur. Estrogens in the amounts seen during pregnancy or used in oral contraceptive agents delay the clearance of sulfobromophthalein and reduce the flow of bile. The proportion of cholic acid in bile acids is increased while the proportion of chenodeoxycholic acid is decreased. These changes may cause the observed increase in cholelithiasis associated with the use of these agents.

Effects on Lipid Metabolism

As noted above, estrogens increase serum triglycerides and free and esterified cholesterol. Phospholipids are also increased, as are high-density lipoproteins. Low-density lipoproteins usually decrease. Although the effects are marked with doses of 100 μg of mestranol or ethinyl estradiol, doses of 50 μg or less have minimal effects. The progestins (particularly the "19-nortestosterone" derivatives) tend to antagonize these effects of estrogen. Preparations containing small amounts of estrogen and a progestin may slightly decrease triglycerides and high-density lipoproteins.

Effects on Carbohydrate Metabolism

The administration of oral contraceptives produces alterations in carbohydrate metabolism similar to those observed in pregnancy. There is a reduction in the rate of absorption of carbohydrates from the gastrointestinal tract. Progesterone increases the basal insulin level and the rise in insulin induced by carbohydrate ingestion. Preparations with more potent progestins such as norgestrel may cause progressive decreases in carbohydrate tolerance over several years. However, the changes in glucose tolerance are reversible on discontinuing medication.

Effects on the Cardiovascular System

These agents cause small increases in cardiac output associated with higher systolic and diastolic blood pressure and heart rate. The pressure returns to normal when treatment is terminated. Although the magnitude of the pressure change is small in most patients, it is marked in a few. It is important that blood pressure be followed in each patient. An increase in blood pressure has been reported to occur in few postmenopausal women treated with estrogens alone.

Effects on the Skin

The oral contraceptives have been noted to increase pigmentation of the skin (chloasma). This effect seems to be enhanced in women with dark complexions and by exposure to ultraviolet light. Some of the androgen-like progestins might increase the production of sebum, causing acne in some patients. However, since ovarian androgen is suppressed, many patients note decreased sebum production, acne, and terminal hair growth. The sequential oral contraceptive preparations as well as estrogens alone often decrease sebum production.

Clinical Uses

The most important use of combined estrogens and progestins is for oral contraception. A large number of preparations are available for this specific purpose, some of which are listed in Table 40-3. They are specially packaged for ease of administration. In general, they are very effective; when these agents are taken according to directions, the risk of conception is extremely small. The pregnancy rate with combination agents is estimated to be about 0.5-1 per 100 woman years at risk. Contraceptive failure has been observed in some patients when one or more doses are missed, if phenytoin is also being used (which may increase catabolism of the compounds), or if antibiotics are taken that alter the enterohepatic cycle.

Progestins and estrogens are also useful in the treatment of endometriosis. When severe dysmenorrhea is the major symptom, the suppression of ovulation with estrogen alone may be followed by painless periods. However, in most patients this approach to therapy is inadequate. The long-term administration of large doses of progestins or combinations of progestins and estrogens prevents the periodic breakdown of the endometrial tissue and in some cases will lead to endometrial fibrosis and prevent the reactivation of implants for prolonged periods.

As is true with most hormonal preparations, many of the undesired effects are physiologic or pharmacologic actions that are objectionable only because they are not pertinent to the situation for which they are being used. Therefore, the product containing the smallest effective amounts of hormones should be selected for use.

Adverse Effects

The incidence of serious known toxicities associated with the use of these drugs is low. There are a number of reversible changes in intermediary metabolism. Minor adverse effects are frequent, but most are mild and many are transient. Continuing problems may respond to simple changes in pill formulation. Although it is not often necessary to discontinue medication for these reasons, as many as one third of all patients started on oral contraception discontinue use for reasons other than a desire to become pregnant.

Mild Adverse Effects

- 1.** Nausea, mastalgia, breakthrough bleeding, and edema are related to the amount of estrogen in the preparation. These effects can often be alleviated by a shift to a preparation containing smaller amounts of estrogen or to agents containing progestins with more androgenic effects.
- 2.** Changes in serum proteins and other effects on endocrine function (see above) must be taken into account when thyroid, adrenal, or pituitary function is being evaluated. Increases in sedimentation rate are thought to be due to increased levels of fibrinogen.
- 3.** Headache is mild and often transient. However, migraine is often made worse and has been reported to be associated with an increased frequency of cerebrovascular accidents. When this occurs or when migraine has its onset during therapy with these agents, treatment should be discontinued.
- 4.** Withdrawal bleeding sometimes fails to occur—most often with combination preparations—and may cause confusion with regard to pregnancy. If this is disturbing to the patient, a different preparation may be tried or other methods of contraception used.

Moderate Adverse Effects

Any of the following may require discontinuance of oral contraceptives:

- 1.** Breakthrough bleeding is the most common problem in using progestational agents alone for contraception. It occurs in as many as 25% of patients. It is more frequently encountered in patients taking low-dose preparations than in those taking combination pills with higher levels of progestin and estrogen. The biphasic and triphasic oral contraceptives (Table 40–3) decrease breakthrough bleeding without increasing the total hormone content.
- 2.** Weight gain is more common with the combination agents containing androgen-like progestins. It can usually be controlled by shifting to preparations with less progestin effect or by dieting.
- 3.** Increased skin pigmentation may occur, especially in dark-skinned women. It tends to increase with time, the incidence being about 5% at the end of the first year and about 40% after 8 years. It is thought to be exacerbated by vitamin B deficiency. It is often reversible upon discontinuance of medication but may disappear very slowly.
- 4.** Acne may be exacerbated by agents containing androgen-like progestins (see Table 40–2), whereas agents containing large amounts of estrogen usually cause marked improvement in acne.
- 5.** Hirsutism may also be aggravated by the "19-nortestosterone" derivatives, and combinations

containing nonandrogenic progestins are preferred in these patients.

6. Ureteral dilation similar to that observed in pregnancy has been reported, and bacteriuria is more frequent.

7. Vaginal infections are more common and more difficult to treat in patients who are receiving oral contraceptives.

8. Amenorrhea occurs in some patients. Following cessation of administration of oral contraceptives, 95% of patients with normal menstrual histories resume normal periods and all but a few resume normal cycles during the next few months. However, some patients remain amenorrheic for several years. Many of these patients also have galactorrhea. Patients who have had menstrual irregularities before taking oral contraceptives are particularly susceptible to prolonged amenorrhea when the agents are discontinued. Prolactin levels should be measured in these patients, since many have prolactinomas.

Severe Adverse Effects

Vascular Disorders

Thromboembolism was one of the earliest of the serious unanticipated effects to be reported and has been the most thoroughly studied.

Venous Thromboembolic Disease

Superficial or deep thromboembolic disease in women not taking oral contraceptives occurs in about one patient per 1000 woman years. The overall incidence of these disorders in patients taking low-dose oral contraceptives is about threefold higher. The risk for this disorder is increased during the first month of contraceptive use and remains constant for several years or more. The risk returns to normal within a month when use is discontinued. The risk of venous thrombosis or pulmonary embolism is increased among women with predisposing conditions such as stasis, altered clotting factors such as antithrombin III, increased levels of homocysteine, or injury. Genetic disorders, including mutations in the genes governing the production of protein C (factor V Leiden), protein S, hepatic cofactor II, and others, markedly increase the risk of venous thromboembolism. The incidence of these disorders is too low for cost-effective screening by current methods, but prior episodes or a family history may be helpful in identifying patients with increased risk.

The incidence of venous thromboembolism is related to the estrogen but not the progestin content of oral contraceptives and is not related to age, parity, mild obesity, or cigarette smoking. Decreased venous blood flow, endothelial proliferation in veins and arteries, and increased coagulability of blood resulting from changes in platelet functions and fibrinolytic systems contribute to the increased incidence of thrombosis. The major plasma inhibitor of thrombin, antithrombin III, is substantially decreased during oral contraceptive use. This change occurs in the first month of treatment and lasts as long as treatment persists, reversing within a month thereafter.

Myocardial Infarction

The use of oral contraceptives is associated with a slightly higher risk of myocardial infarction in women who are obese, have a history of preeclampsia or hypertension, or have hyperlipoproteinemia or diabetes. There is a much higher risk in women who smoke. The risk attributable to oral contraceptives in women 30–40 years of age who do not smoke is about 4 cases

per 100,000 users per year, as compared with 185 cases per 100,000 among women 40–44 who smoke heavily. The association with myocardial infarction is thought to involve acceleration of atherogenesis because of decreased glucose tolerance, decreased levels of HDL, increased levels of LDL, and increased platelet aggregation. In addition, facilitation of coronary arterial spasm may also play a role in some of these patients. The progestational component of oral contraceptives decreases HDL cholesterol levels, in proportion to the androgenic activity of the progestin. The net effect, therefore, will depend on the specific composition of the pill used and the patient's susceptibility to the particular effects. Recent studies suggest that risk of infarction is not increased in past users who have discontinued oral contraceptives.

Cerebrovascular Disease

The risk of strokes is concentrated in women over age 35. It is increased in current users of oral contraceptives but not in past users. However, subarachnoid hemorrhages have been found to be increased among both current and past users and may increase with time. The risk of thrombotic or hemorrhagic stroke attributable to oral contraceptives (based on older, higher-dose preparations) has been estimated to about 37 cases per 100,000 users per year.

In summary, available data indicate that oral contraceptives increase the risk of various cardiovascular disorders at all ages and among both smokers and nonsmokers. However, this risk appears to be concentrated in women 35 years of age or older who are heavy smokers. It is clear that these risk factors must be considered in each individual patient for whom oral contraceptives are being considered.

Gastrointestinal Disorders

Many cases of cholestatic jaundice have been reported in patients taking progestin-containing drugs. The differences in incidence of these disorders from one population to another suggest that genetic factors may be involved. The jaundice caused by these agents is similar to that produced by other 17-alkyl-substituted steroids. It is most often observed in the first three cycles and is particularly common in women with a history of cholestatic jaundice during pregnancy. Jaundice and pruritus disappear 1–8 weeks after the drug is discontinued.

These agents have also been found to increase the incidence of symptomatic gallbladder disease, including cholecystitis and cholangitis. This is probably the result of the alterations responsible for jaundice and bile acid changes described above.

It also appears that the incidence of hepatic adenomas is increased in women taking oral contraceptives. Ischemic bowel disease secondary to thrombosis of the celiac and superior and inferior mesenteric arteries and veins has also been reported in women using these drugs.

Depression

Depression of sufficient degree to require cessation of therapy occurs in about 6% of patients treated with some preparations.

Cancer

The occurrence of malignant tumors in patients taking oral contraceptives has been studied extensively. It is now clear that these compounds *reduce* the risk of endometrial and ovarian cancer. The lifetime risk of breast cancer in the population as a whole does not seem to be affected by oral

contraceptive use. Some studies have shown an increased risk in younger women, and it is possible that tumors that develop in younger women become clinically apparent sooner. The relation of risk of cervical cancer to oral contraceptive use is still controversial. It should be noted that a number of recent studies associate the use of oral contraceptives by women with cervical infection with the human papillomavirus to an increased risk of cervical cancer.

Other

In addition to the above effects, a number of other adverse reactions have been reported for which a causal relation has not been established. These include alopecia, erythema multiforme, erythema nodosum, and other skin disorders.

Contraindications & Cautions

These drugs are contraindicated in patients with thrombophlebitis, thromboembolic phenomena, and cardiovascular and cerebrovascular disorders or a past history of these conditions. They should not be used to treat vaginal bleeding when the cause is unknown. They should be avoided in patients with known or suspected tumor of the breast or other estrogen-dependent neoplasm. Since these preparations have caused aggravation of preexisting disorders, they should be avoided or used with caution in patients with liver disease, asthma, eczema, migraine, diabetes, hypertension, optic neuritis, retrobulbar neuritis, or convulsive disorders.

The oral contraceptives may produce edema, and for that reason they should be used with great caution in patients in heart failure or in whom edema is otherwise undesirable or dangerous.

Estrogens may increase the rate of growth of fibroids. Therefore, for women with these tumors, agents with the smallest amounts of estrogen and the most androgenic progestins should be selected. The use of progestational agents alone for contraception might be especially useful in such patients (see below).

These agents are contraindicated in adolescents in whom epiphyseal closure has not yet been completed.

Women using oral contraceptives must be made aware of an important interaction that occurs with antimicrobial drugs. Because the normal gastrointestinal flora increases the enterohepatic cycling (and bioavailability) of estrogens, antimicrobial drugs that interfere with these organisms may reduce the efficacy of oral contraceptives. Additionally, coadministration with potent inducers of the hepatic microsomal metabolizing enzymes, such as rifampin, may increase liver catabolism of estrogens or progestins and diminish the efficacy of oral contraceptives.

Contraception with Progestins Alone

Small doses of progestins administered orally or by implantation under the skin can be used for contraception. They are particularly suited for use in patients for whom estrogen administration is undesirable. They are about as effective as intrauterine devices or combination pills containing 20–30 µg of ethinyl estradiol. There is a high incidence of abnormal bleeding.

Effective contraception can also be achieved by injecting 150 mg of depot medroxyprogesterone acetate (**DMPA**) every 3 months. After a 150 mg dose, ovulation is inhibited for at least 14 weeks. Almost all users experience episodes of unpredictable spotting and bleeding, particularly during the first year of use. Spotting and bleeding decrease with time, and amenorrhea is common. This

preparation is not desirable for women planning a pregnancy soon after cessation of therapy because ovulation suppression can persist for as long as 18 months after the last injection. However, ovulation usually returns in a much shorter time. Long-term DMPA use reduces menstrual blood loss and is associated with a decreased risk of endometrial cancer. Suppression of endogenous estrogen secretion may be associated with a reversible reduction in bone density, and changes in plasma lipids are associated with an increased risk of atherosclerosis.

The progestin implant method utilizes the subcutaneous implantation of capsules containing a progestin (L-norgestrel). These capsules release one fifth to one third as much steroid as oral agents, are extremely effective, and last for 5–6 years. The low levels of hormone have little effect on lipoprotein and carbohydrate metabolism or blood pressure. The disadvantages include the need for surgical insertion and removal of capsules and some irregular bleeding rather than predictable menses. An association of intracranial hypertension with implanted norgestrel has been observed in a small number of women. Patients experiencing headache or visual disturbances should be checked for papilledema.

Contraception with progestins is useful in patients with hepatic disease, hypertension, psychosis or mental retardation, or prior thromboembolism. The side effects include headache, dizziness, bloating and weight gain of 1–2 kg, and a reversible reduction of glucose tolerance.

Postcoital Contraceptives

Pregnancy can be prevented following coitus by the administration of estrogens alone or in combination with progestins ("**morning after**" contraception). When treatment is begun within 72 hours, it is effective 99% of the time. Some effective schedules are shown in Table 40–4. The hormones are often administered with antiemetics, since 40% of the patients have nausea or vomiting. Other adverse effects include headache, dizziness, breast tenderness, and abdominal and leg cramps.

Table 40–4. Schedules for Use of Postcoital Contraceptives.

Conjugated estrogens: 10 mg three times daily for 5 days

Ethinyl estradiol: 2.5 mg twice daily for 5 days

Diethylstilbestrol: 50 mg daily for 5 days

L-Norgestrel: 0.75 mg twice daily for 1 day (eg, Plan B¹)

Norgestrel, 0.5 mg, with ethinyl estradiol, 0.05 mg (eg, Ovral, Preven¹): Four tablets (two immediately and two at 12 hours)

Mifepristone, 600 mg once with misoprostol 400 µg once

¹ Sold as emergency contraceptive kits.

Mifepristone (RU 486), an antagonist at progesterone (and glucocorticoid) receptors, has been shown to have a luteolytic effect and is effective as a postcoital contraceptive when combined with a prostaglandin (see below).

Beneficial Effects of Oral Contraceptives

It has become apparent that reduction in the dose of the constituents of oral contraceptives has markedly reduced mild and severe adverse effects, providing a relatively safe and convenient method of contraception for many young women. Treatment with oral contraceptives has now been shown to be associated with many benefits unrelated to contraception. These include a reduced risk of ovarian cysts, ovarian and endometrial cancer, and benign breast disease. There is a lower incidence of ectopic pregnancy. Iron deficiency and rheumatoid arthritis are less common, and premenstrual symptoms, dysmenorrhea, endometriosis, acne, and hirsutism may be ameliorated with their use.

Estrogen & Progesterone Inhibitors & Antagonists

Tamoxifen & Related Partial Agonist Estrogens

Tamoxifen is a competitive partial agonist inhibitor of estradiol at the estrogen receptor and is extensively used in the palliative treatment of advanced breast cancer in postmenopausal women. It is a nonsteroidal agent (see structure below) that is given orally. Peak plasma levels are reached in a few hours. Tamoxifen has an initial half-life of 7–14 hours in the circulation and is predominantly excreted by the liver. It is used in doses of 10–20 mg twice daily. Hot flushes and nausea and vomiting occur in 25% of patients, and many other minor adverse effects are observed. Studies of patients treated with tamoxifen as adjuvant therapy for early breast cancer have shown a 35% decrease in contralateral breast cancer. However, adjuvant therapy extended beyond 5 years in patients with breast cancer has shown no further improvement in outcome. **Toremifene** is a structurally similar compound with very similar properties, indications, and toxicities.

Prevention of the expected loss of lumbar spine bone density and plasma lipid changes consistent with a reduction in the risk for atherosclerosis have also been reported in tamoxifen-treated patients following spontaneous or surgical menopause. However, this agonist activity also affects the uterus and increases the risk of endometrial cancer.

Raloxifene is another partial estrogen agonist-antagonist at some but not all target tissues. It has similar effects on lipids and bone but appears not to stimulate the endometrium or breast. Because of its apparent tissue selectivity it has been described as a **selective estrogen receptor modulator (SERM)**, a term that could also be applied to tamoxifen and toremifene. Although subject to a high first-pass effect, raloxifene has a very large volume of distribution and a long half-life (> 24 hours),

so it can be taken once a day. Raloxifene has been approved in the USA for the prevention of postmenopausal osteoporosis.

Clomiphene is an older partial agonist, a weak estrogen that also acts as a competitive inhibitor of endogenous estrogens. It has found use as an ovulation-inducing agent (see below).

Mifepristone

Mifepristone (RU 486) is a "19-norsteroid" that binds strongly to the progesterone receptor and inhibits the activity of progesterone. The drug has luteolytic properties in 80% of women when given in the midluteal period. The mechanism of this effect is unknown, but it may provide the basis for using mifepristone as a contraceptive (as opposed to an abortifacient). However, because the compound has a long half-life, large doses may prolong the follicular phase of the subsequent cycle and so make it difficult to use continuously for this purpose. A single dose of 600 mg is an effective emergency postcoital contraceptive, though it may result in delayed ovulation in the following cycle. As noted in Chapter 39: Adrenocorticosteroids & Adrenocortical Antagonists, the drug also binds to and acts as an antagonist at the glucocorticoid receptor. Limited clinical studies suggest that mifepristone or other analogs with similar properties may be useful in the treatment of endometriosis, Cushing's syndrome, breast cancer, and possibly other neoplasms such as meningiomas that contain glucocorticoid or progesterone receptors.

Mifepristone's major use thus far has been to terminate early pregnancies. Doses of 400–600 mg/d for 4 days or 800 mg/d for 2 days successfully terminated pregnancy in over 85% of the women studied. The major adverse effect was prolonged bleeding that on most occasions did not require treatment. The combination of a single oral dose of 600 mg of mifepristone and a vaginal pessary containing 1 mg of prostaglandin E₁ or oral misoprostol has been found to effectively terminate pregnancy in over 95% of patients treated during the first 7 weeks after conception. The adverse effects of the medications included vomiting, diarrhea, and abdominal or pelvic pain. As many as 5% of patients have vaginal bleeding requiring intervention. Because of these adverse effects, RU 486 is administered only by physicians at family planning centers. It is not in use in the United States at the time of this writing.

ZK 98734 (lilopristone) is a potent experimental progesterone inhibitor and abortifacient in doses of 25 mg twice daily. Like mifepristone, it also appears to have antiglucocorticoid activity.

Danazol

Danazol, an isoxazole derivative of ethisterone (17 α -ethinyltestosterone) with weak progestational, androgenic, and glucocorticoid activities, is used to suppress ovarian function. Danazol inhibits the midcycle surge of LH and FSH and can prevent the compensatory increase in LH and FSH following castration in animals, but it does not significantly lower or suppress basal LH or FSH levels in normal women. Danazol binds to androgen, progesterone, and glucocorticoid receptors and can translocate the androgen receptor into the nucleus to initiate androgen-specific RNA synthesis. It does not bind to intracellular estrogen receptors, but it does bind to sex hormone-binding and corticosteroid-binding globulins. It inhibits P450_{scc} (the cholesterol side chain-cleaving enzyme), 3 β -hydroxysteroid dehydrogenase, 17 α -hydroxysteroid dehydrogenase, P450_{c17} (17 α -hydroxylase), P450_{c11} (11 β -hydroxylase), and P450_{c21} (21 β -hydroxylase). However, it does not inhibit aromatase, the enzyme required for estrogen synthesis. It increases the mean clearance of progesterone, probably by competing with the hormone for binding proteins, and may have similar effects on other active steroid hormones. Ethisterone, a major metabolite of danazol, has both progestational and mild androgenic effects.

Danazol is slowly metabolized in humans, having a half-life of over 15 hours. This results in stable circulating levels when the drug is administered twice daily. It is highly concentrated in the liver, adrenals, and kidneys and is excreted in both feces and urine.

Danazol has been employed as an inhibitor of gonadal function and has found its major use in the treatment of endometriosis. For this purpose, it can be given in a dosage of 600 mg/d. The dosage is reduced to 400 mg/d after 1 month and to 200 mg/d in 2 months. About 85% of patients show marked improvement in 3–12 months.

Danazol has also been used for the treatment of fibrocystic disease of the breast and hematologic or allergic disorders, including hemophilia, Christmas disease, idiopathic thrombocytopenic purpura, and angioneurotic edema.

The major adverse effects are weight gain, edema, decreased breast size, acne and oily skin, increased hair growth, deepening of the voice, headache, hot flushes, changes in libido, and muscle cramps. Although mild adverse effects are very common, it is seldom necessary to discontinue the drug because of them. Occasionally, because of its inherent glucocorticoid activity, danazol may cause adrenal suppression.

Danazol should be used with great caution in patients with hepatic dysfunction, since it has been reported to produce mild to moderate hepatocellular damage in some patients, as evidenced by enzyme changes. It is also contraindicated during pregnancy and breast feeding, as it may produce urogenital abnormalities in the offspring.

Other Inhibitors

The prototypical steroidal inhibitor of aromatase (the enzyme required for estrogen synthesis) is **testolactone**. It is a weak inhibitor of the enzyme, and large quantities need to be administered to achieve clinical effect.

Anastrozole, a selective nonsteroidal inhibitor of aromatase, is effective in some women whose breast tumors have become resistant to tamoxifen. It is approved for use in such patients. **Letrozole** is similar. **Exemestane**, a steroid molecule, is an irreversible inhibitor of aromatase. Like anastrozole and letrozole, it is approved for use in women with advanced breast cancer (Chapter 55:

Cancer Chemotherapy).

Several other aromatase inhibitors are undergoing clinical trials in patients with breast cancer.

Fadrozole is a newer oral nonsteroidal (triazole) inhibitor of aromatase activity. These compounds appear to be as effective as tamoxifen. In addition to their use in breast cancer, aromatase inhibitors have been successfully employed as adjuncts to androgen antagonists in the treatment of precocious puberty and as primary treatment in the excessive aromatase syndrome.

Fulvestrant is a pure estrogen receptor antagonist that has been somewhat more effective than those with partial agonist effects and is effective in some patients who have become resistant to tamoxifen. ICI 164,384 inhibits dimerization of the occupied estrogen receptor and interferes with its binding to DNA. It has also been used experimentally in breast cancer patients who have become resistant to tamoxifen.

GnRH and its analogs (**nafarelin**, **buserelin**, etc) have become important in both stimulating and inhibiting ovarian function. They are discussed in Chapter 37: Hypothalamic & Pituitary Hormones.

Ovulation-Inducing Agents

Clomiphene

Clomiphene citrate, a partial estrogen agonist, is closely related to the estrogen chlorotrianisene (Figure 40–3). This compound is active when taken orally. Very little is known about its metabolism, but about half of the compound is excreted in the feces within 5 days after administration. It has been suggested that clomiphene is slowly excreted from an enterohepatic pool.

Pharmacologic Effects

Mechanisms of Action

Clomiphene is a partial agonist at estrogen receptors. The estrogenic agonist effects are best demonstrated in animals with marked gonadal deficiency. Clomiphene has also been shown to effectively inhibit the action of stronger estrogens. In humans it leads to an increase in the secretion of gonadotropins and estrogens by inhibiting estradiol's negative feedback effect on the gonadotropins.

Effects

The pharmacologic importance of this compound rests on its ability to stimulate ovulation in women with oligomenorrhea or amenorrhea and ovulatory dysfunction. The majority of patients suffer from polycystic ovary syndrome, a common disorder affecting about 7% of women of reproductive age. The syndrome is characterized by gonadotropin-dependent ovarian hyperandrogenism associated with oligo- or anovulation and infertility. The disorder is frequently accompanied by adrenal hyperandrogenism. Clomiphene has been suggested in order to block an inhibitory influence of estrogens on the hypothalamus, causing an ovulatory surge of gonadotropins and leading to ovulation.

Clinical Uses

Clomiphene is used for the treatment of disorders of ovulation in patients wishing to become

pregnant. Usually, a single ovulation is induced by a single course of therapy, and the patient must be treated repeatedly until pregnancy is achieved, since normal ovulatory function does not usually resume. The compound is of no use in patients with ovarian or pituitary failure.

When clomiphene is administered in doses of 100 mg daily for 5 days, a rise in plasma LH and FSH is observed after several days. In patients who ovulate, the initial rise is followed by a second rise of gonadotropin levels just prior to ovulation.

Adverse Effects

The most common adverse effects in patients treated with this drug are hot flushes, which resemble those experienced by menopausal patients. They tend to be mild, and disappear when the drug is discontinued. There have been occasional reports of eye symptoms due to intensification and prolongation of afterimages. These are generally of short duration. Headache, constipation, allergic skin reactions, and reversible hair loss have been reported occasionally.

The effective use of clomiphene is associated with some stimulation of the ovaries and usually with ovarian enlargement. The degree of enlargement tends to be greater and its incidence higher in patients who have enlarged ovaries at the beginning of therapy.

A variety of other symptoms such as nausea and vomiting, increased nervous tension, depression, fatigue, breast soreness, weight gain, urinary frequency, and heavy menses have also been reported. However, these appear to result from the hormonal changes associated with an ovulatory menstrual cycle rather than from the medication. The incidence of multiple pregnancy is approximately 10%. Clomiphene has not been shown to have an adverse effect when inadvertently given to women who are already pregnant.

Contraindications & Cautions

Special precautions should be observed in patients with enlarged ovaries. These women are thought to be more sensitive to this drug and should receive small doses. Any patient who complains of abdominal symptoms should be examined carefully. Maximum ovarian enlargement occurs after the 5-day course has been completed, and many patients can be shown to have a palpable increase in ovarian size by the seventh to tenth days. Treatment with clomiphene for more than a year may be associated with an increased risk for low-grade ovarian cancer; however, the evidence for this effect is not conclusive.

Special precautions must also be taken in patients who have visual symptoms associated with clomiphene therapy, since these symptoms may make activities such as driving more hazardous.

Dosages

The recommended dosage of clomiphene citrate at the beginning of therapy is 50 mg/d for 5 days. If ovulation occurs, this same course may be repeated until pregnancy is achieved. If ovulation does not occur, the dosage is doubled to 100 mg/d for 5 days. If ovulation and menses occur, the next course can be started on the fifth day of the cycle. Experience to date suggests that patients who do not ovulate after three courses of 100 mg/d of clomiphene are not likely to respond to continued therapy. However, larger doses are effective in some individuals. Clomiphene is sometimes used in combination with gonadotropins, ie, a combination of LH and FSH.

About 80% of patients with anovulatory disorders or amenorrhea can be expected to respond by

having ovulatory cycles. Approximately half of these patients become pregnant.

Other Drugs Used in Ovulatory Disorders

In addition to clomiphene, a variety of other hormonal and nonhormonal agents are used in treating anovulatory disorders. They are discussed in Chapter 37: Hypothalamic & Pituitary Hormones.

Katzung PHARMACOLOGY, 9e > Section VII. Endocrine Drugs > Chapter 40. The Gonadal Hormones & Inhibitors >

The Testis (Androgens & Anabolic Steroids, Antiandrogens, & Male Contraception)

The testis, like the ovary, has both gametogenic and endocrine functions. The onset of gametogenic function of the testes is controlled largely by the secretion of FSH by the pituitary. High concentrations of testosterone locally are also required for continuing sperm production in the seminiferous tubules. The Sertoli cells in the seminiferous tubules may be the source of the estradiol produced in the testes via aromatization of locally produced testosterone. With LH stimulation, testosterone is produced by the interstitial or Leydig cells found in the spaces between the seminiferous tubules.

The Sertoli cells in the testis synthesize and secrete a variety of active proteins, including müllerian duct inhibitory factor, inhibin, and activin. As in the ovary, inhibin and activin appear to be the product of three genes that produce a common alpha subunit and two beta subunits, A and B. Activin is composed of the two beta subunits ($\beta_A\beta_B$). There are two inhibins (A and B), which contain the alpha subunit and one of the beta subunits. Activin stimulates pituitary FSH release and is structurally similar to transforming growth factor- β , which also increases FSH. The inhibins in conjunction with testosterone and dihydrotestosterone are responsible for the feedback inhibition of pituitary FSH secretion.

Androgens & Anabolic Steroids

In humans, the most important androgen secreted by the testis is testosterone. The pathways of synthesis of testosterone in the testes are similar to those previously described for the adrenal and ovary (Figures 39–1 and 40–2).

In men, approximately 8 mg of testosterone is produced daily. About 95% is produced by the Leydig cells and only 5% by the adrenal. The testis also secretes small amounts of another potent androgen, dihydrotestosterone, as well as androstenedione and dehydroepiandrosterone, which are weak androgens. Pregnenolone and progesterone and their 17-hydroxylated derivatives are also released in small amounts. Plasma levels of testosterone in males are about 0.6 $\mu\text{g}/\text{dL}$ after puberty and appear to decline after age 50. Testosterone is also present in the plasma of women in concentrations of approximately 0.03 $\mu\text{g}/\text{dL}$ and is derived in approximately equal parts from the ovaries and adrenals and by the peripheral conversion of other hormones.

About 65% of circulating testosterone is bound to sex hormone-binding globulin. SHBG is increased in plasma by estrogen, by thyroid hormone, and in patients with cirrhosis of the liver. It is decreased by androgen and growth hormone and is lower in obese individuals. Most of the remaining testosterone is bound to albumin. Approximately 2% remains free and available to enter cells and bind to intracellular receptors.

Metabolism

In many target tissues, testosterone is converted to dihydrotestosterone by 5 α -reductase. In these tissues, dihydrotestosterone is the major active androgen. The conversion of testosterone to estradiol by P450 aromatase also occurs in some tissues, including adipose tissue, liver, and the hypothalamus, where it may be of importance in regulating gonadal function.

The major pathway for the degradation of testosterone in humans occurs in the liver, with the reduction of the double bond and ketone in the A ring, as is seen in other steroids with a Δ^4 -ketone configuration in the A ring. This leads to the production of inactive substances such as androsterone and etiocholanolone that are then conjugated and excreted in the urine.

Androstenedione, dehydroepiandrosterone (DHEA), and dehydroepiandrosterone sulfate (DHEAS) are also produced in significant amounts in humans, though largely in the adrenal rather than in the testes. They contribute slightly to the normal maturation process (adrenarche) supporting other androgen-dependent pubertal changes in the human, primarily development of pubic and axillary hair and bone maturation. As noted in Chapter 39: Adrenocorticosteroids & Adrenocortical Antagonists and 65: Botanicals ("Herbal Medications") & Nutritional Supplements, recent studies suggest that DHEA and DHEAS may have other central nervous system and metabolic effects and may prolong life in rabbits. In men they may improve the sense of well-being and inhibit atherosclerosis. In a recent placebo-controlled clinical trial in patients with systemic lupus erythematosus, DHEA demonstrated clear beneficial effects (see Adrenal Androgens, Chapter 39: Adrenocorticosteroids & Adrenocortical Antagonists). Adrenal androgens are to a large extent metabolized in the same fashion as testosterone. Both steroids—but particularly androstenedione—can be converted by peripheral tissues to estrone in very small amounts (1–5%). The P450 aromatase enzyme responsible for this conversion is also found in the brain and is thought to play an important role in development.

Physiologic Effects

In the normal male, testosterone or its active metabolite 5 α -dihydrotestosterone is responsible for the many changes that occur in puberty. In addition to the general growth-promoting properties of androgens on the body tissues, these hormones are responsible for penile and scrotal growth. Changes in the skin include the appearance of pubic, axillary, and beard hair. The sebaceous glands become more active, and the skin tends to become thicker and oilier. The larynx grows and the vocal cords become thicker, leading to a lower-pitched voice. Skeletal growth is stimulated and epiphyseal closure accelerated. Other effects include growth of the prostate and seminal vesicles, darkening of the skin, and increased skin circulation. Androgens play an important role in stimulating and maintaining sexual function in men. Androgens increase lean body mass and stimulate body hair growth and sebum secretion. Metabolic effects include the reduction of hormone binding and other carrier proteins and increased liver synthesis of clotting factors, triglyceride lipase, α_1 -antitrypsin, haptoglobin, and sialic acid. They also stimulate renal erythropoietin secretion and decrease high-density lipoprotein levels.

Synthetic Steroids with Androgenic & Anabolic Action

Testosterone, when administered by mouth, is rapidly absorbed. However, it is largely converted to inactive metabolites, and only about one sixth of the dose administered is available in active form. Testosterone can be administered parenterally, but it has a more prolonged absorption time and greater activity in the propionate, enanthate, undecanoate, or cypionate ester forms. These derivatives are hydrolyzed to release free testosterone at the site of injection. Testosterone derivatives alkylated at the 17 position, eg, methyltestosterone and fluoxymesterone, are active when given by mouth.

Testosterone and its derivatives have been used for their anabolic effects as well as for the treatment of testosterone deficiency. Although testosterone and other known active steroids can be isolated in pure form and measured by weight, biologic assays are still used in the investigation of new compounds. In some of these studies in animals, the anabolic effects of the compound as measured by trophic effects on muscles or the reduction of nitrogen excretion may be dissociated from the other androgenic effects. This has led to the marketing of compounds claimed to have anabolic activity associated with only weak androgenic effects. Unfortunately, this dissociation is less marked in humans than in the animals used for testing (Table 40–5), and all are potent androgens.

Table 40–5. Androgens: Preparations Available and Relative Androgenic: Anabolic Activity in Animals.

	Androgenic: Anabolic Activity
Testosterone	1:1
Testosterone cypionate	1:1
Testosterone enanthate	1:1
Testosterone propionate	1:1
Methyltestosterone	1:1
Fluoxymesterone	1:2
Methandrostenolone (methandienone)	1:3
Oxymetholone	1:3
Ethylestrenol	1:4–1:8
Oxandrolone	1:3–1:13
Nandrolone phenpropionate	1:3–1:6
Nandrolone decanoate	1:2.5–1:4
Stanozolol	1:3–1:6
Dromostanolone propionate	1:3–1:4

Pharmacologic Effects

Mechanisms of Action

Like other steroids, testosterone acts intracellularly in target cells. In skin, prostate, seminal vesicles, and epididymis, it is converted to 5 α -dihydrotestosterone. In these tissues, dihydrotestosterone is the dominant androgen. The distribution of this enzyme in the fetus is different and has important developmental implications.

Testosterone and dihydrotestosterone bind to the intracellular androgen receptor, initiating a series of events similar to those described above for estradiol and progesterone, leading to growth, differentiation, and synthesis of a variety of enzymes and other functional proteins.

Effects

In the male at puberty, androgens cause development of the secondary sex characteristics (see above). In the adult male, large doses of testosterone—when given alone—or its derivatives suppress the secretion of gonadotropins and result in some atrophy of the interstitial tissue and the tubules of the testes. Since fairly large doses of androgens are required to suppress gonadotropic secretion, it has been postulated that inhibin, in combination with androgens, is responsible for the feedback control of secretion. In women, androgens are capable of producing changes similar to those observed in the prepubertal male. These include growth of facial and body hair, deepening of the voice, enlargement of the clitoris, frontal baldness, and prominent musculature. The natural androgens stimulate erythrocyte production.

The administration of androgens reduces the excretion of nitrogen into the urine, indicating an increase in protein synthesis or a decrease in protein breakdown within the body. This effect is much more pronounced in women and children than in normal men.

Clinical Uses

Androgen Replacement Therapy in Men

Androgens are used to replace or augment endogenous androgen secretion in hypogonadal men (Table 40–6). Even in the presence of pituitary deficiency, androgens are used rather than gonadotropin except when normal spermatogenesis is to be achieved. In patients with hypopituitarism, androgens are not added to the treatment regimen until puberty, at which time they are instituted in gradually increasing doses to achieve the growth spurt and the development of secondary sex characteristics. In these patients, therapy should be started with long-acting agents such as testosterone enanthate in doses of 50 mg intramuscularly, initially every 4, then every 3, and finally every 2 weeks, with each change taking place at 3-month intervals. The dose is then doubled to 100 mg every 2 weeks until maturation is complete. Finally, it is changed to the adult replacement dose of 200 mg at 2-week intervals. Testosterone propionate, though potent, has a short duration of action and is not practical for long-term use. Testosterone undecanoate can be given orally, administering large amounts of the steroid twice daily (eg, 40 mg/d); however, this is not recommended because oral testosterone administration has been associated with liver tumors. Testosterone can also be administered transdermally; skin patches or gels are available for scrotal or other skin area application. Two applications daily are usually required for replacement therapy. Implanted pellets and other longer-acting preparations are under study. The development of polycythemia or hypertension may require some reduction in dose.

Table 40–6. Androgen Preparations for Replacement Therapy.

	Route of Administration	Dosage
Methyltestosterone	Oral	25–50 mg/d
	Sublingual (buccal)	5–10 mg/d
Fluoxymesterone	Oral	2–10 mg/d
Testosterone propionate	Sublingual (buccal)	5–20 mg/d
	Intramuscular	10–50 mg three times weekly
Testosterone enanthate	Intramuscular	See text
Testosterone cypionate	Intramuscular	See text

Testosterone	Transdermal	2.5–10 mg/d
	Topical gel (1%)	5–10 g gel/d

Gynecologic Disorders

Androgens are used occasionally in the treatment of certain gynecologic disorders, but the undesirable effects in women are such that they must be used with great caution. Androgens have been used to reduce breast engorgement during the postpartum period, usually in conjunction with estrogens. The weak androgen danazol is used in the treatment of endometriosis (see above).

Androgens are sometimes given in combination with estrogens for replacement therapy in the postmenopausal period in an attempt to eliminate the endometrial bleeding that may occur when only estrogens are used and to enhance libido. They are also used for chemotherapy of breast tumors in premenopausal women.

Use As Protein Anabolic Agents

Androgens and anabolic steroids have been used in conjunction with dietary measures and exercises in an attempt to reverse protein loss after trauma, surgery, or prolonged immobilization and in patients with debilitating diseases.

Anemia

In the past, large doses of androgens were employed in the treatment of refractory anemias such as aplastic anemia, Fanconi's anemia, sickle cell anemia, myelofibrosis, and hemolytic anemias. Recombinant erythropoietin has largely replaced androgens for this purpose.

Osteoporosis

Androgens and anabolic agents have been used in the treatment of osteoporosis, either alone or in conjunction with estrogens. With the exception of substitution therapy in hypogonadism, bisphosphonates have largely replaced androgen use for this purpose.

Use As Growth Stimulators

These agents have been used to stimulate growth in boys with delayed puberty. If the drugs are used carefully, these children will probably achieve their expected adult height. If treatment is too vigorous, the patient may grow rapidly at first but will not achieve full final stature because of the accelerated epiphysial closure that occurs. It is difficult to control this type of therapy adequately even with frequent x-ray examination of the epiphyses, since the action of the hormones on epiphysial centers may continue for many months after therapy is discontinued.

Anabolic Steroid and Androgen Abuse in Sports

The use of anabolic steroids by athletes has received worldwide attention. Many athletes and their coaches believe that anabolic steroids—in doses 10–200 times larger than the daily normal production—increase strength and aggressiveness, thereby improving competitive performance. Although such effects have been demonstrated in women, many studies have failed to unequivocally demonstrate them in men. Placebo effects and the potential impact of minimal

changes in championship competitions make evaluation of these studies very difficult. However, the adverse effects of these drugs clearly make their use inadvisable.

Aging

Androgen production falls with age in men and may contribute to the decline in muscle mass, strength, and libido. Preliminary studies of androgen replacement in aging males with low androgen levels show an increase in lean body mass and hematocrit and a decrease in bone turnover. Longer studies will be required to assess the usefulness of this therapy.

Adverse Effects

The adverse effects of these compounds are due largely to their masculinizing actions and are most noticeable in women and prepubertal children. In women, the administration of more than 200–300 mg of testosterone per month is usually associated with hirsutism, acne, amenorrhea, clitoral enlargement, and deepening of the voice. These effects may occur with even smaller doses in some women. Some of the androgenic steroids exert progestational activity leading to endometrial bleeding upon discontinuation. These hormones also alter serum lipids and could conceivably increase susceptibility to atherosclerotic disease in women. Except under the most unusual circumstances, androgens should not be used in infants. Recent studies in animals suggest that administration of androgens in early life may have profound effects on maturation of central nervous system centers governing sexual development, particularly in the female. Administration of these drugs to pregnant women may lead to masculinization or undermasculinization of the external genitalia in the female and male fetus, respectively. Although the above-mentioned effects may be less marked with the anabolic agents, they do occur.

Sodium retention and edema are not common but must be carefully watched for in patients with heart and kidney disease.

Most of the synthetic androgens and anabolic agents are 17-alkyl-substituted steroids. Administration of drugs with this structure is often associated with evidence of hepatic dysfunction, eg, increase in sulfobromophthalein retention and aspartate aminotransferase (AST) levels. Alkaline phosphatase values are also elevated. These changes usually occur early in the course of treatment, and the degree is proportionate to the dose. Bilirubin levels occasionally increase until clinical jaundice is apparent. The cholestatic jaundice is reversible upon cessation of therapy, and permanent changes do not occur. In older males, prostatic hyperplasia may develop, causing urinary retention.

Replacement therapy in men may cause acne, sleep apnea, erythrocytosis, gynecomastia, and azoospermia. Supraphysiologic doses of androgens produce azoospermia and decrease in testicular size, both of which may take months to recover after cessation of therapy. The alkylated androgens in high doses can produce peliosis hepatica, cholestasis, and hepatic failure. They lower plasma HDL₂ and may increase LDL. Hepatic adenomas and carcinomas have also been reported. Behavioral effects include psychologic dependence, increased aggressiveness, and psychotic symptoms.

Contraindications & Cautions

The use of androgenic steroids is contraindicated in pregnant women or women who may become pregnant during the course of therapy.

Androgens should not be administered to male patients with carcinoma of the prostate or breast. Until more is known about the effects of these hormones on the central nervous system in developing children, they should be avoided in infants and young children.

Special caution is required in giving these drugs to children to produce a growth spurt. In most patients, the use of somatotropin is more appropriate (Chapter 37: Hypothalamic & Pituitary Hormones).

Care should be exercised in the administration of these drugs to patients with renal or cardiac disease predisposed to edema. If sodium and water retention occurs, it will respond to diuretic therapy.

Methyltestosterone therapy is associated with creatinuria, but the significance of this finding is not known.

Caution: Several cases of hepatocellular carcinoma have been reported in patients with aplastic anemia treated with androgen anabolic therapy. Colony-stimulating factors (Chapter 33: Agents Used in Anemias; Hematopoietic Growth Factors) should be used instead.

Androgen Suppression & Antiandrogens

Androgen Suppression

The treatment of advanced prostatic carcinoma often requires orchiectomy or large doses of estrogens to reduce available endogenous androgen. The psychologic effects of the former and gynecomastia produced by the latter make these approaches undesirable. As noted in Chapter 37: Hypothalamic & Pituitary Hormones, the gonadotropin-releasing hormone analogs such as goserelin, nafarelin, buserelin, and leuprolide acetate produce gonadal suppression when blood levels are continuous rather than pulsatile (see Chapter 37: Hypothalamic & Pituitary Hormones and Figure 40–5). **Leuprolide acetate** is injected subcutaneously daily in doses of 1 mg (or depot leuprolide is given once every month or every 3 months) for the treatment of prostatic carcinoma. Goserelin is administered once every 4 weeks as a subcutaneous slow-release injection. Although testosterone levels fall to 10% of their initial values after a month with either of these drugs, they *increase* significantly in the beginning. This increase is usually associated with a flare of tumor activity and an increase in symptoms. The combination of a GnRH agonist and flutamide, an androgen antagonist (or equivalent, see below), can prevent the initial stimulation and provide a more effective inhibition of androgenic activity.

Figure 40–5.

Control of androgen secretion and activity and some sites of action of antiandrogens. (1), competitive inhibition of GnRH receptors; (2), stimulation (+, pulsatile administration) or inhibition via desensitization of GnRH receptors (-, continuous administration); (3), decreased synthesis of testosterone in the testis; (4), decreased synthesis of dihydrotestosterone by inhibition

of 5 α -reductase; (5), competition for binding to cytosol androgen receptors.

GnRH antagonists have also been under study, since they would have the advantage of eliminating the surge of androgen secretion seen at the beginning of GnRH analog therapy. Most of the compounds studied have the capacity to release histamine and are unsuitable for use. However, newer agents with less histamine-releasing activity are being studied.

Antiandrogens

The potential usefulness of antiandrogens for the treatment of patients producing excessive amounts of testosterone has led to the search for effective drugs that can be used for this purpose. Several approaches to the problem, especially inhibition of synthesis and receptor antagonism, have met with some success.

Steroid Synthesis Inhibitors

Ketoconazole, used primarily for the treatment of fungal disease, is an inhibitor of adrenal and gonadal steroid synthesis, as described in Chapter 39: Adrenocorticosteroids & Adrenocortical Antagonists. It does not affect ovarian aromatase, but it reduces human placental aromatase activity. It displaces estradiol and dihydrotestosterone from sex hormone-binding protein in vitro and increases the estradiol:testosterone ratio in plasma in vivo by a different mechanism. However, it does not appear to be clinically useful in women with increased androgens because of the toxicity associated with prolonged use of the 400–800 mg/d required. The drug has also been used experimentally to treat prostatic carcinoma, but the results have not been encouraging. Men treated with ketoconazole often develop reversible gynecomastia during therapy; this may be due to the demonstrated increase in the estradiol:testosterone ratio.

Conversion of Steroid Precursors to Androgens

Several compounds have been developed that inhibit the 17-hydroxylation of progesterone or pregnenolone, thereby preventing the action of the side chain-splitting enzyme and the further transformation of these steroid precursors to active androgens. A few of these compounds have been tested clinically but have been too toxic for prolonged use.

Since dihydrotestosterone—not testosterone—appears to be the essential androgen in the prostate, androgen effects in this and similar dihydrotestosterone-dependent tissues can be reduced by an inhibitor of 5 α -reductase (Figure 40–5). **Finasteride**, a steroid-like inhibitor of this enzyme, is orally active and produces a reduction in dihydrotestosterone levels within 8 hours after administration that lasts for about 24 hours. The half-life is about 8 hours (longer in elderly individuals). Forty to 50 percent of the dose is metabolized; more than half is excreted in the feces. Finasteride has been reported to be moderately effective in reducing prostate size in men with benign prostatic hyperplasia and is approved for this use in the USA. The dosage is 5 mg/d. Its use in advanced prostatic carcinoma is under study. The drug is not approved for use in women or children, though it has been used successfully in the treatment of hirsutism in women and early male pattern baldness in men (1 mg/d).

Receptor Inhibitors

Cyproterone and **cyproterone acetate** are effective antiandrogens that inhibit the action of androgens at the target organ. The acetate form has a marked progestational effect that suppresses the feedback enhancement of LH and FSH, leading to a more effective antiandrogen effect. These compounds have been used in women for the treatment of hirsutism and in men to decrease excessive sexual drive and are being studied in other conditions in which the reduction of androgenic effects would be useful. Cyproterone acetate in a dosage of 2 mg/d administered concurrently with an estrogen is used in the treatment of hirsutism in women, doubling as a contraceptive pill; it has orphan drug status in the USA.

Flutamide, a substituted anilide, is a potent antiandrogen that has been used in the treatment of prostatic carcinoma. Though not a steroid, it behaves like a competitive antagonist at the androgen receptor. It is rapidly metabolized in humans. It frequently causes mild gynecomastia (probably by increasing testicular estrogen production) and occasionally causes mild reversible hepatic toxicity. Administration of this compound causes some improvement in most patients who have not had prior endocrine therapy. Preliminary studies indicate that flutamide is also useful in the management of excess androgen effect in women.

Bicalutamide and **nilutamide** are potent orally active antiandrogens that can be administered as a single daily dose and are used in patients with metastatic prostate carcinoma. Studies in patients with carcinoma of the prostate indicate that they are well tolerated. Bicalutamide is recommended for use in combination with a GnRH analog (to reduce tumor flare) and may have fewer gastrointestinal side effects than flutamide. A dosage of 150–200 mg/d (when used alone) is required to reduce prostate-specific antigen levels to those achieved by castration, but, in combination with a GnRH analog, 50 mg/d may be adequate. Nilutamide is approved for use following surgical castration in a dosage of 300 mg/d for 30 days followed by 150 mg/d.

Spirolactone, a competitive inhibitor of aldosterone (see Chapter 15: Diuretic Agents), also competes with dihydrotestosterone for the androgen receptors in target tissues. It also reduces 17 α -

hydroxylase activity, lowering plasma levels of testosterone and androstenedione. It is used in dosages of 50–200 mg/d for the treatment of hirsutism in women and appears to be as effective as finasteride, flutamide, or cyproterone in this condition.

Chemical Contraception in Men

Although many studies have been conducted, an effective oral contraceptive for men has not yet been found. For example, various androgens, including testosterone and testosterone enanthate, in a dosage of 400 mg per month, produced azoospermia in less than half the men treated. Minor adverse reactions, including gynecomastia and acne, were encountered. Testosterone in combination with danazol was well tolerated but no more effective than testosterone alone. Androgens in combination with a progestin such as medroxyprogesterone acetate were no more effective. However, preliminary studies indicate that the intramuscular administration of 100 mg of testosterone enanthate weekly together with 500 mg of levonorgestrel daily orally can produce azoospermia in 94% of men.

Cyproterone acetate, a very potent progestin and antiandrogen, also produces oligospermia; however, it does not cause reliable contraception.

At present, pituitary hormones—and potent antagonist analogs of GnRH—are receiving increased attention. A GnRH antagonist in combination with testosterone has been shown to produce reversible azoospermia in nonhuman primates.

Gossypol

Extensive trials of this cottonseed derivative have been conducted in China. This compound destroys elements of the seminiferous epithelium but does not alter the endocrine function of the testis in a major fashion.

Gossypol

In Chinese studies, large numbers of men were treated with 20 mg/d of gossypol or gossypol acetic acid for 2 months, followed by a maintenance dosage of 60 mg/wk. On this regimen, 99% of men developed sperm counts below 4 million/mL. Preliminary data indicate that recovery (return of normal sperm count) following discontinuance of gossypol administration is more apt to occur in men whose counts do not fall to extremely low levels and when administration is not continued for more than 2 years. Hypokalemia is the major adverse effect and may lead to transient paralysis. The drug has also been tried as an intravaginal spermicide contraceptive.

Preparations Available¹

Estrogens

Conjugated estrogens (Premarin)

Oral: 0.3, 0.625, 0.9, 1.25, 2.5 mg tablets

Parenteral: 25 mg/5 mL for IM, IV injection

Vaginal: 0.625 mg/g cream base

Dienestrol (Ortho Dienestrol, DV)

Vaginal: 10 mg/g cream

Diethylstilbestrol diphosphate (Stilphostrol)

Oral: 50 mg tablets

Parenteral: 50 mg/mL injection

Esterified estrogens (Menest, Estratab)

Oral: 0.3, 0.625, 1.25, 2.5 mg tablets

Estradiol cypionate in oil (generic, Depo-Estradiol Cypionate)

Parenteral: 5 mg/mL for IM injection

Estradiol (generic, Estrace)

Oral: 0.5, 1, 2 mg tablets

Vaginal: 0.1 mg/g cream

Estradiol transdermal (Estraderm, others)

Transdermal: patches with 0.025, 0.0375, 0.05, 0.075, 0.1 mg/d release rates

Estradiol valerate in oil (generic)

Parenteral: 10, 20, 40 mg/mL for IM injection

Estrone aqueous suspension (generic, Kestrone 5)

Parenteral: 5 mg/mL for injection

Estropipate (generic, Ogen)

Oral: 0.625, 1.25, 2.5, 5 mg tablets

Vaginal: 1.5 mg/g cream base

Ethinyl estradiol (Estinyl)

Oral: 0.02, 0.05, 0.5 mg tablets

Progestins

Hydroxyprogesterone caproate (generic, Hylutin)

Parenteral: 125, 250 mg/mL for IM injection

Levonorgestrel (Norplant)

Kit for subcutaneous implant: 6 capsules of 36 mg each

Medroxyprogesterone acetate (generic, Provera)

Oral: 2.5, 5, 10 mg tablets

Parenteral (Depo-Provera): 150, 400 mg/mL for IM injection

Megestrol acetate (generic, Megace)

Oral: 20, 40 mg tablets; 40 mg/mL suspension

Norethindrone acetate (generic, Aygestin)

Oral: 5 mg tablets

Norgestrel (Ovrette) (See also Table 40–3)

Oral: 0.075 mg tablets

Progesterone (generic)

Oral: 100 mg capsules

Topical: 8% vaginal gel

Parenteral: 50 mg/mL in oil for IM injection

Androgens & Anabolic Steroids

Fluoxymesterone (generic, Halotestin)

Oral: 2, 5, 10 mg tablets

Methyltestosterone (generic)

Oral: 10, 25 mg tablets; 10 mg capsules; 10 mg buccal tablets

Parenteral: 200 mg/mL injection

Nandrolone decanoate (Deca-Durabolin, others)

Parenteral: 100, 200 mg/mL in oil for injection

Oxandrolone (Oxandrin)

Oral: 2.5 mg tablets

Oxymetholone (Androl-50)

Oral: 50 mg tablets

Stanozolol (Winstrol)

Oral: 2 mg tablets

Testolactone (Teslac)

Oral: 50 mg tablets

Testosterone aqueous (generic, others)

Parenteral: 25, 50, 100 mg/mL suspension for IM injection

Testosterone cypionate in oil (generic, others)

Parenteral: 100, 200 mg/mL for IM injection

Testosterone enanthate in oil (generic)

Parenteral: 200 mg/mL for IM injection

Testosterone propionate in oil (generic, Testex)

Parenteral: 100 mg/mL for IM injection

Testosterone transdermal system

Patch (Testoderm): 4, 5, 6 mg/24 h release rate

Patch (Androderm): 2.5, 5 mg/24 h release rate

Gel (Androgel): 25, 50 mg total

Testosterone pellets (Testopel)

Parenteral: 75 mg/pellet for parenteral injection (not IV)

Antagonists & Inhibitors

(See Also Chapter 37: Hypothalamic & Pituitary Hormones)

Anastrozole (Arimidex)

Oral: 1 mg tablets

Bicalutamide (Casodex)

Oral: 50 mg tablets

Clomiphene (generic, Clomid, Serophene, Milophene)

Oral: 50 mg tablets

Danazol (generic, Danocrine)

Oral: 50, 100, 200 mg capsules

Dutasteride (Avodart)

Oral: 0.5 mg tablets

Exemestane (Aromasin)

Oral: 25 mg tablets

Finasteride

Oral: 1 mg tablets (Propecia); 5 mg tablets (Proscar)

Flutamide (Eulexin)

Oral: 125 mg capsules

Fulvestrant (Faslodex)

Parenteral: 50 mg/mL for IM injection

Letrozole (Femara)

Oral: 2.5 mg tablets

Mifepristone (Mifeprex)

Oral: 200 mg tablets

Nilutamide (Nilandron)

Oral: 50, 150 mg tablets

Raloxifene (Evista)

Oral: 60 mg tablets

Tamoxifen (generic, Nolvadex)

Oral: 10, 20 mg tablets

Toremifene (Fareston)

Oral: 60 mg tablets

¹ Oral contraceptives are listed in Table 40–3.

Chapter 41. Pancreatic Hormones & Antidiabetic Drugs

Katzung PHARMACOLOGY, 9e > Section VII. Endocrine Drugs > Chapter 41. Pancreatic Hormones & Antidiabetic Drugs >

The Endocrine Pancreas

* Deceased.

The endocrine pancreas in the adult human consists of approximately 1 million islets of Langerhans interspersed throughout the pancreatic gland. Within the islets, at least four hormone-producing cells are present (Table 41–1). Their hormone products include **insulin**, the storage and anabolic hormone of the body; **islet amyloid polypeptide (IAPP, or amylin)**, whose metabolic function remains undefined; **glucagon**, the hyperglycemic factor that mobilizes glycogen stores; **somatostatin**, a universal inhibitor of secretory cells; and **pancreatic peptide**, a small protein that facilitates digestive processes by a mechanism not yet clarified.

Table 41–1. Pancreatic Islet Cells and Their Secretory Products.

Cell Types	Approximate Percent of Islet Mass	Secretory Products
A cell (alpha)	20	Glucagon, proglucagon
B cell (beta)	75	Insulin, C-peptide, proinsulin, islet amyloid polypeptide (IAPP)

D cell (delta)	3–5	Somatostatin
F cell (PP cell) ¹	< 2	Pancreatic polypeptide (PP)

¹Within pancreatic polypeptide-rich lobules of adult islets, located only in the posterior portion of the head of the human pancreas, glucagon cells are scarce (< 0.5%) and F cells make up as much as 80% of the cells.

The elevated blood glucose associated with diabetes mellitus results from absent or inadequate pancreatic insulin secretion, with or without concurrent impairment of insulin action. The disease states underlying the diagnosis of diabetes mellitus are now classified into four categories: type 1, "insulin-dependent diabetes," type 2, "noninsulin-dependent diabetes," type 3, "other," and type 4, "gestational diabetes mellitus" (Expert Committee 2002, Mayfield, 1998).

Type 1 Diabetes Mellitus

The hallmark of type 1 diabetes is selective B cell destruction and severe or absolute insulin deficiency. Administration of insulin is essential in patients with type 1 diabetes. Type 1 diabetes is further subdivided into immune and idiopathic causes. The immune form is the most common form of type 1 diabetes. In the USA, this form is diagnosed in approximately 1,500,000 individuals. Although most patients are younger than 30 years of age at the time of diagnosis, the onset can occur at any age. Type 1 diabetes is found in all ethnic groups, but the highest incidence is in people from northern Europe and from Sardinia. Susceptibility appears to involve a multifactorial genetic linkage but only 15–20% of patients have a positive family history.

Type 2 Diabetes Mellitus

Type 2 diabetes is characterized by tissue resistance to the action of insulin combined with a relative deficiency in insulin secretion. A given individual may have more resistance or more B cell deficiency, and the abnormalities may be mild or severe. Although insulin is produced by the B cells in these patients, it is inadequate to overcome the resistance, and the blood glucose rises. The impaired insulin action also affects fat metabolism, resulting in increased free fatty acid flux and triglyceride levels, and reciprocally low high-density lipoprotein (HDL) levels.

Individuals with type 2 diabetes may not require insulin to survive, but 30% or more will benefit from insulin therapy to control the blood glucose. It is likely that 10–20% of individuals in whom type 2 diabetes was initially diagnosed actually have both type 1 and type 2, or have a slowly progressing type 1, and ultimately will require full insulin replacement. Although persons with type 2 diabetes ordinarily will not develop ketosis, ketoacidosis may occur as the result of stress such as infection or use of medication that enhances resistance, eg, corticosteroids. Dehydration in untreated and poorly controlled individuals with type 2 diabetes can lead to a life-threatening condition called "non-ketotic hyperosmolar coma". In this condition, the blood glucose may rise to 6–20 times the normal range and an altered mental state develops or the person loses consciousness. Urgent medical care and rehydration is required.

Type 3 Diabetes Mellitus

The type 3 designation refers to multiple **other** specific causes of an elevated blood glucose:

nonpancreatic diseases, drug therapy, etc. For a complete, detailed list the reader is referred to Expert Committee, 2002 or Mayfield, 1998.

Type 4 Diabetes Mellitus

Gestational Diabetes (GDM) is defined as any abnormality in glucose levels noted for the first time during pregnancy. Gestational diabetes is diagnosed in approximately 4% of all pregnancies in the USA. During pregnancy, the placenta and placental hormones create an insulin resistance that is most pronounced in the last trimester. Risk assessment for diabetes is suggested starting at the first prenatal visit. High risk individuals should be screened immediately. Screening may be deferred in lower risk women until the 24th to 28th week of gestation.

Insulin

Chemistry

Insulin is a small protein with a molecular weight in humans of 5808. It contains 51 amino acids arranged in two chains (A and B) linked by disulfide bridges; there are species differences in the amino acids of both chains. Proinsulin, a long single-chain protein molecule, is processed within the Golgi apparatus and packaged into granules, where it is hydrolyzed into insulin and a residual connecting segment called C-peptide by removal of four amino acids (shown in dashed circles in Figure 41-1).

Figure 41-1.

Structure of human proinsulin and commercially available insulin analogs. Insulin is shown as the shaded (darker color) peptide chains, A and B. Species differences in the A and B chains and amino acid modifications for insulin aspart, lispro, and glargine are noted.

Insulin and C-peptide are secreted in equimolar amounts in response to all insulin secretagogues; a small quantity of unprocessed or partially hydrolyzed proinsulin is released as well. While proinsulin may have some mild hypoglycemic action, C-peptide has no known physiologic function. Granules within the B cells store the insulin in the form of crystals consisting of two atoms of zinc and six molecules of insulin. The entire human pancreas contains up to 8 mg of insulin, representing approximately 200 biologic units. Originally, the unit was defined on the basis of the hypoglycemic activity of insulin in rabbits. With improved purification techniques, the unit is presently defined on the basis of weight, and present insulin standards used for assay purposes contain 28 units per milligram.

Insulin Secretion

Insulin is released from pancreatic B cells at a low basal rate and at a much higher stimulated rate in response to a variety of stimuli, especially glucose. Other stimulants such as other sugars (eg, mannose), certain amino acids (eg, leucine, arginine), and vagal activity are recognized. One mechanism of stimulated insulin release is diagrammed in Figure 41–2. As shown in the figure, hyperglycemia results in increased intracellular ATP levels, which close the ATP-dependent potassium channels. Decreased outward potassium efflux results in depolarization of the B cell and opening of voltage-gated calcium channels. The resulting increased intracellular calcium triggers secretion of the hormone. As noted below, the insulin secretagogue drug group (sulfonylureas, meglitinides, and D-phenylalanine) exploits parts of this mechanism.

Figure 41-2.

One model of control of insulin release from the pancreatic B cell by glucose and by sulfonylurea drugs. In the resting cell with normal (low) ATP levels, potassium diffuses down its concentration gradient through ATP-gated potassium channels, maintaining the intracellular potential at a fully polarized, negative level. Insulin release is minimal. If glucose concentration rises, ATP production increases, potassium channels close, and depolarization of the cell results. As in muscle and nerve, voltage-gated calcium channels open in response to depolarization, allowing more calcium to enter the cell. Increased intracellular calcium results in increased insulin secretion. Insulin secretagogues close the ATP-dependent potassium channel, thereby depolarizing the membrane and causing increased insulin release by the same mechanism. Insulin Degradation

The liver and kidney are the two main organs that remove insulin from the circulation. The liver normally clears the blood of approximately 60% of the insulin released from the pancreas by virtue of its location as the terminal site of portal vein blood flow, with the kidney removing 35–40% of the endogenous hormone. However, in insulin-treated diabetics receiving subcutaneous insulin injections, this ratio is reversed, with as much as 60% of exogenous insulin being cleared by the kidney and the liver removing no more than 30–40%. The half-life of circulating insulin is 3–5 minutes.

Measurement of Circulating Insulin

The radioimmunoassay of insulin permits detection of insulin in picomolar quantities. The assay is based on antibodies developed in guinea pigs against bovine or pork insulin. Because of the similarities between these two insulins and human insulin, the assay successfully measures the human hormone as well.

With this assay, basal insulin values of 5–15 $\mu\text{U/mL}$ (30–90 pmol/L) are found in normal humans, with a peak rise to 60–90 $\mu\text{U/mL}$ (360–540 pmol/L) during meals. Similar assays for measuring all of the known hormones of the endocrine pancreas (including C-peptide and proinsulin) have been developed.

The Insulin Receptor

Once insulin has entered the circulation, it is bound by specialized receptors that are found on the membranes of most tissues. The biologic responses promoted by these insulin-receptor complexes have been identified in the primary target tissues, ie, liver, muscle, and adipose tissue. The receptors bind insulin with high specificity and affinity in the picomolar range. The full insulin receptor consists of two covalently linked heterodimers, each containing an α subunit, which is entirely extracellular and constitutes the recognition site, and a β subunit that spans the membrane (Figure 41–3). The β subunit contains a tyrosine kinase. The binding of an insulin molecule to the α subunits at the outside surface of the cell activates the receptor and through a conformational change brings the catalytic loops of the opposing cytoplasmic β subunits into closer proximity thereby facilitating phosphorylation of tyrosine residues and tyrosine kinase activity.

Figure 41–3.

Schematic diagram of the insulin receptor heterodimer in the activated state. IRS, insulin receptor substrate; tyr, tyrosine; P, phosphate.

The first proteins to be phosphorylated by the activated receptor tyrosine kinases are the docking proteins, insulin receptor substrate-1 and -2 (IRS-1, IRS-2). After tyrosine phosphorylation at several critical sites, IRS-1 and IRS-2 bind to and activate other kinases—most importantly phosphatidylinositol-3-kinase—that produce further phosphorylations or to an adaptor protein such as growth factor receptor-binding protein 2 that translates the insulin signal to a guanine nucleotide-releasing factor that ultimately activates the GTP binding protein ras, and the mitogen activated protein kinase (MAPK) system. The particular IRS-phosphorylated tyrosine kinases have binding specificity with downstream molecules based on their surrounding 4–5 amino acid sequences or motifs that recognize specific Src homology 2 (SH2) domains on the other protein. This network of phosphorylations within the cell represents insulin's second message and results in multiple effects including translocation of glucose transporters (especially GLUT-4, Table 41–2) to the cell membrane with a resultant increase in glucose uptake; glycogen synthase activity and increased glycogen formation; multiple effects on protein synthesis, lipolysis, and lipogenesis; and activation of transcription factors that enhance DNA synthesis and cell growth and division.

Table 41–2. Glucose Transporters.

Transporter	Tissues	Glucose K_m (mmol/L)	Function
GLUT 1	All tissues, especially red cells, brain	1–2	Basal uptake of glucose; transport across the blood-brain barrier
GLUT 2	B cells of pancreas; liver, kidney; gut	15–20	Regulation of insulin release, other aspects of glucose homeostasis
GLUT 3	Brain, kidney, placenta, other tissues	< 1	Uptake into neurons, other tissues
GLUT 4	Muscle, adipose	≈ 5	Insulin-mediated uptake of glucose
GLUT 5	Gut, kidney	1–2	Absorption of fructose

Various hormonal agents (eg, glucocorticoids) lower the affinity of insulin receptors for insulin; growth hormone in excess increases this affinity slightly. Aberrant serine and threonine phosphorylation of the insulin receptor β subunits or IRS molecules may result in insulin resistance and functional receptor down-regulation.

Effects of Insulin on Its Targets

Insulin promotes the storage of fat as well as glucose (both sources of energy) within specialized target cells (Figure 41–4) and influences cell growth and the metabolic functions of a wide variety of tissues (Table 41–3).

Figure 41–4.

Insulin promotes synthesis (from circulating nutrients) and storage of glycogen, triglycerides, and

protein in its major target tissues: liver, fat, and muscle. The release of insulin from the pancreas is stimulated by increased blood glucose, vagal nerve stimulation, and other factors (see text).

Table 41–3. Endocrine Effects of Insulin.

Effect on liver:

Reversal of catabolic features of insulin deficiency

Inhibits glycogenolysis

Inhibits conversion of fatty acids and amino acids to keto acids

Inhibits conversion of amino acids to glucose

Anabolic action

Promotes glucose storage as glycogen (induces glucokinase and glycogen synthase, inhibits phosphorylase)

Increases triglyceride synthesis and very low density lipoprotein formation

Effect on muscle:

Increased protein synthesis

Increases amino acid transport

Increases ribosomal protein synthesis

Increased glycogen synthesis

Increases glucose transport

Induces glycogen synthase and inhibits phosphorylase

Effect on adipose tissue:

Increased triglyceride storage

Lipoprotein lipase is induced and activated by insulin to hydrolyze triglycerides from lipoproteins

Glucose transport into cell provides glycerol phosphate to permit esterification of fatty acids supplied by lipoprotein transport

Intracellular lipase is inhibited by insulin

Characteristics of Available Insulin Preparations

Commercial insulin preparations differ in a number of ways, including differences in the recombinant DNA production techniques, amino acid sequence, concentration, solubility, and the time of onset and duration of their biologic action. In 2003, seventeen insulin formulations were available in the USA.

Principal Types and Duration of Action of Insulin Preparations

Four principal types of insulins are available: (1) rapid-acting, with very fast onset and short duration; (2) short-acting, with rapid onset of action; (3) intermediate-acting; and (4) long-acting, with slow onset of action (Figure 41–5, Table 41–4). Rapid-acting and short-acting insulins are dispensed as clear solutions at neutral pH and contain small amounts of zinc to improve their

stability and shelf-life. All other commercial insulins have been modified to provide prolonged action and are, with the exception of insulin glargine, dispensed as turbid suspensions at neutral pH with either protamine in phosphate buffer (neutral protamine Hagedorn [NPH] insulin) or varying concentrations of zinc in acetate buffer (ultralente and lente insulins). Insulin glargine is the only soluble long-acting insulin. The goal of subcutaneous insulin therapy is to replace the normal basal (overnight, fasting, and between meal) as well as prandial (mealtime) insulin. Current regimens generally use intermediate- or long-acting insulins to provide basal or background coverage, and rapid-acting or short-acting insulin to meet the mealtime requirements. The latter insulins are given as supplemental doses to correct high blood sugars. Intensive therapy ("tight control") attempts to restore near-normal glucose patterns throughout the day while minimizing the risk of hypoglycemia. An exact reproduction of the normal glycemic profile is technically not possible because of the limitations inherent in subcutaneous administration of insulin. The most sophisticated insulin regimen delivers rapid-acting insulin through a continuous subcutaneous insulin infusion device; alternative intensive regimens referred to as multiple daily injections (MDI) use long-acting or intermediate-acting insulins with multiple boluses of rapid-acting or short-acting insulin. Conventional therapy presently consists of split-dose injections of mixtures of rapid- or short-acting and intermediate-acting insulins.

Table 41–4. Some Insulin Preparations Available in the USA.^{1,2}

Preparation	Species Source	Concentration
Rapid-acting insulins		
Insulin lispro, Humalog (Lilly)	Human analog	U100
Insulin Aspart, Novolog (Novo Nordisk)	Human analog	U100
Short-acting insulins		
Regular (Novo Nordisk) ³	Human	U100
Regular Humulin (Lilly)	Human	U100, U500
Velosulin BR (Novo Nordisk) ⁴	Human	U100
Intermediate-acting insulins		
Lente Humulin (Lilly)	Human	U100
Lente (Novo Nordisk)	Human	U100
NPH Humulin (Lilly)	Human	U100
NPH (Novo Nordisk)	Human	U100
Premixed insulins (% NPH, % regular)		
Novolin 70/30 (Novo Nordisk)	Human	U100
Humulin 70/30 and 50/50 (Lilly)	Human	U100
Premixed (% NP-analog, % rapid acting analog)		
50/50 NPL, Lispro (Lilly)	Human analog	U100
75/25 NPL, Lispro (Lilly)	Human analog	U100
70/30 NPA, Aspart (NovoNordisk)	Human analog	U100

Long-acting insulins		
Ultralente Humulin U (Lilly)	Human	U100
Insulin glargine-lantus (Aventis/Hoechst Marion Roussel)	Human	U100

¹ Modified and reproduced, with permission, from Katzung BG (editor): *Drug Therapy*, 2nd ed. Originally published by Appleton & Lange. Copyright © 1991 by The McGraw-Hill Companies, Inc.

² All of these agents (except insulin lispro, insulin aspart, insulin glargine, and U500 regular Humulin) are available without a prescription. All insulins should be refrigerated and brought to room temperature just before injection.

³ Novo Nordisk human insulins are termed Novolin R, L, and N.

⁴ Velosulin contains phosphate buffer, which favors its use to prevent insulin aggregation in pump tubing but precludes its being mixed with lente insulin.

Rapid-Acting Insulin

Two rapid-acting insulin analogs are commercially available: **insulin lispro** and **insulin aspart**. The rapid-acting insulins permit more physiologic prandial insulin replacement because their rapid onset and early peak action more closely mimics normal endogenous prandial insulin secretion than does regular insulin, and they have the additional benefit of allowing insulin to be taken immediately before the meal without sacrificing glucose control. Their duration of action is rarely more than 3–5 hours, which decreases the risk of late postmeal hypoglycemia. They have the lowest variability of absorption of all available insulin formulations.

Insulin lispro, the first monomeric insulin analog to be marketed, is produced by recombinant technology wherein two amino acids near the carboxyl terminal of the B chain have been reversed in position: proline at position B28 has been moved to B29 and lysine at position B29 has been moved to B28 (Figure 41–1). Reversing these two amino acids does not interfere in any way with insulin lispro's binding to the insulin receptor, its circulating half-life, or with its immunogenicity, all of which are identical with those of human regular insulin. However, the advantage of this analog is its very low propensity—in contrast to human insulin—to self-associate in antiparallel fashion and form dimers. To enhance the shelf-life of insulin in vials, insulin lispro is stabilized into hexamers by a cresol preservative. When injected subcutaneously, the drug quickly dissociates into monomers and is rapidly absorbed with onset of action within 5–15 minutes, and reaching peak activity as early as 1 hour. The time to peak action is relatively constant, regardless of the dose. Its duration is seldom more than 3–5 hours.

Insulin lispro has a low variability of absorption (5%) of all the commercial insulin preparations—compared with 25% for regular insulin and 25–50% or more for intermediate-acting and long-acting insulins. Although not specifically approved for use in continuous subcutaneous insulin infusion (CSII) pumps, when used in these devices or in intensive insulin regimens, insulin lispro is associated with significantly improved glycemic control compared with regular insulin, without increased incidence of hypoglycemia.

Insulin aspart is created by the substitution of the B28 proline with a negatively charged aspartic acid (Figure 41–1). This modification reduces the normal ProB28 and GlyB23 monomer-monomer

interaction, thereby inhibiting insulin self-aggregation. Insulin aspart rapidly breaks into monomers after subcutaneous injection, displays an onset of action within 10–20 minutes, and exerts a peak effect within 1 hour, with an average duration of action of no longer than 3–5 hours. Its absorption and activity profile is similar to insulin lispro and more reproducible than regular insulin, but it has similar binding, activity, and mitogenicity characteristics to regular insulin and equivalent immunogenicity. Insulin aspart is approved for subcutaneous administration by injection as well as through CSII devices.

Short-Acting Insulin

Regular insulin is a short-acting soluble crystalline zinc insulin made by recombinant DNA techniques to produce a molecule identical to human insulin. Its effect appears within 30 minutes and peaks between 2 and 3 hours after subcutaneous injection and generally lasts 5–8 hours. In high concentrations, eg, in the vial, regular insulin molecules self-aggregate in antiparallel fashion to form dimers that stabilize around zinc ions to create insulin hexamers. The hexameric nature of regular insulin causes a delayed onset and prolongs the time to peak action. After subcutaneous injection, the insulin hexamers are too large and bulky to be transported across the vascular endothelium into the bloodstream. As the insulin depot is diluted by interstitial fluid and the concentration begins to fall, the hexamers break down into dimers and finally monomers. This results in three different rates of absorption of the injected insulin, with the final monomeric phase having the fastest uptake out of the injection site. As with all older insulin formulations, the duration of action as well as the time of onset and the intensity of peak action increase with the size of the dose. Clinically, this is a critical issue because the pharmacokinetics and pharmacodynamics of small doses of regular, NPH, lente, and ultralente, insulins differ greatly from those of large doses. Short-acting soluble insulin is the only type that should be administered intravenously as the dilution causes the hexameric insulin to immediately dissociate into monomers. It is particularly useful for intravenous therapy in the management of diabetic ketoacidosis and when the insulin requirement is changing rapidly, such as after surgery or during acute infections.

Intermediate-Acting and Long-Acting Insulins

Lente Insulin

Lente insulin is a mixture of 30% semilente (an amorphous precipitate of insulin with zinc ions in acetate buffer that has a relatively rapid onset of action) with 70% ultralente insulin (a poorly soluble crystal of zinc insulin that has a delayed onset and prolonged duration of action). These two components provide a combination of relatively rapid absorption with sustained long action, making lente insulin a useful therapeutic agent. As with regular insulin, the time of onset, time to peak, and duration of action are dose-dependent.

NPH (Neutral Protamine Hagedorn, or Isophane) Insulin

NPH insulin is an intermediate-acting insulin wherein absorption and the onset of action is delayed by combining appropriate amounts of insulin and protamine so that neither is present in an uncomplexed form ("isophane"). Protamine is a mixture of six major and some minor compounds of similar structure isolated from the sperm of rainbow trout. They appear to be basic, arginine-rich peptides with an average molecular weight of approximately 4400. To form an isophane complex (one in which neither component retains any free binding sites), approximately a 1:10 ratio by weight of protamine to insulin is required, representing approximately six molecules of insulin per molecule of protamine. After subcutaneous injection, proteolytic tissue enzymes degrade the protamine to permit absorption of insulin.

The onset and duration of action of NPH insulin are similar to those of lente insulin (Figure 41–5); it is usually mixed with regular, lispro, or aspart insulin and given two to four times daily for insulin replacement in patients with type 1 diabetes. The dose regulates the action profile, specifically, small doses have lower, earlier peaks and a short duration of action with the converse true for large doses.

Figure 41–5.

Extent and duration of action of various types of insulin as indicated by the glucose infusion rates (mg/kg/min) required to maintain a constant glucose concentration. The durations of action shown are typical of an average dose of 0.2–0.3 U/kg; with the exception of insulin lispro and insulin aspart, duration increases considerably when dosage is increased.

Ultralente Insulin

There has recently been a resurgence in the use of ultralente insulin, in combination with multiple injections of rapid-acting insulin, as a means of attempting optimal control in patients with type 1 diabetes. Human insulin (Humulin U [Lilly]) is the only ultralente insulin available in the USA. In contrast to the older animal insulin-based formulations, human ultralente has a shorter duration of action and more pronounced peak effect. To create a smoother background insulin profile and minimize the peak effect, it is recommended that the daily dose of human ultralente be split into two or more doses. This is especially needed in patients with type 1 diabetes to achieve basal insulin levels throughout the 24 hours that are more comparable to those achieved in normal subjects by basal endogenous secretion or by the overnight infusion rate programmed into insulin pumps.

Insulin Glargine

Insulin glargine is a soluble, "peakless" (ie, having a broad plasma concentration plateau), ultra-long-acting insulin analog. This product was designed to provide reproducible, convenient, background insulin replacement. The attachment of two arginine molecules to the B chain carboxyl

terminal and substitution of a glycine for asparagine at the A21 position created an analog that is soluble in solution but precipitates in the more neutral body pH after subcutaneous injection. Individual insulin molecules slowly dissolve away from the crystalline depot and provide a low, continuous level of circulating insulin. Insulin glargine has a slow onset of action (1–1.5 hours) and achieves a maximum effect after 4–5 hours. This maximum activity is maintained for 11–24 hours or longer. Glargine is usually given once daily, although some very insulin-sensitive individuals will benefit from split (twice a day) dosing. To maintain solubility, the formulation is unusually acidic (pH 4.0) and insulin glargine should not be mixed with other insulin. Separate syringes must be used to minimize the risk of contamination and subsequent loss of efficacy. The absorption pattern of insulin glargine appears to be independent of the anatomic site of injection, and this drug is associated with less immunogenicity than human insulin in animal studies. Glargine's interaction with the insulin receptor is similar to that of native insulin and shows no increase in mitogenic activity in vitro. It has sixfold to sevenfold greater binding than native insulin to the IGF1 receptor, but the clinical significance of this is unclear.

Mixtures of Insulins

Since intermediate-acting insulins require several hours to reach adequate therapeutic levels, their use in type 1 diabetic patients requires supplements of lispro, aspart, or regular insulin before meals. For convenience, these are often mixed together in the same syringe before injection. When regular insulin is used, NPH is preferred to lente insulin as the intermediate-acting component in these mixtures because increased proportions of lente to regular insulin may retard the rapid action of admixed regular insulin, particularly if not injected immediately after mixing. This is due to precipitation of the regular insulin by excess zinc. Premixed formulations of 70%/30% NPH and regular and 50%/50% NPH and regular are available in the USA. Insulin lispro and aspart can be *acutely* mixed (ie, just before injection) with either NPH, lente, or ultralente insulin without affecting their rapid absorption. However, *premixed* preparations have thus far been unstable. To remedy this, intermediate insulins composed of isophane complexes of protamine with insulin lispro and insulin aspart have been developed. These intermediate insulins have been designated as "NPL" (neutral protamine lispro) and "NPA" (neutral protamine aspart) and have the same duration of action as NPH insulin. They have the advantage of permitting formulation as premixed combinations of NPL and insulin lispro, and NPA and insulin aspart and they have been shown to be safe and effective in clinical trials. The FDA has approved 50%/50% and 75%/30% NPL/insulin lispro and a 70%/30% NPA/insulin aspart premixed formulations. Additional ratios are available abroad. Insulin glargine must be given as a separate injection. It is not miscible acutely or in a premixed preparation with any other insulin formulation.

Species of Insulin

Beef and Pork Insulins

Historically, commercial insulin in the USA contained beef or pork insulin. Beef insulin differs by three amino acids from human insulin, whereas only a single amino acid distinguishes pork and human insulins (Figure 41–1). The beef hormone is slightly more antigenic than pork insulin in humans. Of the insulins manufactured from animal sources, only purified pork insulin is still available and it requires special ordering.

Human insulin, which is now less expensive than monospecies pork insulin and is also less immunogenic, has supplanted purified pork insulins.

Human Insulins

Mass production of human insulin by recombinant DNA techniques is now carried out by inserting the human proinsulin gene into *Escherichia coli* or yeast and treating the extracted proinsulin to form the human insulin molecule.

Human insulin from *E coli* is available for clinical use as Humulin (Lilly) and dispensed as either regular, NPH, lente, or ultralente Humulin. Human insulin prepared biosynthetically in yeast is marketed by Novo Nordisk as human insulin injection in regular, lente, and NPH forms: Novolin R, Monotard Human Insulin (Novolin L), and Novolin N. The same company also produces a human insulin marketed as Velosulin (regular) that contains a phosphate buffer. This reduces aggregation of regular insulin molecules when used in infusion pumps. However, because of the tendency of phosphate to precipitate zinc ions, Velosulin should not be mixed with any of the lente insulins.

Human insulins appear to be as effective as—and considerably less immunogenic in diabetic patients than—beef-pork insulin mixtures and slightly less immunogenic than pork insulin.

Concentration

Currently, all insulins in the USA and Canada are available in a concentration of 100 U/mL (U100) and are dispensed in 10 mL vials. A limited supply of U500 regular human insulin is available for use in rare cases of severe insulin resistance in which larger doses of insulin are required.

Insulin Delivery Systems

The standard mode of insulin therapy is subcutaneous injection using conventional disposable needles and syringes. During the last 3 decades, much effort has gone into exploration of other means of administration.

Portable Pen Injectors

To facilitate multiple subcutaneous injections of insulin, particularly during intensive insulin therapy, portable pen-sized injectors have been developed. These contain cartridges of insulin and replaceable needles. Disposable insulin pens are also available for selected formulations. These include regular insulin, insulin lispro, insulin aspart, NPH insulin, and premixed 70%/30% and 50%/50% NPH/regular, 75% NPL/25% lispro, 50% NPL/50% lispro, and 70% NPA/30% aspart insulin. They have been well accepted by patients because they eliminate the need to carry syringes and bottles of insulin to the workplace and while traveling.

Continuous Subcutaneous Insulin Infusion Devices (Csi, Insulin Pumps)

Continuous subcutaneous insulin infusion devices are external open-loop pumps for insulin delivery. The devices have a user-programmable pump that delivers individualized basal and bolus insulin replacement doses based on blood glucose self-monitoring results. Normally, the 24-hour background basal rates are relatively constant from day to day, although temporarily altered rates can be superimposed to adjust for a short-term change in requirement. For example, the basal delivery rate might need to be decreased for several hours because of the increased insulin sensitivity associated with strenuous activity. In contrast, the bolus amounts frequently vary and are used to correct high blood glucose levels and to cover mealtime insulin requirements based on the carbohydrate content of the food and concurrent activity. The pump—which contains an insulin reservoir, the program chip, the keypad, and the display screen—is about the size of a pager. It is usually placed on a belt or in a pocket, and the insulin is infused through thin plastic tubing that is connected to the subcutaneously inserted infusion set. The abdomen is the favored site for the

infusion set, although flanks and thighs are also used. The insulin reservoir, tubing, and infusion set need to be changed using sterile techniques every 2 or 3 days. CSII delivery is regarded as the most physiologic method of insulin replacement.

The use of these devices is encouraged for individuals who are unable to obtain target control while on multiple injection regimens and in circumstances where excellent glycemic control is desired, such as during pregnancy. Their optimal use requires responsible involvement and commitment by the patient. Velosulin (a regular insulin) and insulin aspart are the only insulins specifically approved for pump use. Although not formally approved for pump use, insulin lispro has been successfully delivered through CSII devices since it became commercially available. Insulins aspart and lispro are preferred pump insulins because their favorable pharmacokinetic attributes allow glycemic control without increasing the risk of hypoglycemia.

Inhaled Insulin

Clinical trials are in progress to evaluate the safety and efficacy of finely powdered and aerosolized insulin formulations delivered by inhalation. Insulin is readily absorbed into the bloodstream through alveolar walls, but the challenge has been to create particles that are small enough to pass through the bronchial tree without being trapped and still enter the alveoli in sufficient amounts to have a clinical effect. Insulin delivered by the inhaled route should have a rapid onset and a relatively short duration of action and could be used to cover mealtime insulin requirements or to correct high glucose levels, but not to provide background or basal insulin coverage. Safety concerns regarding pulmonary fibrosis or hypertension and excessive antibody formation may preclude or delay approval.

Treatment with Insulin

The current classification of diabetes mellitus identifies a group of patients who have virtually no insulin secretion and whose survival depends on administration of exogenous insulin. This insulin-dependent group (type 1) represents 5–10% of the diabetic population in the USA. Most type 2 diabetics do not require exogenous insulin for survival, but many need exogenous supplementation of their endogenous secretion to achieve optimum health. It is estimated that as many as 20% of type 2 diabetics in the USA (2–2.5 million people) are presently taking insulin.

Benefit of Glycemic Control in Diabetes Mellitus

The consensus of the American Diabetes Association is that intensive insulin therapy associated with comprehensive self-management training should become standard therapy in most type 1 patients after puberty (see Benefits of Tight Glycemic Control in Type 1 Diabetes). Exceptions include patients with advanced renal disease and the elderly, since the risks of hypoglycemia outweigh the benefit of tight glycemic control in these groups. In children under the age of 7 years, the extreme susceptibility of the developing brain to damage from hypoglycemia contraindicates attempts at intensive glycemic control, particularly since diabetic complications do not seem to occur until some years after the onset of puberty. A similar conclusion regarding the benefits of tight control in type 2 diabetes was reached as the result of a large study in the United Kingdom.

Complications of Insulin Therapy

Hypoglycemia

Mechanisms and Diagnosis

Hypoglycemic reactions are the most common complication of insulin therapy. They may result from a delay in taking a meal, inadequate carbohydrate consumed, unusual physical exertion, or a dose of insulin that is too large for immediate needs.

Rapid development of hypoglycemia in individuals with intact hypoglycemic awareness causes signs of autonomic hyperactivity, both sympathetic (tachycardia, palpitations, sweating, tremulousness) and parasympathetic (nausea, hunger) and may progress to convulsions and coma if untreated.

In individuals exposed to frequent hypoglycemic episodes during tight glycemic control, autonomic warning signals of hypoglycemia are less frequent or even absent. This dangerous acquired condition is termed "hypoglycemic unawareness." When patients lack the early warning signs of low blood glucose, they may not take corrective measures in time. In patients with persistent, untreated hypoglycemia, the manifestations of insulin excess may develop—confusion, weakness, bizarre behavior, coma, seizures—at which point they may not be able to procure or safely swallow glucose-containing foods. Hypoglycemic awareness may be restored by preventing frequent hypoglycemic episodes. An identification bracelet, necklace, or card in the wallet or purse, as well as some form of rapidly absorbed glucose, should be carried by every diabetic who is receiving hypoglycemic drug therapy.

Treatment of Hypoglycemia

All of the manifestations of hypoglycemia are relieved by glucose administration. To expedite absorption, simple sugar or glucose should be given, preferably in a liquid form. To treat mild hypoglycemia in a patient who is conscious and able to swallow, orange juice, glucose gel, or any sugar-containing beverage or food may be given. If more severe hypoglycemia has produced unconsciousness or stupor, the treatment of choice is to give 20–50 mL of 50% glucose solution by intravenous infusion over a period of 2–3 minutes. If intravenous therapy is not available, 1 mg of glucagon injected either subcutaneously or intramuscularly will usually restore consciousness within 15 minutes to permit ingestion of sugar. If the patient is stuporous and glucagon is not available, small amounts of honey or syrup can be inserted into the buccal pouch. In general, however, oral feeding is contraindicated in unconscious patients. Emergency medical services should be called for all episodes of severely impaired consciousness.

Immunopathology of Insulin Therapy

At least five molecular classes of insulin antibodies may be produced during the course of insulin therapy in diabetes: IgA, IgD, IgE, IgG, and IgM. There are two major types of immune disorders in these patients:

Insulin Allergy

Insulin allergy, an immediate type hypersensitivity, is a rare condition in which local or systemic urticaria results from histamine release from tissue mast cells sensitized by anti-insulin IgE antibodies. In severe cases, anaphylaxis results. Because sensitivity is often to noninsulin protein contaminants, the highly purified and human insulins have markedly reduced the incidence of insulin allergy, especially local reactions.

Immune Insulin Resistance

A low titer of circulating IgG anti-insulin antibodies that neutralize the action of insulin to a

negligible extent develops in most insulin-treated patients. Rarely, the titer of insulin antibodies will lead to insulin resistance and may be associated with other systemic autoimmune processes such as lupus erythematosus.

Lipodystrophy at Injection Sites

Injection of older insulin preparations sometimes led to atrophy of subcutaneous fatty tissue at the site of injection. This type of immune complication is almost never seen since the development of human insulin preparations of neutral pH. Injection of these newer preparations directly into the atrophic area often results in restoration of normal contours. Hypertrophy of subcutaneous fatty tissue remains a problem, even with the purified insulins, if injected repeatedly at the same site. However, this may be corrected by avoidance of that specific injection site or with liposuction.

Katzung PHARMACOLOGY, 9e > Section VII. Endocrine Drugs > Chapter 41. Pancreatic Hormones & Antidiabetic Drugs >

Benefits of Tight Glycemic Control in Diabetes

A long-term randomized prospective study involving 1441 type 1 patients in 29 medical centers reported in 1993 that "near normalization" of blood glucose resulted in a delay in onset and a major slowing of progression of microvascular and neuropathic complications of diabetes during follow-up periods of up to 10 years (Diabetes Control and Complications Trial [DCCT] Research Group, 1993).

In the intensively treated group a mean glycosylated hemoglobin of 7.2% (normal, < 6%) and a mean blood glucose of 155 mg/dL were achieved, while in the conventionally treated group, glycosylated hemoglobin averaged 8.9% with an average blood glucose of 225 mg/dL. Over the study period, which averaged 7 years, there was an approximately 60% reduction in risk in the tight control group compared with the standard control group with regard to diabetic retinopathy, nephropathy, and neuropathy.

The United Kingdom Prospective Diabetes Study (UKPDS) was a very large randomized prospective study carried out to study the effects of intensive glycemic control with several types of therapies and the effects of blood pressure control in type 2 diabetic patients. A total of 3867 newly diagnosed type 2 diabetic patients were studied over 10 years. A significant fraction of these were overweight and hypertensive. Patients were given dietary treatment alone or intensive therapy with insulin, chlorpropamide, glyburide, or glipizide. Metformin was an option for patients with inadequate response to other therapies. Tight control of blood pressure was added as a variable, with an angiotensin-converting enzyme inhibitor, β -blocker or, in some cases, a calcium channel blocker available for this purpose.

Tight control of diabetes, with reduction of HbA_{1c} from 9.1% to 7%, was shown to reduce the risk of microvascular complications overall compared with conventional therapy (mostly diet alone, which decreased HbA_{1c} to 7.9%). Cardiovascular complications were not noted for any particular therapy; metformin treatment alone reduced the risk of macrovascular disease (myocardial infarction, stroke).

Tight control of hypertension also had a surprisingly significant effect on microvascular disease (as well as more conventional hypertension-related sequela) in these diabetic patients. These studies show that tight glycemic control benefits both type 1 and type 2 patients.

Oral Antidiabetic Agents

Four categories of oral antidiabetic agents are now available in the USA: **insulin secretagogues** (sulfonylureas, meglitinides, D-phenylalanine derivatives), **biguanides**, **thiazolidinediones**, and **α -glucosidase inhibitors**. The sulfonylureas and biguanides have been available the longest and are the traditional initial treatment choice for type 2 diabetes. Novel classes of rapidly acting insulin secretagogues, the meglitinides and D-phenylalanine derivatives, are alternatives to the short-acting sulfonylurea, tolbutamide. The thiazolidinediones, under development since the early 1980s, are very effective agents that reduce insulin resistance. α -Glucosidase inhibitors have a relatively weak antidiabetic effect and significant adverse effects, and they are used primarily as adjunctive therapy in individuals who cannot achieve their glycemic goals with other medications.

Insulin Secretagogues: Sulfonylureas

Mechanism of Action

The major action of sulfonylureas is to increase insulin release from the pancreas (Table 41–5). Two additional mechanisms of action have been proposed—a reduction of serum glucagon levels and closure of potassium channels in extrapancreatic tissues. The latter is of unknown clinical significance.

Table 41–5. Regulation of Insulin Release in Humans.¹

Stimulants of insulin release

Glucose, mannose

Leucine

Vagal stimulation

Sulfonylureas

Amplifiers of glucose-induced insulin release

Enteric hormones:

Glucagon-like peptide 1(7–37)

Gastrin inhibitory peptide

Cholecystokinin

Secretin, gastrin

Neural amplifiers:

β -Adrenoceptor stimulation

Amino acids:

Arginine

Inhibitors of insulin release

Neural: α -Sympathomimetic effect of catecholamines

Humoral: Somatostatin

Drugs: Diazoxide, phenytoin, vinblastine, colchicine

Insulin Release from Pancreatic B Cells

Sulfonylureas bind to a 140 kDa high-affinity sulfonyl-urea receptor that is associated with a B cell inward rectifier ATP-sensitive potassium channel. Binding of a sulfonylurea inhibits the efflux of potassium ions through the channel (Figure 41–2) and results in depolarization. Depolarization, in turn, opens a voltage-gated calcium channel and results in calcium influx and the release of preformed insulin.

Reduction of Serum Glucagon Concentrations

Chronic administration of sulfonylureas to type 2 diabetics reduces serum glucagon levels, which may contribute to the hypoglycemic effect of the drugs. The mechanism for this suppressive effect of sulfonylureas on glucagon levels is unclear but appears to involve indirect inhibition due to enhanced release of both insulin and somatostatin, which inhibit A cell secretion.

Potassium Channel Closure in Extrapancreatic Tissues

Insulin secretagogues bind to sulfonylurea receptors in potassium channels in extrapancreatic tissues but the binding affinity varies among the drug classes and is much less avid than for the B cell receptors. The clinical significance of extrapancreatic binding is not known.

Efficacy & Safety of the Sulfonylureas

In 1970, the University Group Diabetes Program (UGDP) in the USA reported that the number of deaths due to cardiovascular disease in diabetic patients treated with tolbutamide was excessive compared with either insulin-treated patients or those receiving placebos. Due to design flaws, this study and its conclusions were not generally accepted. A study in the United Kingdom, the UKPDS, did not find an untoward cardiovascular effect of sulfonylurea usage in their large, long-term study.

The sulfonylureas continue to be widely prescribed and six are available in the USA (Table 41–6). They are conventionally divided into first-generation and second-generation agents, which differ primarily in their potency and adverse effects. The first-generation sulfonylureas are increasingly difficult to procure, and as the second-generation agents become generic and less expensive, the earlier compounds probably will be discontinued.

Table 41–6. Sulfonureas.

Sulfonylurea	Chemical Structure
Tolbutamide (Orinase)	
Tolazamide (Tolinase)	
Chlorpropamide (Diabinese)	
Glyburide (gli-benclamide ¹) (DiaBeta, Micronase, Glynase PresTab)	
Glipizide (gly-diazinamide ¹) (Glucotrol, Glucotrol XL)	
Glimepiride (Amaryl)	

¹Outside USA.

²Elimination half-life considerably shorter (see text).

First-Generation Sulfonylureas

Tolbutamide is well absorbed but rapidly metabolized in the liver. Its duration of effect is relatively short, with an elimination half-life of 4–5 hours, and it is best administered in divided doses. Because of its short half-life, it is the safest sulfonylurea for use in elderly diabetics. Prolonged hypoglycemia has been reported rarely, mostly in patients receiving certain drugs (eg,

dicumarol, phenylbutazone, some sulfonamides) that inhibit the metabolism of tolbutamide.

Chlorpropamide has a half-life of 32 hours and is slowly metabolized in the liver to products that retain some biologic activity; approximately 20–30% is excreted unchanged in the urine. Chlorpropamide also interacts with the drugs mentioned above that depend on hepatic oxidative catabolism, and it is contraindicated in patients with hepatic or renal insufficiency. Dosages in excess of 500 mg daily increase the risk of jaundice. The average maintenance dosage is 250 mg daily, given as a single dose in the morning. Prolonged hypoglycemic reactions are more common in elderly patients, and the drug is contraindicated in this group. Other side effects include a hyperemic flush after alcohol ingestion in genetically predisposed patients and dilutional hyponatremia. Hematologic toxicity (transient leukopenia, thrombocytopenia) occurs in less than 1% of patients.

Tolazamide is comparable to chlorpropamide in potency but has a shorter duration of action. Tolazamide is more slowly absorbed than the other sulfonylureas, and its effect on blood glucose does not appear for several hours. Its half-life is about 7 hours. Tolazamide is metabolized to several compounds that retain hypoglycemic effects. If more than 500 mg/d is required, the dose should be divided and given twice daily. Dosages larger than 1000 mg daily do not further improve the degree of blood glucose control.

Second-Generation Sulfonylureas

The second-generation sulfonylureas are more frequently prescribed in the USA than the first-generation agents because they have fewer adverse effects and drug interactions. These potent sulfonylurea compounds—glyburide, glipizide, and glimepiride—should be used with caution in patients with cardiovascular disease or in elderly patients, in whom hypoglycemia would be especially dangerous.

Glyburide is metabolized in the liver into products with very low hypoglycemic activity. The usual starting dosage is 2.5 mg/d or less, and the average maintenance dosage is 5–10 mg/d given as a single morning dose; maintenance dosages higher than 20 mg/d are not recommended. A formulation of "micronized" glyburide (Glynase PresTab) is available in a variety of tablet sizes. However, there is some question as to its bioequivalence with nonmicronized formulations, and the FDA recommends careful monitoring to retitrate dosage when switching from standard glyburide doses or from other sulfonylurea drugs.

Glyburide has few adverse effects other than its potential for causing hypoglycemia. Flushing has rarely been reported after ethanol ingestion and the compound slightly enhances free water clearance. Glyburide is contraindicated in the presence of hepatic impairment and in patients with renal insufficiency.

Glipizide has the shortest half-life (2–4 hours) of the more potent agents. For maximum effect in reducing postprandial hyperglycemia, this agent should be ingested 30 minutes before breakfast, since absorption is delayed when the drug is taken with food. The recommended starting dosage is 5 mg/d, with up to 15 mg/d given as a single dose. When higher daily dosages are required, they should be divided and given before meals. The maximum total daily dosage recommended by the manufacturer is 40 mg/d, although some studies indicate that the maximum therapeutic effect is achieved by 15–20 mg of the drug. An extended-release preparation (Glucotrol XL) provides 24-hour action after a once-daily morning dose (maximum of 20 mg/d). However, this formulation appears to have sacrificed its lower propensity for severe hypoglycemia compared with longer-acting glyburide without showing any demonstrable therapeutic advantages over the latter (which

can be obtained as a generic drug).

Because of its shorter half-life, glipizide is much less likely than glyburide to produce serious hypoglycemia. At least 90% of glipizide is metabolized in the liver to inactive products, and 10% is excreted unchanged in the urine. Glipizide therapy is therefore contraindicated in patients with significant hepatic or renal impairment, who would therefore be at high risk for hypoglycemia.

Glimepiride is approved for once-daily use as monotherapy or in combination with insulin. Glimepiride achieves blood glucose lowering with the lowest dose of any sulfonylurea compound. A single daily dose of 1 mg has been shown to be effective, and the recommended maximal daily dose is 8 mg. It has a long duration of effect with a half-life of 5 hours, allowing once-daily dosing and thereby improving compliance. It is completely metabolized by the liver to inactive products.

Secondary Failure & Tachyphylaxis to Sulfonylureas

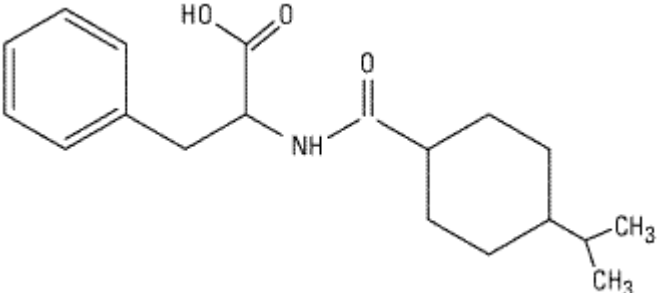

Secondary failure, ie, failure to maintain a good response to sulfonylurea therapy over the long term—remains a disconcerting problem in the management of type 2 diabetes. A progressive decrease in B cell mass, reduction in physical activity, decline in lean body mass, or increase in ectopic fat deposition in chronic type 2 diabetes also may contribute to secondary failure.

Insulin Secretagogues: Meglitinides

The meglitinides are a relatively new class of insulin secretagogues. **Repaglinide**, the first member of the group, was approved for clinical use in 1998 (Table 41–7). These drugs modulate B cell insulin release by regulating potassium efflux through the potassium channels previously discussed. There is overlap with the sulfonylureas in their molecular sites of action since the meglitinides have two binding sites in common with the sulfonylureas and one unique binding site. Unlike the sulfonylureas, they have no direct effect on insulin exocytosis.

Table 41–7. Other Insulin Secretagogues.

Drug	Chemical Structure	Oral Dose	t _{1/2}	Duration of Action (hours)
Repaglinide (Prandin)		0.25–4 mg before meals	1 hour	4–5

Nateglinide (Starlix)		60–120 mg before meals	1 hour	4
--------------------------	------------------------------------------------------------------------------------	---------------------------------	-----------	---

Repaglinide has a very fast onset of action, with a peak concentration and peak effect within approximately 1 hour after ingestion, but the duration of action is 5–8 hours. It is hepatically cleared by CYP3A4 with a plasma half-life of 1 hour. Because of its rapid onset, repaglinide is indicated for use in controlling postprandial glucose excursions. The drug should be taken just before each meal in doses of 0.25–4 mg (maximum, 16 mg/d); hypoglycemia is a risk if the meal is delayed or skipped or contains inadequate carbohydrate. This drug should be used cautiously in individuals with renal and hepatic impairment. Repaglinide is approved as monotherapy or in combination with biguanides. There is no sulfur in its structure, so repaglinide may be used in type 2 diabetic individuals with sulfur or sulfonamide allergy.

Insulin Secretagogue: D-Phenylalanine Derivative

Nateglinide, a D-phenylalanine derivative, is the latest insulin secretagogue to become clinically available. Nateglinide stimulates very rapid and transient release of insulin from B cells through closure of the ATP-sensitive K^+ channel. It also partially restores initial insulin release in response to an intravenous glucose tolerance test. This may be a significant advantage of the drug because type 2 diabetes is associated with loss of this initial insulin response. The restoration of more normal insulin secretion may suppress glucagon release early in the meal and result in less endogenous or hepatic glucose production. Nateglinide may have a special role in the treatment of individuals with isolated postprandial hyperglycemia, but it has minimal effect on overnight or fasting glucose levels. It is efficacious when given alone or in combination with nonsecretagogue oral agents (such as metformin). In contrast to other insulin secretagogues, dose titration is not required.

Nateglinide is ingested just prior to meals. It is absorbed within 20 minutes after oral administration with a time to peak concentration of less than 1 hour and is hepatically metabolized by CYP2C9 and CYP3A4 with a half-life of 1.5 hours. The overall duration of action is less than 4 hours.

Nateglinide amplifies the insulin secretory response to a glucose load but has a markedly diminished effect in the presence of normoglycemia. The incidence of hypoglycemia may be the lowest of all the secretagogues, and it has the advantage of being safe in individuals with very reduced renal function.

Biguanides

The structure of metformin is shown below. Phenformin (an older biguanide) was discontinued in the USA because of its association with lactic acidosis and because there was no documentation of any long-term benefit from its use.

Metformin

Mechanisms of Action

A full explanation of the biguanides' mechanism of action remains elusive. Their blood glucose-lowering action does not depend on the presence of functioning pancreatic B cells. Patients with type 2 diabetes have considerably less fasting hyperglycemia as well as lower postprandial hyperglycemia after biguanides; however, hypoglycemia during biguanide therapy is essentially unknown. These agents are therefore more appropriately termed "euglycemic" agents. Currently proposed mechanisms of action include (1) direct stimulation of glycolysis in tissues, with increased glucose removal from blood; (2) reduced hepatic and renal gluconeogenesis; (3) slowing of glucose absorption from the gastrointestinal tract, with increased glucose to lactate conversion by enterocytes; and (4) reduction of plasma glucagon levels.

Metabolism & Excretion

Metformin has a half-life of 1.5–3 hours, is not bound to plasma proteins, is not metabolized, and is excreted by the kidneys as the active compound. As a consequence of metformin's blockade of gluconeogenesis, the drug may impair the hepatic metabolism of lactic acid. In patients with renal insufficiency, biguanides accumulate and thereby increase the risk of lactic acidosis, which appears to be a dose-related complication.

Clinical Use

Biguanides have been most often prescribed for patients whose hyperglycemia is due to ineffective insulin action, ie, insulin resistance syndrome. Because metformin is an insulin-sparing agent and does not increase weight or provoke hypoglycemia, it offers obvious advantages over insulin or sulfonylureas in treating hyperglycemia in such individuals. The UKPDS reported that metformin therapy decreases the risk of macrovascular as well as microvascular disease; this is in contrast to the other therapies, which only modified microvascular morbidity. Biguanides are also indicated for use in combination with insulin secretagogues or thiazolidinediones in type 2 diabetics in whom oral monotherapy is inadequate. Metformin is useful in the prevention of type 2 diabetes; the landmark Diabetes Prevention Program concluded that metformin is efficacious in preventing the new onset of type 2 diabetes in middle-aged, obese individuals with impaired glucose tolerance and fasting hyperglycemia. Interestingly, metformin did not prevent diabetes in older, leaner pre-diabetics.

The dosage of metformin is from 500 mg to a maximum of 2.55 g daily, with the lowest effective dose being recommended. A common schedule would be to begin with a single 500 mg tablet given with breakfast for several days. If this is tolerated without gastrointestinal discomfort and hyperglycemia persists, a second 500 mg tablet may be added with the evening meal. If further dose increases are required after 1 week, an additional 500 mg tablet can be added to be taken with the midday meal, or the larger (850 mg) tablet can be prescribed twice daily or even three times daily (the maximum recommended dosage) if needed. Dosage should always be divided, since ingestion of more than 1000 mg at any one time usually provokes significant gastrointestinal side effects.

Toxicities

The most frequent toxic effects of metformin are gastrointestinal (anorexia, nausea, vomiting, abdominal discomfort, diarrhea) and occur in up to 20% of patients. They are dose related, tend to occur at the onset of therapy, and are often transient. However, metformin may have to be discontinued in 3–5% of patients because of persistent diarrhea. Absorption of vitamin B₁₂ appears to be reduced during long-term metformin therapy, and annual screening of serum vitamin B₁₂ levels and red blood cell parameters has been encouraged by the manufacturer to determine the need for vitamin B₁₂ injections. In the absence of hypoxia or renal or hepatic insufficiency, lactic acidosis is less common with metformin therapy than with phenformin therapy.

Biguanides are contraindicated in patients with renal disease, alcoholism, hepatic disease, or conditions predisposing to tissue anoxia (eg, chronic cardiopulmonary dysfunction), because of an increased risk of lactic acidosis induced by biguanide drugs in the presence of these diseases.

Thiazolidinediones

Thiazolidinediones (Tzds) act to decrease insulin resistance. Their primary action is the nuclear regulation of genes involved in glucose and lipid metabolism and adipocyte differentiation. Tzds are ligands of **peroxisome proliferator-activated receptor-gamma (PPAR- γ)**, part of the steroid and thyroid superfamily of nuclear receptors. These PPAR receptors are found in muscle, fat, and liver. PPAR- γ receptors are complex and modulate the expression of the genes involved in lipid and glucose metabolism, insulin signal transduction, and adipocyte and other tissue differentiation. The available Tzds do not have identical clinical effects and new drug development will focus on defining PPAR effects and designing ligands that have selective action—much like the selective estrogen receptor ligands (see Chapter 40: The Gonadal Hormones & Inhibitors).

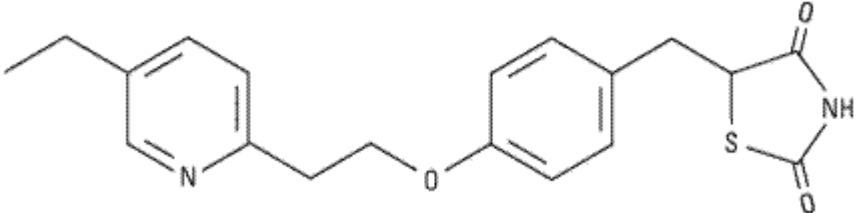

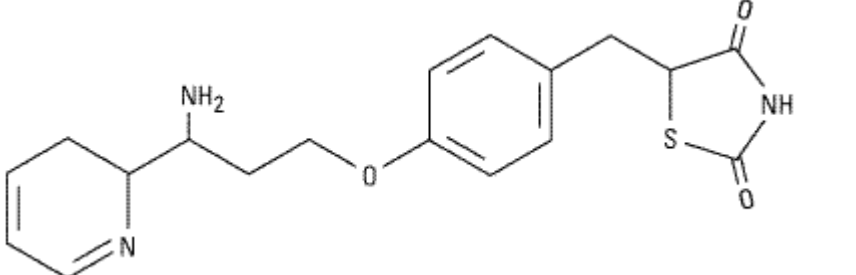

In addition to targeting adipocytes, myocytes, and hepatocytes, Tzds also have significant effects on vascular endothelium, the immune system, the ovaries, and tumor cells. Some of these responses may be independent of the PPAR- γ pathway.

In persons with diabetes, a major site of Tzd action is adipose tissue, where the drug promotes glucose uptake and utilization and modulates synthesis of lipid hormones or cytokines and other proteins involved in energy regulation. Tzds also regulate adipocyte apoptosis and differentiation. Numerous other effects have been documented in animal studies but applicability to human tissues has yet to be determined.

Two thiazolidinediones are currently available: pioglitazone and rosiglitazone (Table 41–8). Their distinct side chains create differences in therapeutic action, metabolism, metabolite profile, and adverse effects. A third compound, troglitazone, was withdrawn from the market because of hepatic toxicity thought to be related to its side chain.

Table 41–8. Thiazolidinediones.

Thiazolidinedione	Chemical Structure	Oral Dose

Pioglitazone (Actos)		15–45 mg once daily
Rosiglitazone (Avandia)		2–8 mg once daily

Pioglitazone may have PPAR- α as well as PPAR- γ activity. It is absorbed within 2 hours of ingestion; although food may delay uptake, total bioavailability is not affected. Pioglitazone is metabolized by CYP2C8 and CYP3A4 to active metabolites. The bioavailability of numerous other drugs also degraded by these enzymes may be affected by pioglitazone therapy, including estrogen-containing oral contraceptives; additional methods of contraception are advised. Pioglitazone may be taken once daily; the usual starting dose is 15–30 mg. The triglyceride lowering effect is more significant than that observed with rosiglitazone. Pioglitazone is approved as a monotherapy and in combination with metformin, sulfonylureas, and insulin for the treatment of type 2 diabetes.

Rosiglitazone is rapidly absorbed and highly protein bound. It is metabolized in the liver to minimally active metabolites, predominantly by CYP2C8 and to a lesser extent by CYP2C9. It is administered once or twice daily; 4–8 mg is the usual total dose. Rosiglitazone shares the common Tzd adverse effects but does not seem to have any significant drug interactions. The drug is approved for use in type 2 diabetes as monotherapy or in combination with a biguanide or sulfonylurea.

Tzds are considered "euglycemics" and are efficacious in about 70% of new users. The overall response is similar to sulfonylurea and biguanide monotherapy. Individuals experiencing secondary failure to other oral agents should benefit from the addition (rather than substitution) of a Tzd. Because their mechanism of action involves gene regulation, the Tzds have a slow onset and offset of activity over weeks or even months. Combination therapy with sulfonylureas and insulin can lead to hypoglycemia and may require dosage adjustment. Long-term therapy is associated with a drop in triglyceride levels and a slight rise in HDL and low-density lipoprotein (LDL) cholesterol values. An adverse effect common to both Tzds is fluid retention, which presents as a mild anemia and peripheral edema especially when used in combination with insulin or insulin secretagogues. Many users have a dose-related weight gain (average 1–3 kg), which may be fluid-related. These agents should not be used during pregnancy, in the presence of significant liver disease, or if there is a concurrent diagnosis of heart failure. Anovulatory women may resume ovulation and should be counseled on the increased risk of pregnancy. Because of the hepatotoxicity observed with troglitazone, the FDA continues to require regular monitoring of liver function tests for the first year after initiation of Tzd therapy. To date, hepatotoxicity has not been associated with rosiglitazone or pioglitazone.

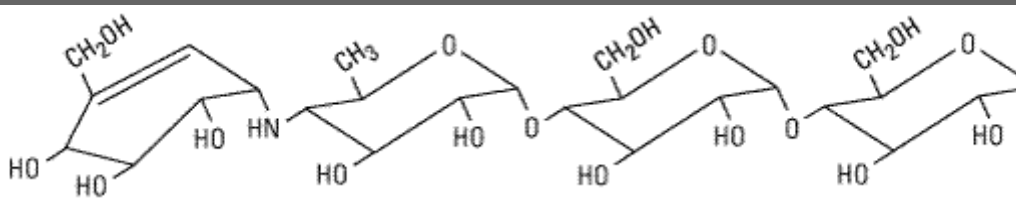

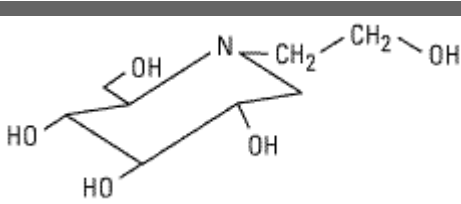

Thiazolidinediones have a theoretical benefit in the prevention of type 2 diabetes. One study

reported that troglitazone therapy significantly decreased the recurrence of diabetes mellitus in high risk Hispanic women with a prior history of gestational diabetes. Other trials using clinically available Tzds are in progress.

Alpha Glucosidase Inhibitors

Only monosaccharides, such as glucose and fructose, can be transported out of the intestinal lumen and into the bloodstream. Complex starches, oligosaccharides, and disaccharides must be broken down into individual monosaccharides before being absorbed in the duodenum and upper jejunum. This digestion is facilitated by enteric enzymes, including pancreatic α -amylase, and α -glucosidases that are attached to the brush border of the intestinal cells. **Acarbose** and **miglitol** (Table 41–9) are competitive inhibitors of the intestinal α -glucosidases and reduce the postprandial digestion and absorption of starch and disaccharides. Miglitol differs structurally from acarbose and is six times more potent in inhibiting sucrase. Although the binding affinity of the two compounds differs, acarbose and miglitol both target the α -glucosidases: sucrase, maltase, glycoamylase, dextranase. Miglitol alone has effects on isomaltase and on β -glucosidases, which split β -linked sugars such as lactose. Acarbose alone has a small effect on α -amylase. The consequence of enzyme inhibition is to minimize upper intestinal digestion and defer digestion (and thus absorption) of the ingested starch and disaccharides to the distal small intestine, thereby lowering postmeal glycemic excursions as much as 45–60 mg/dL and creating an insulin-sparing effect. Monotherapy with these drugs is associated with a modest drop (0.5–1%) in glycohemoglobin levels and a 20–25 mg/dL fall in fasting glucose levels. They are FDA-approved for use in individuals with type 2 diabetes as monotherapy and in combination with sulfonylureas, where the glycemic effect is additive. Both acarbose and miglitol are taken in doses of 25–100 mg just prior to ingesting the first portion of each meal; therapy should be initiated with the lowest dose and slowly titrated upward.

Table 41–9. Alpha-Glucosidase Inhibitors.

Alpha-glucosidase Inhibitor	Chemical Structure	Oral Dose
Acarbose (Precose)		25–100 mg before meals
Miglitol (Glyset)		25–100 mg before meals

Prominent adverse effects include flatulence, diarrhea, and abdominal pain and result from the appearance of undigested carbohydrate in the colon that is then fermented into short-chain fatty

to carbohydrate induces the expression of α -glucosidase in the jejunum and ileum, increasing distal small intestine glucose absorption and minimizing the passage of carbohydrate into the colon. Although not a problem with monotherapy or combination therapy with a biguanide, hypoglycemia may occur with concurrent sulfonylurea treatment. Hypoglycemia should be treated with glucose (dextrose) and not sucrose, whose breakdown may be blocked. These drugs are contraindicated in patients with inflammatory bowel disease or any intestinal condition that could be worsened by gas and distention. Because both miglitol and acarbose are absorbed from the gut, these medications should not be prescribed in individuals with renal impairment. Acarbose has been associated with reversible hepatic enzyme elevation and should be used with caution in the presence of hepatic disease.

The STOP-NIDDM trial demonstrated that α -glucosidase therapy in prediabetic individuals successfully prevented a significant number of new cases of type 2 diabetes and helped restore β cell function. Diabetes prevention may become a further indication for this class of medications.

Combination Therapy with Oral Antidiabetic Agents & Insulin

Combination Therapy in Type 2 Diabetes Mellitus

Bedtime insulin has been suggested as an adjunct to oral antidiabetic therapy in patients with type 2 diabetes patients who have not responded to maximal oral therapy. Clinical practice has evolved to include sulfonylureas, meglitinides, D-phenylalanine derivatives, biguanides, thiazolidinediones, or α -glucosidase inhibitors given in conjunction with insulin.

Individuals unable to achieve glycemic control with bedtime insulin as described above generally require full insulin replacement and multiple daily injections of insulin. Insulin secretagogues are redundant when an individual is receiving multiple daily insulin injections, but cases of severe insulin resistance may benefit from the addition of one of the biguanides, thiazolidinediones, or α -glucosidase inhibitors. In some cases, multiple oral agents have been required together with insulin. When oral agents are added to the regimen of someone already taking insulin, the blood glucose should be closely monitored and the insulin dosage decreased as needed to avoid hypoglycemia.

Combination Therapy in Type 1 Diabetes Mellitus

There is no indication for combining insulin with insulin secretagogues (sulfonylureas, meglitinides, or D-phenylalanine derivatives) in individuals with type 1 diabetes. Type 1 diabetics with diets very high in starch may benefit from the addition of α -glucosidase inhibitors, but this is not typically practiced in the USA.

Glucagon

Chemistry & Metabolism

Glucagon is synthesized in the A cells of the pancreatic islets of Langerhans (see Table 41–1). Glucagon is a peptide—identical in all mammals—consisting of a single chain of 29 amino acids, with a molecular weight of 3485. Selective proteolytic cleavage converts a large precursor molecule of approximately 18,000 MW to glucagon. One of the precursor intermediates consists of a 69-amino-acid peptide called **glicentin**, which contains the glucagon sequence interposed between

peptide extensions.

Glucagon is extensively degraded in the liver and kidney as well as in plasma, and at its tissue receptor sites. Because of its rapid inactivation by plasma, chilling of the collecting tubes and addition of inhibitors of proteolytic enzymes are necessary when samples of blood are collected for immunoassay of circulating glucagon. Its half-life in plasma is between 3 and 6 minutes, which is similar to that of insulin.

"Gut Glucagon"

Glicentin immunoreactivity has been found in cells of the small intestine as well as in pancreatic A cells and in effluents of perfused pancreas. The intestinal cells secrete **enteroglucagon**, a family of glucagon-like peptides, of which glicentin is a member, along with glucagon-like peptides 1 and 2 (GLP-1 and GLP-2). Unlike the pancreatic A cell, these intestinal cells lack the enzymes to convert glucagon precursors to true glucagon by removing the carboxyl terminal extension from the molecule.

The function of the enteroglucagons has not been clarified, although smaller peptides can bind hepatic glucagon receptors where they exert partial activity. A derivative of the 37-amino-acid form of GLP-1 that lacks the first six amino acids (GLP-1[7–37]) is a potent stimulant of insulin release. It represents the predominant form of GLP in the human intestine and has been termed "insulintropin." It has been considered as a potential therapeutic agent in type 2 diabetes. However, it requires continuous subcutaneous infusion to produce a sustained lowering of both fasting and postprandial hyperglycemia in type 2 diabetic patients; therefore, its clinical usefulness is limited.

Pharmacologic Effects of Glucagon

Metabolic Effects

The first six amino acids at the amino terminal of the glucagon molecule bind to specific receptors on liver cells. This leads to a G_s protein-linked increase in adenylyl cyclase activity and the production of cAMP, which facilitates catabolism of stored glycogen and increases gluconeogenesis and ketogenesis. The immediate pharmacologic result of glucagon infusion is to raise blood glucose at the expense of stored hepatic glycogen. There is no effect on skeletal muscle glycogen, presumably because of the lack of glucagon receptors on skeletal muscle. Pharmacologic amounts of glucagon cause release of insulin from normal pancreatic B cells, catecholamines from pheochromocytoma, and calcitonin from medullary carcinoma cells.

Cardiac Effects

Glucagon has a potent inotropic and chronotropic effect on the heart, mediated by the cAMP mechanism described above. Thus, it produces an effect very similar to that of β -adrenoceptor agonists without requiring functioning β -receptors.

Effects on Smooth Muscle

Large doses of glucagon produce profound relaxation of the intestine. In contrast to the above effects of the peptide, this action on the intestine may be due to mechanisms other than adenylyl cyclase activation.

Clinical Uses

Severe Hypoglycemia

The major use of glucagon is for emergency treatment of severe hypoglycemic reactions in patients with type 1 diabetes when unconsciousness precludes oral feedings and use of intravenous glucose is not possible. Recombinant glucagon is currently available in 1 mg vials for parenteral use (Glucagon Emergency Kit). Nasal sprays have been developed for this purpose but have not yet received FDA approval.

Endocrine Diagnosis

Several tests use glucagon to diagnose endocrine disorders. In patients with type 1 diabetes mellitus, a standard test of pancreatic B cell secretory reserve utilizes 1 mg of glucagon administered as an intravenous bolus. Since insulin-treated patients develop circulating anti-insulin antibodies that interfere with radioimmunoassays of insulin, measurements of C-peptide are used to indicate B cell secretion.

Beta-Blocker Poisoning

Glucagon is sometimes useful for reversing the cardiac effects of an overdose of β -blocking agents because of its ability to increase cAMP production in the heart. However, it is not clinically useful in the treatment of cardiac failure.

Radiology of the Bowel

Glucagon has been used extensively in radiology as an aid to x-ray visualization of the bowel because of its ability to relax the intestine.

Adverse Reactions

Transient nausea and occasional vomiting can result from glucagon administration. These are generally mild, and glucagon is relatively free of severe adverse reactions.

Katzung PHARMACOLOGY, 9e > Section VII. Endocrine Drugs > Chapter 41. Pancreatic Hormones & Antidiabetic Drugs >

Islet Amyloid Polypeptide (Iapp, Amylin)

IAPP is a 37-amino-acid peptide originally derived from islet amyloid deposits in pancreas material from patients with long-standing type 2 diabetes or insulinomas. It is produced by pancreatic B cells, packaged within B cell granules in a concentration 1–2% that of insulin, and secreted in response to B cell secretagogues. Approximately one molecule of IAPP is released for every ten molecules of insulin. A physiologic effect has not been established; however, pharmacologic doses inhibit the action of insulin to promote muscle uptake of glucose. IAPP appears to be a member of the superfamily of neuroregulatory peptides, with 46% homology with the calcitonin gene-related peptide CGRP (see Chapter 17: Vasoactive Peptides). Whereas CGRP inhibits insulin secretion, this has not been demonstrated at physiologic concentrations of IAPP. Clinical trials have begun to evaluate IAPP and its analogs, eg, **pramlintide**, as adjuncts to insulin therapy in type 1 diabetic patients with recurrent episodes of severe insulin-induced hypoglycemia—episodes that are generally refractory to usual preventive measures.

Preparations Available¹

Sulfonylureas

Acetohexamide (Dymelor) (rarely used)

Oral: 250, 500 mg tablets

Chlorpropamide (generic, Diabinese)

Oral: 100, 250 mg tablets

Glimepiride (Amaryl)

Oral: 1, 2, 4 mg tablets

Glipizide (generic, Glucotrol, Glucotrol XL)

Oral: 5, 10 mg tablets; 5, 10 mg extended release tablets

Glyburide (generic, DiaBeta, Micronase, Glynase PresTab)

Oral: 1.25, 2.5, 5 mg tablets; 1.5, 3, 4.5, 6 mg Glynase PresTab, micronized tablets

Tolazamide (generic, Tolinase)

Oral: 100, 250, 500 mg tablets

Tolbutamide (generic, Orinase)

Oral: 500 mg tablets

Meglitinide & Related Drugs

Repaglinide (Prandin)

Oral: 0.5, 1, 2 mg tablets

Nateglinide (Starlix)

Oral: 60, 120 mg tablets

Biguanide & Biguanide Combinations

Metformin (Glucophage, Glucophage XR)

Oral: 500, 850, 1000 mg tablets; extended-release (XR): 500 mg tablets

Metformin Combinations

Glipizide plus metformin (Metaglip)

Oral: 2.5/250, 2.5/500, 5/500 mg tablets

Glyburide plus metformin (Glucovance)

Oral: 1.25/250, 2.5/500, 5/500 mg tablets

Rosiglitazone plus metformin (Avandamet)

Oral: 1/500, 2/500, 4/500 mg tablets

Thiazolidinedione Derivatives

Pioglitazone (Actos)

Oral: 15, 30, 45 mg tablets

Rosiglitazone (Avandia)

Oral: 2, 4, 8 mg tablets

Alpha Glucosidase Inhibitors

Acarbose (Precose)

Oral: 50, 100 mg tablets

Miglitol (Glyset)

Oral: 25, 50, 100 mg tablets

Glucagon

Glucagon (generic)

Parenteral: 1 mg lyophilized powder to reconstitute for injection

¹ See Table 41–4 for Insulin Preparations.

Chapter 42. Agents That Affect Bone Mineral Homeostasis

Basic Pharmacology

Calcium and phosphate, the major mineral constituents of bone, are also two of the most important minerals for general cellular function. Accordingly, the body has evolved a complex set of mechanisms by which calcium and phosphate homeostasis are carefully maintained (Figure 42–1). Approximately 98% of the 1–2 kg of calcium and 85% of the 1 kg of phosphorus in the human adult are found in bone, the principal reservoir for these minerals. These functions are dynamic, with constant remodeling of bone and ready exchange of bone mineral with that in the extracellular fluid. Bone also serves as the principal structural support for the body and provides the space for hematopoiesis. Thus, abnormalities in bone mineral homeostasis can lead not only to a wide variety of cellular dysfunctions (eg, tetany, coma, muscle weakness) but also to disturbances in structural support of the body (eg, osteoporosis with fractures) and loss of hematopoietic capacity (eg, infantile osteopetrosis).

Figure 42–1.

Some mechanisms contributing to bone mineral homeostasis. Calcium and phosphorus concentrations in the serum are controlled principally by two hormones, $1,25(\text{OH})_2\text{D}_3$ (*D*) and parathyroid hormone (*PTH*), through their action on absorption from the gut and from bone and on excretion in the urine. Both hormones increase input of calcium and phosphorus from bone into the serum; vitamin D also increases absorption from the gut. Vitamin D decreases urinary excretion of both calcium and phosphorus, while PTH reduces calcium but increases phosphorus excretion. Calcitonin (*CT*) is a less critical hormone for calcium homeostasis, but in pharmacologic concentrations CT can reduce serum calcium and phosphorus by inhibiting bone resorption and stimulating their renal excretion. Feedback effects are not shown.

Calcium and phosphate enter the body from the intestine. The average American diet provides 600–1000 mg of calcium per day, of which approximately 100–250 mg is absorbed. This figure represents net absorption, since both absorption (principally in the duodenum and upper jejunum) and secretion (principally in the ileum) occur. The amount of phosphorus in the American diet is about the same as that of calcium. However, the efficiency of absorption (principally in the jejunum) is greater, ranging from 70% to 90% depending on intake. In the steady state, renal excretion of calcium and phosphate balances intestinal absorption. In general, over 98% of filtered calcium and 85% of filtered phosphate is reabsorbed by the kidney. The movement of calcium and phosphate across the intestinal and renal epithelia is closely regulated. Intrinsic disease of the intestine (eg, nontropical sprue) or kidney (eg, chronic renal failure) disrupts bone mineral homeostasis.

Two hormones serve as the principal regulators of calcium and phosphate homeostasis: the peptide parathyroid hormone (PTH) and the steroid vitamin D. Vitamin D is a prohormone rather than a true hormone, since it must be further metabolized to gain biologic activity. Other hormones—calcitonin, prolactin, growth hormone, insulin, thyroid hormone, glucocorticoids, and sex steroids— influence calcium and phosphate homeostasis under certain physiologic circumstances and can be considered secondary regulators. Deficiency or excess of these secondary regulators within a physiologic range does not produce the disturbance of calcium and phosphate homeostasis that is observed in situations of deficiency or excess of PTH and vitamin D. However, certain of these secondary regulators—especially calcitonin, glucocorticoids, and estrogens—are useful therapeutically and will be discussed in subsequent sections.

In addition to these hormonal regulators, calcium and phosphate themselves, other ions such as sodium and fluoride, and a variety of drugs (bisphosphonates, plicamycin, and diuretics) also alter calcium and phosphate homeostasis.

Principal Hormonal Regulators of Bone Mineral Homeostasis

Parathyroid Hormone

Parathyroid hormone (**PTH**) is a single-chain peptide hormone composed of 84 amino acids. It is produced in the parathyroid gland in a precursor form of 115 amino acids, the remaining 31 amino terminal amino acids being cleaved off prior to secretion. Within the gland is a calcium-sensitive protease capable of cleaving the intact hormone into fragments. Biologic activity resides in the amino terminal region such that synthetic 1–34 PTH is fully active. Loss of the first two amino terminal amino acids eliminates most biologic activity.

The metabolic clearance of intact PTH is rapid, with a half-time of disappearance measured in minutes. Most of the clearance occurs in the liver and kidney. The biologically inactive carboxyl terminal fragments produced during metabolism of the intact hormone have a much lower clearance, especially in renal failure. This accounts in part for the very high PTH values often observed in the past in patients with renal failure when measured by radioimmunoassays directed against the carboxyl terminal region of the molecule. However, most PTH assays currently in use measure the intact hormone by a double antibody method, so that this circumstance is less frequently encountered in clinical practice. PTH regulates calcium and phosphate flux across cellular membranes in bone and kidney, resulting in increased serum calcium and decreased serum phosphate. In bone, PTH increases the activity and number of osteoclasts, the cells responsible for bone resorption. However, this stimulation of osteoclasts is not a direct effect. Rather, PTH acts on the osteoblast (the bone-forming cell) to induce a membrane-bound protein called **RANK ligand**. This factor acts on osteoclasts and osteoclast precursors to increase both the numbers and the activity of osteoclasts. This action increases bone turnover or bone remodeling, a specific sequence of cellular events initiated by osteoclastic bone resorption and followed by osteoblastic bone formation. Although both bone resorption and bone formation are enhanced by PTH, the net effect of excess PTH is to increase bone resorption. PTH in low and intermittent doses may actually increase bone formation without first stimulating bone resorption. This has led to the recent approval of recombinant PTH 1-34(**teriparatide**) for the treatment of osteoporosis. In the kidney, PTH increases the ability of the nephron to reabsorb calcium and magnesium but reduces its ability to reabsorb phosphate, amino acids, bicarbonate, sodium, chloride, and sulfate. Another important action of PTH on the kidney is its stimulation of 1,25-dihydroxyvitamin D (1,25[OH]₂D) production.

Vitamin D

Vitamin D is a secosteroid produced in the skin from 7-dehydrocholesterol under the influence of ultraviolet irradiation. Vitamin D is also found in certain foods and is used to supplement dairy products. Both the natural form (vitamin D₃, cholecalciferol) and the plant-derived form (vitamin D₂, ergocalciferol) are present in the diet. These forms differ in that ergocalciferol contains a double bond (C₂₂₋₂₃) and an additional methyl group in the side chain (Figure 42-2). In humans this difference apparently is of little physiologic consequence, and the following comments apply equally well to both forms of vitamin D.

Figure 42-2.

Conversion of 7-dehydrocholesterol to vitamin D₃ and metabolism of D₃ to 1,25(OH)₂D₃ and 24,25(OH)₂D₃. Control of the latter step is exerted primarily at the level of the kidney, where low serum phosphorus, low serum calcium, and high parathyroid hormone favor the production of 1,25(OH)₂D₃. The inset shows the side chain for ergosterol. Ergosterol undergoes similar transformation to vitamin D₂ (ergocalciferol), which, in turn, is metabolized to 25(OH)D₂, 1,25(OH)₂D₂, and 24,25(OH)₂D₂. In humans, corresponding D₂ and D₃ derivatives have

equivalent effects and potency. They are therefore referred to in the text without a subscript.

Vitamin D is a prohormone that serves as precursor to a number of biologically active metabolites (Figure 42–2). Vitamin D is first hydroxylated in the liver to form 25-hydroxyvitamin D (25[OH]D). This metabolite is further converted in the kidney to a number of other forms, the best-studied of which are 1,25-dihydroxyvitamin D (1,25[OH]₂D) and 24,25-dihydroxyvitamin D (24,25[OH]₂D). Of the natural metabolites, only vitamin D, 25(OH)D (as **calcifediol**), and 1,25(OH)₂D (as **calcitriol**) are available for clinical use (see Table 42–1). Moreover, a number of analogs of 1,25(OH)₂ are being synthesized in an effort to extend the usefulness of this metabolite to a variety of nonclassic conditions. **Calcipotriene** (calcipotriol), for example, is currently being used to treat psoriasis, a hyperproliferative skin disorder. **Doxercalciferol** and **paricalcitol** have recently been approved for the treatment of secondary hyperparathyroidism in patients with renal failure. Other analogs are being investigated for the treatment of various malignancies. The regulation of vitamin D metabolism is complex, involving calcium, phosphate, and a variety of hormones, the most important of which is PTH, which stimulates the production of 1,25(OH)₂D by the kidney.

Table 42–1. Vitamin D and Its Clinically Available Metabolites and Analogs.

Chemical and Generic Names	Abbreviation
Vitamin D ₃ ; cholecalciferol	D ₃
Vitamin D ₂ ; ergocalciferol	D ₂
25-Hydroxyvitamin D ₃ ; calcifediol	25(OH)D ₃
1,25-Dihydroxyvitamin D ₃ ; calcitriol	1,25(OH) ₂ D ₃
24,25-Dihydroxyvitamin D ₃ ; secalcifediol	24,25(OH) ₂ D ₃
Dihydrotachysterol	DHT
Calcipotriene (calcipotriol)	None
1 α -Hydroxyvitamin D ₂ ; doxercalciferol	1 α (OH)D ₂
19-nor-1,25-Dihydroxyvitamin D ₂ ; paricalcitol	19-nor-1,25(OH)D ₂

Vitamin D and its metabolites circulate in plasma tightly bound to a carrier protein, the vitamin D-binding protein. This α -globulin binds 25(OH)D and 24,25(OH)₂D with comparable high affinity and vitamin D and 1,25(OH)₂D with lower affinity. In normal subjects, the terminal half-life of injected calcifediol is 23 days, whereas in anephric subjects it is 42 days. The half-life of 24,25(OH)₂D is probably similar. Tracer studies with vitamin D have shown a rapid clearance from the blood. The liver appears to be the principal organ for clearance. Excess vitamin D is stored in adipose tissue. The metabolic clearance of calcitriol in humans indicates a rapid turnover, with a

vitamin D-binding protein. As a result, their clearance is very rapid, with a terminal half-life measured in minutes. Such analogs have little of the hypercalcemic, hypercalciuric effects of calcitriol, an important aspect of their use for the management of conditions such as psoriasis and hyperparathyroidism.

The mechanism of action of the vitamin D metabolites remains under active investigation. However, calcitriol is well established as the most potent agent with respect to stimulation of intestinal calcium and phosphate transport and bone resorption. Calcitriol appears to act on the intestine both by induction of new protein synthesis (eg, calcium-binding protein) and by modulation of calcium flux across the brush border and basolateral membranes by a means that does not require new protein synthesis. The molecular action of calcitriol on bone has received less attention. However, like PTH, calcitriol can induce RANK ligand in osteoblasts and proteins such as osteocalcin, which may regulate the mineralization process. The metabolites 25(OH)D and 24,25(OH)₂D are far less potent stimulators of intestinal calcium and phosphate transport or bone resorption. However, 25(OH)D appears to be more potent than 1,25(OH)₂D in stimulating renal reabsorption of calcium and phosphate and may be the major metabolite regulating calcium flux and contractility in muscle. Specific receptors for 1,25(OH)₂D exist in target tissues. However, the role and even the existence of receptors for 25(OH)D and 24,25(OH)₂D remain controversial.

The receptor for 1,25(OH)₂D exists in a wide variety of tissues—not just bone, gut, and kidney. In these "nonclassic" tissues, 1,25(OH)₂D exerts a number of actions including regulation of parathyroid hormone secretion from the parathyroid gland, insulin secretion from the pancreas, cytokine production by macrophages and T cells, and proliferation and differentiation of a large number of cells, including cancer cells. Thus, the clinical utility of 1,25(OH)₂D analogs is likely to expand.

Interaction of PTH & Vitamin D

A summary of the principal actions of PTH and vitamin D on the three main target tissues—intestine, kidney, and bone—is presented in Table 42–2. The net effect of PTH is to raise serum calcium and reduce serum phosphate; the net effect of vitamin D is to raise both. Regulation of calcium and phosphate homeostasis is achieved through a variety of feedback loops. Calcium is the principal regulator of PTH secretion. It binds to a novel ion recognition site that is part of a G_q protein-coupled receptor and links changes in intracellular free calcium concentration to changes in extracellular calcium. As serum calcium levels rise and bind to this receptor, intracellular calcium levels increase and inhibit PTH secretion. Phosphate regulates PTH secretion indirectly by forming complexes with calcium in the serum. Since it is the ionized concentration of calcium that is detected by the parathyroid gland, increases in serum phosphate levels reduce the ionized calcium and lead to enhanced PTH secretion. Such feedback regulation is appropriate to the net effect of PTH to raise serum calcium and reduce serum phosphate levels. Likewise, both calcium and phosphate at high levels reduce the amount of 1,25(OH)₂D produced by the kidney and increase the amount of 24,25(OH)₂D produced. Since 1,25(OH)₂D raises serum calcium and phosphate, whereas 24,25(OH)₂D has less effect, such feedback regulation is again appropriate. 1,25(OH)₂D itself directly inhibits PTH secretion (independently of its effect on serum calcium) by a direct action on PTH gene transcription. This provides yet another negative feedback loop, because PTH is a major stimulus for 1,25(OH)₂D production. This ability of 1,25(OH)₂D to inhibit PTH secretion directly is being exploited using calcitriol analogs that have less effect on serum calcium. Such drugs are proving useful in the management of secondary hyperparathyroidism accompanying renal failure and may be useful in selected cases of primary hyperparathyroidism.

Table 42–2. Actions of PTH and vitamin D on Gut, Bone, and Kidney.

	PTH	Vitamin D
Intestine	Increased calcium and phosphate absorption (by increased 1,25(OH) ₂ D production)	Increased calcium and phosphate absorption by 1,25 [OH] ₂ D
Kidney	Decreased calcium excretion, increased phosphate excretion	Calcium and phosphate excretion may be decreased by 25(OH)D and 1,25(OH) ₂ D
Bone	Calcium and phosphate resorption increased by high doses. Low doses may increase bone formation.	Increased calcium and phosphate resorption by 1,25(OH) ₂ D; bone formation may be increased by 24,25(OH) ₂ D
Net effect on serum levels	Serum calcium increased, serum phosphate decreased	Serum calcium and phosphate both increased

Secondary Hormonal Regulators of Bone Mineral Homeostasis

A number of hormones modulate the actions of PTH and vitamin D in regulating bone mineral homeostasis. Compared with that of PTH and vitamin D, the physiologic impact of such secondary regulation on bone mineral homeostasis is minor. However, in pharmacologic amounts, a number of these hormones have actions on the bone mineral homeostatic mechanisms that can be exploited therapeutically.

Calcitonin

The calcitonin secreted by the parafollicular cells of the mammalian thyroid is a single-chain peptide hormone with 32 amino acids and a molecular weight of 3600. A disulfide bond between positions 1 and 7 is essential for biologic activity. Calcitonin is produced from a precursor with MW 15,000. The circulating forms of calcitonin are multiple, ranging in size from the monomer (MW 3600) to forms with an apparent molecular weight of 60,000. Whether such heterogeneity includes precursor forms or covalently linked oligomers is not known. Because of its heterogeneity, calcitonin is standardized by bioassay in rats. Activity is compared to a standard maintained by the British Medical Research Council (MRC) and expressed as MRC units.

Human calcitonin monomer has a half-life of about 10 minutes with a metabolic clearance of 8–9 mL/kg/min. Salmon calcitonin has a longer half-life and a reduced metabolic clearance (3 mL/kg/min), making it more attractive as a therapeutic agent. Much of the clearance occurs in the kidney, although little intact calcitonin appears in the urine.

The principal effects of calcitonin are to lower serum calcium and phosphate by actions on bone and kidney. Calcitonin inhibits osteoclastic bone resorption. Although bone formation is not impaired at first after calcitonin administration, with time both formation and resorption of bone are reduced. Thus, the early hope that calcitonin would prove useful in restoring bone mass has not been realized. In the kidney, calcitonin reduces both calcium and phosphate reabsorption as well as reabsorption of other ions, including sodium, potassium, and magnesium. Tissues other than bone

and kidney are also affected by calcitonin. Calcitonin in pharmacologic amounts decreases gastrin secretion and reduces gastric acid output while increasing secretion of sodium, potassium, chloride, and water in the gut. Pentagastrin is a potent stimulator of calcitonin secretion (as is hypercalcemia), suggesting a possible physiologic relationship between gastrin and calcitonin. In the adult human, no readily demonstrable problem develops in cases of calcitonin deficiency (thyroidectomy) or excess (medullary carcinoma of the thyroid). However, the ability of calcitonin to block bone resorption and lower serum calcium makes it a useful drug for the treatment of Paget's disease, hypercalcemia, and osteoporosis.

Glucocorticoids

Glucocorticoid hormones alter bone mineral homeostasis by antagonizing vitamin D-stimulated intestinal calcium transport, by stimulating renal calcium excretion, and by blocking bone formation. Although these observations underscore the negative impact of glucocorticoids on bone mineral homeostasis, these hormones have proved useful in reversing the hypercalcemia associated with lymphomas and granulomatous diseases such as sarcoidosis (in which production of $1,25[\text{OH}]_2\text{D}$ is increased), or in cases of vitamin D intoxication. Prolonged administration of glucocorticoids is a common cause of osteoporosis in adults and stunted skeletal development in children.

Estrogens

Estrogens can prevent accelerated bone loss during the immediate postmenopausal period and at least transiently increase bone in the postmenopausal subject. The prevailing hypothesis advanced to explain these observations is that estrogens reduce the bone-resorbing action of PTH. Estrogen administration leads to an increased $1,25(\text{OH})_2\text{D}$ level in blood, but estrogens have no direct effect on $1,25(\text{OH})_2\text{D}$ production in vitro. The increased $1,25(\text{OH})_2\text{D}$ levels in vivo following estrogen treatment may result from decreased serum calcium and phosphate and increased PTH. Estrogen receptors have been found in bone, suggesting that estrogen may have direct effects on bone remodeling. Recent case reports of men lacking the estrogen receptor or unable to produce estrogen because of aromatase deficiency noted marked osteopenia and failure to close epiphyses, further substantiating the role of estrogen in bone development, even in men. The principal therapeutic application for estrogen administration in disorders of bone mineral homeostasis is the treatment or prevention of postmenopausal osteoporosis. This application will increase as estrogen analogs lacking some of the deleterious effects of estrogen are developed (see New Therapies for Osteoporosis).

Nonhormonal Agents Affecting Bone Mineral Homeostasis

Bisphosphonates

The bisphosphonates are analogs of pyrophosphate in which the P–O–P bond has been replaced with a nonhydrolyzable P–C–P bond (Figure 42–3). **Etidronate**, **pamidronate**, and **alendronate** have now been joined by **risedronate**, **tiludronate**, and **zoledronate** for clinical use, and newer forms are likely to be available soon. The bisphosphonates owe at least part of their clinical usefulness and toxicity to their ability to retard formation and dissolution of hydroxyapatite crystals within and outside the skeletal system. However, the exact mechanism by which they selectively inhibit bone resorption is not clear.

Figure 42–3.

Inorganic pyrophosphoric acid

Ethane-1-hydroxy-1,1-bisphosphonate (etidronate)

3-Amino-1-hydroxy-propylidene bisphosphonate (pamidronate)

4-Amino-1-hydroxy-butyldiene bisphosphonate (alendronate)

The structure of pyrophosphate and of the first three bisphosphonates—etidronate, pamidronate, and alendronate—that were approved for use in the USA.

The results from animal and clinical studies indicate that less than 10% of an oral dose of these drugs is absorbed. Food reduces absorption even further, necessitating their administration on an empty stomach. Because it causes gastric irritation, pamidronate is not available as an oral preparation. However, with the possible exception of etidronate, all currently available bisphosphonates have this complication. Nearly half of the absorbed drug accumulates in bone; the remainder is excreted unchanged in the urine. Decreased renal function, esophageal motility disorders, and peptic ulcer disease are the main contraindications to the use of these drugs. The portion bound to bone is retained for months, depending on the turnover of bone itself.

Etidronate and the other bisphosphonates exert a variety of effects on bone mineral homeostasis. Their physicochemical action of reducing hydroxyapatite formation and dissolution make them clinically useful. In particular, bisphosphonates are being evaluated for the treatment of hypercalcemia associated with malignancy, osteoporosis, and syndromes of ectopic calcification. Their usefulness in the management of Paget's disease is well established. Only alendronate and risedronate have been approved for the treatment of osteoporosis, but other bisphosphonates are being developed for this purpose. (See New Therapies for Osteoporosis.) Contrary to expectations, alendronate appears to increase bone mineral density well beyond the 2-year period predicted for a drug whose effects are limited to blocking bone resorption. The bisphosphonates exert a variety of other cellular effects, including inhibition of $1,25(\text{OH})_2\text{D}$ production, inhibition of intestinal calcium transport, metabolic changes in bone cells such as inhibition of glycolysis, inhibition of cell growth, and changes in acid and alkaline phosphatase. Amino bisphosphonates such as alendronate

have recently been found to block farnesyl pyrophosphate synthase, an enzyme in the mevalonate pathway that appears to be critical for osteoclast survival. Statins, which block mevalonate synthesis, stimulate bone formation at least in animal studies. Thus, the mevalonate pathway appears to be important in bone cell function and provides new targets for drug development. These effects vary depending on the bisphosphonate being studied (ie, only amino bisphosphonates have this property) and may account for some of the clinical differences observed in the effects of the various bisphosphonates on bone mineral homeostasis. However, with the exception of the induction of a mineralization defect by higher than approved doses of etidronate and gastric and esophageal irritation by pamidronate and by high doses of alendronate, these drugs have proved to be remarkably free of adverse effects. Esophageal irritation can be minimized by taking the drug with a full glass of water and remaining upright for 30 minutes.

Plicamycin (Mithramycin)

Plicamycin is a cytotoxic antibiotic (see Chapter 55: Cancer Chemotherapy) that has been used clinically for two disorders of bone mineral metabolism: Paget's disease and hypercalcemia. The cytotoxic properties of the drug appear to involve its binding to DNA and interruption of DNA-directed RNA synthesis. The reasons for its usefulness in the treatment of Paget's disease and hypercalcemia are unclear but may relate to the need for protein synthesis to sustain bone resorption. The doses required to treat Paget's disease and hypercalcemia are about one tenth the amounts required to achieve cytotoxic effects.

Thiazides

The chemistry and pharmacology of this family of drugs are covered in Chapter 15: Diuretic Agents. The principal application of thiazides in the treatment of bone mineral disorders is in reducing renal calcium excretion. Thiazides may increase the effectiveness of parathyroid hormone in stimulating reabsorption of calcium by the renal tubules or may act on calcium reabsorption secondarily by increasing sodium reabsorption in the proximal tubule. In the distal tubule, thiazides block sodium reabsorption at the luminal surface, increasing the calcium-sodium exchange at the basolateral membrane and thus enhancing calcium reabsorption into the blood at this site. Thiazides have proved to be quite useful in reducing the hypercalciuria and incidence of stone formation in subjects with idiopathic hypercalciuria. Part of their efficacy in reducing stone formation may lie in their ability to decrease urine oxalate excretion and increase urine magnesium and zinc levels (both of which inhibit calcium oxalate stone formation).

Fluoride

Fluoride is well established as effective for the prophylaxis of dental caries and has been under investigation for the treatment of osteoporosis. Both therapeutic applications originated from epidemiologic observations that subjects living in areas with naturally fluoridated water (1–2 ppm) had less dental caries and fewer vertebral compression fractures than subjects living in nonfluoridated water areas. Fluoride is accumulated by bones and teeth, where it may stabilize the hydroxyapatite crystal. Such a mechanism may explain the effectiveness of fluoride in increasing the resistance of teeth to dental caries, but it does not explain new bone growth.

Fluoride in drinking water appears to be most effective in preventing dental caries if consumed prior to the eruption of the permanent teeth. The optimum concentration in drinking water supplies is 0.5–1 ppm. Topical application is most effective if done just as the teeth erupt. There is little further benefit to giving fluoride after the permanent teeth are fully formed. Excess fluoride in drinking water leads to mottling of the enamel proportionate to the concentration above 1 ppm.

Because of the paucity of agents that stimulate new bone growth in patients with osteoporosis, the use of fluoride for this disorder has been examined (see Osteoporosis). Results of earlier studies indicated that fluoride alone without adequate calcium supplementation produced osteomalacia. More recent studies, in which calcium supplementation has been adequate, have demonstrated an improvement in calcium balance, an increase in bone mineral, and an increase in trabecular bone volume. However, studies of the ability of fluoride to reduce fractures reach opposite conclusions. Adverse effects observed—at the doses used for testing fluoride's effect on bone—include nausea and vomiting, gastrointestinal blood loss, arthralgias, and arthritis in a substantial proportion of patients. Such effects are usually responsive to reduction of the dose or giving fluoride with meals (or both). At present, fluoride is not approved by the Food and Drug Administration for use in osteoporosis.

Katzung PHARMACOLOGY, 9e > Section VII. Endocrine Drugs > Chapter 42. Agents That Affect Bone Mineral Homeostasis >

Clinical Pharmacology

Disorders of bone mineral homeostasis generally present with abnormalities in serum or urine calcium levels (or both), often accompanied by abnormal serum phosphate levels. These abnormal mineral concentrations may themselves cause symptoms requiring immediate treatment (eg, coma in malignant hypercalcemia, tetany in hypocalcemia). More commonly, they serve as clues to an underlying disorder in hormonal regulators (eg, primary hyperparathyroidism), target tissue response (eg, chronic renal failure), or drug misuse (eg, vitamin D intoxication). In such cases, treatment of the underlying disorder is of prime importance.

Since bone and kidney play central roles in bone mineral homeostasis, conditions that alter bone mineral homeostasis usually affect either or both of these tissues secondarily. Effects on bone can result in osteoporosis (abnormal loss of bone; remaining bone histologically normal), osteomalacia (abnormal bone formation due to inadequate mineralization), or osteitis fibrosa (excessive bone resorption with fibrotic replacement of resorption cavities). Biochemical markers of skeletal involvement include changes in serum levels of the skeletal isoenzyme of alkaline phosphatase and osteocalcin (reflecting osteoblastic activity) and urine levels of hydroxyproline and pyridinoline cross-links (reflecting osteoclastic activity). The kidney becomes involved when the calcium-times-phosphate product in serum exceeds the point at which ectopic calcification occurs (nephrocalcinosis) or when the calcium-times-oxalate (or phosphate) product in urine exceeds saturation, leading to nephrolithiasis. Subtle early indicators of such renal involvement include polyuria, nocturia, and hyposthenuria. Radiologic evidence of nephrocalcinosis and stones is not generally observed until later. The degree of the ensuing renal failure is best followed by monitoring the decline in creatinine clearance.

Abnormal Serum Calcium & Phosphate Levels

Hypercalcemia

Hypercalcemia causes central nervous system depression, including coma, and is potentially lethal. Its major causes (other than thiazide therapy) are hyperparathyroidism and cancer with or without bone metastases. Less common causes are hypervitaminosis D, sarcoidosis, thyrotoxicosis, milk-alkali syndrome, adrenal insufficiency, and immobilization. With the possible exception of hypervitaminosis D, these latter disorders seldom require emergency lowering of serum calcium. A number of approaches are used to manage the hypercalcemic crisis.

Saline Diuresis

In hypercalcemia of sufficient severity to produce symptoms, rapid reduction of serum calcium is required. The first steps include rehydration with saline and diuresis with furosemide. Most patients presenting with severe hypercalcemia have a substantial component of prerenal azotemia owing to dehydration, which prevents the kidney from compensating for the rise in serum calcium by excreting more calcium in the urine. Therefore, the initial infusion of 500–1000 mL/h of saline to reverse the dehydration and restore urine flow can by itself substantially lower serum calcium. The addition of a loop diuretic such as furosemide not only enhances urine flow but also inhibits calcium reabsorption in the ascending limb of the loop of Henle (see Chapter 15: Diuretic Agents). Monitoring central venous pressure is important to forestall the development of heart failure and pulmonary edema in predisposed subjects. In many subjects, saline diuresis will suffice to reduce serum calcium levels to a point at which more definitive diagnosis and treatment of the underlying condition can be achieved. If this is not the case or if more prolonged medical treatment of hypercalcemia is required, the following agents are available (discussed in order of preference).

Bisphosphonates

Etidronate, 7.5 mg/kg in 250–500 mL saline, infused over several hours each day for 3 days, has proved quite useful in treating hypercalcemia of malignancy. More recently, pamidronate, 60–90 mg, infused over 2–4 hours, and zoledronate, 4 mg, infused over 15 minutes, have been approved for the same indication and appear to be more effective. This form of treatment is remarkably free of toxicity. The effects generally persist for weeks, but treatment can be repeated after a 7-day interval if necessary and if renal function is not impaired.

Calcitonin

Calcitonin has proved useful as ancillary treatment in a large number of patients. Calcitonin by itself seldom restores serum calcium to normal, and refractoriness frequently develops. However, its lack of toxicity permits frequent administration at high doses (200 MRC units or more). An effect on serum calcium is observed within 4–6 hours and lasts for 6–10 hours. Calcimar (salmon calcitonin) is available for parenteral and nasal administration.

Gallium Nitrate

Gallium nitrate is approved by the Food and Drug Administration for the management of hypercalcemia of malignancy and is undergoing trials for the treatment of advanced Paget's disease. This drug acts by inhibiting bone resorption. At a dosage of 200 mg/m² body surface area per day given as a continuous intravenous infusion in 5% dextrose for 5 days, gallium nitrate proved superior to calcitonin in reducing serum calcium in cancer patients. Because of potential nephrotoxicity, patients should be well-hydrated and have good renal output before starting the infusion.

Plicamycin (Mithramycin)

Because of its toxicity, plicamycin (mithramycin) is not the drug of first choice for the treatment of hypercalcemia. However, when other forms of therapy fail, 25–50 µg/kg given intravenously usually lowers serum calcium substantially within 24–48 hours. This effect can last for several days. This dose can be repeated as necessary. The most dangerous toxic effect is sudden thrombocytopenia followed by hemorrhage. Hepatic and renal toxicity can also occur. Hypocalcemia, nausea, and vomiting may limit therapy. Use of this drug must be accompanied by

careful monitoring of platelet counts, liver and kidney function, and serum calcium levels.

Phosphate

Giving intravenous phosphate is probably the fastest and surest way to reduce serum calcium, but it is a hazardous procedure if not done properly. Intravenous phosphate should be used only after other methods of treatment (pamidronate, calcitonin, saline diuresis with furosemide, and plicamycin) have failed to control symptomatic hypercalcemia. Phosphate must be given slowly (50 mmol or 1.5 g elemental phosphorus over 6–8 hours) and the patient switched to oral phosphate (1–2 g/d elemental phosphorus, as one of the salts indicated below) as soon as symptoms of hypercalcemia have cleared. The risks of intravenous phosphate therapy include sudden hypocalcemia, ectopic calcification, acute renal failure, and hypotension. Oral phosphate can also lead to ectopic calcification and renal failure if serum calcium and phosphate levels are not carefully monitored, but the risk is less and the time of onset much longer. Phosphate is available in oral and intravenous forms as the sodium or potassium salt. Amounts required to provide 1 g of elemental phosphorus are as follows:

Intravenous:

In-Phos: 40 mL

Hyper-Phos-K: 15 mL

Oral:

Fleet Phospho-Soda: 6.2 mL

Neutra-Phos: 300 mL

K-Phos-Neutral: 4 tablets

Glucocorticoids

Glucocorticoids have no clear role in the acute treatment of hypercalcemia. However, the chronic hypercalcemia of sarcoidosis, vitamin D intoxication, and certain cancers may respond within several days to glucocorticoid therapy. Prednisone in oral doses of 30–60 mg daily is generally used, though equivalent doses of other glucocorticoids are effective. The rationale for the use of glucocorticoids in these diseases differs, however. The hypercalcemia of sarcoidosis is secondary to increased production of $1,25(\text{OH})_2\text{D}$, possibly by the sarcoid tissue itself. Glucocorticoid therapy directed at the reduction of sarcoid tissue results in restoration of normal serum calcium and $1,25(\text{OH})_2\text{D}$ levels. The treatment of hypervitaminosis D with glucocorticoids probably does not alter vitamin D metabolism significantly but is thought to reduce vitamin D-mediated intestinal calcium transport. An action of glucocorticoids to reduce vitamin D-mediated bone resorption has not been excluded, however. The effect of glucocorticoids on the hypercalcemia of cancer is probably twofold. The malignancies responding best to glucocorticoids (ie, multiple myeloma and related lymphoproliferative diseases) are sensitive to the lytic action of glucocorticoids, so part of the effect may be related to decreased tumor mass and activity. Glucocorticoids have also been shown to inhibit the secretion or effectiveness of cytokines elaborated by multiple myeloma and related cancers that stimulate osteoclastic bone resorption. Other causes of hypercalcemia—particularly primary hyperparathyroidism—do not respond to glucocorticoid therapy.

Hypocalcemia

The main features of hypocalcemia are neuromuscular—tetany, paresthesias, laryngospasm, muscle cramps, and convulsions. The major causes of hypocalcemia in the adult are hypoparathyroidism, vitamin D deficiency, renal failure, and malabsorption. Neonatal hypocalcemia is a common disorder that usually resolves without therapy. The roles of PTH, vitamin D, and calcitonin in the neonatal syndrome are under active investigation. Large infusions of citrated blood can produce hypocalcemia by the formation of citrate-calcium complexes. Calcium and vitamin D (or its metabolites) form the mainstay of treatment of hypocalcemia.

Calcium

A number of calcium preparations are available for intravenous, intramuscular, and oral use. Calcium gluceptate (0.9 meq calcium/mL), calcium gluconate (0.45 meq calcium/mL), and calcium chloride (0.68–1.36 meq calcium/mL) are available for intravenous therapy. Calcium gluconate is the preferred form because it is less irritating to veins. Oral preparations include calcium carbonate (40% calcium), calcium lactate (13% calcium), calcium phosphate (25% calcium), and calcium citrate (21% calcium). Calcium carbonate is often the preparation of choice because of its high percentage of calcium, ready availability (eg, Tums), low cost, and antacid properties. In achlorhydric patients, calcium carbonate should be given with meals to increase absorption or the patient switched to calcium citrate, which is somewhat better absorbed. Combinations of vitamin D and calcium are available, but treatment must be tailored to the individual patient and individual disease, a flexibility lost by fixed-dosage combinations. Treatment of severe symptomatic hypocalcemia can be accomplished with slow infusion of 5–20 mL of 10% calcium gluconate. Rapid infusion can lead to cardiac arrhythmias. Less severe hypocalcemia is best treated with oral forms sufficient to provide approximately 400–800 mg of elemental calcium (1–2 g calcium carbonate) per day. Dosage must be adjusted to avoid hypercalcemia and hypercalciuria.

Vitamin D

When rapidity of action is required, 1,25(OH)₂D₃ (calcitriol), 0.25–1 µg daily, is the vitamin D metabolite of choice, since it is capable of raising serum calcium within 24–48 hours. Calcitriol also raises serum phosphate, though this action is usually not observed early in treatment. The combined effects of calcitriol and all other vitamin D metabolites and analogs on both calcium and phosphate make careful monitoring of these mineral levels especially important to avoid ectopic calcification secondary to an abnormally high serum calcium × phosphate product. Since the choice of the appropriate vitamin D metabolite or analog for long-term treatment of hypocalcemia depends on the nature of the underlying disease, further discussion of vitamin D treatment will be found under the headings of the specific diseases.

Hyperphosphatemia

Hyperphosphatemia is a frequent complication of renal failure but is also found in all types of hypoparathyroidism (idiopathic, surgical, and pseudo), vitamin D intoxication, and the rare syndrome of tumoral calcinosis. Emergency treatment of hyperphosphatemia is seldom necessary but can be achieved by dialysis or glucose and insulin infusions. In general, control of hyperphosphatemia involves restriction of dietary phosphate plus the use of phosphate binding gels such as sevelamer and of calcium supplements. Because of their potential to induce aluminum-associated bone disease, aluminum-containing antacids should be used sparingly and only when other measures fail to control the hyperphosphatemia.

Hypophosphatemia

A variety of conditions are associated with hypophosphatemia, including primary hyperparathyroidism, vitamin D deficiency, idiopathic hypercalciuria, vitamin D-resistant rickets, various other forms of renal phosphate wasting (eg, Fanconi's syndrome), overzealous use of phosphate binders, and parenteral nutrition with inadequate phosphate content. Acute hypophosphatemia may lead to a reduction in the intracellular levels of high-energy organic phosphates (eg, ATP), interfere with normal hemoglobin-to-tissue oxygen transfer by decreasing red cell 2,3-diphosphoglycerate levels, and lead to rhabdomyolysis. However, clinically significant acute effects of hypophosphatemia are seldom seen, and emergency treatment is generally not indicated. The long-term effects of hypophosphatemia include proximal muscle weakness and abnormal bone mineralization (osteomalacia). Therefore, hypophosphatemia should be avoided during other forms of therapy and treated in conditions such as hypophosphatemic rickets of which it is a cardinal feature. Oral forms of phosphate available for use are listed above in the section on hypercalcemia.

Specific Disorders Involving the Bone Mineral-Regulating Hormones

Primary Hyperparathyroidism

This rather common disease, if associated with symptoms and significant hypercalcemia, is best treated surgically. Oral phosphate and bisphosphonates have been tried but cannot be recommended. Asymptomatic patients with mild disease in general do not get worse and may be left untreated. The **calcimimetic agents**, a new class of drugs that act through the calcium receptor, are in clinical trials. If they prove efficacious, medical management of this disease will need to be reconsidered.

Hypoparathyroidism

In the absence of PTH (idiopathic or surgical hypoparathyroidism) or a normal target tissue response to PTH (pseudohypoparathyroidism), serum calcium falls and serum phosphate rises. In such patients, $1,25(\text{OH})_2\text{D}$ levels are usually low, presumably reflecting the lack of stimulation by PTH of $1,25(\text{OH})_2\text{D}$ production. The skeletons of patients with idiopathic or surgical hypoparathyroidism are normal except for a slow turnover rate. A number of patients with pseudohypoparathyroidism appear to have osteitis fibrosa, suggesting that the normal or high PTH levels found in such patients are capable of acting on bone but not on the kidney. The distinction between pseudohypoparathyroidism and idiopathic hypoparathyroidism is made on the basis of normal or high PTH levels but deficient renal response (ie, diminished excretion of cAMP or phosphate) in patients with pseudohypoparathyroidism.

The principal therapeutic concern is to restore normocalcemia and normophosphatemia. Under most circumstances, vitamin D (25,000–100,000 units three times per week) and dietary calcium supplements suffice. More rapid increments in serum calcium can be achieved with calcitriol, though it is not clear that this metabolite offers a substantial advantage over vitamin D itself for long-term therapy. Many patients treated with vitamin D develop episodes of hypercalcemia. This complication is more rapidly reversible with cessation of therapy using calcitriol rather than vitamin D. This would be of importance to the patient in whom such hypercalcemic crises are common. Dihydroxycholesterol and $25(\text{OH})\text{D}$ have not received much study as therapy for hypoparathyroidism, though both should be effective. Whether they offer advantages over vitamin D sufficient to justify their added expense remains to be seen.

Nutritional Rickets

Vitamin D deficiency, once thought to be rare in this country, is being recognized more often, especially in the pediatric and geriatric populations on vegetarian diets and with reduced sunlight exposure. This problem can be avoided by daily intake of 400–800 units of vitamin D and treated by higher dosages (4000 units per day). No other metabolite is indicated. The diet should also contain adequate amounts of calcium and phosphate.

Chronic Renal Failure

The major problems of chronic renal failure that impact on bone mineral homeostasis are the loss of $1,25(\text{OH})_2\text{D}$ and $24,25(\text{OH})_2\text{D}$ production, the retention of phosphate that reduces ionized calcium levels, and the secondary hyperparathyroidism that results. With the loss of $1,25(\text{OH})_2\text{D}$ production, less calcium is absorbed from the intestine and less bone is resorbed under the influence of PTH. As a result hypocalcemia usually develops, furthering the development of hyperparathyroidism. The bones show a mixture of osteomalacia and osteitis fibrosa.

In contrast to the hypocalcemia that is more often associated with chronic renal failure, some patients may become hypercalcemic from two causes (in addition to overzealous treatment with calcium). The most common cause of hypercalcemia is the development of severe secondary (sometimes referred to as tertiary) hyperparathyroidism. In such cases, the PTH level in blood is very high. Serum alkaline phosphatase levels also tend to be high. Treatment often requires parathyroidectomy.

A less common circumstance leading to hypercalcemia is development of a form of osteomalacia characterized by a profound decrease in bone cell activity and loss of the calcium buffering action of bone. In the absence of kidney function, any calcium absorbed from the intestine accumulates in the blood. Therefore, such patients are very sensitive to the hypercalcemic action of $1,25(\text{OH})_2\text{D}$. These individuals generally have a high serum calcium but nearly normal alkaline phosphatase and PTH levels. The bone in such patients generally has a high aluminum content, especially in the mineralization front, which may block normal bone mineralization. These patients do not respond favorably to parathyroidectomy. Deferoxamine, an agent used to chelate iron (see Chapter 58: Heavy Metal Intoxication & Chelators), also binds aluminum and is being used as therapy for this disorder.

Use of Vitamin D Preparations

The choice of vitamin D preparation to be used in the setting of chronic renal failure in the dialysis patient depends on the type and extent of bone disease and hyperparathyroidism. No consensus has been reached regarding the advisability of using any vitamin D metabolite in the predialysis patient. $1,25(\text{OH})_2\text{D}_3$ (calcitriol) will rapidly correct hypocalcemia and at least partially reverse the secondary hyperparathyroidism and osteitis fibrosa. Many patients with muscle weakness and bone pain gain an improved sense of well-being.

Dihydroxycholesterol, an analog of $1,25(\text{OH})_2\text{D}$, is also available for clinical use, though it is used much less frequently than calcitriol. Dihydroxycholesterol appears to be as effective as calcitriol, differing principally in its time course of action; calcitriol increases serum calcium in 1–2 days, whereas dihydroxycholesterol requires 1–2 weeks. For an equipotent dose (0.2 mg dihydroxycholesterol versus 0.5 μg calcitriol), dihydroxycholesterol costs about one fourth as much as calcitriol. A disadvantage of dihydroxycholesterol is the inability to measure it in serum. Neither dihydroxycholesterol nor calcitriol corrects the osteomalacic component of renal osteodystrophy in the majority of patients, and neither should be used in patients with hypercalcemia, especially if the bone disease is primarily osteomalacic.

Calcifediol (25[OH]D₃) may also be used to advantage. Calcifediol is less effective than calcitriol in stimulating intestinal calcium transport, so that hypercalcemia is less of a problem with calcifediol. Like dihydrotachysterol, calcifediol requires several weeks to restore normocalcemia in hypocalcemic individuals with chronic renal failure. Presumably because of the reduced ability of the diseased kidney to metabolize calcifediol to more active metabolites, high doses (50–100 µg daily) must be given to achieve the supraphysiologic serum levels required for therapeutic effectiveness.

Vitamin D has been used in treating renal osteodystrophy. However, patients with a substantial degree of renal failure who are thus unable to convert vitamin D to its active metabolites usually are refractory to vitamin D. Its use is decreasing as more effective alternatives become available.

Two analogs of calcitriol, doxercalciferol and paricalcitol, are approved for the treatment of secondary hyperparathyroidism of chronic renal failure. Their principal advantage is that they are less likely than calcitriol to induce hypercalcemia. Their biggest impact will be in patients in whom the use of calcitriol may lead to unacceptably high serum calcium levels.

Regardless of the drug employed, careful attention to serum calcium and phosphate levels is required. Calcium supplements (dietary and in the dialysate) and phosphate restriction (dietary and with oral ingestion of phosphate binders) should be employed along with the use of vitamin D metabolites. Monitoring serum PTH and alkaline phosphatase levels is useful in determining whether therapy is correcting or preventing secondary hyperparathyroidism. Although not generally available, percutaneous bone biopsies for quantitative histomorphometry may help in choosing appropriate therapy and following the effectiveness of such therapy. Unlike the rapid changes in serum values, changes in bone morphology require months to years. Monitoring serum levels of the vitamin D metabolites is useful to determine compliance, absorption, and metabolism.

Intestinal Osteodystrophy

A number of gastrointestinal and hepatic diseases result in disordered calcium and phosphate homeostasis that ultimately leads to bone disease. The bones in such patients show a combination of osteoporosis and osteomalacia. Osteitis fibrosa does not occur (as it does in renal osteodystrophy). The common features that appear to be important in this group of diseases are malabsorption of calcium and vitamin D. Liver disease may, in addition, reduce the production of 25(OH)D from vitamin D, though the importance of this in all but patients with terminal liver failure remains in dispute. The malabsorption of vitamin D is probably not limited to exogenous vitamin D. The liver secretes into bile a substantial number of vitamin D metabolites and conjugates that are reabsorbed in (presumably) the distal jejunum and ileum. Interference with this process could deplete the body of endogenous vitamin D metabolites as well as limit absorption of dietary vitamin D.

In mild forms of malabsorption, vitamin D (25,000–50,000 units three times per week) should suffice to raise serum levels of 25(OH)D into the normal range. Many patients with severe disease do not respond to vitamin D. Clinical experience with the other metabolites is limited, but both calcitriol and calcifediol have been used successfully in doses similar to those recommended for treatment of renal osteodystrophy. Theoretically, calcifediol should be the drug of choice under these conditions, since no impairment of the renal metabolism of 25(OH)D to 1,25(OH)₂D and 24,25(OH)₂D exists in these patients. Both calcitriol and 24,25(OH)₂D may be of importance in reversing the bone disease. As in the other diseases discussed, treatment of intestinal osteodystrophy with vitamin D and its metabolites should be accompanied by appropriate dietary calcium supplementation and monitoring of serum calcium and phosphate levels.

Osteoporosis

Osteoporosis is defined as abnormal loss of bone predisposing to fractures. The estimated annual cost of fractures in older women and men in the USA was \$13.8 billion (Incidence and costs, 1996). It is most common in postmenopausal women but also occurs in men. It may occur as a side effect of chronic administration of glucocorticoids or other drugs; as a manifestation of endocrine disease such as thyrotoxicosis or hyperparathyroidism; as a feature of malabsorption syndrome; as a consequence of alcohol abuse and cigarette smoking; or without obvious cause (idiopathic). The ability of some agents to reverse the bone loss of osteoporosis is shown in Figure 42–4. The postmenopausal form of osteoporosis may be accompanied by lower 1,25(OH)₂D levels and reduced intestinal calcium transport. This form of osteoporosis is due to estrogen deficiency and can be treated with estrogen (cycled with a progestin in women with a uterus to prevent endometrial carcinoma). However, concern that estrogen increases the risk of breast cancer and fails to reduce the development of heart disease has reduced enthusiasm for this form of therapy. Several estrogen-like drugs called SERMs (selective estrogen receptor modulators) have been developed that avoid the increased risk of breast and uterine cancer associated with estrogen while maintaining the benefit to bone. **Raloxifene** is such a drug approved for treatment of osteoporosis. Like tamoxifen, it appears to reduce the risk of breast cancer. Raloxifene protects against spine fractures but not hip fractures—unlike bisphosphonates and teriparatide, which protect against both. Raloxifene does not prevent hot flashes and imposes the same increased risk of thrombophlebitis as estrogen. To counter the reduced intestinal calcium transport associated with osteoporosis, vitamin D therapy is often employed in addition to dietary calcium supplementation. There is no clear evidence that pharmacologic doses of vitamin D are of much additional benefit beyond cyclic estrogens and calcium supplementation. However, in several large studies, vitamin D supplementation (400–800 IU/d) has been shown to be useful. In addition, calcitriol and its analog 1 α (OH)D₃ have been shown to increase bone mass and reduce fractures in several recent studies. Use of these agents for osteoporosis is not FDA-approved, though they are used in other countries.

Figure 42–4.

Typical changes in bone mineral density with time after the onset of menopause, with and without treatment. In the untreated condition, bone is lost during aging in both men and women. Fluoride and PTH promote new bone formation and can increase bone mineral density in subjects who

respond to it throughout the period of treatment. In contrast, estrogen, calcitonin, and bisphosphonates block bone resorption. This leads to a transient increase in bone mineral density because bone formation is not initially decreased. However, with time, both bone formation and bone resorption are decreased and bone mineral density reaches a new plateau.

Despite early promise that **fluoride** might be useful in the prevention or treatment of postmenopausal osteoporosis, this form of therapy remains controversial. A new formulation of fluoride (slow release, lower dose) appears to avoid much of the toxicity of earlier formulations and may reduce fracture rates. This formulation is under consideration for approval by the FDA.

Teriparatide, the recombinant form of PTH 1-34, has recently been approved for treatment of osteoporosis. Teriparatide is given in a dosage 20 μg subcutaneously daily. Like fluoride, teriparatide stimulates new bone formation, but unlike fluoride this new bone appears structurally normal and is associated with a substantial reduction in the incidence of fractures.

Calcitonin is approved for use in the treatment of postmenopausal osteoporosis. It has been shown to increase bone mass and reduce fractures, but only in the spine. It does not appear to be as effective as bisphosphonates or teriparatide.

Bisphosphonates are potent inhibitors of bone resorption. They increase bone density and reduce the risk of fractures in the hip, spine, and other locations. **Alendronate** and **risedronate** are approved for the treatment of osteoporosis, using either daily dosing schedules: alendronate 10 mg/d, risedronate 5 mg/d; or weekly schedules: alendronate 70 mg/wk, risedronate 35 mg/wk. These drugs are effective in men as well as women and for various causes of osteoporosis.

X-Linked & Autosomal Dominant Hypophosphatemia

These disorders are manifested by the appearance of rickets and hypophosphatemia in children, though they may first present in adults. X-linked hypophosphatemia is caused by mutations in a gene encoding a protein called PHEX, which appears to be an endopeptidase. Mutations in the gene responsible for the autosomal dominant form target a newly discovered member of the fibroblast growth factor (FGF) family, FGF23. The current concept is that FGF23 blocks the renal uptake of phosphate and blocks $1,25(\text{OH})_2\text{D}_3$ production. Normally PHEX cleaves and inactivates FGF23. Mutations in PHEX inactivate this enzyme, allowing FGF23 to accumulate. Similarly, mutations in FGF23 can prevent cleavage by PHEX. In either case, intact and biologically active FGF23 accumulates, leading to phosphate wasting in the urine and hypophosphatemia.

Phosphate is critical to normal bone mineralization; when phosphate stores are deficient, a clinical and pathologic picture resembling vitamin D-deficient rickets develops. However, such children fail to respond to the usual doses of vitamin D employed in the treatment of nutritional rickets. A defect in $1,25(\text{OH})_2\text{D}$ production by the kidney has also been noted, because the serum $1,25(\text{OH})_2\text{D}$ levels tend to be low relative to the degree of hypophosphatemia observed. This combination of low serum phosphate and low or low-normal serum $1,25(\text{OH})_2\text{D}$ provides the rationale for treating such patients with oral phosphate (1–3 g daily) and calcitriol (0.25–2 μg daily). Reports of such combination therapy are encouraging in this otherwise debilitating disease.

Vitamin D-Dependent Rickets Types I & II

These distinctly different autosomal recessive diseases present as childhood rickets that does not respond to conventional doses of vitamin D. Type I vitamin D-dependent rickets is due to an isolated deficiency of $1,25(\text{OH})_2\text{D}$ production caused by mutations in $25(\text{OH})\text{D}-1\alpha$ -hydroxylase. This condition can be treated with vitamin D (4000 units daily) or calcitriol (0.25–0.5 μg daily).

Type II vitamin D-dependent rickets is caused by a target tissue defect in response to $1,25(\text{OH})_2\text{D}$. Studies have shown a number of point mutations in the gene for the $1,25(\text{OH})_2\text{D}$ receptor, which disrupt the functions of this receptor and lead to this syndrome. The serum levels of $1,25(\text{OH})_2\text{D}$ are very high in type II but not in type I. Treatment with large doses of calcitriol has been claimed to be effective in restoring normocalcemia. Such patients are totally refractory to vitamin D. One recent report indicates a reversal of resistance to calcitriol when $24,25(\text{OH})_2\text{D}$ was given. These diseases are rare.

Nephrotic Syndrome

Patients with nephrotic syndrome can lose vitamin D metabolites in the urine, presumably by loss of the vitamin D-binding protein. Such patients may have very low $25(\text{OH})\text{D}$ levels. Some of them develop bone disease. It is not yet clear what value vitamin D therapy has in such patients, since this complication of the nephrotic syndrome has only recently been recognized, and therapeutic trials with vitamin D (or any other vitamin D metabolite) have not yet been carried out. Since the problem is not related to vitamin D metabolism, one would not anticipate any advantage in using the more expensive vitamin D metabolites in place of vitamin D itself.

Idiopathic Hypercalciuria

This syndrome, characterized by hypercalciuria and nephrolithiasis with normal serum calcium and PTH levels, has been subdivided into three groups of patients: (1) hyperabsorbers, patients with increased intestinal absorption of calcium, resulting in high-normal serum calcium, low-normal PTH, and a secondary increase in urine calcium; (2) renal calcium leakers, patients with a primary decrease in renal reabsorption of filtered calcium, leading to low-normal serum calcium and high-normal serum PTH; and (3) renal phosphate leakers, patients with a primary decrease in renal reabsorption of phosphate, leading to stimulation of $1,25(\text{OH})_2\text{D}$ production, increased intestinal calcium absorption, increased ionized serum calcium, low-normal PTH levels, and a secondary increase in urine calcium. There is some disagreement about this classification, and in many cases patients are not readily categorized. Many such patients present with mild hypophosphatemia, and oral phosphate has been used with some success to reduce stone formation. However, a clear role for phosphate in the treatment of this disorder has not been established. Therapy with hydrochlorothiazide, up to 50 mg twice daily, or chlorthalidone, 50–100 mg daily, is recommended, although equivalent doses of other thiazide diuretics work as well. Loop diuretics such as furosemide and ethacrynic acid should not be used, since they increase urinary calcium excretion. The major toxicity of thiazide diuretics, besides hypokalemia, hypomagnesemia, and hyperglycemia, is hypercalcemia. This is seldom more than a biochemical observation unless the patient has a disease such as hyperparathyroidism in which bone turnover is accelerated. Accordingly, one should screen patients for such disorders before starting thiazide therapy and monitor serum and urine calcium when therapy has begun.

An alternative to thiazides is allopurinol. Some studies indicate that hyperuricosuria is associated with idiopathic hypercalcemia and that a small nidus of urate crystals could lead to the calcium oxalate stone formation characteristic of idiopathic hypercalcemia. Allopurinol, 300 mg daily, may reduce stone formation by reducing uric acid excretion.

Other Disorders of Bone Mineral Homeostasis

Paget's Disease of Bone

Paget's disease is a localized bone disease characterized by uncontrolled osteoclastic bone

resorption with secondary increases in bone formation. This new bone is poorly organized, however. The cause of Paget's disease is obscure, though some studies suggest that a slow virus may be involved. The disease is fairly common, though symptomatic bone disease is less common. The biochemical parameters of elevated serum alkaline phosphatase and urinary hydroxyproline are useful for diagnosis. Along with the characteristic radiologic and bone scan findings, these biochemical determinations provide good markers by which to follow therapy. The goal of treatment is to reduce bone pain and stabilize or prevent other problems such as progressive deformity, hearing loss, high-output cardiac failure, and immobilization hypercalcemia. Calcitonin and bisphosphonates are the first-line agents for this disease. Treatment failures may respond to plicamycin. Calcitonin is administered subcutaneously or intramuscularly in doses of 50–100 MRC units every day or every other day. Nasal inhalation at 200–400 units per day is also effective. Higher or more frequent doses have been advocated when this initial regimen is ineffective. Improvement in bone pain and reduction in serum alkaline phosphatase and urine hydroxyproline levels require weeks to months. Often a patient who responds well initially will lose the response to calcitonin. This refractoriness is not correlated with the development of antibodies.

Sodium etidronate, alendronate, risedronate, and tiludronate are the bisphosphonates currently approved for clinical use in this condition in the USA. However, other bisphosphonates, including pamidronate, are being used in other countries. The recommended dosages of bisphosphonates are etidronate, 5 mg/kg/d; alendronate, 40 mg/d; risedronate, 30 mg/d; and tiludronate, 400 mg/d. Long-term (months to years) remission may be expected in patients who respond to these agents. Treatment should not exceed 6 months per course but can be repeated after 6 months if necessary. The principal toxicity of etidronate is the development of osteomalacia and an increased incidence of fractures when the dosage is raised substantially above 5 mg/kg/d. The newer bisphosphonates such as risedronate and alendronate do not share this side effect. Some patients treated with etidronate develop bone pain similar in nature to the bone pain of osteomalacia. This subsides after stopping the drug. The principal side effect of alendronate and the newer bisphosphonates is gastric irritation when used at these high doses. This is reversible on cessation of the drug.

The use of a potentially lethal cytotoxic drug such as plicamycin in a generally benign disorder such as Paget's disease is recommended only when other less toxic agents (calcitonin, alendronate) have failed and the symptoms are debilitating. Insufficient clinical data on long-term use of plicamycin are available to determine its usefulness for extended therapy. However, short courses involving 15–25 $\mu\text{g}/\text{kg}/\text{d}$ intravenously for 5–10 days followed by 15 $\mu\text{g}/\text{kg}$ intravenously each week have been used to control the disease.

Enteric Oxaluria

Patients with short bowel syndromes associated with fat malabsorption can present with renal stones composed of calcium and oxalate. Such patients characteristically have normal or low urine calcium levels but elevated urine oxalate levels. The reasons for the development of oxaluria in such patients are thought to be twofold: first, in the intestinal lumen, calcium (which is now bound to fat) fails to bind oxalate and no longer prevents its absorption; second, enteric flora, acting on the increased supply of nutrients reaching the colon, produce larger amounts of oxalate. Although one would ordinarily avoid treating a patient with calcium oxalate stones with calcium supplementation, this is precisely what is done in patients with enteric oxaluria. The increased intestinal calcium binds the excess oxalate and prevents its absorption. One to 2 g of calcium carbonate can be given daily in divided doses, with careful monitoring of urinary calcium and oxalate to be certain that urinary oxalate falls without a dangerous increase in urinary calcium.

New Therapies for Osteoporosis

Bone undergoes a continuous remodeling process involving bone resorption and formation. Any process that disrupts this balance by increasing resorption relative to formation results in osteoporosis. Inadequate sex hormone production is a major cause of osteoporosis in men and women. Estrogen replacement therapy at menopause is a well-established means of preventing osteoporosis in the female, but many women fear its adverse effects, particularly the increased risk of breast cancer from continued estrogen use (the well-demonstrated increased risk of endometrial cancer is prevented by cycling with a progestin), and do not like the persistence of menstrual bleeding that often accompanies this form of therapy. Medical enthusiasm for this treatment has waned with the demonstration that it does not protect against heart disease. Raloxifene is the first of the selective estrogen receptor modulators (SERMs; see Chapter 40: The Gonadal Hormones & Inhibitors) to be approved for the prevention of osteoporosis. Raloxifene shares some of the beneficial effects of estrogen on bone without increasing the risk of breast or endometrial cancer (it may actually reduce the risk of breast cancer). Although not as effective as estrogen in increasing bone density, raloxifene has been shown to reduce vertebral fractures.

Nonhormonal forms of therapy for osteoporosis with proved efficacy in reducing fracture risk have also been developed. Bisphosphonates such as alendronate and risedronate have been conclusively shown to increase bone density and reduce fractures over at least 5 years when used continuously at a dosage of 10 mg/d or 70 mg/wk for alendronate and 5 mg/d or 35 mg/wk for risedronate. Side-by-side trials between alendronate and calcitonin (another approved nonestrogen drug for osteoporosis) indicated greater efficacy for alendronate. Bisphosphonates are poorly absorbed and must be given on an empty stomach or infused intravenously. At the higher oral doses used in the treatment of Paget's disease, alendronate causes gastric irritation, but this is not a significant problem at the doses recommended for osteoporosis when patients are instructed to take the drug with a glass of water and remain upright. The most recently approved drug for osteoporosis is teriparatide, the recombinant form of PTH₁₋₃₄. Unlike other approved drugs for osteoporosis, teriparatide stimulates bone formation rather than inhibiting bone resorption. However, teriparatide must be given daily by subcutaneous injection. Its efficacy in preventing fractures appears to be at least as great as that of the bisphosphonates.

Thus, we now have several well-validated, efficacious forms of treatment for this common debilitating disease.

Preparations Available

Vitamin D, Metabolites, and Analogs

Calcifediol (Calderol)

Oral: 20, 50 µg capsules

Calcitriol

Oral (Rocaltrol): 0.25, 0.5 µg capsules, 1 µg/mL solution

Parenteral (Calcijex): 1 µg/mL for injection

Cholecalciferol [D₃] (vitamin D₃, Delta-D)

Oral: 400, 1000 IU tablets

Dihydropachysterol [DHT] (DHT, Hytakerol)

Oral: 0.125 mg tablets, capsules; 0.2, 0.4 mg tablets; 0.2 mg/mL intensol solution

Doxercalciferol (Hectoral)

Oral: 2.5 µg capsules

Ergocalciferol [D₂] (vitamin D₂, Calciferol, Drisdol)

Oral: 50,000 IU capsules; 8000 IU/mL drops

Parenteral: 500,000 IU/mL for injection

Paricalcitol (Zemplar)

Parenteral: 5 µg/mL for injection

Calcium

Calcium acetate [25% calcium] (PhosLo)

Oral: 668 mg (167 mg calcium) tablets; 333.5 mg (84.5 mg calcium), 667 mg (169 mg calcium) capsules

Calcium carbonate [40% calcium] (generic, Tums, Cal-Sup, Os-Cal 500, others)

Oral: Numerous forms available containing 260–600 mg calcium per unit

Calcium chloride [27% calcium] (generic)

Parenteral: 10% solution for IV injection only

Calcium citrate [21% calcium] (generic, Citracal)

Oral: 950 mg (200 mg calcium), 2376 mg (500 mg calcium)

Calcium glubionate [6.5% calcium] (Calcionate, Calciquid)

Oral: 1.8 g (115 mg calcium)/5 mL syrup

Calcium gluceptate [8% calcium] (Calcium Gluceptate)

Parenteral: 1.1 g/5 mL solution for IM or IV injection

Calcium gluconate [9% calcium] (generic)

Oral: 500 mg (45 mg calcium), 650 mg (58.5 mg calcium), 975 mg (87.75 mg calcium), 1 g (90 mg calcium) tablets

Parenteral: 10% solution for IV or IM injection

Calcium lactate [13% calcium] (generic)

Oral: 650 mg (84.5 mg calcium), 770 mg (100 mg calcium) tablets

Tricalcium phosphate [39% calcium] (Posture)

Oral: 1565 mg (600 mg calcium) tablets (as phosphate)

Phosphate and Phosphate Binder

Phosphate

Oral (Fleet Phospho-soda): solution containing 2.5 g phosphate/5 mL (816 mg phosphorus/5 mL; 751 mg sodium/5 mL)

Oral (K-Phos-Neutral): tablets containing 250 mg phosphorus, 298 mg sodium

Oral (Neutra-Phos): For reconstitution in 75 mL water, packet containing 250 mg phosphorus; 164 mg sodium; 278 mg potassium

Oral (Neutra-Phos-K): For reconstitution in 75 mL water, packet containing 250 mg phosphorus; 556 mg potassium; 0 mg sodium

Parenteral (potassium or sodium phosphate): 3 mmol/mL

Sevelamer (Renagel)

Oral: 403 mg capsules

Other Drugs

Alendronate (Fosamax)

Oral: 5, 10, 35, 40, 70 mg tablets

Calcitonin-Salmon

Nasal spray (Miacalcin): 200 IU/puff

Parenteral (Calcimar, Miacalcin, Salmonine): 200 IU/mL for injection

Etidronate (Didronel)

Oral: 200, 400 mg tablets

Parenteral: 300 mg/6 mL for IV injection

Gallium nitrate (Ganite)

Parenteral: 500 mg/20 mL vial

Pamidronate (generic, Aredia)

Parenteral: 30, 60, 90 mg/vial

Plicamycin (mithramycin) (Mithracin)

Parenteral: 2.5 mg per vial powder to reconstitute for injection

Risedronate (Actonel)

Oral: 5, 30, 35 mg tablets

Sodium fluoride (generic)

Oral: 0.55 mg (0.25 mg F), 1.1 mg (0.5 mg F), 2.2 mg (1.0 mg F) tablets; drops

Teriparatide (Forteo)

Subcutaneous: 250 µg/mL from prefilled pen (3 mL)

Tiludronate (Skelid)

Oral: 200 mg tablets

Zoledronic acid (Zometa)

Parenteral: 4 mg/vial

Chapter 43. Beta-Lactam Antibiotics & Other Inhibitors of Cell Wall Synthesis

Katzung PHARMACOLOGY, 9e > Section VIII. Chemotherapeutic Drugs > Chapter 43. Beta-Lactam Antibiotics & Other Inhibitors of Cell Wall Synthesis >

Beta-Lactam Compounds

Penicillins

The penicillins are classified as β -lactam drugs because of their unique four-membered lactam ring. They share features of chemistry, mechanism of action, pharmacologic and clinical effects, and immunologic characteristics with cephalosporins, monobactams, carbapenems, and β -lactamase inhibitors, which also are β -lactam compounds.

Chemistry

All penicillins have the basic structure shown in Figure 43–1. A thiazolidine ring (A) is attached to a β -lactam ring (B) that carries a secondary amino group (RNH–). Substituents (R; examples shown in Figure 43–2) can be attached to the amino group. Structural integrity of the 6-aminopenicillanic acid nucleus is essential for the biologic activity of these compounds. If the β -lactam ring is enzymatically cleaved by bacterial β -lactamases, the resulting product, penicilloic acid, lacks antibacterial activity.

Figure 43–1.

Substituted 6-aminopenicillanic acid

Substituted 7-aminocephalosporanic acid

**Substituted 3-amino-4-methylmonobactamic acid
(aztreonam)**

**Substituted 3-hydroxyethylcarbapenemic acid
(imipenem)**

Core structures of four β -lactam antibiotic families. The ring marked B in each structure is the β -lactam ring. The penicillins are susceptible to bacterial metabolism and inactivation by amidases and lactamases at the points shown. Note that the carbapenems have a different stereochemical configuration in the lactam ring that apparently imparts resistance to β -lactamases. Substituents for the penicillin and cephalosporin families are shown in Figures 43-2 and 43-6, respectively.

Figure 43-2.

6-Aminopenicillanic acid

The following structures can each be substituted at the R to produce a new penicillin.

Penicillin G (benzylpenicillin):

High activity against gram-positive bacteria. Low activity against gram-negative bacteria. Acid-labile. Destroyed by β -lactamase. 60% protein-bound.

Oxacillin (no Cl atoms); cloxacillin (one Cl); flucloxacillin (one Cl and isoxazolyl penicillins):

Similar to methicillin in β -lactamase resistance. Can be taken orally. Highly protein-bound.

Nafcillin (ethoxynaphthamidopenicillin):

Similar to isoxazolyl penicillins. Less strongly protein-bound (90%). Resistant to staphylococcal β -lactamase.

Ampicillin (alpha-aminobenzylpenicillin):

Similar to Penicillin G (destroyed by β -lactamase) and more active against gram-negative bacteria. -COONa instead of NH₂ group.

Ticarcillin:

Similar to carbenicillin but gives higher blood levels. Piperacillin, azlocillin, and mezlocillin resemble ticarcillin in action against gram-negative aerobes.

Amoxicillin:

Similar to ampicillin but better absorbed.

Side chains of some penicillins (R groups of Figure 43-1).

Classification

The attachment of different substituents to 6-aminopenicillanic acid determines the essential pharmacologic and antibacterial properties of the resulting molecules. Penicillins can be assigned to one of three groups (below). Within each of these groups are compounds that are relatively stable to gastric acid and suitable for oral administration, eg, penicillin V, dicloxacillin, and amoxicillin. The side chains of some representatives of each group are shown in Figure 43–2, with a few distinguishing characteristics.

Penicillins (eg, penicillin G)

These have the greatest activity against gram-positive organisms, gram-negative cocci, and non- β -lactamase-producing anaerobes. However, they have little activity against gram-negative rods. They are susceptible to hydrolysis by β -lactamases.

Antistaphylococcal Penicillins (eg, nafcillin)

These penicillins are resistant to staphylococcal β -lactamases. They are active against staphylococci and streptococci but inactive against enterococci, anaerobic bacteria, and gram-negative cocci and rods.

Extended-Spectrum Penicillins (Ampicillin and the Antipseudomonal Penicillins)

These drugs retain the antibacterial spectrum of penicillin and have improved activity against gram-negative organisms, but they are destroyed by β -lactamases.

Penicillin Units and Formulations

The activity of penicillin G was originally defined in units. Crystalline sodium penicillin G contains approximately 1600 units/mg (1 unit = 0.6 μ g; 1 million units of penicillin = 0.6 g). Semisynthetic penicillins are prescribed by weight rather than units. The **minimum inhibitory concentration (MIC)** of any penicillin (or other antimicrobial) is usually given in μ g/mL. Most penicillins are dispensed as the sodium or potassium salt of the free acid. Potassium penicillin G contains about 1.7 meq of K^+ per million units of penicillin (2.8 meq/g). Nafcillin contains Na^+ , 2.8 meq/g. Procaine salts and benzathine salts of penicillin G provide repository forms for intramuscular injection. In dry crystalline form, penicillin salts are stable for long periods (eg, for years at 4 °C). Solutions lose their activity rapidly (eg, 24 hours at 20 °C) and must be prepared fresh for administration.

Mechanism of Action

Penicillins, like all β -lactam antibiotics, inhibit bacterial growth by interfering with a specific step in bacterial cell wall synthesis. The cell wall is a rigid outer layer that is not found in animal cells. It completely surrounds the cytoplasmic membrane (Figure 43–3), maintaining the shape of the cell and preventing cell lysis from high osmotic pressure. The cell wall is composed of a complex cross-linked polymer, peptidoglycan (murein, mucopeptide), consisting of polysaccharides and polypeptides. The polysaccharide contains alternating amino sugars, *N*-acetylglucosamine and *N*-acetylmuramic acid (Figure 43–4). A five-amino-acid peptide is linked to the *N*-acetylmuramic acid sugar. This peptide terminates in D-alanyl-D-alanine. Penicillin-binding proteins (PBPs) catalyze the transpeptidase reaction that removes the terminal alanine to form a crosslink with a nearby peptide, which gives cell wall its structural rigidity. β -Lactam antibiotics are structural analogs of the natural D-Ala-D-Ala substrate and they are covalently bound by PBPs at the active site. After a β -lactam antibiotic has attached to the PBP, the transpeptidation reaction is inhibited (Figure 43–5),

peptidoglycan synthesis is blocked, and the cell dies. The exact mechanism responsible for cell death is not completely understood, but autolysins, bacterial enzymes that remodel and break down cell wall, are involved. Penicillins and cephalosporins are bactericidal only if cells are actively growing and synthesizing cell wall.

Figure 43–3.

A highly simplified diagram of the cell envelope of a gram-negative bacterium. The outer membrane, a lipid bilayer, is present in gram-negative but not gram-positive organisms. It is penetrated by porins, proteins that form channels providing hydrophilic access to the cytoplasmic membrane. The peptidoglycan layer is unique to bacteria and is much thicker in gram-positive organisms than in gram-negative ones. Together, the outer membrane and the peptidoglycan layer constitute the cell wall. Penicillin-binding proteins (PBPs) are membrane proteins that cross-link peptidoglycan. β -lactamases, if present, reside in the periplasmic space or on the outer surface of the cytoplasmic membrane, where they may destroy β -lactam antibiotics that penetrate the outer membrane.

Figure 43–4.

↓ **Transpeptidase**

Cephalosporins & Cephameycins

Cephalosporins and cephamycins are similar to penicillins chemically, in mechanism of action, and in toxicity. Cephalosporins are more stable than penicillins to many bacterial β -lactamases and therefore usually have a broader spectrum of activity. Cephalosporins are not active against enterococci and *Listeria monocytogenes*.

Chemistry

The nucleus of the cephalosporins, 7-aminocephalosporanic acid (Figure 43–6), bears a close resemblance to 6-aminopenicillanic acid (Figure 43–1). The intrinsic antimicrobial activity of natural cephalosporins is low, but the attachment of various R₁ and R₂ groups has yielded drugs of good therapeutic activity and low toxicity (Figure 43–6). The cephalosporins have molecular weights of 400–450. They are soluble in water and relatively stable to pH and temperature changes. Cephalosporins can be classified into four major groups or generations, depending mainly on the spectrum of antimicrobial activity. As a general rule, first-generation compounds have better activity against gram-positive organisms and the later compounds exhibit improved activity against gram-negative aerobic organisms.

Figure 43–6.

7-Aminoccephalosporanic acid nucleus. The following structures can each be substituted at R_1 and R_2 to produce the named derivatives.

Other Beta Lactam Drugs

Monobactams

These are drugs with a monocyclic β -lactam ring (Figure 43–1). They are relatively resistant to β lactamases and active against gram-negative rods (including pseudomonas and serratia). They have no activity against gram-positive bacteria or anaerobes. Aztreonam is the only monobactam available in the USA. It resembles aminoglycosides in its spectrum of activity. Aztreonam is given intravenously every 8 hours in a dose of 1–2 g, providing peak serum levels of 100 $\mu\text{g/mL}$. The half-life is 1–2 hours and is greatly prolonged in renal failure.

Penicillin-allergic patients tolerate aztreonam without reaction. Occasional skin rashes and elevations of serum aminotransferases occur during administration of aztreonam, but major toxicity has not yet been reported. The clinical usefulness of aztreonam has not been fully defined.

Beta-Lactamase Inhibitors (Clavulanic Acid, Sulbactam, & Tazobactam)

These substances resemble β -lactam molecules (Figure 43–7) but themselves have very weak antibacterial action. They are potent inhibitors of many but not all bacterial β lactamases and can protect hydrolyzable penicillins from inactivation by these enzymes. β -Lactamase inhibitors are most active against Ambler class A β lactamases (plasmid-encoded transposable element [TEM] β -lactamases in particular) such as those produced by staphylococci, *H influenzae*, *N gonorrhoeae*, salmonella, shigella, *E coli*, and *K pneumoniae*. They are not good inhibitors of class C β -lactamases, which typically are chromosomally encoded and inducible, produced by enterobacter, citrobacter, serratia, and pseudomonas, but they do inhibit chromosomal β lactamases of legionella, bacteroides, and branhamella.

Figure 43–7.

Structures of β -lactamase inhibitors.

The three inhibitors differ slightly with respect to pharmacology, stability, potency, and activity, but these differences are of little therapeutic significance. β -Lactamase inhibitors are available only in fixed combinations with specific penicillins. The antibacterial spectrum of the combination is determined by the companion penicillin, not the β -lactamase inhibitor. (The fixed combinations available in the USA are listed in the Preparations Available section.) An inhibitor will extend the spectrum of a penicillin provided that the inactivity of the penicillin is due to destruction by β

lactamase and that the inhibitor is active against the β -lactamase that is produced. Thus, ampicillin-sulbactam is active against β -lactamase-producing *S aureus* and *H influenzae* but not *Serratia*, which produces a β -lactamase that is not inhibited by sulbactam. Similarly, if a strain of *P aeruginosa* is resistant to piperacillin, it will also be resistant to piperacillin-tazobactam, since tazobactam does not inhibit the chromosomal β -lactamase.

The indications for penicillin- β -lactamase inhibitor combinations are empirical therapy for infections caused by a wide range of potential pathogens in both immunocompromised and immunocompetent patients and treatment of mixed aerobic and anaerobic infections, such as intra-abdominal infections. Doses are the same as those used for the single agents except that the recommended dosage of piperacillin in the piperacillin-tazobactam combination is 3 g every 6 hours. This is less than the recommended 3–4 g every 4–6 hours for piperacillin alone, raising concerns about the use of the combination for treatment of suspected pseudomonal infection. Adjustments for renal insufficiency are made based on the penicillin component.

Carbapenems

The carbapenems are structurally related to β -lactam antibiotics (Figure 43–1). Ertapenem, imipenem, and meropenem are licensed for use in the USA. Imipenem has a wide spectrum with good activity against many gram-negative rods, including *Pseudomonas aeruginosa*, gram-positive organisms, and anaerobes. It is resistant to most β -lactamases but not metallo- β -lactamases. *Enterococcus faecium*, methicillin-resistant strains of staphylococci, *Clostridium difficile*, *Burkholderia cepacia*, and *Stenotrophomonas maltophilia* are resistant. Imipenem is inactivated by dehydropeptidases in renal tubules, resulting in low urinary concentrations. Consequently, it is administered together with an inhibitor of renal dehydropeptidase, cilastatin, for clinical use. Meropenem is similar to imipenem but has slightly greater activity against gram-negative aerobes and slightly less activity against gram-positives. It is not significantly degraded by renal dehydropeptidase and does not require an inhibitor. Ertapenem is less active than meropenem or imipenem against *Pseudomonas aeruginosa* and acinetobacter species. It is not degraded by renal dehydropeptidase.

Carbapenems penetrate body tissues and fluids well, including the cerebrospinal fluid. All are cleared renally, and the dose must be reduced in patients with renal insufficiency. The usual dose of imipenem is 0.25–0.5 g given intravenously every 6–8 hours (half-life 1 hour). The usual adult dose of meropenem is 1 g intravenously every 8 hours. Ertapenem has the longest half-life (4 hours) and is administered as a once-daily dose of 1 g intravenously or intramuscularly. Intramuscular ertapenem is irritating, and for that reason the drug is formulated with 1% lidocaine for administration by this route.

A carbapenem is indicated for infections caused by susceptible organisms that are resistant to other available drugs and for treatment of mixed aerobic and anaerobic infections. Carbapenems are active against many highly penicillin-resistant strains of pneumococci. A carbapenem is the β -lactam antibiotic of choice for treatment of enterobacter infections, since it is resistant to destruction by the β -lactamase produced by these organisms. Strains of *Pseudomonas aeruginosa* may rapidly develop resistance to imipenem or meropenem, so simultaneous use of an aminoglycoside is recommended for infections caused by those organisms. Ertapenem is insufficiently active against *P aeruginosa* and should not be used to treat infections caused by that organism. Imipenem or meropenem with or without an aminoglycoside may be effective treatment for febrile neutropenic patients.

The most common adverse effects of carbapenems—which tend to be more common with

imipenem—are nausea, vomiting, diarrhea, skin rashes, and reactions at the infusion sites. Excessive levels of imipenem in patients with renal failure may lead to seizures. Meropenem and ertapenem are less likely to cause seizures than imipenem. Patients allergic to penicillins may be allergic to carbapenems as well.

Katzung PHARMACOLOGY, 9e > Section VIII. Chemotherapeutic Drugs > Chapter 43. Beta-Lactam Antibiotics & Other Inhibitors of Cell Wall Synthesis >

Other Inhibitors of Cell Wall Synthesis

Vancomycin

Vancomycin is an antibiotic produced by *Streptococcus orientalis*. With the single exception of flavobacterium, it is active only against gram-positive bacteria, particularly staphylococci. Vancomycin is a glycopeptide of molecular weight 1500. It is water-soluble and quite stable.

Mechanisms of Action & Basis of Resistance

Vancomycin inhibits cell wall synthesis by binding firmly to the D-Ala-D-Ala terminus of nascent peptidoglycan pentapeptide (Figure 43–5). This inhibits the transglycosylase, preventing further elongation of peptidoglycan and cross-linking. The peptidoglycan is thus weakened and the cell becomes susceptible to lysis. The cell membrane is also damaged, which contributes to the antibacterial effect.

Resistance to vancomycin in enterococci is due to modification of the D-Ala-D-Ala binding site of the peptidoglycan building block in which the terminal D-Ala is replaced by D-lactate. This results in the loss of a critical hydrogen bond that facilitates high-affinity binding of vancomycin to its target and loss of activity. This mechanism is also present in vancomycin-resistant *S aureus* strains (MIC ≥ 32 $\mu\text{g/mL}$), which have acquired the enterococcal resistance determinants. The mechanism for reduced vancomycin susceptibility of vancomycin-intermediate strains (MICs = 8–16 $\mu\text{g/mL}$) is not known.

Antibacterial Activity

Vancomycin is bactericidal for gram-positive bacteria in concentrations of 0.5–10 $\mu\text{g/mL}$. Most pathogenic staphylococci, including those producing β -lactamase and those resistant to nafcillin and methicillin, are killed by 4 $\mu\text{g/mL}$ or less. Vancomycin kills staphylococci relatively slowly and only if cells are actively dividing; the rate is less than that of the penicillins both in vitro and in vivo. Vancomycin is synergistic with gentamicin and streptomycin against *E faecium* and *E faecalis* strains that do not exhibit high levels of aminoglycoside resistance.

Pharmacokinetics

Vancomycin is poorly absorbed from the intestinal tract and is administered orally only for the treatment of antibiotic-associated enterocolitis caused by *Clostridium difficile*. Parenteral doses must be administered intravenously. A 1 hour intravenous infusion of 1 g produces blood levels of 15–30 $\mu\text{g/mL}$ for 1–2 hours. The drug is widely distributed in the body. Cerebrospinal fluid levels 7–30% of simultaneous serum concentrations are achieved if there is meningeal inflammation. Ninety percent of the drug is excreted by glomerular filtration. In the presence of renal insufficiency, striking accumulation may occur (Table 43–2). In functionally anephric patients, the

half-life of vancomycin is 6–10 days. The drug is not removed by hemodialysis.

Clinical Uses

The main indication for parenteral vancomycin is sepsis or endocarditis caused by methicillin-resistant staphylococci. However, vancomycin is not as effective as an antistaphylococcal penicillin for treatment of serious infections such as endocarditis caused by methicillin-susceptible strains. Vancomycin in combination with gentamicin is an alternative regimen for treatment of enterococcal endocarditis in a patient with serious penicillin allergy. Vancomycin (in combination with cefotaxime, ceftriaxone, or rifampin) is also recommended for treatment of meningitis suspected or known to be caused by a highly penicillin-resistant strain of pneumococcus (ie, MIC > 1 $\mu\text{g}/\text{mL}$). The recommended dosage is 30 mg/kg/d in two or three divided doses. A typical dosing regimen for most infections in adults with normal renal function is 1 g every 12 hours. The dosage in children is 40 mg/kg/d in three or four divided doses. Clearance of vancomycin is directly proportionate to creatinine clearance, and the dose is reduced accordingly in patients with renal insufficiency (see Moellering et al, 1981, for guidelines). For functionally anephric adult patients, a 1 g dose administered once a week is usually sufficient. Patients receiving a prolonged course of therapy should have serum concentrations checked. Recommended peak serum concentrations are 20–50 $\mu\text{g}/\text{mL}$, and trough concentrations are 5–15 $\mu\text{g}/\text{mL}$.

Oral vancomycin, 0.125–0.25 g every 6 hours, is used to treat antibiotic-associated enterocolitis caused by *Clostridium difficile*. However, because of the emergence of vancomycin-resistant enterococci and the strong selective pressure of oral vancomycin for these resistant organisms, metronidazole is strongly preferred as initial therapy and vancomycin should be reserved for treatment of refractory cases.

Adverse Reactions

Adverse reactions are encountered in about 10% of cases. Most reactions are minor. Vancomycin is irritating to tissue, resulting in phlebitis at the site of injection. Chills and fever may occur. Ototoxicity is rare and nephrotoxicity uncommon with current preparations. However, administration with another ototoxic or nephrotoxic drug, such as an aminoglycoside, increases the risk of these toxicities. Ototoxicity can be minimized by maintaining peak serum concentrations below 60 $\mu\text{g}/\text{mL}$. Among the more common reactions is the so-called "red man" or "red neck" syndrome. This infusion-related flushing is caused by release of histamine. It can be largely prevented by prolonging the infusion period to 1–2 hours or increasing the dosing interval.

Teicoplanin

Teicoplanin is a glycopeptide antibiotic that is very similar to vancomycin in mechanism of action and antibacterial spectrum. Unlike vancomycin, it can be given intramuscularly as well as intravenously. Teicoplanin has a long half-life (45–70 hours), permitting once-daily dosing. This drug is available in Europe but has not been approved for use in the United States.

Fosfomycin

Fosfomycin trometamol, a stable salt of fosfomycin (**phosphonomycin**), inhibits a very early stage of bacterial cell wall synthesis (Figure 43–5). An analog of phosphoenolpyruvate, it is structurally unrelated to any other antimicrobial agent. It inhibits the cytoplasmic enzyme enolpyruvate transferase by covalently binding to the cysteine residue of the active site and blocking the addition of phosphoenolpyruvate to UDP-*N*-acetylglucosamine. This reaction is the first step in the

formation of UDP-*N*-acetylmuramic acid, the precursor of *N*-acetylmuramic acid, which is found only in bacterial cell walls. The drug is transported into the bacterial cell by glycerophosphate or glucose 6-phosphate transport systems. Resistance is due to inadequate transport of drug into the cell.

Fosfomycin is active against both gram-positive and gram-negative organisms at concentrations \approx 125 $\mu\text{g}/\text{mL}$. Susceptibility tests should be performed in growth medium supplemented with glucose 6-phosphate to minimize false-positive indications of resistance. In vitro synergism occurs when fosfomycin is combined with β -lactam antibiotics, aminoglycosides, or fluoroquinolones.

Fosfomycin trometamol is available in both oral and parenteral formulations, though only the oral preparation is approved for use in the United States. Oral bioavailability is approximately 40%. Peak serum concentrations are 10 $\mu\text{g}/\text{mL}$ and 30 $\mu\text{g}/\text{mL}$ following a 2 g or 4 g oral dose, respectively. The half-life is approximately 4 hours. The active drug is excreted by the kidney, with urinary concentrations exceeding MICs for most urinary tract pathogens.

Fosfomycin is approved for use as a single 3 g dose for treatment of uncomplicated lower urinary tract infections in women. The drug appears to be safe for use in pregnancy.

Bacitracin

Bacitracin is a cyclic peptide mixture first obtained from the Tracy strain of *Bacillus subtilis* in 1943. It is active against gram-positive microorganisms. Bacitracin inhibits cell wall formation by interfering with dephosphorylation in cycling of the lipid carrier that transfers peptidoglycan subunits to the growing cell wall (Figure 43–5). There is no cross-resistance between bacitracin and other antimicrobial drugs.

Bacitracin is markedly nephrotoxic if administered systemically, producing proteinuria, hematuria, and nitrogen retention. Hypersensitivity reactions (eg, skin rashes) are rare. Because of its marked toxicity when used systemically, it is limited to topical use. Bacitracin is poorly absorbed. Topical application results in local antibacterial activity without significant systemic toxicity. The small amounts of bacitracin that are absorbed are excreted by glomerular filtration.

Bacitracin, 500 units/g in an ointment base (often combined with polymyxin or neomycin), is useful for the suppression of mixed bacterial flora in surface lesions of the skin, in wounds, or on mucous membranes. Solutions of bacitracin containing 100–200 units/mL in saline can be employed for irrigation of joints, wounds, or the pleural cavity.

Cycloserine

Cycloserine is an antibiotic produced by *Streptomyces orchidaceus*. It is water-soluble and very unstable at acid pH. Cycloserine inhibits many gram-positive and gram-negative organisms, but it is used almost exclusively to treat tuberculosis caused by strains of *M tuberculosis* resistant to first-line agents. Cycloserine is a structural analog of D-alanine and inhibits the incorporation of D-alanine into peptidoglycan pentapeptide by inhibiting alanine racemase, which converts L-alanine to D-alanine, and D-alanyl-D-alanine ligase (Figure 43–5). After ingestion of 0.25 g of cycloserine blood levels reach 20–30 $\mu\text{g}/\text{mL}$ —sufficient to inhibit many strains of mycobacteria and gram-negative bacteria. The drug is widely distributed in tissues. Most of the drug is excreted in active form into the urine. The dosage for treating tuberculosis is 0.5 to 1 g/d in two or three divided doses.

Cycloserine causes serious dose-related central nervous system toxicity with headaches, tremors, acute psychosis, and convulsions. If oral dosages are maintained below 0.75 g/d, such effects can usually be avoided.

Preparations Available

Penicillins

Amoxicillin (generic, Amoxil, others)

Oral: 125, 200, 250, 400 mg chewable tablets; 500, 875 mg tablets; 250, 500 mg capsules; powder to reconstitute for 50, 125, 200, 250, 400 mg/mL solution

Amoxicillin/potassium clavulanate (generic, Augmentin)*

* Clavulanate content varies with the formulation; see package insert.

Oral: 250, 500, 875 mg tablets; 125, 200, 250, 400 mg chewable tablets; 1000 mg extended release tablet powder to reconstitute for 125, 200, 250 mg/5 mL suspension

Ampicillin (generic)

Oral: 250, 500 mg capsules; powder to reconstitute for 125, 250 mg suspensions

Parenteral: powder to reconstitute for injection (125, 250, 500 mg, 1, 2 g per vial)

Ampicillin/sulbactam sodium (generic, Unasyn)[†]

[†]Sulbactam content is half the ampicillin content.

Parenteral: 1, 2 g ampicillin powder to reconstitute for IV or IM injection

Carbenicillin (Geocillin)

Oral: 382 mg tablets

Dicloxacillin (generic)

Oral: 250, 500 mg capsules

Mezlocillin (Mezlin)

Parenteral: powder to reconstitute for injection (in 1, 2, 3, 4 g vials)

Nafcillin (generic)

Oral: 250 mg capsules

Parenteral: 1, 2 g per IV piggyback units

Oxacillin (generic)

Oral: 250, 500 mg capsules; powder to reconstitute for 250 mg/5 mL solution

Parenteral: powder to reconstitute for injection (0.5, 1, 2, 10 g per vial)

Penicillin G (generic, Pentids, Pfizerpen)

Oral: 0.2, 0.25, 0.4, 0.5, 0.8 million unit tablets; powder to reconstitute 400,000 units/5 mL suspension

Parenteral: powder to reconstitute for injection (1, 2, 3, 5, 10, 20 million units)

Penicillin G benzathine (Permapen, Bicillin)

Parenteral: 0.6, 1.2, 2.4 million units per dose

Penicillin G procaine (generic)

Parenteral: 0.6, 1.2 million units/mL for IM injection only

Penicillin V (generic, V-Cillin, Pen-Vee K, others)

Oral: 250, 500 mg tablets; powder to reconstitute for 125, 250 mg/5 mL solution

Piperacillin (Pipracil)

Parenteral: powder to reconstitute for injection (2, 3, 4 g per vial)

Piperacillin and tazobactam sodium (Zosyn)[‡]

[‡] Tazobactam content is 12.5% of the piperacillin content.

Parenteral: 2, 3, 4 g powder to reconstitute for IV injection

Ticarcillin (Ticar)

Parenteral: powder to reconstitute for injection (1, 3, 6 g per vial)

Ticarcillin/clavulanate potassium (Timentin)[§]

[§] Clavulanate content 0.1 g.

Parenteral: 3 g powder to reconstitute for injection

Cephalosporins & Other Beta-Lactam Drugs

Narrow Spectrum (First-Generation) Cephalo-sporins

Cefadroxil (generic, Duricef)

Oral: 500 mg capsules; 1 g tablets; 125, 250, 500 mg/5 mL suspension

Cefazolin (generic, Ancef, Kefzol)

Parenteral: powder to reconstitute for injection (0.25, 0.5, 1 g per vial or IV piggyback unit)

Cephalexin (generic, Keflex, others)

Oral: 250, 500 mg capsules and tablets; 1 g tablets; 125, 250 mg/5 mL suspension

Cephalothin (generic, Keflin)[¶]

[¶]Not available in the USA.

Parenteral: powder to reconstitute for injection and solution for injection (1 g per vial or infusion pack)

Cephapirin (Cefadyl)

Parenteral: powder to reconstitute for injection (1 g per vial or IV piggyback unit)

Cephradine (generic, Velosef)

Oral: 250, 500 mg capsules; 125, 250 mg/5 mL suspension

Parenteral: powder to reconstitute for injection (0.25, 0.5, 1, 2 g per vial)

Intermediate Spectrum (Second-Generation) Cephalosporins

Cefaclor (generic, Ceclor)

Oral: 250, 500 mg capsules; 375, 500 mg extended-release tablets; powder to reconstitute for 125, 187, 250, 375 mg/5 mL suspension

Cefamandole (Mandol)

Parenteral: 1, 2 g (in vials) for IM, IV injection

Cefmetazole (Zefazone)

Parenteral: 1, 2 g powder for IV injection

Cefonicid (Monocid)

Parenteral: powder to reconstitute for injection (1, 10 g per vial)

Cefotetan (Cefotan)

Parenteral: powder to reconstitute for injection (1, 2, 10 g per vial)

Cefoxitin (Mefoxin)

Parenteral: powder to reconstitute for injection (1, 2, 10 g per vial)

Cefprozil (Cefzil)

Oral: 250, 500 mg tablets; powder to reconstitute 125, 250 mg/5 mL suspension

Cefuroxime (generic, Ceftin, Kefurox, Zinacef)

Oral: 125, 250, 500 mg tablets; 125, 250 mg/5 mL suspension

Parenteral: powder to reconstitute for injection (0.75, 1.5, 7.5 g per vial or infusion pack)

Loracarbef (Lorabid)

Oral: 200, 400 mg capsules; powder for 100, 200 mg/5 mL suspension

Broad-Spectrum (Third- & Fourth-Generation) Cephalosporins

Cefdinir (Omnicef)

Oral: 300 mg capsules; 125 mg/5 mL suspension

Cefditoren (Spectracef)

Oral: 200 mg tablets

Cefepime (Maxipime)

Parenteral: powder for injection 0.5, 1, 2 g

Cefixime (Suprax)

Oral: 200, 400 mg tablets; powder for oral suspension, 100 mg/5 mL

Cefoperazone (Cefobid)

Parenteral: powder to reconstitute for injection (1, 2 g per vial, 10 g bulk)

Cefotaxime (Claforan)

Parenteral: powder to reconstitute for injection (0.5, 1, 2 g per vial)

Cefpodoxime proxetil (Vantin)

Oral: 100, 200 mg tablets; 50, 100 mg granules for suspension in 5 mL

Ceftazidime (generic, Fortaz, Tazidime)

Parenteral: powder to reconstitute for injection (0.5, 1, 2 g per vial)

Ceftibuten (Cedax)

Oral: 400 mg capsules; 90, 180 mg/5 mL powder for oral suspension

Ceftizoxime (Cefizox)

Parenteral: powder to reconstitute for injection and solution for injection (0.5, 1, 2 g per vial)

Ceftriaxone (Rocephin)

Parenteral: powder to reconstitute for injection (0.25, 0.5, 1, 2, 10 g per vial)

Carbapenems & Monobactam

Aztreonam (Azactam)

Parenteral: powder to reconstitute for injection (0.5, 1, 2 g)

Ertapenem (Invanz)

Parenteral: 1 g powder to reconstitute for intravenous (0.9% NaCl diluent) or intramuscular (1% lidocaine diluent) injection

Imipenem/cilastatin (Primaxin)

Parenteral: powder to reconstitute for injection (250, 500, 750 mg imipenem per vial)

Meropenem (Merrem IV)

Parenteral: powder for injection (0.5, 1 g per vial)

Other Drugs Discussed in This Chapter

Cycloserine (Seromycin Pulvules)

Oral: 250 mg capsules

Fosfomycin (Monurol)

Oral: 3 g packet

Vancomycin (generic, Vancocin, Vancoled)

Oral: 125, 250 mg Pulvules; powder to reconstitute for 250 mg/5 mL, 500 mg/6 mL solution

Parenteral: 0.5, 1, 5, 10 g powder to reconstitute for IV injection

Chapter 44. Chloramphenicol, Tetracyclines, Macrolides, Clindamycin, & Streptogramins

Chloramphenicol, Tetracyclines, Macrolides, Clindamycin, & Streptogramins: Introduction

The drugs described in this chapter all share the property of inhibiting bacterial protein synthesis by binding to and interfering with their ribosomes.

Katzung PHARMACOLOGY, 9e > Section VIII. Chemotherapeutic Drugs > Chapter 44. Chloramphenicol, Tetracyclines, Macrolides, Clindamycin, & Streptogramins >

Chloramphenicol

Crystalline chloramphenicol is a neutral, stable compound with the following structure:

It is soluble in alcohol but poorly soluble in water. Chloramphenicol succinate, which is used for parenteral administration, is highly water-soluble. It is hydrolyzed in vivo with liberation of free chloramphenicol.

Antimicrobial Activity

Chloramphenicol is a potent inhibitor of microbial protein synthesis. It binds reversibly to the 50S subunit of the bacterial ribosome (Figure 44–1). It inhibits the peptidyl transferase step of protein synthesis. Chloramphenicol is a bacteriostatic broad-spectrum antibiotic that is active against both aerobic and anaerobic gram-positive and gram-negative organisms. It is active also against rickettsiae but not chlamydiae. Most gram-positive bacteria are inhibited at concentrations of 1–10 $\mu\text{g}/\text{mL}$, and many gram-negative bacteria are inhibited by concentrations of 0.2–5 $\mu\text{g}/\text{mL}$. *Haemophilus influenzae*, *Neisseria meningitidis*, and some strains of bacteroides are highly susceptible, and for them chloramphenicol may be bactericidal.

Figure 44–1.

Steps in bacterial protein synthesis and targets of (1) chloramphenicol; (2) macrolides, clindamycin, and type B streptogramins; and (3) tetracyclines. The 70S ribosomal mRNA complex is shown with its 50S and 30S subunits. The peptidyl tRNA at the donor site donates the growing peptide chain to the aminoacyl tRNA at the acceptor site in a reaction catalyzed by peptidyl transferase. The tRNA, discharged of its peptide, is released from the donor site to make way for translocation of the newly formed peptidyl tRNA. The acceptor site is then free to be occupied by the next "charged" aminoacyl tRNA.

Low-level resistance may emerge from large populations of chloramphenicol-susceptible cells by selection of mutants that are less permeable to the drug. Clinically significant resistance is due to production of chloramphenicol acetyltransferase, a plasmid-encoded enzyme that inactivates the drug.

Pharmacokinetics

The usual dosage of chloramphenicol is 50–100 mg/kg/d. After oral administration, crystalline chloramphenicol is rapidly and completely absorbed. A 1 g oral dose produces blood levels between 10 and 15 $\mu\text{g/mL}$. Chloramphenicol palmitate is a prodrug that is hydrolyzed in the intestine to yield free chloramphenicol. The parenteral formulation, chloramphenicol succinate, yields free chloramphenicol by hydrolysis, giving blood levels somewhat lower than those achieved with orally administered drug. After absorption, chloramphenicol is widely distributed to virtually all tissues and body fluids, including the central nervous system and cerebrospinal fluid such that the concentration of chloramphenicol in brain tissue may be equal to that in serum. The drug penetrates cell membranes readily. Most of the drug is inactivated either by conjugation with glucuronic acid (principally in the liver) or by reduction to inactive aryl amines. Excretion of active chloramphenicol (about 10% of the total dose administered) and of inactive degradation products (about 90% of the total) occurs by way of the urine. A small amount of active drug is excreted into bile or feces. The systemic dosage of chloramphenicol need not be altered in renal insufficiency, but it must be reduced markedly in hepatic failure. Newborns less than a week old and premature infants also clear chloramphenicol less well, and the dosage should be reduced to 25 mg/kg/d.

Clinical Uses

Because of potential toxicity, bacterial resistance, and the availability of other effective drugs (eg, cephalosporins), chloramphenicol is all but obsolete as a systemic drug. It may be considered for treatment of serious rickettsial infections, such as typhus or Rocky Mountain spotted fever, in children for whom tetracyclines are contraindicated, ie, those under 8 years of age. It is an alternative to a β -lactam antibiotic for treatment of meningococcal meningitis occurring in patients who have major hypersensitivity reactions to penicillin or bacterial meningitis caused by penicillin-resistant strains of pneumococci. The dosage is 50–100 mg/kg/d in four divided doses.

Chloramphenicol is occasionally used topically in the treatment of eye infections because of its wide antibacterial spectrum and its penetration of ocular tissues and the aqueous humor. It is ineffective for chlamydial infections.

Adverse Reactions

Gastrointestinal Disturbances

Adults occasionally develop nausea, vomiting, and diarrhea. This is rare in children. Oral or vaginal candidiasis may occur as a result of alteration of normal microbial flora.

Bone Marrow Disturbances

Chloramphenicol commonly causes a dose-related reversible suppression of red cell production at dosages exceeding 50 mg/kg/d after 1–2 weeks. Aplastic anemia is a rare consequence of chloramphenicol administration by any route. It is an idiosyncratic reaction unrelated to dose, though it occurs more frequently with prolonged use. It tends to be irreversible and can be fatal. Aplastic anemia probably develops in one of every 24,000–40,000 patients who have taken chloramphenicol.

Toxicity for Newborn Infants

Newborn infants lack an effective glucuronic acid conjugation mechanism for the degradation and detoxification of chloramphenicol. Consequently, when infants are given dosages above 50 mg/kg/d, the drug may accumulate, resulting in the **gray baby syndrome**, with vomiting, flaccidity, hypothermia, gray color, shock, and collapse. To avoid this toxic effect, chloramphenicol should be used with caution in infants and the dosage limited to 50 mg/kg/d or less (during the first week of life) in full-term infants and 25 mg/kg/d in premature infants.

Interaction with Other Drugs

Chloramphenicol inhibits hepatic microsomal enzymes that metabolize several drugs. Half-lives are prolonged, and the serum concentrations of phenytoin, tolbutamide, chlorpropamide, and warfarin are increased. Like other bacteriostatic inhibitors of microbial protein synthesis, chloramphenicol can antagonize bactericidal drugs such as penicillins or aminoglycosides.

Tetracyclines

All of the tetracyclines have the basic structure shown below:

	R ₇	R ₆	R ₅	Renal Clearance (mL/min)
Chlortetracycline	—Cl	—CH ₃	—H	35
Oxytetracycline	—H	—CH ₃	—OH	90
Tetracycline	—H	—CH ₃	—H	65
Demeclocycline	—Cl	—H	—H	35
Methacycline	—H	≡CH ₂ *	—OH	31
Doxycycline	—H	—CH ₃ *	—OH	16
Minocycline	—N(CH ₃) ₂	—H	—H	10

*There is no —OH at position 6 on methacycline and doxycycline.

Free tetracyclines are crystalline amphoteric substances of low solubility. They are available as hydrochlorides, which are more soluble. Such solutions are acid and, with the exception of chlortetracycline, fairly stable. Tetracyclines chelate divalent metal ions, which can interfere with their absorption and activity.

Antimicrobial Activity

Tetracyclines are broad-spectrum bacteriostatic antibiotics that inhibit protein synthesis. They are active against many gram-positive and gram-negative bacteria, including anaerobes, rickettsiae, chlamydiae, mycoplasmas, and L forms; and against some protozoa, eg, amebas. The antibacterial activities of most tetracyclines are similar except that tetracycline-resistant strains may remain susceptible to doxycycline or minocycline, drugs that are less rapidly transported by the pump that is responsible for resistance (see Resistance). Differences in clinical efficacy are minor and attributable largely to features of absorption, distribution, and excretion of individual drugs.

Tetracyclines enter microorganisms in part by passive diffusion and in part by an energy-dependent process of active transport. Susceptible cells concentrate the drug intracellularly. Once inside the cell, tetracyclines bind reversibly to the 30S subunit of the bacterial ribosome, blocking the binding of aminoacyl-tRNA to the acceptor site on the mRNA-ribosome complex (Figure 44–1). This prevents addition of amino acids to the growing peptide.

Resistance

Three mechanisms of resistance to tetracycline have been described: (1) decreased intracellular accumulation due to either impaired influx or increased efflux by an active transport protein pump; (2) ribosome protection due to production of proteins that interfere with tetracycline binding to the ribosome; and (3) enzymatic inactivation of tetracyclines. The most important of these is production

of an efflux pump. The pump protein is encoded on a plasmid and may be transmitted by transduction or by conjugation. Because these plasmids commonly encode resistance genes for other drugs, eg, aminoglycosides, sulfonamides, and chloramphenicol, tetracycline resistance is a marker for resistance to multiple drugs.

Pharmacokinetics

Tetracyclines mainly differ in their absorption after oral administration and their elimination. Absorption after oral administration is approximately 30% for chlortetracycline; 60–70% for tetracycline, oxytetracycline, demeclocycline, and methacycline; and 95–100% for doxycycline and minocycline. A portion of an orally administered dose of tetracycline remains in the gut lumen, modifies intestinal flora, and is excreted in the feces. Absorption occurs mainly in the upper small intestine and is impaired by food (except doxycycline and minocycline); by divalent cations (Ca^{2+} , Mg^{2+} , Fe^{2+}) or Al^{3+} ; by dairy products and antacids, which contain multivalent cations; and by alkaline pH. Specially buffered tetracycline solutions are formulated for intravenous administration.

Tetracyclines are 40–80% bound by serum proteins. Oral dosages of 500 mg every 6 hours of tetracycline hydrochloride or oxytetracycline produce peak blood levels of 4–6 $\mu\text{g}/\text{mL}$. Peak levels of 2–4 $\mu\text{g}/\text{mL}$ are achieved with a 200 mg dose of doxycycline or minocycline. Intravenously injected tetracyclines give somewhat higher levels only temporarily. Tetracyclines are distributed widely to tissues and body fluids except for cerebrospinal fluid, where concentrations are 10–25% of those in serum. Minocycline reaches very high concentrations in tears and saliva, which makes it useful for eradication of the meningococcal carrier state. Tetracyclines cross the placenta to reach the fetus and are also excreted in milk. As a result of chelation with calcium, tetracyclines are bound to—and damage—growing bones and teeth. Carbamazepine, phenytoin, barbiturates, and chronic alcohol ingestion may shorten the half-life of doxycycline 50% by induction of hepatic enzymes that metabolize the drug.

Tetracyclines are excreted mainly in bile and urine. Concentrations in bile exceed those in serum tenfold. Some of the drug excreted in bile is reabsorbed from the intestine (enterohepatic circulation) and contributes to maintenance of serum levels. Ten to 50 percent of various tetracyclines is excreted into the urine, mainly by glomerular filtration. Ten to 40 percent of the drug in the body is excreted in feces. Doxycycline, in contrast to other tetracyclines, is eliminated by nonrenal mechanisms, does not accumulate significantly in renal failure, and requires no dosage adjustment, making it the tetracycline of choice for use in the setting of renal insufficiency.

Tetracyclines are classified as short-acting (chlortetracycline, tetracycline, oxytetracycline), intermediate-acting (demeclocycline and methacycline), or long-acting (doxycycline and minocycline) based on serum half-lives of 6–8 hours, 12 hours, and 16–18 hours, respectively. The almost complete absorption and slow excretion of doxycycline and minocycline allow for once-daily dosing.

Clinical Uses

A tetracycline is the drug of choice in infections with *Mycoplasma pneumoniae*, chlamydiae, rickettsiae, and some spirochetes. They are used in combination regimens to treat gastric and duodenal ulcer disease caused by *Helicobacter pylori*. They may be employed in various gram-positive and gram-negative bacterial infections, including vibrio infections, provided the organism is not resistant. In cholera, tetracyclines rapidly stop the shedding of vibrios, but tetracycline resistance has appeared during epidemics. Tetracyclines remain effective in most chlamydial infections, including sexually transmitted diseases. Tetracyclines are no longer recommended for

treatment of gonococcal disease because of resistance. A tetracycline—usually in combination with an aminoglycoside—is indicated for plague, tularemia, and brucellosis. Tetracyclines are sometimes employed in the treatment of protozoal infections, eg, those due to *Entamoeba histolytica* or *Plasmodium falciparum*. Other uses include treatment of acne, exacerbations of bronchitis, community-acquired pneumonia, Lyme disease, relapsing fever, leptospirosis, and some nontuberculous mycobacterial infections (eg, *Mycobacterium marinum*). Tetracyclines formerly were used for a variety of common infections, including bacterial gastroenteritis, pneumonia (other than mycoplasmal or chlamydial pneumonia), and urinary tract infections. However, many strains of bacteria causing these infections now are resistant, and other agents have largely supplanted tetracyclines.

Minocycline, 200 mg orally daily for 5 days, can eradicate the meningococcal carrier state, but because of side-effects and resistance of many meningococcal strains, rifampin is preferred. Demeclocycline inhibits the action of ADH in the renal tubule and has been used in the treatment of inappropriate secretion of ADH or similar peptides by certain tumors (see Chapter 15: Diuretic Agents).

Oral Dosage

The oral dosage for rapidly excreted tetracyclines, equivalent to tetracycline hydrochloride, is 0.25–0.5 g four times daily for adults and 20–40 mg/kg/d for children (8 years of age and older). For severe systemic infections, the higher dosage is indicated, at least for the first few days. The daily dose is 600 mg for demeclocycline or methacycline, 100 mg once or twice a day for doxycycline, and 100 mg twice a day for minocycline. Doxycycline is the tetracycline of choice because it can be given as a once-daily dose and its absorption is not significantly affected by food. All tetracyclines chelate with metals, and none should be administered with milk, antacids, or ferrous sulfate. To avoid deposition in growing bones or teeth, tetracyclines should be avoided for pregnant women and for children under 8 years of age.

Parenteral Dosage

Several tetracyclines are available for intravenous injection in doses of 0.1–0.5 g every 6–12 hours (similar to oral doses), depending on the agent. Intramuscular injection is not recommended because of pain and inflammation at the injection site. Doxycycline is the preferred agent, at a dosage of 100 mg every 12–24 hours.

Adverse Reactions

Hypersensitivity reactions (drug fever, skin rashes) to tetracyclines are uncommon. Most adverse effects are due to direct toxicity of the drug or to alteration of microbial flora.

Gastrointestinal Adverse Effects

Nausea, vomiting, and diarrhea are the most common reasons for discontinuing tetracycline medication. These effects are attributable to direct local irritation of the intestinal tract. Nausea, anorexia, and diarrhea can usually be controlled by administering the drug with food or carboxymethylcellulose, reducing drug dosage, or discontinuing the drug.

Tetracyclines modify the normal flora, with suppression of susceptible coliform organisms and overgrowth of pseudomonas, proteus, staphylococci, resistant coliforms, clostridia, and candida. This can result in intestinal functional disturbances, anal pruritus, vaginal or oral candidiasis, or

enterocolitis with shock and death. Pseudomembranous enterocolitis associated with *Clostridium difficile* should be treated with metronidazole.

Bony Structures and Teeth

Tetracyclines are readily bound to calcium deposited in newly formed bone or teeth in young children. When the drug is given during pregnancy, it can be deposited in the fetal teeth, leading to fluorescence, discoloration, and enamel dysplasia; it can also be deposited in bone, where it may cause deformity or growth inhibition. If the drug is given for long periods to children under 8 years of age, similar changes can result.

Liver Toxicity

Tetracyclines can probably impair hepatic function, especially during pregnancy, in patients with preexisting hepatic insufficiency and when high doses are given intravenously. Hepatic necrosis has been reported with daily doses of 4 g or more intravenously.

Kidney Toxicity

Renal tubular acidosis and other renal injury resulting in nitrogen retention have been attributed to the administration of outdated tetracycline preparations. Tetracyclines given along with diuretics may produce nitrogen retention. Tetracyclines other than doxycycline may accumulate to toxic levels in patients with impaired kidney function.

Local Tissue Toxicity

Intravenous injection can lead to venous thrombosis. Intramuscular injection produces painful local irritation and should be avoided.

Photosensitization

Systemic tetracycline administration, especially of demeclocycline, can induce sensitivity to sunlight or ultraviolet light, particularly in fair-skinned persons.

Vestibular Reactions

Dizziness, vertigo, nausea, and vomiting have been particularly noted with doxycycline at doses above 100 mg. With dosages of 200–400 mg/d of minocycline, 35–70% of patients will have these reactions.

Medical & Social Implications of Overuse

Tetracyclines have been extensively used in animal feeds to enhance growth. This practice has contributed to the spread of tetracycline resistance among enteric bacteria and of plasmids that encode tetracycline resistance genes.

Katzung PHARMACOLOGY, 9e > Section VIII. Chemotherapeutic Drugs > Chapter 44.
Chloramphenicol, Tetracyclines, Macrolides, Clindamycin, & Streptogramins >

Macrolides

The macrolides are a group of closely related compounds characterized by a macrocyclic lactone ring (usually containing 14 or 16 atoms) to which deoxy sugars are attached. The prototype drug, erythromycin, which consists of two sugar moieties attached to a 14-atom lactone ring, was obtained in 1952 from *Streptomyces erythreus*. Clarithromycin and azithromycin are semisynthetic derivatives of erythromycin.

Erythromycin

Chemistry

The general structure of erythromycin is shown above with the macrolide ring and the sugars desosamine and cladinose. It is poorly soluble in water (0.1%) but dissolves readily in organic solvents. Solutions are fairly stable at 4 °C but lose activity rapidly at 20 °C and at acid pH. Erythromycins are usually dispensed as various esters and salts.

Antimicrobial Activity

Erythromycin is effective against gram-positive organisms, especially pneumococci, streptococci, staphylococci, and corynebacteria, in plasma concentrations of 0.02–2 µg/mL. Mycoplasma, legionella, *Chlamydia trachomatis*, *C psittaci*, *C pneumoniae*, helicobacter, listeria, and certain mycobacteria (*Mycobacterium kansasii*, *Mycobacterium scrofulaceum*) are also susceptible. Gram-negative organisms such as neisseria species, *Bordetella pertussis*, *Bartonella henselae*, and *B quintana* (etiologic agents of cat-scratch disease and bacillary angiomatosis), some rickettsia species, *Treponema pallidum*, and campylobacter species are susceptible. *Haemophilus influenzae* is somewhat less susceptible.

The antibacterial action of erythromycin may be inhibitory or bactericidal, particularly at higher concentrations, for susceptible organisms. Activity is enhanced at alkaline pH. Inhibition of protein synthesis occurs via binding to the 50S ribosomal RNA. Protein synthesis is inhibited because aminoacyl translocation reactions and the formation of initiation complexes are blocked (Figure 44–

1).

Resistance

Resistance to erythromycin is usually plasmid-encoded. Three mechanisms have been identified: (1) reduced permeability of the cell membrane or active efflux; (2) production (by Enterobacteriaceae) of esterases that hydrolyze macrolides; and (3) modification of the ribosomal binding site (so-called ribosomal protection) by chromosomal mutation or by a macrolide-inducible or constitutive methylase. Efflux and methylase production account for the vast majority of cases of resistance in gram-positive organisms. Cross-resistance is complete between erythromycin and the other macrolides. Constitutive methylase production also confers resistance to structurally unrelated but mechanistically similar compounds such as clindamycin and streptogramin B (so-called macrolide-lincosamide-streptogramin, or MLS-type B, resistance), which share the same ribosomal binding site. Because nonmacrolides are poor inducers of the methylase, strains expressing an inducible methylase will appear susceptible *in vitro*. However, constitutive mutants that are resistant can be selected out and emerge during therapy with clindamycin.

Pharmacokinetics

Erythromycin base is destroyed by stomach acid and must be administered with enteric coating. Food interferes with absorption. Stearates and esters are fairly acid-resistant and somewhat better absorbed. The lauryl salt of the propionyl ester of erythromycin (erythromycin estolate) is the best-absorbed oral preparation. Oral dosage of 2 g/d results in serum erythromycin base and ester concentrations of approximately 2 $\mu\text{g}/\text{mL}$. However, only the base is microbiologically active, and its concentration tends to be similar regardless of the formulation. A 500 mg intravenous dose of erythromycin lactobionate produces serum concentrations of 10 $\mu\text{g}/\text{mL}$ 1 hour after dosing. The serum half-life is approximately 1.5 h normally and 5 hours in patients with anuria. Adjustment for renal failure is not necessary. Erythromycin is not removed by dialysis. Large amounts of an administered dose are excreted in the bile and lost in feces, and only 5% is excreted in the urine. Absorbed drug is distributed widely except to the brain and cerebrospinal fluid. Erythromycin is taken up by polymorphonuclear leukocytes and macrophages. It traverses the placenta and reaches the fetus.

Clinical Uses

An erythromycin is the drug of choice in corynebacterial infections (diphtheria, corynebacterial sepsis, erythrasma); in respiratory, neonatal, ocular, or genital chlamydial infections; and in treatment of community-acquired pneumonia because its spectrum of activity includes the pneumococcus, mycoplasma, and legionella. Erythromycin is also useful as a penicillin substitute in penicillin-allergic individuals with infections caused by staphylococci (assuming that the isolate is susceptible), streptococci, or pneumococci. Emergence of erythromycin resistance in strains of group A streptococci and pneumococci (penicillin-resistant pneumococci in particular) has made macrolides less attractive as first-line agents for treatment of pharyngitis, skin and soft tissue infections, and pneumonia. Erythromycin has been recommended as prophylaxis against endocarditis during dental procedures in individuals with valvular heart disease, though clindamycin, which is better tolerated, has largely replaced it. Although erythromycin estolate is the best-absorbed salt, it imposes the greatest risk of adverse reactions. Therefore, the stearate or succinate salt may be preferred.

The oral dosage of erythromycin base, stearate, or estolate is 0.25–0.5 g every 6 hours (for children, 40 mg/kg/d). The dosage of erythromycin ethylsuccinate is 0.4–0.6 g every 6 hours. Oral

erythromycin base (1 g) is sometimes combined with oral neomycin or kanamycin for preoperative preparation of the colon. The intravenous dosage of erythromycin gluceptate or lactobionate is 0.5–1.0 g every 6 hours for adults and 20–40 mg/kg/d for children. The higher dosage is recommended when treating pneumonia caused by legionella species.

Adverse Reactions

Gastrointestinal Effects

Anorexia, nausea, vomiting, and diarrhea occasionally accompany oral administration. Gastrointestinal intolerance, which is due to a direct stimulation of gut motility, is the most frequent reason for discontinuing erythromycin and substituting another antibiotic.

Liver Toxicity

Erythromycins, particularly the estolate, can produce acute cholestatic hepatitis (fever, jaundice, impaired liver function), probably as a hypersensitivity reaction. Most patients recover from this, but hepatitis recurs if the drug is readministered. Other allergic reactions include fever, eosinophilia, and rashes.

Drug Interactions

Erythromycin metabolites can inhibit cytochrome P450 enzymes and thus increase the serum concentrations of numerous drugs, including theophylline, oral anticoagulants, cyclosporine, and methylprednisolone. Erythromycin increases serum concentrations of oral digoxin by increasing its bioavailability.

Clarithromycin

Clarithromycin is derived from erythromycin by addition of a methyl group and has improved acid stability and oral absorption compared with erythromycin. Its mechanism of action is the same as that of erythromycin. Clarithromycin and erythromycin are virtually identical with respect to antibacterial activity except that clarithromycin is more active against *Mycobacterium avium* complex (see Chapter 47: Antimycobacterial Drugs). Clarithromycin also has activity against *M. leprae* and *Toxoplasma gondii*. Erythromycin-resistant streptococci and staphylococci are also resistant to clarithromycin.

A 500 mg dose produces serum concentrations of 2–3 $\mu\text{g/mL}$. The longer half-life of clarithromycin (6 hours) compared with erythromycin permits twice-daily dosing. The recommended dosage is 250–500 mg twice daily. Clarithromycin penetrates most tissues well, with concentrations equal to or exceeding serum concentrations.

Clarithromycin is metabolized in the liver. The major metabolite is 14-hydroxyclearithromycin, which also has antibacterial activity. A portion of active drug and this major metabolite is eliminated in the urine, and dosage reduction (eg, a 500 mg loading dose, then 250 mg once or twice daily) is recommended for patients with creatinine clearances less than 30 mL/min. Clarithromycin has drug interactions similar to those described for erythromycin.

The advantages of clarithromycin compared with erythromycin are lower frequency of gastrointestinal intolerance and less frequent dosing. Except for the specific organisms noted above, the two drugs are otherwise therapeutically very similar, and the choice of one over the other

usually turns on issues of cost (clarithromycin being much more expensive) and tolerability.

Azithromycin

Azithromycin, a 15-atom lactone macrolide ring compound, is derived from erythromycin by addition of a methylated nitrogen into the lactone ring of erythromycin. Its spectrum of activity and clinical uses are virtually identical to those of clarithromycin. Azithromycin is active against *M avium* complex and *T gondii*. Azithromycin is slightly less active than erythromycin and clarithromycin against staphylococci and streptococci and slightly more active against *H influenzae*. Azithromycin is highly active against chlamydia.

Azithromycin differs from erythromycin and clarithromycin mainly in pharmacokinetic properties. A 500 mg dose of azithromycin produces relatively low serum concentrations of approximately 0.4 µg/mL. However, azithromycin penetrates into most tissues (except cerebrospinal fluid) and phagocytic cells extremely well, with tissue concentrations exceeding serum concentrations by 10- to 100-fold. The drug is slowly released from tissues (tissue half-life of 2–4 days) to produce an elimination half-life approaching 3 days. These unique properties permit once-daily dosing and shortening of the duration of treatment in many cases. For example, a single 1 g dose of azithromycin is as effective as a 7-day course of doxycycline for chlamydial cervicitis and urethritis. Community-acquired pneumonia can be treated with azithromycin given as a 500 mg loading dose, followed by a 250 mg single daily dose for the next 4 days.

Azithromycin is rapidly absorbed and well tolerated orally. It should be administered 1 hour before or 2 hours after meals. Aluminum and magnesium antacids do not alter bioavailability but delay absorption and reduce peak serum concentrations. Because it has a 15-member (not 14-member) lactone ring, azithromycin does not inactivate cytochrome P450 enzymes and therefore is free of the drug interactions that occur with erythromycin and clarithromycin.

Ketolides

Ketolides are semisynthetic 14-membered-ring macrolides, differing from erythromycin by substitution of a 3-keto group for the neutral sugar L-cladinose. **Telithromycin** is approved for clinical use. It is active in vitro against *S pyogenes*, *S pneumoniae*, *S aureus*, *H influenzae*, *Moraxella catarrhalis*, mycoplasmas, legionella species, chlamydia species, *Helicobacter pylori*, *N gonorrhoeae*, *Bacteroides fragilis*, *T gondii*, and nontuberculosis mycobacteria. Many macrolide-resistant strains are susceptible to ketolides because the structural modification of these compounds renders them poor substrates for efflux-pump mediated resistance and they bind to ribosomes of some bacterial species with higher affinity than macrolides.

Oral bioavailability is 57%, and tissue and intracellular penetration is generally good. Telithromycin is metabolized in the liver and eliminated by a combination of biliary and urinary routes of excretion. It is administered as a once-daily dose of 800 mg, which results in peak serum concentrations of approximately 2 µg/mL. Telithromycin is indicated for treatment of respiratory tract infections, including community-acquired bacterial pneumonia, acute exacerbations of chronic bronchitis, sinusitis, and streptococcal pharyngitis. Telithromycin is a reversible inhibitor of the CYP3A4 enzyme system.

Katzung PHARMACOLOGY, 9e > Section VIII. Chemotherapeutic Drugs > Chapter 44. Chloramphenicol, Tetracyclines, Macrolides, Clindamycin, & Streptogramins >

Clindamycin

Clindamycin is a chlorine-substituted derivative of **lincomycin**, an antibiotic that is elaborated by *Streptomyces lincolnensis*. Lincomycin, although structurally distinct, resembles erythromycin in activity, but it is toxic and no longer used.

Antibacterial Activity

Streptococci, staphylococci, and pneumococci are inhibited by clindamycin, 0.5–5 $\mu\text{g/mL}$. Enterococci and gram-negative aerobic organisms are resistant (in contrast to their susceptibility to erythromycin). Bacteroides species and other anaerobes, both gram-positive and gram-negative, are usually susceptible. *Clostridium difficile*, an important cause of pseudomembranous colitis, is resistant. Clindamycin, like erythromycin, inhibits protein synthesis by interfering with the formation of initiation complexes and with aminoacyl translocation reactions. The binding site for clindamycin on the 50S subunit of the bacterial ribosome is identical with that for erythromycin. Resistance to clindamycin, which generally confers cross-resistance to other macrolides, is due to (1) mutation of the ribosomal receptor site; (2) modification of the receptor by a constitutively expressed methylase (see section on erythromycin resistance, above); and (3) enzymatic inactivation of clindamycin. Gram-negative aerobic species are intrinsically resistant because of poor permeability of the outer membrane.

Pharmacokinetics

Oral dosages of clindamycin, 0.15–0.3 g every 6 hours (10–20 mg/kg/d for children), yield serum levels of 2–3 $\mu\text{g/mL}$. When administered intravenously, 600 mg of clindamycin every 8 hours gives levels of 5–15 $\mu\text{g/mL}$. The drug is about 90% protein-bound. Excretion is mainly via the liver, bile, and urine. Clindamycin penetrates well into most tissues, with brain and cerebrospinal fluid being important exceptions. It penetrates well into abscesses and is actively taken up and concentrated by phagocytic cells. Clindamycin is metabolized by the liver, and both active drug and active metabolites are excreted in bile. The half-life is about 2.5 hours in normal individuals, increasing to 6 hours in patients with anuria. No dosage adjustment is required for renal failure.

Clinical Uses

Clindamycin is indicated for treatment of severe anaerobic infection caused by bacteroides and other anaerobes that often participate in mixed infections. Clindamycin, sometimes in combination with an aminoglycoside or cephalosporin, is used to treat penetrating wounds of the abdomen and the gut; infections originating in the female genital tract, eg, septic abortion and pelvic abscesses; or

aspiration pneumonia. Clindamycin is now recommended instead of erythromycin for prophylaxis of endocarditis in patients with valvular heart disease who are undergoing certain dental procedures. Clindamycin plus primaquine is an effective alternative to trimethoprim-sulfamethoxazole for moderate to moderately severe *Pneumocystis carinii* pneumonia in AIDS patients. It is also used in combination with pyrimethamine for AIDS-related toxoplasmosis of the brain.

Adverse Effects

Common adverse effects are diarrhea, nausea, and skin rashes. Impaired liver function (with or without jaundice) and neutropenia sometimes occur. Severe diarrhea and enterocolitis have followed clindamycin administration. Antibiotic-associated colitis that has followed administration of clindamycin and other drugs is caused by toxigenic *C difficile*. This potentially fatal complication must be recognized promptly and treated with metronidazole, 500 mg orally or intravenously three times a day (the preferred therapy), or vancomycin, 125 mg orally four times a day (less desirable given the increasing prevalence of vancomycin-resistant enterococci). Relapse may occur. Variations in the local prevalence of *C difficile* may account for the great differences in incidence of antibiotic-associated colitis. For unknown reasons, neonates given clindamycin may become colonized with toxigenic *C difficile* but do not develop colitis.

Katzung PHARMACOLOGY, 9e > Section VIII. Chemotherapeutic Drugs > Chapter 44.
Chloramphenicol, Tetracyclines, Macrolides, Clindamycin, & Streptogramins >

Streptogramins

Quinupristin-dalfopristin is a combination of two streptogramins—quinupristin, a streptogramin B, and dalfopristin, a streptogramin A—in a 30:70 ratio. It is rapidly bactericidal for most organisms except *Enterococcus faecium*, which is killed slowly. It has a prolonged postantibiotic effect (up to 10 hours for *S aureus*) that may account for its prolonged antibacterial activity despite relatively short half-lives of the parent drugs. Quinupristin-dalfopristin is active against gram-positive cocci, including multidrug-resistant strains of streptococci, penicillin-resistant strains of *S pneumoniae*, methicillin-susceptible and -resistant strains of staphylococci, and *E faecium* (but not *E faecalis*). Minimum inhibitory concentrations are 1 µg/mL or less. Resistance is due to modification of the quinupristin binding site (MLS-B type), enzymatic inactivation of dalfopristin, or efflux. Quinupristin is not an inducer of MLS-B resistance, but strains constitutively expressing the methylase may be inhibited but not killed by quinupristin-dalfopristin.

Quinupristin-dalfopristin is administered intravenously at a dosage of 7.5 mg/kg every 8–12 hours. Peak serum concentrations following an infusion of 7.5 mg/kg over 60 minutes are 3 µg/mL for quinupristin and 7 µg/mL for dalfopristin. Quinupristin and dalfopristin are rapidly metabolized, with half-lives of 0.85 and 0.7 hours, respectively. Elimination of approximately 75% of the parent compounds and their metabolites is by the fecal route. Renal elimination accounts for less than 20%. Dose adjustment is not necessary for renal failure, peritoneal dialysis, or hemodialysis. Patients with hepatic insufficiency may not tolerate the drug at usual doses, however, because of increased area under the concentration curve of both parent drugs and metabolites. This may necessitate a dose reduction to 7.5 mg/kg every 12 hours or 5 mg/kg every 8 hours in some patients. Quinupristin and dalfopristin are not metabolized by cytochrome P450 enzymes but significantly inhibit CYP 3A4, which metabolizes warfarin, diazepam, astemizole, terfenadine, cisapride, nonnucleo- side reverse transcriptase inhibitors, and cyclosporine, among others. Dosage reduction of cyclosporine may be necessary.

Quinupristin-dalfopristin is approved for treatment of infections caused by vancomycin-resistant

strains of *E faecium* but not *E faecalis*, which is intrinsically resistant, probably because of an efflux-type resistance mechanism. Quinupristin-dalfopristin also is likely to be approved for treatment of bacteremia or respiratory tract infections caused by methicillin-resistant staphylococci, streptococci, and penicillin-susceptible and penicillin-resistant strains of *S pneumoniae*. The principal toxicities are infusion-related events, such as pain at the infusion site, and an arthralgia-myalgia syndrome.

Katzung PHARMACOLOGY, 9e > Section VIII. Chemotherapeutic Drugs > Chapter 44.
Chloramphenicol, Tetracyclines, Macrolides, Clindamycin, & Streptogramins >

Oxazolidinones

Linezolid is a member of the oxazolidinones, a new class of synthetic antimicrobials. It is active against gram-positive organisms including staphylococci, streptococci, enterococci, gram-positive anaerobic cocci, and gram-positive rods such as corynebacteria and *Listeria monocytogenes*. It is primarily a bacteriostatic agent except for streptococci for which it is bactericidal. There is modest in vitro activity against *Mycobacterium tuberculosis*.

Linezolid inhibits protein synthesis by preventing formation of the ribosome complex that initiates protein synthesis. Its unique binding site, located on 23S ribosomal RNA of the 50S subunit, results in no cross-resistance with other drug classes. Resistance is caused by mutation of the linezolid binding site on 23S ribosomal RNA.

The principal toxicity of linezolid is hematologic—reversible and generally mild. Thrombocytopenia is the most common manifestation (seen in approximately 3% of treatment courses), particularly when the drug is administered for longer than 2 weeks. Neutropenia may also occur, most commonly in patients with a predisposition to or underlying bone marrow suppression. Linezolid is 100% bioavailable after oral administration and has a half-life of 4–6 hours. It is metabolized by oxidative metabolism, yielding two inactive metabolites. It is neither an inducer nor an inhibitor of cytochrome P450 enzymes. Peak serum concentrations average 18 µg/mL following a 600 mg oral dose. The recommended dose for most indications is 600 mg twice daily, either orally or intravenously. It is approved for vancomycin-resistant *E faecium* infections; nosocomial pneumonia; community-acquired pneumonia; and skin infections, complicated or uncomplicated. It should be reserved for treatment of infections caused by multiply drug-resistant gram-positive bacteria.

Chloramphenicol, Tetracyclines, Macrolides, Clindamycin, & Streptogramins >

Preparations Available

Chloramphenicol

Chloramphenicol (generic, Chloromycetin)

Oral: 250 mg capsules; 150 mg/5 mL suspension

Parenteral: 100 mg powder to reconstitute for injection

Tetracyclines

Demeclocycline (Declomycin)

Oral: 150, 300 mg tablets; 150 mg capsules

Doxycycline (generic, Vibramycin, others)

Oral: 50, 100 mg tablets and capsules; powder to reconstitute for 25 mg/5 mL suspension; 50 mg/5 mL syrup

Parenteral: 100, 200 mg powder to reconstitute for injection

Methacycline (Randomycin)

Oral: 150, 300 mg capsules

Minocycline (Minocin)

Oral: 50, 100 mg tablets and capsules; 50 mg/5 mL suspension

Parenteral: 100 mg powder to reconstitute for injection

Oxytetracycline (generic, Terramycin)

Oral: 250 mg capsules

Parenteral: 50, 125 mg/mL for IM injection

Tetracycline (generic, Achromycin V, others)

Oral: 100, 250, 500 mg capsules; 250, 500 mg tablets; 125 mg/5 mL suspension

Parenteral: 100, 250 mg powder to reconstitute for IM injection; 250, 500 mg powder to reconstitute for IV injection

Macrolides

Azithromycin (Zithromax)

Oral: 250 mg capsules; powder for 100, 200 mg/5 mL oral suspension

Clarithromycin (Biaxin)

Oral: 250, 500 mg tablets, 500 mg extended release tablets; granules for 125, 250 mg/5 mL oral suspension

Erythromycin (generic, Ilotycin, Ilosone, E-Mycin, Erythrocin, others)

Oral (base): 250, 333, 500 mg enteric-coated tablets

Oral (base) delayed-release: 333 mg tablets, 250 capsules

Oral (estolate): 500 mg tablets; 250 mg capsules; 125, 250 mg/5 mL suspension

Oral (ethylsuccinate): 200, 400 mg film-coated tablets; 200, 400 mg/5 mL suspension

Oral (stearate): 250, 500 mg film-coated tablets

Parenteral: lactobionate, 0.5, 1 g powder to reconstitute for IV injection

Ketolides

Telithromycin (Proteck)

Oral: 800 mg tablets

Lincomycins

Clindamycin (generic, Cleocin)

Oral: 75, 150, 300 mg capsules; 75 mg/5 mL granules to reconstitute for solution

Parenteral: 150 mg/mL in 2, 4, 6, 60 mL vials for injection

Streptogramins

Quinupristin and dalfopristin (Synercid)

Parenteral: 30:70 formulation in 500 mg vial for reconstitution for IV injection

Oxazolidinones

Linezolid (Zyvox)

Oral: 400, 600 mg tablets; 100 mg powder for solution

Parenteral: 2 mg/mL for IV infusion

Chapter 45. Aminoglycosides & Spectinomycin

Katzung PHARMACOLOGY, 9e > Section VIII. Chemotherapeutic Drugs > Chapter 45.
Aminoglycosides & Spectinomycin >

Aminoglycosides & Spectinomycin: Introduction

The drugs described in this chapter are, like those described in Chapter 44: Chloramphenicol, Tetracyclines, Macrolides, Clindamycin, & Streptogramins, protein synthesis inhibitors that interfere with ribosomal function. These agents are useful mainly against aerobic gram-negative microorganisms.

Katzung PHARMACOLOGY, 9e > Section VIII. Chemotherapeutic Drugs > Chapter 45.
Aminoglycosides & Spectinomycin >

Aminoglycosides

Aminoglycosides are a group of bactericidal antibiotics originally obtained from various streptomyces species and sharing chemical, antimicrobial, pharmacologic, and toxic characteristics. The group includes **streptomycin, neomycin, kanamycin, amikacin, gentamicin, tobramycin, sisomicin, netilmicin**, and others.

Aminoglycosides are used most widely against gram-negative enteric bacteria, especially in bacteremia and sepsis, in combination with vancomycin or a penicillin for endocarditis, and for treatment of tuberculosis. Streptomycin is the oldest and best-studied of the aminoglycosides. Gentamicin, tobramycin, and amikacin are the most widely employed aminoglycosides at present. Neomycin and kanamycin are now largely limited to topical or oral use.

General Properties of Aminoglycosides

Physical and Chemical Properties

Aminoglycosides have a hexose ring, either streptidine (in streptomycin) or 2-deoxystreptamine (other aminoglycosides), to which various amino sugars are attached by glycosidic linkages (Figures 45–1 and 45–2). They are water-soluble, stable in solution, and more active at alkaline than at acid pH. Aminoglycosides frequently exhibit synergism with β -lactams or vancomycin in vitro. In combination they eradicate organisms more rapidly than would be predicted from the activity of either single agent. However, at high concentrations aminoglycosides may complex with β -lactam drugs, resulting in loss of activity, and they should not be mixed together for administration.

Figure 45–1.

Figure 45-2.

Kanamycin R = H

Gentamicin, netilmicin

	Ring I			Ring II
	R ₁	R ₂	C4-C5 bond	R ₃
Gentamicin C ₁	CH ₃	CH ₃	Single	H
Gentamicin C ₂	CH ₃	H	Single	H
Gentamicin C _{1a}	H	H	Single	H
Netilmicin	H	H	Double	C ₂ H ₅

Tobramycin

Structures of several important aminoglycoside antibiotics. Ring II is 2-deoxystreptamine. The resemblance between kanamycin and amikacin and between gentamicin, netilmicin, and tobramycin can be seen. The circled numerals on the kanamycin molecule indicate points of attack of plasmid-mediated bacterial transposon, one that can integrate this drug. ① ② and ③

Katzung PHARMACOLOGY, 9e > Section VIII. Chemotherapeutic Drugs > Chapter 45.
Aminoglycosides & Spectinomycin >

Spectinomycin

Spectinomycin is an aminocyclitol antibiotic that is structurally related to aminoglycosides. It lacks amino sugars and glycosidic bonds.

Spectinomycin

While active in vitro against many gram-positive and gram-negative organisms, spectinomycin is used almost solely as an alternative treatment for gonorrhea in patients who are allergic to penicillin or whose gonococci are resistant to other drugs. The vast majority of gonococcal isolates are inhibited by 6 μ g/mL of spectinomycin. Strains of gonococci may be resistant to spectinomycin, but there is no cross-resistance with other drugs used in gonorrhea. Spectinomycin is rapidly absorbed after intramuscular injection. A single dose of 40 mg/kg up to a maximum of 2 g is given. There is pain at the injection site and occasionally fever and nausea. Nephrotoxicity and anemia have been observed rarely.

Kanamycin(Kantrex)

Oral: 500 mg capsules

Parenteral: 500, 1000 mg for IM, IV injection; 75 mg for pediatric injection

Neomycin(generic, Mycifradin)

Oral: 500 mg tablets; 125 mg/5 mL solution

Netilmicin (Netromycin)

Parenteral: 100 mg/mL for IM, IV injection

Paromomycin(Humatin)

Oral: 250 mg capsules

Spectinomycin(Trobicin)

Parenteral: 2 g powder to reconstitute for IM injection

Streptomycin (generic)

Parenteral: 400 mg/mL for IM injection

Tobramycin(generic, Nebcin)

Parenteral: 10, 40 mg/mL for IM, IV injection; powder to reconstitute for injection

Chapter 46. Sulfonamides, Trimethoprim, & Quinolones

Katzung PHARMACOLOGY, 9e > Section VIII. Chemotherapeutic Drugs > Chapter 46. Sulfonamides, Trimethoprim, & Quinolones >

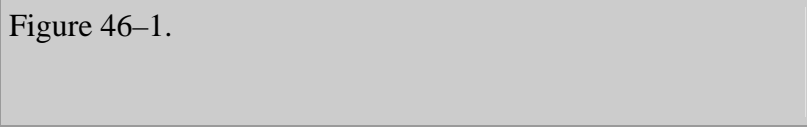

Antifolate Drugs

Sulfonamides

Chemistry

The basic formula of the sulfonamides and their structural similarity to *p*-aminobenzoic acid (PABA) are shown in Figure 46–1. Sulfonamides with varying physical, chemical, pharmacologic, and antibacterial properties are produced by attaching substituents to the amido group ($-\text{SO}_2-\text{NH}-\text{R}$) or the amino group ($-\text{NH}_2$) of the sulfanilamide nucleus. Sulfonamides tend to be much more soluble at alkaline than at acid pH. Most can be prepared as sodium salts, which are used for intravenous administration.

Figure 46–1.

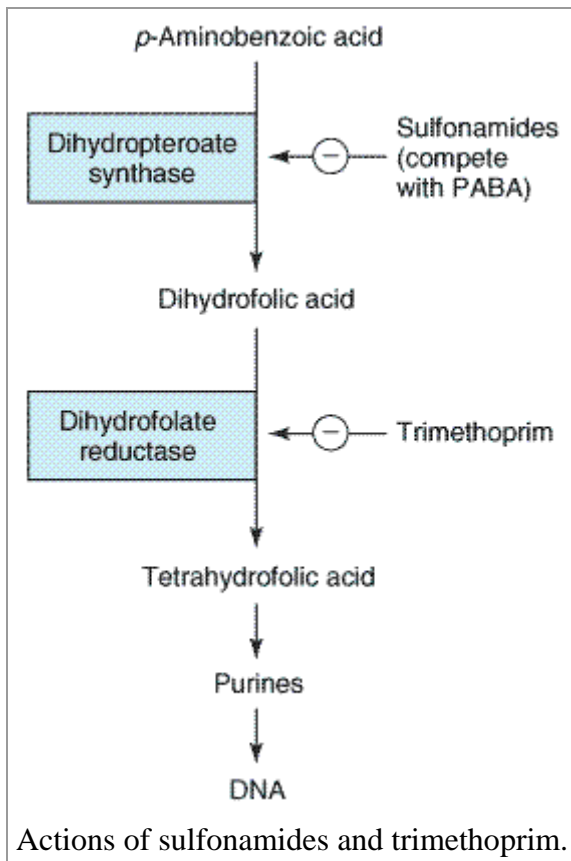

Antimicrobial Activity

Susceptible microorganisms require extracellular PABA in order to form dihydrofolic acid (Figure 46–2), an essential step in the production of purines and the synthesis of nucleic acids. Sulfonamides are structural analogs of PABA that competitively inhibit dihydropteroate synthase. They inhibit growth by reversibly blocking folic acid synthesis. Sulfonamides inhibit both gram-positive and gram-negative bacteria, nocardia, *Chlamydia trachomatis*, and some protozoa. Some enteric bacteria, such as *E coli*, klebsiella, salmonella, shigella, and enterobacter, are inhibited. Interestingly, rickettsiae are not inhibited by sulfonamides but are actually stimulated in their growth.

Figure 46–2.

Resistance

Mammalian cells (and some bacteria) lack the enzymes required for folate synthesis and depend upon exogenous sources of folate; therefore, they are not susceptible to sulfonamides. Sulfonamide resistance may occur as a result of mutations that cause overproduction of PABA, cause production of a folic acid-synthesizing enzyme that has low affinity for sulfonamides, or cause a loss of permeability to the sulfonamide. Dihydropteroate synthase with low sulfonamide affinity is often encoded on a plasmid that is transmissible and can disseminate rapidly and widely. Sulfonamide-resistant cells may be present in susceptible bacterial populations and can emerge under selective pressure.

Pharmacokinetics

Sulfonamides can be divided into three major groups: (1) oral, absorbable; (2) oral, nonabsorbable; and (3) topical. Sodium salts of sulfonamides in 5% dextrose in water can be given intravenously, but except for sulfamethoxazole-trimethoprim combinations, these are rarely used. The oral, absorbable sulfonamides can be classified as short-, medium-, or long-acting on the basis of their half-lives (Table 46–1). They are absorbed from the stomach and small intestine and distributed widely to tissues and body fluids (including the central nervous system and cerebrospinal fluid), placenta, and fetus. Absorbed sulfonamides become bound to serum proteins to an extent varying from 20% to over 90%. Therapeutic concentrations are in the range of 40–100 µg/mL of blood. Peak blood levels generally occur 2–6 hours after oral administration.

Table 46–1. Pharmacokinetic Properties of Some Sulfonamides and Trimethoprim.

Drug	Half-Life	Oral Absorption
Sulfonamides		
Sulfacytine	Short	Prompt (peak levels in 1–4 hours)
Sulfisoxazole	Short (6 hours)	Prompt
Sulfamethizole	Short (9 hours)	Prompt
Sulfadiazine	Intermediate (10–17 hours)	Slow (peak levels in 4–8 hours)
Sulfamethoxazole	Intermediate (10–12 hours)	Slow
Sulfapyridine	No data	Slow
Sulfadoxine	Long (7–9 days)	Intermediate
Pyrimidines		
Trimethoprim	Intermediate (11 hours)	Prompt

A portion of absorbed drug is acetylated or glucuronidated in the liver. Sulfonamides and inactivated metabolites are then excreted into the urine, mainly by glomerular filtration. In significant renal failure, the dosage of sulfonamide must be reduced.

Clinical Uses

Sulfonamides are infrequently used as single agents. Formerly drugs of choice for infections such as *Pneumocystis jiroveci* (formerly *P. carinii*) pneumonia, toxoplasmosis, nocardiosis, and occasionally other bacterial infections, they have been largely supplanted by the fixed drug combination of trimethoprim-sulfamethoxazole. Many strains of formerly susceptible species, including meningococci, pneumococci, streptococci, staphylococci, and gonococci, are now resistant. Nevertheless, sulfonamides can be useful for treatment of urinary tract infections due to susceptible organisms and in other special clinical situations discussed below.

Oral Absorbable Agents

Sulfisoxazole and sulfamethoxazole are short- to medium-acting agents that are used almost exclusively to treat urinary tract infections. The usual adult dosage is 1 g of sulfisoxazole four times daily or 1 g of sulfamethoxazole two or three times daily.

Sulfadiazine achieves therapeutic concentrations in cerebrospinal fluid and in combination with pyrimethamine is first-line therapy for treatment of acute toxoplasmosis. Pyrimethamine, an antiprotozoal agent, is a potent inhibitor of dihydrofolate reductase. The combination of sulfadiazine and pyrimethamine is synergistic because these drugs block sequential steps in the folate synthetic pathway blockade (Figure 46–2). The dosage of sulfadiazine is 1 g four times daily, with pyrimethamine given as a 75 mg loading dose followed by a 25 mg once-daily dose. Folinic acid, 10 mg orally each day, should also be administered to minimize bone marrow suppression.

Sulfadoxine is the only long-acting sulfonamide currently available in the United States. Urinary excretion—especially of the free form—is very slow, resulting in prolonged drug levels in serum. Sulfadoxine is available only as Fansidar, a combination formulation with pyrimethamine, which is used as a second-line agent in treatment for malaria (Chapter 53: Antiprotozoal Drugs).

Oral Nonabsorbable Agents

Sulfasalazine (salicylazosulfapyridine) is widely used in ulcerative colitis, enteritis, and other inflammatory bowel disease (see Chapter 63: Drugs Used in the Treatment of Gastrointestinal Diseases).

Topical Agents

Sodium sulfacetamide ophthalmic solution or ointment is effective treatment for bacterial conjunctivitis and as adjunctive therapy for trachoma. Mafenide acetate is used topically to prevent bacterial colonization and infection of burn wounds. Mafenide is absorbed from burn sites, and systemic levels are produced. The drug and its primary metabolite also inhibit carbonic anhydrase and can cause metabolic acidosis, a side effect that limits its usefulness. Silver sulfadiazine is a much less toxic topical sulfonamide and is preferred to mafenide for prevention of infection of burn wounds.

Adverse Reactions

All sulfonamides and their derivatives, including carbonic anhydrase inhibitors, thiazides, furosemide, bumetanide, torsemide, diazoxide, and the sulfonamide hypoglycemic agents, are cross-allergenic. The most common adverse effects are fever, skin rashes, exfoliative dermatitis, photosensitivity, urticaria, nausea, vomiting, diarrhea, and difficulties referable to the urinary tract (see below). Stevens-Johnson syndrome, although relatively uncommon (ie, less than 1% of treatment courses), is a particularly serious and potentially fatal type of skin and mucous membrane eruption associated with sulfonamide use. Other unwanted effects include stomatitis, conjunctivitis, arthritis, hematopoietic disturbances (see Urinary Tract Disturbances), hepatitis, and, rarely, polyarteritis nodosa and psychosis.

Urinary Tract Disturbances

Sulfonamides may precipitate in urine, especially at neutral or acid pH, producing crystalluria, hematuria, or even obstruction. This is rarely a problem with the more soluble sulfonamides (eg, sulfisoxazole). Sulfadiazine when given in large doses, particularly if fluid intake is poor, can cause crystalluria. Crystalluria is treated by administration of sodium bicarbonate to alkalinize the urine and fluids to maintain adequate hydration. Sulfonamides have also been implicated in various types of nephrosis and in allergic nephritis.

Hematopoietic Disturbances

Sulfonamides can cause hemolytic or aplastic anemia, granulocytopenia, thrombocytopenia, or leukemoid reactions. Sulfonamides may provoke hemolytic reactions in patients whose red cells are deficient in glucose-6-phosphate dehydrogenase. Sulfonamides taken near the end of pregnancy increase the risk of kernicterus in newborns.

Trimethoprim & Trimethoprim-Sulfamethoxazole Mixtures

Trimethoprim, a trimethoxybenzylpyrimidine, inhibits bacterial dihydrofolic acid reductase about 50,000 times more efficiently than the same enzyme of mammalian cells. Pyrimethamine, another benzylpyrimidine, inhibits the activity of dihydrofolic acid reductase of protozoa more than that of mammalian cells. Dihydrofolic acid reductases convert dihydrofolic acid to tetrahydrofolic acid, a step leading to the synthesis of purines and ultimately to DNA. Trimethoprim or pyrimethamine, given together with sulfonamides, produces sequential blocking in this metabolic sequence, resulting in marked enhancement (synergism) of the activity of both drugs (Figure 46–2). The

combination often is bactericidal, compared to the bacteriostatic activity of a sulfonamide alone.

Resistance

Resistance to trimethoprim can result from reduced cell permeability, overproduction of dihydrofolate reductase, or production of an altered reductase with reduced drug binding. Resistance can emerge by mutation, though more commonly it is due to plasmid-encoded trimethoprim-resistant dihydrofolate reductases. These resistant enzymes may be located within transposons on conjugative plasmids that exhibit a broad host range, accounting for rapid and widespread dissemination of trimethoprim resistance among numerous bacterial species.

Pharmacokinetics

Trimethoprim is usually given orally, alone or in combination with sulfamethoxazole, the latter chosen because it has a similar half-life. Trimethoprim-sulfamethoxazole can also be given intravenously. Trimethoprim is absorbed efficiently from the gut and distributed widely in body fluids and tissues, including cerebrospinal fluid. Because trimethoprim is more lipid-soluble than sulfamethoxazole, it has a larger volume of distribution than the latter drug. Therefore, when 1 part of trimethoprim is given with 5 parts of sulfamethoxazole (the ratio in the formulation), the peak plasma concentrations are in the ratio of 1:20, which is optimal for the combined effects of these drugs *in vitro*. About 65–70% of each participant drug is protein-bound, and 30–50% of the sulfonamide and 50–60% of the trimethoprim (or their respective metabolites) are excreted in the urine within 24 hours. The dose should be reduced by half for patients with creatinine clearances of 15 to 30 mL/min.

Trimethoprim (a weak base of pK_a 7.2) concentrates in prostatic fluid and in vaginal fluid, which are more acid than plasma. Therefore, it has more antibacterial activity in prostatic and vaginal fluids than many other antimicrobial drugs.

Clinical Uses

Oral Trimethoprim

Trimethoprim can be given alone (100 mg twice daily) in acute urinary tract infections. Most community-acquired organisms tend to be susceptible to the high concentrations that are found in the urine (200–600 µg/mL).

Oral Trimethoprim-Sulfamethoxazole

A combination of trimethoprim-sulfamethoxazole is effective treatment for *P jiroveci* pneumonia, shigellosis, systemic salmonella infections (caused by ampicillin- or chloramphenicol-resistant organisms), complicated urinary tract infections, prostatitis, some nontuberculous mycobacterial infections, and many others. It is active against many respiratory tract pathogens, including the pneumococcus, haemophilus species, *Moraxella catarrhalis*, and *Klebsiella pneumoniae* (but not *Mycoplasma pneumoniae*), making it a potentially useful alternative to β-lactam drugs for treatment of upper respiratory tract infections and community-acquired bacterial pneumonia. However, the increasing prevalence of strains of *E coli* (up to 30% or more) and pneumococci (particularly penicillin-resistant strains, but also some penicillin-susceptible strains) that are resistant to trimethoprim-sulfamethoxazole must be considered before using this combination for empirical therapy of upper urinary tract infections or pneumonia.

Two double-strength tablets (trimethoprim 160 mg plus sulfamethoxazole 800 mg) given every 12 hours is effective treatment for urinary tract infections and prostatitis. One half of the regular size (single-strength) tablet given three times weekly for many months may serve as prophylaxis in recurrent urinary tract infections of some women. Two double-strength tablets every 12 hours is effective treatment for infections caused by susceptible strains of shigella and salmonella. The dosage for children treated for shigellosis, urinary tract infection, or otitis media is 8 mg/kg trimethoprim and 40 mg/kg sulfamethoxazole every 12 hours.

Infections with *P jiroveci* and some other pathogens can be treated orally with high doses of the combination (dosed on the basis of the trimethoprim component at 15–20 mg/kg) or can be prevented in immunosuppressed patients by one double-strength tablet daily or three times weekly.

Intravenous Trimethoprim-Sulfamethoxazole

A solution of the mixture containing 80 mg trimethoprim plus 400 mg sulfamethoxazole per 5 mL diluted in 125 mL of 5% dextrose in water can be administered by intravenous infusion over 60–90 minutes. It is the agent of choice for moderately severe to severe pneumocystis pneumonia. It may be used for gram-negative bacterial sepsis, including that caused by some multidrug-resistant species such as enterobacter and serratia; shigellosis; typhoid fever; or urinary tract infection caused by a susceptible organism when the patient is unable to take the drug by mouth. The dosage is 10–20 mg/kg/d of the trimethoprim component.

Oral Pyrimethamine with Sulfonamide

Pyrimethamine and sulfadiazine have been used for treatment of leishmaniasis and toxoplasmosis. In falciparum malaria, the combination of pyrimethamine with sulfadoxine (Fansidar) has been employed (see Chapter 53: Antiprotozoal Drugs).

Adverse Effects

Trimethoprim produces the predictable adverse effects of an antifolate drug, especially megaloblastic anemia, leukopenia, and granulocytopenia. This can be prevented by the simultaneous administration of folic acid, 6–8 mg/d. Use of folic acid to prevent hematologic

toxicity resulting from trimethoprim-sulfamethoxazole during treatment of pneumocystis pneumonia in AIDS patients is associated with increased morbidity and treatment failures and is not recommended. In addition, the combination trimethoprim-sulfamethoxazole may cause all of the untoward reactions associated with sulfonamides. Nausea and vomiting, drug fever, vasculitis, renal damage, and central nervous system disturbances occasionally occur also. Patients with AIDS and pneumocystis pneumonia have a particularly high frequency of untoward reactions to trimethoprim-sulfamethoxazole, especially fever, rashes, leukopenia, diarrhea, elevations of hepatic aminotransferases, hyperkalemia, and hyponatremia.

Katzung PHARMACOLOGY, 9e > Section VIII. Chemotherapeutic Drugs > Chapter 46.
Sulfonamides, Trimethoprim, & Quinolones >

DNA Gyrase Inhibitors

Fluoroquinolones

The important quinolones are synthetic fluorinated analogs of nalidixic acid. They are active against a variety of gram-positive and gram-negative bacteria. Quinolones block bacterial DNA synthesis by inhibiting bacterial topoisomerase II (DNA gyrase) and topoisomerase IV. Inhibition of DNA gyrase prevents the relaxation of positively supercoiled DNA that is required for normal transcription and replication. Inhibition of topoisomerase IV interferes with separation of replicated chromosomal DNA into the respective daughter cells during cell division.

Earlier quinolones (nalidixic acid, oxolinic acid, cinoxacin) did not achieve systemic antibacterial levels. These agents were useful only for treatment of lower urinary tract infections (see below); nalidixic acid and cinoxacin are still available. Fluorinated derivatives (ciprofloxacin, levofloxacin, and others; Figure 46–3 and Table 46–2) have greatly improved antibacterial activity compared with nalidixic acid and achieve bactericidal levels in blood and tissues.

Sparfloxacin	18	92			50% renal, 50% fecal
Trovafloracin	11	88	2.2	200	Nonrenal

Antibacterial Activity

Fluoroquinolones were originally developed because of their excellent activity against gram-negative aerobic bacteria; they had limited activity against gram-positive organisms. Several newer agents have improved activity against gram-positive cocci. This relative activity against gram-negative versus gram-positive species is useful for classification of these agents. Norfloxacin is the least active of the fluoroquinolones against both gram-negative and gram-positive organisms, with MICs fourfold to eightfold higher than those of ciprofloxacin, the prototype drug. Ciprofloxacin, enoxacin, lomefloxacin, levofloxacin, ofloxacin, and pefloxacin comprise a second group of similar agents possessing excellent gram-negative activity and moderate to good activity against gram-positive bacteria. Minimum inhibitory concentrations (MICs) for gram-negative cocci and bacilli, including Enterobacteriaceae, pseudomonas, neisseria, haemophilus, and campylobacter, are 1–2 μ g/mL and often less. Methicillin-susceptible strains of *S aureus* are generally susceptible to these fluoroquinolones, but methicillin-resistant strains of staphylococci are often resistant. Streptococci and enterococci tend to be less susceptible than staphylococci, and efficacy in infections caused by these organisms is limited. Ciprofloxacin is the most active agent of this group against gram-negatives, *P aeruginosa* in particular. Levofloxacin, the L-isomer of ofloxacin and twice as potent, has superior activity against gram-positive organisms, including *S pneumoniae*.

Gatifloxacin, moxifloxacin, sparfloxacin, and trovafloracin comprise a third group of fluoroquinolones with improved activity against gram-positive organisms, particularly *S pneumoniae* and to some extent staphylococci. Although MICs of these agents for staphylococci are lower than those of ciprofloxacin (and the other compounds mentioned in the paragraph above) and may fall within the susceptible range, it is not known whether the enhanced activity is sufficient to permit use of these agents for treatment of infections caused by ciprofloxacin-resistant strains. None of these agents are as active as ciprofloxacin against gram-negative organisms. Fluoroquinolones also are active against agents of atypical pneumonia (eg, mycoplasmas and chlamydiae) and against intracellular pathogens such as legionella species and some mycobacteria, including *Mycobacterium tuberculosis* and *M avium* complex. Moxifloxacin and trovafloracin, in addition to enhanced gram-positive activity, also have good activity—which other fluoroquinolones lack—against anaerobic bacteria.

Resistance

During fluoroquinolone therapy, resistant organisms emerge with a frequency of about one in 10^7 – 10^9 , especially among staphylococci, pseudomonas, and serratia. Resistance is due to one or more point mutations in the quinolone binding region of the target enzyme or to a change in the permeability of the organism. DNA gyrase is the primary target in *E coli*, with single-step mutants exhibiting amino acid substitution in the A subunit of gyrase. Topoisomerase IV is a secondary target in *E coli* that is altered in mutants expressing higher levels of resistance. In staphylococci and streptococci, the situation is reversed: topoisomerase IV is usually the primary target, and gyrase is the secondary target. Resistance to one fluoroquinolone, particularly if of high level, generally confers cross-resistance to all other members of this class. With the increasing use of fluoroquinolones for a variety of infections, including respiratory tract infections, fluoroquinolone resistance has emerged among strains of *Streptococcus pneumoniae*.

Pharmacokinetics

After oral administration, the fluoroquinolones are well absorbed (bioavailability of 80–95%) and distributed widely in body fluids and tissues (Table 46–2). Serum half-lives range from 3 hours (norfloxacin and ciprofloxacin) up to 10 (pefloxacin and fleroxacin) or longer (sparfloxacin). The relatively long half-lives of levofloxacin, moxifloxacin, sparfloxacin, and trovafloxacin permit once-daily dosing. The pharmacokinetics of ofloxacin and levofloxacin are identical. Oral absorption is impaired by divalent cations, including those in antacids. Serum concentrations of intravenously administered drug are similar to those of orally administered drug. Alatrovafloxacin is the inactive, prodrug form of trovafloxacin for parenteral administration. It is rapidly converted to the active compound. Concentrations in prostate, kidney, neutrophils, and macrophages exceed serum concentrations. Most fluoroquinolones are eliminated by renal mechanisms, either tubular secretion or glomerular filtration (Table 46–2). Dose adjustment is required for patients with creatinine clearances less than 50 mL/min, the exact adjustment depending upon the degree of renal impairment and the specific fluoroquinolone being used. Dose adjustment for renal failure is not necessary for trovafloxacin or moxifloxacin. Nonrenally cleared fluoroquinolones are contraindicated in patients with hepatic failure.

Clinical Uses

Fluoroquinolones are effective in urinary tract infections even when caused by multidrug-resistant bacteria, eg, pseudomonas. Norfloxacin 400 mg, ciprofloxacin 500 mg, and ofloxacin 400 mg given orally twice daily are all effective. These agents are also effective for bacterial diarrhea caused by shigella, salmonella, toxigenic *E coli*, or campylobacter. Fluoroquinolones (except norfloxacin, which does not achieve adequate systemic concentrations) have been employed in infections of soft tissues, bones, and joints and in intra-abdominal and respiratory tract infections, including those caused by multidrug-resistant organisms such as pseudomonas and enterobacter.

Ciprofloxacin and ofloxacin are effective for gonococcal infection, including disseminated disease, and ofloxacin is effective for chlamydial urethritis or cervicitis. Ciprofloxacin is a second-line agent for legionellosis. Ciprofloxacin or levofloxacin is occasionally used for treatment of tuberculosis and atypical mycobacterial infections. They may be suitable for eradication of meningococci from carriers or for prophylaxis of infection in neutropenic patients.

Owing to their marginal activity against the pneumococcus, fluoroquinolones have not been routinely recommended for empirical treatment of pneumonia and other upper respiratory tract infections. However, levofloxacin, gatifloxacin, and moxifloxacin, with their enhanced gram-positive activity and activity against atypical pneumonia agents (eg, chlamydia, mycoplasma, and legionella), are likely to be effective and used increasingly for treatment of upper and lower

respiratory tract infections.

Adverse Effects

Fluoroquinolones are extremely well tolerated. The most common effects are nausea, vomiting, and diarrhea. Occasionally, headache, dizziness, insomnia, skin rash, or abnormal liver function tests develop. Trovafloxacin has been associated with acute hepatitis and hepatic failure, which has led to its restricted indications. Photosensitivity has been reported with lomefloxacin and pefloxacin. Grepafloxacin was withdrawn by the manufacturer shortly after approval because of QT_c interval prolongation and its tendency to cause cardiac arrhythmias. QT_c prolongation may also occur with other fluoroquinolones—particularly sparfloxacin but also gatifloxacin, levofloxacin, and moxifloxacin. Ideally, these agents should be avoided or used with caution in patients with known QT_c interval prolongation or uncorrected hypokalemia; in those receiving class IA (eg, quinidine or procainamide) or class III antiarrhythmic agents (sotalol, ibutilide, amiodarone); and in patients who are receiving other agents known to increase the QT_c interval (eg, erythromycin, tricyclic antidepressants). Gatifloxacin has been associated with hyperglycemia in diabetic patients and with hypoglycemia in patients also receiving oral hypoglycemic agents.

Fluoroquinolones may damage growing cartilage and cause an arthropathy. Thus, they are not routinely recommended for use in patients under 18 years of age. However, the arthropathy is reversible, and there is a growing consensus that fluoroquinolones may be used in children in some cases (eg, for treatment of pseudomonal infections in patients with cystic fibrosis). Tendinitis, a rare complication that has been reported in adults, is potentially more serious because of the risk of tendon rupture. They should be avoided during pregnancy in the absence of specific data documenting their safety.

Nalidixic Acid & Cinoxacin

Nalidixic acid, the first antibacterial quinolone (Figure 46–3), was introduced in 1963. It is not fluorinated and is excreted too rapidly to be useful for systemic infections. Oxolinic acid and cinoxacin are similar in structure and function to nalidixic acid. Their mechanism of action is the same as that of the fluoroquinolones. These agents were useful only for the treatment of urinary tract infections and are rarely used now, having been made obsolete by the more efficacious fluorinated quinolones.

Sulfonamides, Trimethoprim, & Quinolones >

Preparations Available

General-Purpose Sulfonamides

Sulfadiazine (generic)

Oral: 500 mg tablets

Sulfamethizole (Thiosulfil Forte)

Oral: 500 mg tablets

Sulfamethoxazole (generic, Gantanol, others)

Oral: 500 mg tablets; 500 mg/5 mL suspension

Sulfanilamide (AVC)

Vaginal cream: 15%

Sulfisoxazole (generic, Gantrisin)

Oral: 500 mg tablets; 500 mg/5 mL syrup

Ophthalmic: 4% solution

Sulfonamides for Special Applications

Mafenide (Sulfamylon)

Topical: 85 mg/g cream; 5% solution

Silver sulfadiazine (generic, Silvadene)

Topical: 10 mg/g cream

Sulfacetamide sodium (generic)

Ophthalmic: 1, 10, 15, 30% solutions; 10% ointment

Trimethoprim

Trimethoprim (generic, Proloprim, Trimplex)

Oral: 100, 200 mg tablets

Trimethoprim-sulfamethoxazole [co-trimoxazole, TMP-SMZ] (generic, Bactrim, Septra, others)

Oral: 80 mg trimethoprim + 400 mg sulfamethoxazole per single-strength tablet; 160 mg trimethoprim + 800 mg sulfamethoxazole per double-strength tablet; 40 mg trimethoprim + 200 mg sulfamethoxazole per 5 mL suspension

Parenteral: 80 mg trimethoprim + 400 mg sulfamethoxazole per 5 mL for infusion (in 5 mL ampules and 5, 10, 20, 30, 50 mL vials)

Quinolones & Fluoroquinolones

Cinoxacin (generic, Cinobac)

Oral: 250, 500 mg capsules

Ciprofloxacin (Cipro, Cipro I.V.)

Oral: 250, 500, 750 mg tablets; 50, 100 mg/mL suspension

Parenteral: 2, 10 mg/mL for IV infusion

Ophthalmic (Ciloxan): 3 mg/mL solution; 3.3 mg/g ointment

Enoxacin (Penetrex)

Oral: 200, 400 mg tablets

Gatifloxacin (Tequin)

Oral: 200, 400 mg tablets

Parenteral: 200, 400 mg for IV injection

Levofloxacin (Levaquin)

Oral: 250, 500, 750 mg for injection

Parenteral: 250, 500 mg for IV injection

Ophthalmic (Quixin): 5 mg/mL solution

Lomefloxacin (Maxaquin)

Oral: 400 mg tablets

Moxifloxacin (Avelox, Avelox I.V.)

Oral: 400 mg tablets

Parenteral: 400 mg in IV bag

Nalidixic acid (NegGram)

Oral: 250, 500, 1000 mg caplets; 250 mg/5 mL suspension

Norfloxacin (Noroxin)

Oral: 400 mg tablets

Ofloxacin (Floxin)

Oral: 200, 300, 400 mg tablets

Parenteral: 200 mg in 50 mL 5% D/W for IV administration; 20, 40 mg/mL for IV injection

Ophthalmic (Ocuflox): 3 mg/mL solution

Sparfloxacin (Zagam)

Oral: 200 mg tablets

Trovafloxacin (Trovan)

Oral: 100, 200 mg tablets

Intravenous: formulated as alatrovafloxacin 200 mg and 300 mg vials for IV infusion

Chapter 47. Antimycobacterial Drugs

Katzung PHARMACOLOGY, 9e > Section VIII. Chemotherapeutic Drugs > Chapter 47.
Antimycobacterial Drugs >

Antimycobacterial Drugs: Introduction

Most antibiotics are more effective against rapidly growing organisms than against slowly growing ones. Because mycobacteria are very slowly growing organisms, they are relatively resistant to antibiotics. Mycobacterial cells can also be dormant and thus completely resistant to many drugs—or killed only very slowly by the few drugs that are active. The lipid-rich mycobacterial cell wall is impermeable to many agents. A substantial proportion of mycobacterial organisms are intracellular, residing within macrophages, and inaccessible to drugs that penetrate poorly. Finally, mycobacteria are notorious for their ability to develop resistance to any single drug. Combinations of drugs are required to overcome these obstacles and to prevent emergence of resistance during the course of therapy. The response of mycobacterial infections to chemotherapy is slow, and treatment must be administered for months to years depending on which drugs are used. The various drugs used to treat tuberculosis, which is caused by *Mycobacterium tuberculosis* and the closely related *M bovis*, atypical mycobacterial infections, and leprosy, which is caused by *M leprae*, are described in this chapter.

Katzung PHARMACOLOGY, 9e > Section VIII. Chemotherapeutic Drugs > Chapter 47.
Antimycobacterial Drugs >

Drugs Used in Tuberculosis

Isoniazid (INH), rifampin, pyrazinamide, ethambutol, and streptomycin are the five first-line agents for treatment of tuberculosis (Table 47–1). Isoniazid and rifampin are the two most active drugs. An isoniazid-rifampin combination administered for 9 months will cure 95–98% of cases of tuberculosis caused by susceptible strains. The addition of pyrazinamide to an isoniazid-rifampin combination for the first 2 months allows the total duration of therapy to be reduced to 6 months without loss of efficacy (Table 47–2). In practice, therapy is initiated with a four-drug regimen of isoniazid, rifampin, pyrazinamide, and either ethambutol or streptomycin until susceptibility of the clinical isolate has been determined. Neither ethambutol nor streptomycin adds substantially to the overall activity of the regimen (ie, the duration of treatment cannot be further reduced if either drug is used), but they do provide additional coverage should the isolate prove to be resistant to isoniazid, rifampin, or both. Unfortunately, such resistance occurs in up to 10% of cases in the United States. Most patients with tuberculosis can be treated entirely as outpatients, with

hospitalization being required only for those who are seriously ill or who require diagnostic evaluation.

Table 47–1. Antimicrobials Used in the Treatment of Tuberculosis.	
Drug	Typical Adult Dosage ¹
First-line agents (in approximate order of preference)	
Isoniazid	300 mg/d
Rifampin	600 mg/d
Pyrazinamide	25 mg/kg/d
Ethambutol	15–25 mg/kg/d
Streptomycin	15 mg/kg/d
Second-line agents	
Amikacin	15 mg/kg/d
Aminosalicylic acid	8–12 g/d
Capreomycin	15 mg/kg/d
Ciprofloxacin	1500 mg/d, divided
Clofazimine	200 mg/d
Cycloserine	500–1000 mg/d, divided
Ethionamide	500–750 mg/d
Levofloxacin	500 mg/d
Rifabutin	300 mg/d ²
Rifapentine	600 mg once or twice weekly
¹ Assuming normal renal function. ² 150 mg/d if used concurrently with a protease inhibitor.	

Table 47–2. Recommended Duration of Therapy for Tuberculosis.	
Regimen (in Approximate Order of Preference)	Duration in Months
Isoniazid, rifampin, pyrazinamide	6
Isoniazid, rifampin	9
Rifampin, ethambutol, pyrazinamide	6
Rifampin, ethambutol	12
Isoniazid, ethambutol	18
All others	≥ 24

Isoniazid (INH)

Isoniazid is the most active drug for the treatment of tuberculosis caused by susceptible strains. It is a small (MW 137), simple molecule freely soluble in water. The structural similarity to pyridoxine is shown below.

In vitro, isoniazid inhibits most tubercle bacilli in a concentration of 0.2 µg/mL or less and is bactericidal for actively growing tubercle bacilli. Isoniazid is less effective against atypical mycobacterial species. Isoniazid is able to penetrate into phagocytic cells and thus is active against both extracellular and intracellular organisms.

Mechanism of Action & Basis of Resistance

Isoniazid inhibits synthesis of mycolic acids, which are essential components of mycobacterial cell walls. Isoniazid is a prodrug that is activated by KatG, the mycobacterial catalase-peroxidase. The activated form of isoniazid exerts its lethal effect by forming a covalent complex with an acyl carrier protein (AcpM) and KasA, a beta-ketoacyl carrier protein synthetase, which blocks mycolic acid synthesis. Resistance to isoniazid has been associated with mutations resulting in overexpression of *inhA*, which encodes an NADH-dependent acyl carrier protein reductase; mutation or deletion of *katG*; promoter mutations resulting in overexpression of *ahpC*, a putative virulence gene involved in protection of the cell from oxidative stress; and mutations in *kasA*. Overproducers of *inhA* express low-level isoniazid resistance and cross-resistance to ethionamide. *KatG* mutants express high-level isoniazid resistance and are usually not cross-resistant to ethionamide.

Resistant mutants occur in susceptible mycobacterial populations with a frequency of about 1 bacillus in 10⁶. Since tuberculous lesions often contain more than 10⁸ tubercle bacilli, resistant mutants are readily selected out if isoniazid is given as the sole drug. However, addition of a second independently acting drug, to which resistance also emerges at a frequency of 1 in 10⁶ to 1 in 10⁸, is effective. The odds that a bacillus is resistant to both drugs are approximately 1 in 10⁶ × 10⁶, or 1 in 10¹², which is several orders of magnitude more than the number of infecting organisms. Single-

drug therapy with isoniazid and failure to use isoniazid plus at least one other drug to which the infecting strain is susceptible (which is tantamount to single-drug therapy) has led to the 10–20% prevalence of isoniazid resistance in clinical isolates from the Caribbean and Southeast Asia. Currently, about 8–10% of primary clinical isolates in the United States are isoniazid-resistant.

Pharmacokinetics

Isoniazid is readily absorbed from the gastrointestinal tract. The administration of a 300-mg oral dose (5 mg/kg in children) results in peak plasma concentrations of 3–5 μ g/mL within 1–2 hours. Isoniazid diffuses readily into all body fluids and tissues. The concentration in the central nervous system and cerebrospinal fluid ranges between 20% and 100% of simultaneous serum concentrations.

Metabolism of isoniazid, especially acetylation by liver *N*-acetyltransferase, is genetically determined (see Chapter 4: Drug Biotransformation). The average concentration of isoniazid in the plasma of rapid acetylators is about one third to one half of that in slow acetylators and average half-lives are less than 1 hour and 3 hours, respectively. Rapid acetylators were once thought to be more prone to hepatotoxicity, but this has not been proved. More rapid clearance of isoniazid by rapid acetylators is of no therapeutic consequence when appropriate doses are administered daily, but subtherapeutic concentrations may occur if drug is administered as a once-weekly dose.

Isoniazid metabolites and a small amount of unchanged drug are excreted mainly in the urine. The dose need not be adjusted in renal failure, but one third to one half of the normal dose is recommended in severe hepatic insufficiency.

Clinical Uses

The usual dosage of isoniazid is 5 mg/kg/d, with a typical adult dose being 300 mg given once daily. Up to 10 mg/kg/d may be used for serious infections or if malabsorption is a problem. A 15 mg/kg dose, or 900 mg, may be used in a twice-weekly dosing regimen in combination with a second antituberculous agent (eg, rifampin 600 mg). Pyridoxine, 25–50 mg/d is recommended for those with conditions predisposing to neuropathy, an adverse effect of isoniazid. Isoniazid is usually given by mouth but can be given parenterally in the same dosage.

Isoniazid as a single agent is also indicated for treatment of latent tuberculosis, which is usually determined by a positive tuberculin skin test. Isoniazid is routinely recommended for individuals who are at greatest risk for developing active disease after being infected such as very young children, persons who test positive within 2 years after a documented negative skin test (ie, recent converters), and immunocompromised individuals, especially HIV-infected and AIDS patients. Isoniazid is also indicated for prevention of tuberculosis in close contacts of active cases of pulmonary tuberculosis. The dosage is 300 mg/d (5 mg/kg/d) or 900 mg twice weekly for 9 months.

Adverse Reactions

The incidence and severity of untoward reactions to isoniazid are related to dosage and duration of administration.

Allergic Reactions

Fever and skin rashes are occasionally seen. Drug-induced systemic lupus erythematosus has been reported.

Direct Toxicity

Isoniazid-induced hepatitis is the most frequent major toxic effect. This is distinct from the minor increases in liver aminotransferases (up to three or four times normal) seen in 10–20% of patients, who usually are asymptomatic. Such increases do not require cessation of the drug. Clinical hepatitis with loss of appetite, nausea, vomiting, jaundice, and right upper quadrant pain occurs in 1% of isoniazid recipients and can be fatal, particularly if the drug is not discontinued promptly. There is histologic evidence of hepatocellular damage and necrosis. The risk of hepatitis depends on age. It occurs rarely under age 20, in 0.3% of those aged 21–35, 1.2% of those aged 36–50, and 2.3% for those aged 50 and above. The risk of hepatitis is greater in alcoholics and possibly during pregnancy and the postpartum period. Development of isoniazid hepatitis contraindicates further use of the drug.

Peripheral neuropathy is observed in 10–20% of patients given dosages greater than 5 mg/kg/d but is infrequently seen with the standard 300 mg adult dose. It is more likely to occur in slow acetylators and patients with predisposing conditions such as malnutrition, alcoholism, diabetes, AIDS, and uremia. Neuropathy is due to a relative pyridoxine deficiency. Isoniazid promotes excretion of pyridoxine, and this toxicity is readily reversed by administration of pyridoxine in a dosage as low as 10 mg/d. Central nervous system toxicity, which is less common, includes memory loss, psychosis, and seizures. These may also respond to pyridoxine.

Miscellaneous other reactions include hematologic abnormalities, provocation of pyridoxine deficiency anemia, tinnitus, and gastrointestinal discomfort. Isoniazid can reduce the metabolism of phenytoin, increasing its blood level and toxicity.

Rifampin

Rifampin is a large (MW 823), complex semisynthetic derivative of rifamycin, an antibiotic produced by *Streptomyces mediterranei*. It is active in vitro against gram-positive and gram-negative cocci, some enteric bacteria, mycobacteria, and chlamydia. Susceptible organisms are inhibited by less than 1 µg/mL, but resistant mutants are present in all microbial populations at a frequency of approximately 1:10⁶. Administration of rifampin as a single drug selects for these highly resistant organisms. There is no cross-resistance to other classes of antimicrobial drugs, but there is cross-resistance to other rifamycin derivatives, eg, rifabutin.

Antimycobacterial Activity, Resistance, & Pharmacokinetics

Rifampin binds strongly to the β subunit of bacterial DNA-dependent RNA polymerase and thereby inhibits RNA synthesis. Resistance results from one of several possible point mutations in *rpoB*, the gene for the beta subunit of RNA polymerase. These mutations prevent binding of rifampin to RNA polymerase. Human RNA polymerase does not bind rifampin and is not inhibited by it. Rifampin is bactericidal for mycobacteria. It readily penetrates most tissues and into phagocytic cells. It can kill organisms that are poorly accessible to many other drugs, such as intracellular organisms and those sequestered in abscesses and lung cavities.

Rifampin is well absorbed after oral administration and excreted mainly through the liver into bile. It then undergoes enterohepatic recirculation, with the bulk excreted as a deacylated metabolite in feces and a small amount in the urine. Dosage adjustment for renal insufficiency is not necessary. Usual doses result in serum levels of 5–7 µg/mL. Rifampin is distributed widely in body fluids and tissues. Rifampin is relatively highly protein-bound, but adequate cerebrospinal fluid concentrations are achieved only in the presence of meningeal inflammation.

Clinical Uses

Mycobacterial Infections

Rifampin, usually 600 mg/d (10 mg/kg/d) orally, is administered together with isoniazid, ethambutol, or another antituberculous drug in order to prevent emergence of drug-resistant mycobacteria. In some short-course therapies, 600 mg of rifampin is given twice weekly. Rifampin 600 mg daily or twice weekly for 6 months also is effective in some atypical mycobacterial infections and in leprosy when used together with a sulfone. Rifampin is an alternative to isoniazid prophylaxis for patients who are unable to take isoniazid or who have had close contact with a case of active tuberculosis caused by an isoniazid-resistant, rifampin-susceptible strain.

Other Indications

Rifampin is used in a variety of other clinical situations. An oral dosage of 600 mg twice daily for 2 days can eliminate meningococcal carriage. Rifampin, 20 mg/kg/d for 4 days, is used as prophylaxis in contacts of children with *Haemophilus influenzae* type b disease. Rifampin combined with a second agent is used to eradicate staphylococcal carriage. Rifampin combination therapy is also indicated for treatment of serious staphylococcal infections such as osteomyelitis and prosthetic valve endocarditis. Rifampin has been recommended also for use in combination with ceftriaxone or vancomycin in treatment of meningitis caused by highly penicillin-resistant strains of pneumococci.

Adverse Reactions

Rifampin imparts a harmless orange color to urine, sweat, tears, and contact lenses (soft lenses may be permanently stained). Occasional adverse effects include rashes, thrombocytopenia, and nephritis. It may cause cholestatic jaundice and occasionally hepatitis. Rifampin commonly causes light chain proteinuria. If administered less often than twice weekly, rifampin causes a flu-like syndrome characterized by fever, chills, myalgias, anemia, thrombocytopenia, and sometimes is associated with acute tubular necrosis. Rifampin strongly induces most cytochrome P450 isoforms (CYP1A2, CYP2C9, CYP2C19, CYP2D6, and CYP3A4), which increases the elimination of numerous other drugs including methadone, anticoagulants, some anticonvulsants, protease inhibitors, and contraceptives. Likewise, administration of rifampin with ketoconazole, cyclosporine, or chloramphenicol results in significantly lower serum levels of these drugs. Ketoconazole in turn may reduce rifampin serum concentrations by interfering with absorption.

Ethambutol

Ethambutol is a synthetic, water-soluble, heat-stable compound, the dextro- isomer of the structure shown below, dispensed as the dihydrochloride salt.

Ethambutol

Susceptible strains of *M tuberculosis* and other mycobacteria are inhibited in vitro by ethambutol, 1–5 µg/mL. Ethambutol is an inhibitor of mycobacterial arabinosyl transferases, which are encoded

by the *embCAB* operon. Arabinosyl transferases are involved in the polymerization reaction of arabinoglycan, an essential component of the mycobacterial cell wall. Resistance to ethambutol is due to mutations resulting in overexpression of *emb* gene products or within the *embB* structural gene.

Ethambutol is well absorbed from the gut. Following ingestion of 25 mg/kg, a blood level peak of 2–5 µg/mL is reached in 2–4 hours. About 20% of the drug is excreted in feces and 50% in urine in unchanged form. Ethambutol accumulates in renal failure, and the dose should be reduced by half if creatinine clearance is less than 10 mL/min. Ethambutol crosses the blood-brain barrier only if the meninges are inflamed. Concentrations in cerebrospinal fluid are highly variable, ranging from 4% to 64% of serum levels in the setting of meningeal inflammation.

As with all antituberculous drugs, resistance to ethambutol emerges rapidly when the drug is used alone. Therefore, ethambutol is always given in combination with other antituberculous drugs.

Clinical Use

Ethambutol hydrochloride, 15–25 mg/kg, is usually given as a single daily dose in combination with isoniazid or rifampin. The higher dose is recommended for treatment of tuberculous meningitis. The dose of ethambutol is 50 mg/kg when a twice-weekly dosing schedule is used.

Adverse Reactions

Hypersensitivity to ethambutol is rare. The most common serious adverse event is retrobulbar neuritis causing loss of visual acuity and red-green color blindness. This dose-related side effect is more likely to occur at a dosage of 25 mg/kg/d continued for several months. With dosages of 15 mg/kg/d or less, visual disturbances are very rare. Periodic visual acuity testing is desirable if the 25 mg/kg/d dosage is used. Ethambutol is relatively contraindicated in children too young to permit assessment of visual acuity and red-green color discrimination.

Pyrazinamide

Pyrazinamide (PZA) is a relative of nicotinamide, stable, slightly soluble in water, and quite inexpensive. At neutral pH, it is inactive *in vitro*, but at pH 5.5 it inhibits tubercle bacilli and some other mycobacteria at concentrations of approximately 20 µg/mL. Drug is taken up by macrophages and exerts its activity against intracellular organisms residing within this acidic environment.

Pyrazinamide is converted to pyrazinoic acid, the active form of the drug, by mycobacterial pyrazinamidase, which is encoded by *pncA*. The drug target and mechanism of action are unknown. Resistance is due to mutations in *pncA* that impair conversion of pyrazinamide to its active form. Impaired uptake of pyrazinamide may also contribute to resistance.

Pyrazinamide (PZA)

Clinical Use

Serum concentrations of 30–50 $\mu\text{g}/\text{mL}$ at 1–2 hours after oral administration are achieved with dosages of 25 mg/kg/d. Pyrazinamide is well absorbed from the gastrointestinal tract and widely distributed in body tissues, including inflamed meninges. The half-life is 8–11 hours. A 50–70 mg/kg dose is used for twice-weekly or thrice-weekly treatment regimens. Pyrazinamide is an important front-line drug used in conjunction with isoniazid and rifampin in short-course (ie, 6-month) regimens as a "sterilizing" agent active against residual intracellular organisms that may cause relapse. Tubercle bacilli develop resistance to pyrazinamide fairly readily, but there is no cross-resistance with isoniazid or other antimycobacterial drugs.

Adverse Reactions

Major adverse effects of pyrazinamide include hepatotoxicity (in 1–5% of patients), nausea, vomiting, drug fever, and hyperuricemia. The latter occurs uniformly and is not a reason to halt therapy. Hyperuricemia may provoke acute gouty arthritis.

Streptomycin

The mechanism of action and other pharmacologic features of streptomycin have been discussed in Chapter 45: Aminoglycosides & Spectinomycin. Most tubercle bacilli are inhibited by streptomycin, 1–10 $\mu\text{g}/\text{mL}$, in vitro. Nontuberculosis species of mycobacteria other than *Mycobacterium avium* complex (MAC) and *Mycobacterium kansasii* are resistant. All large populations of tubercle bacilli contain some streptomycin-resistant mutants. On average, 1 in 10^8 tubercle bacilli can be expected to be resistant to streptomycin at levels of 10–100 $\mu\text{g}/\text{mL}$. Resistance is due to a point mutation in either the *rpsL* gene encoding the S12 ribosomal protein gene or *rrs*, encoding 16S ribosomal rRNA, that alters the ribosomal binding site.

Streptomycin penetrates into cells poorly, and consequently it is active mainly against extracellular tubercle bacilli. Additional drugs are needed to eliminate intracellular organisms, which constitute a significant proportion of the total mycobacterial burden. Streptomycin crosses the blood-brain barrier and achieves therapeutic concentrations with inflamed meninges.

Clinical Use in Tuberculosis

Streptomycin sulfate remains an important drug in the treatment of tuberculosis. It is employed when an injectable drug is needed or desirable, principally in individuals with severe, possibly life-threatening forms of tuberculosis, eg, meningitis and disseminated disease, and in treatment of infections resistant to other drugs. The usual dosage is 15 mg/kg/d intramuscularly or intravenously daily for adults (20–40 mg/kg/d, not to exceed 1–1.5 g, for children) for several weeks, followed by 1–1.5 g two or three times weekly for several months. Serum concentrations of approximately 40 $\mu\text{g}/\text{mL}$ are achieved 30–60 minutes after intramuscular injection of a 15 mg/kg dose. Other drugs are always given simultaneously to prevent emergence of resistance.

Adverse Reactions

Streptomycin is ototoxic and nephrotoxic. Vertigo and hearing loss are the most common side effects and may be permanent. Toxicity is dose-related, and the risk is increased in the elderly. As with all aminoglycosides, the dose must be adjusted according to renal function (see Chapter 45: Aminoglycosides & Spectinomycin). Toxicity can be reduced by limiting therapy to no more than 6 months whenever possible.

Alternative Second-Line Drugs for Tuberculosis

The alternative drugs listed below are usually considered only (1) in the case of resistance to the drugs of first choice (which occurs with increasing frequency); (2) in case of failure of clinical response to conventional therapy; and (3) when expert guidance is available to deal with the toxic effects. For many of the second-line drugs listed below, the dosage, emergence of resistance, and long-term toxicity have not been fully established.

Ethionamide

Ethionamide is chemically related to isoniazid and also blocks the synthesis of mycolic acids. It is poorly water soluble and available only in oral form. It is metabolized by the liver.

Ethionamide

Most tubercle bacilli are inhibited in vitro by ethionamide, 2.5 $\mu\text{g}/\text{mL}$, or less. Some other species of mycobacteria also are inhibited by ethionamide, 10 $\mu\text{g}/\text{mL}$. Serum concentrations in plasma and tissues of approximately 20 $\mu\text{g}/\text{mL}$ are achieved by a dosage of 1 g/d. Cerebrospinal fluid concentrations are equal to those in serum. A 1 g/d dosage, although effective in the treatment of tuberculosis, is poorly tolerated because of the intense gastric irritation and neurologic symptoms that commonly occur. Ethionamide is also hepatotoxic. Neurologic symptoms may be alleviated by pyridoxine.

Ethionamide is administered at an initial dosage of 250 mg once daily, which is increased in 250 mg increments to the recommended dosage of 1 g/d (or 15 mg/kg/d) if possible. The 1 g/d dosage, although theoretically desirable, is seldom tolerated, and one often must settle for a total daily dose of 500–750 mg.

Resistance to ethionamide as a single agent develops rapidly in vitro and in vivo. There can be low-level cross-resistance between isoniazid and ethionamide.

Capreomycin

Capreomycin is a peptide protein synthesis inhibitor antibiotic obtained from *Streptomyces capreolus*. Daily injection of 1 g intramuscularly results in blood levels of 10 $\mu\text{g}/\text{mL}$ or more. Such concentrations in vitro are inhibitory for many mycobacteria, including multidrug-resistant strains of *M tuberculosis*.

Capreomycin (15 mg/kg/d) is an important injectable agent for treatment of drug-resistant tuberculosis. Strains of *M tuberculosis* that are resistant to streptomycin or amikacin (eg, the multidrug-resistant W strain) usually are susceptible to capreomycin. Resistance to capreomycin, when it occurs, may be due to an *rrs* mutation.

Capreomycin is nephrotoxic and ototoxic. Tinnitus, deafness, and vestibular disturbances occur. The injection causes significant local pain, and sterile abscesses may occur.

Dosing of capreomycin is the same as streptomycin. Toxicity is reduced if 1 g is given two or three times weekly after an initial response has been achieved with a daily dosing schedule.

Cycloserine

Cycloserine is an inhibitor of cell wall synthesis and is discussed in Chapter 43: Beta-Lactam Antibiotics & Other Inhibitors of Cell Wall Synthesis. Concentrations of 15–20 $\mu\text{g}/\text{mL}$ inhibit many strains of *M tuberculosis*. The dosage of cycloserine in tuberculosis is 0.5–1 g/d in two divided doses. Cycloserine is cleared renally, and the dose should be reduced by half if creatinine clearance is less than 50 mL/min.

The most serious toxic effects are peripheral neuropathy and central nervous system dysfunction, including depression and psychotic reactions. Pyridoxine 150 mg/d should be given with cycloserine as this ameliorates neurologic toxicity. Adverse effects, which are most common during the first 2 weeks of therapy, occur in 25% or more of patients, especially at higher doses. Side effects can be minimized by monitoring peak serum concentrations. The peak concentration is reached 2–4 hours after dosing. The recommended range of peak concentrations is 20–40 $\mu\text{g}/\text{mL}$.

Aminosalicylic Acid (PAS)

Aminosalicylic acid is a folate synthesis antagonist that is active almost exclusively against *M tuberculosis*. It is structurally similar to *p*-aminobenzoic acid (PABA) and to the sulfonamides (see Chapter 46: Sulfonamides, Trimethoprim, & Quinolones).

Aminosalicylic acid (PAS)

Tubercle bacilli are usually inhibited in vitro by aminosalicylic acid, 1–5 $\mu\text{g}/\text{mL}$. Aminosalicylic acid is readily absorbed from the gastrointestinal tract. Serum levels are 50 $\mu\text{g}/\text{mL}$ or more after a 4 g oral dose. The dosage is 8–12 g/d orally for adults and 300 mg/kg/d for children. The drug is widely distributed in tissues and body fluids except the cerebrospinal fluid. Aminosalicylic acid is rapidly excreted in the urine, in part as active aminosalicylic acid and in part as the acetylated compound and other metabolic products. Very high concentrations of aminosalicylic acid are reached in the urine, which can result in crystalluria.

Aminosalicylic acid, formerly a first-line agent for treatment of tuberculosis, is used infrequently now because other oral drugs are better-tolerated. Gastrointestinal symptoms often accompany full doses of aminosalicylic acid. Anorexia, nausea, diarrhea, and epigastric pain and burning may be diminished by giving aminosalicylic acid with meals and with antacids. Peptic ulceration and hemorrhage may occur. Hypersensitivity reactions manifested by fever, joint pains, skin rashes, hepatosplenomegaly, hepatitis, adenopathy, and granulocytopenia, often occur after 3–8 weeks of aminosalicylic acid therapy, making it necessary to stop aminosalicylic acid administration temporarily or permanently.

Kanamycin & Amikacin

The aminoglycoside antibiotics are discussed in Chapter 45: Aminoglycosides & Spectinomycin. Kanamycin has been used for treatment of tuberculosis caused by streptomycin-resistant strains, but the availability of less toxic alternatives (eg, capreomycin and amikacin) have rendered it obsolete.

The role of amikacin in treatment of tuberculosis has increased with the increasing incidence and prevalence of multidrug-resistant tuberculosis. Prevalence of amikacin-resistant strains is low (less than 5%), and most multidrug-resistant strains remain amikacin-susceptible. *M tuberculosis* is inhibited at concentrations of 1 µg/mL or less. Amikacin is also active against atypical mycobacteria. There is no cross-resistance between streptomycin and amikacin, but kanamycin resistance often indicates resistance to amikacin as well. Serum concentrations of 30–50 µg/mL are achieved 30–60 minutes after a 15 mg/kg intravenous infusion. Amikacin is indicated for treatment of tuberculosis suspected or known to be caused by streptomycin-resistant or multidrug-resistant strains. Amikacin must be used in combination with at least one and preferably two or three other drugs to which the isolate is susceptible for treatment of drug-resistant cases. The recommended dosage is 15 mg/kg/d intramuscularly or intravenously daily for 5 days a week for the first 2 months of therapy and then 1–1.5 g two or three times weekly to complete a 6-month course.

Ciprofloxacin & Levofloxacin

These drugs are discussed in Chapter 46: Sulfonamides, Trimethoprim, & Quinolones. In addition to their activity against many gram-positive and gram-negative bacteria, ciprofloxacin and levofloxacin inhibit strains of *M tuberculosis* at concentrations less than 2 µg/mL. They are also active against atypical mycobacteria. Ofloxacin was used in the past, but levofloxacin is preferred because it is the L-isomer of ofloxacin (a racemic mixture of D- and L-stereoisomers), the active antibacterial component of ofloxacin, and it can be administered once daily. Levofloxacin tends to be slightly more active in vitro than ciprofloxacin against *M tuberculosis*; ciprofloxacin is slightly more active against atypical mycobacteria. Serum concentrations of 2–4 µg/mL and 4–8 µg/mL are achieved with standard oral doses of ciprofloxacin and levofloxacin, respectively.

Fluoroquinolones are an important recent addition to the drugs available for tuberculosis, especially for strains that are resistant to first-line agents. Resistance, which may result from any one of several single point mutations in the gyrase A subunit, develops rapidly if a fluoroquinolone is used as a single agent; thus, the drug must be used in combination with two or more other active agents. The standard dosage of ciprofloxacin is 750 mg orally twice a day. That of levofloxacin is 500–750 mg as a single daily dose.

Rifabutin (Ansamycin)

This antibiotic is derived from rifamycin and is related to rifampin. It has significant activity against *M tuberculosis*, *M avium-intracellulare* and *M fortuitum* (see below). Its activity is similar to that of rifampin, and cross-resistance with rifampin is virtually complete. Some rifampin-resistant strains may appear susceptible to rifabutin in vitro, but a clinical response is unlikely because the molecular basis of resistance, *rpoB* mutation, is the same. Rifabutin is both substrate and inducer of cytochrome P450 enzymes. Because it is a less potent inducer, rifabutin is indicated in place of rifampin for treatment of tuberculosis in HIV-infected patients who are receiving concurrent antiretroviral therapy with a protease inhibitor or nonnucleoside reverse transcriptase inhibitor (eg, efavirenz)—drugs which also are cytochrome P450 substrates. The usual dose of rifabutin is 300 mg/d unless the patient is receiving a protease inhibitor, in which case the dose should be reduced to 150 mg/d. If efavirenz (also a P450 inducer) is used, the recommended dose of rifabutin is 450

mg/d. (See Havlir 1999, and Centers 1998, for details.)

Rifabutin is effective in prevention and treatment of disseminated atypical mycobacterial infection in AIDS patients with CD4 counts below 50/ μ L. It is also effective for preventive therapy of tuberculosis, either alone in a 6-month regimen or with pyrazinamide in a 2-month regimen.

Rifapentine

Rifapentine is an analog of rifampin. It is active against both *M tuberculosis* and *M avium*. As with all rifamycins, it is a bacterial RNA polymerase inhibitor, and cross-resistance between rifampin and rifapentine is complete. Like rifampin, rifapentine is a potent inducer of cytochrome P450 enzymes, and it has the same drug interaction profile. Toxicity is similar to that of rifampin. Rifapentine and its microbiologically active metabolite, 25-desacetyl-rifapentine, have an elimination half-life of 13 hours. Rifapentine is indicated for treatment of tuberculosis caused by rifampin-susceptible strains. The dose is 600 mg once or twice weekly. Whether rifapentine is as effective as rifampin has not been established, and rifampin therefore remains the rifamycin of choice for treatment of tuberculosis.

Katzung PHARMACOLOGY, 9e > Section VIII. Chemotherapeutic Drugs > Chapter 47. Antimycobacterial Drugs >

Drugs Active Against Atypical Mycobacteria

About 10% of mycobacterial infections seen in clinical practice in the USA are caused not by *M tuberculosis* or *M leprae* but by nontuberculous or so-called "atypical" mycobacteria. These organisms have distinctive laboratory characteristics, occur in the environment, and are not communicable from person to person. Disease caused by these organisms is often less severe than tuberculosis. As a general rule, these mycobacterial species are less susceptible than *M tuberculosis* to antituberculous drugs. On the other hand, agents such as erythromycin, sulfonamides, or tetracycline, which are not effective against *M tuberculosis*, may be effective against atypical strains. Emergence of resistance during therapy is also a problem with these mycobacterial species, and active infection should be treated with combinations of drugs. *M kansasii* is susceptible to rifampin and ethambutol but relatively resistant to isoniazid and completely resistant to pyrazinamide. A three-drug combination of isoniazid, rifampin, and ethambutol is the conventional treatment for *M kansasii* infection. A few representative pathogens, with the clinical presentation and the drugs to which they are often susceptible, are given in Table 47–3.

Table 47–3. Clinical Features and Treatment Options for Infections with Atypical Mycobacteria.

Species	Clinical Features	Treatment Options
<i>M kansasii</i>	Resembles tuberculosis	Ciprofloxacin, clarithromycin, ethambutol, isoniazid, rifampin, trimethoprim-sulfamethoxazole
<i>M marinum</i>	Granulomatous cutaneous disease	Amikacin, clarithromycin, ethambutol, doxycycline, minocycline, rifampin, trimethoprim-sulfamethoxazole
<i>M scrofulaceum</i>	Cervical adenitis in children	Amikacin, erythromycin (or other macrolide), rifampin, streptomycin. (Surgical excision is

		often curative and the treatment of choice.)
<i>M avium</i> complex	Pulmonary disease in patients with chronic lung disease; disseminated infection in AIDS	Amikacin, azithromycin, clarithromycin, ciprofloxacin, ethambutol, ethionamide, rifabutin
<i>M chelonae</i>	Abscess, sinus tract, ulcer; bone, joint, tendon infection	Amikacin, doxycycline, imipenem, macrolides, tobramycin
<i>M fortuitum</i>	Abscess, sinus tract, ulcer; bone, joint, tendon infection	Amikacin, ceftioxin, ciprofloxacin, doxycycline, ofloxacin, trimethoprim-sulfamethoxazole
<i>M ulcerans</i>	Skin ulcers	Isoniazid, streptomycin, rifampin, minocycline. (Surgical excision may be effective.)

M avium complex (MAC), which includes both *M avium* and *M intracellulare*, is an important and common cause of disseminated disease in late stages of AIDS (CD4 counts < 50/ μ L).

Mycobacterium avium complex is much less susceptible than *M tuberculosis* to most antituberculous drugs. Combinations of agents are required to suppress the disease. Disseminated MAC is incurable and therapy is life-long if CD4 counts are below 200/ μ L. The need for multidrug therapy frequently leads to side effects that can be difficult to manage. Azithromycin, 500 mg once daily, or clarithromycin, 500 mg twice daily, plus ethambutol, 15 mg/kg/d, is an effective and well-tolerated regimen for treatment of disseminated disease. Some authorities recommend use of a third agent, such as ciprofloxacin 750 mg twice daily or rifabutin, 300 mg once daily. Other agents that may be useful are listed in Table 47–3. Rifabutin in a single daily dose of 300 mg has been shown to reduce the incidence of *M avium* complex bacteremia in AIDS patients with CD4 < 200/ μ L but may not offer a survival advantage. Clarithromycin also effectively prevents MAC bacteremia in AIDS patients, but if breakthrough bacteremia occurs, the isolate often is resistant to both clarithromycin and azithromycin, precluding the use of the most effective drugs for treatment.

Antimycobacterial Drugs >

Drugs Used in Leprosy

Mycobacterium leprae has never been grown in vitro, but animal models, such as growth in injected mouse footpads, have permitted laboratory evaluation of drugs. Only those drugs that have the widest clinical use are presented here. Because of increasing reports of dapsone resistance, treatment of leprosy with combinations of the drugs listed below is recommended.

Dapsone & Other Sulfones

Several drugs closely related to the sulfonamides have been used effectively in the long-term treatment of leprosy. The most widely used is dapsone (diaminodiphenylsulfone). Like the sulfonamides, it inhibits folate synthesis. Resistance can emerge in large populations of *M leprae*, eg, in lepromatous leprosy, if very low doses are given. Therefore, the combination of dapsone, rifampin, and clofazimine is recommended for initial therapy. Dapsone may also be used to prevent and treat *Pneumocystis jiroveci* pneumonia in AIDS.

Sulfones are well absorbed from the gut and widely distributed throughout body fluids and tissues. Dapsone's half-life is 1–2 days, and drug tends to be retained in skin, muscle, liver, and kidney. Skin heavily infected with *M leprae* may contain several times as much of the drug as normal skin. Sulfones are excreted into bile and reabsorbed in the intestine. Excretion into urine is variable, and most excreted drug is acetylated. In renal failure, the dose may have to be adjusted. The usual adult dosage in leprosy is 100 mg daily. For children, the dose is proportionately less depending on weight.

Dapsone is usually well tolerated. Many patients develop some hemolysis, particularly if they have glucose-6-phosphate dehydrogenase deficiency. Methemoglobinemia is common, but usually is not a problem clinically. Gastrointestinal intolerance, fever, pruritus, and various rashes occur. During dapsone therapy of lepromatous leprosy, erythema nodosum leprosum often develops. It is sometimes difficult to distinguish reactions to dapsone from manifestations of the underlying illness. Erythema nodosum leprosum may be suppressed by **corticosteroids** or by **thalidomide**.

Rifampin

This drug (see Rifapentine) in a dosage of 600 mg daily can be strikingly effective in lepromatous leprosy. Because of the probable risk of emergence of rifampin-resistant *M leprae*, the drug is given in combination with dapsone or another antileprosy drug. A single monthly dose of 600 mg may be beneficial in combination therapy.

Clofazimine

Clofazimine is a phenazine dye that can be used as an alternative to dapsone. Its mechanism of action is unknown but may involve DNA binding.

Absorption of clofazimine from the gut is variable, and a major portion of the drug is excreted in feces. Clofazimine is stored widely in reticuloendothelial tissues and skin, and its crystals can be seen inside phagocytic reticuloendothelial cells. It is slowly released, so that the serum half-life may be 2 months.

Clofazimine is given for sulfone-resistant leprosy or when patients are intolerant to sulfone. A common dosage is 100 mg/d orally. The most prominent untoward effect is skin discoloration ranging from red-brown to nearly black. Gastrointestinal intolerance occurs occasionally.

Preparations Available

Drugs Used in Tuberculosis

Aminosalicylate sodium (Paser)

Oral: 4 g delayed release granules

Capreomycin(Capastat Sulfate)

Parenteral: 1 g powder to reconstitute for injection

Cycloserine(Seromycin Pulvules)

Oral: 250 mg capsules

Ethambutol(Myambutol)

Oral: 100, 400 mg tablets

Ethionamide(Trecator-SC)

Oral: 250 mg tablets

Isoniazid (generic)

Oral: 50, 100, 300 mg tablets; syrup, 50 mg/5 mL

Parenteral: 100 mg/mL for injection

Pyrazinamide (generic)

Oral: 500 mg tablets

Rifabutin(Mycobutin)

Oral: 150 mg capsules

Rifampin(generic, Rifadin, Rimactane)

Oral: 150, 300 mg capsules

Parenteral: 600 mg powder for IV injection

Rifapentine (Priftin)

Oral: 150 mg tablets

Streptomycin (generic)

Parenteral: 1 g lyophilized for IM injection

Drugs Used in Leprosy

Clofazimine(Lamprene)

Oral: 50 mg capsules

Dapsone(generic)

Oral: 25, 100 mg tablets

Chapter 48. Antifungal Agents

Katzung PHARMACOLOGY, 9e > Section VIII. Chemotherapeutic Drugs > Chapter 48.
Antifungal Agents >

Antifungal Agents: Introduction

Human fungal infections have increased dramatically in incidence and severity in recent years, due mainly to advances in surgery, cancer treatment, and critical care accompanied by increases in the use of broad-spectrum antimicrobials and the HIV epidemic. These changes have resulted in increased numbers of patients at risk for fungal infections.

Pharmacotherapy of fungal disease has been revolutionized by the introduction of the relatively nontoxic oral azole drugs and the echinocandins. Combination therapy is being reconsidered, and new formulations of old agents are becoming available. Unfortunately, the appearance of azole-resistant organisms, as well as the rise in the number of patients at risk for mycotic infections, has created new challenges

The antifungal drugs presently available fall into several categories: systemic drugs (oral or parenteral) for systemic infections, oral drugs for mucocutaneous infections, and topical drugs for mucocutaneous infections.

Katzung PHARMACOLOGY, 9e > Section VIII. Chemotherapeutic Drugs > Chapter 48.
Antifungal Agents >

Systemic Antifungal Drugs for Systemic Infections

Amphotericin B

Amphotericin A and B are antifungal antibiotics produced by *Streptomyces nodosus*. Amphotericin A is not in clinical use.

Chemistry

Amphotericin B is an amphoteric polyene macrolide (polyene = containing many double bonds; macrolide = containing a large lactone ring of 12 or more atoms). It is nearly insoluble in water, and is therefore prepared as a colloidal suspension of amphotericin B and sodium desoxycholate for intravenous injection. Several new formulations have been developed in which amphotericin B is packaged in a lipid-associated delivery system (see Table 48–1 and Liposomal Amphotericin B).

Table 48–1. Properties of Conventional Amphotericin B and Some Lipid Formulations.¹

Drug	Physical Form	Dosing (mg/kg/d)	C _{max}	Clearance	Nephrotoxicity	Infusional Toxicity	Daily Cost
Conventional formulation							
Fungizone	Micelles	1	—	—	—	—	24
Lipid formulations							
AmBisome	Spheres	3–5	↑	↓	↓	↓	1300
Amphotec	Disks	5	↓	↑	↓	↑(?)	660
Abelcet	Ribbons	5	↓	↑	↓	↓(?)	570

¹Changes in C_{max} (peak plasma concentration), clearance, nephrotoxicity, and infusional toxicity are relative to conventional amphotericin B.

Pharmacokinetics

Amphotericin B is poorly absorbed from the gastrointestinal tract. Oral amphotericin B is thus effective only on fungi within the lumen of the tract and cannot be used for treatment of systemic disease. The intravenous injection of 0.6 mg/kg/d of amphotericin B results in average blood levels of 0.3–1 µg/mL; the drug is more than 90% bound by serum proteins. While it is mostly metabolized, some amphotericin B is excreted slowly in the urine over a period of several days. The serum *t*_{1/2} is approximately 15 days. Hepatic impairment, renal impairment, and dialysis have little impact on drug concentrations and therefore no dose adjustment is required. The drug is widely distributed in most tissues, but only 2–3% of the blood level is reached in cerebrospinal fluid, thus occasionally necessitating intrathecal therapy for certain types of fungal meningitis.

Mechanism of Action

Amphotericin B is selective in its fungicidal effect because it exploits the difference in lipid composition of fungal and mammalian cell membranes. **Ergosterol**, a cell membrane sterol, is found in the cell membrane of fungi, whereas the predominant sterol of bacteria and human cells is **cholesterol**. Amphotericin B binds to ergosterol and alters the permeability of the cell by forming amphotericin B-associated pores in the cell membrane. As suggested by its chemistry, amphotericin B combines avidly with lipids (ergosterol) along the double bond-rich side of its structure and associates with water molecules along the hydroxyl-rich side. This amphipathic characteristic facilitates pore formation by multiple amphotericin molecules, with the lipophilic portions around the outside of the pore and the hydrophilic regions lining the inside. The pore allows the leakage of intracellular ions and macromolecules, eventually leading to cell death. Some binding to human

membrane sterols does occur, probably accounting for the drug's prominent toxicity.

Resistance to amphotericin B occurs if ergosterol binding is impaired, either by decreasing the membrane concentration of ergosterol or by modifying the sterol target molecule to reduce its affinity for the drug.

Adverse Effects

The toxicity of amphotericin B can be divided into two broad categories: immediate reactions, related to the infusion of the drug, and those occurring more slowly.

Infusion-Related Toxicity

These reactions are nearly universal and consist of fever, chills, muscle spasms, vomiting, headache, and hypotension. They can be ameliorated by slowing the infusion rate or decreasing the daily dose. Premedication with antipyretics, antihistamines, meperidine, or corticosteroids can be helpful. When starting therapy, many clinicians administer a test dose of 1 mg intravenously to gauge the severity of the reaction. This can serve as a guide to an initial dosing regimen and premedication strategy.

Slower Toxicity

Renal damage is the most significant toxic reaction. Renal impairment occurs in nearly all patients treated with clinically significant doses of amphotericin. The degree of azotemia is variable and often stabilizes during therapy, but can be serious enough to necessitate dialysis. A reversible component is associated with decreased renal perfusion and represents a form of prerenal renal failure. An irreversible component results from renal tubular injury and subsequent dysfunction. The irreversible form of amphotericin nephrotoxicity usually occurs in the setting of prolonged administration (> 4 g cumulative dose). Renal toxicity commonly presents with renal tubular acidosis and severe potassium and magnesium wasting. There is some evidence that the prerenal component can be attenuated with sodium loading, and it is common practice to administer normal saline infusions with the daily doses of amphotericin B.

Abnormalities of liver function tests are occasionally seen, as is a varying degree of anemia due to reduced erythropoietin production by damaged renal tubular cells. After intrathecal therapy with amphotericin, seizures and a chemical arachnoiditis may develop, often with serious neurologic sequelae.

Antifungal Activity

Amphotericin B remains the antifungal agent with the broadest spectrum of action. It has activity against the clinically significant yeasts, including *Candida albicans* and *Cryptococcus neoformans*; the organisms causing endemic mycoses, including *Histoplasma capsulatum*, *Blastomyces dermatitidis*, and *Coccidioides immitis*; and the pathogenic molds, such as *Aspergillus fumigatus* and mucor. Some fungal organisms such as *Candida lusitanae* and *Pseudallescheria boydii* display intrinsic amphotericin B resistance.

Clinical Use

Owing to its broad spectrum of activity and fungicidal action, amphotericin B remains the drug of choice for nearly all life-threatening mycotic infections. It is often used as the initial induction

regimen for serious fungal infections and is then replaced by one of the newer azole drugs (see Azoles) for chronic therapy or prevention of relapse. Such induction therapy is especially important for immunosuppressed patients and those with severe fungal pneumonia, cryptococcal meningitis with altered mental status, or sepsis syndrome due to fungal infection. Once a clinical response has been elicited, these patients will then often continue maintenance therapy with an azole; therapy may be lifelong in patients at high risk for disease relapse. Amphotericin has also been used as empiric therapy for selected patients in whom the risks of leaving a systemic fungal infection untreated are high. The most common such patient is the cancer patient with neutropenia who remains febrile on broad-spectrum antibiotics.

For treatment of systemic fungal disease, amphotericin B is given by slow intravenous infusion at a dosage of 0.5–1 mg/kg/d. It is usually continued to a defined total dose (eg, 1–2 g), rather than a defined time span, as used with other antimicrobial drugs.

Intrathecal therapy for fungal meningitis is poorly tolerated and fraught with difficulties related to maintaining cerebrospinal fluid access. Thus, intrathecal therapy with amphotericin B is being increasingly supplanted by other therapies but remains an option in cases of fungal central nervous system infections that have not responded to other agents.

Local administration of amphotericin B has been used with success. Mycotic corneal ulcers and keratitis can be cured with topical drops as well as by direct subconjunctival injection. Fungal arthritis has been treated with adjunctive local injection directly into the joint. Candiduria responds to bladder irrigation with amphotericin B, and this route has been shown to produce no significant systemic toxicity.

Flucytosine

Flucytosine (5-FC) was discovered in 1957 during a search for novel antineoplastic agents. While devoid of anticancer properties, it became apparent that it was a potent antifungal agent. Flucytosine is a water-soluble pyrimidine analog related to the chemotherapeutic agent fluorouracil (5-FU). Its spectrum of action is much narrower than that of amphotericin B.

Flucytosine

Pharmacokinetics

Flucytosine is currently available in North America only in an oral formulation. The dosage is 100–150 mg/kg/d in patients with normal renal function. It is well (> 90%) absorbed, with serum concentrations peaking 1–2 hours after an oral dose. It is poorly protein-bound and penetrates well into all body fluid compartments, including the cerebrospinal fluid. It is eliminated by glomerular filtration with a half-life of 3–4 hours and is removed by hemodialysis. Levels rise rapidly with renal impairment and can lead to toxicity. Toxicity is more likely to occur in AIDS patients and in the presence of renal insufficiency. Peak serum concentrations should be measured periodically in

patients with renal insufficiency and maintained between 50 and 100 $\mu\text{g/mL}$.

Mechanism of Action

Flucytosine is taken up by fungal cells via the enzyme cytosine permease. It is converted intracellularly first to 5-FU and then to 5-fluorodeoxyuridine monophosphate (F-dUMP) and fluorouridine triphosphate (FUTP), which inhibit DNA and RNA synthesis, respectively. Human cells are unable to convert the parent drug to its active metabolites.

Synergy with amphotericin B has been demonstrated in vitro and in vivo. It may be related to enhanced penetration of the flucytosine through amphotericin-damaged fungal cell membranes. In vitro synergy with azole drugs has also been seen, although the mechanism is unclear.

Resistance is thought to be mediated through altered metabolism of flucytosine, and, while uncommon in primary isolates, it develops rapidly in the course of flucytosine monotherapy.

Adverse Effects

The adverse effects of flucytosine result from metabolism (possibly by intestinal flora) to the toxic antineoplastic compound fluorouracil. Bone marrow toxicity with anemia, leukopenia, and thrombocytopenia are the most common adverse effects, with derangement of liver enzymes occurring less frequently. A form of toxic enterocolitis can occur. There seems to be a narrow therapeutic window, with an increased risk of toxicity at higher drug levels and resistance developing rapidly at subtherapeutic concentrations. The use of drug concentration measurements may be helpful in reducing the incidence of toxic reactions, especially when flucytosine is combined with nephrotoxic agents such as amphotericin B.

Clinical Use

The spectrum of activity of flucytosine is restricted to *Cryptococcus neoformans*, some candida species, and the dematiaceous molds that cause chromoblastomycosis. Flucytosine is not used as a single agent because of its demonstrated synergy with other agents and to avoid the development of secondary resistance. Clinical use at present is confined to combination therapy, either with amphotericin B for cryptococcal meningitis or with itraconazole for chromoblastomycosis.

Azoles

Azoles are synthetic compounds that can be classified as either imidazoles or triazoles according to the number of nitrogen atoms in the five-membered azole ring as indicated below. The imidazoles consist of ketoconazole, miconazole, and clotrimazole (Figure 48–1). The latter two drugs are now used only in topical therapy. The triazoles include itraconazole, fluconazole, and voriconazole.

Triazole nucleus

Figure 48-1.

Structural formulas of some antifungal azoles.

Pharmacology

The pharmacology of each of the azoles is unique and accounts for some of the variations in clinical use. Table 48-2 summarizes the differences among four of the azoles.

Table 48–2. Pharmacologic Properties of Four Systemic Azole Drugs.

	Water Solubility	Absorption	CSF:Serum Concentration Ratio	t_{1/2} (Hours)	Elimination	Formulations
Ketoconazole	Low	Variable	< 0.1	7–10	Hepatic	Oral
Itraconazole	Low	Variable	< 0.01	24–42	Hepatic	Oral, IV
Fluconazole	High	High	> 0.7	22–31	Renal	Oral, IV
Voriconazole	High	High	...	6	Hepatic	Oral, IV

Mechanism of Action

The antifungal activity of azole drugs results from the reduction of ergosterol synthesis by inhibition of fungal cytochrome P450 enzymes. The specificity of azole drugs results from their greater affinity for fungal than for human cytochrome P450 enzymes. Imidazoles exhibit a lesser degree of specificity than the triazoles, accounting for their higher incidence of drug interactions and side effects.

Resistance to azoles occurs via multiple mechanisms. Once rare, increasing numbers of resistant strains are being reported, suggesting that increasing use of these agents for prophylaxis and therapy may be selecting for clinical drug resistance in certain settings.

Clinical Use

The spectrum of action of these medications is quite broad, ranging from many candida species, *Cryptococcus neoformans*, the endemic mycoses (blastomycosis, coccidioidomycosis, histoplasmosis), the dermatophytes, and, in the case of itraconazole and voriconazole, even aspergillus infections. They are also useful in the treatment of intrinsically amphotericin-resistant organisms such as *Pseudallescheria boydii*.

Adverse Effects

As a group, the azoles are relatively nontoxic. The most common adverse reaction is relatively minor gastrointestinal upset. All azoles have been reported to cause abnormalities in liver enzymes and, very rarely, clinical hepatitis. Adverse effects specific to individual agents are discussed below.

Drug Interactions

All azole drugs affect the mammalian cytochrome P450 system of enzymes to some extent, and consequently they are prone to drug interactions. The most significant reactions are indicated below.

Ketoconazole

Ketoconazole was the first oral azole introduced into clinical use. It is distinguished from triazoles by its greater propensity to inhibit mammalian cytochrome P450 enzymes, ie, it is less selective for fungal P450 than are the newer azoles. As a result, systemic ketoconazole has fallen out of clinical

use in the USA and will not be discussed in any detail here. Its dermatologic use is discussed in Chapter 62: Dermatologic Pharmacology.

Itraconazole

Itraconazole is available in oral and intravenous formulations and is used at a dosage of 100–400 mg/d. Drug absorption is increased by food and by low gastric pH. Like other lipid-soluble azoles, it interacts with hepatic microsomal enzymes, though to a lesser degree than ketoconazole. An important drug interaction is reduced bioavailability of itraconazole when taken with rifamycins (rifampin, rifabutin, rifapentine). It does not affect mammalian steroid synthesis, and its effects on the metabolism of other hepatically cleared medications are much less than those of ketoconazole. While itraconazole displays potent antifungal activity, effectiveness can be limited by reduced bioavailability. Newer formulations, including an oral liquid and an intravenous preparation, have utilized cyclodextran as a carrier molecule to enhance solubility and bioavailability. Like ketoconazole, it penetrates poorly into the cerebrospinal fluid. Itraconazole is the azole of choice for treatment of disease due to the dimorphic fungi *histoplasma*, *blastomyces*, and *sporothrix*. While itraconazole has activity against *aspergillus* species, this agent has been replaced by voriconazole as the azole of choice for aspergillosis. Itraconazole is used extensively in the treatment of dermatophytoses and onychomycosis.

Fluconazole

Fluconazole displays a high degree of water solubility and good cerebrospinal fluid penetration. Unlike ketoconazole and itraconazole, its oral bioavailability is high. Drug interactions are also less common because fluconazole has the least effect of all the azoles on hepatic microsomal enzymes. Because of fewer hepatic enzyme interactions and better gastrointestinal tolerance, fluconazole has the widest therapeutic index of the azoles, permitting more aggressive dosing in a variety of fungal infections. The drug is available in oral and intravenous formulations and is used at a dosage of 100–800 mg/d.

Fluconazole is the azole of choice in the treatment and secondary prophylaxis of cryptococcal meningitis. Intravenous fluconazole has been shown to be equivalent to amphotericin B in treatment of candidemia in ICU patients with normal white blood cell counts. Fluconazole is the agent most commonly used for the treatment of mucocutaneous candidiasis. Activity against the dimorphic fungi is limited to coccidioidal disease, and in particular for meningitis, where high doses of fluconazole often obviate the need for intrathecal amphotericin B. Fluconazole displays no activity against *aspergillus* or other filamentous fungi.

Prophylactic use of fluconazole has been demonstrated to reduce fungal disease in bone marrow transplant recipients and AIDS patients, but the emergence of fluconazole-resistant fungi has raised concerns about this indication.

Voriconazole

Voriconazole is the newest triazole to be licensed in the USA. It is available in intravenous and oral formulations. The recommended dosage is 400 mg/d. The drug is well absorbed orally, with a bioavailability exceeding 90%, and exhibits less protein binding than itraconazole. Metabolism is predominantly hepatic, but the propensity for inhibition of mammalian P450 appears to be low. Observed toxicities include rash, elevated hepatic enzymes, and transient visual disturbances. Visual disturbances are common, occurring in up to 30% of patients receiving voriconazole, and include blurring and changes in color vision or brightness. These visual changes usually occur

immediately after a dose of voriconazole and resolve within 30 minutes.

Voriconazole is similar to itraconazole in its spectrum of action, having excellent activity against candida species (including fluconazole-resistant species such as *C krusei*) and the dimorphic fungi. Voriconazole is less toxic than amphotericin B and may be more effective in the treatment of invasive aspergillosis.

Echinocandins

Echinocandins are the newest class of antifungal agent to be developed. They are large cyclic peptides linked to a long-chain fatty acid. **Caspofungin** is the only licensed agent in this category of antifungals, although several related agents are under active investigation.

Pharmacology

Caspofungin is available only in an intravenous form. The drug is administered as a single loading dose of 70 mg, followed by a daily dose of 50 mg. Caspofungin is water-soluble and highly protein-bound. The half-life is 9–11 hours, and the metabolites are excreted by the kidneys and gastrointestinal tract. Dosage adjustments are required only in the presence of severe hepatic insufficiency.

Mechanism of Action

Caspofungin acts at the level of the fungal cell wall by inhibiting the synthesis of $\beta(1-3)$ glucan. This results in disruption of the fungal cell wall and cell death.

Adverse Effects

Caspofungin is extremely well tolerated, with minor gastrointestinal side effects and flushing reported infrequently. Elevated liver enzymes have been noted in several patients receiving caspofungin in combination with cyclosporine, and this combination should be avoided.

Clinical Use

Caspofungin is currently licensed only for salvage therapy in patients with invasive aspergillosis who have failed to respond to amphotericin B. Clinical studies indicate that caspofungin is active also against candida species in the setting of mucocutaneous candidiasis and candidal bloodstream infections.

Katzung PHARMACOLOGY, 9e > Section VIII. Chemotherapeutic Drugs > Chapter 48.
Antifungal Agents >

Liposomal Amphotericin B

Therapy with amphotericin B is often limited by toxicity, especially drug-induced renal impairment. This has led to the development of lipid drug formulations on the assumption that lipid-packaged drug will bind to the mammalian membrane less readily, permitting the use of effective doses of the drug with lower toxicity. Liposomal amphotericin preparations package the active drug in lipid delivery vehicles, in contrast to the colloidal suspensions currently in use. Amphotericin binds to the lipids in these vehicles with an affinity between that for fungal ergosterol and that for human cholesterol. The lipid vehicle then serves as an amphotericin reservoir, reducing nonspecific binding

to human cell membranes. This preferential binding allows for a reduction of toxicity without sacrificing efficacy and permits use of larger doses. Furthermore, some fungi contain lipases that may liberate free amphotericin B directly at the site of infection.

Three such formulations are now available and have differing pharmacologic properties as summarized in Table 48–1. While clinical trials have demonstrated different renal and infusion-related toxicities for these preparations compared with regular amphotericin B, there are no trials comparing the different formulations with each other. Limited studies have suggested at best a moderate improvement in the clinical efficacy of the lipid formulations compared to conventional amphotericin B. Because the lipid preparations are much more expensive, their use is usually restricted to patients intolerant to, or not responding to, conventional amphotericin treatment.

Katzung PHARMACOLOGY, 9e > Section VIII. Chemotherapeutic Drugs > Chapter 48.
Antifungal Agents >

Systemic Antifungal Drugs for Mucocutaneous Infections

Griseofulvin

Griseofulvin is a very insoluble fungistatic drug derived from a species of penicillium. Its only use is in the systemic treatment of dermatophytosis (Chapter 62: Dermatologic Pharmacology). It is administered in a microcrystalline form at a dosage of 1 g/d. Absorption is improved when it is given with fatty foods. Griseofulvin's mechanism of action at the cellular level is unclear, but it is deposited in newly forming skin where it binds to keratin, protecting the skin from new infection. Since its action is to prevent infection of these new skin structures, it must be administered for 2–6 weeks for skin and hair infections to allow the replacement of infected keratin by the resistant structures. Nail infections may require therapy for months to allow regrowth of the new protected nail and is often followed by relapse. Adverse effects include an allergic syndrome much like serum sickness, hepatitis, and drug interactions with warfarin and phenobarbital. Griseofulvin has been largely replaced by newer antifungal medications such as itraconazole and terbinafine.

Terbinafine

Terbinafine is a synthetic allylamine that is available in an oral formulation and is used at a dosage of 250 mg/d. It is used in the treatment of dermatophytoses, especially onychomycosis (see Chapter 62: Dermatologic Pharmacology). Like griseofulvin, it is a keratophilic medication, but unlike griseofulvin, it is fungicidal. Like the azole drugs, it interferes with ergosterol biosynthesis, but rather than interacting with the P450 system, terbinafine inhibits the fungal enzyme squalene epoxidase. This leads to the accumulation of the sterol squalene, which is toxic to the organism. One tablet given daily for 12 weeks achieves a cure rate of up to 90% for onychomycosis and is more effective than griseofulvin or itraconazole. Adverse effects are rare, consisting primarily of gastrointestinal upset and headache. Terbinafine does not seem to affect the P450 system and has demonstrated no significant drug interactions to date.

Antifungal Agents >

Topical Antifungal Therapy

Nystatin

Nystatin is a polyene macrolide much like amphotericin B. It is too toxic for parenteral administration and is only used topically. It is currently available in creams, ointments, suppositories, and other forms for application to skin and mucous membranes. Nystatin is not absorbed to a significant degree from skin, mucous membranes, or the gastrointestinal tract. As a result, it has little toxicity, though oral use is often limited by the unpleasant taste.

Nystatin is active against most candida species and is most commonly used for suppression of local candidal infections. Some common indications include oropharyngeal thrush, vaginal candidiasis, and intertriginous candidal infections.

Topical Azoles

The two azoles most commonly used topically are clotrimazole and miconazole; several others are available (see Preparations Available). Both are available over-the-counter and are often used for vulvovaginal candidiasis. Oral clotrimazole troches are available for treatment of oral thrush and are a pleasant-tasting alternative to nystatin. In cream form, both agents are useful for dermatophytic infections, including tinea corporis, tinea pedis, and tinea cruris. Absorption is negligible, and adverse effects are rare.

Topical and shampoo forms of ketoconazole are also available and useful in the treatment of seborrheic dermatitis and pityriasis versicolor. Several other azoles are available for topical use (see Preparations Available).

Topical Allylamines

Terbinafine and naftifine are allylamines available as topical creams (see Chapter 62: Dermatologic Pharmacology). Both are effective for treatment of tinea cruris and tinea corporis. These are prescription drugs in the USA.

Katzung PHARMACOLOGY, 9e > Section VIII. Chemotherapeutic Drugs > Chapter 48.
Antifungal Agents >

Preparations Available

Amphotericin B

Parenteral:

Conventional formulation (Amphotericin B, Fungizone): 50 mg powder for injection

Lipid formulations:

(Abelcet): 100 mg/20 mL suspension for injection

(AmBisome): 50 mg powder for injection

(Amphotec): 50, 100 mg powder for injection

Topical: 3% cream, lotion, ointment

Butaconazole (Femstat, Mycelex-3)

Topical: 2% vaginal cream

Butenafine (Mentax)

Topical: 1% cream

Caspofungin (Cancidas)

Parenteral: 50, 70 mg powder for injection

Clotrimazole (Lotrimin, others)

Topical: 1% cream, solution, lotion; 100, 200 mg vaginal suppositories

Econazole (Spectazole)

Topical: 1% cream

Fluconazole (Diflucan)

Oral: 50, 100, 150, 200 mg tablets; powder for 10, 40 mg/mL suspension

Parenteral: 2 mg/mL in 100 and 200 mL vials

Flucytosine (Ancobon)

Oral: 250, 500 mg capsules

Griseofulvin (Grifulvin, Grisactin, Fulvicin P/G)

Oral microsize: 125, 250 mg capsules; 250 mg tablets, 125 mg/5 mL suspension

Oral ultramicrosize:* 125, 165, 250, 330 mg tablets

* Ultramicrosize formulations of griseofulvin are approximately 1.5 times more potent, milligram for milligram, than the microsize preparations.

Itraconazole (Sporanox)

Oral: 100 mg capsules; 10 mg/mL solution

Parenteral: 10 mg/mL for IV infusion

Ketoconazole (generic, Nizoral)

Oral: 200 mg tablets

Topical: 2% cream, shampoo

Miconazole (Micatin, others)

Topical: 2% cream, powder, spray; 100, 200 mg vaginal suppositories

Naftifine (Naftin)

Topical: 1% cream, gel

Natamycin (Natacyn)

Topical: 5% ophthalmic suspension

Nystatin (generic, Mycostatin)

Oral: 500,000 unit tablets

Topical: 100,000 units/g cream, ointment, powder; 100,000 units vaginal tablets

Oxiconazole (Oxistat)

Topical: 1% cream, lotion

Sulconazole (Exelderm)

Topical: 1% cream, lotion

Terbinafine (Lamisil)

Oral: 250 mg tablets

Topical: 1% cream, gel

Terconazole (Terazol 3, Terazol 7)

Topical: 0.4%, 0.8% vaginal cream; 80 mg vaginal suppositories

Tioconazole (Vagistat-1)

Topical: 6.5% vaginal ointment

Tolnaftate (generic, Aftate, Tinactin)

Topical: 1% cream, gel, solution, aerosol powder

Voriconazole (Vfend)

Oral: 50, 200 mg tablets

Parenteral: 200 mg vials, reconstituted to a 5 mg/mL solution

Antiviral Agents >

Acronyms & Other Names

3TC: Lamivudine
ara-A: Vidarabine
AZT: Zidovudine (previously azidothymidine)
CMV: Cytomegalovirus
CYP: Cytochrome P450
d4T: Stavudine
ddC: Zalcitabine
ddl: Didanosine
EBV: Epstein-Barr virus
HAART: Highly active antiretroviral therapy
HBV: Hepatitis B virus
HCV: Hepatitis C virus
HHV-6, -8: Human herpesvirus-6, -8
HIV: Human immunodeficiency virus
HSV-1, -2: Herpes simplex virus-1, -2
IDU, IDUR: Idoxuridine
IFN: Interferon
NNRTI: Nonnucleoside reverse transcriptase inhibitor
NRTI: Nucleoside reverse transcriptase inhibitor
PI: Protease inhibitor
RSV: Respiratory syncytial virus
VZV: Varicella-zoster virus

Antiviral Agents >

Antiviral Agents: Introduction

Viruses are obligate intracellular parasites; their replication depends primarily on synthetic processes of the host cell. Consequently, to be effective, antiviral agents must either block viral entry into or exit from the cell or be active inside the host cell. As a corollary, nonselective inhibitors of virus replication may interfere with host cell function and produce toxicity. The search for chemicals that inhibit virus-specific functions is currently one of the most active areas of pharmacologic investigation.

Research in antiviral chemotherapy began in the early 1950s, when the search for anticancer drugs generated several new compounds capable of inhibiting viral DNA synthesis. The two first-generation antivirals, 5-iododeoxyuridine and trifluorothymidine, had poor specificity (ie, they inhibited host cellular as well as viral DNA) that rendered them too toxic for systemic use. However, both are effective when used topically for the treatment of herpes keratitis.

Recent research has focused on the identification of agents with greater selectivity, in vivo stability, and lack of toxicity. Selective antiretroviral agents that inhibit a critical HIV-1 enzyme such as

reverse transcriptase or the protease required for final packaging of the virus particle have become available. In many viral infections, replication of the virus peaks at or before the manifestation of clinical symptoms. Optimal clinical efficacy in many viral illnesses therefore depends either on early initiation of therapy (eg, acyclovir for treatment of varicella or zoster infection) or on prevention of infection (eg, chemoprophylaxis against influenza A using a neuraminidase inhibitor or amantadine. Alternatively, potent inhibition of viral replication may be of clinical benefit in chronic illnesses such as HIV infection or viral hepatitis.

Viral replication consists of several steps: (1) adsorption to and penetration into susceptible host cells; (2) uncoating of viral nucleic acid; (3) synthesis of early regulatory proteins, eg, nucleic acid polymerases; (4) synthesis of RNA or DNA; (5) synthesis of late, structural proteins; (6) assembly (maturation) of viral particles; and (7) release from the cell. Antiviral agents can potentially target any of these steps (Figure 49–1).

Figure 49–1.

The major sites of antiviral drug action. (Modified and reproduced, with permission, from Trevor AT, Katzung BG, Masters SM: *Pharmacology: Examination & Board Review*, 6th ed. McGraw-Hill, 2002.)

Agents to Treat Herpes Simplex Virus (HSV) & Varicella Zoster Virus (VZV) Infections

Three oral agents are licensed for the treatment of HSV and VZV infections: acyclovir, valacyclovir, and famciclovir. They have similar mechanisms of action and similar indications for clinical use; all are well tolerated. Acyclovir, licensed first, has been the most extensively studied; in addition, it is the only anti-HSV agent available for intravenous use in the United States. Neither valacyclovir nor famciclovir have been fully evaluated in pediatric patients; thus, they are not indicated for the treatment of varicella infection.

Acyclovir

Acyclovir (Figure 49–2) is an acyclic guanosine derivative with clinical activity against HSV-1, HSV-2, and VZV. In vitro activity against Epstein-Barr virus, cytomegalovirus, and human herpesvirus-6 is present but comparatively weaker.

Figure 49–2.

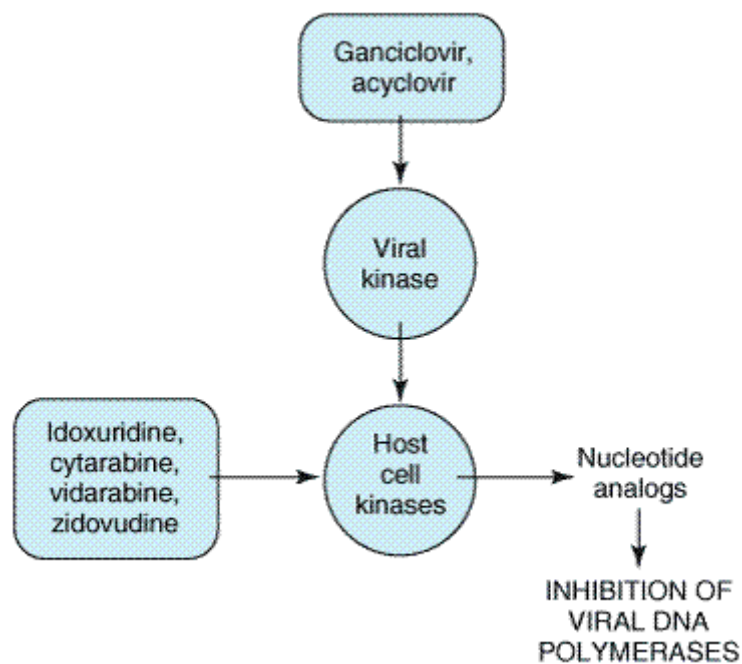

Chemical structures of some representative antiherpes agents.

Mechanism of Action

Acyclovir requires three phosphorylation steps for activation. It is converted first to the monophosphate derivative by the virus-specified thymidine kinase and then to the di- and triphosphate compounds by the host's cellular enzymes (Figure 49–3). Because it requires the viral kinase for initial phosphorylation, acyclovir is selectively activated and accumulates only in infected cells. Acyclovir triphosphate inhibits viral DNA synthesis by two mechanisms: competitive inhibition with deoxyGTP for the viral DNA polymerase, resulting in binding to the DNA template as an irreversible complex; and chain termination following incorporation into the viral DNA.

Figure 49–3.

Antiviral actions of purine and pyrimidine analogs. Acyclovir and ganciclovir (top) are phosphorylated first by viral kinase to the monophosphate. This intermediate and the drugs shown on the left are then phosphorylated by host cell kinases to the nucleotide analogs that inhibit viral replication. (Modified and reproduced, with permission, from Trevor AT, Katzung BG, Masters SM: *Pharmacology: Examination & Board Review*, 6th ed. McGraw-Hill, 2002.)

Pharmacokinetics

The bioavailability of oral acyclovir is 15–20% and is unaffected by food. Peak serum concentrations of approximately 1 $\mu\text{g/mL}$ after a 200 mg oral dose and 1.5–2 $\mu\text{g/mL}$ after an 800 mg dose are reached 1.5–2 hours after dosing. Peak serum concentrations are 10 $\mu\text{g/mL}$ and 20 $\mu\text{g/mL}$ after intravenous infusions (over 1 hour) of 5 mg/kg and 10 mg/kg, respectively. Topical formulations produce local concentrations that may exceed 10 $\mu\text{g/mL}$ in herpetic lesions, but systemic concentrations are undetectable.

Acyclovir is cleared primarily by glomerular filtration and tubular secretion. The half-life is approximately 3 hours in patients with normal renal function and 20 hours in patients with anuria. Acyclovir is readily cleared by hemodialysis but not by peritoneal dialysis.

Acyclovir diffuses into most tissues and body fluids to produce concentrations that are 50–100% of those in serum. Cerebrospinal fluid concentrations are 50% of serum values.

Clinical Uses

Oral acyclovir has multiple uses (Table 49–1). In primary genital herpes, oral acyclovir shortens by approximately 5 days the duration of symptoms, the time of viral shedding, and the time to resolution of lesions; in recurrent genital herpes, the time course is shortened by 1–2 days. Treatment of primary genital herpes does not alter the frequency or severity of recurrent outbreaks. Long-term chronic suppression of genital herpes with oral acyclovir decreases the frequency both of symptomatic recurrences and of asymptomatic viral shedding in patients with frequent recurrences, thus decreasing sexual transmission. However, outbreaks may resume upon discontinuation of suppressive acyclovir. In recurrent herpes labialis, oral acyclovir reduces the mean duration of pain but not the time to healing. Oral acyclovir decreases the total number of lesions and duration of varicella (if begun within 24 hours after the onset of rash) and cutaneous zoster (if begun within 72 hours). However, because VZV is less susceptible to acyclovir than HSV, higher doses are required (Table 49–1). A meta-analysis suggested that acyclovir was superior to placebo in reducing the duration of "zoster-associated pain," a continuous variable combining acute and chronic pain. When given prophylactically to patients undergoing organ transplantation, oral acyclovir (200 mg every 8 hours or 800 mg every 12 hours) or intravenous acyclovir (5 mg/kg every 8 hours) prevents reactivation of HSV infection. The benefit of acyclovir for prevention of CMV infections in transplant patients is controversial.

Table 49–1. Agents to Treat or Prevent Herpes Simplex Virus (HSV) and Varicella-Zoster Virus (VZV) Infections.

Agent	Route of Administration	Use	Recommended Adult Dosage and Regimen
Acyclovir ¹	Oral	First episode genital herpes	400 mg tid or 200 mg five times daily
		Recurrent genital herpes	400 mg tid or 200 mg five times daily or 800 mg bid
		Genital herpes suppression	400 mg bid
		Herpes proctitis	400 mg five times daily
		Mucocutaneous herpes in the immunocompromised host	400 mg five times daily
		Varicella	20 mg/kg (maximum 800 mg) four times daily
		Zoster	800 mg five times daily
	Intravenous	Severe HSV infection	5 mg/kg q8h
		Herpes encephalitis	10–15 mg/kg q8h
		Neonatal HSV infection	20 mg/kg q8h
		Varicella or zoster in the immunosuppressed host	10 mg/kg q8h
Famciclovir ¹	Oral	First episode genital herpes	250 mg tid
		Recurrent genital herpes	125 mg bid
		Genital herpes suppression	250 mg bid

		Zoster	500 mg tid
Valacyclovir ¹	Oral	First episode genital herpes	1 g bid
		Recurrent genital herpes	500 mg bid
		Genital herpes suppression	500 mg daily or twice daily
		Zoster	1 g tid
Foscarnet ¹	Intravenous	Acyclovir-resistant HSV and VZV infections	40 mg/kg q8-12h
Penciclovir	Topical	Recurrent herpes labialis	Thin film covering lesion every 2 hours
Trifluridine	Topical	Herpes keratitis	1 drop every 2 hours
		Acyclovir-resistant HSV infection	Thin film covering lesion five times daily

¹Dosage must be reduced in patients with renal insufficiency.

Intravenous acyclovir is the treatment of choice for herpes simplex encephalitis, neonatal HSV infection, and serious HSV or VZV infections (Table 49–1). In immunocompromised patients with zoster, intravenous acyclovir reduces the incidence of cutaneous and visceral dissemination.

Topical acyclovir is much less effective than oral therapy for primary HSV infection. It is of no benefit in treating recurrences.

Resistance

Resistance to acyclovir can develop in HSV or VZV through alteration in either the viral thymidine kinase or the DNA polymerase. Infections that are clinically resistant to acyclovir have been reported in immunocompromised hosts. Most clinical isolates are resistant on the basis of deficient thymidine kinase activity and thus are cross-resistant to valacyclovir, famciclovir, and ganciclovir. Agents such as foscarnet, cidofovir, and trifluridine do not require activation by viral thymidine kinase and thus have preserved activity against the most prevalent acyclovir-resistant strains.

Adverse Reactions

Acyclovir is generally well tolerated. Nausea, diarrhea, and headache have occasionally been reported. Intravenous infusion may be associated with reversible renal dysfunction due to crystalline nephropathy or neurologic toxicity (eg, tremors, delirium, seizures); however, these are uncommon with adequate hydration and avoidance of rapid infusion rates. Chronic daily suppressive use of acyclovir for more than 10 years has not been associated with untoward effects. High doses of acyclovir cause testicular atrophy in rats, but there has been no evidence of teratogenicity to date in a cumulative registry and no effect on sperm production was demonstrated in a placebo-controlled trial of patients receiving daily chronic acyclovir.

Valacyclovir

Valacyclovir is the L-valyl ester of acyclovir. It is rapidly converted to acyclovir after oral administration, resulting in serum levels three to five times greater than those achieved with oral acyclovir and approximating those resulting from intravenous acyclovir administration. Oral

bioavailability is about 48%. As with acyclovir, uses of valacyclovir include treatment of first attacks or recurrences of genital herpes, suppression of frequently recurrent genital herpes, treatment of herpes zoster infection, and, recently, as a 1-day treatment for orolabial herpes (Table 49–1). Valacyclovir has also been shown to be effective in preventing cytomegalovirus disease after organ transplantation when compared with placebo. In general, comparative studies have shown similar or slightly improved efficacy of valacyclovir versus acyclovir for all indications; furthermore, valacyclovir therapy was associated with a shorter duration of zoster-associated pain than acyclovir in one study, as well as a lower frequency of postherpetic neuralgia. Once-daily dosing of valacyclovir (500 mg) as chronic suppression in persons with recurrent genital herpes has recently been shown to markedly decrease the risk of sexual transmission. Valacyclovir is generally well tolerated, although nausea, diarrhea, and headache may occur. AIDS patients receiving high-dosage valacyclovir chronically (ie, 8 g/d) had an increased incidence of gastrointestinal intolerance as well as thrombotic microangiopathies such as thrombotic thrombocytopenic purpura and hemolytic-uremic syndrome. In transplant patients receiving valacyclovir (8 g/d), non-dose-limiting confusion and hallucinations were the most frequent side effects.

Famciclovir

Famciclovir is the diacetyl ester prodrug of 6-deoxypenciclovir, an acyclic guanosine analog (Figure 49–2). After oral administration, famciclovir is rapidly converted by first-pass metabolism to penciclovir, which shares many features with acyclovir. It is active *in vitro* against HSV-1, HSV-2, VZV, EBV, and HBV. Activation by phosphorylation is catalyzed by the virus-specified thymidine kinase in infected cells, followed by competitive inhibition of the viral DNA polymerase to block DNA synthesis. Unlike acyclovir, penciclovir does not cause chain termination. Penciclovir triphosphate has lower affinity for the viral DNA polymerase than acyclovir triphosphate, but it achieves higher intracellular concentrations and has a more prolonged intracellular effect in experimental systems. The most commonly encountered clinical mutants of HSV are thymidine kinase-deficient and are cross-resistant to acyclovir and famciclovir.

Pharmacokinetics

The bioavailability of penciclovir from orally administered famciclovir is 70%; less than 20% is plasma protein-bound. A peak serum concentration of 2 $\mu\text{g/mL}$ is achieved following a 250 mg oral dose. Penciclovir triphosphate has an intracellular half-life of 10 hours in HSV-1-infected cells, 20 hours in HSV-2-infected cells, and 7 hours in VZV-infected cells *in vitro*. Penciclovir is excreted primarily in the urine.

Clinical Uses

Oral famciclovir is effective for the treatment of first and recurrent genital herpes attacks and for chronic daily suppression (Table 49–1). It is also used to treat acute herpes zoster (shingles). In controlled trials in immunocompetent patients with zoster, famciclovir was similar to acyclovir in rates of cutaneous healing but was associated with a shorter duration of postherpetic neuralgia. Comparison of famciclovir to valacyclovir for treatment of herpes zoster in immunocompetent patients showed similar rates of cutaneous healing and pain resolution. However, neither drug decreased the incidence of postherpetic neuralgia.

Adverse Reactions

Oral famciclovir is generally well tolerated, although headache, diarrhea, and nausea may occur. As with acyclovir, testicular toxicity has been demonstrated in animals receiving repeated doses.

However, men receiving daily famciclovir (250 mg every 12 hours) had no changes in sperm morphology or motility. The incidence of mammary adenocarcinoma was also increased in female rats receiving famciclovir for 2 years.

Penciclovir

The guanosine analog penciclovir is the active metabolite of famciclovir (see above). Topical application of 1% penciclovir cream is effective for the treatment of recurrent herpes labialis in immunocompetent adults (Table 49–1). When therapy was initiated within 1 hour after the onset of signs or symptoms and continued every 2 hours during waking hours for 4 days, treatment with topical penciclovir resulted in a shortening of the mean duration of lesions, lesion pain, and virus shedding by approximately one-half day compared with placebo. Side effects are uncommon.

Trifluridine

Trifluridine (trifluorothymidine) is a fluorinated pyrimidine nucleoside that inhibits viral DNA synthesis. The compound has in vitro activity against HSV-1, HSV-2, vaccinia, and some adenoviruses. It is phosphorylated intracellularly to its active form by cellular enzymes, then competes with thymidine triphosphate for incorporation by the viral DNA polymerase. Incorporation of trifluridine triphosphate into both viral and cellular DNA prevents its systemic use. Application of a 1% solution is effective in treating primary keratoconjunctivitis and recurrent epithelial keratitis due to HSV-1 and HSV-2. Topical application of trifluridine solution, alone or in combination with interferon alfa, has been used successfully in the treatment of acyclovir-resistant HSV infections.

Antiviral Agents >

Agents to Treat Cytomegalovirus (CMV) Infections

Ganciclovir

Ganciclovir is an acyclic guanosine analog (Figure 49–2) that requires triphosphorylation for activation prior to inhibiting the viral DNA polymerase. Initial phosphorylation is catalyzed by the virus-specified protein kinase phosphotransferase UL97 in CMV-infected cells. The activated compound competitively inhibits viral DNA polymerase and causes termination of viral DNA elongation. Ganciclovir has in vitro activity against CMV, HSV, VZV, EBV, and HHV-8. Its activity against CMV is up to 100 times greater than that of acyclovir.

Pharmacokinetics

Ganciclovir may be administered intravenously, orally, or via intraocular implant.

A 5 mg/kg dose of ganciclovir administered intravenously over 1 hour produces serum concentrations averaging 6–10 $\mu\text{g/mL}$, with trough levels of approximately 1 $\mu\text{g/mL}$. Cerebrospinal fluid concentrations are approximately 50% of those in serum. Intravitreal concentrations following intravenous administration average 1 $\mu\text{g/mL}$. The half-life is 2–4 hours with normal renal function. Clearance of the drug is linearly related to creatinine clearance. Ganciclovir is readily cleared by hemodialysis. The bioavailability of oral ganciclovir is poor (6–9% when taken with food).

In patients with an intraocular implant, ganciclovir is released into the vitreous cavity at a rate of

approximately 1.4 µg/h.

Clinical Uses

Intravenous ganciclovir has been shown to delay progression of CMV retinitis in patients with AIDS when compared with no treatment (Table 49–2). Dual therapy with foscarnet and ganciclovir has been shown to be more effective in delaying progression of retinitis than either drug administered alone (see Foscarnet, below), although side effects are compounded. Intravenous ganciclovir is also used to treat CMV colitis and esophagitis. Intravenous ganciclovir, followed by either oral ganciclovir or high-dose oral acyclovir, reduces the risk of CMV infection in transplant recipients. Use of intravenous ganciclovir to treat CMV pneumonitis in immunocompromised patients may be beneficial, particularly in combination with intravenous cytomegalovirus immunoglobulin. Oral ganciclovir is indicated for prevention of end-organ CMV disease in AIDS patients and as maintenance therapy of CMV retinitis following induction. Although less effective than intravenous ganciclovir, the risk of myelosuppression and of catheter-related complications is diminished.

Agent	Route of Administration	Use	Recommended Adult Dosage
Cidofovir ¹	Intravenous	CMV retinitis treatment (induction or maintenance)	Induction: 5 mg/kg every 7 days Maintenance: 5 mg/kg every 14 days
Fomivirsen	Intravitreal injection	CMV retinitis treatment (induction or maintenance)	Induction: 330 µg every 14 days Maintenance: 330 µg every 4 weeks
Foscarnet ¹	Intravenous	CMV retinitis treatment (induction or maintenance)	Induction: 60 mg/kg q8h or 90 mg/kg q12h Maintenance: 90–120 mg/kg/d
Ganciclovir ¹	Intravenous	CMV retinitis treatment (induction or maintenance)	Induction: 5 mg/kg q12h Maintenance: 5 mg/kg/d or 6 mg/kg five times per week
	Oral	CMV prophylaxis	1 g tid
		CMV retinitis treatment (maintenance only)	1 g tid
	Intraocular implant	CMV retinitis treatment	4.5 mg every 6–8 months
Valganciclovir ¹	Oral	CMV retinitis treatment (induction or maintenance)	Induction: 900 mg bid

			Maintenance: 900 mg qd The drug should be taken with food.
	Oral	CMV prophylaxis	900 mg qd

¹Dosage must be reduced in patients with renal insufficiency.

Ganciclovir may also be administered intraocularly to treat CMV retinitis, either by direct intravitreal administration or via an intraocular implant. The implant, which achieves high and prolonged intraocular levels of ganciclovir, has been shown to delay progression of retinitis to a greater degree than systemic therapy with ganciclovir. Surgical replacement is required at intervals of 5–8 months. Owing to the lack of systemic protection against end-organ CMV disease (eg, colitis, esophagitis, ventriculitis) in patients treated with the ganciclovir implant alone—as well as the absence of protection against contralateral retinal CMV infection—concurrent therapy with a systemic anti-CMV agent is recommended. A recent study showed that the combination of either intravenous or oral ganciclovir and the ganciclovir intraocular implant in AIDS patients with CMV retinitis resulted in a decreased incidence of Kaposi's sarcoma over 6 months compared with those treated with the implant alone.

Resistance

Sporadic cases of ganciclovir-resistant CMV infection have been reported since the introduction of ganciclovir in the late 1980s; clinical manifestations may include progressive disease or prolonged viremia. Until recently, the majority of resistant cases were in patients with AIDS receiving prolonged therapy with ganciclovir. However, with the advent of more widespread use of oral ganciclovir, often in combination with more intensive immunosuppressive therapies, an increased frequency of ganciclovir-resistant CMV infection has been noted in organ transplant recipients. The most common mechanisms of resistance are mutations in UL97, resulting in decreased levels of the triphosphorylated (ie, active) form of ganciclovir; mutations in UL54, which result in a mutant DNA polymerase, occur less frequently. Isolates with mutations in UL97 are not cross-resistant with cidofovir or foscarnet, while mutations in UL54 may confer cross-resistance to cidofovir (and, less frequently, foscarnet). Performance of antiviral susceptibility testing is recommended in patients in whom resistance is suspected clinically, as is the substitution of alternative therapies (eg, foscarnet), and concomitant reduction in immunosuppressive therapies, if possible. The addition of CMV hyperimmune globulin may also be considered.

Adverse Reactions & Drug Interactions

The most common side effect of systemic ganciclovir treatment (more common with intravenous than with oral administration) is myelosuppression, particularly neutropenia (20–40% of patients). Myelosuppression may be additive in patients receiving ganciclovir in combination with zidovudine, azathioprine, or mycophenolate mofetil. Central nervous system toxicity (headache, changes in mental status, seizures) has been rarely reported. Other potential adverse effects include fever, rash, abnormal liver function, and retinal detachment in patients with CMV retinitis. The drug is mitogenic in mammalian cells and carcinogenic and embryotoxic at high doses in animals and causes aspermatogenesis; the clinical significance of these preclinical data is unclear.

The primary potential adverse effects associated with the intraocular implant are vitreous

hemorrhage and retinal detachment.

Levels of ganciclovir may rise in patients taking concurrent probenecid. Concurrent use of ganciclovir with didanosine may result in increased levels of didanosine.

Valganciclovir

Mechanism of Action

Valganciclovir is a monovalyl ester prodrug that is rapidly hydrolyzed to the active compound ganciclovir (see Ganciclovir) by intestinal and hepatic esterases when administered orally.

Pharmacokinetics

Valganciclovir is well absorbed and rapidly metabolized in the intestinal wall and liver to ganciclovir. The absolute bioavailability of oral valganciclovir is 60%, and steady state AUC increases by 30% with a high-fat meal. The AUC_{0-24hr} resulting from valganciclovir (900 mg once daily) is similar to those noted after 5 mg/kg/d of intravenous ganciclovir. As with ganciclovir, the major route of elimination is renal, through glomerular filtration and active tubular secretion. Plasma concentrations of valganciclovir are reduced by approximately 50% by hemodialysis.

Clinical Uses

Valganciclovir is indicated for the treatment of CMV retinitis in patients with AIDS (Table 49–2). A randomized, open-label study demonstrated similar efficacy of oral valganciclovir and intravenous ganciclovir for induction therapy. Although clinical data assessing maintenance therapy with valganciclovir are not yet available, the pharmacokinetic profile would suggest similarity with intravenous ganciclovir. Potential side effects and drug interactions are those associated with ganciclovir (see Ganciclovir).

Cidofovir

Cidofovir is a cytosine nucleotide analog with in vitro activity against CMV, HSV-1, HSV-2, VZV, EBV, HHV-6, HHV-8, adenovirus, poxviruses, polyomaviruses, and human papillomavirus. In contrast to ganciclovir, phosphorylation of cidofovir to the active diphosphate is independent of viral enzymes. After phosphorylation, cidofovir acts both as a potent inhibitor of and as an alternative substrate for viral DNA polymerase, competitively inhibiting DNA synthesis and becoming incorporated into the viral DNA chain. Isolates with resistance to cidofovir have been selected in vitro; these isolates tend to be cross-resistant with ganciclovir but retain susceptibility to foscarnet. Clinically significant resistance to cidofovir has not been reported to date.

Pharmacokinetics

Although the terminal half-life of cidofovir is about 2.6 hours, the active metabolite, cidofovir diphosphate, has a prolonged intracellular half-life of 17–65 hours, thus allowing widely spaced administration. A separate metabolite, cidofovir phosphocholine, has a half-life of at least 87 hours and may serve as an intracellular reservoir of active drug. Peak serum concentrations when administered with probenecid (see Clinical Uses) are about 19 $\mu\text{g/mL}$. Cerebrospinal fluid penetration is poor after intravenous administration. Elimination involves active renal tubular secretion. High-flux hemodialysis has been shown to reduce the serum levels of cidofovir by approximately 75%.

Clinical Uses

Intravenous cidofovir is effective for the treatment of CMV retinitis. Intravenous cidofovir must be administered with probenecid (2 g at 3 hours prior to the infusion and 1 g at 2 and 8 hours after), which blocks active tubular secretion and decreases nephrotoxicity. Cidofovir dosage must be adjusted for alterations in the calculated creatinine clearance or the presence of urine protein prior to each infusion, and aggressive adjunctive hydration is required. Initiation of cidofovir therapy is contraindicated in patients with existing renal insufficiency. Direct intravitreal administration of cidofovir is not recommended due to ocular toxicity.

Other potential uses of cidofovir that are currently under investigation include treatment of the polyomavirus-associated progressive multifocal leukoencephalopathy syndrome in patients with AIDS, postexposure prophylaxis against smallpox, and topical treatment of molluscum contagiosum. Topical cidofovir is not currently available in a standardized preparation.

Adverse Reactions

The primary adverse effect of intravenous cidofovir is a dose-dependent nephrotoxicity. Concurrent administration of other potentially nephrotoxic agents (eg, amphotericin B, aminoglycosides, nonsteroidal anti-inflammatory drugs, pentamidine, foscarnet) should be avoided. Prior administration of foscarnet may increase the risk of nephrotoxicity. Other potential side effects include uveitis, decreased intraocular pressure, and probenecid-related hypersensitivity reactions. Neutropenia and metabolic acidosis are rare. The drug caused mammary adenocarcinomas in rats and is embryotoxic.

Foscarnet

Foscarnet (phosphonoformic acid) is an inorganic pyrophosphate compound (Figure 49–2) that inhibits viral DNA polymerase, RNA polymerase, and HIV reverse transcriptase directly, without requiring activation by phosphorylation. It has in vitro activity against HSV, VZV, CMV, EBV, HHV-6, HHV-8, and HIV. Resistance to foscarnet in HSV and CMV isolates is due to point mutations in the DNA polymerase gene and is typically associated with prolonged or repeated exposure to the drug. Mutations in the HIV-1 reverse transcriptase gene have also been described. Although foscarnet-resistant CMV isolates are typically cross-resistant to ganciclovir, activity is usually maintained against ganciclovir- and cidofovir-resistant isolates of CMV.

Pharmacokinetics

The drug is available in an intravenous formulation only; poor oral bioavailability and gastrointestinal intolerance preclude oral use. Peak serum concentrations averaging 80–100 $\mu\text{g/mL}$ are achieved following an infusion of 60 mg/kg. Cerebrospinal fluid concentrations are 43–67% of steady state serum concentrations. Although the mean plasma half-life is 4.5–6.8 hours, up to 30% of the drug may be deposited in bone, with a half-life of several months. The clinical repercussions of this are unknown.

Clearance of foscarnet is primarily by the kidney and is directly proportionate to creatinine clearance. Serum drug concentrations are reduced by approximately 50% following a 3-hour hemodialysis.

Clinical Uses

Foscarnet is effective treatment for CMV retinitis, with an efficacy approximately equal to that of ganciclovir (Table 49–2). Foscarnet is also used for treatment of CMV colitis, CMV esophagitis, acyclovir-resistant HSV infection, and acyclovir-resistant VZV infection. The dose of foscarnet must be titrated according to the patient's calculated creatinine clearance prior to each infusion. Use of an infusion pump to control the rate of infusion is important to avoid toxicity, and relatively large volumes of fluid are required because of the drug's poor solubility. The combination of ganciclovir and foscarnet is synergistic in vitro against CMV and has been shown to be superior to either agent as monotherapy in delaying progression of retinitis. Foscarnet has been administered intravitreally for the treatment of CMV retinitis in patients with AIDS, but data regarding efficacy and safety are lacking.

As with ganciclovir, a decrease in the incidence of Kaposi's sarcoma has been observed in patients who have received foscarnet. However, treatment of patients with Kaposi's sarcoma using antiherpes agents has not been successful.

Adverse Reactions

Potential adverse effects of foscarnet include renal insufficiency, hypo- or hypercalcemia, and hypo- or hyperphosphatemia. Saline preloading helps to prevent nephrotoxicity, as does avoidance of concomitant administration of drugs with nephrotoxic potential (eg, amphotericin B, pentamidine, aminoglycosides). The risk of severe hypocalcemia is increased with concomitant use of pentamidine. Penile ulcerations associated with foscarnet therapy may be due to high levels of ionized drug in the urine. Nausea, vomiting, anemia, and fatigue have been reported; the risk of anemia may be additive in patients receiving concurrent zidovudine. Central nervous system toxicities include headache, hallucinations, and seizures. The drug caused chromosomal damage in preclinical studies.

Fomivirsen

Fomivirsen is an oligonucleotide that inhibits human CMV through an antisense mechanism. Binding of fomivirsen to target mRNA results in inhibition of immediate early region 2 protein synthesis, thus inhibiting virus replication. Although resistant isolates have been induced under selection pressure in vitro, clinical resistance has not been observed to date. Cross-resistance between fomivirsen and other anti-CMV agents (ganciclovir, cidofovir, foscarnet) would not be expected. Fomivirsen is injected intravitreally for the treatment of CMV retinitis in patients with AIDS and is indicated for patients who are intolerant of or unresponsive to alternative therapies. The drug is slowly cleared from vitreous with a half-life of approximately 55 hours in humans and is subsequently cleared from the retina. Measurable concentrations of drug are not detected in the systemic circulation following intravitreal administration. Immediate therapy of CMV retinitis with fomivirsen was more effective in delaying progression than deferred treatment in a recent clinical trial. Concurrent systemic anti-CMV therapy is recommended to protect against extraocular and contralateral retinal CMV disease. Potential side effects include iritis and vitreitis as well as increased intraocular pressure and changes in vision. An interval of at least 2–4 weeks is recommended between cidofovir administration and use of fomivirsen because of the risk of ocular inflammation.

Antiviral Agents >

Antiretroviral Agents

A large and increasing number of antiretroviral agents are currently available for treatment of HIV-1-infected patients (Table 49–3). When to initiate therapy is controversial, but it is clear that monotherapy with any one agent should be avoided because of the need for maximal potency to durably inhibit virus replication and to avoid premature development of resistance. A combination of agents (highly active antiretroviral therapy; HAART) is usually effective in reducing plasma HIV RNA levels and in gradually increasing CD4 cell counts, particularly in antiretroviral-naive patients. Also important in selection of agents is optimization of adherence, tolerability, and convenience. Given that many patients will ultimately experience at least one treatment failure, close monitoring of viral load and CD4 cell counts is critical to trigger appropriate changes in therapy. The judicious use of drug resistance testing should be considered in selecting an alternative regimen for a patient who is not responding to therapy.

Table 49–3. Currently Available Antiretroviral Agents.

Agent	Class of Agent ¹	Recommended Adult Dosage (oral unless otherwise indicated)	Administration Recommendation	Common Side Effects	Comments
Abacavir	NRTI	300 mg bid		Rash, hypersensitivity reaction, nausea	Do not rechallenge after hypersensitivity reaction
Amprenavir	PI	1200 mg bid	Separate dosing from didanosine or antacids by 1 hour. Avoid high-fat meals.	Rash, diarrhea, nausea	See footnote 2 for concurrent drug contraindications. Oral solution contraindicated in young children and pregnant women.
Delavirdine	NNRTI	400 mg tid	Separate dosing from didanosine or antacids by 1 hour.	Rash, liver function abnormalities	Teratogenic; see footnote 2 for concurrent drug contraindications
Didanosine ³	NRTI	150–200 mg bid, depending on weight. Enteric-coated: 250–400 mg qd, depending on weight	30 minutes before or 2 hours after meals	Peripheral neuropathy, pancreatitis, diarrhea, hyperuricemia	Contains antacid; avoid alcohol; avoid concurrent neuropathic drugs (eg, didanosine, zalcitabine, isoniazid)

Efavirenz	NNRTI	600 mg qd	Not to be taken with a fatty meal	Dizziness, insomnia, rash, transaminitis	Embryotoxic; see footnote 2 for concurrent drug contraindications
Enfuvirtide	Fusion inhibitor	90 mg bid	Reconstitute for subcutaneous administration	Local injection site reactions	Refrigeration required
Indinavir	PI	800 mg tid	With water or other liquids, 1 hour before or 2 hours after a meal. Drink at least 48 oz of liquid daily. Separate dosing with didanosine by 1 hour.	Nephrolithiasis, nausea, liver function abnormalities	Store in original container, which contains desiccant; see footnote 2 for concurrent drug contraindications
Lamivudine ³	NRTI	150 mg bid or 300 mg qd, depending on weight		Nausea, headache, fatigue	Active against HBV as well as HIV-1
Lopinavir/ritonavir	PI/PI	400 mg/100 mg bid	With food. Separate dosing with didanosine by 1 hour.	Diarrhea, abdominal pain, nausea	The oral solution contains alcohol; store capsules and solution in refrigerator; see footnote 2 for concurrent drug contraindications.
Nelfinavir	PI	750 mg tid or 1250 mg bid	With food	Diarrhea, nausea, flatulence	See footnote 2 for concurrent drug contraindications
Nevirapine	NNRTI	200 mg bid		Rash, hepatitis, nausea, headache	Dose-escalate from 200 mg qd over 14 days to decrease frequency of rash. Avoid concurrent use with ketoconazole, methadone, and

					oral contraceptives.
Ritonavir	PI	600 mg bid	With food. Separate dosing with didanosine by 2 hours.	Nausea, diarrhea, paresthesias, hepatitis	Dose-escalate over 5–10 days to improve tolerance. In combination with saquinavir (400 mg bid), use 400 mg bid ritonavir. Refrigerate capsules but not oral solution. See footnote 2 for concurrent drug contraindications; avoid concurrent oral contraceptives.
Saquinavir hard gel	PI	600 mg tid or 400 mg bid with ritonavir 400 mg bid	Within 2 hours of a full meal	Nausea, diarrhea, rhinitis	Refrigeration recommended; see footnote 2 for concurrent drug contraindications.
Saquinavir soft gel	PI	1200 mg tid or 1800 mg bid or 1600 mg qd with ritonavir 100 mg qd	Within 2 hours of a full meal	Nausea, diarrhea, abdominal pain, dyspepsia	Refrigeration recommended; see footnote 2 for concurrent drug contraindications.
Stavudine ³	NRTI	30–40 mg bid, depending on weight		Peripheral neuropathy, stomatitis	Avoid concurrent neuropathic drugs (eg, didanosine, zalcitabine, isoniazid); avoid concurrent use with zidovudine
Tenofovir ⁴	Nucleotide inhibitor	300 mg qd	With a meal. Separate dosing with didanosine by 1–2 hours	Nausea, vomiting, diarrhea, flatulence	
Zalcitabine ³	NRTI	0.75 mg tid	Avoid	Peripheral	Avoid

			administration with antacids or food	neuropathy; oral ulcerations	concurrent neuropathic drugs (eg, didanosine, stavudine, isoniazid)
Zidovudine ³	NRTI	200 mg tid or 300 mg bid		Anemia, neutropenia, nausea, insomnia	Avoid concurrent myelosuppressive drugs (eg, ganciclovir, ribavirin)

¹NRTI, nucleoside reverse transcriptase inhibitor; NNRTI, nonnucleoside reverse transcriptase inhibitor; PI, protease inhibitor.

²The following drugs are contraindicated as concurrent medications: astemizole, terfenadine, dihydroergotamine, cisapride, pimozone, midazolam, triazolam, flecainide, propafenone, rifampin, lovastatin, simvastatin, St. John's wort.

³Requires dose reduction in renal insufficiency.

⁴Should not be administered to patients with renal insufficiency.

Nucleoside Reverse Transcriptase Inhibitors (NRTIs)

The NRTIs act by competitive inhibition of HIV-1 reverse transcriptase and can also be incorporated into the growing viral DNA chain to cause termination. Each requires intracytoplasmic activation as a result of phosphorylation by cellular enzymes to the triphosphate form. Most have activity against HIV-2 as well as HIV-1.

Lactic acidemia and severe hepatomegaly with steatosis have been reported with the use of NRTI agents, alone or in combination with other antiretroviral drugs. Obesity, prolonged nucleoside exposure, and risk factors for liver disease have been described as factors that increase risk for lactic acidemia; however, cases have also been reported in patients with no known risk factors. NRTI treatment should be suspended in the setting of rapidly rising aminotransferase levels, progressive hepatomegaly, or metabolic or lactic acidosis of unknown cause. Given their similar mechanism of action, it is probable that these cautions should be applied to treatment with nucleotide inhibitors as well (see Nucleotide Inhibitors).

Zidovudine

Zidovudine (azidothymidine; AZT) is a deoxythymidine analog (Figure 49–4) that is well absorbed from the gut and distributed to most body tissues and fluids, including the cerebrospinal fluid, where drug levels are 60–65% of those in serum. Plasma protein binding is approximately 35%. The serum half-life averages 1 hour, and the intracellular half-life of the phosphorylated compound is 3.3 hours. Zidovudine is eliminated primarily by renal excretion following glucuronidation in the liver. Clearance of zidovudine is reduced by approximately 50% in uremic patients, and toxicity may increase in patients with advanced hepatic insufficiency.

Figure 49–4.

Chemical structures of some reverse transcriptase inhibitors.

As the first licensed antiretroviral agent, zidovudine has been well studied. Zidovudine has been shown to decrease the rate of clinical disease progression and prolong survival in HIV-infected individuals. Efficacy has also been demonstrated in the treatment of HIV-associated dementia and thrombocytopenia. In pregnancy, a regimen of oral zidovudine beginning between 14 and 34 weeks of gestation (100 mg five times a day), intravenous zidovudine during labor (2 mg/kg over 1 hour, then 1 mg/kg/h by continuous infusion), and zidovudine syrup to the neonate from birth through 6 weeks of age (2 mg/kg every 6 hours) has been shown to reduce the rate of vertical (mother-to-newborn) transmission of HIV by up to 23%.

As with other NRTI agents, resistance may limit clinical efficacy. High-level zidovudine resistance is generally seen in strains with three or more of the five most common mutations: M41L, D67N, K70R, T215F, and K219Q. However, the emergence of certain mutations that confer decreased susceptibility to one drug (eg, L74V in the case of didanosine and M184V in the case of lamivudine) seems to enhance susceptibility in previously zidovudine-resistant strains. Withdrawal of zidovudine exposure may permit the reversion of zidovudine-resistant HIV-1 isolates to the susceptible wild-type phenotype.

The most common adverse effect of zidovudine is myelosuppression, resulting in anemia or

neutropenia. Gastrointestinal intolerance, headaches, and insomnia may occur but tend to resolve during therapy. Less frequent side effects include thrombocytopenia, hyperpigmentation of the nails, and myopathy. Very high doses can cause anxiety, confusion, and tremulousness. Zidovudine causes vaginal neoplasms in mice; however, no human cases of genital neoplasms have been reported to date. Increased serum levels of zidovudine may occur with concomitant administration of probenecid, phenytoin, methadone, fluconazole, atovaquone, valproic acid, and lamivudine, either through inhibition of first-pass metabolism or through decreased clearance. Zidovudine may decrease phenytoin levels, and this warrants monitoring of serum phenytoin levels in epileptic patients taking both agents. Hematologic toxicity may be increased during coadministration of other myelosuppressive drugs such as ganciclovir, ribavirin, and cytotoxic agents. (See Treatment of HIV-Infected Individuals: Importance of Pharmacokinetic Knowledge.)

Didanosine

Didanosine (ddI) is a synthetic analog of deoxyadenosine (Figure 49–4). At acid pH, hydrolysis of the glycosidic bond between the sugar and the base moieties of ddI will inactivate the compound. Didanosine's AUC is reduced by 55% if it is ingested within 2 hours after a meal. Peak serum concentrations average 1 $\mu\text{g/mL}$ after a 300 mg dose. Cerebrospinal fluid concentrations of the drug are approximately 20% of serum concentrations. Plasma protein binding is low (< 5%). The elimination half-life is 0.6–1.5 hours, but the intracellular half-life of the activated compound is as long as 12–24 hours. The drug is eliminated by glomerular filtration and tubular secretion. Dosage reduction is therefore required for low creatinine clearance, after hemodialysis or during continuous ambulatory peritoneal dialysis, and for low body weight (Table 49–3).

The original formulation, a buffered powder, has been replaced by chewable and dispersible buffered tablets with greater bioavailability (30–40%); a new enteric-coated formulation further improves patient convenience and tolerability. Since the chewable tablets contain both phenylalanine (36.5 mg) and sodium (1380 mg), caution should be exercised in patients with phenylketonuria and those taking sodium-restricted diets. Didanosine should be taken on an empty stomach and, because of the buffered formulation, should be administered at least 2 hours after administration of drugs requiring acidity for optimal absorption (eg, ketoconazole, itraconazole, dapsone).

Resistance to didanosine, due typically to mutation at codon 74 (L74V), may partially restore susceptibility to zidovudine but may confer cross-resistance to abacavir, zalcitabine, and lamivudine. High-level resistance (> 100-fold decreased susceptibility) has not been reported to date.

The major clinical toxicity associated with didanosine therapy is dose-dependent pancreatitis. Other risk factors for pancreatitis (eg, alcoholism, hypertriglyceridemia) are relative contraindications to administration of didanosine, and other drugs with the potential to cause pancreatitis should be avoided. Other reported adverse effects include painful peripheral distal neuropathy, diarrhea, hepatitis, esophageal ulceration, cardiomyopathy, and central nervous system toxicity (headache, irritability, insomnia). Asymptomatic hyperuricemia may precipitate attacks of gout in susceptible individuals. Reports of retinal changes and optic neuritis in patients receiving didanosine—particularly in adults receiving high doses and in children—indicate the utility of periodic retinal examinations.

Fluoroquinolones and tetracyclines should be administered at least 2 hours before or after didanosine in order to avoid decreased antibiotic plasma concentrations due to chelation. Coadministration with ganciclovir results in an increased AUC of didanosine and a decreased AUC

of ganciclovir, while coadministration with methadone results in decreased didanosine serum levels.

Lamivudine

Lamivudine (3TC) is a cytosine analog (Figure 49–4) with in vitro activity against HIV-1 that is synergistic with a variety of antiretroviral nucleoside analogs—including zidovudine and stavudine—against both zidovudine-sensitive and zidovudine-resistant HIV-1 strains. Activity against HBV is described below (see Anti-Hepatitis Agents).

Oral bioavailability exceeds 80% and is not food-dependent. Peak serum levels after standard doses are $1.5 \pm 0.5 \mu\text{g/mL}$, and protein binding is less than 36%. In children, the mean CSF:plasma ratio of lamivudine was 0.2. Mean elimination half-life is 2.5 hours, while the intracellular half-life of the active 5'-triphosphate metabolite in HIV-1-infected cell lines is 10.5–15.5 hours. The majority of lamivudine is eliminated unchanged in the urine, and the dose should be reduced in patients with renal insufficiency or low body weight (Table 49–3). No supplemental doses are required after routine hemodialysis.

Lamivudine therapy rapidly selects—both in vitro and in vivo—for M184V-resistant mutants of HIV, which show high-level resistance to lamivudine and a reduction in susceptibility to abacavir, didanosine, and zalcitabine. Thus, lamivudine, like other antiretroviral agents, is best used in combination therapies that are fully suppressive of viral replication to reduce the generation of resistant mutants. The M184V mutation may restore phenotypic susceptibility to zidovudine, indicating that these two drugs in combination regimens may be particularly beneficial. However, HIV-1 strains resistant to both lamivudine and zidovudine have been isolated.

Potential side effects are headache, insomnia, fatigue, and gastrointestinal discomfort, though these are typically mild. Lamivudine's AUC increases when it is coadministered with trimethoprim-sulfamethoxazole. Peak levels of zidovudine increase when the drug is administered with lamivudine, though this effect is not felt to have clinical significance.

Zalcitabine

Zalcitabine (ddC) is a cytosine analog (Figure 49–4) that has synergistic anti-HIV-1 activity with a variety of antiretroviral agents against both zidovudine-sensitive and zidovudine-resistant strains of HIV-1.

Zalcitabine has a relatively long intracellular half-life of 10 hours (despite its elimination half-life of 2 hours) and high oral bioavailability (> 80%). However, plasma levels decrease by 25–39% when the drug is administered with food or antacids. Plasma protein binding is low (< 4%). Cerebrospinal fluid concentrations are approximately 20% of those in the plasma.

Although a variety of mutations associated with in vitro resistance to zalcitabine have been described (eg, T69D, K65R, M186V), phenotypic resistance appears to be rare, particularly in combination regimens.

Zalcitabine therapy is associated with a dose-dependent peripheral neuropathy that can be treatment-limiting in 10–20% of patients but appears to be slowly reversible if treatment is stopped promptly. The potential for causing peripheral neuropathy constitutes a relative contraindication to use with other drugs that may cause neuropathy, including stavudine, didanosine, and isoniazid. Decreased renal clearance caused by amphotericin B, foscarnet, and aminoglycosides may increase the risk of zalcitabine neuropathy. The other major reported toxicity is oral and esophageal

ulcerations. Pancreatitis occurs less frequently than with didanosine administration, but coadministration of other drugs that cause pancreatitis may increase the frequency of this adverse effect. Headache, nausea, rash, and arthralgias may occur but tend to be mild or resolve during therapy. Cardiomyopathy has rarely been reported. Zalcitabine causes thymic lymphomas in rodents, but no clinical correlates have been observed in humans.

Potential drug interactions include an increased AUC of zalcitabine when administered in combination with probenecid or cimetidine and decreased bioavailability when zalcitabine is coadministered with antacids or metoclopramide. Lamivudine inhibits the phosphorylation of zalcitabine *in vitro*, potentially interfering with its efficacy.

Stavudine

The thymidine analog stavudine (D4T) (Figure 49–4) has high oral bioavailability (86%) that is not food-dependent. The plasma half-life is 1.22 hours; the intracellular half-life is 3.5 hours; and mean cerebrospinal fluid concentrations are 55% of those of plasma. Plasma protein binding is negligible. Excretion is by active tubular secretion and glomerular filtration. The dosage of stavudine should be reduced in patients with renal insufficiency, in those receiving hemodialysis, and for low body weight (Table 49–3).

V75T and I50T mutations are associated with decreased *in vitro* susceptibility to stavudine; the former also confers decreased susceptibility to didanosine and zalcitabine. Clinically significant resistance to stavudine has been rare.

The major dose-limiting toxicity is a dose-related peripheral sensory neuropathy. The frequency of neuropathy may be increased when stavudine is administered with other neuropathy-inducing drugs such as zalcitabine and didanosine. Symptoms typically resolve completely upon discontinuation of stavudine; in such cases, a reduced dosage may be cautiously restarted. Potential adverse effects other than neuropathy include pancreatitis, arthralgias, and elevation in serum aminotransferases. Since zidovudine may reduce the phosphorylation of stavudine, these two drugs should generally not be used together.

Abacavir

In contrast to earlier NRTIs, abacavir is a guanosine analog. It is well absorbed following oral administration (83%), is unaffected by food, and is about 50% bound to plasma proteins. In single-dose studies, the elimination half-life was 1.5 hours. Cerebrospinal fluid levels are approximately one-third those of plasma. The drug is metabolized by alcohol dehydrogenase and glucuronosyltransferase to inactive metabolites that are eliminated primarily in the urine.

High-level resistance to abacavir appears to require at least two or three concomitant mutations (eg, M184V, L74V), and for that reason it tends to develop slowly. Although cross-resistance to lamivudine, didanosine, and zalcitabine has been noted *in vitro* in recombinant strains with abacavir-associated mutations, the clinical significance is unknown.

Hypersensitivity reactions, occasionally fatal, have been reported in 2–5% of patients receiving abacavir. Symptoms, which generally occur within the first 6 weeks of therapy, involve multiple organ systems and include fever, malaise, and gastrointestinal complaints. Skin rash may or may not be present. Laboratory abnormalities such as mildly elevated serum aminotransferase or creatine kinase levels are not specific for this reaction. Although the syndrome tends to resolve quickly with discontinuation of medication, rechallenge with abacavir following discontinuation results in return

of symptoms within hours and may be fatal. Other adverse events may include rash, nausea and vomiting, diarrhea, headache, and fatigue. Adverse effects that appear to be infrequent include pancreatitis, hyperglycemia, and hypertriglyceridemia. Clinically significant adverse drug interactions have not been reported to date, though coadministration of alcohol and abacavir may result in an increase in abacavir's AUC.

Nucleotide Inhibitors

Tenofovir

Tenofovir disoproxilfumarate is a prodrug that is converted in vivo to tenofovir, an acyclic nucleoside phosphonate (nucleotide) analog of adenosine. Like the NRTIs, tenofovir competitively inhibits HIV reverse transcriptase and causes chain termination after incorporation into DNA.

The oral bioavailability of tenofovir from tenofovir disoproxilfumarate, a water-soluble diester prodrug of the active ingredient tenofovir, in fasted patients is approximately 25%. Oral bioavailability is increased if the drug is ingested following a high-fat meal (increased AUC by about 40%); therefore, taking the drug along with a meal is recommended. Maximum serum concentrations are achieved in about 1 hour after taking the medication. Elimination occurs by a combination of glomerular filtration and active tubular secretion. However, only 70–80% of the dose is recovered in the urine, allowing for the possibility of hepatic metabolism as well as alteration in hepatic insufficiency; the latter has not been studied.

Tenofovir is indicated for use in combination with other antiretroviral agents. Initial studies demonstrated potent HIV-1 suppression in treatment-experienced adults with evidence of viral replication despite ongoing antiretroviral therapy; similar benefit in antiretroviral-naïve patients has yet to be demonstrated. The once-daily dosing regimen of tenofovir lends added convenience.

Varying degrees of cross-resistance to tenofovir by preexisting zidovudine-associated mutations (eg, M41L, L210W) may occur and diminish virologic response; these appear to depend on the number of specific mutations present. Presence of the 65R mutation also reduces virologic response. However, virologic response to tenofovir is not diminished in the lamivudine-abacavir-associated M184V mutation. Cross-resistance with protease inhibitor agents is unlikely.

Gastrointestinal complaints (eg, nausea, diarrhea, vomiting, and flatulence) are the most common side effects but rarely require discontinuation of therapy. Preclinical studies in several animal species have demonstrated bone toxicity (eg, osteomalacia); however, to date there has been no evidence of bone toxicity in humans. Tenofovir may compete with other drugs that are actively secreted by the kidneys, such as cidofovir, acyclovir, and ganciclovir. Tenofovir is not metabolized by the cytochrome P450 system, so drug interactions with agents metabolized by this system are unlikely. As with the NRTIs, lactic acidosis and hepatomegaly with steatosis should be watched for.

Nonnucleoside Reverse Transcriptase Inhibitors (NNRTIs)

The NNRTIs bind directly to a site on the HIV-1 reverse transcriptase, resulting in blockade of RNA- and DNA-dependent DNA polymerase activities. The binding site is near to but distinct from that of the NRTIs. Unlike the latter group of agents, the NNRTIs neither compete with nucleoside triphosphates nor require phosphorylation to be active. Resistance to an NNRTI is generally rapid with monotherapy and is associated with the K103N mutation as well as the less critical Y181C/I mutation; cross-resistance among this class of agents, although observed in vitro, is of unknown clinical significance. There is no cross-resistance between the NNRTIs and the NRTIs or the

protease inhibitors.

A syndrome of drug hypersensitivity has been described in patients receiving NNRTIs as well as in those receiving amprenavir or abacavir. Serious rashes, including Stevens-Johnson syndrome, have occurred.

Nevirapine

The oral bioavailability of nevirapine is excellent (> 90%) and is not food-dependent. The drug is highly lipophilic, approximately 60% protein-bound, and achieves cerebrospinal fluid levels that are 45% of those in plasma. It is extensively metabolized by the CYP3A isoform to hydroxylated metabolites and then excreted, primarily in the urine.

Nevirapine is typically used as a component of a combination antiretroviral regimen. In addition, a single dose of nevirapine (200 mg) has recently been shown to be effective in the prevention of transmission of HIV from mother to newborn when administered to women at the onset of labor and followed by a 2-mg/kg oral dose given to the neonate within 3 days after delivery.

Severe and life-threatening skin rashes have occurred during nevirapine therapy, including Stevens-Johnson syndrome and toxic epidermal necrolysis. Nevirapine therapy should be immediately discontinued in patients with severe rash and in those with rash accompanied by constitutional symptoms. Rash occurs in approximately 17% of patients, most typically in the first 4–8 weeks of therapy, and is dose-limiting in about 7% of patients. When initiating therapy, gradual dose escalation over 14 days is recommended to decrease the frequency of rash. Fulminant hepatitis may occur in association with rash and fever, typically within the first 6 weeks of initiation of therapy, or may occur without a concomitant rash. Therefore, serial monitoring of liver function tests is strongly recommended. Other frequently reported adverse effects associated with nevirapine therapy are fever, nausea, headache, and somnolence.

Nevirapine is both a substrate and a moderate inducer of CYP3A metabolism, thus resulting in a 1.5-fold to twofold increase in oral clearance of itself and a corresponding decrease in the terminal phase half-life with repeated dosing—as well as decreased levels of indinavir and saquinavir if administered concurrently (see Table 49–4). Owing to an increase in nevirapine and a decrease in ketoconazole levels during coadministration, these two agents should not be given together. Nevirapine levels may increase during coadministration with inhibitors of CYP3A metabolism, such as cimetidine and the macrolide agents, and decrease in the presence of CYP3A inducers such as rifabutin and rifampin (see Table 4–2). Such agents should be coadministered cautiously and only if good alternatives are lacking.

Table 49–4. Drug Interactions Pertaining to Two-Drug Antiretroviral Combinations.

Agent	Drugs That Will Increase Its Serum Levels	Drugs That Will Decrease Its Serum Levels
Amprenavir	Abacavir, delavirdine, indinavir, lopinavir, ritonavir, zidovudine	Didanosine, efavirenz, nevirapine, saquinavir
Delavirdine	Saquinavir	Didanosine, nelfinavir
Didanosine	Tenofovir	Delavirdine
Efavirenz	Ritonavir	

Indinavir	Delavirdine, lopinavir, nelfinavir, zidovudine	Amprenavir, delavirdine, efavirenz, nevirapine, ritonavir
Lamivudine	Nelfinavir	
Lopinavir	Delavirdine, ritonavir	
Nelfinavir	Delavirdine, efavirenz, ritonavir, saquinavir	
Ritonavir	Delavirdine, efavirenz	Didanosine, indinavir, zidovudine
Saquinavir	Delavirdine, lopinavir, nelfinavir, ritonavir	Efavirenz, nevirapine
Stavudine	Indinavir	
Zidovudine	Amprenavir, indinavir, lamivudine	Nelfinavir

Delavirdine

Delavirdine has an oral bioavailability of about 85%, but this is reduced by antacids. It is extensively bound (about 98%) to plasma proteins. Cerebrospinal fluid levels average only 0.4% of the corresponding plasma concentrations, representing about 20% of the fraction not bound to plasma proteins. Caution should be used when administering delavirdine to patients with hepatic insufficiency because clinical experience in this situation is limited.

Skin rash occurs in about 18% of patients receiving delavirdine; it typically occurs during the first month of therapy and does not preclude rechallenge. However, severe rash such as erythema multiforme and Stevens-Johnson syndrome have rarely been reported. Other adverse effects may include headache, fatigue, nausea, diarrhea, and increased serum aminotransferase levels. Delavirdine has been shown to be teratogenic in rats, causing ventricular septal defects and other malformations at exposures not unlike those achieved in humans. Thus, pregnancy should be avoided when taking delavirdine.

Delavirdine is extensively metabolized to inactive metabolites by the CYP3A and CYP2D6 enzymes. However, it also inhibits CYP3A and thus inhibits its own metabolism. In addition to its interactions with other antiretroviral agents (see Table 49–4), delavirdine will result in increased levels of numerous agents (Table 49–3). Dose reduction of indinavir and saquinavir should be considered if they are administered concurrently with delavirdine. Delavirdine plasma concentrations are reduced in the presence of antacids, phenytoin, phenobarbital, carbamazepine, rifabutin, and rifampin; concentrations are increased during coadministration with clarithromycin, fluoxetine, dexamethasone, and ketoconazole.

Efavirenz

Efavirenz can be given once daily because of its long half-life (40–55 hours). It is moderately well absorbed following oral administration (45%), and bioavailability is increased to about 65% following a high-fat meal. Peak plasma concentrations are seen 3–5 hours after administration of daily doses; steady state plasma concentrations are reached in 6–10 days. Efavirenz is principally metabolized by CYP3A4 and CYP2B6 to inactive hydroxylated metabolites; the remainder is eliminated in the feces as unchanged drug. It is highly bound to albumin (> 99%). Cerebrospinal fluid levels range from 0.3% to 1.2% of plasma levels; these are approximately three times higher than the free fraction of efavirenz in the plasma. Because there is limited experience to date, caution is advised with use in patients with hepatic impairment.

The principal adverse effects of efavirenz involve the central nervous system (dizziness, drowsiness, insomnia, headache, confusion, amnesia, agitation, delusions, depression, nightmares, euphoria); these may occur in up to 50% of patients. They tend to occur during the first days of therapy and may resolve while medication is continued; administration at bedtime may be helpful. However, psychiatric symptoms may be severe. Skin rash has also been reported early in therapy in up to 28% of patients, is usually mild to moderate, and typically resolves despite continuation. Other potential adverse reactions include nausea and vomiting, diarrhea, crystalluria, elevated liver enzymes, and an increase in total serum cholesterol by 10–20%. High rates of fetal abnormalities occurred in pregnant monkeys exposed to efavirenz in doses roughly equivalent to the human dosage of 600 mg/d. Therefore, pregnancy should be avoided in women receiving efavirenz.

Efavirenz is a substrate, an inhibitor, and a moderate inducer of CYP3A4, thus inducing its own metabolism and interacting with the metabolism of many other drugs. Decreased plasma concentrations would be expected if efavirenz is administered concurrently with agents that induce CYP3A4 activity, including phenobarbital, rifampin, and rifabutin. The AUC of ethinyl estradiol is increased if coadministered with efavirenz, and levels of clarithromycin are decreased. Efavirenz may reduce plasma methadone levels by 50% and thus should not be concurrently used. Coadministration of efavirenz with drugs that are highly dependent on CYP3A for clearance is contraindicated (see Table 4–2). Interactions with other antiretroviral agents are summarized in Table 49–4. The dose of indinavir should be increased if coadministered with efavirenz. Coadministration of efavirenz with saquinavir is to be avoided because of decreases in saquinavir plasma concentrations.

Protease Inhibitors

During the later stages of the HIV growth cycle, the Gag and Gag-Pol gene products are translated into polyproteins and then become immature budding particles. Protease is responsible for cleaving these precursor molecules to produce the final structural proteins of the mature virion core. By preventing cleavage of the Gag-Pol polyprotein, protease inhibitors result in the production of immature, noninfectious viral particles. Unfortunately, specific genotypic alterations that confer phenotypic resistance is fairly common with these agents, thus contraindicating monotherapy. The issue of cross-resistance among agents in this class of drugs is complex and requires further investigation; it appears to require a minimum of four substitutions in the gene.

A syndrome of redistribution and accumulation of body fat that includes central obesity, dorsocervical fat enlargement (buffalo hump), peripheral and facial wasting, breast enlargement, and a cushingoid appearance has been observed in patients receiving antiretroviral therapy. Although controversial, these abnormalities appear to be particularly associated with the use of protease inhibitors. Concurrent increases in triglyceride and LDL levels, along with glucose intolerance and insulin resistance, have been noted as well. The cause is not yet known.

Protease inhibitors have also been associated with increased spontaneous bleeding in patients with hemophilia A or B.

All of the antiretroviral protease inhibitors are substrates of the CYP3A4 isoenzyme. As such, there is a potential for drug-drug interactions. In addition, however, certain of the protease inhibitors are CYP3A4 inhibitors as well (eg, amprenavir, indinavir, lopinavir, nelfinavir, ritonavir, and saquinavir), thus having the potential to cause decreased clearance and increased plasma concentrations of other substrate drugs. For this reason, the CYP3A4 inhibitors should not be administered concurrently with agents that are heavily metabolized by CYP3A (see Table 4–2). Ritonavir also functions as a CYP3A4 inducer, such that potential drug-drug interactions may be

clinically beneficial (see Ritonavir).

Saquinavir

In its original formulation as a hard gel capsule (saquinavir-H; Invirase), oral saquinavir was poorly bioavailable (about 4% in the fed state). It was therefore largely replaced in clinical use by a soft gel capsule formulation (saquinavir-S; Fortovase), in which absorption was increased approximately threefold. However, reformulation of saquinavir-H for once-daily dosing in combination with low-dose ritonavir (see Ritonavir) has both improved antiviral efficacy and decreased the gastrointestinal side effects typically associated with saquinavir-S. Moreover, coadministration of saquinavir-H with ritonavir results in blood levels of saquinavir similar to those associated with saquinavir-S, thus capitalizing on the pharmacokinetic interaction of the two agents.

Both formulations of saquinavir should be taken within 2 hours after a fatty meal for enhanced absorption. Saquinavir has a large volume of distribution but is 98% protein-bound; penetration into the cerebrospinal fluid is negligible. The elimination half-life is 12 hours. Excretion is primarily in the feces. Reported adverse effects include gastrointestinal discomfort (nausea, diarrhea, abdominal discomfort, dyspepsia; these are more common with Fortovase) and rhinitis. Although refrigeration is recommended for storage, the capsules are stable at room temperature for up to 3 months.

Saquinavir is subject to extensive first-pass metabolism by CYP3A4, and functions as a CYP3A4 inhibitor as well as a substrate; thus, it should be used with the same precautions regarding drug-drug interactions as the other protease inhibitors. Coadministration with the CYP3A4 inhibitor ritonavir has been adopted by clinicians because inhibition of first-pass metabolism of saquinavir by ritonavir can result in higher—and thus more efficacious—levels of saquinavir (see Table 49–3 and Table 49–4). Liver function tests should be monitored if saquinavir is coadministered with delavirdine.

The most common critical mutations are L90M and G48V, conferring an approximately tenfold decrease in susceptibility.

Ritonavir

Ritonavir is an inhibitor of HIV-1 and HIV-2 proteases with high bioavailability (about 75%) that increases when the drug is given with food. Metabolism to an active metabolite occurs via the CYP3A and CYP2D6 isoforms; excretion is primarily in the feces. Caution is advised when administering the drug to persons with impaired hepatic function. Capsules (but not the oral solution) should be refrigerated for storage.

Resistance is associated with mutations at positions 84, 82, 71, 63, and 46, of which the I84V mutation appears to be the most critical.

The most common adverse effects of ritonavir are gastrointestinal disturbances, paresthesias (circumoral and peripheral), elevated serum aminotransferase levels, altered taste, and hypertriglyceridemia. Nausea, vomiting, and abdominal pain typically occur during the first few weeks of therapy, and patients should be told to expect them. Slow dose escalation over 4–5 days is recommended to decrease the frequency of dose-limiting side effects. Liver adenomas and carcinomas have been induced in male mice receiving ritonavir; no similar effects have been observed to date in humans.

Ease of administration is limited by ritonavir's numerous drug interactions. Ritonavir is both a

substrate and an inhibitor of CYP3A4; as such, coadministration with agents heavily metabolized by CYP3A must be approached with the same precautions discussed above. In addition, since ritonavir is an inhibitor of the CYP3A4 isoenzyme, concurrent administration with other PIs results in increased plasma levels of the latter drugs; these interactions have been exploited to permit more convenient dosing (see Table 49–3 and Table 49–4).

Lopinavir/Ritonavir

Several studies have shown enhanced efficacy or improved tolerability of two protease inhibitors administered together. Lopinavir 100/ritonavir 400 is a licensed combination in which subtherapeutic doses of ritonavir inhibit the CYP3A-mediated metabolism of lopinavir, thereby resulting in increased exposure to lopinavir. Trough levels of lopinavir are greater than the median HIV-1 wild type 50% inhibitory concentration, thus maintaining potent viral suppression as well as providing a pharmacologic barrier to the emergence of resistance. In addition to improved patient compliance because of the reduced pill burden with twice-daily dosing, lopinavir/ritonavir is generally well tolerated.

Absorption is enhanced with food. Lopinavir is 98–99% protein-bound and is extensively metabolized by the CYP3A isozyme of the hepatic cytochrome P450 system, which is inhibited by ritonavir. Serum levels of lopinavir may be increased in patients with hepatic impairment.

The most common adverse effects are diarrhea, abdominal pain, nausea, vomiting, and asthenia. Potential drug-drug interactions are extensive (see Ritonavir and Table 49–4). Drugs that are highly dependent on CYP3A or CYP2D6 for clearance and for which elevated plasma concentrations may be serious or clinically significant—including those listed in Table 49–4 as well as those listed in Table 4–2—should not be given with lopinavir/ritonavir. Coadministration with rifampin, carbamazepine, phenobarbital, phenytoin, dexamethasone, or St. John's wort (*Hypericum perforatum*) may reduce levels of lopinavir.

Indinavir

Indinavir must be consumed on an empty stomach for maximal absorption. Oral bioavailability is about 65%, and the drug is about 60% protein-bound. Indinavir has the highest cerebrospinal fluid penetration of the existing protease inhibitors—up to 76% of serum levels. Excretion is primarily fecal. An increase in AUC by 60% and in half-life from 1.8 to 2.8 hours in the setting of hepatic insufficiency necessitates dose reduction.

Resistance may be associated with multiple mutations, and the number of codon alterations (typically substitutions) present tends to predict the level of phenotypic resistance. Mutations at positions at 46 or 82 seem to predict phenotypic resistance most consistently. Resistance to indinavir is associated with a loss of susceptibility to ritonavir; however, susceptibility to other protease inhibitors in indinavir-resistant isolates is less predictable.

The most common adverse effects are indirect hyperbilirubinemia and nephrolithiasis due to crystallization of the drug. Nephrolithiasis can occur within days after initiating therapy, with an estimated incidence of 3–15%, and may be associated with renal failure. Consumption of at least 48 oz of water daily is important to maintain adequate hydration and prevent nephrolithiasis. Thrombocytopenia, elevations of serum aminotransferase levels, nausea, diarrhea, and irritability have also been reported. There have also been rare cases of acute hemolytic anemia. In rats, high doses of indinavir are associated with development of thyroid adenomas.

Since indinavir is a substrate as well as an inhibitor of CYP3A4, numerous and complex drug interactions can occur as described above. Indinavir levels decrease with concurrent use of rifabutin, fluconazole, St. John's wort, and rifampin. Caution is advised with other 3A4 inducers also, including phenobarbital, phenytoin, carbamazepine, and dexamethasone. Dose reduction of indinavir should be considered if coadministered with delavirdine, ketoconazole, or itraconazole, while an increase in the dose of indinavir is indicated if the drug is coadministered with efavirenz or rifabutin.

Nelfinavir

Nelfinavir has higher absorption in the fed state (increased AUC by two- to threefold), is extensively protein-bound (> 98%), undergoes metabolism by CYP3A, and is excreted primarily in the feces. The plasma half-life in humans is 3.5–5 hours. The D30N mutation appears to be particularly closely linked with phenotypic resistance in isolates obtained from clinical trials.

The most frequent adverse effects associated with nelfinavir are diarrhea and flatulence. Diarrhea can be dose-limiting but often responds to antidiarrheal medications. Like the other protease inhibitors, nelfinavir is an inhibitor of the CYP3A system, and multiple drug interactions may occur as described above. Interactions with antiretroviral agents are summarized in Table 49–4; others may be found in Table 4–2.

Amprenavir

Amprenavir is rapidly absorbed from the gastrointestinal tract and can be taken with or without food. However, high-fat meals may decrease absorption and thus should be avoided. The plasma half-life is relatively long (7–10.6 hours). Protein binding is about 90%. Amprenavir is metabolized in the liver by CYP3A4; it is contraindicated in the setting of hepatic insufficiency.

The key *in vitro* resistance mutation to amprenavir appears to be I50V. Evidence to date suggests that cross-resistance to other members of the protease inhibitor class of drugs may be less prevalent with amprenavir than with previously available compounds.

The most common adverse effects of amprenavir have been nausea, diarrhea, vomiting, perioral paresthesias, depression, and rash. Up to 3% of patients in clinical trials to date have had rashes (including Stevens-Johnson syndrome) severe enough to warrant drug discontinuation.

Amprenavir is both a substrate and an inhibitor of CYP3A4 and is contraindicated with numerous other drugs (see Table 49–3 and Table 4–2). The oral solution, which contains propylene glycol, is contraindicated in young children, pregnant women, and in those using metronidazole or disulfiram.

Fusion Inhibitors

Enfuvirtide

Enfuvirtide (formerly called T-20) is a newly approved antiretroviral agent of a novel class, ie, a fusion inhibitor that blocks entry into the cell. Enfuvirtide, a synthetic 36-amino-acid peptide, binds to the gp41 subunit of the viral envelope glycoprotein, preventing the conformational changes required for the fusion of the viral and cellular membranes.

Resistance to enfuvirtide can occur, and the frequency and mechanisms of this phenomenon are currently being investigated. However, enfuvirtide completely lacks cross-resistance to the other

currently approved antiretroviral drug classes.

The drug is administered subcutaneously in combination with other antiretroviral agents in treatment-experienced patients with persistent HIV-1 replication despite ongoing therapy. Protein binding is high (92%), and metabolism appears to be by proteolytic hydrolysis without involvement of the cytochrome p450 system. Elimination half-life is 3.8 hours, and time to peak concentration is 8 hours.

The most common side effects associated with enfuvirtide therapy are local injection site reactions. Hypersensitivity reactions may occur, are of varying severity, and may recur on rechallenge. Eosinophilia has also been noted. No interactions have been identified that would require alteration of other antiretroviral drugs.

Investigational Antiretroviral Agents

New therapies are being sought offering the advantages of once-daily dosing, smaller pill size, lower incidences of adverse effects, new viral targets, and activity against virus that is resistant to other agents. Agents under evaluation or reformulation for once-daily dosing include stavudine and nevirapine. The NRTI agents amdoxovir and emtricitabine, the NNRTI agents DPC-083 and TMC-125, and the protease inhibitors atazanavir, tipranavir, and fosamprenavir (the prodrug of amprenavir) are among the new agents currently in development. In addition, new drug classes such as entry inhibitors and integrase inhibitors are under clinical investigation.

Treatment of HIV-Infected Individuals: Importance of Pharmacokinetic Knowledge

In addition to knowledge about the clinical efficacy, adverse effect profile, and likelihood of emergence of resistance, the physician caring for an HIV-infected patient must be well versed in basic pharmacokinetics as well. Such patients are frequently taking multiple medications, including combinations of antiretroviral agents, prophylaxis or treatment for opportunistic infections, and opioid pain medications or methadone for maintenance therapy.

For example, an HIV-infected patient receiving ganciclovir for treatment of cytomegalovirus retinitis may be unable to tolerate concomitant therapies with the potential for additive myelosuppression, including zidovudine, ribavirin, or the interferons. Addition of colony-stimulating factor therapy for cytopenias or substitution of a different, nonmyelodepressant drug for ganciclovir may ultimately be necessary. In a patient taking didanosine (ddI), the ingestion of many other antiretroviral agents that may comprise their combination regimen, including delavirdine, indinavir, amprenavir, and tenofovir, must be separated by 2 or more hours in order to avoid interference with their absorption. Prescription of abacavir may be complicated by the fact that alcohol decreases the AUC of abacavir by 41%; the patient should be made aware of this potentially harmful interaction. The NNRTI agents and protease inhibitors for treatment of HIV infection are all metabolized by the cytochrome P450 enzyme system, primarily the 3A4 isoform. Many are also either inducers or inhibitors of CYP3A4 as well. Their myriad potential drug-drug interactions necessitate great caution during the treatment of AIDS patients. For example, an increased incidence of rifabutin-associated uveitis due to increased levels when given in combination with ritonavir is an important consideration when considering the addition of an agent for the prophylaxis or treatment against *Mycobacterium avium* complex (MAC) infection in a patient already on an effective HAART regimen. Similarly, the addition of clarithromycin for prophylaxis

against MAC could potentially increase serum levels of delavirdine, ritonavir, and indinavir; conversely, levels of clarithromycin increase in the presence of indinavir and ritonavir but decrease with efavirenz. Most recently, however, these interactions have been used to advantage in the form of dual protease inhibitor regimens, based upon resultant increased plasma concentrations (C_{max} , C_{min} , and AUC) of the substrate (eg, saquinavir) when coadministered with an inducer (eg, ritonavir). Improved drug exposure, increased antiviral potency, more convenient dosing, and improved tolerability due to the use of lower doses are some of the benefits, thus improving patient adherence to the regimen. A newly licensed coformulation of lopinavir with ritonavir takes advantage of this phenomenon, known as "protease inhibitor boosting." Thus, a thorough working knowledge of potential drug-drug interactions is essential in the care of patients.

Katzung PHARMACOLOGY, 9e > Section VIII. Chemotherapeutic Drugs > Chapter 49.
Antiviral Agents >

Anti-Hepatitis Agents

Agents effective against hepatitis B virus (HBV) and hepatitis C virus (HCV) are now available (see Table 49–5). Although treatment is suppressive rather than curative, the high prevalence of these infections worldwide, with their concomitant morbidity and mortality, reflect a critical need for improved therapeutics.

Table 49–5. Drugs Used to Treat Viral Hepatitis.

Agent	Indication	Recommended Adult Dosage	Route of Administration
Hepatitis B			
Lamivudine ¹	Chronic hepatitis B	100 mg once daily	Oral
Adefovir ¹	Chronic hepatitis B	10 mg once daily	Oral
Interferon alfa-2b	Chronic hepatitis B	5 million units once daily or 10 million units three times weekly	Subcutaneous or intramuscular
Hepatitis C			
Interferon alfa-2b	Acute hepatitis C	5 million units once daily for 3 weeks, then 5 million units three times weekly	Subcutaneous or intramuscular
Interferon alfa-2a	Chronic hepatitis C ²	3 million units three times weekly	Subcutaneous or intramuscular
Interferon alfa-2b	Chronic hepatitis C ²	3 million units three times weekly	Subcutaneous or intramuscular
Interferon alfacon-1	Chronic hepatitis C ²	9 μ g three times weekly (consider 15 μ g three times weekly if patient relapses or is unresponsive)	Subcutaneous
Pegylated	Chronic	180 μ g once weekly	Subcutaneous

interferon alfa-2a	hepatitis C ²		
Pegylated interferon alfa-2b	Chronic hepatitis C ²	40–150 µg once weekly, according to weight	Subcutaneous

¹Dosage must be reduced in patients with renal insufficiency.

²For all agents, combination therapy with oral ribavirin is recommended if tolerated (dosage, 1000–1200 mg/d according to weight).

Lamivudine

The pharmacokinetics and safety profile of lamivudine are described above (see Lamivudine). The more prolonged intracellular half-life in HBV cell lines (17–19 hours) than in HIV-infected cell lines (see above) allows for lower doses, administered less frequently, for hepatitis. Lamivudine can be safely administered to patients with decompensated liver disease.

Lamivudine achieves almost universal HBV DNA suppression, with decreases in viral replication by about 3–4 log copies in most patients. Response to lamivudine is more rapid than to interferon (see below), with HBV DNA levels decreasing by approximately 97% after 2 weeks of therapy and 98% by 1 year. However, evidence of viral replication recurs in over 80% upon discontinuation of therapy. Seroconversion of HBeAg antigen from positive to negative occurs in only about 20% of patients; yet in patients who do achieve seroconversion with lamivudine, the response is typically sustained. Progression to liver fibrosis is less frequent in patients treated with lamivudine compared with placebo. The height of the pretreatment serum ALT level may be the best predictor of HBeAg seroconversion.

Chronic therapy with lamivudine in patients with hepatitis may ultimately be limited by the emergence of lamivudine-resistant HBV isolates with YMDD mutation. Emergence of this mutation, which typically occurs within 8–9 months of therapy, is associated with reappearance of detectable levels of HBV DNA. The estimated rate of YMDD mutation is about 20% per year.

In the doses used for HBV infection, lamivudine has an excellent safety profile. No evidence of mitochondrial toxicity has been reported.

Adefovir

Although initially and abortively developed for treatment of HIV infection, adefovir has been recently approved, at lower and less toxic doses, for treatment of HBV infection. Like tenofovir (see Antiretroviral Agents), adefovir is a nucleotide analog. As an analog of adenosine monophosphate, adefovir is phosphorylated by cellular kinases to the active diphosphate metabolite; it then competitively inhibits HBV DNA polymerase and results in chain termination after incorporation into the viral DNA.

Oral bioavailability is about 59% and is unaffected by meals. Peak serum levels occur at a median of 1.75 hours after dosing, and the terminal elimination half-life is approximately 7.5 hours. Protein binding is less than 4%. Adefovir is renally excreted by a combination of glomerular filtration and active tubular secretion. Dosing interval should be modified in patients with impaired renal

function. Approximately 35% of the adefovir dose is removed during a 4-hour hemodialysis.

Recent placebo-controlled trials showed that adefovir resulted in significant suppression of HBV replication and improvement in liver histology and fibrosis at 1 year. However, as with lamivudine, serum HBV DNA reappeared following cessation of therapy.

Adefovir maintains activity against lamivudine-resistant strains of HBV, and no resistance to adefovir was detected in patients who had received continuous treatment for up to 1 year.

Adefovir is associated with a dose-dependent nephrotoxicity. The risk is low for treatment durations of up to 1 year at its recommended dosage for HBV but may rise in patients with preexisting renal dysfunction or in those treated for longer durations. Also, as with the antiretroviral nucleoside analogs (see Nucleoside Reverse Transcriptase Inhibitors), lactic acidosis and severe hepatomegaly with steatosis may occur. When coadministered with ibuprofen, the AUC of adefovir is increased by about 23%, apparently due to higher oral bioavailability.

Interferon Alfa

Interferons are endogenous proteins that exert complex antiviral, immunomodulatory, and antiproliferative activities through cellular metabolic processes involving synthesis of both RNA and protein (see Chapter 56: Immunopharmacology). They appear to function by binding to specific membrane receptors on the cell surface and initiating a series of intracellular events that include enzyme induction, suppression of cell proliferation, immunomodulatory activities, and inhibition of virus replication. They are classified according to the cell type from which they were derived, and each of the three immunologically distinct major classes of human interferons has unique physicochemical characteristics and different producer cells, inducers, and biologic effects.

Interferon alfa preparations are available for treatment of both HBV and HCV virus infections. Interferon alfa-2b is the only preparation licensed for treatment of HBV infection and for acute hepatitis C. Interferon alfa-2b leads to loss of HBeAg, normalization of serum aminotransferases, and sustained histologic improvement in approximately one-third of patients with chronic hepatitis B, thus reducing the risk of progressive liver disease.

In acute hepatitis C, the rate of clearance of the virus without therapy is estimated to be 15–30%. No therapy has yet been proved effective in the treatment of acute hepatitis C; however, a recent study suggested that interferon alfa-2b, in doses higher than those used for treatment of chronic hepatitis C (see Table 49–5), resulted in a sustained rate of clearance of 98%.

Several interferon alfa preparations are available for the treatment of patients with chronic hepatitis C infection, including interferon alfa-2a, interferon alfa-2b, interferon alfacon-2, pegylated interferon alfa-2a, and pegylated interferon alfa-2b, as described below. Factors associated with a favorable response to therapy include HCV genotype 2 or 3, absence of cirrhosis on liver biopsy, and low pretreatment HCV RNA levels. For all agents, combination therapy with oral ribavirin in patients with chronic hepatitis C is more effective than monotherapy with either interferon or ribavirin alone, increasing the percentage of previously untreated patients with a sustained virologic response from approximately 16% to approximately 40%. Therefore, monotherapy is recommended only in patients who cannot tolerate ribavirin. The time to maximal response may range from 24 weeks to 48 weeks of therapy.

Interferon alfa-2a and interferon alfa-2b may be administered subcutaneously or intramuscularly, while interferon alfacon-1 is administered subcutaneously (see Table 49–5). Maximum serum

concentrations occur approximately 4 hours after intramuscular administration and approximately 7 hours after subcutaneous administration; elimination half-life is 2–5 hours for interferon alfa-2a and 2b, depending on the route of administration. The half-life of interferon alfacon-1 in patients with chronic hepatitis C ranged from 6 hours to 10 hours. Alfa interferons are filtered at the glomeruli and undergo rapid proteolytic degradation during tubular reabsorption, such that detection in the systemic circulation is negligible. Liver metabolism and subsequent biliary excretion are considered minor pathways.

Typical side effects are constitutional in nature, including a flu-like syndrome within 6 hours after dosing in more than 30% of patients that tends to resolve upon continued administration. Other potential adverse effects include thrombocytopenia, granulocytopenia, elevation in serum aminotransferase levels, induction of autoantibodies, nausea, fatigue, headache, arthralgias, rash, alopecia, anorexia, hypotension, and edema. Severe neuropsychiatric side effects may occur. Absolute contraindications to therapy are psychosis, severe depression, neutropenia, thrombocytopenia, symptomatic heart disease, decompensated cirrhosis, uncontrolled seizures, and a history of organ transplantation (other than liver). Alfa interferons are abortifacient in primates and should not be administered in pregnancy.

Pegylated Interferon Alfa

Pegylated interferon alfa-2a (peginterferon alfa-2a) and pegylated interferon alfa-2b (peginterferon alfa-2b) have recently been introduced for the treatment of patients with chronic hepatitis C infection. In these agents, a linear or branched polyethylene glycol (PEG) moiety is attached to interferon by a covalent bond. Reduced clearance and sustained absorption results in an increased half-life and steadier drug concentrations, allowing for less frequent dosing.

In comparison with the nonpegylated interferon alfa compounds, the pegylated products have substantially longer terminal half-lives and slower clearance. Maximum serum concentrations occur between 15 hours and 44 hours after dosing and are sustained for up to 48–72 hours. For pegylated interferon alfa-2a, maximum serum concentrations occur at 72–96 hours after dosing and are sustained for up to 168 hours. In patients with chronic hepatitis C, the mean terminal half-life was 80 hours for pegylated interferon alfa-2a (versus 5.1 hours for interferon alfa-2a) and was about 40 hours for pegylated interferon alfa-2b (versus 2–3 hours for interferon alfa-2b). Renal elimination accounts for about 30% of clearance, and clearance is reduced by approximately half in subjects with impaired renal function. Although dose reduction in renal insufficiency is not specifically recommended, caution is advised in this setting.

Efficacy appears to be superior to therapy with nonpegylated interferons in controlled clinical trials, particularly as regards the proportion of patients with sustained virologic responses. As with the nonpegylated interferon alfa agents, combination therapy of the pegylated interferon alfa compounds with ribavirin is more effective than monotherapy.

Adverse events are similar to those of the interferon alfa agents described above. The PEG molecule is a nontoxic polymer that is readily excreted in the urine.

Ribavirin

Ribavirin is a guanosine analog that is phosphorylated intracellularly by host cell enzymes. Although its mechanism of action has not been fully elucidated, it appears to interfere with the synthesis of guanosine triphosphate, to inhibit capping of viral messenger RNA, and to inhibit the viral RNA-dependent RNA polymerase of certain viruses. Ribavirin triphosphate inhibits the

replication of a wide range of DNA and RNA viruses, including influenza A and B, parainfluenza, respiratory syncytial virus, paramyxoviruses, HCV, and HIV-1.

The absolute oral bioavailability of ribavirin is about 64%, increases with high-fat meals, and decreases with coadministration of antacids. Since elimination is mostly through the urine, clearance is decreased in patients with creatinine clearances less than 30 mL/min.

Ribavirin capsules in combination with subcutaneous interferon alfa-2b are effective for the treatment of chronic hepatitis C infection in patients with compensated liver disease (see Anti-Hepatitis Agents, above). Monotherapy with ribavirin alone is not effective.

Approximately 10–20% of patients experience a dose-dependent hemolytic anemia that may be dose-limiting. Other side effects are depression, fatigue, irritability, rash, cough, insomnia, nausea, and pruritus. Absolute contraindications to ribavirin therapy include anemia, end-stage renal failure, severe heart disease, and pregnancy. Ribavirin is both teratogenic in animals and mutagenic in mammalian cells.

Investigational Agents

The nucleoside analogs entecavir and clevudine, the nucleotide analog emtricitabine, and the immunologic modulators therafirm-HBV and thymosin alpha-1 are new agents under evaluation for the treatment of HBV infection.

Katzung PHARMACOLOGY, 9e > Section VIII. Chemotherapeutic Drugs > Chapter 49.
Antiviral Agents >

Anti-Influenza Agents

Amantadine & Rimantadine

Amantadine (1-aminoadamantane hydrochloride) and its α -methyl derivative, rimantadine, are cyclic amines that inhibit uncoating of the viral RNA of influenza A within infected host cells, thus preventing its replication. Rimantadine is four to ten times more active than amantadine in vitro. Steady state peak plasma levels in healthy young adults average 0.5–0.8 $\mu\text{g/mL}$ for amantadine; elderly persons require only one half of the weight-adjusted dose for young adults to achieve equivalent trough plasma levels of 0.3 $\mu\text{g/mL}$. While amantadine is excreted unmetabolized in the urine, rimantadine undergoes extensive metabolism by hydroxylation, conjugation, and glucuronidation before urinary excretion. Dose reductions are required for both agents in the elderly, in renal insufficiency, and for rimantadine in patients with marked hepatic insufficiency. No supplemental doses of either agent are required after hemodialysis. Plasma half-life is 12–18 hours for amantadine and 24–36 hours for rimantadine.

Both amantadine and rimantadine, in doses of 100 mg twice daily or 200 mg once daily, are approximately 70–90% protective in the prevention of clinical illness by influenza A. The effectiveness of postexposure prophylaxis is inconsistent. When begun within 1–2 days after the onset of clinical symptoms of influenza, both drugs reduce the duration of fever and systemic complaints by 1–2 days.

The primary target for both agents is the M2 protein within the viral membrane; this target incurs both specificity against influenza A (since influenza B contains a different protein in its membrane) and a mutation-prone site, causing the rapid development of resistance in up to 50% of treated

individuals. Transmission of resistant virus to household contacts has been documented. Cross-resistance to zanamivir and oseltamivir does not occur.

The most common adverse effects are gastrointestinal intolerance and central nervous system complaints (eg, nervousness, difficulty in concentrating, lightheadedness); the latter are less frequent with rimantadine than with amantadine. The central nervous system toxicity of amantadine may be increased with concomitant antihistamines, anticholinergic drugs, hydrochlorothiazide, and trimethoprim-sulfamethoxazole. Serious neurotoxic reactions, occasionally fatal, may occur in association with high amantadine plasma concentrations (1–5 $\mu\text{g/mL}$). Acute amantadine overdose is associated with anticholinergic effects. Amantadine is teratogenic and embryotoxic in rodents, and birth defects have been reported after exposure during pregnancy.

Zanamivir & Oseltamivir

Neuraminidase is an essential viral glycoprotein for virus replication and release. The neuraminidase inhibitors zanamivir and oseltamivir have recently been approved for the treatment of acute uncomplicated influenza infection. When a 5-day course of therapy is initiated within 36–48 hours after the onset of symptoms, use of either agent shortens the severity and duration of illness and may decrease the incidence of respiratory complications in children and adults. Unlike amantadine and rimantadine, zanamivir and oseltamivir have activity against both influenza A and influenza B. Zanamivir is administered via oral inhaler. The compound displays poor oral bioavailability, limited plasma protein binding, rapid renal clearance, and absence of significant metabolism. Nasal and throat discomfort may occur—as well as bronchospasm in patients with reactive airway disease.

Oseltamivir is an orally administered prodrug that is activated in the gut and liver. Dosage is 75 mg twice daily. The half-life of oseltamivir is 6–10 hours, and excretion is primarily in the urine. In addition to treatment of influenza, prophylaxis once daily may be effective in preventing influenza. Potential side effects include nausea and vomiting, which may be decreased by administration with food.

Decreased susceptibility to zanamivir and oseltamivir in vitro is associated with mutations in viral neuraminidase or hemagglutinin. A resistant virus was recovered from an immunocompromised patient who had received zanamivir for 2 weeks. However, the incidence and clinical significance of resistance are not yet known.

Katzung PHARMACOLOGY, 9e > Section VIII. Chemotherapeutic Drugs > Chapter 49.
Antiviral Agents >

Other Antiviral Agents

Interferons

Interferons have been studied for numerous clinical indications. In addition to HBV and HCV infections (see Anti-Hepatitis Agents, above), intralesional injection of interferon alfa-2b or alfa-n3 may be used for treatment of condylomata acuminata.

Ribavirin

In addition to oral administration for hepatitis C infection in combination with interferon alfa (see above), aerosolized ribavirin is administered by nebulizer (20 mg/mL for 12–18 hours per day for

3–7 days) to children and infants with severe respiratory syncytial virus (RSV) bronchiolitis or pneumonia, reducing the severity and duration of illness. Aerosolized ribavirin has also been used to treat influenza A and B infection but has not gained widespread use. Aerosolized ribavirin is generally well tolerated but may cause conjunctival or bronchial irritation. Health care workers should be protected against extended inhalation exposure.

Intravenous ribavirin decreases mortality in Lassa fever and other viral hemorrhagic fevers if started early. Clinical benefit has been reported in cases of severe measles pneumonitis, and continuous infusion of ribavirin decreased virus shedding in several patients with severe lower respiratory tract influenza or parainfluenza infections. Peak plasma concentrations are approximately tenfold higher than with oral administration and occur earlier (ie, at 0.5 hours after dosing). At steady state, cerebrospinal fluid levels are about 70% of those in plasma.

Palivizumab

Palivizumab is a humanized monoclonal antibody directed against the F glycoprotein on the surface of RSV. It was recently approved for the prevention of RSV infection in high-risk infants and children such as premature infants and those with bronchopulmonary dysplasia. A placebo-controlled trial utilizing once-monthly intramuscular injections (15 mg/kg) for 5 months beginning at the start of the RSV season demonstrated a 55% reduction in the risk of hospitalization for RSV in treated patients. The major observed adverse effect has been elevation in serum aminotransferase levels.

Imiquimod

Imiquimod is an immune response modifier shown to be effective in the topical treatment of external genital and perianal warts (ie, condyloma acuminatum; see Chapter 62: Dermatologic Pharmacology). The mechanism of action against these human papillomavirus (HPV)-induced lesions is unknown. The 5% cream is to be applied three times weekly. Local skin reactions are the most common side effect.

Antiviral Agents >

Preparations Available

Abacavir(Ziagen)

Oral: 300 mg tablets; 20 mg/mL solution

Oral (Trizir): 300 mg tablets in combination with 150 mg lamivudine and 300 mg zidovudine

Acyclovir(generic, Zovirax)

Oral: 200 mg capsules; 400, 800 mg tablets; 200 mg/5 mL suspension

Parenteral: 50 mg/mL; powder to reconstitute for injection (500, 1000 mg/vial)

Topical: 5% ointment

Adefovir(Hepsera)

Oral: 10 mg tablets

Amantadine(generic, Symmetrel)

Oral: 100 mg capsules, tablets; 50 mg/5 mL syrup

Amprenavir(Agenerase)

Oral: 50, 150 mg capsules; 15 mg/mL solution

Cidofovir(Vistide)

Parenteral: 375 mg/vial (75 mg/mL) for IV injection

Delavirdine(Rescriptor)

Oral: 100, 200 mg tablets

Didanosine(dideoxyinosine, ddI)

Oral (Videx): 25, 50, 100, 150, 200 mg tablets; 100, 167, 250 mg powder for oral solution; 2, 4 g powder for pediatric solution

Oral (Videx-EC): 125, 200, 250, 400 mg delayed release capsules

Efavirenz(Sustiva)

Oral: 50, 100, 200 mg capsules; 600 mg tablets

Enfuvirtide(Fuzeon)

Parenteral: 90 mg/mL for injection

Famciclovir(Famvir)

Oral: 125, 250, 500 mg tablets

Fomivirsen(Vitravene)

Intravitreal: 6.6 mg/mL for injection

Foscarnet(Foscavir)

Parenteral: 24 mg/mL for IV injection

Ganciclovir(Cytovene)

Oral: 250, 500 mg capsules

Parenteral: 500 mg/vial for IV injection

Intraocular implant (Vitraser): 4.5 mg ganciclovir/implant

Idoxuridine (Herplex)

Ophthalmic: 0.1% solution

Imiquimod(Aldera)

Topical: 5% cream

Indinavir(Crixivan)

Oral: 100, 200, 333, 400 mg capsules

Interferon alfa-2a(Roferon-A)

Parenteral: 3, 6, 9, 36 million IU vials

Interferon alfa-2b(Intron-A)

Parenteral: 3, 5, 10, 18, 25, and 50 million IU vials

Interferon alfa-2b(Rebetron)

Parenteral: 3 million IU vials (supplied with oral ribavirin, 200 mg capsules)

Interferon alfa-n3(Alferon N)

Parenteral: 5 million IU/vial

Interferon alfacon-1 (Infergen)

Parenteral: 9 and 15 µg vials

Lamivudine(Epivir)

Oral (Epivir): 150, 300 mg tablets; 10 mg/mL oral solution

Oral (Epivir-HBV): 100 mg tablets; 5 mg/mL solution

Oral (Combivir): 150 mg tablets in combination with 300 mg zidovudine

Oral (Trizir): 300 mg tablets in combination with 150 mg lamivudine and 300 mg zidovudine

Lopinavir/ritonavir (Kaletra)

Oral: 133.3 mg/33.3 mg capsules; 400 mg/100 mg per 5 mL solution

Nelfinavir(Viracept)

Oral: 250 mg tablets; 50 mg/g powder

Nevirapine(Viramune)

Oral: 200 mg tablets; 50 mg/5 mL suspension

Oseltamivir(Tamiflu)

Oral: 75 mg capsules; powder to reconstitute as suspension (12 mg/mL)

Palivizumab(Synagis)

Parenteral: 50, 100 mg/vial

Peginterferon alfa-2a(pegylated interferon-alfa 2a, Pegasys)

Parenteral: 180 µg/mL

Peginterferon alfa-2b(pegylated interferon-alfa 2b, PEG-Intron)

Parenteral: powder to reconstitute as 100, 160, 240, 300 µg/mL injection

Penciclovir(Denavir)

Topical: 1% cream

Ribavirin

Aerosol (Virazole): powder to reconstitute for aerosol; 6 gm/100 mL vial

Oral (Rebetol): 200 mg capsules

Oral (Rebetron): 200 mg in combination with 3 million units interferon alfa-2b (Intron-A)

Rimantadine(Flumadine)

Oral: 100 mg tablets; 50 mg/5 mL syrup

Ritonavir(Norvir)

Oral: 100 mg capsules; 80 mg/mL oral solution

Saquinavir

Oral (Invirase): 200 mg hard gel capsules

Oral (Fortovase): 200 mg soft gel capsules

Stavudine(Zerit)

Oral: 15, 20, 30, 40 mg capsules; powder for 1 mg/mL oral solution

Tenofovir(Viread)

Oral: 300 mg tablets

Trifluridine(Viroptic)

Topical: 1% ophthalmic solution

Valacyclovir(Valtrex)

Oral: 500, 1000 mg tablets

Valgancyclovir (Valcyte)

Oral: 450 mg capsules

Zalcitabine(dideoxycytidine, ddC) (Hivid)

Oral: 0.375, 0.75 mg tablets

Zanamivir(Relenza)

Inhalational: 5 mg/rotadisk

Zidovudine(azidothymidine, AZT) (Retrovir)

Oral: 100 mg capsules, 300 mg tablets, 50 mg/5 mL syrup

Oral (Combivir): 300 mg tablets in combination with 150 mg lamivudine

Oral (Trizir): 300 mg tablets in combination with 150 mg lamivudine and 300 mg zidovudine

Parenteral: 10 mg/mL

Chapter 50. Miscellaneous Antimicrobial Agents; Disinfectants, Antiseptics, & Sterilants

Katzung PHARMACOLOGY, 9e > Section VIII. Chemotherapeutic Drugs > Chapter 50.
Miscellaneous Antimicrobial Agents; Disinfectants, Antiseptics, & Sterilants >

Metronidazole, Mupirocin, Polymyxins, & Urinary Antiseptics

Metronidazole

Metronidazole is a nitroimidazole antiprotozoal drug (see Chapter 53: Antiprotozoal Drugs) that

also has potent antibacterial activity against anaerobes, including bacteroides and clostridium species. It is well absorbed after oral administration, widely distributed in tissues, and reaches serum levels of 4–6 $\mu\text{g}/\text{mL}$ after a 250 mg oral dose. Metronidazole can also be given intravenously or by rectal suppository. The drug penetrates well into the cerebrospinal fluid, reaching levels similar to those in serum. Metronidazole is metabolized in the liver and may accumulate in hepatic insufficiency.

Metronidazole is indicated for treatment of anaerobic or mixed intra-abdominal infections, vaginitis (trichomonas, bacterial vaginosis), antibiotic-associated enterocolitis, and brain abscess. The typical dosage is 500 mg three times daily orally or intravenously (30 mg/kg/d). Vaginitis may respond to a single 2 g dose. A vaginal gel is available for topical use.

Adverse effects include nausea, diarrhea, stomatitis, and peripheral neuropathy with prolonged use. Metronidazole has a disulfiram-like effect, and patients should be instructed to avoid alcohol. Although teratogenic in some animals, metronidazole has not been associated with this effect in humans.

Other properties of metronidazole are discussed in Chapter 53: Antiprotozoal Drugs.

Mupirocin

Mupirocin (pseudomonic acid) is a natural product produced by *Pseudomonas fluorescens*. It is rapidly inactivated after absorption, and systemic levels are undetectable. It is available as an ointment for topical application.

Mupirocin is active against gram-positive cocci, and its use is directed against *S aureus*, both methicillin-susceptible and methicillin-resistant strains. Mupirocin inhibits and kills staphylococci by inhibiting isoleucyl tRNA synthetase. Low-level resistance, defined as a minimum inhibitory concentration (MIC) of up to 100 $\mu\text{g}/\text{mL}$, is due to point mutation in the gene of the target enzyme. Low-level resistance has been observed after prolonged use, but local concentrations achieved with topical application are well above this MIC, and this level of resistance does not lead to clinical failure. High-level resistance, with MICs exceeding 1000 $\mu\text{g}/\text{mL}$, is due to the presence of a second isoleucyl tRNA synthetase gene, which is plasmid-encoded. High-level resistance results in complete loss of activity. Strains with high-level resistance have caused nosocomial (hospital) outbreaks of staphylococcal infection and colonization.

Mupirocin is indicated for topical treatment of minor skin infections, such as impetigo. Topical application over large infected areas, such as decubitus ulcers or open surgical wounds, has been identified as an important factor leading to emergence of mupirocin-resistant strains and is not recommended. Mupirocin is also indicated for intranasal application for elimination of methicillin-resistant *S aureus* carriage by patients or health care workers.

Polymyxins

The polymyxins are a group of basic peptides active against gram-negative bacteria. Polymyxins act like cationic detergents. They attach to and disrupt bacterial cell membranes. They also bind and inactivate endotoxin. Gram-positive organisms, proteus, and neisseria are resistant. Only polymyxin B is available in the USA.

Owing to their significant toxicity with systemic administration, polymyxins are now restricted to topical use. Ointments containing polymyxin B, 0.5 mg/g, in mixtures with bacitracin or neomycin

(or both) are commonly applied to infected superficial skin lesions.

Urinary Antiseptics

Urinary antiseptics are oral agents that exert antibacterial activity in the urine but have little or no systemic antibacterial effect. Their usefulness is limited to lower urinary tract infections. Prolonged suppression of bacteriuria by means of urinary antiseptics may be desirable in chronic urinary tract infections where eradication of infection by short-term systemic therapy has not been possible.

Nitrofurantoin

Nitrofurantoin is bacteriostatic and bactericidal for many gram-positive and gram-negative bacteria. *P aeruginosa* and many strains of proteus are resistant, but in nitrofurantoin-susceptible populations resistant mutants are rare. Clinical drug resistance emerges slowly. There is no cross-resistance between nitrofurantoin and other antimicrobial agents.

Nitrofurantoin is well absorbed after ingestion. It is metabolized and excreted so rapidly that no systemic antibacterial action is achieved. The drug is excreted into the urine by both glomerular filtration and tubular secretion. With average daily doses, concentrations of 200 µg/mL are reached in urine. In renal failure, urine levels are insufficient for antibacterial action, but high blood levels may cause toxicity.

The average daily dose for urinary tract infection in adults is 100 mg orally taken four times daily with food or milk. Nitrofurantoin is contraindicated in patients with severe renal insufficiency. Oral nitrofurantoin can be given for months for the suppression of chronic urinary tract infection. It is desirable to keep urinary pH below 5.5, which greatly enhances drug activity. A single daily dose of nitrofurantoin, 100 mg, can prevent recurrent urinary tract infections in some women.

Anorexia, nausea, and vomiting are the principal side effects of nitrofurantoin. Neuropathies and hemolytic anemia occur in glucose-6-phosphate dehydrogenase deficiency. Nitrofurantoin antagonizes the action of nalidixic acid. Rashes, pulmonary infiltration, and other hypersensitivity reactions have been reported.

Methenamine Mandelate & Methenamine Hippurate

Methenamine mandelate is the salt of mandelic acid and methenamine and possesses properties of both of these urinary antiseptics. Methenamine hippurate is the salt of hippuric acid and methenamine. Below pH 5.5, methenamine releases formaldehyde, which is antibacterial. Mandelic acid or hippuric acid taken orally is excreted unchanged in the urine, in which these drugs are bactericidal for some gram-negative bacteria when pH is less than 5.5.

Methenamine mandelate, 1 g four times daily, or methenamine hippurate, 1 g twice daily by mouth (children, 50 mg/kg/d or 30 mg/kg/d, respectively), is used only as a urinary antiseptic. Acidifying agents (eg, ascorbic acid, 4–12 g/d) may be given to lower urinary pH below 5.5. Sulfonamides should not be given at the same time because they may form an insoluble compound with the formaldehyde released by methenamine. Persons taking methenamine mandelate may exhibit falsely elevated tests for catecholamine metabolites.

The action of methenamine mandelate or hippurate is nonspecific against many different microorganisms and consists of the simultaneous effects of formaldehyde and acidity. Microorganisms such as proteus that make a strongly alkaline urine through release of ammonia

from urea are usually resistant.

Katzung PHARMACOLOGY, 9e > Section VIII. Chemotherapeutic Drugs > Chapter 50. Miscellaneous Antimicrobial Agents; Disinfectants, Antiseptics, & Sterilants >

Disinfectants, Antiseptics, & Sterilants

Disinfectants are strong chemical agents that inhibit or kill microorganisms (Table 50–1). **Antiseptics** are disinfecting agents with sufficiently low toxicity for host cells that they can be used directly on skin, mucous membranes, or wounds. **Sterilants** kill both vegetative cells and spores when applied to materials for appropriate times and temperatures. Some of the terms used in this context are defined in Table 50–2.

	Bacteria				Viruses		Other		
	Gram-positive	Gram-negative	Acid-fast	Spores	Lipophilic	Hydrophilic	Fungi	Amebic Cysts	Prions
Alcohols (isopropanol, ethanol)	HS	HS	S	R	S	V	—	—	R
Aldehydes (glutaraldehyde, formaldehyde)	HS	HS	MS	S (slow)	S	MS	S	—	R
Chlorhexidine gluconate	HS	MS	R	R	V	R	—	—	R
Sodium hypochlorite, chlorine dioxide	HS	HS	MS	S (pH 7.6)	S	S (at high conc)	MS	S	MS (at high conc)
Hexachlorophene	S (slow)	R	R	R	R	R	R	R	R
Povidone, iodine	HS	HS	S	S (at high conc)	S	R	S	S	R
Phenols, quaternary ammonium compounds	HS	HS	±	R	S	R	—	—	R
Strong oxidizing agents, cresols	HS	MS to R	R	R	S	R	R	R	R

Key: HS, highly susceptible; S, susceptible; MS, moderately susceptible; R, resistant; V, variable;

—, no data.	
Table 50–2. Commonly Used Terms Related to Chemical and Physical Killing of Microorganisms.	
Antisepsis	Application of an agent to living tissue for the purpose of preventing infection
Decontamination	Destruction or marked reduction in number or activity of microorganisms
Disinfection	Chemical or physical treatment that destroys most vegetative microbes or viruses, but not spores, in or on inanimate surfaces
Sanitization	Reduction of microbial load on an inanimate surface to a level considered acceptable for public health purposes
Sterilization	A process intended to kill or remove all types of microorganisms, including spores, and usually including viruses with an acceptable low probability of survival
Pasteurization	A process that kills nonsporulating microorganisms by hot water or steam at 65–100 °C

The process of disinfection prevents infection by reducing the number of potentially infective organisms either by killing, removing, or diluting them. Disinfection can be accomplished by application of chemical agents or use of physical agents such as ionizing irradiation, dry or moist heat, or superheated steam (autoclave, 120 °C) to kill microorganisms. Often a combination of agents is used, eg, water and moderate heat over time (pasteurization); ethylene oxide and moist heat (a sterilant); or addition of disinfectant to a detergent. Prevention of infection also can be achieved by washing, which dilutes the potentially infectious organism, or by establishing a barrier, eg, gloves, condom, or respirator, which prevents the pathogen from entry into the host.

Handwashing is the most important means of preventing transmission of infectious agents from person to person or from regions of high microbial load, eg, mouth, nose, or gut, to potential sites of infection. Regular handwashing is best done without disinfectants to minimize drying, irritation, and sensitization of the skin. Soap and warm water efficiently and effectively remove bacteria. Skin disinfectants along with detergent and water are usually used preoperatively as a surgical scrub for surgeons' hands and the patient's surgical incision.

Evaluation of effectiveness of antiseptics, disinfectants, and sterilants, although seemingly simple in principle, is very complex. Factors in any evaluation include the intrinsic resistance of the microorganism, the number of the microorganisms present, mixed populations of organisms, amount of organic material present (eg blood, feces, tissue), concentration and stability of disinfectant or sterilant, time and temperature of exposure, pH, and hydration and binding of the agent to surfaces. Specific, standardized assays of activity are defined for each use. Toxicity for humans also must be evaluated. The Environmental Protection Agency (EPA) regulates disinfectants and sterilants and the Food and Drug Administration regulates antiseptics.

Users of antiseptics, disinfectants, and sterilants need to consider their short-term and long-term toxicity since they may have general biocidal activity and may accumulate in the environment or in the body of the patient or caregiver using the agent. Disinfectants and antiseptics may also become contaminated by resistant microorganisms—eg, spores, *Pseudomonas aeruginosa*, or *Serratia marcescens*—and actually transmit infection. Most topical antiseptics interfere with wound healing to some degree. Simple cleansing with soap and water is less damaging than antiseptics to wounds.

Topical antibiotics with a narrow spectrum of action and low toxicity (eg, bacitracin and mupirocin) can be used for temporary control of bacterial growth and are generally preferred to antiseptics. Methenamine mandelate releases formaldehyde in a low antibacterial concentration at acid pH and can be an effective urinary antiseptic for long-term control of urinary tract infections.

Some of the chemical classes of antiseptics, disinfectants, and sterilants are described briefly below. The reader is referred to the general references for descriptions of physical disinfection and sterilization methods.

Alcohols

The two alcohols most frequently used for antiseptics and disinfection are ethanol and isopropyl alcohol (isopropanol). They are rapidly active, killing vegetative bacteria, *M tuberculosis*, and many fungi and inactivating lipophilic viruses. The optimum bactericidal concentration is 60–90% by volume in water. They probably act by denaturation of proteins. They are not used as sterilants because they are not sporicidal, do not penetrate protein-containing organic material, may not be active against hydrophilic viruses, and lack residual action because they evaporate completely. The alcohols are useful in situations where sinks with running water are not available for washing with soap and water. Their skin-drying effect can be partially alleviated by addition of emollients to the formulation.

Alcohols are flammable and must be stored in cool, well-ventilated areas. Alcohols must be allowed to evaporate before use of cautery, electrosurgery, or laser surgery. They may be damaging if applied directly to corneal tissue. Therefore, instruments such as tonometers that have been disinfected in alcohol should be rinsed with sterile water or the alcohol allowed to evaporate before they are used.

Chlorhexidine

Chlorhexidine is a cationic biguanide with very low water solubility. Water-soluble chlorhexidine digluconate is used in water-based formulations as an antiseptic. It is active against vegetative bacteria and mycobacteria and has moderate activity against fungi and viruses. It strongly adsorbs to bacterial membranes, causing leakage of small molecules and precipitation of cytoplasmic proteins. It is active at pH 5.5–7.0. Chlorhexidine gluconate is slower in its action than alcohols, but because of its persistence it has residual activity when used repeatedly, producing bactericidal action equivalent to alcohols. It is most effective against gram-positive cocci and less active against gram-positive and gram-negative rods. Spore germination is inhibited by chlorhexidine. Chlorhexidine digluconate is resistant to inhibition by blood and organic materials. However, anionic and nonionic agents in moisturizers, neutral soaps, and surfactants may neutralize its action. Chlorhexidine digluconate formulations of 4% concentration have slightly greater antibacterial activity than newer 2% formulations. Chlorhexidine 0.5% in 70% alcohol formulations are available in some countries. Chlorhexidine has a very low skin-sensitizing or irritating capacity. Oral toxicity is low because chlorhexidine is poorly absorbed from the alimentary tract. Chlorhexidine must not be used during surgery on the middle ear because it causes sensorineural deafness. Similar neural toxicity may be encountered during neurosurgery.

Halogens

Iodine

Iodine in a 1:20,000 solution is bactericidal in 1 minute and kills spores in 15 minutes. Tincture of

iodine USP contains 2% iodine and 2.4% sodium iodide in alcohol. It is the most active antiseptic for intact skin. It is not commonly used because of serious hypersensitivity reactions that may occur and because of its staining of clothing and dressings.

Iodophors

Iodophors are complexes of iodine with a surface-active agent such as **polyvinyl pyrrolidone (PVP; povidone-iodine)**. Iodophors retain the activity of iodine. They kill vegetative bacteria, mycobacteria, fungi, and lipid-containing viruses. They may be sporicidal upon prolonged exposure. Iodophors can be used as antiseptics or disinfectants, the latter containing more free iodine. The amount of free iodine is low, but it is released as the solution is diluted. An iodophor solution must be diluted according to the manufacturer's directions in order to obtain full activity.

Iodophors are less irritating and less likely to produce skin hypersensitivity than tincture of iodine. They act as rapidly as chlorhexidine and have a broader spectrum of action, including sporicidal action, but they lack the persistent action of chlorhexidine.

Chlorine

Chlorine is a strong oxidizing agent and universal disinfectant that is most commonly provided as a 5.25% **sodium hypochlorite** solution, a typical formulation for **household bleach**. As formulations may vary, the exact concentration should be verified on the label. A 1:10 dilution of household bleach provides 5000 ppm of available chlorine. The Centers for Disease Control and Prevention recommends this concentration for disinfection of blood spills. Less than 5 ppm kills vegetative bacteria, whereas up to 5000 ppm is necessary to kill spores. A concentration of 1000–10,000 ppm is tuberculocidal. One hundred ppm kills vegetative fungal cells in 1 hour, but fungal spores require 500 ppm. Viruses are inactivated by 200–500 ppm. Dilutions of 5.25% sodium hypochlorite made up in pH 7.5–8.0 tap water retain their activity for months when kept in tightly closed, opaque containers. Frequent opening and closing of the container reduces the activity markedly.

Because chlorine is inactivated by blood, serum, feces, and protein-containing materials, surfaces should be cleaned before chlorine disinfectant is applied. Undissociated hypochlorous acid (HOCl) is the active biocidal agent. When pH is increased, the less active hypochlorite ion, OCl⁻, is formed. When hypochlorite solutions contact formaldehyde, the carcinogen *bis*-chloromethyl is formed. Rapid evolution of irritating chlorine gas occurs when hypochlorite solutions are mixed with acid and urine. Solutions are corrosive to aluminum, silver, and stainless steel.

Alternative chlorine-releasing compounds include **chlorine dioxide** and **chloramine T**. These agents retain chlorine longer and have a prolonged bactericidal action.

Phenolics

Phenol itself (perhaps the oldest of the surgical antiseptics) is no longer used even as a disinfectant because of its corrosive effect on tissues, its toxicity upon absorption, and its carcinogenic effect. These adverse actions are diminished by forming derivatives in which a functional group replaces a hydrogen atom in the aromatic ring. The phenolic agents most commonly used are ***o*-phenylphenol**, ***o*-benzyl-*p*-chlorophenol**, and ***p*-tertiary amylphenol**. Mixtures of phenolic derivatives are often used. Some of these are derived from coal tar distillates, eg, cresols and xylenols. Skin absorption and skin irritation still occur with these derivatives, and appropriate care is necessary in their use. Detergents are often added to formulations to clean and remove organic material that may decrease the activity of a phenolic compound.

Phenolic compounds disrupt cell walls and membranes, precipitate proteins, and inactivate enzymes. They are bactericidal (including mycobacteria), fungicidal, and capable of inactivating lipophilic viruses. They are not sporicidal. Dilution and time of exposure recommendations of the manufacturer must be followed.

Phenolic disinfectants are used for hard surface decontamination in hospitals and laboratories, eg, floors, beds, and counter or bench tops. They are not recommended for use in nurseries and especially bassinets, where their use has been associated with hyperbilirubinemia. Use of **hexachlorophene** as a skin disinfectant has caused cerebral edema and convulsions in premature infants and occasionally in adults.

Quaternary Ammonium Compounds

The quaternary ammonium compounds ("quats") are cationic surface-active detergents. The active cation has at least one long water-repellent hydrocarbon chain, which causes the molecules to concentrate as an oriented layer on the surface of solutions and colloidal or suspended particles. The charged nitrogen portion of the cation has high affinity for water and prevents separation out of solution. The bactericidal action of quaternary compounds has been attributed to inactivation of energy-producing enzymes, denaturation of proteins, and disruption of the cell membrane. These agents are bacteriostatic, fungistatic, sporistatic, and also inhibit algae. They are bactericidal for gram-positive bacteria and moderately active against gram-negative bacteria. Lipophilic viruses are inactivated. They are not tuberculocidal or sporicidal, and they do not inactivate hydrophilic viruses. Quaternary ammonium compounds bind to the surface of colloidal protein in blood, serum, and milk and to fibers present in cotton, mops, cloths, and paper towels used to apply them, which can cause inactivation of the agent by removing it from solution. They are inactivated by anionic detergents (soaps), by many nonionic detergents, and by calcium, magnesium, ferric, and aluminum ions.

Quaternary compounds are used for sanitation of noncritical surfaces (floors, bench tops, etc). Their low toxicity has led to their use as sanitizers in food production facilities. CDC recommends that quaternary ammonium compounds such as **benzalkonium chloride** not be used as antiseptics because several outbreaks of infections have occurred that were due to growth of pseudomonas and other gram-negative bacteria in quaternary ammonium antiseptic solutions.

Aldehydes

Formaldehyde and **glutaraldehyde** are used for disinfection or sterilization of instruments such as fiberoptic endoscopes, respiratory therapy equipment, hemodialyzers, and dental handpieces that can not withstand exposure to the high temperatures of steam sterilization. They are not corrosive for metal, plastic, or rubber. These agents have a broad spectrum of activity against microorganisms and viruses. They act by alkylation of chemical groups in proteins and nucleic acids. Failures of disinfection or sterilization can occur as a result of dilution below the known effective concentration, the presence of organic material, and the failure of liquid to penetrate into small channels in the instruments. Automatic circulating baths are available that increase penetration of aldehyde solution into the instrument while decreasing exposure of the operator to irritating fumes.

Formaldehyde is available as a 40% w/v solution in water (100% **formalin**). An 8% formaldehyde solution in water has a broad spectrum of activity against bacteria, fungi, and viruses. Sporicidal activity may take as long as 18 hours. Its rapidity of action is increased by solution in 70% isopropanol. Formaldehyde solutions are used for high-level disinfection of hemodialyzers, preparation of vaccines, and preservation and embalming of tissues. The 4% formaldehyde (10%

formalin) solutions used for fixation of tissues and embalming may not be mycobactericidal.

Glutaraldehyde is a dialdehyde (1,5-pentanedial). Solutions of 2% w/v glutaraldehyde are most commonly used. The solution must be alkalized to pH 7.4–8.5 for activation. Activated solutions are bactericidal, sporicidal, fungicidal, and virucidal for both lipophilic and hydrophilic viruses. Glutaraldehyde has greater sporicidal activity than formaldehyde, but its tuberculocidal activity may be less. Lethal action against mycobacteria and spores may require prolonged exposure. Once activated, solutions have a shelf life of 14 days, after which polymerization reduces activity. Other means of activation and stabilization can increase the shelf life. Since glutaraldehyde solutions are frequently reused, the most common reason for loss of activity is dilution and exposure to organic material. Test strips to measure residual activity are recommended.

Formaldehyde has a characteristic pungent odor and is highly irritating to respiratory mucous membranes and eyes at concentrations of 2–5 ppm. OSHA has declared that formaldehyde is a potential carcinogen and has established an employee exposure standard that limits the 8-hour time-weighted average (TWA) exposure to 0.75 ppm. Protection of health care workers from exposure to glutaraldehyde concentrations greater than 0.2 ppm is advisable. Increased air exchange, enclosure in hoods with exhausts, tight-fitting lids on exposure devices, and use of protective personal equipment such as goggles, respirators, and gloves may be necessary to achieve these exposure limits.

Peroxygen Compounds

The peroxygen compounds, **hydrogen peroxide** and **peracetic acid**, have high killing activity and a broad spectrum against bacteria, spores, viruses, and fungi when used in appropriate concentration. They have the advantage that their decomposition products are not toxic and do not injure the environment. They are powerful oxidizers that are used primarily as disinfectants and sterilants.

Hydrogen peroxide is a very effective disinfectant when used for inanimate objects or materials with low organic content such as water. Organisms with the enzymes catalase and peroxidase rapidly degrade hydrogen peroxide. The innocuous degradation products are oxygen and water. Concentrated solutions containing 90% w/v H₂O₂ are prepared electrochemically. When diluted in high-quality deionized water to 6% and 3% and put into clean containers, they remain stable. Hydrogen peroxide has been proposed for disinfection of respirators, acrylic resin implants, plastic eating utensils, soft contact lenses, and cartons intended to contain milk or juice products. Concentrations of 10–25% hydrogen peroxide are sporicidal. Vapor phase hydrogen peroxide (VPHP) is a cold gaseous sterilant that has the potential to replace the toxic or carcinogenic gases ethylene oxide and formaldehyde. VPHP does not require a pressurized chamber and is active at temperatures as low as 4 °C and concentrations as low as 4 mg/L. It is incompatible with liquids and cellulose products. It penetrates the surface of some plastics.

Peracetic acid (CH₃COOOH) is prepared commercially from 90% hydrogen peroxide, acetic acid, and sulfuric acid as a catalyst. It is explosive in the pure form. It is usually used in dilute solution and transported in containers with vented caps to prevent increased pressure as oxygen is released. Peracetic acid is more active than hydrogen peroxide as a bactericidal and sporicidal agent. Concentrations of 250–500 ppm are effective against a broad range of bacteria in 5 minutes at pH 7.0 at 20 °C. Bacterial spores are inactivated by 500–30,000 ppm peracetic acid. Only slightly increased concentrations are necessary in the presence of organic matter. Viruses require variable exposures. Enteroviruses require 2000 ppm for 15–30 minutes for inactivation.

An automated machine has been developed for sterilization of medical, surgical, and dental instruments. It uses buffered peracetic acid liquid of 0.1–0.5% concentration. Peracetic acid sterilization systems have been adopted for hemodialyzers. The food processing and beverage industries use peracetic acid extensively because the breakdown products in high dilution do not produce objectionable odor, taste, or toxicity. Since rinsing is not necessary in this use, time and money are saved.

Peracetic acid is a potent tumor promoter but a weak carcinogen. It is not mutagenic in the Ames test.

Heavy Metals

Heavy metals, principally mercury and silver, are now rarely used as disinfectants. Mercury is an environmental hazard, and some pathogenic bacteria have developed plasmid-mediated resistance to mercurials. Hypersensitivity to thimerosal is common, possibly in as high as 40% of the population. These compounds are absorbed from solution by rubber and plastic closures. Nevertheless, **thimerosal** 0.001–0.004% is still used as a preservative of vaccines, antitoxins, and immune sera.

Inorganic silver salts are strongly bactericidal. **Silver nitrate**, 1:1000, has been most commonly used, particularly as a preventive for gonococcal ophthalmitis in newborns. Antibiotic ointments have replaced silver nitrate for this indication. **Silver sulfadiazine** slowly releases silver and is used to suppress bacterial growth in burn wounds (see Chapter 46: Sulfonamides, Trimethoprim, & Quinolones).

Sterilants

For many years, pressurized **steam (autoclaving)** at 120 °C for 30 minutes has been the basic method for sterilizing instruments and decontaminating materials. When autoclaving is not possible, as is the case with lensed instruments and materials containing plastic and rubber, **ethylene oxide**—diluted with either fluorocarbon or carbon dioxide to diminish explosive hazard—was used at 440–1200 mg/L at 45–60 °C with 30–60% relative humidity. The higher concentrations have been used to increase penetration.

Ethylene oxide is classified as a mutagen and carcinogen. The OSHA permissible exposure limit (PEL) for ethylene oxide is 1 ppm calculated as a time-weighted average. Alternative sterilants now being used increasingly include vapor phase hydrogen peroxide, peracetic acid, ozone, gas plasma, chlorine dioxide, formaldehyde, and propylene oxide. Each of these sterilants has potential advantages and problems. Automated peracetic acid systems are being used increasingly for high-level decontamination and sterilization of endoscopes and hemodialyzers because of their effectiveness, automated features, and the low toxicity of the residual products of sterilization.

Preservatives

Disinfectants are used as preservatives to prevent the overgrowth of bacteria and fungi in pharmaceutical products, laboratory sera and reagents, cosmetic products, and contact lenses. Multi-use vials of medication that may be reentered through a rubber diaphragm, and eye and nose drops, require preservatives. Preservatives should not be irritant or toxic to tissues to which they will be applied, must be effective in preventing growth of microorganisms likely to contaminate them, and must have sufficient solubility and stability to remain active.

Commonly used preservative agents include organic acids such as **benzoic acid** and salts, the **parabens**, (alkyl esters of *p*-hydroxybenzoic acid), sorbic acid and salts, phenolic compounds, quaternary ammonium compounds, alcohols, and mercurials such as thimerosal in 0.001–0.004% concentration.

Miscellaneous Antimicrobial Agents; Disinfectants, Antiseptics, & Sterilants >

Preparations Available

Miscellaneous Antimicrobial Drugs

Methenamine hippurate (Hiprex, Urex)

Oral: 1.0 g tablets

Methenamine mandelate (generic)

Oral: 0.5, 1 g tablets; 0.5 g/5 mL suspension

Metronidazole(generic, Flagyl)

Oral: 250, 500 mg tablets; 375 mg capsules; 750 mg extended-release tablets

Parenteral: 5 mg/mL; 500 mg for injection

Mupirocin(Bactroban)

Topical: 2% ointment, cream

Nitrofurantoin(Macrochantin, generic)

Oral: 25, 50, 100 mg capsules

Polymyxin B (Polymyxin B Sulfate)

Parenteral: 500,000 units per vial for injection

Ophthalmic: 500,000 units per vial

Disinfectants, Antiseptics, & Sterilants

Benzalkonium (generic, Zephiran)

Topical: 17% concentrate; 50% solution; 1:750 solution

Benzoyl peroxide(generic)

Topical: 2.5%, 5%, 10% liquid; 5%, 5.5%, 10% lotion; 5%, 10% cream; 2.5%, 4%, 5%, 6%, 10%,

20% gel

Chlorhexidine gluconate (Hibiclens, Hibistat, others)

Topical: 2, 4% cleanser, sponge; 0.5% rinse in 70% alcohol

Oral rinse (Peridex, Periogard): 0.12%

Glutaraldehyde (Cidex)

Instruments: 2, 3.2% solution

Hexachlorophene (pHisoHex)

Topical: 3% liquid; 0.23% foam

Iodine aqueous (generic, Lugol's Solution)

Topical: 2–5% in water with 2.4% sodium iodide or 10% potassium iodide

Iodine tincture (generic)

Topical: 2% iodine or 2.4% sodium iodide in 47% alcohol, in 15, 30, 120 mL and in larger quantities

Nitrofurazone (generic, Furacin)

Topical: 0.2% solution, ointment, and cream

Oxychlorosene sodium (Clorpactin)

Topical: 2 g powder for solution for irrigation, instillation, or rinse

Povidone-iodine(generic, Betadine)

Topical: available in many forms, including aerosol, ointment, antiseptic gauze pads, skin cleanser (liquid or foam), solution, and swabsticks

Silver nitrate(generic)

Topical: 10, 25, 50% solution

Thimerosal (generic, Mersol)

Topical: 1:1000 tincture and solution

Chapter 51. Clinical Use of Antimicrobial Agents

Katzung PHARMACOLOGY, 9e > Section VIII. Chemotherapeutic Drugs > Chapter 51. Clinical Use of Antimicrobial Agents >

Clinical Use of Antimicrobial Agents: Introduction

The development of antimicrobial drugs represents one of the most important advances in therapeutics, both in the control or cure of serious infections and in the prevention and treatment of infectious complications of other therapeutic modalities such as cancer chemotherapy and surgery. However, there is overwhelming evidence that antimicrobial agents are vastly overprescribed in outpatient settings in the United States, and the availability of antimicrobial agents without prescription in many developing countries has—by facilitating the development of resistance—already severely limited therapeutic options in the treatment of life-threatening infections. Therefore, the clinician should first determine whether antimicrobial therapy is warranted for a given patient. The specific questions one should ask include the following:

1. Is an antimicrobial agent indicated on the basis of clinical findings? Or is it prudent to wait until such clinical findings become apparent?
2. Have appropriate clinical specimens been obtained to establish a microbiologic diagnosis?
3. What are the likely etiologic agents for the patient's illness?
4. What measures should be taken to protect individuals exposed to the index case to prevent secondary cases, and what measures should be implemented to prevent further exposure?
5. Is there clinical evidence (eg, from clinical trials) that antimicrobial therapy will confer clinical benefit for the patient?

Once a specific cause is identified based upon specific microbiologic tests, the following further questions should be considered:

1. If a specific microbial pathogen is identified, can a narrower-spectrum agent be substituted for the initial empirical drug?
2. Is one agent or a combination of agents necessary?
3. What is the optimal dose, route of administration, and duration of therapy?
4. What specific tests (eg, susceptibility testing) should be undertaken to identify patients who will not respond to treatment?
5. What adjunctive measures can be undertaken to eradicate the infection? For example, is surgery feasible for removal of devitalized tissue or foreign bodies—or drainage of an abscess—into which antimicrobial agents may be unable to penetrate? Is it possible to decrease the dosage of immunosuppressive therapy in patients who have undergone organ transplantation or to give immunomodulatory drugs or antitoxins to patients with preexisting immune deficiency?

Katzung PHARMACOLOGY, 9e > Section VIII. Chemotherapeutic Drugs > Chapter 51. Clinical Use of Antimicrobial Agents >

Empirical Antimicrobial Therapy

Antimicrobial agents are frequently used before the pathogen responsible for a particular illness or the susceptibility to a particular antimicrobial agent is known. This use of antimicrobial agents is called empirical (or presumptive) therapy and is based upon experience with a particular clinical

entity. The usual justification for empirical therapy is the hope that early intervention will improve the outcome, and in the best case this has been established by placebo-controlled, double-blind prospective clinical trials. For example, treatment of febrile episodes in neutropenic cancer patients with empirical antimicrobial therapy has been demonstrated to have impressive morbidity and mortality benefits even though the specific bacterial agent responsible for fever is determined for only a minority of such episodes. Conversely, there are many clinical situations in which empirical therapy may not be useful or may actually be harmful. For example, neutropenic patients with fever and pulmonary infiltrates may have a wide variety of causes for their clinical illness, including viruses, bacteria, mycobacteria, fungi, protozoa, and noninfectious disorders. In this setting, it may be more prudent to obtain specimens by sputum culture or via bronchoalveolar lavage early in order to offer narrow-spectrum therapy based upon culture results.

Lastly, there are many clinical entities, such as certain episodes of community-acquired pneumonia, in which it is difficult to identify a specific pathogen. In such cases, a clinical response to empirical therapy may be an important clue to the likely pathogen.

Approach to Empirical Therapy

Initiation of empirical therapy should follow a specific and systematic approach.

Formulate a Clinical Diagnosis of Microbial Infection

Using all available data, the clinician should conclude that there is anatomic evidence of infection (eg, pneumonia, cellulitis, sinusitis).

Obtain Specimens for Laboratory Examination

Examination of stained specimens by microscopy or simple examination of an uncentrifuged sample of urine for white blood cells and bacteria may provide important etiologic clues in a very short time.

Formulate a Microbiologic Diagnosis

The history, physical examination, and immediately available laboratory results (eg, Gram's stain of urine or sputum) may provide highly specific information. For example, in a young man with urethritis and a Gram-stained smear from the urethral meatus demonstrating intracellular gram-negative diplococci, the most likely pathogen is *Neisseria gonorrhoeae*. In the latter instance, however, the clinician should be aware that a significant number of patients with gonococcal urethritis have uninformative Gram stains for the organism and that a significant number of patients with gonococcal urethritis harbor concurrent chlamydial infection that is not demonstrated on the Gram-stained smear.

Determine the Necessity for Empirical Therapy

This is an important clinical decision based partly upon experience and partly upon data from clinical trials. Empirical therapy is indicated when there is a significant risk of serious morbidity if therapy is withheld until a specific pathogen is detected by the clinical laboratory.

In other settings, empirical therapy may be indicated for public health reasons rather than for demonstrated superior outcome of therapy in a specific patient. For example, urethritis in a young sexually active man usually requires treatment for *N gonorrhoeae* and *Chlamydia trachomatis*

despite the absence of microbiologic confirmation at the time of diagnosis. Because there is a high risk of noncompliance with follow-up visits in this patient population, empirical therapy is warranted to ensure cure of the infection at the first visit in order to prevent further transmission.

Institute Treatment

Selection of empirical therapy may be based upon the microbiologic diagnosis or a clinical diagnosis without available microbiologic clues. If no microbiologic information is available, the antimicrobial spectrum of the agent or agents chosen must necessarily be broader, taking into account the most likely pathogens responsible for the patient's illness.

Choice of Antimicrobial Agent

Selection from among several drugs depends upon **host factors** which include the following: (1) concomitant disease states (eg, AIDS, severe chronic liver disease); (2) prior adverse drug effects; (3) impaired elimination or detoxification of the drug (this may be genetically predetermined but more frequently is associated with impaired renal or hepatic function due to underlying disease); (4) age of the patient; and (5) pregnancy status.

Pharmacologic factors include (1) the kinetics of absorption, distribution, and elimination; (2) the ability of the drug to be delivered to the site of infection; (3) the potential toxicity of an agent; and (4) pharmacokinetic or pharmacodynamic interactions with other drugs.

Knowledge of the susceptibility of an organism to a specific agent in a hospital or community setting is important in the selection of empirical therapy. Pharmacokinetic differences among agents with similar antimicrobial spectrums may be exploited to reduce the frequency of dosing (eg, ceftriaxone may be conveniently given every 24 hours). Lastly, increasing consideration is being given to the cost of antimicrobial therapy, especially when multiple agents with comparable efficacy and toxicity are available for a specific infection.

Brief guides to empirical therapy based upon presumptive microbial diagnosis and site of infection are given in Tables 51–1 and 51–2.

Table 51–1. Empiric Antimicrobial Therapy Based on Microbiologic Etiology.		
Suspected or Proved Disease or Pathogen	Drugs of First Choice	Alternative Drugs
Gram-negative cocci (aerobic)		
<i>Moraxella (Branhamella) catarrhalis</i>	TMP-SMZ, ¹ cephalosporin (second- or third-generation)	Erythromycin, quinolone, clarithromycin, azithromycin
<i>Neisseria gonorrhoeae</i> ²	Ceftriaxone, cefixime	Spectinomycin, quinolone
<i>Neisseria meningitidis</i>	Penicillin G	Chloramphenicol, cephalosporin (third-generation) ³

Gram-negative rods (aerobic)		
<i>E coli</i> , klebsiella, proteus	Cephalosporin (first- or second-generation), TMP-SMZ	Quinolone, aminoglycoside
Enterobacter, citrobacter, serratia	TMP-SMZ, quinolone, imipenem	Antipseudomonal penicillin, ⁴ aminoglycoside ⁵ , cefepime
Shigella	Quinolone	TMP-SMZ, ampicillin, cefixime, ceftriaxone
Salmonella	TMP-SMZ, quinolone, cephalosporin (third-generation)	Chloramphenicol, ampicillin
<i>Campylobacter jejuni</i>	Erythromycin	Tetracycline, quinolone
Brucella species	Doxycycline + rifampin or aminoglycoside ⁵	Chloramphenicol + aminoglycoside or TMP-SMZ
<i>Helicobacter pylori</i>	Bismuth + metronidazole + tetracycline or amoxicillin	Proton pump inhibitor + amoxicillin and clarithromycin
Vibrio species	Tetracycline	Quinolone, TMP-SMZ
<i>Pseudomonas aeruginosa</i>	Antipseudomonal penicillin + aminoglycoside ⁵	Antipseudomonal penicillin + quinolone; cefepime, ceftazidime, imipenem, or aztreonam ± aminoglycoside
<i>Burkholderia cepacia</i> (formerly <i>Pseudomonas cepacia</i>)	TMP-SMZ	Ceftazidime, chloramphenicol
<i>Stenotrophomonas maltophilia</i> (formerly <i>Xanthomonas maltophilia</i>)	TMP-SMZ	Minocycline, ticarcillin-clavulanate, quinolone
Legionella species	Azithromycin + rifampin or quinolone + rifampin	Clarithromycin, erythromycin, doxycycline
Gram-positive cocci (aerobic)		
Streptococcus pneumoniae, penicillin-susceptible (MIC ≤2)	Penicillin ⁶	Doxycycline, ceftriaxone, cefuroxime, erythromycin, imipenem, meropenem, linezolid
penicillin-resistant (MIC ≥4)	Ceftriaxone, vancomycin	Carbapenems, linezolid
<i>Streptococcus pyogenes</i> (group A)	Penicillin, clindamycin	Erythromycin, cephalosporin (first-generation)
<i>Streptococcus agalactiae</i> (group B)	Penicillin (+ aminoglycoside? ⁵)	Vancomycin

Viridans streptococci	Penicillin	Cephalosporin (first- or third-generation), vancomycin
<i>Staphylococcus aureus</i>		
Beta-lactamase-negative	Penicillin	Cephalosporin (first-generation), vancomycin
Beta-lactamase-positive	Penicillinase-resistant penicillin ⁷	As above
Methicillin-resistant	Vancomycin	TMP-SMZ, minocycline, linezolid, quinupristin-dalfopristin
Enterococcus species ⁸	Penicillin ± aminoglycoside ⁵	Vancomycin ± aminoglycoside
Gram-positive rods (aerobic)		
Bacillus species (non-anthraxis)	Vancomycin	Imipenem, quinolone, clindamycin
Listeria species	Ampicillin (± aminoglycoside ⁵)	TMP-SMZ
Nocardia species	Sulfadiazine, TMP-SMZ	Minocycline, imipenem, amikacin
Anaerobic bacteria		
Gram-positive (clostridia, peptococcus, actinomyces, peptostreptococcus)	Penicillin, clindamycin	Vancomycin, imipenem, chloramphenicol
<i>Clostridium difficile</i>	Metronidazole	Vancomycin, bacitracin
<i>Bacteroides fragilis</i>	Metronidazole, clindamycin	Chloramphenicol, imipenem, beta-lactam–beta-lactamase-inhibitor combinations
Fusobacterium, prevotella, porphyromonas	Metronidazole, clindamycin, penicillin	As for <i>B fragilis</i>
Mycobacteria		
<i>Mycobacterium tuberculosis</i>	Isoniazid + rifampin + ethambutol + pyrazinamide	Streptomycin, quinolone, amikacin, ethionamide, cycloserine, PAS
<i>Mycobacterium leprae</i>		
Multibacillary	Dapsone + rifampin + clofazimine	
Paucibacillary	Dapsone + rifampin	
<i>Mycoplasma pneumoniae</i>	Tetracycline, erythromycin	Azithromycin, clarithromycin, quinolone
Chlamydia		
<i>trachomatis</i>	Tetracycline, azithromycin	Clindamycin, ofloxacin

<i>pneumoniae</i>	Tetracycline, erythromycin	Clarithromycin, azithromycin
<i>psittaci</i>	Tetracycline	Chloramphenicol
Spirochetes		
<i>Borrelia recurrentis</i>	Doxycycline	Erythromycin, chloramphenicol, penicillin
<i>Borrelia burgdorferi</i>		
Early	Doxycycline, amoxicillin, ceftriaxone	Cefuroxime axetil, penicillin
Late		
<i>Leptospira</i> species	Penicillin	Tetracycline
<i>Treponema</i> species	Penicillin	Tetracycline, azithromycin, ceftriaxone
Fungi		
<i>Aspergillus</i> species	Amphotericin B, voriconazole	Itraconazole, caspofungin
<i>Blastomyces</i> species	Amphotericin B	Itraconazole, ketoconazole ⁹
<i>Candida</i> species, <i>torulopsis</i> species	Amphotericin B, caspofungin	Fluconazole, itraconazole
<i>Cryptococcus</i>	Amphotericin B ± flucytosine (5-FC)	Fluconazole
<i>Coccidioides immitis</i>	Amphotericin B	Fluconazole, itraconazole, ketoconazole
<i>Histoplasma capsulatum</i>	Amphotericin B	Itraconazole
Mucoraceae (rhizopus, absidia)	Amphotericin B	
<i>Sporothrix schenckii</i>	Amphotericin B	Itraconazole

¹Trimethoprim-sulfamethoxazole (TMP-SMZ) is a mixture of one part trimethoprim plus five parts sulfamethoxazole.

²Quinolones are not recommended for empiric therapy of gonococcal infections acquired in Southeast Asia, Hawaii, and the Pacific Coast of the United States. Azithromycin 2 g is an alternative agent for the treatment of gonococcal urethritis and cervicitis.

³First-generation cephalosporins: Cephalothin, cephapirin, or cefazolin for parenteral administration; cephalexin or cephadrine for oral administration. Second-generation cephalosporins: Cefuroxime, cefamandole, cefonicid for parenteral administration; cefaclor, cefuroxime axetil, cefprozil, ceftibuten for oral administration. Third-generation cephalosporins: Cefoperazone, cefotaxime, ceftizoxime, ceftriaxone for parenteral administration; cefixime, cefpodoxime for oral administration.

⁴Antipseudomonal penicillin: Carbenicillin, ticarcillin, azlocillin, mezlocillin, piperacillin.

⁵Generally, streptomycin and gentamicin are used to treat infections with gram-positive organisms, whereas gentamicin, tobramycin, and amikacin are used to treat infections with gram-negatives.

⁶See footnote 3 in Table 51–2 for guidelines on the treatment of penicillin-resistant pneumococcal meningitis.

⁷Parenteral nafcillin, oxacillin; or methicillin; oral dicloxacillin, cloxacillin, or oxacillin.

⁸There is no regimen that is reliably bactericidal for vancomycin-resistant enterococcus. Regimens that have been reported to be efficacious include single-drug therapy with chloramphenicol, tetracycline, nitrofurantoin (for urinary tract infection); potential regimens for bacteremia include ampicillin + vancomycin and ampicillin + ciprofloxacin + gentamicin.

⁹Ketoconazole does not penetrate the central nervous system and is unsatisfactory for meningitis.

Table 51–2. Empiric Antimicrobial Therapy Based on Site of Infection.

Presumed Site of Infection	Common Pathogens	Drugs of First Choice	Alternative Drugs
Bacterial endocarditis			
Acute	<i>Staphylococcus aureus</i>	Penicillinase-resistant penicillin ¹ + gentamicin	Vancomycin + gentamicin
Subacute	Viridans streptococci, enterococci	Penicillin + gentamicin	Vancomycin + gentamicin
Septic arthritis			
Child	<i>H influenzae</i> , <i>S aureus</i> , β-hemolytic streptococci	Ceftriaxone	Ampicillin-sulbactam
Adult, nongonococcal	<i>S aureus</i> , Enterobacteriaceae	Cefazolin	Vancomycin, quinolone
Acute otitis media, sinusitis	<i>H influenzae</i> , <i>S pneumoniae</i> , <i>M catarrhalis</i>	Amoxicillin	Amoxicillin-clavulanate, cefuroxime axetil, TMP-SMZ
Cellulitis	<i>S aureus</i> , group A streptococcus	Penicillinase-resistant penicillin, cephalosporin (first-generation) ²	Vancomycin
Meningitis			
Neonate	Group B streptococcus, <i>E coli</i> , listeria	Ampicillin + cephalosporin (third-generation)	Ampicillin + aminoglycoside, chloramphenicol

Child	<i>H influenzae</i> , pneumococcus, meningococcus	Ceftriaxone or cefotaxime ± vancomycin ³	Chloramphenicol
Adult	Pneumococcus, meningococcus	Ceftriaxone, cefotaxime	Vancomycin + ceftriaxone or cefotaxime ³
Peritonitis due to ruptured viscus	Coliforms, <i>B fragilis</i>	Metronidazole + cephalosporin (third-generation), piperacillin-tazobactam	Imipenem
Pneumonia			
Neonate	As in neonatal meningitis		
Child	Pneumococcus, <i>S aureus</i> , <i>H influenzae</i>	Ceftriaxone, cefuroxime, cefotaxime	Ampicillin-sulbactam
Adult (community-acquired)	Pneumococcus, mycoplasma, legionella, <i>H influenzae</i> , <i>S aureus</i> , <i>C pneumonia</i> , coliforms	Outpatient: Erythromycin, amoxicillin, doxycycline Inpatient: Macrolide ⁴ + cefotaxime, ceftriaxone	Outpatient: Azithromycin, clarithromycin, quinolone Inpatient: Macrolide + piperacillin-tazobactam, ticarcillin-clavulanate, or cefuroxime; quinolone
Septicemia	Any	Vancomycin + aminoglycoside + cephalosporin (third-generation) or piperacillin + tazobactam	
Septicemia with granulocytopenia	Any	Antipseudomonal penicillin + aminoglycoside; ceftazidime; cefepime; consider addition of amphotericin B if fever persists beyond 5 days of empiric therapy	

¹See footnote 7, Table 51–1.

²See footnote 3, Table 51–1.

³When meningitis with penicillin-resistant pneumococcus is suspected, empiric therapy with this regimen is recommended.

⁴Erythromycin, clarithromycin, or azithromycin (an azalide) may be used.

Katzung PHARMACOLOGY, 9e > Section VIII. Chemotherapeutic Drugs > Chapter 51. Clinical Use of Antimicrobial Agents >

Antimicrobial Therapy of Infections with Known Etiology

Interpretation of Culture Results

Properly obtained and processed specimens for culture frequently yield reliable information about the cause of infection. The lack of a confirmatory microbiologic diagnosis may be due to the following:

- (1) Sample error, eg, obtaining cultures after antimicrobial agents have been administered.
- (2) Noncultivable or slow-growing organisms, (*Histoplasma capsulatum*, bartonella species), where cultures are often discarded before sufficient growth has occurred for detection.
- (3) Requesting *bacterial* cultures when infection is due to other organisms.
- (4) Not recognizing the need for special media or isolation techniques (eg, charcoal yeast extract agar for isolation of legionella species, shell-vial tissue culture system for rapid isolation of CMV).

Even in the setting of a classic infectious disease for which isolation techniques have been established for decades (eg, pneumococcal pneumonia, pulmonary tuberculosis, streptococcal pharyngitis), the sensitivity of the culture technique may be inadequate to identify all cases of the disease.

Guiding Antimicrobial Therapy of Established Infections

Susceptibility Testing

Testing bacterial pathogens in vitro for their susceptibility to antimicrobial agents is extremely valuable in confirming susceptibility, ideally to a narrow-spectrum nontoxic antimicrobial drug. Tests measure the concentration of drug required to inhibit growth of the organism (minimal inhibitory concentration [MIC]) or to kill the organism (minimal bactericidal concentration [MBC]). The results of these tests can then be correlated with known drug concentrations in various body compartments. Only MICs are routinely measured in most infections, whereas in infections in which bactericidal therapy is required for eradication of infection (eg, meningitis, endocarditis, sepsis in the granulocytopenic host), MBC measurements occasionally may be useful.

Specialized Assay Methods

Beta-Lactamase Assay

For some bacteria (eg, haemophilus species), the susceptibility patterns of strains are similar except for the production of β -lactamase. In these cases, extensive susceptibility testing may not be required and a direct test for β -lactamase utilizing a chromogenic β -lactam substrate (nitrocephin disk) may be substituted.

Synergy Studies

These in vitro tests attempt to measure synergistic, additive, indifferent, or antagonistic drug interactions. In general, these tests have not been standardized and have not correlated well with clinical outcome. (See section on combination chemotherapy for details.)

Monitoring Therapeutic Response: Duration of Therapy

The therapeutic response may be monitored microbiologically or clinically. Cultures of specimens

taken from infected sites should eventually become sterile or demonstrate eradication of the pathogen and are useful for documenting recurrence or relapse. Follow-up cultures may also be useful for detecting superinfections or the development of resistance. Clinically, the patient's systemic manifestations of infection (malaise, fever, leukocytosis) should abate and the clinical findings should improve (eg, as shown by clearing of radiographic infiltrates or lessening hypoxemia in pneumonia).

The duration of therapy required for cure depends on the pathogen, the site of infection, and host factors (immunocompromised patients generally require longer courses of treatment). Precise data on duration of therapy exist for some infections (eg, streptococcal pharyngitis, syphilis, gonorrhea, tuberculosis, cryptococcal meningitis in non-AIDS patients). In many other situations, duration of therapy is determined empirically. For serious infections, continuing therapy for 7–10 days after the patient has become afebrile is a good rule of thumb. For recurrent infections (eg, sinusitis, urinary tract infections), longer courses of antimicrobial therapy are frequently necessary for eradication.

Clinical Failure of Antimicrobial Therapy

When the patient has an inadequate clinical or microbiologic response to antimicrobial therapy selected by *in vitro* susceptibility testing, systematic investigation should be undertaken to determine the cause of failure. Errors in susceptibility testing are rare, but the original results should be confirmed by repeat testing. Drug dosing and absorption should be scrutinized and tested directly using serum measurements, pill counting, or directly observed therapy.

The clinical data should be reviewed to determine whether the patient's immune function is adequate and, if not, what can be done to maximize it. For example, are adequate numbers of granulocytes present and are HIV infection, malnutrition, or underlying malignancy present? The presence of abscesses or foreign bodies should also be considered. Lastly, culture and susceptibility testing should be repeated to determine if superinfection has occurred with another organism or if the original pathogen has developed drug resistance.

Antimicrobial Pharmacodynamics

The time course of drug concentration is closely related to the antimicrobial effect at the site of infection and to any toxic effects. Pharmacodynamic factors include pathogen susceptibility testing, drug bactericidal versus bacteriostatic activity, and drug synergism, antagonism, and postantibiotic effects. Together with pharmacokinetics, pharmacodynamic information permits the selection of optimal antimicrobial dosage regimens.

Bacteriostatic Versus Bactericidal Activity

Antibacterial agents may be classified as bacteriostatic or bactericidal (Table 51–3). For agents that are primarily bacteriostatic, inhibitory drug concentrations are much lower than bactericidal drug concentrations. In general, cell wall-active agents are bactericidal, and drugs that inhibit protein synthesis are bacteriostatic.

Table 51–3. Bacteriostatic and Bactericidalantibacterial Agents.

Bactericidal agents
Aminoglycosides

Bacitracin
Beta-lactam antibiotics
Isoniazid
Metronidazole
Polymyxins
Pyrazinamide
Quinolones
Quinupristin-dalfopristin
Rifampin
Vancomycin
Bacteriostatic agents
Chloramphenicol
Clindamycin
Ethambutol
Macrolides
Nitrofurantoin
Novobiocin
Oxazolidinones
Sulfonamides
Tetracyclines
Trimethoprim

The classification of antibacterial agents as bactericidal or bacteriostatic has limitations. Some agents that are considered to be bacteriostatic may be bactericidal against selected organisms. On the other hand, enterococci are inhibited but not killed by vancomycin, penicillin, or ampicillin used as single agents.

Bacteriostatic and bactericidal agents are equivalent for the treatment of most infectious diseases in immunocompetent hosts. Bactericidal agents should be selected over bacteriostatic ones in circumstances in which local or systemic host defenses are impaired. Bactericidal agents are required for treatment of endocarditis and other endovascular infections, meningitis, and infections in neutropenic cancer patients.

Bactericidal agents can be divided into two groups: agents that exhibit **concentration-dependent killing** (eg, aminoglycosides and quinolones) and agents that exhibit **time-dependent killing** (eg, β -lactams and vancomycin). For drugs whose killing action is concentration-dependent, the rate and extent of killing increase with increasing drug concentrations. Concentration-dependent killing is one of the pharmacodynamic factors responsible for the efficacy of once-daily dosing of aminoglycosides.

For drugs whose killing action is time-dependent, bactericidal activity continues as long as serum concentrations are greater than the MBC. Drug concentrations of time-dependent killing agents that

lack a postantibiotic effect should be maintained above the MIC for the entire interval between doses.

Postantibiotic Effect

Persistent suppression of bacterial growth after limited exposure to an antimicrobial agent is known as the postantibiotic effect (PAE). The PAE can be expressed mathematically as follows:

$$PAE = T - C$$

where T is the time required for the viable count in the test (in vitro) culture to increase tenfold above the count observed immediately before drug removal and C is the time required for the count in an untreated culture to increase tenfold above the count observed immediately after completion of the same procedure used on the test culture. The PAE reflects the time required for bacteria to return to logarithmic growth.

Proposed mechanisms include (1) recovery after reversible nonlethal damage to cell structures; (2) persistence of the drug at a binding site or within the periplasmic space; and (3) the need to synthesize new enzymes before growth can resume. Most antimicrobials possess significant in vitro PAEs (≥ 1.5 hours) against susceptible gram-positive cocci (Table 51–4). Antimicrobials with significant PAEs against susceptible gram-negative bacilli are limited to carbapenems and agents that inhibit protein or DNA synthesis.

Table 51–4. Antibacterial Agents with In Vitro Postantibiotic Effects ≥ 1.5 Hours.	
Against gram-positive cocci	
Aminoglycosides	
Carbapenems	
Cephalosporins	
Chloramphenicol	
Clindamycin	
Macrolides	
Oxazolidinones	
Penicillins	
Quinolones

Tetracyclines	
Trimethoprim	
Vancomycin	
Against gram-negative bacilli	
Aminoglycosides	

Carbapenems
Chloramphenicol
Quinolones
Rifampin
Tetracyclines

In vivo PAEs are usually much longer than in vitro PAEs. This is thought to be due to **postantibiotic leukocyte enhancement (PALE)** and exposure of bacteria to subinhibitory antibiotic concentrations. The efficacy of once-daily dosing regimens is in part due to the PAE. Aminoglycosides and quinolones possess concentration-dependent PAEs; thus, high doses of aminoglycosides given once daily result in enhanced bactericidal activity and extended PAEs. This combination of pharmacodynamic effects allows aminoglycoside serum concentrations that are below the MICs of target organisms to remain effective for extended periods of time.

Pharmacokinetic Considerations

Route of Administration

Many antimicrobial agents have similar pharmacokinetic properties when given orally or parenterally (ie, tetracyclines, trimethoprim-sulfamethoxazole, quinolones, chloramphenicol, metronidazole, clindamycin, rifampin, and fluconazole). In most cases, oral therapy with these drugs is equally effective, less costly, and results in fewer complications than parenteral therapy.

The intravenous route is preferred in the following situations: (1) for critically ill patients; (2) for patients with bacterial meningitis or endocarditis; (3) for patients with nausea, vomiting, gastrectomy, or diseases that may impair oral absorption; and (4) when giving antimicrobials that are poorly absorbed following oral administration.

Conditions That Alter Antimicrobial Pharmacokinetics

Various diseases and physiologic states alter the pharmacokinetics of antimicrobial agents. Impairment of renal or hepatic function may result in decreased elimination. Table 51–5 lists drugs that require dosage reduction in patients with renal or hepatic insufficiency. Failure to reduce antimicrobial agent dosage in such patients may cause toxic side effects. Conversely, patients with burns, cystic fibrosis, or trauma may have increased dosage requirements for selected agents. The pharmacokinetics of antimicrobials are also altered in the elderly, in neonates, and in pregnancy.

Table 51–5. Antimicrobial Agents That Require Dosage Adjustment or Are Contraindicated in Patients with Renal or Hepatic Impairment.

Dosage Adjustment Needed in Renal Impairment	Contraindicated in Renal Impairment	Dosage Adjustment Needed in Hepatic Impairment
Acyclovir, adefovir, amantadine, aminoglycosides, aztreonam,	Cidofovir, itraconazole (IV), methenamine,	Amprenavir, caspofungin,

cephalosporins, ¹ clarithromycin, cycloserine, didanosine, ethambutol, famciclovir, fluconazole, flucytosine, foscarnet, ganciclovir, imipenem, lamivudine, meropenem, penicillins, ³ quinolones, ⁴ rimantadine, stavudine, terbinafine, trimethoprim-sulfamethoxazole, valacyclovir, vancomycin, zalcitabine, zidovudine	nalidixic acid, nitrofurantoin, ribavirin, sulfonamides (long-acting), tetracyclines ²	chloramphenicol, clindamycin, erythromycin, indinavir, metronidazole, rimantadine, voriconazole
------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------	---------------------------------------------------------------------------------------------------	-------------------------------------------------------------------------------------------------

¹Except cefoperazone and ceftriaxone.

²Except doxycycline and possibly minocycline.

³Except antistaphylococcal penicillins (eg, nafcillin and dicloxacillin).

⁴Except trovafloxacin and moxifloxacin.

Drug Concentrations in Body Fluids

Most antimicrobial agents are well distributed to most body tissues and fluids. Penetration into the cerebrospinal fluid is an exception. Most do not penetrate uninflamed meninges to an appreciable extent. In the presence of meningitis, however, the cerebrospinal fluid concentrations of many antimicrobials increase (Table 51–6).

Table 51–6. Cerebrospinal Fluid (CSF) Penetration of Selected Antimicrobials.

Antimicrobial Agent	CSF Concentration (Uninflamed Meninges) as Percent of Serum Concentration	CSF Concentration (Inflamed Meninges) as Percent of Serum Concentration
Ampicillin	2–3	2–100
Aztreonam	2	5
Cefotaxime	22.5	27–36
Ceftazidime	0.7	20–40
Ceftriaxone	0.8–1.6	16
Cefuroxime	20	17–88
Ciprofloxacin	6–27	26–37
Imipenem	3.1	11–41
Meropenem	0–7	1–52
Nafcillin	2–15	5–27
Penicillin G	1–2	8–18
Sulfamethoxazole	40	12–47
Trimethoprim	< 41	12–69
Vancomycin	0	1–53

Monitoring Serum Concentrations of Antimicrobial Agents

For most antimicrobial agents, the relationship between dose and therapeutic outcome is well established, and serum concentration monitoring is unnecessary for these drugs. To justify routine serum concentration monitoring, it should be established (1) that a direct relationship exists between drug concentrations and efficacy or toxicity; (2) that substantial interpatient variability exists in serum concentrations on standard doses; (3) that a small difference exists between therapeutic and toxic serum concentrations; (4) that the clinical efficacy or toxicity of the drug is delayed or difficult to measure; and (5) that an accurate assay is available.

In clinical practice, serum concentration monitoring is routinely performed on patients receiving aminoglycosides. Despite the lack of supporting evidence for its utility or need, serum vancomycin concentration monitoring is also widespread. Flucytosine serum concentration monitoring has been shown to reduce toxicity when doses are adjusted to maintain peak concentrations below 100 μ g/mL.

Katzung PHARMACOLOGY, 9e > Section VIII. Chemotherapeutic Drugs > Chapter 51. Clinical Use of Antimicrobial Agents >

Management of Antimicrobial Drug Toxicity

Owing to the large number of antimicrobials available, it is usually possible to select an effective alternative in patients who develop serious drug toxicity (Table 51–1). However, for some infections there are no effective alternatives to the drug of choice. For example, in patients with neurosyphilis who have a history of anaphylaxis to penicillin, it is necessary to perform skin testing and desensitization to penicillin. It is important to obtain a clear history of drug allergy and other adverse drug reactions. A patient with a documented antimicrobial allergy should carry a card with the name of the drug and a description of the reaction. Cross-reactivity between penicillins and cephalosporins is less than 10%. Cephalosporins may be administered to patients with penicillin-induced maculopapular rashes but should be avoided in patients with a history of penicillin-induced immediate hypersensitivity reactions. The cross-reactivity between penicillins and imipenem may exceed 50%. On the other hand, aztreonam does not cross-react with penicillins and can be safely administered to patients with a history of penicillin-induced anaphylaxis. For mild reactions, it may be possible to continue therapy with use of adjunctive agents or dosage reduction.

Adverse reactions to antimicrobials occur with increased frequency in several groups, including neonates, geriatric patients, renal failure patients, and AIDS patients. Dosage adjustment of the drugs listed in Table 51–5 is essential for the prevention of adverse effects in patients with renal failure. In addition, several agents are contraindicated in patients with renal impairment because of increased rates of serious toxicity (Table 51–5). See the preceding chapters for discussions of specific drugs.

Polypharmacy also predisposes to drug interactions. Although the mechanism is not known, AIDS patients have an unusually high incidence of toxicity to a number of drugs, including clindamycin, aminopenicillins, and sulfonamides. Many of these reactions, including rash and fever, may respond to dosage reduction or treatment with corticosteroids and antihistamines. Other examples are discussed in the preceding chapters and in Appendix II.

Antimicrobial Drug Combinations

Rationale for Combination Antimicrobial Therapy

Most infections should be treated with a single antimicrobial agent. Although indications for combination therapy exist, antimicrobial combinations are often overused in clinical practice. The unnecessary use of antimicrobial combinations increases toxicity and costs and may occasionally result in reduced efficacy due to antagonism of one drug by another. Antimicrobial combinations should be selected for one or more of the following reasons:

- (1) To provide broad-spectrum empirical therapy in seriously ill patients.
- (2) To treat polymicrobial infections such as intra-abdominal abscesses. The antimicrobial combination chosen should cover the most common known or suspected pathogens but need not cover all possible pathogens. The availability of antimicrobials with excellent polymicrobial coverage (eg, β -lactamase inhibitor combinations or imipenem) may reduce the need for combination therapy in the setting of polymicrobial infections.
- (3) To decrease the emergence of resistant strains. The value of combination therapy in this setting has been clearly demonstrated for tuberculosis.
- (4) To decrease dose-related toxicity by using reduced doses of one or more components of the drug regimen. The use of flucytosine in combination with amphotericin B for the treatment of cryptococcal meningitis in non-HIV-infected patients allows for a reduction in amphotericin B dosage with decreased amphotericin B-induced nephrotoxicity.
- (5) To obtain enhanced inhibition or killing. This use of antimicrobial combinations is discussed in the paragraphs that follow.

Synergism & Antagonism

When the inhibitory or killing effects of two or more antimicrobials used together are significantly greater than expected from their effects when used individually, synergism is said to result. Synergism is marked by a fourfold or greater reduction in the MIC or MBC of each drug when used in combination versus when used alone.

The interaction between two antimicrobial agents can be expressed by the fractional inhibitory concentration (FIC) index:

$$FIC_{\text{index}} = FIC_A + FIC_B$$

$$FIC_A = \frac{\text{MIC of drug A in combination}}{\text{MIC of drug A alone}}$$

$$FIC_B = \frac{\text{MIC of drug B in combination}}{\text{MIC of drug B alone}}$$

The fractional *bactericidal* concentration (FBC) index can be determined by substituting MBCs for

MICs in the above equations. Synergism for combinations of two drugs requires an FIC or FBC index of ≤ 0.5 . Antagonism occurs when the combined inhibitory or killing effects of two or more antimicrobials are significantly less than expected when the drugs are used individually. Antibiotic antagonism is marked by an FIC or FBC index of 4 or more.

Mechanisms of Synergistic Action

The need for synergistic combinations of antimicrobials has been clearly established for the treatment of enterococcal endocarditis. Bactericidal activity is essential for the optimal management of bacterial endocarditis. Penicillin or ampicillin in combination with gentamicin or streptomycin is superior to monotherapy with a penicillin or vancomycin. When tested alone, penicillins and vancomycin are only bacteriostatic against susceptible enterococcal isolates. When these agents are combined with an aminoglycoside, however, bactericidal activity results. The addition of gentamicin or streptomycin to penicillin allows for a reduction in the duration of therapy for selected patients with viridans streptococcal endocarditis. There is some evidence that synergistic combinations of antimicrobials may be of benefit in the treatment of gram-negative bacillary infections in febrile neutropenic cancer patients and in systemic infections caused by *Pseudomonas aeruginosa*.

Other synergistic antimicrobial combinations have been shown to be more effective than monotherapy with individual components. Trimethoprim-sulfamethoxazole has been successfully used for the treatment of bacterial infections and *Pneumocystis jiroveci* (*carinii*) pneumonia.* Beta-lactamase inhibitors restore the activity of intrinsically active but hydrolyzable β -lactams against organisms such as *S aureus* and *Bacteroides fragilis*. Three major mechanisms of antimicrobial synergism have been established:

- 1. Blockade of Sequential Steps in a Metabolic Sequence:** Trimethoprim-sulfamethoxazole is the best-known example of this mechanism of synergy (see Chapter 46: Sulfonamides, Trimethoprim, & Quinolones). Blockade of the two sequential steps in the folic acid pathway by trimethoprim-sulfamethoxazole results in a much more complete inhibition of growth than achieved by either component alone.
- 2. Inhibition of Enzymatic Inactivation:** Enzymatic inactivation of β -lactam antibiotics is a major mechanism of antibiotic resistance. Inhibition of β -lactamase by β -lactamase inhibitor drugs (eg, sulbactam) results in synergism.
- 3. Enhancement of Antimicrobial Agent Uptake:** Penicillins and other cell wall-active agents can increase the uptake of aminoglycosides by a number of bacteria, including staphylococci, enterococci, streptococci, and *P aeruginosa*. It is thought that enterococci are intrinsically resistant to aminoglycosides because of permeability barriers. Similarly, amphotericin B is thought to enhance the uptake of flucytosine by fungi.

**Pneumocystis jiroveci* is a fungal organism found in humans (*P carinii* infects animals) that responds to antiprotozoal drugs. See Chapter 53: Antiprotozoal Drugs.

Mechanisms of Antagonistic Action

There are few clinically relevant examples of antimicrobial antagonism. The most striking example was reported in a study of patients with pneumococcal meningitis. Patients who were treated with the combination of penicillin and chlortetracycline had a mortality rate of 79% versus a mortality rate of 21% in patients who received penicillin monotherapy (illustrating the first mechanism set

forth below).

The use of an antagonistic antimicrobial combination does not preclude other potential beneficial interactions. For example, rifampin may antagonize the action of antistaphylococcal penicillins or vancomycin against staphylococci. However, the aforementioned antimicrobials may prevent the emergence of resistance to rifampin.

Two major mechanisms of antimicrobial antagonism have been established:

1. Inhibition of Cidal Activity by Static Agents: Bacteriostatic agents such as tetracyclines and chloramphenicol can antagonize the action of bactericidal cell wall-active agents because cell wall-active agents require that the bacteria be actively growing and dividing.

2. Induction of Enzymatic Inactivation: Some gram-negative bacilli, including enterobacter species, *P aeruginosa*, *Serratia marcescens*, and *Citrobacter freundii*, possess inducible β -lactamases. Beta-lactam antibiotics such as imipenem, ceftiofur, and ampicillin are potent inducers of β -lactamase production. If an inducing agent is combined with an intrinsically active but hydrolyzable β -lactam such as piperacillin, antagonism may result.

Katzung PHARMACOLOGY, 9e > Section VIII. Chemotherapeutic Drugs > Chapter 51. Clinical Use of Antimicrobial Agents >

Antimicrobial Prophylaxis

Antimicrobial agents are effective in preventing infections in many settings. Antimicrobial prophylaxis should be used in circumstances in which efficacy has been demonstrated and benefits outweigh the risks of prophylaxis. Antimicrobial prophylaxis may be divided into surgical prophylaxis and nonsurgical prophylaxis.

Surgical Prophylaxis

Surgical wound infections are a major category of nosocomial infections. The estimated annual cost of surgical wound infections in the United States is \$1.5 billion.

The National Research Council (NRC) Wound Classification Criteria have served as the basis for recommending antimicrobial prophylaxis. The NRC criteria consist of four classes (see National Research Council (NRC) Wound Classification Criteria).

The Study of the Efficacy of Nosocomial Infection Control (SENIC) identified four independent risk factors for postoperative wound infections: operations on the abdomen, operations lasting more than 2 hours, contaminated or dirty wound classification, and the presence of at least three medical diagnoses. Patients with at least two SENIC risk factors who undergo clean surgical procedures are at increased risk of developing surgical wound infections and should receive antimicrobial prophylaxis.

Surgical procedures that necessitate the use of antimicrobial prophylaxis include contaminated and clean-contaminated operations, selected operations in which postoperative infection may be catastrophic such as open heart surgery, clean procedures that involve placement of prosthetic materials, and any procedure in an immunocompromised host. The operation should carry a significant risk of postoperative site infection or cause significant bacterial contamination.

General principles of antimicrobial surgical prophylaxis include the following:

- (1) The antibiotic should be active against common surgical wound pathogens; unnecessarily broad coverage should be avoided.
- (2) The antibiotic should have proved efficacy in clinical trials.
- (3) The antibiotic must achieve concentrations greater than the MIC of suspected pathogens, and these concentrations must be present at the time of incision.
- (4) The shortest possible course—ideally a single dose—of the most effective and least toxic antibiotic should be used.
- (5) The newer broad-spectrum antibiotics should be reserved for therapy of resistant infections.
- (6) If all other factors are equal, the least expensive agent should be used.

The proper selection and administration of antimicrobial prophylaxis is of utmost importance. Common indications for surgical prophylaxis are shown in Table 51–7. Cefazolin is the prophylactic agent of choice for head and neck, gastroduodenal, biliary tract, gynecologic, and clean procedures. Local wound infection patterns should be considered when selecting antimicrobial prophylaxis. The selection of vancomycin over cefazolin may be necessary in hospitals with high rates of methicillin-resistant *S aureus* or *Staphylococcus epidermidis* infections. The antibiotic should be present in adequate concentrations at the operative site prior to incision and throughout the procedure; initial dosing is dependent on the volume of distribution, peak levels, clearance, protein binding, and bioavailability. Parenteral agents should be administered during the interval beginning 60 minutes before incision; administration up to the time of incision is preferred. In cesarean section, the antibiotic is administered after umbilical cord clamping. If short-acting agents such as ceftiofur are used, doses should be repeated if the procedure exceeds 3–4 hours in duration. Single-dose prophylaxis is effective for most procedures and results in decreased toxicity and antimicrobial resistance.

Table 51–7. Recommendations for Surgical Antimicrobial Prophylaxis.

Type of Operation	Common Pathogens	Drug of Choice
Cardiac (with median sternotomy)	Staphylococci, enteric gram-negative rods	Cefazolin
Noncardiac, thoracic	Staphylococci, streptococci, enteric gram-negative rods	Cefazolin
Vascular (abdominal and lower extremity)	Staphylococci, enteric gram-negative rods	Cefazolin
Neurosurgical (craniotomy)	Staphylococci	Cefazolin
Orthopedic (with hardware insertion)	Staphylococci	Cefazolin
Head and neck (with entry into the oropharynx)	<i>S aureus</i> , oral flora	Cefazolin

Gastroduodenal (high-risk patients ¹)	<i>S aureus</i> , oral flora, enteric gram-negative rods	Cefazolin
Biliary tract (high-risk patients ²)	<i>S aureus</i> , enterococci, enteric gram-negative rods	Cefazolin
Colorectal (elective surgery)	Enteric gram-negative rods, anaerobes	Oral erythromycin plus neomycin ³
Colorectal (emergency surgery or obstruction)	Enteric gram-negative rods, anaerobes	Cefoxitin, cefotetan, or cefmetazole
Appendectomy	Enteric gram-negative rods, anaerobes	Cefoxitin, ceftizoxime, cefotetan, or cefmetazole
Hysterectomy	Enteric gram-negative rods, anaerobes, enterococci, group B streptococci	Cefazolin
Cesarean section	Enteric gram-negative rods, anaerobes, enterococci, group B streptococci	Cefazolin ⁴

¹Gastric procedures for cancer, ulcer, bleeding, or obstruction; morbid obesity; suppression of gastric acid secretion.

²Age > 60, acute cholecystitis, prior biliary tract surgery, common duct stones, jaundice, or diabetes mellitus.

³In conjunction with mechanical bowel preparation.

⁴Administer immediately following cord clamping.

Improper administration of antimicrobial prophylaxis leads to excessive surgical wound infection rates. Common errors in antibiotic prophylaxis include selection of the wrong antibiotic, administering the first dose too early or too late, failure to repeat doses during prolonged procedures, excessive duration of prophylaxis, and inappropriate use of broad-spectrum antibiotics.

Nonsurgical Prophylaxis

Nonsurgical prophylaxis includes the administration of antimicrobials to prevent colonization or asymptomatic infection as well as the administration of drugs following colonization by or inoculation of pathogens but before the development of disease. Nonsurgical prophylaxis is indicated in individuals who are at high risk for temporary exposure to selected virulent pathogens and in patients who are at increased risk for developing infection because of underlying disease (eg, immunocompromised hosts). Prophylaxis is most effective when directed against organisms that are predictably susceptible to antimicrobial agents. Common indications for nonsurgical prophylaxis are listed in Table 51–8.

Table 51–8. Recommendations for Nonsurgical Antimicrobial Prophylaxis.

Infection to Be Prevented	Indication	Drug of Choice	Efficacy
Anthrax	Suspected exposure	Ciprofloxacin or doxycycline	Proposed effective
Cholera	Close contacts of a case	Tetracycline	Proposed effective
Diphtheria	Unimmunized contacts	Penicillin or erythromycin	Proposed effective
Endocarditis	Dental, oral, or upper respiratory tract procedures ¹ in at-risk patients ²	Amoxicillin or clindamycin	Proposed effective
	Genitourinary or gastrointestinal procedures ³ in at-risk patients ²	Ampicillin or vancomycin and gentamicin	Proposed effective
Genital herpes simplex	Recurrent infection (\geq 4 episodes per year)	Acyclovir	Excellent
Influenza B	Unvaccinated geriatric patients, immunocompromised hosts, and healthcare workers during outbreaks	Oseltamivir	Good
Perinatal herpes simplex type 2 infection	Mothers with primary HSV or frequent recurrent genital HSV	Acyclovir	Proposed effective
Group B streptococcal (GBS) infection	Mothers with cervical or vaginal GBS colonization and their newborns with one or more of the following: (a) onset of labor or membrane rupture before 37 weeks' gestation, (b) prolonged rupture of membranes (> 12 hours), (c) maternal intrapartum fever, (d) history of GBS bacteriuria during pregnancy, (e) mothers who have given birth to infants who had early GBS disease or with a history of streptococcal bacteriuria during pregnancy	Ampicillin or penicillin	Excellent
<i>Haemophilus influenzae</i> type B infection	Close contacts of a case in incompletely immunized children (< 48 months old)	Rifampin	Excellent
HIV infection	Health care workers exposed to blood after needle-stick injury	Zidovudine and lamivudine \pm indinavir or nelfinavir	Good
	Pregnant HIV-infected women who are at \geq 14 weeks of gestation	Zidovudine	Excellent
	Newborns of HIV-infected women for the first 6 weeks of life, beginning 8–12 hours after birth		

Influenza A	Unvaccinated geriatric patients, immunocompromised hosts, and health care workers during outbreaks	Amantadine	Good
Malaria	Travelers to areas endemic for chloroquine-susceptible disease	Chloroquine	Excellent
	Travelers to areas endemic for chloroquine-resistant disease	Mefloquine	Excellent
Meningococcal infection	Close contacts of a case	Rifampin	Excellent
<i>Mycobacterium avium</i> complex	HIV-infected patients with CD4 count < 75/ μ L	Azithromycin or clarithromycin	Excellent
Otitis media	Recurrent infection	Amoxicillin	Good
Pertussis	Close contacts of a case	Erythromycin	Excellent
Plague	Close contacts of a case	Tetracycline	Proposed effective
Pneumococemia	Children with sickle cell disease or asplenia	Penicillin	Excellent
<i>Pneumocystis jiroveci</i> pneumonia (PCP)	High-risk patients (eg AIDS, leukemia, transplant)	Trimethoprim-sulfamethoxazole	Excellent
Rheumatic fever	History of rheumatic fever or known rheumatic heart disease	Benzathine penicillin	Excellent
Toxoplasmosis	HIV-infected patients with IgG antibody to <i>Toxoplasma</i> and CD4 count < 100/ μ L	Trimethoprim-sulfamethoxazole	Good
Tuberculosis	Persons with positive tuberculin skin tests and one or more of the following: (a) HIV infection, (b) close contacts with newly diagnosed disease, (c) recent skin test conversion, (d) medical conditions that increase the risk of developing tuberculosis, (e) age < 35	Isoniazid, rifampin or pyrazinamide	Excellent
Urinary tract infections (UTI)	Recurrent infection	Trimethoprim-sulfamethoxazole	Excellent

¹Prophylaxis is recommended for the following: dental procedures known to induce gingival or mucosal bleeding, tonsillectomy or adenoidectomy, surgical procedures that involve respiratory mucosa, and rigid bronchoscopy.

²Risk factors include the following: prosthetic heart valves, previous bacterial endocarditis, congenital cardiac malformations, rheumatic and other acquired valvular dysfunction, and mitral valve prolapse with valvular regurgitation.

³Prophylaxis is recommended for the following: surgical procedures that involve intestinal mucosa, sclerotherapy for esophageal varices, esophageal or urethral dilation, biliary tract surgery, cystoscopy, urethral catheterization or urinary tract surgery in the presence of urinary tract infection, prostatic surgery, incision and drainage of infected tissue, vaginal hysterectomy, and

vaginal delivery in the presence of infection.

Katzung PHARMACOLOGY, 9e > Section VIII. Chemotherapeutic Drugs > Chapter 51. Clinical Use of Antimicrobial Agents >

National Research Council (NRC) Wound Classification Criteria

Clean: Elective, primarily closed procedure; respiratory, gastrointestinal, biliary, genitourinary, or oropharyngeal tract not entered; no acute inflammation and no break in technique; expected infection rate $\approx 2\%$.

Clean contaminated: Urgent or emergency case that is otherwise clean; elective, controlled opening of respiratory, gastrointestinal, biliary, or oropharyngeal tract; minimal spillage or minor break in technique; expected infection rate $\approx 10\%$.

Contaminated: Acute nonpurulent inflammation present; major technique break or major spill from hollow organ; penetrating trauma less than 4 hours old; chronic open wounds to be grafted or covered; expected infection rate about 20%.

Dirty: Purulence or abscess present; preoperative perforation of respiratory, gastrointestinal, biliary, or oropharyngeal tract; penetrating trauma more than 4 hours old; expected infection rate about 40%.

Chapter 52. Basic Principles of Antiparasitic Chemotherapy

Katzung PHARMACOLOGY, 9e > Section VIII. Chemotherapeutic Drugs > Chapter 52. Basic Principles of Antiparasitic Chemotherapy >

Basic Principles of Antiparasitic Chemotherapy: Introduction

In its general scientific sense, the term "parasite" includes all of the known infectious agents such as viruses, bacteria, fungi, protozoa, and helminths. In this and the two following chapters, the term is used in a restricted sense to denote the protozoa and helminths. It has been estimated that 3 billion (3×10^9) humans suffer from parasitic infections, plus a much greater number of domestic and wild animals. Although these diseases constitute the most widespread human health problem in the world today, they have for various reasons also been the most neglected.

In theory, the parasitic infections should be relatively easy to treat because the etiologic agents are known in almost all cases. Furthermore, recent advances in cell culture techniques have made possible in vitro cultivation of many of the important parasites. These advances have not only laid to rest the traditional view that parasites somehow depend on a living host for their existence but have also enabled us to study parasites by methods similar to those employed in investigations of bacteria, including biochemistry, molecular biology, and immunologic pharmacology. However, many problems remain to be solved before more effective chemotherapeutic agents will be discovered and made available for all of the parasitic diseases.

Targets of Chemotherapy

A rational approach to antiparasitic chemotherapy requires comparative biochemical and physiologic investigations of host and parasite to discover differences in essential processes that

will permit selective inhibition in the parasite and not in the host. One might expect that the parasite would have many deficiencies in its metabolism associated with its parasitic nature. This is true of many parasites—the oversimplified metabolic pathways are usually indispensable for survival of the parasite and thus represent points of vulnerability. However, oversimplified metabolic pathways are not the only opportunity for attack. Although the parasite lives in a metabolically luxurious environment and may become "lazy," the environment is not entirely friendly and the parasite must have defense mechanisms in order to survive—ie, to defend itself against immunologic attack, proteolytic digestion, etc, by the host. In some instances, necessary nutrients are not supplied to the parasite from the host, though the latter can obtain the same nutrients from the diet. In this situation, the parasite will have acquired the synthetic activity needed for its survival. Finally, the great evolutionary distance between host and parasite has in some cases resulted in sufficient differences among individual enzymes or functional pathways to allow selective inhibition of the parasite. Thus, there can be three major types of potential targets for chemotherapy of parasitic diseases: (1) unique essential enzymes found only in the parasite; (2) similar enzymes found in both host and parasite but indispensable only for the parasite; and (3) common biochemical functions found in both parasite and host but with different pharmacologic properties. Examples of specific targets and drugs that act on them are summarized in Table 52–1. This chapter discusses antiparasitic mechanisms based upon these examples and provides background information for the drugs described in Chapter 53: Antiprotozoal Drugs and Chapter 54: Clinical Pharmacology of the Anthelmintic Drugs.

Table 52–1. Identified Targets for Chemotherapy in Parasites.

Targets	Parasites	Inhibitors
Unique essential enzymes		
Enzymes for dihydropteroate synthesis	Apicomplexa	Sulfones and sulfonamides
Glycolipid synthesis	African trypanosomes	None
Pyruvate:ferrodoxin oxidoreductase	Anaerobic protozoa	Nitroimidazoles
Pyruvate phosphate dikinase	Anaerobic protozoa	None
Nucleoside phosphotransferase	Flagellated protozoa	Allopurinol riboside and formycin B
Trypanothione reductase and peroxidase	Kinetoplastida	Nifurtimox
Indispensable enzymes		
Lanosterol C-14 α demethylase	<i>Leishmania</i> and <i>Trypanosoma cruzi</i>	Azoles
Purine phosphoribosyl transferase	Protozoa	Allopurinol
Purine nucleoside kinase	<i>Trichomonas vaginalis</i> and <i>Entamoeba histolytica</i>	None
Ornithine decarboxylase	African trypanosomes	α -Difluoromethylornithine
(S)-Adenosylmethionine decarboxylase	African trypanosomes	Diamidines

Glycolytic enzymes	Kinetoplastida	Glycerol plus salicylhydroxamic acid and suramin
Common indispensable biochemical functions with different pharmacologic properties		
Dihydrofolate reductase-thymidylate synthase bifunctional enzyme	Apicomplexa and Kinetoplastida	Pyrimethamine
Thiamin transporter	Coccidia	Amprolium
Mitochondrial electron transporter	Apicomplexa	4-Hydroxyquinolines and 2-hydroxy-naphthoquinones
Microtubules	Helminth	Benzimidazoles
Nervous synaptic transmission	Helminth and ectoparasite	Levamisole, piperazine, milbemycins, and avermectins

Katzung PHARMACOLOGY, 9e > Section VIII. Chemotherapeutic Drugs > Chapter 52. Basic Principles of Antiparasitic Chemotherapy >

Essential Enzymes Found Only in Parasites

These enzymes would appear to be the cleanest targets for chemotherapy. Like enzymes involved in the synthesis of bacterial cell walls (see Chapter 43: Beta-Lactam Antibiotics & Other Inhibitors of Cell Wall Synthesis), inhibition of these enzymes should have no effect on the host. Unfortunately, only a few of these enzymes have been discovered among the parasitic protozoa. Furthermore, their usefulness as chemotherapeutic targets is sometimes limited because of the development of drug resistance. Examples of important target enzymes in this category are discussed in the following pages.

Enzymes for Dihydropteroate Synthesis

Intracellular protozoa of the phylum Apicomplexa such as plasmodium, toxoplasma, and eimeria have long been known to respond to sulfonamides and sulfones. This has led to the assumption that Apicomplexa must synthesize their own folate in order to survive. The reaction of 2-amino-4-hydroxy-6-hydroxymethyl-dihydropteridine diphosphate with *p*-aminobenzoate to form 7,8-dihydropteroate has been demonstrated in cell-free extracts of the human malaria parasite *Plasmodium falciparum*. 2-Amino-4-hydroxy-6-hydroxymethyl-dihydropteridine pyrophosphokinase and 7,8-dihydropteroate synthase have also been identified. Sulfathiazole, sulfaguanidine, and sulfanilamide act as competitive inhibitors of *p*-aminobenzoate. It has not been possible to demonstrate dihydrofolate synthase activity in the parasites, which raises the possibility that 7,8-dihydropteroate may have substituted for dihydrofolate in malaria parasites. Similar lack of recognition of folate as substrate was also observed in the dihydrofolate reductase of *Eimeria tenella*, a parasite of chickens.

However, lack of utilization of exogenous folate may not fully explain the apparently indispensable nature of the synthesis of 7,8-dihydropteroate in plasmodium, toxoplasma, and eimeria. It is known that most of the folate molecules in mammalian cells are linked with polyglutamates in the cytoplasm and are transported across cell membranes with difficulty. It may compound the problem of obtaining 7,8-dihydropteroate or dihydrofolate for the parasite and makes all of the enzymes

involved in their synthesis attractive targets for anti-Apicocomplexa chemotherapy.

The gene encoding 7,8-dihydropteroate synthase was cloned from *P falciparum* and found to encode a bifunctional enzyme that includes the pyrophosphokinase at the amino terminal of the protein. Discrepancies were observed in the sequences of 7,8-dihydropteroate synthase portion of the genes from sulfadoxine-sensitive versus sulfadoxine-resistant *P falciparum*, thus confirming that this enzyme is the target for the antimalarial sulfonamide drugs.

The sulfones and sulfonamides synergize with the inhibitors of dihydrofolate reductase, and the combinations have been effective in controlling malaria, toxoplasmosis, and coccidiosis. Fansidar, a combination of sulfadoxine and pyrimethamine, has been successful in controlling some strains of chloroquine-resistant *Plasmodium falciparum* malaria (see Chapter 53: Antiprotozoal Drugs). However, reports of Fansidar resistance have increased in recent years. New inhibitors effective against the sulfonamide-resistant 7,8-dihydropteroate synthase are needed.

The pharmacologic properties of parasite 7,8-dihydropteroate synthases may differ from those of the bacterial enzymes. For instance, metachloridine and 2-ethoxy-*p*-aminobenzoate are both ineffective against sulfonamide-sensitive bacteria, but the former has antimalarial activity and the latter is effective against infection by the chicken parasite *Eimeria acervulina*; both activities can be reversed by *p*-aminobenzoate.

Pyruvate:Ferredoxin Oxidoreductase

Certain anaerobic protozoal parasites lack mitochondria and mitochondrial activities for generating ATP and disposing of electrons. They possess, instead, ferredoxin-like or flavodoxin-like low-redox-potential electron transport proteins. In trichomonad flagellates and rumen ciliates, the process takes place in a membrane-limited organelle called the hydrogenosome. By the actions of pyruvate:ferredoxin oxidoreductase (PFOR) and hydrogenase in the hydrogenosome, H₂ is produced by these organisms under anaerobic conditions as the major means of electron disposition. Although entamoeba species and *Giardia lamblia* have no hydrogenosome, a ferredoxin has been isolated from *Entamoeba histolytica*, and the genes encoding ferredoxin and pyruvate:ferredoxin oxidoreductase have been isolated from *E histolytica* and *G lamblia*.

Pyruvate:ferredoxin oxidoreductase has no counterpart in mammalian systems. In contrast to the mammalian pyruvate dehydrogenase complex, pyruvate:ferredoxin oxidoreductase is incapable of reducing pyridine nucleotides because of its low redox potential (approximately -400 mV). However, this low potential can also transfer electrons from pyruvate to the nitro groups of metronidazole and other 5-nitroimidazole derivatives to form cytotoxic reduced products that bind to DNA and proteins. This is apparently why anaerobic protozoal species are highly susceptible to drugs such as metronidazole. Despite the recent development of drug resistance in some *Trichomonas vaginalis* strains and the possibility of carcinogenic properties (see Chapter 53: Antiprotozoal Drugs), metronidazole remains the drug of choice for controlling anaerobic protozoal parasite infections. Nitazoxanide, an agent recently approved for use against *G lamblia* and *Cryptosporidium parvum*, apparently acts through an active metabolite, tizoxanide, which inhibits the pyruvate:ferredoxin oxidoreductase pathway.

Though pyruvate:ferredoxin oxidoreductase activates the prodrug metronidazole, it may not perform an essential function in the anaerobic parasites. The enzyme activity was significantly lower in metronidazole-resistant *G lamblia*. Some aerobic metronidazole-resistant *T vaginalis* strains have no detectable pyruvate:ferredoxin oxidoreductase activity but are viable. A knockdown of expression of this enzyme in *G lamblia* by ribozyme-antisense chimeric RNA resulted in

facilitated cell growth under aerobic condition and metronidazole resistance.

Pyruvate Phosphate Dikinase

Glycolysis provides the main source of ATP in *Trypanosoma brucei*, *E histolytica*, and *G lamblia*, which possess pyruvate kinase as well as a pyruvate phosphate dikinase for converting phosphoenolpyruvate (PEP) to pyruvate and generating ATP. Pyruvate phosphate dikinase is not a homolog of pyruvate kinase but is closely related to PEP synthase from bacteria. The enzyme catalyzes conversion of PEP to pyruvate accompanied by the synthesis of ATP from AMP and pyrophosphate. Genes encoding the enzyme have been isolated from *E histolytica* and *G lamblia* and have demonstrated considerable structural divergences. No specific inhibitor of this enzyme has yet been identified.

Nucleoside Phosphotransferases

All the protozoal parasites studied thus far are deficient in de novo synthesis of purine nucleotides. The various purine salvage pathways in these parasites are thus essential for their survival and growth. Among the leishmania species, a unique salvage enzyme has been identified—purine nucleoside phosphotransferase—that can transfer the phosphate group from a variety of monophosphate esters, including *p*-nitrophenylphosphate, to the 5' position of purine nucleosides. This enzyme also phosphorylates purine nucleoside analogs such as allopurinol riboside, formycin B, 9-deazainosine, and thiopurinol riboside, converting them to the corresponding nucleotides. These nucleotides are either further converted to triphosphates and eventually incorporated into nucleic acid of leishmania or become inhibitors of other essential enzymes in purine metabolism. Consequently, allopurinol riboside, formycin B, 9-deazainosine, and thiopurinol riboside all act as antileishmanial agents both in vitro and in vivo. Allopurinol riboside is particularly interesting because it is remarkably nontoxic to the mammalian host.

The mechanism of action of these purine nucleoside analogs is thus not by blocking purine salvage in leishmania because there are many other major purine salvage enzymes in the organism that remain unaffected. The nucleoside transferase is a minor enzyme, but it recognizes a number of false substrates and converts them to products toxic to leishmania. This approach of identifying "subversive substrates" for a purine salvage enzyme as potential antiparasitic targets does not depend on the lack of de novo purine nucleotide synthesis in these parasites. It could be applied—in any parasite—to any enzyme that happens to recognize a subversive substrate.

Trichomonad flagellates appear to be deficient in de novo synthesis of both purines and pyrimidines. Their salvage thus becomes indispensable for these parasites. In *T vaginalis*, for instance, the supply route for thymidine 5'-monophosphate (TMP) is provided by a single salvage pathway that converts exogenous thymidine to TMP by the action of a thymidine phosphotransferase. The enzyme activity is not affected by thymidine kinase inhibitors such as acyclovir but is inhibitable by guanosine or 5-fluorodeoxyuridine; both compounds also inhibit the in vitro growth of the parasites. This enzyme is an attractive target for chemotherapeutic treatment of the anaerobic protozoal parasites.

Purine Nucleoside Kinase

Exogenous adenosine is the precursor of the entire purine nucleotide pool in *T vaginalis* through its partial conversion to inosine and the action of purine nucleoside kinase, a unique enzyme in the organism, which converts adenosine and inosine to the corresponding nucleotides. It performs a critical role in *T vaginalis* purine salvage and has a unique substrate specificity suitable as a target

of chemotherapy.

Trypanothione Synthase, Reductase, & Peroxidase

Protozoa with kinetoplasts are unusual in that a considerable proportion of their intracellular spermidine and glutathione is found in the unique conjugate N^1-N^8 -(glutathionyl)spermidine, which has been assigned the name trypanothione. Trypanothione synthase, reductase, and peroxidase activities have been detected in these parasites. A knockout of the gene encoding trypanothione reductase from the African trypanosome *Trypanosoma brucei* resulted in apparent cessation of growth of the organism. Nifurtimox, a nitrofur derivative effective in treating Chagas' disease (caused by *Trypanosoma cruzi*), has been found to be a potent inhibitor of trypanothione reductase, and other inhibitors are under study. No extensive studies of trypanothione synthetase or peroxidase have been performed. The antitrypanosomal trivalent arsenicals are taken up by the African trypanosome *Trypanosoma brucei* and complex with trypanothione, forming a product that is also an effective inhibitor of trypanothione reductase.

Glycolipid Synthetic Enzymes

The variant surface glycoprotein on the plasma membranes of bloodstream African trypanosomes provides the organisms with the means of evading host immune responses. The glycoprotein is anchored to the cell surface by a glycosyl phosphatidylinositol that contains myristate as its only fatty acid component. Thus, the introduction of a subversive substrate to replace myristate from the glycolipid anchor could result in loss of the variant surface glycoprotein, which might suppress development of trypanosomes in mammalian blood. A myristate analog, 10-(propoxy)decanoic acid, was found incorporated into the glycolipid and also active against *T brucei* in in vitro tests. However, further validation of this approach to antitrypanosomal chemotherapy must await results of in vivo tests.

Shikimate Pathway Enzymes

The availability of *P falciparum* genome database led to the identification of shikimate pathway enzymes in this organism. The pathway is known to exist in bacteria, fungi, algae, and plants but not in mammals. A herbicide, glyphosate, known to inhibit the enzyme 5'-enolpyruvylshikimate 3-phosphate synthase, was found to inhibit growth of *P falciparum*. However, it is not known if the in vitro antimalarial action of glyphosate is by inhibiting this enzyme. Furthermore, the shikimate pathway leads to biosynthesis of aromatic amino acids. Since *P falciparum* grows on digested hemoglobin, it is not clear if biosynthesis of aromatic amino acids plays an essential role in this organism.

Isoprenoid Biosynthetic Enzymes

A mevalonate-independent isoprenoid biosynthetic pathway occurring only among bacteria, algae, and plants was also identified in *P falciparum* and *T gondii*. **Fosmidomycin**, known to inhibit 1-deoxy-D-xylulose-5-phosphate isomerase in this pathway, was found to also inhibit in vitro growth of *P falciparum* and to cure *P vinckei* infection in mice. However, the same questions about whether the pathway plays an indispensable role in this parasitic organism and whether fosmidomycin inhibits the parasites by inhibiting the particular enzyme remain to be answered.

Enzymes Indispensable Only in Parasites

Because of the many metabolic deficiencies among parasites resulting from the unique environments in which parasites live in their hosts, there are enzymes whose functions may be essential for the survival of the parasites, but the same enzymes are not indispensable to the host—ie, the host may be able to survive the complete loss of these enzyme functions by achieving the same result through alternative pathways. This discrepancy opens up opportunities for antiparasitic chemotherapy, though insufficiently selective inhibition of parasite enzymes remains an important safety concern.

Lanosterol C-14 α Demethylase

T. cruzi and leishmania contain ergosterol as the principal sterol in plasma membranes. The **azole antifungal agents** (eg, ketoconazole, miconazole, itraconazole), which are known to act by inhibiting the cytochrome P450-dependent C-14 α demethylation of lanosterol in the ergosterol biosynthetic pathway, also inhibit growth of *T. cruzi* and leishmania by blocking C-14 α demethylation of lanosterol in these parasites. Recently, an antifungal bistriazole, D0870, demonstrated encouraging in vivo anti-*T. cruzi* activity in mouse infection models. It is thus likely that lanosterol C-14 α demethylase plays an essential role in ergosterol synthesis and therefore qualifies as a target for chemotherapy against *T. cruzi* and leishmania.

The same C-14 α demethylation of lanosterol is also required for cholesterol synthesis in mammals. As rather nonselective inhibitors of lanosterol C-14 α demethylases, the azoles may exert a variety of endocrine side effects by inhibiting this enzyme in the adrenal glands and gonads while remaining acceptable as systemic antifungal agents. Because of its excessive toxicity, D0870 was not developed as an antifungal or antiparasitic agent. However, since human and yeast lanosterol C-14 α demethylases share only 38–42% sequence identities, there may be a good chance of designing inhibitors that are more selective against the fungal or parasitic enzymes.

Purine Phosphoribosyl Transferases

The absence of de novo purine nucleotide synthesis in protozoal parasites as well as in the trematode *Schistosoma mansoni* is reflected in the relative importance of purine phosphoribosyl transferases in many parasite species.

G. lamblia has an exceedingly simple scheme of purine salvage. It possesses only two pivotal enzymes: the adenine and guanine phosphoribosyl transferases, which convert exogenous adenine and guanine to the corresponding nucleotides. There is no salvage of hypoxanthine, xanthine, or any purine nucleosides and no interconversion between adenine and guanine nucleotides in the parasite. Functions of the two phosphoribosyl transferases are thus both essential for the survival and development of *G. lamblia* (Figure 52–1). The guanine phosphoribosyl transferase is an interesting enzyme because it does not recognize hypoxanthine, xanthine, or adenine as substrate. This substrate specificity distinguishes the giardia enzyme from the mammalian enzyme, which uses hypoxanthine, and the bacterial one, which uses xanthine as substrate. Design of a highly specific inhibitor of this enzyme is thus possible. The crystal structures of both guanine and adenine phosphoribosyltransferases from *G. lamblia* have been solved recently, which should provide good opportunities for specific inhibitor design.

Indispensable Biochemical Functions Found in Both Parasite & Host But with Different Pharmacologic Properties

In the parasite, these functions have differentiated sufficiently to become probable targets for antiparasitic chemotherapy, not because of the parasitic nature of the organism or its unique environment but, more likely, because of the long evolutionary distances separating the parasite and the host. It is thus difficult to discover these targets through studying metabolic deficiency or special nutritional requirements of the parasite. They have usually been found by investigating the modes of action of some well-established antiparasitic agents discovered by screening methods in the past. More recently, comparison of genome databases between the host and the parasite has become practical. The target may not be a single well-defined enzyme but may include transporters, receptors, cellular structural components, or other specific functions essential for survival of the parasite.

Dihydrofolate Reductase-Thymidylate Synthase Bifunctional Enzyme

Dihydrofolate reductase (DHFR), a classic target in antimicrobial and anticancer chemotherapy, has been shown to be a useful therapeutic target in plasmodium, toxoplasma, and eimeria species. **Pyrimethamine** is the prototypical DHFR inhibitor, exerting inhibitory effects in all three groups. However, pyrimethamine resistance in *P. falciparum* has become widespread in recent years. This is largely attributable to specific point mutations in *P. falciparum* DHFR that have rendered the enzyme less susceptible to the inhibitor.

A highly unusual feature of DHFR in Apicomplexa and Kinetoplastida is its association with thymidylate synthase in the same protein. DHFR activity is always located at the amino terminal portion, while the thymidylate synthase activity resides in the carboxyl terminal. The two enzyme functions do not appear to be interdependent; eg, the DHFR portion of the *P. falciparum* enzyme molecule was found to function normally in the absence of the thymidylate synthase portion. It is likely that since the protozoan parasites do not perform de novo synthesis of purine nucleotides, the primary function of the tetrahydrofolate produced by DHFR is to provide 5,10-methylenetetrahydrofolate only for the thymidylate synthase-catalyzed reaction. Physical association of the two enzymes may improve efficiency of TMP synthesis. If an effective means of disrupting the coordination between the two activities can be developed, this bifunctional protein may qualify as a target for antiparasitic therapy.

Thiamin Transporter

Carbohydrate metabolism provides the main energy source in coccidia. Diets deficient in thiamin, riboflavin, or nicotinic acid—all cofactors in carbohydrate metabolism—result in suppression of parasitic infestation of chickens by *E. tenella* and *E. acervulina*. A thiamin analog, **amprolium**—1-[(4-amino-2-propyl-5-pyrimidinyl)-methyl]-2-picolinium chloride—has long been used as an effective anticoccidial agent in chickens and cattle with relatively low host toxicity. The antiparasitic activity of amprolium is reversible by thiamin and is recognized to involve inhibition of thiamin transport in the parasite. Unfortunately, amprolium has a rather narrow spectrum of antiparasitic activity; it has poor activity against toxoplasmosis, a closely related parasitic infection.

Mitochondrial Electron Transporter

Mitochondria of *E tenella* appear to lack cytochrome c and to contain cytochrome o—a cytochrome oxidase commonly found in the bacterial respiratory chain—as the terminal oxidase. Certain 4-hydroxyquinoline derivatives such as buquinolate, decoquinolate, and methyl benzoate that have long been known to be relatively nontoxic and effective anticoccidial agents have been found to act on the parasites by inhibiting mitochondrial respiration. Direct investigation on isolated intact *E tenella* mitochondria indicated that the 4-hydroxyquinolines have no effect on NADH oxidase or succinoxidase activity but that they are extremely potent inhibitors of NADH- or succinate-induced mitochondrial respiration. On the other hand, the ascorbate-induced *E tenella* mitochondrial respiration was totally unsusceptible to these 4-hydroxyquinolines. The block by the anticoccidial agents thus may be located between the oxidases and cytochrome b in the electron transport chain. A certain component at this location must be essential for mediating the electron transport and would appear to be highly sensitive to the 4-hydroxyquinolines. This component must be a very specific chemotherapeutic target in eimeria species, since the 4-hydroxyquinolines have no effect on chicken liver and mammalian mitochondrial respiration and no activity against any parasites other than eimeria.

Many 2-hydroxynaphthoquinones have demonstrated therapeutic activities against Apicomplexa. **Parvaquinone** and **buparvaquinone** have been developed for the treatment of theileriosis in cattle and other domestic animals. **Atovaquone** is an antimalarial drug and is also used in the treatment of *Pneumocystis jiroveci* and *P carinii* infections. The 2-hydroxynaphthoquinones are analogs of ubiquinone. The primary site of action of atovaquone in *Plasmodium* is the cytochrome bc₁ complex, where an apparent drug-binding site is present in cytochrome b. In plasmodium, ubiquinone also plays an important role as an electron acceptor for dihydroorotate oxidase. Consequently, pyrimidine biosynthesis in plasmodium is also inhibited by atovaquone. This chemical compound has also been found to be active against *T gondii* cysts in the brains of infected mice.

A major problem in the use of the antiparasitic 4-hydroxyquinolones and 2-hydroxynaphthoquinones is resistance that can develop with extraordinarily high frequency. It may be attributable to their mitochondrial site of action, which is known to have a high frequency of mutation.

Microtubules

Microtubules are an important part of the cytoskeleton and the mitotic spindle and consist of α - and β -tubulin subunit proteins. Recent comparisons of α - and β -tubulins from several species of parasitic nematodes indicated the presence of multiple isoforms with varying isoelectric points. This variation is interesting not only in pointing out the evolutionary relations among eukaryotic cells but useful also in classifying the tubulins in parasites as potential targets for antiparasitic chemotherapy. A group of benzimidazole derivatives have long been established as highly effective anthelmintics. **Mebendazole** was among the first such anthelmintics found to act primarily by blocking transport of secretory granules and movement of other subcellular organelles in the parasitic nematode *Ascaris lumbricoides*. This inhibition coincides with the disappearance of cytoplasmic microtubules from the intestinal cells of the worm. The microtubular systems of the host cells are unaffected by the treatment. Mebendazole and **fenbendazole**, another anthelmintic benzimidazole, have also been shown to compete with colchicine binding to *A lumbricoides* embryonic tubulins with 250–400 times higher potencies than the binding competition to bovine brain tubulins. These differential binding affinities may explain the selective toxicity of benzimidazoles toward parasitic nematodes.

Synaptic Transmission

Invertebrate nervous systems in helminths and arthropods differ from those of vertebrates in important ways. The motoneurons in invertebrates, for example, are unmyelinated and are thus more susceptible to disturbances of nerve membranes than are the myelinated somatic motor fibers of vertebrates. Muscle fibers in arthropods are innervated by excitatory synapses, in which L-glutamic acid is the neurotransmitter, and by inhibitory nerves, which have γ -aminobutyric acid (GABA) as transmitter. Cholinergic nerves are concentrated in the central nervous system of arthropods. In nematodes, free-living species, eg, *Caenorhabditis elegans*, and gastrointestinal parasitic species, eg, *A lumbricoides*, appear to have identical neuronal systems and synaptic transmission. Cholinergic excitatory and glutamate inhibitory synapses are found in the ventral central cords, and GABAergic inhibitory synapses are identified at the neuromuscular junctions of the worms. The mammalian hosts, on the other hand, have mainly nicotinic receptors at the neuromuscular junctions (see Chapter 6: Introduction to Autonomic Pharmacology), and the GABA synapses and GABA_A receptors are primarily confined within the central nervous system protected by the blood-brain barrier (Chapter 21: Introduction to the Pharmacology of CNS Drugs).

Neurotoxicant anthelmintics must be administered systemically to mammalian hosts to reach the parasitic nematodes. Therefore, if absorbed, they must be nontoxic to the nervous system of the host. Furthermore, they must penetrate the thick cuticle of the nematodes in order to be effective. It is therefore difficult to find a useful anthelmintic that acts on the nervous system of these parasites. Nevertheless, the majority of presently available anthelmintics do act on the nerves of nematodes. They can be classified into three groups: (1) those acting as ganglionic nicotinic acetylcholine agonists; (2) those acting directly or indirectly as GABA agonists; and (3) those acting on the chloride ion channel. The first category includes **levamisole**, **pyrantel pamoate**, **oxantel pamoate**, and **bephenium**. The acetylcholine receptors at the neuromuscular junctions of nematodes are of the ganglionic nicotinic type; these agonists are quite effective in causing muscular contraction of the worms. Experimentally, the ganglionic nicotinic antagonist mecamylamine can reverse the action of these anthelmintics.

The second category consists of only one drug, **piperazine**, an older agent that apparently acts as a GABA agonist at the neuromuscular junction and causes flaccid paralysis of the nematode.

The third category consists of a family of natural compounds, the **milbemycins** and **avermectins**. They act on the ventral cord interneuron and on the motoneuron junction of arthropods to cause paralysis by facilitating the opening of the chloride ion channel. Therefore, both the milbemycins and the avermectins are potent anthelmintics, insecticides, and antiectoparasitic agents with no cross-resistance problems with agents acting on the cholinergic systems. Picrotoxin, a specific blocker of the chloride ion channel, can reverse all of the physiologic effects of these drugs (see Chapter 21: Introduction to the Pharmacology of CNS Drugs).

Ivermectin, a simple derivative of the mixture of avermectin B_{1a} and avermectin B_{1b}, is highly effective as an anthelmintic in domestic animals. It is also effective in controlling onchocerciasis by eliminating the microfilariae. It is currently in wide clinical use in West Africa. Avermectins have little effect on the mammalian central nervous system because they do not cross the blood-brain barrier readily. However, when isolated mammalian brain synaptosomes and synaptic membranes are used as models for investigation, specific high-affinity binding sites for the avermectins can be identified in GABAergic nerves. This drug binding stimulates GABA release from the presynaptic end of the GABA nerve and enhances the postsynaptic GABA binding. Avermectins also stimulate benzodiazepine binding to its receptor and enhance diazepam muscle relaxant activity *in vivo*. There is little doubt that milbemycins and avermectins act on chloride channels associated with GABA receptors and amplify GABA functions in the mammalian central nervous system. In the free-living nematode, *C elegans*, however, avermectin was found to interact with glutamate-gated

chloride ion channels. The complementary DNA encoding an avermectin-sensitive, glutamate-gated chloride channel was recently identified and isolated. This channel may be an attractive target for future studies of antinematode chemotherapy.

Little is known about the nervous systems of cestodes and trematodes except that they probably differ from those of nematodes, since milbemycins and avermectins have no effect on them. However, a highly effective antischistosomal and antitapeworm agent, **praziquantel** (see Chapter 54: Clinical Pharmacology of the Anthelmintic Drugs), is known to enhance Ca^{2+} influx and induce muscular contraction in those parasites, though it exerts no action on nematodes or insects. Some benzodiazepine derivatives have activities similar to those of praziquantel; these activities are unrelated to the anxiolytic activities in the mammalian central nervous system. The nerves and muscles in schistosomes and tapeworms are thus interesting subjects for future chemotherapeutic studies.

Drugs Whose Mechanisms Have Not Yet Been Conclusively Identified

In spite of considerable progress in defining the mechanisms of action of the drugs described above, there are still wide gaps in our understanding of a number of other important antiparasitic agents. These include the compounds presented in Table 52–2. From the biochemical activities that have been identified for them, it appears that many are capable of binding DNA, and some can uncouple oxidative phosphorylation in mammals. These types of activity, which are toxic to the host but could also be involved in the antiparasitic action, may have been preferentially detectable in random screens routinely used for antiparasitic agents in the past.

Table 52–2. Some Major Antiparasitic Agents with Undefined Mechanisms of Action.

Antiparasitic Agents	Possibly Relevant Biochemical Activities
Antiamebiasis agents	
Diloxanide furoate	Unknown
Emetine	Inhibitor of eukaryote protein synthesis
Halogenated hydroxyquinolines	Unknown
Paromomycin	Inhibitor of prokaryote protein synthesis
Antifascioliasis agents	
Bithionol	Oxidative phosphorylation uncoupler
Rafoxanide	Oxidative phosphorylation uncoupler
Antifilariasis agent	
Diethylcarbamazine	Inhibitor of lipoxygenase
Antileishmaniasis agents	
Amphotericin B	Voltage-dependent channel maker in cell membrane
Pentavalent antimonials	Unknown
Antimalarials	
Chloroquine	DNA binding, lysosomal neutralization, and hemoeporphyrin binding

Primaquine	Its quinoline quinone metabolite is an oxidant
Quinacrine	DNA binding and flavoenzyme inhibition
Quinine	DNA binding and membrane binding
Antischistosomal agents	
Praziquantel	Opening of Ca ²⁺ channels
Hycanthone	DNA binding
Metrifonate	Acetylcholinesterase inhibition
Niridazole	Metabolites binding to DNA
Oxamniquine	DNA binding
Trivalent antimonials	Inhibition of phosphofructokinase
Antitapeworm agent	
Niclosamide	Oxidative phosphorylation uncoupler
Antitrypanosomiasis agent	
Melarsen oxide	Inhibitor of trypanothione reductase

Chapter 53. Antiprotozoal Drugs

Katzung PHARMACOLOGY, 9e > Section VIII. Chemotherapeutic Drugs > Chapter 53.
Antiprotozoal Drugs >

Treatment of Malaria

Four species of plasmodium cause human malaria: *Plasmodium falciparum*, *P vivax*, *P malariae*, and *P ovale*. Although all may cause significant illness, *P falciparum* is responsible for nearly all serious complications and deaths. Drug resistance is an important therapeutic problem, most notably with *P falciparum*.

Parasite Life Cycle

An anopheline mosquito inoculates plasmodium sporozoites to initiate human infection. Circulating sporozoites rapidly invade liver cells, and exoerythrocytic stage tissue schizonts mature in the liver. Merozoites are subsequently released from the liver and invade erythrocytes. Only erythrocytic parasites cause clinical illness. Repeated cycles of infection can lead to the infection of many erythrocytes and serious disease. Sexual stage gametocytes also develop in erythrocytes before being taken up by mosquitoes, where they develop into infective sporozoites.

In *P falciparum* and *P malariae* infection, only one cycle of liver cell invasion and multiplication occurs, and liver infection ceases spontaneously in less than 4 weeks. Thus, treatment that eliminates erythrocytic parasites will cure these infections. In *P vivax* and *P ovale* infections, a dormant hepatic stage, the hypnozoite, is not eradicated by most drugs, and subsequent relapses can therefore occur after therapy directed against erythrocytic parasites. Eradication of both erythrocytic and hepatic parasites is required to cure these infections.

Drug Classification

Several classes of antimalarial drugs are available (Table 53–1; Figure 53–1). Drugs that eliminate developing or dormant liver forms are called **tissue schizonticides**; those that act on erythrocytic parasites are **blood schizonticides**; and those that kill sexual stages and prevent transmission to mosquitoes are **gametocides**. No one available agent can reliably effect a **radical cure**, ie, eliminate both hepatic and erythrocytic stages. Few available agents are **causal prophylactic drugs**, ie, capable of preventing erythrocytic infection. However, all effective chemoprophylactic agents kill erythrocytic parasites before they grow sufficiently in number to cause clinical disease.

Drug	Class	Use
Chloroquine	4-Aminoquinoline	Treatment and chemoprophylaxis of infection with sensitive parasites
Amodiaquine ¹	4-Aminoquinoline	Treatment of infection with some chloroquine-resistant <i>P falciparum</i> strains
Quinine	Quinoline methanol	Oral treatment of infections with chloroquine-resistant <i>P falciparum</i>
Quinidine	Quinoline methanol	Intravenous therapy of severe infections with <i>P falciparum</i>
Mefloquine	Quinoline methanol	Chemoprophylaxis and treatment of infections with <i>P falciparum</i>
Primaquine	8-Aminoquinoline	Radical cure and terminal prophylaxis of infections with <i>P vivax</i> and <i>P ovale</i>
Sulfadoxine-pyrimethamine (Fansidar)	Folate antagonist combination	Treatment of infections with some chloroquine-resistant <i>P falciparum</i>
Proguanil ¹	Folate antagonist	Chemoprophylaxis (with chloroquine)
Doxycycline	Tetracycline	Treatment (with quinine) of infections with <i>P falciparum</i> ; chemoprophylaxis
Halofantrine ¹	Phenanthrene methanol	Treatment of infections with some chloroquine-resistant <i>P falciparum</i>
Lumefantrine ¹	Amyl alcohol	Treatment of <i>P falciparum</i> malaria in fixed combination with artemether (Coartem)
Artemisinins ¹	Sesquiterpene lactone endoperoxides	Treatment of infection with multidrug-resistant <i>P falciparum</i>
Atovaquone-proguanil (Malarone)	Quinone-folate antagonist combination	Treatment and chemoprophylaxis of <i>P falciparum</i> infection

Treatment of Amebiasis

Amebiasis is infection with *Entamoeba histolytica*. This agent can cause asymptomatic intestinal infection, mild to moderate colitis, severe intestinal infection (dysentery), ameboma, liver abscess, and other extraintestinal infections. The choice of drugs for amebiasis depends on the clinical presentation (Figure 53–2; Table 53–4).

Figure 53–2.

Structural formulas of other antiprotozoal drugs.

Table 53–4. Treatment of Amebiasis.¹

Clinical Setting	Drugs of Choice and Adult Dosage	Alternative Drugs and Adult Dosage
Asymptomatic intestinal infection	Luminal agent: Diloxanide furoate, ² 500 mg 3 times daily for 10 days <i>or</i> – Iodoquinol, 650 mg 3 times daily for 21 days <i>or</i> – Paromomycin, 10 mg/kg 3 times daily for 7 days	
Mild to moderate intestinal infection	Metronidazole, 750 mg 3 times daily (or 500 mg IV every 6 hours) for 10 days <i>plus</i> – Luminal agent (see above)	Luminal agent (see above) <i>plus either</i> – Tetracycline, 250 mg 3 times daily for 10 days <i>or</i> – Erythromycin, 500 mg 4 times daily for 10 days
Severe intestinal infection	Metronidazole, 750 mg 3 times daily (or 500 mg IV every 6 hours) for 10 days <i>plus</i> – Luminal agent (see above)	Luminal agent (see above) <i>plus either</i> – Tetracycline, 250 mg 3 times daily for 10 days <i>or</i> – Dehydroemetine ³ or emetine, ² 1 mg/kg SC or IM for 3–5 days
Hepatic abscess, ameboma, and other extraintestinal disease	Metronidazole, 750 mg 3 times daily (or 500 mg IV every 6 hours) for 10 days <i>plus</i> – Luminal agent (see above)	Dehydroemetine ³ or emetine, ² 1 mg/kg SC or IM for 8–10 days, followed by (liver abscess only) chloroquine, 500 mg twice daily for 2 days, then 500 mg daily for 21 days <i>plus</i> – Luminal agent (see above)

¹Route is oral unless otherwise indicated. See text for additional details and cautions.

²Not available in the USA.

³Available in the USA only from the Drug Service, CDC, Atlanta (404-639-3670).

Treatment of Specific Forms of Amebiasis

Asymptomatic Intestinal Infection

Asymptomatic carriers generally are not treated in endemic areas but in nonendemic areas they are treated with a luminal amebicide. A tissue amebicidal drug is unnecessary. Standard luminal amebicides are diloxanide furoate, iodoquinol, and paromomycin. Each drug eradicates carriage in about 80–90% of patients with a single course of treatment. Therapy with a luminal amebicide is also required in the treatment of all other forms of amebiasis.

Amebic Colitis

Metronidazole plus a luminal amebicide is the treatment of choice for colitis and dysentery. Tetracyclines and erythromycin are alternative drugs for moderate colitis but are not effective against extraintestinal disease. Dehydroemetine or emetine can also be used, but these agents are best avoided (when possible) because of their toxicity.

Extraintestinal Infections

The treatment of choice is metronidazole plus a luminal amebicide. A 10-day course of metronidazole cures over 95% of uncomplicated liver abscesses. For unusual cases where initial therapy with metronidazole has failed, aspiration of the abscess and the addition of chloroquine to a repeat course of metronidazole should be considered. Dehydroemetine and emetine are toxic alternative drugs.

Metronidazole

Metronidazole, a nitroimidazole (Figure 53–2), is the drug of choice for the treatment of extraluminal amebiasis. It kills trophozoites but not cysts of *E histolytica* and effectively eradicates intestinal and extraintestinal tissue infections.

Chemistry & Pharmacokinetics

Oral metronidazole is readily absorbed and permeates all tissues by simple diffusion. Intracellular concentrations rapidly approach extracellular levels. Peak plasma concentrations are reached in 1–3 hours. Protein binding is low (< 20%), and the half-life of the unchanged drug is 7.5 hours. The drug and its metabolites are excreted mainly in the urine. Plasma clearance of metronidazole is decreased in patients with impaired liver function.

Mechanism of Action

The nitro group of metronidazole is chemically reduced in anaerobic bacteria and sensitive protozoans. Reactive reduction products appear to be responsible for antimicrobial activity.

Clinical Uses

Amebiasis

Metronidazole is the drug of choice for the treatment of all tissue infections with *E histolytica*. It is not reliably effective against luminal parasites and so must be used with a luminal amebicide to ensure eradication of the infection. Tinidazole, a related nitroimidazole, appears to have similar activity and a better toxicity profile than metronidazole, but it is not available in the USA.

Giardiasis

Metronidazole is the treatment of choice for giardiasis. The dosage for giardiasis is much lower—and the drug thus better tolerated—than that for amebiasis. Efficacy after a single treatment is about 90%. Tinidazole is equally effective.

Trichomoniasis

Metronidazole is the treatment of choice. A single dose of 2 g is effective. Metronidazole-resistant organisms may lead to treatment failures. Tinidazole may be effective against some of these infections, but it is not available in the USA. Such cases may require repeat courses of metronidazole at higher doses than normally recommended—or topical therapy.

Adverse Effects & Cautions

Nausea, headache, dry mouth, or a metallic taste in the mouth occurs commonly. Infrequent adverse effects include vomiting, diarrhea, insomnia, weakness, dizziness, thrush, rash, dysuria, dark urine, vertigo, paresthesias, and neutropenia. Taking the drug with meals lessens gastrointestinal irritation. Pancreatitis and severe central nervous system toxicity (ataxia, encephalopathy, seizures) are rare. Metronidazole has a disulfiram-like effect, so that nausea and vomiting can occur if alcohol is ingested during therapy. The drug should be used with caution in patients with central nervous system disease. Intravenous infusions have rarely caused seizures or peripheral neuropathy. The dosage should be adjusted for patients with severe liver or renal disease.

Metronidazole has been reported to potentiate the anticoagulant effect of coumarin-type anticoagulants. Phenytoin and phenobarbital may accelerate elimination of the drug, while cimetidine may decrease plasma clearance. Lithium toxicity may occur when the drug is used with metronidazole.

Metronidazole and its metabolites are mutagenic in bacteria. Chronic administration of large doses led to tumorigenicity in mice. Data on teratogenicity are inconsistent. Metronidazole is thus best avoided in pregnant or nursing women, though congenital abnormalities have not clearly been associated with use in humans.

Iodoquinol

Iodoquinol (diiodohydroxyquin) is a halogenated hydroxyquinoline. It is an effective luminal amebicide that is commonly used with metronidazole to treat amebic infections. Its pharmacokinetic properties are poorly understood. Ninety percent of the drug is retained in the intestine and excreted in the feces. The remainder enters the circulation, has a half-life of 11–14 hours, and is excreted in the urine as glucuronides.

The mechanism of action of iodoquinol against trophozoites is unknown. It is effective against organisms in the bowel lumen but not against trophozoites in the intestinal wall or extraintestinal tissues.

Infrequent adverse effects include diarrhea—which usually stops after several days—anorexia, nausea, vomiting, abdominal pain, headache, rash, and pruritus. The drug may increase protein-bound serum iodine, leading to a decrease in measured ¹³¹I uptake that persists for months. Some halogenated hydroxyquinolines can produce severe neurotoxicity with prolonged use at greater than recommended doses. Iodoquinol is not known to produce these effects at its recommended dosage, and this dosage should never be exceeded.

Iodoquinol should be taken with meals to limit gastrointestinal toxicity. It should be used with caution in patients with optic neuropathy, renal or thyroid disease, or nonamebic hepatic disease. The drug should be discontinued if it produces persistent diarrhea or signs of iodine toxicity (dermatitis, urticaria, pruritus, fever). It is contraindicated in patients with intolerance to iodine.

Diloxanide Furoate

Diloxanide furoate is a dichloroacetamide derivative. It is an effective luminal amebicide but is not active against tissue trophozoites. In the gut, diloxanide furoate is split into diloxanide and furoic acid; about 90% of the diloxanide is rapidly absorbed and then conjugated to form the glucuronide, which is promptly excreted in the urine. The unabsorbed diloxanide is the active antiamebic substance. The mechanism of action of diloxanide furoate is unknown.

Diloxanide furoate is considered by many the drug of choice for asymptomatic luminal infections, but it is no longer available in the USA. It is used with a tissue amebicide, usually metronidazole, to treat serious intestinal and extraintestinal infections. Diloxanide furoate does not produce serious adverse effects. Flatulence is common, but nausea and abdominal cramps are infrequent and rashes are rare. The drug is not recommended in pregnancy.

Paromomycin Sulfate

Paromomycin sulfate is an aminoglycoside antibiotic (see also Chapter 45: Aminoglycosides & Spectinomycin) that is not significantly absorbed from the gastrointestinal tract. It is used only as a luminal amebicide and has no effect against extraintestinal amebic infections. The small amount absorbed is slowly excreted unchanged, mainly by glomerular filtration. However, the drug may accumulate with renal insufficiency and contribute to renal toxicity. Paromomycin is an effective luminal amebicide that appears to have similar efficacy and probably less toxicity than other agents; in a recent study, it was superior to diloxanide furoate in clearing asymptomatic infections. Adverse effects include occasional abdominal distress and diarrhea. Paromomycin should be avoided in patients with significant renal disease and used with caution in persons with gastrointestinal ulcerations. Parenteral paromomycin is under investigation for the treatment of visceral leishmaniasis.

Emetine & Dehydroemetine

Emetine, an alkaloid derived from ipecac, and dehydroemetine, a synthetic analog, are effective against tissue trophozoites of *E histolytica*, but because of major toxicity concerns they have been almost completely replaced by metronidazole. The drugs are administered parenterally because oral preparations are absorbed erratically. They accumulate in tissues and are eliminated slowly via the kidneys.

The use of emetine and dehydroemetine is limited to unusual circumstances in which severe amebiasis warrants effective therapy and metronidazole cannot be used. Dehydroemetine is preferred over emetine because of its somewhat better toxicity profile. The drugs should be used to treat amebic dysentery or amebic liver abscess for the minimum period needed to relieve severe symptoms (usually 3–5 days).

Emetine and dehydroemetine should be administered subcutaneously (preferred) or intramuscularly (but never intravenously) in a supervised setting. Adverse effects are generally mild when the drugs are used for 3–5 days but increase with prolonged use. They should not be used for more than 10 days. Pain and tenderness in the area of injection are frequent, and sterile abscesses may develop. Diarrhea is common. Other adverse effects are nausea, vomiting, muscle weakness and discomfort, and minor electrocardiographic changes. Serious toxicities include cardiac arrhythmias, heart failure, and hypotension. The drugs should not be used in patients with cardiac or renal disease, in young children, or in pregnancy unless absolutely necessary.

Antiprotozoal Drugs >

Other Antiprotozoal Drugs

See Table 53–5 for a list of drugs used in the treatment of other protozoal infections. Important drugs that are not covered elsewhere in this or other chapters are discussed below.

Table 53–5. Treatment of Other Protozoal Infections.		
Organism or Clinical Setting	Drugs of Choice ¹	Alternative Drugs
<i>Babesia</i> species	Clindamycin, 600 mg 3 times daily for 7 days <i>plus</i> — Quinine, 650 mg for 7 days	Atovaquone <i>or</i> azithromycin
<i>Balantidium coli</i>	Tetracycline, 500 mg 4 times daily for 10 days	Metronidazole, 750 mg 3 times daily for 5 days
<i>Cryptosporidium</i> species	Paromomycin, 500–750 mg 3 or 4 times daily for 10 days	Azithromycin, 500 mg daily for 21 days ²
<i>Cyclospora cayentanensis</i>	Trimethoprim-sulfamethoxazole, one double-strength tablet 4 times daily for 7–14 days	
<i>Dientamoeba fragilis</i>	Iodoquinol, 650 mg 3 times daily for 20 days	Tetracycline, 500 mg 4 times daily for 10 days <i>or</i> — Paromomycin, 500 mg

		3 times daily for 7 days
<i>Giardia lamblia</i>	Metronidazole, 250 mg 3 times daily for 5 days <i>or</i> – Tinidazole, ³ 2 g once	Furazolidone, 100 mg 4 times daily for 7 days <i>or</i> – Albendazole, 400 mg daily for 5 days ²
<i>Isospora belli</i>	Trimethoprim-sulfamethoxazole, one double-strength tablet 4 times daily for 10 days, then twice daily for 21 days	Pyrimethamine, 75 mg daily for 14 days <i>plus</i> – Folinic acid, 10 mg daily for 14 days
Microsporidia	Albendazole, 400 mg twice daily for 20–30 days	
Leishmaniasis, visceral (<i>L donovani</i> , <i>L chagasi</i> , <i>L infantum</i>) or mucosal (<i>L braziliensis</i>)	Sodium stibogluconate, ⁴ 20 mg/kg/d IV or IM for 28 days	Meglumine antimonate ² <i>or</i> – Pentamidine <i>or</i> – Amphotericin B <i>or</i> – Miltefosine ²
Cutaneous (<i>L major</i> , <i>L tropica</i> , <i>L mexicana</i> , <i>L braziliensis</i>)	Sodium stibogluconate, ⁴ 20 mg/kg/d IV or IM for 20 days	Meglumine antimonate ² <i>or</i> – Ketoconazole <i>or</i> – Pentamidine <i>or</i> – Topical or intralesional therapies
<i>Pneumocystis jiroveci</i> , <i>P carinii</i> ⁵	Trimethoprim-sulfamethoxazole, 15–20 mg trimethoprim component/kg/d IV, or two double-strength tablets every 8 hours for 21 days	Pentamidine <i>or</i> –

		Trimethoprim-dapsone <i>or</i> – Clindamycin <i>plus</i> primaquine <i>or</i> – Atovaquone
<i>Toxoplasma gondii</i>		
Acute, congenital, immunocompromised	Pyrimethamine <i>plus</i> clindamycin <i>plus</i> folinic acid	Pyrimethamine <i>plus</i> sulfadiazine <i>plus</i> folinic acid
Pregnancy	Spiramycin, 3 g daily until delivery	
<i>Trichomonas vaginalis</i>	Metronidazole, 2 g once or 250 mg 3 times daily for 7 days	Tinidazole ³
<i>Trypanosoma brucei</i>		
Hemolympathic	Suramin ⁴	Pentamidine <i>or</i> – Eflornithine
Advanced CNS disease	Melarsoprol ⁴	Eflornithine
<i>Trypanosoma cruzi</i>	Nifurtimox ⁴ <i>or</i> – Benznidazole ³	

¹Established, relatively simple dosing regimens are provided. Route is oral unless otherwise indicated. See text for additional information, toxicities, cautions, and discussions of dosing for the more rarely used drugs, many of which are highly toxic.

²Nitazoxanide is also available for pediatric use.

³Not available in the USA.

⁴Available in the USA only from the Drug Service, CDC, Atlanta (404-639-3670).

⁵*P jiroveci* (*carinii* in animals) has traditionally been considered a protozoan because of its morphology and drug sensitivity, but recent molecular analyses have shown it to be most closely related to fungi.

Pentamidine

Pentamidine has activity against trypanosomatid protozoans and against *P jiroveci*, but toxicity is significant.

Chemistry & Pharmacokinetics

Pentamidine is an aromatic diamidine (Figure 53–2) formulated as an isethionate salt. Pentamidine is only administered parenterally. The drug leaves the circulation rapidly, with an initial half-life of about 6 hours, but it is bound avidly by tissues. Pentamidine thus accumulates and is eliminated very slowly, with a terminal elimination half-life of about 12 days. The drug can be detected in urine 6 or more weeks after treatment. Only trace amounts of pentamidine appear in the central nervous system, so it is not effective against central nervous system African trypanosomiasis. Pentamidine can also be inhaled as a nebulized powder for the prevention of pneumocystosis. Absorption into the systemic circulation after inhalation appears to be minimal. The mechanism of action of pentamidine is unknown.

Clinical Uses

Pneumocystosis

Pentamidine is a well-established alternative therapy for pulmonary and extrapulmonary disease caused by *P jiroveci*. The drug has somewhat lower efficacy and greater toxicity than trimethoprim-sulfamethoxazole. The standard dosage is now 3 mg/kg/d intravenously for 21 days. Significant adverse reactions are common, and with multiple regimens now available to treat *P jiroveci* infection, pentamidine is best reserved for patients with severe disease who cannot tolerate or fail other drugs.

Pentamidine is also an alternative agent for primary or secondary prophylaxis against pneumocystosis in immunocompromised individuals, including patients with advanced AIDS. For this indication, pentamidine is administered as an inhaled aerosol (300 mg inhaled monthly). The drug is well-tolerated in this form. Its efficacy is very good but clearly less than that of daily trimethoprim-sulfamethoxazole. Because of its cost and ineffectiveness against nonpulmonary disease, it is best reserved for patients who cannot tolerate oral chemoprophylaxis with other drugs.

African Trypanosomiasis (Sleeping Sickness)

Pentamidine has been used since 1940 as an alternative to suramin for the early hemolympathic stage of disease caused by *Trypanosoma brucei* (especially *T brucei gambiense*). The drug can also be used with suramin. Pentamidine should not be used to treat late trypanosomiasis with central nervous system involvement. A number of dosing regimens have been described, generally providing 2–4 mg/kg daily or on alternate days for a total of 10–15 doses. Pentamidine has also been used for chemoprophylaxis against African trypanosomiasis, with dosing of 4 mg/kg every 3–6 months.

Leishmaniasis

Pentamidine is an alternative to sodium stibogluconate for the treatment of visceral leishmaniasis, although resistance has been reported. The drug has been successful in some cases that have failed therapy with antimonials. The dosage is 2–4 mg/kg intramuscularly daily or every other day for up to 15 doses, and a second course may be necessary. Pentamidine has also shown success against cutaneous leishmaniasis, but it is not routinely used for this purpose.

Adverse Effects & Cautions

Pentamidine is a highly toxic drug, with adverse effects noted in about 50% of patients receiving 4 mg/kg/d. Rapid intravenous administration can lead to severe hypotension, tachycardia, dizziness, and dyspnea, so the drug should be administered slowly (over 2 hours) and patients should be recumbent and monitored closely during treatment. With intramuscular administration, pain at the injection site is common and sterile abscesses may develop.

Pancreatic toxicity is common. Hypoglycemia due to inappropriate insulin release often appears 5–7 days after onset of treatment, can persist for days to several weeks, and may be followed by hyperglycemia. Reversible renal insufficiency is also common. Other adverse effects include rash, metallic taste, fever, gastrointestinal symptoms, abnormal liver function tests, acute pancreatitis, hypocalcemia, thrombocytopenia, hallucinations, and cardiac arrhythmias. Inhaled pentamidine is generally well-tolerated but may cause cough, dyspnea, and bronchospasm.

Sodium Stibogluconate

Pentavalent antimonials, including sodium stibogluconate (pentostam; Figure 53–2) and meglumine antimonate, are generally considered first-line agents for cutaneous and visceral leishmaniasis. The drugs are rapidly absorbed after intravenous (preferred) or intramuscular administration and eliminated in two phases, with short (about 2 hour) and much longer (> 24 hour) half-lives. Treatment is given once daily at a dose of 20 mg/kg/d intravenously or intramuscularly for 20 days in cutaneous leishmaniasis and 28 days in visceral and mucocutaneous disease.

The mechanism of action of the antimonials is unknown. Their efficacy against different species may vary, possibly based on local drug resistance patterns. Cure rates are generally quite good, but resistance to sodium stibogluconate is increasing in some endemic areas. Some authorities have advocated initial therapy with other agents (eg, amphotericin B) in areas (such as parts of India) where therapy with sodium stibogluconate is commonly ineffective.

Few adverse effects occur initially, but the toxicity of stibogluconate increases over the course of therapy. Most common are gastrointestinal symptoms, fever, headache, myalgias, arthralgias, and rash. Intramuscular injections can be very painful and lead to sterile abscesses. Electrocardiographic changes may occur, most commonly T wave changes and QT prolongation. These changes are generally reversible, but continued therapy may lead to dangerous arrhythmias. Thus, the electrocardiogram should be monitored during therapy. Hemolytic anemia and serious liver, renal, and cardiac effects are rare.

Nitazoxanide

Nitazoxanide is a nitrothiazolyl-salicylamide prodrug. Nitazoxanide was recently approved in the USA for use in children against *G lamblia* and *Cryptosporidium parvum*. The drug is converted to an active metabolite, tizoxanide, which inhibits the pyruvate:ferredoxin oxidoreductase pathway. It is rapidly absorbed and converted to tizoxanide and tizoxanide conjugates, which are subsequently excreted in both urine and feces. Nitazoxanide appears to have activity against metronidazole-resistant protozoal strains and is well tolerated. Unlike metronidazole, nitazoxanide and its metabolites appear to be free of mutagenic effects. Other organisms that may be susceptible to nitazoxanide include *E histolytica*, *Helicobacter pylori*, *A lumbricoides*, several tapeworms, and *Fasciola hepatica*.

The recommended dosage for children is 100–200 mg twice daily for 3 days. The adult dosage has

not been established.

Other Drugs for Trypanosomiasis & Leishmaniasis

Currently available therapies for all forms of trypanosomiasis are seriously deficient in both efficacy and safety. Availability of these therapies is also a concern, as they remain available mainly through donation or nonprofit production by pharmaceutical companies.

Suramin

Suramin is a sulfated naphthylamine that was introduced in the 1920s. It is the first-line therapy for early hemolymphatic African trypanosomiasis (especially *T. brucei gambiense* infection), but because it does not enter the central nervous system, it is not effective against advanced disease. The drug's mechanism of action is unknown. It is administered intravenously and displays complex pharmacokinetics with very tight protein binding. It has a short initial half-life but a terminal elimination half-life of about 50 days. The drug is slowly cleared by renal excretion.

Suramin is administered after a 200-mg intravenous test dose. Regimens that have been used include 1 g on days 1, 3, 7, 14, and 21 or 1 g each week for 5 weeks. Combination therapy with pentamidine may improve efficacy. Suramin can also be used for chemoprophylaxis against African trypanosomiasis. Adverse effects are common. Immediate reactions can include fatigue, nausea, vomiting, and, more rarely, seizures, shock, and death. Later reactions include fever, rash, headache, paresthesias, neuropathies, renal abnormalities including proteinuria, chronic diarrhea, hemolytic anemia, and agranulocytosis.

Melarsoprol

Melarsoprol is a trivalent arsenical that has been available since 1949 and is first-line therapy for advanced central nervous system African trypanosomiasis. After intravenous administration it is excreted rapidly, but clinically relevant concentrations accumulate in the central nervous system within 4 days. Melarsoprol is administered in propylene glycol by slow intravenous infusion at a dosage of 3.6 mg/kg/d for 3–4 days, with repeated courses at weekly intervals if needed. A new regimen of 2.2 mg/kg daily for 10 days had efficacy and toxicity similar to what was observed with three courses over 26 days. Melarsoprol is extremely toxic. The use of such a toxic drug is justified only by the severity of advanced trypanosomiasis and the lack of available alternatives. Immediate adverse effects include fever, vomiting, abdominal pain, and arthralgias. The most important toxicity is a reactive encephalopathy that generally appears within the first week of therapy (in 5–10% of patients) and is probably due to disruption of trypanosomes in the central nervous system. Common consequences of the encephalopathy include cerebral edema, seizures, coma, and death. Other serious toxicities include renal and cardiac disease and hypersensitivity reactions. Failure rates with melarsoprol appear to have increased recently in parts of Africa, suggesting the possibility of drug resistance.

Eflornithine

Eflornithine (difluoromethylornithine), an inhibitor of ornithine decarboxylase, is the only new drug registered to treat African trypanosomiasis in the last half-century. It is a second therapy for advanced central nervous system African trypanosomiasis and is less toxic than melarsoprol but not as widely available. The drug had very limited availability until recently, when it was developed for use as a topical depilatory cream, leading to donation of the drug for the treatment of trypanosomiasis. Eflornithine is administered intravenously, and good central nervous system drug

levels are achieved. Peak plasma levels are reached rapidly, and the elimination half-life is about 3 hours. The usual regimen is 100 mg/kg intravenously every 6 hours for 7–14 days (14 days was superior for a newly diagnosed infection). An oral formulation is also available and under clinical investigation. Eflornithine appears to be as effective as melarsoprol against advanced *T brucei gambiense* infection, but its efficacy against *T brucei rhodesiense* is limited by drug resistance. Toxicity from eflornithine is significant, but considerably less than that from melarsoprol. Adverse effects include diarrhea, vomiting, anemia, thrombocytopenia, leukopenia, and seizures. These effects are generally reversible. Increased experience with eflornithine and increased availability of the compound in endemic areas may lead to its replacement of suramin, pentamidine, and melarsoprol for the treatment of *T brucei gambiense* infection.

Nifurtimox

Nifurtimox, a nitrofuran, is the most commonly used drug for American trypanosomiasis (Chagas' disease). Nifurtimox is also under study for the treatment of African trypanosomiasis. Nifurtimox is well absorbed after oral administration and eliminated with a plasma half-life of about 3 hours. The drug is administered at a dose of 8–10 mg/kg/d (divided into 3–4 doses) orally for 3–4 months for the treatment of acute Chagas' disease. Nifurtimox decreases the severity of acute disease and usually eliminates detectable parasites, but it is often ineffective in fully eradicating infection. Thus, it often fails to prevent progression to the gastrointestinal and cardiac syndromes associated with chronic infection that are the most important clinical consequences of *Trypanosoma cruzi* infection. Efficacy may vary in different parts of South America, possibly related to drug resistance in some areas. Nifurtimox does not appear to be effective in the treatment of chronic Chagas' disease. Toxicity related to nifurtimox is common. Adverse effects include nausea, vomiting, abdominal pain, fever, rash, restlessness, insomnia, neuropathies, and seizures. These effects are generally reversible but often lead to cessation of therapy before completion of a standard course.

Benznidazole

Benznidazole is an orally administered nitroimidazole that appears to have efficacy similar to that of nifurtimox for the treatment of acute Chagas' disease. Availability of the drug is currently limited. Important toxicities include peripheral neuropathy, rash, gastrointestinal symptoms, and myelosuppression.

Amphotericin

This important antifungal drug (see Chapter 48: Antifungal Agents) is an alternative therapy for visceral leishmaniasis, especially in parts of India with high-level resistance to sodium stibogluconate, but its use is limited in developing countries by difficulty of administration, cost, and toxicity.

Miltefosine

Miltefosine is an alkylphosphocholine analog that has recently shown efficacy for the treatment of visceral leishmaniasis. In a recent phase III study, the drug was administered orally with daily doses of 2.5 mg/kg for 28 days and provided excellent clinical results. A 100 mg daily dose is recommended in adults. Vomiting and diarrhea are common but generally short-lived toxicities. Transient elevations in liver enzymes are also seen. The drug should be avoided in pregnancy because of its teratogenic effects. Miltefosine is registered for the treatment of visceral leishmaniasis in India, and—considering the serious limitations of other drugs, including parenteral administration, toxicity, and resistance—it may become the treatment of choice for that disease.

Preparations Available in the USA

Albendazole (Albenza)

Oral: 200 mg tablets

Atovaquone (Mepron)

Oral: 750 mg/5 mL suspension

Atovaquone-proguanil (Malarone)

Oral: 250 mg atovaquone + 100 mg proguanil tablets; pediatric 62.5 mg atovaquone + 25 mg proguanil tablets

Chloroquine (generic, Aralen)

Oral: 250, 500 mg tablets (equivalent to 150, 300 mg base, respectively)

Parenteral: 50 mg/mL (equivalent to 40 mg/mL base) for injection

Clindamycin (generic, Cleocin)

Oral: 75, 150, 300 mg capsules; 75 mg/5 mL suspension

Parenteral: 150 mg/mL for injection

Doxycycline (generic, Vibramycin)

Oral: 20, 50, 100 mg capsules; 50, 100 mg tablets; 25 mg/5 mL suspension; 50 mg/5 mL syrup

Parenteral: 100, 200 mg for injection

Dehydroemetine*

Eflornithine (Ornidyl)

Parenteral: 200 mg/mL for injection

Halofantrine (Halfan)

Oral: 250 mg tablets

Iodoquinol (Yodoxin)

Oral: 210, 650 mg tablets

Mefloquine (generic, Lariam)

Oral: 250 mg tablets

Melarsoprol (Mel B)*

Metronidazole (generic, Flagyl)

Oral: 250, 500 mg tablets; 375 mg capsules; extended-release 750 mg tablets

Parenteral: 5 mg/mL

Nifurtimox*

Nitazoxanide (Alinia)

Oral: powder for 100 mg/5 mL oral solution

Paromomycin (Humatin)

Oral: 250 mg capsules

Pentamidine (Pentam 300, Pentacarinat, pentamidine isethionate)

Parenteral: 300 mg powder for injection

Aerosol (Nebupent): 300 mg powder

Primaquine (generic)

Oral: 26.3 mg (equivalent to 15 mg base) tablet

Pyrimethamine (Daraprim)

Oral: 25 mg tablets

Quinidine gluconate (generic)

Parenteral: 80 mg/mL (equivalent to 50 mg/mL base) for injection

Quinine (generic)

Oral: 260 mg tablets; 200, 260, 325 mg capsules

Sodium stibogluconate*

Sulfadoxine and pyrimethamine (Fansidar)

Oral: 500 mg sulfadoxine plus 25 mg pyrimethamine tablets

Suramin*

* Available in the USA only from the Drug Service, CDC, Atlanta (404-639-3670).

Chapter 54. Clinical Pharmacology of the Anthelmintic Drugs

Katzung PHARMACOLOGY, 9e > Section VIII. Chemotherapeutic Drugs > Chapter 54. Clinical Pharmacology of the Anthelmintic Drugs >

Clinical Pharmacology of the Anthelmintic Drugs: Introduction

Table 54–1 lists the major helminthic infections and provides a guide to the drug of choice and alternative drugs for each infection. In the text that follows, these drugs are arranged alphabetically. In general, parasites should be identified before treatment is started.

Infesting Organism	Drug of Choice	Alternative Drugs
Roundworms (nematodes)		
<i>Ascaris lumbricoides</i> (roundworm)	Albendazole ¹ or pyrantel pamoate or mebendazole	Piperazine
<i>Trichuris trichiura</i> (whipworm)	Mebendazole or albendazole ¹	Oxantel/pyrantel pamoate ²
<i>Necator americanus</i> (hookworm); <i>Ancylostoma duodenale</i> (hookworm)	Pyrantel pamoate ¹ or mebendazole or albendazole ¹	
<i>Strongyloides stercoralis</i> (threadworm)	Ivermectin	Thiabendazole, albendazole ¹
<i>Enterobius vermicularis</i> (pinworm)	Mebendazole or pyrantel pamoate	Albendazole ¹
<i>Trichinella spiralis</i> (trichinosis)	Mebendazole; ¹ add corticosteroids for severe infection	Albendazole; ¹ add corticosteroids for severe infection
Trichostrongylus species	Pyrantel pamoate ¹ or mebendazole ¹	Albendazole ¹
Cutaneous larva migrans (creeping eruption)	Albendazole ¹ or ivermectin ¹	Thiabendazole (topical)
Visceral larva migrans	Albendazole ¹	Mebendazole ¹

<i>Angiostrongylus cantonensis</i>	Thiabendazole	Albendazole ¹ or mebendazole ¹
<i>Wuchereria bancrofti</i> (filariasis); <i>Brugia malayi</i> (filariasis); tropical eosinophilia; <i>Loa loa</i> (loiasis)	Diethylcarbamazine ³	Ivermectin ¹
<i>Onchocerca volvulus</i> (onchocerciasis)	Ivermectin	
<i>Dracunculus medinensis</i> (guinea worm)	Metronidazole ¹	Thiabendazole ¹ or mebendazole ¹
<i>Capillaria philippinensis</i> (intestinal capillariasis)	Albendazole ¹	Mebendazole ¹ or thiabendazole ¹
Flukes (trematodes)		
<i>Schistosoma haematobium</i> (bilharziasis)	Praziquantel	Metrifonate ²
<i>Schistosoma mansoni</i>	Praziquantel	Oxamniquine
<i>Schistosoma japonicum</i>	Praziquantel	
<i>Clonorchis sinensis</i> (liver fluke); opisthorchis species	Praziquantel	Albendazole ¹
<i>Paragonimus westermani</i> (lung fluke)	Praziquantel ¹	Bithionol ³
<i>Fasciola hepatica</i> (sheep liver fluke)	Bithionol ³ or triclabendazole ²	
<i>Fasciolopsis buski</i> (large intestinal fluke)	Praziquantel ¹ or niclosamide ²	
<i>Heterophyes heterophyes</i> ; <i>Metagonimus yokogawai</i> (small intestinal flukes)	Praziquantel ¹ or niclosamide ²	
Tapeworms (cestodes)		
<i>Taenia saginata</i> (beef tapeworm)	Praziquantel ¹ or niclosamide ²	Mebendazole ^{1,3}
<i>Diphyllobothrium latum</i> (fish tapeworm)	Praziquantel ¹ or niclosamide ²	
Tapeworms (cestodes)		
<i>Taenia solium</i> (pork tapeworm)	Praziquantel ¹ or niclosamide ²	
Cysticercosis (pork tapeworm larval stage)	Albendazole	Praziquantel ¹
<i>Hymenolepis nana</i> (dwarf tapeworm)	Praziquantel ¹	Niclosamide ²

<i>Echinococcus granulosus</i> (hydatid disease); <i>Echinococcus multilocularis</i>	Albendazole	
--------------------------------------------------------------------------------------	-------------	--

¹ Available in the USA but not labeled for this indication.

² Not available in the USA but available in some other countries.

³ Available in the USA only from the Parasitic Disease Drug Service, Parasitic Diseases Branch, Centers for Disease Control and Prevention, Atlanta 30333. Telephone 404-639-3670.

Katzung PHARMACOLOGY, 9e > Section VIII. Chemotherapeutic Drugs > Chapter 54. Clinical Pharmacology of the Anthelmintic Drugs >

Albendazole

Albendazole, a broad-spectrum oral anthelmintic, is the drug of choice and is approved in the USA for treatment of hydatid disease and cysticercosis. It is also used for the treatment of pinworm and hookworm infections, ascariasis, trichuriasis, and strongyloidiasis, though it is not labeled for these conditions.

Chemistry & Pharmacokinetics

Albendazole is a benzimidazole carbamate. After oral administration, it is erratically absorbed (increased with a fatty meal) and then rapidly undergoes first-pass metabolism in the liver to the active metabolite albendazole sulfoxide. It reaches variable maximum plasma concentrations about 3 hours after a 400 mg oral dose, and its plasma half-life is 8–12 hours. The sulfoxide is mostly protein-bound, distributes well to tissues, and enters bile, cerebrospinal fluid, and hydatid cysts. Albendazole metabolites are excreted in the urine.

Albendazole

Anthelmintic Actions

Benzimidazoles are thought to act against nematodes by inhibiting microtubule synthesis. Albendazole also has larvicidal effects in hydatid disease, cysticercosis, ascariasis, and hookworm infection and ovicidal effects in ascariasis, ancylostomiasis, and trichuriasis.

Clinical Uses

Albendazole is administered on an empty stomach when used against intraluminal parasites but with a fatty meal when used against tissue parasites.

Ascariasis, Trichuriasis, and Hookworm and Pinworm Infections

For adults and children over 2 years of age, the treatment is a single dose of 400 mg orally (repeated for 2–3 days for heavy ascaris infections and in 2 weeks for pinworm infections). These treatments achieve high cure rates for these roundworm infections and marked reduction in egg counts in those not cured.

Hydatid Disease

Albendazole is the treatment of choice for medical therapy and is a useful adjunct to surgical removal or aspiration of cysts. It is more active against *E granulosus* than *E multilocularis*. Dosing is 400 mg twice daily with meals for 1 month or longer. Daily therapy for up to 6 months has been well tolerated. One reported therapeutic strategy is to treat with albendazole and praziquantel, to assess response after 1 month or more, and, depending on the response, to then manage the patient with continued chemotherapy or combined surgical and drug therapy.

Neurocysticercosis

Indications for medical therapy for neurocysticercosis are controversial, as anthelmintic therapy is not clearly superior to therapy with corticosteroids alone and may exacerbate neurologic disease. Therapy is probably most appropriate for symptomatic parenchymal or intraventricular cysts. Corticosteroids are usually given with the anthelmintic drug to decrease inflammation caused by dying organisms. Albendazole is now generally considered the drug of choice over praziquantel because of its shorter course, lower cost, improved penetration into the subarachnoid space, and increased drug levels (as opposed to decreased levels of praziquantel) when administered with corticosteroids. Albendazole is given in a dosage of 400 mg twice a day for up to 21 days.

Other Infections

Albendazole is the drug of choice in the treatment of **cutaneous larva migrans** (400 mg daily for 3 days), visceral larva migrans (400 mg twice daily for 5 days), **intestinal capillariasis** (400 mg daily for 10 days), microsporidial infections (400 mg twice daily for 2 weeks or longer), and **gnathostomiasis** (400 mg twice daily for 3 weeks). It also has activity against **trichinosis** (400 mg twice daily for 1–2 weeks) and **clonorchiasis** (400 mg twice daily for 1 week). There have been reports of some effectiveness in treatment of **opisthorchiasis**, **toxocariasis**, and **loiasis** and conflicting reports of effectiveness in **giardiasis** and **taeniasis**.

Adverse Reactions, Contraindications, & Cautions

When used for 1–3 days, albendazole is nearly free of significant adverse effects. Mild and transient epigastric distress, diarrhea, headache, nausea, dizziness, lassitude, and insomnia can occur. In long-term use for hydatid disease, albendazole is well tolerated, but it can cause abdominal distress, headaches, fever, fatigue, alopecia, increases in liver enzymes, and pancytopenia.

Blood counts and liver function studies should be followed during long-term therapy. The drug should not be given to patients with known hypersensitivity to other benzimidazole drugs or to those with cirrhosis. The safety of albendazole in pregnancy and in children under 2 years of age has not been established.

Katzung PHARMACOLOGY, 9e > Section VIII. Chemotherapeutic Drugs > Chapter 54. Clinical Pharmacology of the Anthelmintic Drugs >

Bithionol

Bithionol is the drug of choice for the treatment of **fascioliasis (sheep liver fluke)**. An alternative drug, triclabendazole, is not available in the USA.

Bithionol is also an alternative drug in the treatment of pulmonary paragonimiasis.

Pharmacokinetics

After ingestion, bithionol reaches peak blood levels in 4–8 hours. Excretion appears to be mainly via the kidney.

Clinical Uses

For treatment of paragonimiasis and fascioliasis, the dosage of bithionol is 30–50 mg/kg in two or three divided doses, given orally after meals on alternate days for 10–15 doses. For pulmonary paragonimiasis, cure rates are over 90%. For cerebral paragonimiasis, repeat courses of therapy may be necessary.

Adverse Reactions, Contraindications, & Cautions

Adverse effects, which occur in up to 40% of patients, are generally mild and transient, but occasionally their severity requires interruption of therapy. These problems include diarrhea, abdominal cramps, anorexia, nausea, vomiting, dizziness, and headache. Skin rashes may occur after a week or more of therapy, suggesting a reaction to antigens released from dying worms.

Bithionol should be used with caution in children under 8 years of age because there has been limited experience in this age group.

Katzung PHARMACOLOGY, 9e > Section VIII. Chemotherapeutic Drugs > Chapter 54. Clinical Pharmacology of the Anthelmintic Drugs >

Diethylcarbamazine Citrate

Diethylcarbamazine is a drug of choice in the treatment of filariasis, loiasis, and tropical eosinophilia. It has been replaced by ivermectin for the treatment of onchocerciasis.

Chemistry & Pharmacokinetics

Diethylcarbamazine, a synthetic piperazine derivative, is marketed as a citrate salt. It is rapidly absorbed from the gastrointestinal tract; after a 0.5 mg/kg dose, peak plasma levels are reached within 1–2 hours. The plasma half-life is 2–3 hours in the presence of acidic urine but about 10 hours if the urine is alkaline. The drug rapidly equilibrates with all tissues except fat. It is excreted, principally in the urine, as unchanged drug and the N-oxide metabolite. Dosage may have to be reduced in patients with persistent urinary alkalosis or renal impairment.

Anthelmintic Actions

Diethylcarbamazine immobilizes microfilariae and alters their surface structure, displacing them from tissues and making them more susceptible to destruction by host defense mechanisms. The mode of action against adult worms is unknown.

Clinical Uses

The drug should be taken after meals.

Wuchereria Bancrofti, Brugia Malayi, Brugia Timori, and Loa Loa

Diethylcarbamazine is the drug of choice for treatment of infections with these parasites because of its efficacy and lack of serious toxicity. Microfilariae of all species are rapidly killed; adult parasites are killed more slowly, often requiring several courses of treatment. The drug is highly effective against adult *L loa*. The extent to which *W bancrofti* and *B malayi* adults are killed is not known, but after appropriate therapy microfilariae do not reappear in the majority of patients.

These infections are treated for 2 or (for *L loa*) 3 weeks, with initial low doses to reduce the incidence of allergic reactions to dying microfilariae. This regimen is 50 mg (1 mg/kg in children) on day 1, three 50 mg doses on day 2, three 100 mg doses (2 mg/kg in children) on day 3, and then 2 mg/kg three times per day to complete the 2–3 week course.

Antihistamines may be given for the first few days of therapy to limit allergic reactions, and corticosteroids should be started and doses of diethylcarbamazine lowered or interrupted if severe reactions occur. Cures may require several courses of treatment.

Diethylcarbamazine may also be used for chemoprophylaxis (300 mg weekly or 300 mg on 3 successive days each month for loiasis; 50 mg monthly for bancroftian and Malayan filariasis).

Other Uses

For tropical eosinophilia, diethylcarbamazine is given orally at a dosage of 2 mg/kg three times daily for 7 days. Diethylcarbamazine is effective in *Mansonella streptocerca* infections, since it kills both adults and microfilariae. Limited information suggests that the drug is not effective, however, against adult *Mansonella ozzardi* or *M perstans* and that it has limited activity against microfilariae of these parasites. An important application of diethylcarbamazine has been its use for mass treatment of *W bancrofti* infections to reduce transmission. Weekly or monthly administration regimens have been studied; and, most recently, yearly treatment (with or without ivermectin) markedly reduced reservoirs of infection in Papua New Guinea.

Adverse Reactions, Contraindications, & Cautions

Reactions to diethylcarbamazine, which are generally mild and transient, include headache, malaise, anorexia, weakness, nausea, vomiting, and dizziness. Adverse effects also occur as a result of the release of proteins from dying microfilariae or adult worms. Reactions are particularly severe with onchocerciasis, but diethylcarbamazine is generally no longer used for this infection, as ivermectin is equally efficacious and less toxic. Reactions to dying microfilariae are usually mild in *W bancrofti*, more intense in *B malayi*, and occasionally severe in *L loa* infections. Reactions include fever, malaise, papular rash, headache, gastrointestinal symptoms, cough, chest pain, and muscle or joint pain. Leukocytosis is common. Eosinophilia may increase with treatment. Proteinuria may also occur. Symptoms are most likely to occur in patients with heavy loads of microfilariae. Retinal hemorrhages and, rarely, encephalopathy have been described.

Between the third and twelfth days of treatment, local reactions may occur in the vicinity of dying adult or immature worms. These include lymphangitis with localized swellings in *W bancrofti* and *B malayi*, small wheals in the skin in *L loa*, and flat papules in *M streptocerca* infections. Patients

with attacks of lymphangitis due to *W bancrofti* or *B malayi* should be treated during a quiescent period between attacks.

Caution is advised when using diethylcarbamazine in patients with hypertension or renal disease.

Katzung PHARMACOLOGY, 9e > Section VIII. Chemotherapeutic Drugs > Chapter 54. Clinical Pharmacology of the Anthelmintic Drugs >

Ivermectin

Ivermectin is the drug of choice in strongyloidiasis and onchocerciasis. It is also an alternative drug for a number of other helminthic infections.

Chemistry & Pharmacokinetics

Ivermectin, a semisynthetic macrocyclic lactone, is a mixture of avermectin B_{1a} and B_{1b}. It is derived from the soil actinomycete *Streptomyces avermitilis*.

Ivermectin is used only orally in humans. The drug is rapidly absorbed, reaching maximum plasma concentrations 4 hours after a 12 mg dose. The drug has a wide tissue distribution and a volume of distribution of about 50 L. Its half-life is about 16 hours. Excretion of the drug and its metabolites is almost exclusively in the feces.

Anthelmintic Actions

Ivermectin appears to paralyze nematodes and arthropods by intensifying GABA-mediated transmission of signals in peripheral nerves (see Chapter 52: Basic Principles of Antiparasitic Chemotherapy). In onchocerciasis, ivermectin is microfilaricidal. It does not effectively kill adult worms but blocks the release of microfilariae for some months after therapy. After a single standard dose, microfilariae in the skin diminish rapidly within 2–3 days, remain low for months, and then gradually increase; microfilariae in the anterior chamber of the eye decrease slowly over months, eventually clear, and then gradually return. With repeated doses of ivermectin, the drug does appear to have a low-level microfilaricidal action and to permanently reduce microfilarial production.

Clinical Uses

Onchocerciasis

Treatment is with a single oral dose of 150 µg/kg with water on an empty stomach. Doses are repeated; regimens vary from monthly to less frequent (every 6–12 months) dosing schedules. After acute therapy, treatment is repeated at 12-month intervals until the adult worms die, which may take 10 years or longer. With the first treatment only, patients with microfilariae in the cornea or anterior chamber may be treated with corticosteroids to avoid inflammatory eye reactions.

Ivermectin also now plays a key role in onchocerciasis control. Annual mass treatments have led to major reductions in disease transmission.

Strongyloidiasis

Treatment consists of two daily doses of 200 µg/kg. In immunosuppressed patients with

disseminated infection, repeated treatment is often needed, but cure may not be possible. In this case, suppressive therapy—ie, once monthly—may be helpful.

Other Parasites

Ivermectin reduces microfilariae in *Brugia malayi* and *Mansonella ozzardi* infections but not in *M. perstans* infections. It has been used with diethylcarbamazine for the control of *W. bancrofti*, but it does not kill adult worms, and whether it offers added benefit is uncertain. In **loiasis**, although the drug reduces microfilaria concentrations, it can occasionally induce severe reactions. Ivermectin is also effective in controlling **scabies**, **lice**, and **cutaneous larva migrans** and in eliminating a large proportion of **ascarid worms**.

Adverse Reactions, Contraindications, & Cautions

In strongyloidiasis treatment, infrequent side effects include fatigue, dizziness, nausea, vomiting, abdominal pain, and rashes. In onchocerciasis treatment, the adverse effects are principally from the Mazotti reaction, due to killing of microfilariae. The reaction includes fever, headache, dizziness, somnolence, weakness, rash, increased pruritus, diarrhea, joint and muscle pains, hypotension, tachycardia, lymphadenitis, lymphangitis, and peripheral edema. This reaction starts on the first day and peaks on the second day after treatment. The Mazotti reaction occurs in 5–30% of persons and is generally mild, but it may be more frequent and more severe in individuals who are not long-term residents of onchocerciasis-endemic areas. A more intense Mazotti reaction occurs in 1–3% of persons and a severe reaction in 0.1%, including high fever, hypotension, and bronchospasm. Corticosteroids are indicated in these cases, at times for several days. The Mazotti reaction diminishes with repeated dosing. Swellings and abscesses occasionally occur at 1–3 weeks, presumably at sites of adult worms.

Some patients develop corneal opacities and other eye lesions several days after treatment. These are rarely severe and generally resolve without corticosteroid treatment.

It is best to avoid concomitant use of ivermectin and other drugs that enhance GABA activity, eg, barbiturates, benzodiazepines, and valproic acid. Ivermectin should not be used in pregnancy. Safety in children under 5 years has not been established.

Katzung PHARMACOLOGY, 9e > Section VIII. Chemotherapeutic Drugs > Chapter 54. Clinical Pharmacology of the Anthelmintic Drugs >

Mebendazole

Mebendazole is a synthetic benzimidazole (compare with albendazole) that has a wide spectrum of anthelmintic activity and a low incidence of adverse effects.

Chemistry & Pharmacokinetics

Less than 10% of orally administered mebendazole is absorbed. The absorbed drug is protein-bound (> 90%), rapidly converted to inactive metabolites (primarily during its first pass in the liver), and has a half-life of 2–6 hours. It is excreted mostly in the urine, principally as decarboxylated derivatives. In addition, a portion of absorbed drug and its derivatives are excreted in the bile. Absorption is increased if the drug is ingested with a fatty meal.

Anthelmintic Actions

Mebendazole probably acts by inhibiting microtubule synthesis; the parent drug appears to be the active form. Efficacy of the drug varies with gastrointestinal transit time, with intensity of infection, and perhaps with the strain of parasite. The drug kills hookworm, ascaris, and trichuris eggs.

Clinical Uses

In the USA, mebendazole has been approved for use in ascariasis, trichuriasis, and hookworm and pinworm infection. It can be taken before or after meals; the tablets should be chewed before swallowing. For pinworm infection, the dose is 100 mg once, repeated at 2 weeks. For ascariasis, trichuriasis, hookworm, and trichostrongylus infections, a dosage of 100 mg twice daily for 3 days is used for adults and for children over 2 years of age. Cure rates are 90–100% for pinworm infections, ascariasis, and trichuriasis. Cure rates are lower for hookworm infections, but a marked reduction in the worm burden occurs in those not cured. For intestinal capillariasis, mebendazole is used at a dosage of 400 mg/d in divided doses for 21 or more days. In trichinosis, limited reports suggest efficacy against adult worms in the intestinal tract and tissue larvae. Treatment is three times daily, with fatty foods, at 200–400 mg per dose for 3 days and then 400–500 mg per dose for 10 days. Corticosteroids should be coadministered for severe infections.

Adverse Reactions, Contraindications, & Cautions

Short-term mebendazole therapy for intestinal nematodes is nearly free of adverse effects. Mild nausea, vomiting, diarrhea, and abdominal pain have been reported infrequently. Rare side effects, usually with high-dose therapy, are hypersensitivity reactions (rash, urticaria), agranulocytosis, alopecia, and elevation of liver enzymes.

Mebendazole is teratogenic in animals and therefore contraindicated in pregnancy. It should be used with caution in children under 2 years of age because of limited experience and rare reports of convulsions in this age group. Plasma levels may be decreased by concomitant use of carbamazepine or phenytoin and increased by cimetidine. Mebendazole should be used with caution in those with cirrhosis.

Metrifonate (Trichlorfon)

Metrifonate is a safe, low-cost alternative drug for the treatment of *Schistosoma haematobium* infections. It is not active against *S mansoni* or *S japonicum*. It is not available in the USA.

Chemistry & Pharmacokinetics

Metrifonate, an organophosphate compound, is rapidly absorbed after oral administration. Following the standard oral dose, peak blood levels are reached in 1–2 hours; the half-life is about 1.5 hours. Clearance appears to be through nonenzymatic transformation to dichlorvos, its active metabolite. Metrifonate and dichlorvos are well distributed to the tissues and are completely eliminated in 24–48 hours.

Anthelmintic Actions

The mode of action is thought to be related to cholinesterase inhibition. This inhibition temporarily paralyzes the adult worms, resulting in their shift from the bladder venous plexus to small arterioles of the lungs, where they are trapped, encased by the immune system, and die. The drug is not effective against *S haematobium* eggs; live eggs continue to pass in the urine for several months after all adult worms have been killed.

Clinical Uses

In the treatment of *S haematobium*, a single oral dose of 7.5–10 mg/kg is given three times at 14-day intervals. Cure rates on this schedule are 44–93%, with marked reductions in egg counts in those not cured. Metrifonate was also effective as a prophylactic agent when given monthly to children in a highly endemic area, and it has been used in mass treatment programs. In mixed infections with *S haematobium* and *S mansoni*, metrifonate has been successfully combined with oxamniquine.

Adverse Reactions, Contraindications, & Cautions

Some studies note mild and transient cholinergic symptoms, including nausea and vomiting, diarrhea, abdominal pain, bronchospasm, headache, sweating, fatigue, weakness, dizziness, and vertigo. These symptoms may begin within 30 minutes and persist up to 12 hours.

Metrifonate should not be used after recent exposure to insecticides or drugs that might potentiate cholinesterase inhibition. Metrifonate is contraindicated in pregnancy.

Niclosamide

Niclosamide is a second-line drug for the treatment of most tapeworm infections, but it is not available in the United States.

Chemistry & Pharmacokinetics

Niclosamide is a salicylamide derivative. It appears to be minimally absorbed from the gastrointestinal tract—neither the drug nor its metabolites have been recovered from the blood or urine.

Anthelmintic Actions

Adult worms (but not ova) are rapidly killed, presumably due to inhibition of oxidative phosphorylation or stimulation of ATPase activity.

Clinical Uses

The adult dose of niclosamide is 2 g once, given in the morning on an empty stomach. The tablets must be chewed thoroughly and are then swallowed with water.

T Saginata (Beef Tapeworm), *T Solium* (Pork Tapeworm), and *Diphyllobothrium Latum* (Fish Tapeworm)

A single 2 g dose of niclosamide results in cure rates of over 85% for *D latum* and about 95% for *T saginata*. It is probably equally effective against *T solium*. Cysticercosis is theoretically possible after treatment of *T solium* infections, since viable ova are released into the gut lumen following digestion of segments. However, no such cases of cysticercosis following therapy have been reported.

Other Tapeworms

Praziquantel is superior for *Hymenolepis nana* (dwarf tapeworm) infection. Most patients treated for *Hymenolepis diminuta* and *Dipylidium caninum* infections are cured with a 7-day course of treatment; a few require a second course. Niclosamide is not effective against cysticercosis or hydatid disease.

Intestinal Fluke Infections

Niclosamide can be used as an alternative drug for the treatment of *Fasciolopsis buski*, *Heterophyes heterophyes*, and *Metagonimus yokogawai* infections. The standard dose is given every other day for three doses.

Adverse Reactions, Contraindication, & Cautions

Infrequent, mild, and transitory adverse events include nausea, vomiting, diarrhea, and abdominal

discomfort.

The consumption of alcohol should be avoided on the day of treatment and for 1 day afterward.

The safety of the drug has not been established in pregnancy or for children under 2 years of age.

Katzung PHARMACOLOGY, 9e > Section VIII. Chemotherapeutic Drugs > Chapter 54. Clinical Pharmacology of the Anthelmintic Drugs >

Oxamniquine

Oxamniquine is an alternative to praziquantel for the treatment of *S mansoni* infections. It has also been used extensively for mass treatment. It is not effective against *S haematobium* or *S japonicum*.

Pharmacokinetics

Oxamniquine, a semisynthetic tetrahydroquinoline, is readily absorbed orally. Its plasma half-life is about 2.5 hours. The drug is extensively metabolized to inactive metabolites and excreted in the urine—up to 75% in the first 24 hours. Intersubject variations in serum concentration have been noted, which may explain some treatment failures.

Anthelmintic Actions

Oxamniquine is active against both mature and immature stages of *S mansoni* but does not appear to be cercaricidal. The mechanism of action is unknown. Contraction and paralysis of the worms results in detachment from terminal venules in the mesentery and transit to the liver, where many die; surviving females return to the mesenteric vessels but cease to lay eggs.

Strains of *S mansoni* in different parts of the world vary in susceptibility. Oxamniquine has been effective in instances of praziquantel resistance.

Clinical Uses

Oxamniquine is safe and effective in all stages of *S mansoni* disease, including advanced hepatosplenomegaly. In the acute (Katayama) syndrome, treatment results in disappearance of acute symptoms and clearance of the infection. The drug is generally less effective in children, who require higher doses than adults. It is better-tolerated with food.

Optimal dosage schedules vary for different regions of the world. In the Western Hemisphere and western Africa, the adult oxamniquine dosage is 12–15 mg/kg given once. In northern and southern Africa, standard schedules are 15 mg/kg twice daily for 2 days. In eastern Africa and the Arabian peninsula, standard dosage is 15–20 mg/kg twice in 1 day. Cure rates are 70–95%, with marked reduction in egg excretion in those not cured.

In mixed schistosome infections, oxamniquine has been successfully used in combination with metrifonate.

Adverse Reactions, Contraindications, & Cautions

Mild symptoms, starting about 3 hours after a dose and lasting for several hours, occur in more than

one third of patients. Central nervous system symptoms (dizziness, headache, drowsiness) are most common; nausea and vomiting, diarrhea, colic, pruritus, and urticaria also occur. Infrequent adverse effects are low-grade fever, an orange to red discoloration of the urine, proteinuria, microscopic hematuria, and a transient decrease in leukocytes. Seizures have been reported rarely.

Since the drug makes many patients dizzy or drowsy, it should be used with caution in patients whose work or activity requires mental alertness (eg, no driving for 24 hours). It should be used with caution in those with a history of epilepsy.

Oxamniquine is contraindicated in pregnancy.

Katzung PHARMACOLOGY, 9e > Section VIII. Chemotherapeutic Drugs > Chapter 54. Clinical Pharmacology of the Anthelmintic Drugs >

Piperazine

Piperazine is an alternative for the treatment of ascariasis, with cure rates over 90% when taken for 2 days, but it is not recommended for other helminth infections. Piperazine is available as the hexahydrate and as a variety of salts. It is readily absorbed, and maximum plasma levels are reached in 2–4 hours. Most of the drug is excreted unchanged in the urine in 2–6 hours, and excretion is complete within 24 hours.

Piperazine causes paralysis of ascaris by blocking acetylcholine at the myoneural junction; unable to maintain their position in the host, live worms are expelled by normal peristalsis.

For ascariasis, the dosage of piperazine (as the hexahydrate) is 75 mg/kg (maximum dose, 3.5 g) orally once daily for 2 days. For heavy infections, treatment should be continued for 3–4 days or repeated after 1 week.

Occasional mild adverse effects include nausea, vomiting, diarrhea, abdominal pain, dizziness, and headache. Neurotoxicity and allergic reactions are rare.

Piperazine compounds should not be given to women during pregnancy, to patients with impaired renal or hepatic function, or to those with a history of epilepsy or chronic neurologic disease.

Katzung PHARMACOLOGY, 9e > Section VIII. Chemotherapeutic Drugs > Chapter 54. Clinical Pharmacology of the Anthelmintic Drugs >

Praziquantel

Praziquantel is effective in the treatment of schistosome infections of all species and most other trematode and cestode infections, including cysticercosis. The drug's safety and effectiveness as a single oral dose have also made it useful in mass treatment of several infections.

Chemistry & Pharmacokinetics

Praziquantel is a synthetic isoquinoline-pyrazine derivative. It is rapidly absorbed, with a bioavailability of about 80% after oral administration. Peak serum concentrations are reached 1–3 hours after a therapeutic dose. Cerebrospinal fluid concentrations of praziquantel reach 14–20% of the drug's plasma concentration. About 80% of the drug is bound to plasma proteins. Most of the

drug is rapidly metabolized to inactive mono- and polyhydroxylated products after a first pass in the liver. The half-life is 0.8–1.5 hours. Excretion is mainly via the kidneys (60–80%) and bile (15–35%). Plasma concentrations of praziquantel increase when the drug is taken with a high-carbohydrate meal or with cimetidine; bioavailability is markedly reduced with some antiepileptics (phenytoin, carbamazepine) or with corticosteroids.

Anthelmintic Actions

Praziquantel appears to increase the permeability of trematode and cestode cell membranes to calcium, resulting in paralysis, dislodgement, and death.

In schistosome infections of experimental animals, praziquantel is effective against adult worms and immature stages and it has a prophylactic effect against cercarial infection.

Clinical Uses

Praziquantel tablets are taken with liquid after a meal; they should be swallowed without chewing because their bitter taste can induce retching and vomiting.

Schistosomiasis

Praziquantel is the drug of choice for all forms of schistosomiasis. The dosage is 20 mg/kg for two (*S mansoni* and *S haematobium*) or three (*S japonicum* and *S mekongi*) doses at intervals of 4–6 hours. High cure rates (75–95%) are achieved when patients are evaluated at 3–6 months; there is marked reduction in egg counts in those not cured. The drug is effective in adults and children and is generally well tolerated by patients in the hepatosplenic stage of advanced disease. It is not clear, however, whether the drug can be safely or effectively used during the acute stage of the disease (Katayama fever) because release of antigens from dying immature worms may exacerbate symptoms. Increasing evidence indicates rare *S mansoni* drug resistance, which is treatable with oxamniquine. Effectiveness of the drug for chemoprophylaxis has not been established.

Clonorchiasis, Opisthorchiasis, and Paragonimiasis

The dosage of 25 mg/kg three times for 1 day results in nearly 100% cure rates for clonorchiasis and opisthorchiasis, and a 2 day's course provides 90–100% cure rates for pulmonary paragonimiasis.

Taeniasis and Diphyllobothriasis

A single dose of praziquantel, 5–10 mg/kg, results in nearly 100% cure rates for *T saginata*, *T solium*, and *D latum* infections. For *T solium*, since praziquantel does not kill eggs, it is theoretically possible that larvae released from eggs in the large bowel could penetrate the intestinal wall and give rise to cysticercosis, but this hazard is probably minimal.

Neurocysticercosis

Albendazole is now the preferred drug, but when it is not appropriate or available, praziquantel has similar efficacy. Indications are similar to those for albendazole. The praziquantel dosage is 50 mg/kg/d in three divided doses for 14 days or longer. Clinical responses to therapy vary from dramatic improvements of seizures and other neurologic findings to no response and even progression of the disease. Praziquantel—but not albendazole—has diminished bioavailability when

taken concurrently with a corticosteroid. Recommendations on steroid use in neurocysticercosis vary.

H Nana

Praziquantel is the drug of choice for *H nana* infections and the first drug to be highly effective. A single dose of 25 mg/kg is taken initially and repeated in 1 week.

Hydatid Disease

In hydatid disease, praziquantel kills protoscoleces but does not affect the germinal membrane. Praziquantel is being evaluated as an adjunct with albendazole pre- and postsurgery. In addition to its direct action, praziquantel enhances the plasma concentration of albendazole sulfoxide.

Other Parasites

Limited trials at a dosage of 25 mg/kg three times a day for 1–2 days indicate effectiveness of praziquantel against fasciolopsiasis, metagonimiasis, and other forms of heterophyiasis. Praziquantel was not effective for fascioliasis, however, even at dosages as high as 25 mg/kg three times daily for 3–7 days.

Adverse Reactions, Contraindications, & Cautions

Mild and transient adverse effects are common. They begin within several hours after ingestion and may persist for hours to 1 day. Most frequent are headache, dizziness, drowsiness, and lassitude; others include nausea, vomiting, abdominal pain, loose stools, pruritus, urticaria, arthralgia, myalgia, and low-grade fever. Mild and transient elevations of liver enzymes have been reported. Several days after starting praziquantel, low-grade fever, pruritus, and skin rashes (macular and urticarial), sometimes associated with worsened eosinophilia, may occur, probably due to the release of proteins from dying worms rather than direct drug toxicity. The intensity and frequency of adverse effects increase with dosage such that they occur in up to 50% of patients who receive 25 mg/kg three times in 1 day.

In neurocysticercosis, neurologic abnormalities may be exacerbated by inflammatory reactions around dying parasites. Common findings in patients who do not receive corticosteroids, usually presenting during or shortly after therapy, are headache, meningismus, nausea, vomiting, mental changes, and seizures (often accompanied by increased cerebrospinal fluid pleocytosis). More serious findings, including arachnoiditis, hyperthermia, and intracranial hypertension, may also occur. Corticosteroids are commonly used with praziquantel in the treatment of neurocysticercosis to decrease the inflammatory reaction, but this is controversial, and complicated by knowledge that corticosteroids decrease the plasma level of praziquantel up to 50%. Praziquantel is contraindicated in ocular cysticercosis, as parasite destruction in the eye may cause irreparable damage. Some workers also caution against use of the drug in spinal neurocysticercosis.

The safety of praziquantel in children under age 4 years is not established, but no specific problems in young children have been documented. Indeed, the drug appears to be better tolerated in children than in adults. Praziquantel increased abortion rates in rats and therefore should be avoided in pregnancy if possible. Because the drug induces dizziness and drowsiness, patients should not drive during therapy and should be warned regarding activities requiring particular physical coordination or alertness.

Pyrantel Pamoate

Pyrantel pamoate is a broad-spectrum anthelmintic highly effective for the treatment of pinworm, ascaris, and *Trichostrongylus orientalis* infections. It is moderately effective against both species of hookworm. It is not effective in trichuriasis or strongyloidiasis. Oxantel pamoate, an analog of pyrantel not available in the USA, has been used successfully in the treatment of trichuriasis; the two drugs have been combined for their broad-spectrum anthelmintic activity.

Chemistry & Pharmacokinetics

Pyrantel pamoate is a tetrahydropyrimidine derivative. It is poorly absorbed from the gastrointestinal tract and active mainly against luminal organisms. Peak plasma levels are reached in 1–3 hours. Over half of the administered dose is recovered unchanged in the feces.

Anthelmintic Actions

Pyrantel is effective against mature and immature forms of susceptible helminths within the intestinal tract but not against migratory stages in the tissues or against ova. The drug is a neuromuscular blocking agent that causes release of acetylcholine and inhibition of cholinesterase; this results in paralysis, which is followed by expulsion of worms.

Clinical Uses

The standard dose is 11 mg (base)/kg (maximum, 1 g), given orally once with or without food. For pinworm the dose is repeated in 2 weeks, and cure rates are greater than 95%. The drug is available in the USA without prescription for this indication.

For ascariasis, a single dose yields cure rates of 85–100%. Treatment should be repeated if eggs are found 2 weeks after treatment. For hookworm infections, a single dose is effective against light infections; but for heavy infections, especially with *N americanus*, a 3-day course is necessary to reach 90% cure rates. A course of treatment can be repeated in 2 weeks.

Adverse Reactions, Contraindications, & Cautions

Adverse effects are infrequent, mild, and transient. They include nausea, vomiting, diarrhea, abdominal cramps, dizziness, drowsiness, headache, insomnia, rash, fever, and weakness. Pyrantel should be used with caution in patients with liver dysfunction, since low, transient aminotransferase elevations have been noted in a small number of patients. Experience with the drug in pregnant women and children under age 2 years is limited.

Thiabendazole

Thiabendazole is an alternative to ivermectin for the treatment of strongyloidiasis and cutaneous

larva migrans.

Chemistry & Pharmacokinetics

Thiabendazole is a benzimidazole compound. Although it is a chelating agent that forms stable complexes with a number of metals, including iron, it does not bind calcium.

Thiabendazole is rapidly absorbed after ingestion. With a standard dose, drug concentrations in plasma peak within 1–2 hours; the half-life is 1.2 hours. The drug is almost completely metabolized in the liver to the 5-hydroxy form; 90% is excreted in the urine in 48 hours, largely as the glucuronide or sulfonate conjugate. Thiabendazole can also be absorbed from the skin.

Anthelmintic Actions

The mechanism of action of thiabendazole is probably the same as that of other benzimidazoles (see above). The drug has ovicidal effects for some parasites.

Clinical Uses

The standard dosage, 25 mg/kg (maximum, 1.5 g) twice daily, should be given after meals. Tablets should be chewed. For strongyloides infection, treatment is for 2 days. Cure rates are reportedly 93%. A course can be repeated in 1 week if indicated. In patients with hyperinfection syndrome, the standard dose is continued twice daily for 5–7 days. For cutaneous larva migrans, thiabendazole cream can be applied topically or the oral drug can be given for 2 days (although albendazole is less toxic and therefore preferred).

Adverse Reactions, Contraindications, & Cautions

Thiabendazole is much more toxic than other benzimidazoles or ivermectin, so other agents are now preferred for most indications. Common adverse effects include dizziness, anorexia, nausea, and vomiting. Less frequent problems are epigastric pain, abdominal cramps, diarrhea, pruritus, headache, drowsiness, and neuropsychiatric symptoms. Irreversible liver failure and fatal Stevens-Johnson syndrome have been reported.

Experience with thiabendazole is limited in children weighing less than 15 kg. The drug should not be used in pregnancy or in the presence of hepatic or renal disease.

Katzung PHARMACOLOGY, 9e > Section VIII. Chemotherapeutic Drugs > Chapter 54. Clinical Pharmacology of the Anthelmintic Drugs >

Preparations Available

Albendazole (Albenza, Zentel)

Oral: 200 mg tablets; 100 mg/5 mL suspension

Note: Albendazole is approved in the USA for the treatment of cysticercosis and hydatid disease.

Bithionol (Bitin)

Oral: 200 mg tablets

Note: Bithionol is not marketed in the USA but is available from the Parasitic Disease Drug Service, Centers for Disease Control and Prevention, Atlanta; 404-639-3670.

Diethylcarbamazine (Hetrazan)

Oral: 50 mg tablets

Note: Diethylcarbamazine is no longer marketed in the USA but is available from the Parasitic Disease Drug Service, Centers for Disease Control and Prevention, Atlanta; 404-639-3670.

Ivermectin (Mectizan, Stromectol)

Oral: 3, 6 mg tablets

Note: Ivermectin is approved for use in the USA for the treatment of onchocerciasis and strongyloidiasis. See Chapter 66: Rational Prescribing & Prescription Writing for comment on the unlabeled use of drugs.

Levamisole (Decaris, Ethnor, Ketrax, Solaskil)

Oral: 50, 150 mg tablets and syrup

Mebendazole (generic, Vermox)

Oral: 100 mg chewable tablets; outside the USA, 100 mg/5 mL suspension

Metrifonate (trichlorfon, Bilarcil)

Oral: 100 mg tablets

Note: Metrifonate is not available in the USA.

Niclosamide (Niclocide)

Oral: 500 mg chewable tablets

Note: Niclosamide is not available in the USA.

Oxamniquine (Vansil, Mansil)

Oral: 250 mg capsules; outside the USA, 50 mg/mL syrup

Oxantel pamoate (Quantrel); oxantel/pyrantel pamoate (Telopar)

Oral: tablets containing 100 mg (base) of each drug; suspensions containing 20 or 50 mg (base) per mL

Note: Oxantel pamoate and oxantel/pyrantel pamoate are not available in the USA.

Piperazine (generic, Vermizine)

Oral: piperazine citrate tablets equivalent to 250 mg of the hexahydrate; piperazine citrate syrup equivalent to 500 mg of the hexahydrate per 5 mL

Praziquantel (Biltricide; others outside the USA)

Oral: 600 mg tablets (other strengths outside the USA)

Pyrantel pamoate (Antiminth, Combantrin, Pin-rid, Pin-X)

Oral: 50 mg (base)/mL suspension; 62.5 mg (base) capsules (available without prescription in the USA)

Suramin (Bayer 205, others)

Parenteral: ampules containing 0.5 or 1 g powder to be reconstituted as a 10% solution and used immediately

Note: Suramin is not marketed in the USA but can be obtained from the Parasitic Disease Drug Service, Centers for Disease Control, Atlanta, 404-639-3670.

Thiabendazole (Mintezol)

Oral: 500 mg chewable tablets; suspension, 500 mg/mL

Chapter 53. Antiprotozoal Drugs

Katzung PHARMACOLOGY, 9e > Section VIII. Chemotherapeutic Drugs > Chapter 53. Antiprotozoal Drugs >

Treatment of Malaria

Four species of plasmodium cause human malaria: *Plasmodium falciparum*, *P vivax*, *P malariae*, and *P ovale*. Although all may cause significant illness, *P falciparum* is responsible for nearly all serious complications and deaths. Drug resistance is an important therapeutic problem, most notably with *P falciparum*.

Parasite Life Cycle

An anopheline mosquito inoculates plasmodium sporozoites to initiate human infection. Circulating sporozoites rapidly invade liver cells, and exoerythrocytic stage tissue schizonts mature in the liver. Merozoites are subsequently released from the liver and invade erythrocytes. Only erythrocytic parasites cause clinical illness. Repeated cycles of infection can lead to the infection of many erythrocytes and serious disease. Sexual stage gametocytes also develop in erythrocytes before being taken up by mosquitoes, where they develop into infective sporozoites.

In *P falciparum* and *P malariae* infection, only one cycle of liver cell invasion and multiplication occurs, and liver infection ceases spontaneously in less than 4 weeks. Thus, treatment that

eliminates erythrocytic parasites will cure these infections. In *P vivax* and *P ovale* infections, a dormant hepatic stage, the hypnozoite, is not eradicated by most drugs, and subsequent relapses can therefore occur after therapy directed against erythrocytic parasites. Eradication of both erythrocytic and hepatic parasites is required to cure these infections.

Drug Classification

Several classes of antimalarial drugs are available (Table 53–1; Figure 53–1). Drugs that eliminate developing or dormant liver forms are called **tissue schizonticides**; those that act on erythrocytic parasites are **blood schizonticides**; and those that kill sexual stages and prevent transmission to mosquitoes are **gametocides**. No one available agent can reliably effect a **radical cure**, ie, eliminate both hepatic and erythrocytic stages. Few available agents are **causal prophylactic drugs**, ie, capable of preventing erythrocytic infection. However, all effective chemoprophylactic agents kill erythrocytic parasites before they grow sufficiently in number to cause clinical disease.

Drug	Class	Use
Chloroquine	4-Aminoquinoline	Treatment and chemoprophylaxis of infection with sensitive parasites
Amodiaquine ¹	4-Aminoquinoline	Treatment of infection with some chloroquine-resistant <i>P falciparum</i> strains
Quinine	Quinoline methanol	Oral treatment of infections with chloroquine-resistant <i>P falciparum</i>
Quinidine	Quinoline methanol	Intravenous therapy of severe infections with <i>P falciparum</i>
Mefloquine	Quinoline methanol	Chemoprophylaxis and treatment of infections with <i>P falciparum</i>
Primaquine	8-Aminoquinoline	Radical cure and terminal prophylaxis of infections with <i>P vivax</i> and <i>P ovale</i>
Sulfadoxine-pyrimethamine (Fansidar)	Folate antagonist combination	Treatment of infections with some chloroquine-resistant <i>P falciparum</i>
Proguanil ¹	Folate antagonist	Chemoprophylaxis (with chloroquine)
Doxycycline	Tetracycline	Treatment (with quinine) of infections with <i>P falciparum</i> ; chemoprophylaxis
Halofantrine ¹	Phenanthrene methanol	Treatment of infections with some chloroquine-resistant <i>P falciparum</i>
Lumefantrine ¹	Amyl alcohol	Treatment of <i>P falciparum</i> malaria in fixed combination with artemether (Coartem)
Artemisinins ¹	Sesquiterpene lactone endoperoxides	Treatment of infection with multidrug-resistant <i>P falciparum</i>
Atovaquone-proguanil (Malarone)	Quinone-folate antagonist combination	Treatment and chemoprophylaxis of <i>P falciparum</i> infection

Treatment of Amebiasis

Amebiasis is infection with *Entamoeba histolytica*. This agent can cause asymptomatic intestinal infection, mild to moderate colitis, severe intestinal infection (dysentery), ameboma, liver abscess, and other extraintestinal infections. The choice of drugs for amebiasis depends on the clinical presentation (Figure 53–2; Table 53–4).

Figure 53–2.

Structural formulas of other antiprotozoal drugs.

Table 53–4. Treatment of Amebiasis.¹

Clinical Setting	Drugs of Choice and Adult Dosage	Alternative Drugs and Adult Dosage
Asymptomatic intestinal infection	Luminal agent: Diloxanide furoate, ² 500 mg 3 times daily for 10 days <i>or</i> – Iodoquinol, 650 mg 3 times daily for 21 days <i>or</i> – Paromomycin, 10 mg/kg 3 times daily for 7 days	
Mild to moderate intestinal infection	Metronidazole, 750 mg 3 times daily (or 500 mg IV every 6 hours) for 10 days <i>plus</i> – Luminal agent (see above)	Luminal agent (see above) <i>plus either</i> – Tetracycline, 250 mg 3 times daily for 10 days <i>or</i> – Erythromycin, 500 mg 4 times daily for 10 days
Severe intestinal infection	Metronidazole, 750 mg 3 times daily (or 500 mg IV every 6 hours) for 10 days <i>plus</i> – Luminal agent (see above)	Luminal agent (see above) <i>plus either</i> – Tetracycline, 250 mg 3 times daily for 10 days <i>or</i> – Dehydroemetine ³ or emetine, ² 1 mg/kg SC or IM for 3–5 days
Hepatic abscess, ameboma, and other extraintestinal disease	Metronidazole, 750 mg 3 times daily (or 500 mg IV every 6 hours) for 10 days <i>plus</i> – Luminal agent (see above)	Dehydroemetine ³ or emetine, ² 1 mg/kg SC or IM for 8–10 days, followed by (liver abscess only) chloroquine, 500 mg twice daily for 2 days, then 500 mg daily for 21 days <i>plus</i> – Luminal agent (see above)

¹Route is oral unless otherwise indicated. See text for additional details and cautions.

²Not available in the USA.

³Available in the USA only from the Drug Service, CDC, Atlanta (404-639-3670).

Treatment of Specific Forms of Amebiasis

Asymptomatic Intestinal Infection

Asymptomatic carriers generally are not treated in endemic areas but in nonendemic areas they are treated with a luminal amebicide. A tissue amebicidal drug is unnecessary. Standard luminal amebicides are diloxanide furoate, iodoquinol, and paromomycin. Each drug eradicates carriage in about 80–90% of patients with a single course of treatment. Therapy with a luminal amebicide is also required in the treatment of all other forms of amebiasis.

Amebic Colitis

Metronidazole plus a luminal amebicide is the treatment of choice for colitis and dysentery. Tetracyclines and erythromycin are alternative drugs for moderate colitis but are not effective against extraintestinal disease. Dehydroemetine or emetine can also be used, but these agents are best avoided (when possible) because of their toxicity.

Extraintestinal Infections

The treatment of choice is metronidazole plus a luminal amebicide. A 10-day course of metronidazole cures over 95% of uncomplicated liver abscesses. For unusual cases where initial therapy with metronidazole has failed, aspiration of the abscess and the addition of chloroquine to a repeat course of metronidazole should be considered. Dehydroemetine and emetine are toxic alternative drugs.

Metronidazole

Metronidazole, a nitroimidazole (Figure 53–2), is the drug of choice for the treatment of extraluminal amebiasis. It kills trophozoites but not cysts of *E histolytica* and effectively eradicates intestinal and extraintestinal tissue infections.

Chemistry & Pharmacokinetics

Oral metronidazole is readily absorbed and permeates all tissues by simple diffusion. Intracellular concentrations rapidly approach extracellular levels. Peak plasma concentrations are reached in 1–3 hours. Protein binding is low (< 20%), and the half-life of the unchanged drug is 7.5 hours. The drug and its metabolites are excreted mainly in the urine. Plasma clearance of metronidazole is decreased in patients with impaired liver function.

Mechanism of Action

The nitro group of metronidazole is chemically reduced in anaerobic bacteria and sensitive protozoans. Reactive reduction products appear to be responsible for antimicrobial activity.

Clinical Uses

Amebiasis

Metronidazole is the drug of choice for the treatment of all tissue infections with *E histolytica*. It is not reliably effective against luminal parasites and so must be used with a luminal amebicide to ensure eradication of the infection. Tinidazole, a related nitroimidazole, appears to have similar activity and a better toxicity profile than metronidazole, but it is not available in the USA.

Giardiasis

Metronidazole is the treatment of choice for giardiasis. The dosage for giardiasis is much lower—and the drug thus better tolerated—than that for amebiasis. Efficacy after a single treatment is about 90%. Tinidazole is equally effective.

Trichomoniasis

Metronidazole is the treatment of choice. A single dose of 2 g is effective. Metronidazole-resistant organisms may lead to treatment failures. Tinidazole may be effective against some of these infections, but it is not available in the USA. Such cases may require repeat courses of metronidazole at higher doses than normally recommended—or topical therapy.

Adverse Effects & Cautions

Nausea, headache, dry mouth, or a metallic taste in the mouth occurs commonly. Infrequent adverse effects include vomiting, diarrhea, insomnia, weakness, dizziness, thrush, rash, dysuria, dark urine, vertigo, paresthesias, and neutropenia. Taking the drug with meals lessens gastrointestinal irritation. Pancreatitis and severe central nervous system toxicity (ataxia, encephalopathy, seizures) are rare. Metronidazole has a disulfiram-like effect, so that nausea and vomiting can occur if alcohol is ingested during therapy. The drug should be used with caution in patients with central nervous system disease. Intravenous infusions have rarely caused seizures or peripheral neuropathy. The dosage should be adjusted for patients with severe liver or renal disease.

Metronidazole has been reported to potentiate the anticoagulant effect of coumarin-type anticoagulants. Phenytoin and phenobarbital may accelerate elimination of the drug, while cimetidine may decrease plasma clearance. Lithium toxicity may occur when the drug is used with metronidazole.

Metronidazole and its metabolites are mutagenic in bacteria. Chronic administration of large doses led to tumorigenicity in mice. Data on teratogenicity are inconsistent. Metronidazole is thus best avoided in pregnant or nursing women, though congenital abnormalities have not clearly been associated with use in humans.

Iodoquinol

Iodoquinol (diiodohydroxyquin) is a halogenated hydroxyquinoline. It is an effective luminal amebicide that is commonly used with metronidazole to treat amebic infections. Its pharmacokinetic properties are poorly understood. Ninety percent of the drug is retained in the intestine and excreted in the feces. The remainder enters the circulation, has a half-life of 11–14 hours, and is excreted in the urine as glucuronides.

The mechanism of action of iodoquinol against trophozoites is unknown. It is effective against organisms in the bowel lumen but not against trophozoites in the intestinal wall or extraintestinal tissues.

Infrequent adverse effects include diarrhea—which usually stops after several days—anorexia, nausea, vomiting, abdominal pain, headache, rash, and pruritus. The drug may increase protein-bound serum iodine, leading to a decrease in measured ¹³¹I uptake that persists for months. Some halogenated hydroxyquinolines can produce severe neurotoxicity with prolonged use at greater than recommended doses. Iodoquinol is not known to produce these effects at its recommended dosage, and this dosage should never be exceeded.

Iodoquinol should be taken with meals to limit gastrointestinal toxicity. It should be used with caution in patients with optic neuropathy, renal or thyroid disease, or nonamebic hepatic disease. The drug should be discontinued if it produces persistent diarrhea or signs of iodine toxicity (dermatitis, urticaria, pruritus, fever). It is contraindicated in patients with intolerance to iodine.

Diloxanide Furoate

Diloxanide furoate is a dichloroacetamide derivative. It is an effective luminal amebicide but is not active against tissue trophozoites. In the gut, diloxanide furoate is split into diloxanide and furoic acid; about 90% of the diloxanide is rapidly absorbed and then conjugated to form the glucuronide, which is promptly excreted in the urine. The unabsorbed diloxanide is the active antiamebic substance. The mechanism of action of diloxanide furoate is unknown.

Diloxanide furoate is considered by many the drug of choice for asymptomatic luminal infections, but it is no longer available in the USA. It is used with a tissue amebicide, usually metronidazole, to treat serious intestinal and extraintestinal infections. Diloxanide furoate does not produce serious adverse effects. Flatulence is common, but nausea and abdominal cramps are infrequent and rashes are rare. The drug is not recommended in pregnancy.

Paromomycin Sulfate

Paromomycin sulfate is an aminoglycoside antibiotic (see also Chapter 45: Aminoglycosides & Spectinomycin) that is not significantly absorbed from the gastrointestinal tract. It is used only as a luminal amebicide and has no effect against extraintestinal amebic infections. The small amount absorbed is slowly excreted unchanged, mainly by glomerular filtration. However, the drug may accumulate with renal insufficiency and contribute to renal toxicity. Paromomycin is an effective luminal amebicide that appears to have similar efficacy and probably less toxicity than other agents; in a recent study, it was superior to diloxanide furoate in clearing asymptomatic infections. Adverse effects include occasional abdominal distress and diarrhea. Paromomycin should be avoided in patients with significant renal disease and used with caution in persons with gastrointestinal ulcerations. Parenteral paromomycin is under investigation for the treatment of visceral leishmaniasis.

Emetine & Dehydroemetine

Emetine, an alkaloid derived from ipecac, and dehydroemetine, a synthetic analog, are effective against tissue trophozoites of *E histolytica*, but because of major toxicity concerns they have been almost completely replaced by metronidazole. The drugs are administered parenterally because oral preparations are absorbed erratically. They accumulate in tissues and are eliminated slowly via the kidneys.

The use of emetine and dehydroemetine is limited to unusual circumstances in which severe amebiasis warrants effective therapy and metronidazole cannot be used. Dehydroemetine is preferred over emetine because of its somewhat better toxicity profile. The drugs should be used to treat amebic dysentery or amebic liver abscess for the minimum period needed to relieve severe symptoms (usually 3–5 days).

Emetine and dehydroemetine should be administered subcutaneously (preferred) or intramuscularly (but never intravenously) in a supervised setting. Adverse effects are generally mild when the drugs are used for 3–5 days but increase with prolonged use. They should not be used for more than 10 days. Pain and tenderness in the area of injection are frequent, and sterile abscesses may develop. Diarrhea is common. Other adverse effects are nausea, vomiting, muscle weakness and discomfort, and minor electrocardiographic changes. Serious toxicities include cardiac arrhythmias, heart failure, and hypotension. The drugs should not be used in patients with cardiac or renal disease, in young children, or in pregnancy unless absolutely necessary.

Katzung PHARMACOLOGY, 9e > Section VIII. Chemotherapeutic Drugs > Chapter 53.
Antiprotozoal Drugs >

Other Antiprotozoal Drugs

See Table 53–5 for a list of drugs used in the treatment of other protozoal infections. Important drugs that are not covered elsewhere in this or other chapters are discussed below.

Table 53–5. Treatment of Other Protozoal Infections.		
Organism or Clinical Setting	Drugs of Choice ¹	Alternative Drugs
<i>Babesia</i> species	Clindamycin, 600 mg 3 times daily for 7 days <i>plus</i> — Quinine, 650 mg for 7 days	Atovaquone <i>or</i> azithromycin
<i>Balantidium coli</i>	Tetracycline, 500 mg 4 times daily for 10 days	Metronidazole, 750 mg 3 times daily for 5 days
<i>Cryptosporidium</i> species	Paromomycin, 500–750 mg 3 or 4 times daily for 10 days	Azithromycin, 500 mg daily for 21 days ²
<i>Cyclospora cayetanensis</i>	Trimethoprim-sulfamethoxazole, one double-strength tablet 4 times daily for 7–14 days	
<i>Dientamoeba fragilis</i>	Iodoquinol, 650 mg 3 times daily for 20 days	Tetracycline, 500 mg 4 times daily for 10 days <i>or</i> — Paromomycin, 500 mg

		3 times daily for 7 days
<i>Giardia lamblia</i>	Metronidazole, 250 mg 3 times daily for 5 days <i>or</i> – Tinidazole, ³ 2 g once	Furazolidone, 100 mg 4 times daily for 7 days <i>or</i> – Albendazole, 400 mg daily for 5 days ²
<i>Isospora belli</i>	Trimethoprim-sulfamethoxazole, one double-strength tablet 4 times daily for 10 days, then twice daily for 21 days	Pyrimethamine, 75 mg daily for 14 days <i>plus</i> – Folinic acid, 10 mg daily for 14 days
Microsporidia	Albendazole, 400 mg twice daily for 20–30 days	
Leishmaniasis, visceral (<i>L donovani</i> , <i>L chagasi</i> , <i>L infantum</i>) or mucosal (<i>L braziliensis</i>)	Sodium stibogluconate, ⁴ 20 mg/kg/d IV or IM for 28 days	Meglumine antimonate ² <i>or</i> – Pentamidine <i>or</i> – Amphotericin B <i>or</i> – Miltefosine ²
Cutaneous (<i>L major</i> , <i>L tropica</i> , <i>L mexicana</i> , <i>L braziliensis</i>)	Sodium stibogluconate, ⁴ 20 mg/kg/d IV or IM for 20 days	Meglumine antimonate ² <i>or</i> – Ketoconazole <i>or</i> – Pentamidine <i>or</i> – Topical or intralesional therapies
<i>Pneumocystis jiroveci</i> , <i>P carinii</i> ⁵	Trimethoprim-sulfamethoxazole, 15–20 mg trimethoprim component/kg/d IV, or two double-strength tablets every 8 hours for 21 days	Pentamidine <i>or</i> –

		Trimethoprim-dapsone <i>or</i> – Clindamycin <i>plus</i> primaquine <i>or</i> – Atovaquone
<i>Toxoplasma gondii</i>		
Acute, congenital, immunocompromised	Pyrimethamine <i>plus</i> clindamycin <i>plus</i> folinic acid	Pyrimethamine <i>plus</i> sulfadiazine <i>plus</i> folinic acid
Pregnancy	Spiramycin, 3 g daily until delivery	
<i>Trichomonas vaginalis</i>	Metronidazole, 2 g once or 250 mg 3 times daily for 7 days	Tinidazole ³
<i>Trypanosoma brucei</i>		
Hemolympathic	Suramin ⁴	Pentamidine <i>or</i> – Eflornithine
Advanced CNS disease	Melarsoprol ⁴	Eflornithine
<i>Trypanosoma cruzi</i>	Nifurtimox ⁴ <i>or</i> – Benznidazole ³	

¹Established, relatively simple dosing regimens are provided. Route is oral unless otherwise indicated. See text for additional information, toxicities, cautions, and discussions of dosing for the more rarely used drugs, many of which are highly toxic.

²Nitazoxanide is also available for pediatric use.

³Not available in the USA.

⁴Available in the USA only from the Drug Service, CDC, Atlanta (404-639-3670).

⁵*P jiroveci* (*carinii* in animals) has traditionally been considered a protozoan because of its morphology and drug sensitivity, but recent molecular analyses have shown it to be most closely related to fungi.

Pentamidine

Pentamidine has activity against trypanosomatid protozoans and against *P jiroveci*, but toxicity is significant.

Chemistry & Pharmacokinetics

Pentamidine is an aromatic diamidine (Figure 53–2) formulated as an isethionate salt. Pentamidine is only administered parenterally. The drug leaves the circulation rapidly, with an initial half-life of about 6 hours, but it is bound avidly by tissues. Pentamidine thus accumulates and is eliminated very slowly, with a terminal elimination half-life of about 12 days. The drug can be detected in urine 6 or more weeks after treatment. Only trace amounts of pentamidine appear in the central nervous system, so it is not effective against central nervous system African trypanosomiasis. Pentamidine can also be inhaled as a nebulized powder for the prevention of pneumocystosis. Absorption into the systemic circulation after inhalation appears to be minimal. The mechanism of action of pentamidine is unknown.

Clinical Uses

Pneumocystosis

Pentamidine is a well-established alternative therapy for pulmonary and extrapulmonary disease caused by *P jiroveci*. The drug has somewhat lower efficacy and greater toxicity than trimethoprim-sulfamethoxazole. The standard dosage is now 3 mg/kg/d intravenously for 21 days. Significant adverse reactions are common, and with multiple regimens now available to treat *P jiroveci* infection, pentamidine is best reserved for patients with severe disease who cannot tolerate or fail other drugs.

Pentamidine is also an alternative agent for primary or secondary prophylaxis against pneumocystosis in immunocompromised individuals, including patients with advanced AIDS. For this indication, pentamidine is administered as an inhaled aerosol (300 mg inhaled monthly). The drug is well-tolerated in this form. Its efficacy is very good but clearly less than that of daily trimethoprim-sulfamethoxazole. Because of its cost and ineffectiveness against nonpulmonary disease, it is best reserved for patients who cannot tolerate oral chemoprophylaxis with other drugs.

African Trypanosomiasis (Sleeping Sickness)

Pentamidine has been used since 1940 as an alternative to suramin for the early hemolympathic stage of disease caused by *Trypanosoma brucei* (especially *T brucei gambiense*). The drug can also be used with suramin. Pentamidine should not be used to treat late trypanosomiasis with central nervous system involvement. A number of dosing regimens have been described, generally providing 2–4 mg/kg daily or on alternate days for a total of 10–15 doses. Pentamidine has also been used for chemoprophylaxis against African trypanosomiasis, with dosing of 4 mg/kg every 3–6 months.

Leishmaniasis

Pentamidine is an alternative to sodium stibogluconate for the treatment of visceral leishmaniasis, although resistance has been reported. The drug has been successful in some cases that have failed therapy with antimonials. The dosage is 2–4 mg/kg intramuscularly daily or every other day for up to 15 doses, and a second course may be necessary. Pentamidine has also shown success against cutaneous leishmaniasis, but it is not routinely used for this purpose.

Adverse Effects & Cautions

Pentamidine is a highly toxic drug, with adverse effects noted in about 50% of patients receiving 4 mg/kg/d. Rapid intravenous administration can lead to severe hypotension, tachycardia, dizziness, and dyspnea, so the drug should be administered slowly (over 2 hours) and patients should be recumbent and monitored closely during treatment. With intramuscular administration, pain at the injection site is common and sterile abscesses may develop.

Pancreatic toxicity is common. Hypoglycemia due to inappropriate insulin release often appears 5–7 days after onset of treatment, can persist for days to several weeks, and may be followed by hyperglycemia. Reversible renal insufficiency is also common. Other adverse effects include rash, metallic taste, fever, gastrointestinal symptoms, abnormal liver function tests, acute pancreatitis, hypocalcemia, thrombocytopenia, hallucinations, and cardiac arrhythmias. Inhaled pentamidine is generally well-tolerated but may cause cough, dyspnea, and bronchospasm.

Sodium Stibogluconate

Pentavalent antimonials, including sodium stibogluconate (pentostam; Figure 53–2) and meglumine antimonate, are generally considered first-line agents for cutaneous and visceral leishmaniasis. The drugs are rapidly absorbed after intravenous (preferred) or intramuscular administration and eliminated in two phases, with short (about 2 hour) and much longer (> 24 hour) half-lives. Treatment is given once daily at a dose of 20 mg/kg/d intravenously or intramuscularly for 20 days in cutaneous leishmaniasis and 28 days in visceral and mucocutaneous disease.

The mechanism of action of the antimonials is unknown. Their efficacy against different species may vary, possibly based on local drug resistance patterns. Cure rates are generally quite good, but resistance to sodium stibogluconate is increasing in some endemic areas. Some authorities have advocated initial therapy with other agents (eg, amphotericin B) in areas (such as parts of India) where therapy with sodium stibogluconate is commonly ineffective.

Few adverse effects occur initially, but the toxicity of stibogluconate increases over the course of therapy. Most common are gastrointestinal symptoms, fever, headache, myalgias, arthralgias, and rash. Intramuscular injections can be very painful and lead to sterile abscesses. Electrocardiographic changes may occur, most commonly T wave changes and QT prolongation. These changes are generally reversible, but continued therapy may lead to dangerous arrhythmias. Thus, the electrocardiogram should be monitored during therapy. Hemolytic anemia and serious liver, renal, and cardiac effects are rare.

Nitazoxanide

Nitazoxanide is a nitrothiazolyl-salicylamide prodrug. Nitazoxanide was recently approved in the USA for use in children against *G lamblia* and *Cryptosporidium parvum*. The drug is converted to an active metabolite, tizoxanide, which inhibits the pyruvate:ferredoxin oxidoreductase pathway. It is rapidly absorbed and converted to tizoxanide and tizoxanide conjugates, which are subsequently excreted in both urine and feces. Nitazoxanide appears to have activity against metronidazole-resistant protozoal strains and is well tolerated. Unlike metronidazole, nitazoxanide and its metabolites appear to be free of mutagenic effects. Other organisms that may be susceptible to nitazoxanide include *E histolytica*, *Helicobacter pylori*, *A lumbricoides*, several tapeworms, and *Fasciola hepatica*.

The recommended dosage for children is 100–200 mg twice daily for 3 days. The adult dosage has

not been established.

Other Drugs for Trypanosomiasis & Leishmaniasis

Currently available therapies for all forms of trypanosomiasis are seriously deficient in both efficacy and safety. Availability of these therapies is also a concern, as they remain available mainly through donation or nonprofit production by pharmaceutical companies.

Suramin

Suramin is a sulfated naphthylamine that was introduced in the 1920s. It is the first-line therapy for early hemolymphatic African trypanosomiasis (especially *T brucei gambiense* infection), but because it does not enter the central nervous system, it is not effective against advanced disease. The drug's mechanism of action is unknown. It is administered intravenously and displays complex pharmacokinetics with very tight protein binding. It has a short initial half-life but a terminal elimination half-life of about 50 days. The drug is slowly cleared by renal excretion.

Suramin is administered after a 200-mg intravenous test dose. Regimens that have been used include 1 g on days 1, 3, 7, 14, and 21 or 1 g each week for 5 weeks. Combination therapy with pentamidine may improve efficacy. Suramin can also be used for chemoprophylaxis against African trypanosomiasis. Adverse effects are common. Immediate reactions can include fatigue, nausea, vomiting, and, more rarely, seizures, shock, and death. Later reactions include fever, rash, headache, paresthesias, neuropathies, renal abnormalities including proteinuria, chronic diarrhea, hemolytic anemia, and agranulocytosis.

Melarsoprol

Melarsoprol is a trivalent arsenical that has been available since 1949 and is first-line therapy for advanced central nervous system African trypanosomiasis. After intravenous administration it is excreted rapidly, but clinically relevant concentrations accumulate in the central nervous system within 4 days. Melarsoprol is administered in propylene glycol by slow intravenous infusion at a dosage of 3.6 mg/kg/d for 3–4 days, with repeated courses at weekly intervals if needed. A new regimen of 2.2 mg/kg daily for 10 days had efficacy and toxicity similar to what was observed with three courses over 26 days. Melarsoprol is extremely toxic. The use of such a toxic drug is justified only by the severity of advanced trypanosomiasis and the lack of available alternatives. Immediate adverse effects include fever, vomiting, abdominal pain, and arthralgias. The most important toxicity is a reactive encephalopathy that generally appears within the first week of therapy (in 5–10% of patients) and is probably due to disruption of trypanosomes in the central nervous system. Common consequences of the encephalopathy include cerebral edema, seizures, coma, and death. Other serious toxicities include renal and cardiac disease and hypersensitivity reactions. Failure rates with melarsoprol appear to have increased recently in parts of Africa, suggesting the possibility of drug resistance.

Eflornithine

Eflornithine (difluoromethylornithine), an inhibitor of ornithine decarboxylase, is the only new drug registered to treat African trypanosomiasis in the last half-century. It is a second therapy for advanced central nervous system African trypanosomiasis and is less toxic than melarsoprol but not as widely available. The drug had very limited availability until recently, when it was developed for use as a topical depilatory cream, leading to donation of the drug for the treatment of trypanosomiasis. Eflornithine is administered intravenously, and good central nervous system drug

levels are achieved. Peak plasma levels are reached rapidly, and the elimination half-life is about 3 hours. The usual regimen is 100 mg/kg intravenously every 6 hours for 7–14 days (14 days was superior for a newly diagnosed infection). An oral formulation is also available and under clinical investigation. Eflornithine appears to be as effective as melarsoprol against advanced *T brucei gambiense* infection, but its efficacy against *T brucei rhodesiense* is limited by drug resistance. Toxicity from eflornithine is significant, but considerably less than that from melarsoprol. Adverse effects include diarrhea, vomiting, anemia, thrombocytopenia, leukopenia, and seizures. These effects are generally reversible. Increased experience with eflornithine and increased availability of the compound in endemic areas may lead to its replacement of suramin, pentamidine, and melarsoprol for the treatment of *T brucei gambiense* infection.

Nifurtimox

Nifurtimox, a nitrofuran, is the most commonly used drug for American trypanosomiasis (Chagas' disease). Nifurtimox is also under study for the treatment of African trypanosomiasis. Nifurtimox is well absorbed after oral administration and eliminated with a plasma half-life of about 3 hours. The drug is administered at a dose of 8–10 mg/kg/d (divided into 3–4 doses) orally for 3–4 months for the treatment of acute Chagas' disease. Nifurtimox decreases the severity of acute disease and usually eliminates detectable parasites, but it is often ineffective in fully eradicating infection. Thus, it often fails to prevent progression to the gastrointestinal and cardiac syndromes associated with chronic infection that are the most important clinical consequences of *Trypanosoma cruzi* infection. Efficacy may vary in different parts of South America, possibly related to drug resistance in some areas. Nifurtimox does not appear to be effective in the treatment of chronic Chagas' disease. Toxicity related to nifurtimox is common. Adverse effects include nausea, vomiting, abdominal pain, fever, rash, restlessness, insomnia, neuropathies, and seizures. These effects are generally reversible but often lead to cessation of therapy before completion of a standard course.

Benznidazole

Benznidazole is an orally administered nitroimidazole that appears to have efficacy similar to that of nifurtimox for the treatment of acute Chagas' disease. Availability of the drug is currently limited. Important toxicities include peripheral neuropathy, rash, gastrointestinal symptoms, and myelosuppression.

Amphotericin

This important antifungal drug (see Chapter 48: Antifungal Agents) is an alternative therapy for visceral leishmaniasis, especially in parts of India with high-level resistance to sodium stibogluconate, but its use is limited in developing countries by difficulty of administration, cost, and toxicity.

Miltefosine

Miltefosine is an alkylphosphocholine analog that has recently shown efficacy for the treatment of visceral leishmaniasis. In a recent phase III study, the drug was administered orally with daily doses of 2.5 mg/kg for 28 days and provided excellent clinical results. A 100 mg daily dose is recommended in adults. Vomiting and diarrhea are common but generally short-lived toxicities. Transient elevations in liver enzymes are also seen. The drug should be avoided in pregnancy because of its teratogenic effects. Miltefosine is registered for the treatment of visceral leishmaniasis in India, and—considering the serious limitations of other drugs, including parenteral administration, toxicity, and resistance—it may become the treatment of choice for that disease.

Preparations Available in the USA

Albendazole (Albenza)

Oral: 200 mg tablets

Atovaquone (Mepron)

Oral: 750 mg/5 mL suspension

Atovaquone-proguanil (Malarone)

Oral: 250 mg atovaquone + 100 mg proguanil tablets; pediatric 62.5 mg atovaquone + 25 mg proguanil tablets

Chloroquine (generic, Aralen)

Oral: 250, 500 mg tablets (equivalent to 150, 300 mg base, respectively)

Parenteral: 50 mg/mL (equivalent to 40 mg/mL base) for injection

Clindamycin (generic, Cleocin)

Oral: 75, 150, 300 mg capsules; 75 mg/5 mL suspension

Parenteral: 150 mg/mL for injection

Doxycycline (generic, Vibramycin)

Oral: 20, 50, 100 mg capsules; 50, 100 mg tablets; 25 mg/5 mL suspension; 50 mg/5 mL syrup

Parenteral: 100, 200 mg for injection

Dehydroemetine*

Eflornithine (Ornidyl)

Parenteral: 200 mg/mL for injection

Halofantrine (Halfan)

Oral: 250 mg tablets

Iodoquinol (Yodoxin)

Oral: 210, 650 mg tablets

Mefloquine (generic, Lariam)

Oral: 250 mg tablets

Melarsoprol (Mel B)*

Metronidazole (generic, Flagyl)

Oral: 250, 500 mg tablets; 375 mg capsules; extended-release 750 mg tablets

Parenteral: 5 mg/mL

Nifurtimox*

Nitazoxanide (Alinia)

Oral: powder for 100 mg/5 mL oral solution

Paromomycin (Humatin)

Oral: 250 mg capsules

Pentamidine (Pentam 300, Pentacarinat, pentamidine isethionate)

Parenteral: 300 mg powder for injection

Aerosol (Nebupent): 300 mg powder

Primaquine (generic)

Oral: 26.3 mg (equivalent to 15 mg base) tablet

Pyrimethamine (Daraprim)

Oral: 25 mg tablets

Quinidine gluconate (generic)

Parenteral: 80 mg/mL (equivalent to 50 mg/mL base) for injection

Quinine (generic)

Oral: 260 mg tablets; 200, 260, 325 mg capsules

Sodium stibogluconate*

Sulfadoxine and pyrimethamine (Fansidar)

Oral: 500 mg sulfadoxine plus 25 mg pyrimethamine tablets

Suramin*

* Available in the USA only from the Drug Service, CDC, Atlanta (404-639-3670).

Chapter 54. Clinical Pharmacology of the Anthelmintic Drugs

Katzung PHARMACOLOGY, 9e > Section VIII. Chemotherapeutic Drugs > Chapter 54. Clinical Pharmacology of the Anthelmintic Drugs >

Clinical Pharmacology of the Anthelmintic Drugs: Introduction

Table 54–1 lists the major helminthic infections and provides a guide to the drug of choice and alternative drugs for each infection. In the text that follows, these drugs are arranged alphabetically. In general, parasites should be identified before treatment is started.

Infesting Organism	Drug of Choice	Alternative Drugs
Roundworms (nematodes)		
<i>Ascaris lumbricoides</i> (roundworm)	Albendazole ¹ or pyrantel pamoate or mebendazole	Piperazine
<i>Trichuris trichiura</i> (whipworm)	Mebendazole or albendazole ¹	Oxantel/pyrantel pamoate ²
<i>Necator americanus</i> (hookworm); <i>Ancylostoma duodenale</i> (hookworm)	Pyrantel pamoate ¹ or mebendazole or albendazole ¹	
<i>Strongyloides stercoralis</i> (threadworm)	Ivermectin	Thiabendazole, albendazole ¹
<i>Enterobius vermicularis</i> (pinworm)	Mebendazole or pyrantel pamoate	Albendazole ¹
<i>Trichinella spiralis</i> (trichinosis)	Mebendazole; ¹ add corticosteroids for severe infection	Albendazole; ¹ add corticosteroids for severe infection
Trichostrongylus species	Pyrantel pamoate ¹ or mebendazole ¹	Albendazole ¹
Cutaneous larva migrans (creeping eruption)	Albendazole ¹ or ivermectin ¹	Thiabendazole (topical)
Visceral larva migrans	Albendazole ¹	Mebendazole ¹
<i>Angiostrongylus cantonensis</i>	Thiabendazole	Albendazole ¹ or

		mebendazole ¹
<i>Wuchereria bancrofti</i> (filariasis); <i>Brugia malayi</i> (filariasis); tropical eosinophilia; <i>Loa loa</i> (loiasis)	Diethylcarbamazine ³	Ivermectin ¹
<i>Onchocerca volvulus</i> (onchocerciasis)	Ivermectin	
<i>Dracunculus medinensis</i> (guinea worm)	Metronidazole ¹	Thiabendazole ¹ or mebendazole ¹
<i>Capillaria philippinensis</i> (intestinal capillariasis)	Albendazole ¹	Mebendazole ¹ or thiabendazole ¹
Flukes (trematodes)		
<i>Schistosoma haematobium</i> (bilharziasis)	Praziquantel	Metrifonate ²
<i>Schistosoma mansoni</i>	Praziquantel	Oxamniquine
<i>Schistosoma japonicum</i>	Praziquantel	
<i>Clonorchis sinensis</i> (liver fluke); opisthorchis species	Praziquantel	Albendazole ¹
<i>Paragonimus westermani</i> (lung fluke)	Praziquantel ¹	Bithionol ³
<i>Fasciola hepatica</i> (sheep liver fluke)	Bithionol ³ or triclabendazole ²	
<i>Fasciolopsis buski</i> (large intestinal fluke)	Praziquantel ¹ or niclosamide ²	
<i>Heterophyes heterophyes</i> ; <i>Metagonimus yokogawai</i> (small intestinal flukes)	Praziquantel ¹ or niclosamide ²	
Tapeworms (cestodes)		
<i>Taenia saginata</i> (beef tapeworm)	Praziquantel ¹ or niclosamide ²	Mebendazole ^{1,3}
<i>Diphyllobothrium latum</i> (fish tapeworm)	Praziquantel ¹ or niclosamide ²	
Tapeworms (cestodes)		
<i>Taenia solium</i> (pork tapeworm)	Praziquantel ¹ or niclosamide ²	
Cysticercosis (pork tapeworm larval stage)	Albendazole	Praziquantel ¹
<i>Hymenolepis nana</i> (dwarf tapeworm)	Praziquantel ¹	Niclosamide ²
<i>Echinococcus granulosus</i> (hydatid disease); <i>Echinococcus multilocularis</i>	Albendazole	

¹ Available in the USA but not labeled for this indication.

² Not available in the USA but available in some other countries.

³ Available in the USA only from the Parasitic Disease Drug Service, Parasitic Diseases Branch, Centers for Disease Control and Prevention, Atlanta 30333. Telephone 404-639-3670.

Katzung PHARMACOLOGY, 9e > Section VIII. Chemotherapeutic Drugs > Chapter 54. Clinical Pharmacology of the Anthelmintic Drugs >

Albendazole

Albendazole, a broad-spectrum oral anthelmintic, is the drug of choice and is approved in the USA for treatment of hydatid disease and cysticercosis. It is also used for the treatment of pinworm and hookworm infections, ascariasis, trichuriasis, and strongyloidiasis, though it is not labeled for these conditions.

Chemistry & Pharmacokinetics

Albendazole is a benzimidazole carbamate. After oral administration, it is erratically absorbed (increased with a fatty meal) and then rapidly undergoes first-pass metabolism in the liver to the active metabolite albendazole sulfoxide. It reaches variable maximum plasma concentrations about 3 hours after a 400 mg oral dose, and its plasma half-life is 8–12 hours. The sulfoxide is mostly protein-bound, distributes well to tissues, and enters bile, cerebrospinal fluid, and hydatid cysts. Albendazole metabolites are excreted in the urine.

Anthelmintic Actions

Benzimidazoles are thought to act against nematodes by inhibiting microtubule synthesis. Albendazole also has larvicidal effects in hydatid disease, cysticercosis, ascariasis, and hookworm infection and ovicidal effects in ascariasis, ancylostomiasis, and trichuriasis.

Clinical Uses

Albendazole is administered on an empty stomach when used against intraluminal parasites but with a fatty meal when used against tissue parasites.

Ascariasis, Trichuriasis, and Hookworm and Pinworm Infections

For adults and children over 2 years of age, the treatment is a single dose of 400 mg orally (repeated

for 2–3 days for heavy ascaris infections and in 2 weeks for pinworm infections). These treatments achieve high cure rates for these roundworm infections and marked reduction in egg counts in those not cured.

Hydatid Disease

Albendazole is the treatment of choice for medical therapy and is a useful adjunct to surgical removal or aspiration of cysts. It is more active against *E granulosus* than *E multilocularis*. Dosing is 400 mg twice daily with meals for 1 month or longer. Daily therapy for up to 6 months has been well tolerated. One reported therapeutic strategy is to treat with albendazole and praziquantel, to assess response after 1 month or more, and, depending on the response, to then manage the patient with continued chemotherapy or combined surgical and drug therapy.

Neurocysticercosis

Indications for medical therapy for neurocysticercosis are controversial, as anthelmintic therapy is not clearly superior to therapy with corticosteroids alone and may exacerbate neurologic disease. Therapy is probably most appropriate for symptomatic parenchymal or intraventricular cysts. Corticosteroids are usually given with the anthelmintic drug to decrease inflammation caused by dying organisms. Albendazole is now generally considered the drug of choice over praziquantel because of its shorter course, lower cost, improved penetration into the subarachnoid space, and increased drug levels (as opposed to decreased levels of praziquantel) when administered with corticosteroids. Albendazole is given in a dosage of 400 mg twice a day for up to 21 days.

Other Infections

Albendazole is the drug of choice in the treatment of **cutaneous larva migrans** (400 mg daily for 3 days), visceral larva migrans (400 mg twice daily for 5 days), **intestinal capillariasis** (400 mg daily for 10 days), microsporidial infections (400 mg twice daily for 2 weeks or longer), and **gnathostomiasis** (400 mg twice daily for 3 weeks). It also has activity against **trichinosis** (400 mg twice daily for 1–2 weeks) and **clonorchiasis** (400 mg twice daily for 1 week). There have been reports of some effectiveness in treatment of **opisthorchiasis**, **toxocariasis**, and **loiasis** and conflicting reports of effectiveness in **giardiasis** and **taeniasis**.

Adverse Reactions, Contraindications, & Cautions

When used for 1–3 days, albendazole is nearly free of significant adverse effects. Mild and transient epigastric distress, diarrhea, headache, nausea, dizziness, lassitude, and insomnia can occur. In long-term use for hydatid disease, albendazole is well tolerated, but it can cause abdominal distress, headaches, fever, fatigue, alopecia, increases in liver enzymes, and pancytopenia.

Blood counts and liver function studies should be followed during long-term therapy. The drug should not be given to patients with known hypersensitivity to other benzimidazole drugs or to those with cirrhosis. The safety of albendazole in pregnancy and in children under 2 years of age has not been established.

Katzung PHARMACOLOGY, 9e > Section VIII. Chemotherapeutic Drugs > Chapter 54. Clinical Pharmacology of the Anthelmintic Drugs >

Bithionol

Bithionol is the drug of choice for the treatment of **fascioliasis (sheep liver fluke)**. An alternative drug, triclabendazole, is not available in the USA.

Bithionol is also an alternative drug in the treatment of pulmonary paragonimiasis.

Pharmacokinetics

After ingestion, bithionol reaches peak blood levels in 4–8 hours. Excretion appears to be mainly via the kidney.

Clinical Uses

For treatment of paragonimiasis and fascioliasis, the dosage of bithionol is 30–50 mg/kg in two or three divided doses, given orally after meals on alternate days for 10–15 doses. For pulmonary paragonimiasis, cure rates are over 90%. For cerebral paragonimiasis, repeat courses of therapy may be necessary.

Adverse Reactions, Contraindications, & Cautions

Adverse effects, which occur in up to 40% of patients, are generally mild and transient, but occasionally their severity requires interruption of therapy. These problems include diarrhea, abdominal cramps, anorexia, nausea, vomiting, dizziness, and headache. Skin rashes may occur after a week or more of therapy, suggesting a reaction to antigens released from dying worms.

Bithionol should be used with caution in children under 8 years of age because there has been limited experience in this age group.

Katzung PHARMACOLOGY, 9e > Section VIII. Chemotherapeutic Drugs > Chapter 54. Clinical Pharmacology of the Anthelmintic Drugs >

Diethylcarbamazine Citrate

Diethylcarbamazine is a drug of choice in the treatment of filariasis, loiasis, and tropical eosinophilia. It has been replaced by ivermectin for the treatment of onchocerciasis.

Chemistry & Pharmacokinetics

Diethylcarbamazine, a synthetic piperazine derivative, is marketed as a citrate salt. It is rapidly absorbed from the gastrointestinal tract; after a 0.5 mg/kg dose, peak plasma levels are reached within 1–2 hours. The plasma half-life is 2–3 hours in the presence of acidic urine but about 10 hours if the urine is alkaline. The drug rapidly equilibrates with all tissues except fat. It is excreted, principally in the urine, as unchanged drug and the N-oxide metabolite. Dosage may have to be reduced in patients with persistent urinary alkalosis or renal impairment.

Anthelmintic Actions

Diethylcarbamazine immobilizes microfilariae and alters their surface structure, displacing them from tissues and making them more susceptible to destruction by host defense mechanisms. The mode of action against adult worms is unknown.

Clinical Uses

The drug should be taken after meals.

Wuchereria Bancrofti, Brugia Malayi, Brugia Timori, and Loa Loa

Diethylcarbamazine is the drug of choice for treatment of infections with these parasites because of its efficacy and lack of serious toxicity. Microfilariae of all species are rapidly killed; adult parasites are killed more slowly, often requiring several courses of treatment. The drug is highly effective against adult *L loa*. The extent to which *W bancrofti* and *B malayi* adults are killed is not known, but after appropriate therapy microfilariae do not reappear in the majority of patients.

These infections are treated for 2 or (for *L loa*) 3 weeks, with initial low doses to reduce the incidence of allergic reactions to dying microfilariae. This regimen is 50 mg (1 mg/kg in children) on day 1, three 50 mg doses on day 2, three 100 mg doses (2 mg/kg in children) on day 3, and then 2 mg/kg three times per day to complete the 2–3 week course.

Antihistamines may be given for the first few days of therapy to limit allergic reactions, and corticosteroids should be started and doses of diethylcarbamazine lowered or interrupted if severe reactions occur. Cures may require several courses of treatment.

Diethylcarbamazine may also be used for chemoprophylaxis (300 mg weekly or 300 mg on 3 successive days each month for loiasis; 50 mg monthly for bancroftian and Malayan filariasis).

Other Uses

For tropical eosinophilia, diethylcarbamazine is given orally at a dosage of 2 mg/kg three times daily for 7 days. Diethylcarbamazine is effective in *Mansonella streptocerca* infections, since it kills both adults and microfilariae. Limited information suggests that the drug is not effective, however, against adult *Mansonella ozzardi* or *M perstans* and that it has limited activity against microfilariae of these parasites. An important application of diethylcarbamazine has been its use for mass treatment of *W bancrofti* infections to reduce transmission. Weekly or monthly administration regimens have been studied; and, most recently, yearly treatment (with or without ivermectin) markedly reduced reservoirs of infection in Papua New Guinea.

Adverse Reactions, Contraindications, & Cautions

Reactions to diethylcarbamazine, which are generally mild and transient, include headache, malaise, anorexia, weakness, nausea, vomiting, and dizziness. Adverse effects also occur as a result of the release of proteins from dying microfilariae or adult worms. Reactions are particularly severe with onchocerciasis, but diethylcarbamazine is generally no longer used for this infection, as ivermectin is equally efficacious and less toxic. Reactions to dying microfilariae are usually mild in *W bancrofti*, more intense in *B malayi*, and occasionally severe in *L loa* infections. Reactions include fever, malaise, papular rash, headache, gastrointestinal symptoms, cough, chest pain, and muscle or joint pain. Leukocytosis is common. Eosinophilia may increase with treatment. Proteinuria may also occur. Symptoms are most likely to occur in patients with heavy loads of microfilariae. Retinal hemorrhages and, rarely, encephalopathy have been described.

Between the third and twelfth days of treatment, local reactions may occur in the vicinity of dying adult or immature worms. These include lymphangitis with localized swellings in *W bancrofti* and *B malayi*, small wheals in the skin in *L loa*, and flat papules in *M streptocerca* infections. Patients

with attacks of lymphangitis due to *W bancrofti* or *B malayi* should be treated during a quiescent period between attacks.

Caution is advised when using diethylcarbamazine in patients with hypertension or renal disease.

Katzung PHARMACOLOGY, 9e > Section VIII. Chemotherapeutic Drugs > Chapter 54. Clinical Pharmacology of the Anthelmintic Drugs >

Ivermectin

Ivermectin is the drug of choice in strongyloidiasis and onchocerciasis. It is also an alternative drug for a number of other helminthic infections.

Chemistry & Pharmacokinetics

Ivermectin, a semisynthetic macrocyclic lactone, is a mixture of avermectin B_{1a} and B_{1b}. It is derived from the soil actinomycete *Streptomyces avermitilis*.

Ivermectin is used only orally in humans. The drug is rapidly absorbed, reaching maximum plasma concentrations 4 hours after a 12 mg dose. The drug has a wide tissue distribution and a volume of distribution of about 50 L. Its half-life is about 16 hours. Excretion of the drug and its metabolites is almost exclusively in the feces.

Anthelmintic Actions

Ivermectin appears to paralyze nematodes and arthropods by intensifying GABA-mediated transmission of signals in peripheral nerves (see Chapter 52: Basic Principles of Antiparasitic Chemotherapy). In onchocerciasis, ivermectin is microfilaricidal. It does not effectively kill adult worms but blocks the release of microfilariae for some months after therapy. After a single standard dose, microfilariae in the skin diminish rapidly within 2–3 days, remain low for months, and then gradually increase; microfilariae in the anterior chamber of the eye decrease slowly over months, eventually clear, and then gradually return. With repeated doses of ivermectin, the drug does appear to have a low-level microfilaricidal action and to permanently reduce microfilarial production.

Clinical Uses

Onchocerciasis

Treatment is with a single oral dose of 150 µg/kg with water on an empty stomach. Doses are repeated; regimens vary from monthly to less frequent (every 6–12 months) dosing schedules. After acute therapy, treatment is repeated at 12-month intervals until the adult worms die, which may take 10 years or longer. With the first treatment only, patients with microfilariae in the cornea or anterior chamber may be treated with corticosteroids to avoid inflammatory eye reactions.

Ivermectin also now plays a key role in onchocerciasis control. Annual mass treatments have led to major reductions in disease transmission.

Strongyloidiasis

Treatment consists of two daily doses of 200 µg/kg. In immunosuppressed patients with

disseminated infection, repeated treatment is often needed, but cure may not be possible. In this case, suppressive therapy—ie, once monthly—may be helpful.

Other Parasites

Ivermectin reduces microfilariae in *Brugia malayi* and *Mansonella ozzardi* infections but not in *M. perstans* infections. It has been used with diethylcarbamazine for the control of *W. bancrofti*, but it does not kill adult worms, and whether it offers added benefit is uncertain. In **loiasis**, although the drug reduces microfilaria concentrations, it can occasionally induce severe reactions. Ivermectin is also effective in controlling **scabies**, **lice**, and **cutaneous larva migrans** and in eliminating a large proportion of **ascarid worms**.

Adverse Reactions, Contraindications, & Cautions

In strongyloidiasis treatment, infrequent side effects include fatigue, dizziness, nausea, vomiting, abdominal pain, and rashes. In onchocerciasis treatment, the adverse effects are principally from the Mazotti reaction, due to killing of microfilariae. The reaction includes fever, headache, dizziness, somnolence, weakness, rash, increased pruritus, diarrhea, joint and muscle pains, hypotension, tachycardia, lymphadenitis, lymphangitis, and peripheral edema. This reaction starts on the first day and peaks on the second day after treatment. The Mazotti reaction occurs in 5–30% of persons and is generally mild, but it may be more frequent and more severe in individuals who are not long-term residents of onchocerciasis-endemic areas. A more intense Mazotti reaction occurs in 1–3% of persons and a severe reaction in 0.1%, including high fever, hypotension, and bronchospasm. Corticosteroids are indicated in these cases, at times for several days. The Mazotti reaction diminishes with repeated dosing. Swellings and abscesses occasionally occur at 1–3 weeks, presumably at sites of adult worms.

Some patients develop corneal opacities and other eye lesions several days after treatment. These are rarely severe and generally resolve without corticosteroid treatment.

It is best to avoid concomitant use of ivermectin and other drugs that enhance GABA activity, eg, barbiturates, benzodiazepines, and valproic acid. Ivermectin should not be used in pregnancy. Safety in children under 5 years has not been established.

Katzung PHARMACOLOGY, 9e > Section VIII. Chemotherapeutic Drugs > Chapter 54. Clinical Pharmacology of the Anthelmintic Drugs >

Mebendazole

Mebendazole is a synthetic benzimidazole (compare with albendazole) that has a wide spectrum of anthelmintic activity and a low incidence of adverse effects.

Chemistry & Pharmacokinetics

Less than 10% of orally administered mebendazole is absorbed. The absorbed drug is protein-bound (> 90%), rapidly converted to inactive metabolites (primarily during its first pass in the liver), and has a half-life of 2–6 hours. It is excreted mostly in the urine, principally as decarboxylated derivatives. In addition, a portion of absorbed drug and its derivatives are excreted in the bile. Absorption is increased if the drug is ingested with a fatty meal.

Anthelmintic Actions

Mebendazole probably acts by inhibiting microtubule synthesis; the parent drug appears to be the active form. Efficacy of the drug varies with gastrointestinal transit time, with intensity of infection, and perhaps with the strain of parasite. The drug kills hookworm, ascaris, and trichuris eggs.

Clinical Uses

In the USA, mebendazole has been approved for use in ascariasis, trichuriasis, and hookworm and pinworm infection. It can be taken before or after meals; the tablets should be chewed before swallowing. For pinworm infection, the dose is 100 mg once, repeated at 2 weeks. For ascariasis, trichuriasis, hookworm, and trichostrongylus infections, a dosage of 100 mg twice daily for 3 days is used for adults and for children over 2 years of age. Cure rates are 90–100% for pinworm infections, ascariasis, and trichuriasis. Cure rates are lower for hookworm infections, but a marked reduction in the worm burden occurs in those not cured. For intestinal capillariasis, mebendazole is used at a dosage of 400 mg/d in divided doses for 21 or more days. In trichinosis, limited reports suggest efficacy against adult worms in the intestinal tract and tissue larvae. Treatment is three times daily, with fatty foods, at 200–400 mg per dose for 3 days and then 400–500 mg per dose for 10 days. Corticosteroids should be coadministered for severe infections.

Adverse Reactions, Contraindications, & Cautions

Short-term mebendazole therapy for intestinal nematodes is nearly free of adverse effects. Mild nausea, vomiting, diarrhea, and abdominal pain have been reported infrequently. Rare side effects, usually with high-dose therapy, are hypersensitivity reactions (rash, urticaria), agranulocytosis, alopecia, and elevation of liver enzymes.

Mebendazole is teratogenic in animals and therefore contraindicated in pregnancy. It should be used with caution in children under 2 years of age because of limited experience and rare reports of convulsions in this age group. Plasma levels may be decreased by concomitant use of carbamazepine or phenytoin and increased by cimetidine. Mebendazole should be used with caution in those with cirrhosis.

Metrifonate (Trichlorfon)

Metrifonate is a safe, low-cost alternative drug for the treatment of *Schistosoma haematobium* infections. It is not active against *S mansoni* or *S japonicum*. It is not available in the USA.

Chemistry & Pharmacokinetics

Metrifonate, an organophosphate compound, is rapidly absorbed after oral administration. Following the standard oral dose, peak blood levels are reached in 1–2 hours; the half-life is about 1.5 hours. Clearance appears to be through nonenzymatic transformation to dichlorvos, its active metabolite. Metrifonate and dichlorvos are well distributed to the tissues and are completely eliminated in 24–48 hours.

Anthelmintic Actions

The mode of action is thought to be related to cholinesterase inhibition. This inhibition temporarily paralyzes the adult worms, resulting in their shift from the bladder venous plexus to small arterioles of the lungs, where they are trapped, encased by the immune system, and die. The drug is not effective against *S haematobium* eggs; live eggs continue to pass in the urine for several months after all adult worms have been killed.

Clinical Uses

In the treatment of *S haematobium*, a single oral dose of 7.5–10 mg/kg is given three times at 14-day intervals. Cure rates on this schedule are 44–93%, with marked reductions in egg counts in those not cured. Metrifonate was also effective as a prophylactic agent when given monthly to children in a highly endemic area, and it has been used in mass treatment programs. In mixed infections with *S haematobium* and *S mansoni*, metrifonate has been successfully combined with oxamniquine.

Adverse Reactions, Contraindications, & Cautions

Some studies note mild and transient cholinergic symptoms, including nausea and vomiting, diarrhea, abdominal pain, bronchospasm, headache, sweating, fatigue, weakness, dizziness, and vertigo. These symptoms may begin within 30 minutes and persist up to 12 hours.

Metrifonate should not be used after recent exposure to insecticides or drugs that might potentiate cholinesterase inhibition. Metrifonate is contraindicated in pregnancy.

Niclosamide

Niclosamide is a second-line drug for the treatment of most tapeworm infections, but it is not available in the United States.

Chemistry & Pharmacokinetics

Niclosamide is a salicylamide derivative. It appears to be minimally absorbed from the gastrointestinal tract—neither the drug nor its metabolites have been recovered from the blood or urine.

Anthelmintic Actions

Adult worms (but not ova) are rapidly killed, presumably due to inhibition of oxidative phosphorylation or stimulation of ATPase activity.

Clinical Uses

The adult dose of niclosamide is 2 g once, given in the morning on an empty stomach. The tablets must be chewed thoroughly and are then swallowed with water.

T Saginata (Beef Tapeworm), *T Solium* (Pork Tapeworm), and *Diphyllobothrium Latum* (Fish Tapeworm)

A single 2 g dose of niclosamide results in cure rates of over 85% for *D latum* and about 95% for *T saginata*. It is probably equally effective against *T solium*. Cysticercosis is theoretically possible after treatment of *T solium* infections, since viable ova are released into the gut lumen following digestion of segments. However, no such cases of cysticercosis following therapy have been reported.

Other Tapeworms

Praziquantel is superior for *Hymenolepis nana* (dwarf tapeworm) infection. Most patients treated for *Hymenolepis diminuta* and *Dipylidium caninum* infections are cured with a 7-day course of treatment; a few require a second course. Niclosamide is not effective against cysticercosis or hydatid disease.

Intestinal Fluke Infections

Niclosamide can be used as an alternative drug for the treatment of *Fasciolopsis buski*, *Heterophyes heterophyes*, and *Metagonimus yokogawai* infections. The standard dose is given every other day for three doses.

Adverse Reactions, Contraindication, & Cautions

Infrequent, mild, and transitory adverse events include nausea, vomiting, diarrhea, and abdominal

discomfort.

The consumption of alcohol should be avoided on the day of treatment and for 1 day afterward.

The safety of the drug has not been established in pregnancy or for children under 2 years of age.

Katzung PHARMACOLOGY, 9e > Section VIII. Chemotherapeutic Drugs > Chapter 54. Clinical Pharmacology of the Anthelmintic Drugs >

Oxamniquine

Oxamniquine is an alternative to praziquantel for the treatment of *S mansoni* infections. It has also been used extensively for mass treatment. It is not effective against *S haematobium* or *S japonicum*.

Pharmacokinetics

Oxamniquine, a semisynthetic tetrahydroquinoline, is readily absorbed orally. Its plasma half-life is about 2.5 hours. The drug is extensively metabolized to inactive metabolites and excreted in the urine—up to 75% in the first 24 hours. Intersubject variations in serum concentration have been noted, which may explain some treatment failures.

Anthelmintic Actions

Oxamniquine is active against both mature and immature stages of *S mansoni* but does not appear to be cercaricidal. The mechanism of action is unknown. Contraction and paralysis of the worms results in detachment from terminal venules in the mesentery and transit to the liver, where many die; surviving females return to the mesenteric vessels but cease to lay eggs.

Strains of *S mansoni* in different parts of the world vary in susceptibility. Oxamniquine has been effective in instances of praziquantel resistance.

Clinical Uses

Oxamniquine is safe and effective in all stages of *S mansoni* disease, including advanced hepatosplenomegaly. In the acute (Katayama) syndrome, treatment results in disappearance of acute symptoms and clearance of the infection. The drug is generally less effective in children, who require higher doses than adults. It is better-tolerated with food.

Optimal dosage schedules vary for different regions of the world. In the Western Hemisphere and western Africa, the adult oxamniquine dosage is 12–15 mg/kg given once. In northern and southern Africa, standard schedules are 15 mg/kg twice daily for 2 days. In eastern Africa and the Arabian peninsula, standard dosage is 15–20 mg/kg twice in 1 day. Cure rates are 70–95%, with marked reduction in egg excretion in those not cured.

In mixed schistosome infections, oxamniquine has been successfully used in combination with metrifonate.

Adverse Reactions, Contraindications, & Cautions

Mild symptoms, starting about 3 hours after a dose and lasting for several hours, occur in more than

one third of patients. Central nervous system symptoms (dizziness, headache, drowsiness) are most common; nausea and vomiting, diarrhea, colic, pruritus, and urticaria also occur. Infrequent adverse effects are low-grade fever, an orange to red discoloration of the urine, proteinuria, microscopic hematuria, and a transient decrease in leukocytes. Seizures have been reported rarely.

Since the drug makes many patients dizzy or drowsy, it should be used with caution in patients whose work or activity requires mental alertness (eg, no driving for 24 hours). It should be used with caution in those with a history of epilepsy.

Oxamniquine is contraindicated in pregnancy.

Katzung PHARMACOLOGY, 9e > Section VIII. Chemotherapeutic Drugs > Chapter 54. Clinical Pharmacology of the Anthelmintic Drugs >

Piperazine

Piperazine is an alternative for the treatment of ascariasis, with cure rates over 90% when taken for 2 days, but it is not recommended for other helminth infections. Piperazine is available as the hexahydrate and as a variety of salts. It is readily absorbed, and maximum plasma levels are reached in 2–4 hours. Most of the drug is excreted unchanged in the urine in 2–6 hours, and excretion is complete within 24 hours.

Piperazine causes paralysis of ascaris by blocking acetylcholine at the myoneural junction; unable to maintain their position in the host, live worms are expelled by normal peristalsis.

For ascariasis, the dosage of piperazine (as the hexahydrate) is 75 mg/kg (maximum dose, 3.5 g) orally once daily for 2 days. For heavy infections, treatment should be continued for 3–4 days or repeated after 1 week.

Occasional mild adverse effects include nausea, vomiting, diarrhea, abdominal pain, dizziness, and headache. Neurotoxicity and allergic reactions are rare.

Piperazine compounds should not be given to women during pregnancy, to patients with impaired renal or hepatic function, or to those with a history of epilepsy or chronic neurologic disease.

Katzung PHARMACOLOGY, 9e > Section VIII. Chemotherapeutic Drugs > Chapter 54. Clinical Pharmacology of the Anthelmintic Drugs >

Praziquantel

Praziquantel is effective in the treatment of schistosome infections of all species and most other trematode and cestode infections, including cysticercosis. The drug's safety and effectiveness as a single oral dose have also made it useful in mass treatment of several infections.

Chemistry & Pharmacokinetics

Praziquantel is a synthetic isoquinoline-pyrazine derivative. It is rapidly absorbed, with a bioavailability of about 80% after oral administration. Peak serum concentrations are reached 1–3 hours after a therapeutic dose. Cerebrospinal fluid concentrations of praziquantel reach 14–20% of the drug's plasma concentration. About 80% of the drug is bound to plasma proteins. Most of the

drug is rapidly metabolized to inactive mono- and polyhydroxylated products after a first pass in the liver. The half-life is 0.8–1.5 hours. Excretion is mainly via the kidneys (60–80%) and bile (15–35%). Plasma concentrations of praziquantel increase when the drug is taken with a high-carbohydrate meal or with cimetidine; bioavailability is markedly reduced with some antiepileptics (phenytoin, carbamazepine) or with corticosteroids.

Anthelmintic Actions

Praziquantel appears to increase the permeability of trematode and cestode cell membranes to calcium, resulting in paralysis, dislodgement, and death.

In schistosome infections of experimental animals, praziquantel is effective against adult worms and immature stages and it has a prophylactic effect against cercarial infection.

Clinical Uses

Praziquantel tablets are taken with liquid after a meal; they should be swallowed without chewing because their bitter taste can induce retching and vomiting.

Schistosomiasis

Praziquantel is the drug of choice for all forms of schistosomiasis. The dosage is 20 mg/kg for two (*S mansoni* and *S haematobium*) or three (*S japonicum* and *S mekongi*) doses at intervals of 4–6 hours. High cure rates (75–95%) are achieved when patients are evaluated at 3–6 months; there is marked reduction in egg counts in those not cured. The drug is effective in adults and children and is generally well tolerated by patients in the hepatosplenic stage of advanced disease. It is not clear, however, whether the drug can be safely or effectively used during the acute stage of the disease (Katayama fever) because release of antigens from dying immature worms may exacerbate symptoms. Increasing evidence indicates rare *S mansoni* drug resistance, which is treatable with oxamniquine. Effectiveness of the drug for chemoprophylaxis has not been established.

Clonorchiasis, Opisthorchiasis, and Paragonimiasis

The dosage of 25 mg/kg three times for 1 day results in nearly 100% cure rates for clonorchiasis and opisthorchiasis, and a 2 day's course provides 90–100% cure rates for pulmonary paragonimiasis.

Taeniasis and Diphyllbothriasis

A single dose of praziquantel, 5–10 mg/kg, results in nearly 100% cure rates for *T saginata*, *T solium*, and *D latum* infections. For *T solium*, since praziquantel does not kill eggs, it is theoretically possible that larvae released from eggs in the large bowel could penetrate the intestinal wall and give rise to cysticercosis, but this hazard is probably minimal.

Neurocysticercosis

Albendazole is now the preferred drug, but when it is not appropriate or available, praziquantel has similar efficacy. Indications are similar to those for albendazole. The praziquantel dosage is 50 mg/kg/d in three divided doses for 14 days or longer. Clinical responses to therapy vary from dramatic improvements of seizures and other neurologic findings to no response and even progression of the disease. Praziquantel—but not albendazole—has diminished bioavailability when

taken concurrently with a corticosteroid. Recommendations on steroid use in neurocysticercosis vary.

H Nana

Praziquantel is the drug of choice for *H nana* infections and the first drug to be highly effective. A single dose of 25 mg/kg is taken initially and repeated in 1 week.

Hydatid Disease

In hydatid disease, praziquantel kills protoscoleces but does not affect the germinal membrane. Praziquantel is being evaluated as an adjunct with albendazole pre- and postsurgery. In addition to its direct action, praziquantel enhances the plasma concentration of albendazole sulfoxide.

Other Parasites

Limited trials at a dosage of 25 mg/kg three times a day for 1–2 days indicate effectiveness of praziquantel against fasciolopsiasis, metagonimiasis, and other forms of heterophyiasis. Praziquantel was not effective for fascioliasis, however, even at dosages as high as 25 mg/kg three times daily for 3–7 days.

Adverse Reactions, Contraindications, & Cautions

Mild and transient adverse effects are common. They begin within several hours after ingestion and may persist for hours to 1 day. Most frequent are headache, dizziness, drowsiness, and lassitude; others include nausea, vomiting, abdominal pain, loose stools, pruritus, urticaria, arthralgia, myalgia, and low-grade fever. Mild and transient elevations of liver enzymes have been reported. Several days after starting praziquantel, low-grade fever, pruritus, and skin rashes (macular and urticarial), sometimes associated with worsened eosinophilia, may occur, probably due to the release of proteins from dying worms rather than direct drug toxicity. The intensity and frequency of adverse effects increase with dosage such that they occur in up to 50% of patients who receive 25 mg/kg three times in 1 day.

In neurocysticercosis, neurologic abnormalities may be exacerbated by inflammatory reactions around dying parasites. Common findings in patients who do not receive corticosteroids, usually presenting during or shortly after therapy, are headache, meningismus, nausea, vomiting, mental changes, and seizures (often accompanied by increased cerebrospinal fluid pleocytosis). More serious findings, including arachnoiditis, hyperthermia, and intracranial hypertension, may also occur. Corticosteroids are commonly used with praziquantel in the treatment of neurocysticercosis to decrease the inflammatory reaction, but this is controversial, and complicated by knowledge that corticosteroids decrease the plasma level of praziquantel up to 50%. Praziquantel is contraindicated in ocular cysticercosis, as parasite destruction in the eye may cause irreparable damage. Some workers also caution against use of the drug in spinal neurocysticercosis.

The safety of praziquantel in children under age 4 years is not established, but no specific problems in young children have been documented. Indeed, the drug appears to be better tolerated in children than in adults. Praziquantel increased abortion rates in rats and therefore should be avoided in pregnancy if possible. Because the drug induces dizziness and drowsiness, patients should not drive during therapy and should be warned regarding activities requiring particular physical coordination or alertness.

Pyrantel Pamoate

Pyrantel pamoate is a broad-spectrum anthelmintic highly effective for the treatment of pinworm, ascaris, and *Trichostrongylus orientalis* infections. It is moderately effective against both species of hookworm. It is not effective in trichuriasis or strongyloidiasis. Oxantel pamoate, an analog of pyrantel not available in the USA, has been used successfully in the treatment of trichuriasis; the two drugs have been combined for their broad-spectrum anthelmintic activity.

Chemistry & Pharmacokinetics

Pyrantel pamoate is a tetrahydropyrimidine derivative. It is poorly absorbed from the gastrointestinal tract and active mainly against luminal organisms. Peak plasma levels are reached in 1–3 hours. Over half of the administered dose is recovered unchanged in the feces.

Anthelmintic Actions

Pyrantel is effective against mature and immature forms of susceptible helminths within the intestinal tract but not against migratory stages in the tissues or against ova. The drug is a neuromuscular blocking agent that causes release of acetylcholine and inhibition of cholinesterase; this results in paralysis, which is followed by expulsion of worms.

Clinical Uses

The standard dose is 11 mg (base)/kg (maximum, 1 g), given orally once with or without food. For pinworm the dose is repeated in 2 weeks, and cure rates are greater than 95%. The drug is available in the USA without prescription for this indication.

For ascariasis, a single dose yields cure rates of 85–100%. Treatment should be repeated if eggs are found 2 weeks after treatment. For hookworm infections, a single dose is effective against light infections; but for heavy infections, especially with *N americanus*, a 3-day course is necessary to reach 90% cure rates. A course of treatment can be repeated in 2 weeks.

Adverse Reactions, Contraindications, & Cautions

Adverse effects are infrequent, mild, and transient. They include nausea, vomiting, diarrhea, abdominal cramps, dizziness, drowsiness, headache, insomnia, rash, fever, and weakness. Pyrantel should be used with caution in patients with liver dysfunction, since low, transient aminotransferase elevations have been noted in a small number of patients. Experience with the drug in pregnant women and children under age 2 years is limited.

Thiabendazole

Thiabendazole is an alternative to ivermectin for the treatment of strongyloidiasis and cutaneous

larva migrans.

Chemistry & Pharmacokinetics

Thiabendazole is a benzimidazole compound. Although it is a chelating agent that forms stable complexes with a number of metals, including iron, it does not bind calcium.

Thiabendazole is rapidly absorbed after ingestion. With a standard dose, drug concentrations in plasma peak within 1–2 hours; the half-life is 1.2 hours. The drug is almost completely metabolized in the liver to the 5-hydroxy form; 90% is excreted in the urine in 48 hours, largely as the glucuronide or sulfonate conjugate. Thiabendazole can also be absorbed from the skin.

Anthelmintic Actions

The mechanism of action of thiabendazole is probably the same as that of other benzimidazoles (see above). The drug has ovicidal effects for some parasites.

Clinical Uses

The standard dosage, 25 mg/kg (maximum, 1.5 g) twice daily, should be given after meals. Tablets should be chewed. For strongyloides infection, treatment is for 2 days. Cure rates are reportedly 93%. A course can be repeated in 1 week if indicated. In patients with hyperinfection syndrome, the standard dose is continued twice daily for 5–7 days. For cutaneous larva migrans, thiabendazole cream can be applied topically or the oral drug can be given for 2 days (although albendazole is less toxic and therefore preferred).

Adverse Reactions, Contraindications, & Cautions

Thiabendazole is much more toxic than other benzimidazoles or ivermectin, so other agents are now preferred for most indications. Common adverse effects include dizziness, anorexia, nausea, and vomiting. Less frequent problems are epigastric pain, abdominal cramps, diarrhea, pruritus, headache, drowsiness, and neuropsychiatric symptoms. Irreversible liver failure and fatal Stevens-Johnson syndrome have been reported.

Experience with thiabendazole is limited in children weighing less than 15 kg. The drug should not be used in pregnancy or in the presence of hepatic or renal disease.

Katzung PHARMACOLOGY, 9e > Section VIII. Chemotherapeutic Drugs > Chapter 54. Clinical Pharmacology of the Anthelmintic Drugs >

Preparations Available

Albendazole (Albenza, Zentel)

Oral: 200 mg tablets; 100 mg/5 mL suspension

Note: Albendazole is approved in the USA for the treatment of cysticercosis and hydatid disease.

Bithionol (Bitin)

Oral: 200 mg tablets

Note: Bithionol is not marketed in the USA but is available from the Parasitic Disease Drug Service, Centers for Disease Control and Prevention, Atlanta; 404-639-3670.

Diethylcarbamazine (Hetrazan)

Oral: 50 mg tablets

Note: Diethylcarbamazine is no longer marketed in the USA but is available from the Parasitic Disease Drug Service, Centers for Disease Control and Prevention, Atlanta; 404-639-3670.

Ivermectin (Mectizan, Stromectol)

Oral: 3, 6 mg tablets

Note: Ivermectin is approved for use in the USA for the treatment of onchocerciasis and strongyloidiasis. See Chapter 66: Rational Prescribing & Prescription Writing for comment on the unlabeled use of drugs.

Levamisole (Decaris, Ethnor, Ketrax, Solaskil)

Oral: 50, 150 mg tablets and syrup

Mebendazole (generic, Vermox)

Oral: 100 mg chewable tablets; outside the USA, 100 mg/5 mL suspension

Metrifonate (trichlorfon, Bilarcil)

Oral: 100 mg tablets

Note: Metrifonate is not available in the USA.

Niclosamide (Niclocide)

Oral: 500 mg chewable tablets

Note: Niclosamide is not available in the USA.

Oxamniquine (Vansil, Mansil)

Oral: 250 mg capsules; outside the USA, 50 mg/mL syrup

Oxantel pamoate (Quantrel); oxantel/pyrantel pamoate (Telopar)

Oral: tablets containing 100 mg (base) of each drug; suspensions containing 20 or 50 mg (base) per mL

Note: Oxantel pamoate and oxantel/pyrantel pamoate are not available in the USA.

Piperazine (generic, Vermizine)

Oral: piperazine citrate tablets equivalent to 250 mg of the hexahydrate; piperazine citrate syrup equivalent to 500 mg of the hexahydrate per 5 mL

Praziquantel (Biltricide; others outside the USA)

Oral: 600 mg tablets (other strengths outside the USA)

Pyrantel pamoate (Antiminth, Combantrin, Pin-rid, Pin-X)

Oral: 50 mg (base)/mL suspension; 62.5 mg (base) capsules (available without prescription in the USA)

Suramin (Bayer 205, others)

Parenteral: ampules containing 0.5 or 1 g powder to be reconstituted as a 10% solution and used immediately

Note: Suramin is not marketed in the USA but can be obtained from the Parasitic Disease Drug Service, Centers for Disease Control, Atlanta, 404-639-3670.

Thiabendazole (Mintezol)

Oral: 500 mg chewable tablets; suspension, 500 mg/mL

Chapter 55. Cancer Chemotherapy

Cancer Chemotherapy: Introduction

Acronyms

ABVD: Doxorubicin (adriamycin), bleomycin, vinblastine, dacarbazine

CHOP: Cyclophosphamide, doxorubicin (hydroxydaunorubicin), vincristine (oncovin), prednisone

CMF: Cyclophosphamide, methotrexate, fluorouracil

COP: Cyclophosphamide, vincristine (oncovin), prednisone

FAC: Fluorouracil, doxorubicin (adriamycin), cyclophosphamide

FEC: Fluorouracil, epirubicin, cyclophosphamide

IFL: Irinotecan, fluorouracil, leucovorin

MP: Melphalan, prednisone

MOPP: Mechlorethamine, vincristine (oncovin), procarbazine, prednisone

PCV: Procarbazine, lomustine, vincristine

PEB: Cisplatin (platinum), etoposide, bleomycin

VAD: Vincristine, doxorubicin (adriamycin), dexamethasone

General

Cancer is basically a disease of cells characterized by a shift in the control mechanisms that govern cell proliferation and differentiation. Cells that have undergone neoplastic transformation usually express cell surface antigens that may be of normal fetal type, may display other signs of apparent immaturity, and may exhibit qualitative or quantitative chromosomal abnormalities, including various translocations and the appearance of amplified gene sequences. Such cells proliferate excessively and form local tumors that can compress or invade adjacent normal structures. A small subpopulation of cells within the tumor can be described as tumor stem cells. They retain the ability to undergo repeated cycles of proliferation as well as to migrate to distant sites in the body to colonize various organs in the process called metastasis. Such tumor stem cells thus can express clonogenic or colony-forming capability. Tumor stem cells often have chromosome abnormalities reflecting their genetic instability, which leads to progressive selection of subclones that can survive more readily in the multicellular environment of the host. Quantitative abnormalities in various metabolic pathways and cellular components accompany this neoplastic progression. The invasive and metastatic processes as well as a series of metabolic abnormalities resulting from the cancer cause illness and eventual death of the patient unless the neoplasm can be eradicated with treatment.

Causes of Cancer

The incidence, geographic distribution, and behavior of specific types of cancer are related to multiple factors, including sex, age, race, genetic predisposition, and exposure to environmental carcinogens. Of these factors, environmental exposure is probably most important. Chemical carcinogens (particularly those in tobacco smoke) as well as azo dyes, aflatoxins, asbestos, and benzene have been clearly implicated in cancer induction in humans and animals. Identification of potential carcinogens in the environment has been greatly simplified by the widespread use of the Ames test for mutagenic agents. Ninety percent of carcinogens can be shown to be mutagenic with this assay. Ultimate identification of potential human carcinogens, however, requires testing in at least two animal species.

Certain herpes and papilloma group DNA viruses and type C RNA viruses have also been implicated as causative agents in animal cancers and are responsible for some human cancers as well. Oncogenic RNA viruses all appear to contain a reverse transcriptase enzyme that permits translation of the RNA message of the tumor virus into the DNA code of the infected cell. Thus, the information governing transformation can become a stable part of the genome of the host cell. Expression of virus-induced neoplasia probably also depends on additional host and environmental factors that modulate the transformation process. A specific human retrovirus (HTLV-I) has been identified as being the causative agent for a specific type of human T cell leukemia. The virus that causes AIDS (HIV-1) is closely related. Cellular genes are known that are homologous to the transforming genes of the retroviruses, a family of RNA viruses, and induce oncogenic transformation. These mammalian cellular genes, known as oncogenes, have been shown to code for specific growth factors and their receptors and may be amplified (increased number of gene copies) or modified by a single nucleotide in malignant cells. The *bcl-2* oncogene may be a generalized cell death suppressor gene that directly regulates apoptosis, a pathway of programmed cell death.

Another class of genes, tumor suppressor genes, may be deleted or damaged, with resulting neoplastic change. A single gene in this class, the *p53* gene, has been shown to have mutated from a tumor suppressor gene to an oncogene in a high percentage of cases of several human tumors, including liver, breast, colon, lung, cervix, bladder, prostate, and skin. The normal wild form of this gene appears to play an important role in suppressing neoplastic transformation; mutations in this gene place the cell at high risk.

Cancer Therapeutic Modalities

Cancer is the second most common cause of death in the USA, after heart disease, causing over 500,000 fatalities annually. With present methods of treatment, one third of patients are cured with local modalities (surgery or radiation therapy), which are quite effective when the tumor has not metastasized by the time of treatment. Earlier diagnosis might lead to increased cure rates with such local treatment; however, in the remaining cases, early micrometastasis is a characteristic feature of the neoplasm, indicating that a systemic approach such as chemotherapy is required (often along with surgery or radiation) for effective cancer management. At present, about 50% of patients with cancer can be cured, with chemotherapy contributing to cure in 10–15% of patients.

Cancer chemotherapy, as currently employed, can be curative in certain disseminated neoplasms that have undergone either gross or microscopic spread by the time of diagnosis. These cancers include testicular cancer, non-Hodgkin's lymphoma, Hodgkin's disease, and choriocarcinoma as well as childhood cancers such as acute lymphoblastic leukemia, Burkitt's lymphoma, Wilms' tumor, and embryonal rhabdomyosarcoma. There are also growing numbers of cancers in which the use of chemotherapy combined with initial surgery can increase the cure rate in locally advanced early-stage breast cancer, esophageal cancer, rectal cancer, and osteogenic sarcoma.

For many other forms of disseminated cancer, chemotherapy provides palliative rather than curative therapy at present. Effective palliation results in temporary improvement of the symptoms and signs of cancer and enhancement in the overall quality of life. In the past decade, advances in cancer chemotherapy have also begun to provide evidence that chemical control of neoplasia may become a reality for many forms of cancer. This will probably be achieved through a combined-modality approach in which optimal combinations of surgery, radiotherapy, and chemotherapy are used to eradicate both the primary neoplasm and its occult micrometastases before gross spread can be detected on physical or x-ray examination. Use of hormonal agents to modulate tumor growth is playing an increasing role in hormone-responsive tumors thanks to the development of hormone antagonists and partial agonists. Several recombinant biologic agents have been identified as being active for cancer therapy, including interferon alfa and interleukin-2.

Anticancer Drug Development

A major effort to develop anticancer drugs through both empiric screening and rational design of new compounds has been under way for over 3 decades. Recent advances in this field have included the synthesis of peptides and proteins with recombinant DNA techniques and monoclonal antibodies. The drug development program has employed testing in a few well-characterized transplantable animal tumor systems. Simple in vitro assays for measuring drug sensitivity of a battery of human tumor cells augment and shorten the testing program and are used currently as the primary screening tests for new agents by the National Cancer Institute and many pharmaceutical firms. After new drugs with potential anticancer activity are identified, they are subjected to preclinical toxicologic and limited pharmacologic studies in animals as described in Chapter 5: Basic & Clinical Evaluation of New Drugs. Promising agents that do not have excessive toxicity are then advanced to phase I clinical trials, wherein their pharmacologic and toxic effects are usually tested in patients with advanced cancer. Other features of clinical testing are similar to the procedure for other drugs but may be accelerated.

Ideal anticancer drugs would eradicate cancer cells without harming normal tissues. Unfortunately, no currently available agents meet this criterion, and clinical use of these drugs involves a weighing of benefits against toxicity in a search for a favorable therapeutic index.

Classes of drugs that have recently entered clinical development include signal transduction inhibitors, focused on critical signaling pathways essential for cell growth and proliferation; microtubule inhibitors, directed against the mitotic spindle apparatus; differentiation agents, intended to force neoplastic cells past a maturation block to form end-stage cells with little or no proliferative potential; antimetastatic drugs, designed to perturb surface properties of malignant cells and thus alter their invasive and metastatic potential; antiangiogenic agents, designed to inhibit the formation of tumor vasculature; hypoxic tumor stem cell-specific agents, designed to exploit the greater capacity for reductive reactions in these often therapeutically resistant cells; tumor radiosensitizing and normal tissue radioprotecting drugs, aimed at increased therapeutic effectiveness of radiation therapy; cytoprotective agents, focused on protecting certain normal tissues against the toxic effects of chemotherapy; and biologic response modifiers, which alter tumor-host metabolic and immunologic relationships.

Importance of Neoplastic Cell Burden

Patients with widespread cancer may have up to 10^{12} tumor cells throughout the body at the time of diagnosis (Figure 55–1). If tolerable dosing of an effective drug is capable of killing 99.99% of clonogenic tumor cells, treatment would induce a clinical remission of the neoplasm associated with symptomatic improvement. However, there would still be up to 8 logs of tumor cells (10^8) remaining in the body, including those that might be inherently resistant to the drug because of tumor heterogeneity. There may also be other tumor cells that reside in pharmacologic sanctuary sites (eg, the central nervous system, testes), where effective drug concentrations may be difficult to achieve. When cell cycle-specific drugs are used, the tumor stem cells must also be in the sensitive phase of the cell cycle (not in G_0). For this reason, scheduling of these agents is particularly important. In common bacterial infections, a three-log reduction in microorganisms might be curative because host resistance factors can eliminate residual bacteria through immunologic and microbicidal mechanisms; however, host mechanisms for eliminating even moderate numbers of cancer cells appear to be generally ineffective.

Figure 55–1.

The log-kill hypothesis. Relationship of tumor cell number to time of diagnosis, symptoms, treatment, and survival. Three alternative approaches to drug treatment are shown for comparison with the course of tumor growth when no treatment is given (*dashed line*). In the protocol diagrammed at top, treatment (indicated by the arrows) is given infrequently and the result is manifested as prolongation of survival but with recurrence of symptoms between courses of treatment and eventual death of the patient. The combination chemotherapy treatment diagrammed in the middle section is begun earlier and is more intensive. Tumor cell kill exceeds regrowth, drug resistance does not develop, and "cure" results. In this example, treatment has been continued long after all clinical evidence of cancer has disappeared (1–3 years). This approach has been established as effective in the treatment of childhood acute leukemia, testicular cancers, and Hodgkin's disease. In the treatment diagrammed near the bottom of the graph, early surgery has been employed to remove the primary tumor and intensive adjuvant chemotherapy has been administered long enough (up to 1 year) to eradicate the remaining tumor cells that comprise the occult micrometastases.

Combinations of agents with differing toxicities and mechanisms of action are often employed to overcome the limited log kill of individual anticancer drugs. If drugs display nonoverlapping toxicities, they can be used at almost full dosage, and at least additive cytotoxic effects can be achieved with combination chemotherapy; furthermore, subclones resistant to only one of the agents can potentially be eradicated. Some combinations of anticancer drugs also appear to exert true synergism, wherein the effect of the two drugs is greater than additive. The efficacy of combination chemotherapy has now been validated in many forms of human cancer, and the scientific rationale appears to be sound. As a result, combination chemotherapy is now the standard approach to curative treatment of testicular cancer and lymphomas and to palliative treatment of many other tumor types. This important therapeutic approach was first formulated by Skipper and Schabel and described as the log-kill hypothesis (Figure 55–1).

Growth of acute leukemias and aggressive lymphomas closely follows exponential cell kinetics. In contrast, most human solid tumors do not grow in such a manner; instead, they follow a Gompertzian model of tumor growth and regression. Under Gompertzian kinetics, the growth fraction of the tumor is not constant and peaks when the tumor is about one third of its maximum size.

Importance of Cell Cycle Kinetics

Information on cell and population kinetics of cancer cells explains, in part, the limited effectiveness of most available anticancer drugs. A schematic summary of cell cycle kinetics is presented in Figure 55–2. This information is relevant to the mode of action, indications, and scheduling of **cell cycle-specific (CCS)** and **cell cycle-nonspecific (CCNS)** drugs. Agents falling into these two major classes are summarized in Table 55–1.

Table 55–1. Cell Cycle Effects of Major Classes of Anticancer Drugs.

Cell Cycle-Specific (CCS) Agents	Cell Cycle-Nonspecific (CCNS) Agents
Antimetabolites	Alkylating agents
Capecitabine	Busulfan
Cladribine	Carmustine
Cytarabine	Cyclophosphamide
Fludarabine	Lomustine
Fluorouracil	Mechlorethamine
Gemcitabine	Melphalan
Mercaptopurine	Thiotepa
Methotrexate	Anthracyclines
Thioguanine	Daunorubicin
Antitumor antibiotic	Doxorubicin
Bleomycin	Epirubicin
Epipodophyllotoxins	Idarubicin
Etoposide	Mitoxantrone
Teniposide	Antitumor antibiotics
Taxanes	Dactinomycin
Docetaxel	Mitomycin
Paclitaxel	Camptothecins
Vinca alkaloids	Irinotecan
Vinblastine	Topotecan
Vincristine	Platinum analogs
Vinorelbine	Carboplatin
	Cisplatin

Figure 55–2.

The cell cycle and cancer. A conceptual depiction of the cell cycle phases that all cells—normal and neoplastic—must traverse before and during cell division. The percentages given represent the approximate percentage of time spent in each phase by a typical malignant cell; the duration of G₁, however, can vary markedly. Many of the effective anticancer drugs exert their action on cells traversing the cell cycle and are called cell cycle-specific (CCS) drugs (Table 55–1). A second group of agents called cell cycle-nonspecific (CCNS) drugs can sterilize tumor cells whether they are cycling or resting in the G₀ compartment. CCNS drugs can kill both G₀ and cycling cells (although cycling cells are more sensitive).

In general, CCS drugs are most effective in hematologic malignancies and in solid tumors in which a relatively large proportion of the cells are proliferating or are in the growth fraction. CCNS drugs (many of which bind to cellular DNA and damage these macromolecules) are particularly useful in low growth fraction solid tumors as well as in high growth fraction tumors. In all instances, effective agents sterilize or inactivate tumor stem cells, which are often only a small fraction of the cells within a tumor. Non-stem cells (eg, those that have irreversibly differentiated) are considered sterile by definition and are not a significant component of the cancer problem.

Resistance to Cytotoxic Drugs

A major problem in cancer chemotherapy is drug resistance. Some tumor types, eg, malignant melanoma, renal cell cancer, and brain cancer, exhibit *primary* resistance, ie, absence of response on the first exposure, to currently available standard agents. The presence of inherent drug resistance is felt to be tightly associated with the genomic instability associated with the development of most cancers. *Acquired* resistance develops in a number of drug-sensitive tumor types. Experimentally, drug resistance can be highly specific to a single drug and usually is based on a change in the genetic apparatus of a given tumor cell with amplification or increased expression of one or more specific genes. In other instances, a multidrug-resistant phenotype occurs—resistance to a variety of natural product anticancer drugs of differing structures developing after exposure to a single agent. This form of multidrug resistance is often associated

with increased expression of a normal gene (the *MDR1* gene) for a cell surface glycoprotein (P-glycoprotein) involved in drug efflux. This transport molecule requires ATP to expel a variety of foreign molecules (not limited to antitumor drugs) from the cell. It is expressed constitutively in normal tissues such as the epithelial cells of the kidney, large intestine, and adrenal gland as well as in a variety of tumors. Multidrug resistance can be reversed experimentally by calcium channel blockers, such as verapamil, and a variety of other drugs, which inhibit the transporter. Other mechanisms of multiple drug resistance involve overexpression of the multidrug resistance protein 1 (MRP1), a member of the ATP-binding cassette transmembrane transporter superfamily that now consists of nine members (MRP1-MRP9). MRP1, the most extensively studied, increases resistance to natural product drugs such as anthracyclines, vinca alkaloids, taxanes, and epipodophyllotoxins by functioning as a drug export pump.

Katzung PHARMACOLOGY, 9e > Section VIII. Chemotherapeutic Drugs > Chapter 55. Cancer Chemotherapy >

Basic Pharmacology of Cancer Chemotherapeutic Drugs

Polyfunctional Alkylating Agents

The major clinically useful alkylating agents (Figure 55–3) have a structure containing a bis-(chloroethyl)amine, ethyleneimine, or nitrosourea moiety. Among the bis(chloroethyl)amines, cyclophosphamide, mechlorethamine, melphalan, and chlorambucil are the most useful. Ifosfamide is closely related to cyclophosphamide but has a somewhat different spectrum of activity and toxicity. Thiotepa and busulfan are used for specialized purposes for ovarian cancer and chronic myeloid leukemia, respectively. The major nitrosoureas are carmustine (BCNU), lomustine (CCNU), and semustine (methyl-CCNU). A variety of investigational alkylating agents have been synthesized that link various carrier molecules such as amino acids, nucleic acid bases, hormones, or sugar moieties to a group capable of alkylation; however, successful site-directed alkylation has not been achieved to date.

Figure 55–3.

As a class, the alkylating agents exert cytotoxic effects via transfer of their alkyl groups to various cellular constituents. Alkylations of DNA within the nucleus probably represent the major interactions that lead to cell death. However, these drugs react chemically with sulfhydryl, amino, hydroxyl, carboxyl, and phosphate groups of other cellular nucleophiles as well. The general mechanism of action of these drugs involves intramolecular cyclization to form an ethyleneimonium ion that may directly or through formation of a carbonium ion transfer an alkyl group to a cellular constituent. In addition to alkylation, a secondary mechanism that occurs with nitrosoureas involves carbamylation of lysine residues of proteins through formation of isocyanates.

The major site of alkylation within DNA is the N7 position of guanine (Figure 55-4); however, other bases are also alkylated to lesser degrees, including N1 and N3 of adenine, N3 of cytosine,

and O6 of guanine, as well as phosphate atoms and proteins associated with DNA. These interactions can occur on a single strand or on both strands of DNA through cross-linking, as most major alkylating agents are bifunctional, with two reactive groups. Alkylation of guanine can result in miscoding through abnormal base pairing with thymine or in depurination by excision of guanine residues. The latter effect leads to DNA strand breakage through scission of the sugar-phosphate backbone of DNA. Cross-linking of DNA appears to be of major importance to the cytotoxic action of alkylating agents, and replicating cells are most susceptible to these drugs. Thus, although alkylating agents are not cell cycle-specific, cells are most susceptible to alkylation in late G₁ and S phases of the cell cycle and express block in G₂.

Figure 55–4.

Drug Resistance

The mechanism of acquired resistance to alkylating agents may involve increased capability to repair DNA lesions, decreased permeability of the cell to the alkylating drug, and increased production of glutathione, which inactivates the alkylating agent through conjugation or through increased glutathione *S*-transferase activity, which catalyzes the conjugation.

Pharmacologic Effects

Active alkylating agents have direct vesicant effects and can damage tissues at the site of injection as well as produce systemic toxicity. Toxicities are generally dose-related and occur particularly in

rapidly growing tissues such as bone marrow, the gastrointestinal tract, and the reproductive system. After intravenous injection, nausea and vomiting usually occur within 30–60 minutes with mechlorethamine, cyclophosphamide, or carmustine. The emetogenic effects are mediated by the central nervous system and can be reduced by pretreatment with 5-HT₃ (serotonin) receptor antagonists such as ondansetron or granisetron. Subcutaneous injection of mechlorethamine or carmustine leads to tissue necrosis and sloughing.

Cyclophosphamide in its parent form does not have direct cytotoxic effects, and it must be activated to cytotoxic forms by microsomal enzymes (Figure 55–5). The liver microsomal cytochrome P450 mixed-function oxidase system converts cyclophosphamide to 4-hydroxycyclophosphamide, which is in equilibrium with aldophosphamide. These active metabolites are believed to be delivered by the bloodstream to both tumor and normal tissue, where nonenzymatic cleavage of aldophosphamide to the cytotoxic forms—phosphoramidate mustard and acrolein—occurs. The liver appears to be protected through the enzymatic formation of the inactive metabolites 4-ketocyclophosphamide and carboxyphosphamide.

Figure 55–5.

The major toxicities of alkylating agents are set forth in Table 55–2 and discussed below.

Table 55–2. Alkylating Agents: Dosages and Toxicities.

Alkylating Agent	Single-Agent Dosage	Acute Toxicity	Delayed Toxicity
Mechlorethamine	0.4 mg/kg IV in single or divided doses	Nausea and vomiting, myelosuppression	Moderate depression of peripheral blood count; excessive doses produce severe bone marrow depression with leukopenia, thrombocytopenia, and bleeding; alopecia and hemorrhagic cystitis occasionally occur with cyclophosphamide; cystitis can be prevented with adequate hydration; busulfan is associated with skin pigmentation, pulmonary fibrosis, and adrenal insufficiency
Chlorambucil	0.1–0.2 mg/kg/d orally; 6–12 mg/d	Nausea and vomiting, myelosuppression	
Cyclophosphamide	3.5–5 mg/kg/d orally for 10 days; 1 g/m ² IV as single dose	Nausea and vomiting, myelosuppression	
Melphalan	0.25 mg/kg/d orally for 4 days every 4–6 weeks	Nausea and vomiting, myelosuppression	
Thiotepa (triethylenethiophosphoramide)	0.2 mg/kg IV for 5 days	Nausea and vomiting, myelosuppression	
Busulfan	2–8 mg/d orally; 150–250 mg/course	Nausea and vomiting, myelosuppression	
Carmustine (BCNU)	200 mg/m ² IV every 6 weeks	Nausea and vomiting	Leukopenia, thrombocytopenia, and rarely hepatitis
Lomustine (CCNU)	150 mg/m ² orally every 6 weeks	Nausea and vomiting	
Altretamine	10 mg/kg/d for 21 days	Nausea and vomiting	Leukopenia, thrombocytopenia, and peripheral neuropathy
Procarbazine	50–200 mg/d orally	Nausea and vomiting, flu-like syndrome, drug interactions	Bone marrow depression, central nervous system depression, leukemogenic
Dacarbazine	300 mg/m ² daily IV for 5	Nausea and vomiting	Bone marrow depression

	days		
Cisplatin	20 mg/m ² /d IV for 5 days or 50–70 mg/m ² as single dose every 3 weeks	Nausea and vomiting, myelosuppression	Nephrotoxicity, peripheral sensory neuropathy, ototoxicity, nerve dysfunction.
Carboplatin	AUC 5–7 mgxmin/mL	Myelosuppression, nausea and vomiting	Rarely: peripheral neuropathy, renal toxicity, and hepatic dysfunction
Oxaliplatin	130 mg/m ² IV every 3 weeks or 85 mg/m ² IV every 2 weeks	Nausea and vomiting, laryngopharyngeal dysesthesias	Peripheral sensory neuropathy, diarrhea, myelosuppression, and renal toxicity

Oral administration of alkylating agents has been of great value, and this approach has been developed using relatively less reactive alkylating drugs. Cyclophosphamide, melphalan, chlorambucil, busulfan, and, more recently, temozolomide are those most commonly given via the oral route, and their cytotoxic effects are similar to those observed with parenteral administration. In general, if a tumor is resistant to one alkylating agent, it will be relatively resistant to other agents of this class (though not necessarily to nitrosoureas); however, there are exceptions to this rule depending on the specific tumor. Cyclophosphamide is the most widely used alkylating agent. The oral drug busulfan has a major degree of specificity for the granulocyte series and is therefore of particular value in therapy of chronic myelogenous leukemia. With all oral alkylating agents, some degree of leukopenia is necessary to provide evidence that the drug has been absorbed adequately. Frequent monitoring of blood counts is essential during administration of these agents as the development of severe leukopenia or thrombocytopenia necessitates immediate interruption of therapy.

Nitrosoureas

These drugs appear to be non-cross-resistant with other alkylating agents; all require biotransformation, which occurs by nonenzymatic decomposition, to metabolites with both alkylating and carbamoylating activities. The nitrosoureas are highly lipid-soluble and cross the blood-brain barrier, making them useful in the treatment of brain tumors. The nitrosoureas appear to function by cross-linking through alkylation of DNA. The drugs may be more effective against plateau phase cells than exponentially growing cells, though within a cycling cell population these agents appear to slow cell progression through the DNA synthetic phase. After oral administration of lomustine, peak plasma levels of metabolites appear within 1–4 hours; central nervous system concentrations reach 30–40% of the activity present in the plasma. While the initial plasma half-life is in the range of 6 hours, a second half-life is in the range of 1–2 days. Urinary excretion appears to be the major route of elimination from the body. One naturally occurring sugar-containing nitrosourea, streptozocin, is interesting because it has minimal bone marrow toxicity. This agent has activity in the treatment of insulin-secreting islet cell carcinoma of the pancreas.

Related Drugs Probably Acting As Alkylating Agents

A variety of other compounds have mechanisms of action that involve alkylation. These include procarbazine, dacarbazine, altretamine (hexamethylmelamine), cisplatin, and carboplatin. Dosages and major toxicities are listed in Table 55–2.

Procarbazine

The oral agent procarbazine is a methylhydrazine derivative, and it is commonly used in combination regimens for Hodgkin's disease, non-Hodgkin's lymphoma, and brain tumors. The drug is also leukemogenic and has teratogenic and mutagenic properties.

The mechanism of action of procarbazine is uncertain; however, the drug inhibits the synthesis of DNA, RNA, and protein; prolongs interphase; and produces chromosome breaks. Oxidative metabolism of this drug by microsomal enzymes generates azoprocarbazine and H_2O_2 , which may be responsible for DNA strand scission. A variety of other metabolites of the drug are formed that may be cytotoxic. One metabolite is a weak monoamine oxidase (MAO) inhibitor, and adverse side effects can occur when procarbazine is given with other MAO inhibitors.

There is an increased risk of secondary cancers in the form of acute leukemia, and the carcinogenic potential of procarbazine is felt to be higher than that of most other alkylating agents.

Dacarbazine

Dacarbazine is a synthetic compound that functions as an alkylating agent following metabolic activation by liver microsomal enzymes by oxidative N-demethylation to the monomethyl derivative. This metabolite spontaneously decomposes to 5-aminoimidazole-4-carboxamide, which is excreted in the urine, and diazomethane. The diazomethane generates a methyl carbonium ion that is believed to be the likely cytotoxic species. Dacarbazine is administered parenterally and is not schedule-dependent. It produces marked nausea, vomiting, and myelosuppression. Its major applications are in melanoma, Hodgkin's disease, and soft tissue sarcomas.

Altretamine (Hexamethylmelamine)

Altretamine is structurally similar to triethylenemelamine. It is relatively insoluble and available only in oral form. It is rapidly biotransformed in the liver by demethylation to the pentamethylmelamine and tetramethylmelamine metabolites. This agent is approved for use in ovarian cancer patients who have progressed despite treatment with a regimen based on platinum or an alkylating agent (or both). The main dose-limiting toxicities include nausea, vomiting, and myelosuppression. Neurotoxicity in the form of somnolence, mood changes, and peripheral neuropathy is also observed.

Cisplatin, Carboplatin, & Oxaliplatin

Cisplatin (*cis*-diamminedichloroplatinum [II]) is an inorganic metal complex discovered through the serendipitous observation that neutral platinum complexes inhibited division and induced filamentous growth of *Escherichia coli*. Several platinum analogs have been subsequently synthesized. While the precise mechanism of action of cisplatin is still undefined, it is thought to act in somewhat the same way as alkylating agents. It kills cells in all stages of the cell cycle, inhibits DNA biosynthesis, and binds DNA through the formation of interstrand cross-links. The primary binding site is the N7 of guanine, but covalent interaction with adenine and cytosine also occurs.

The platinum complexes appear to synergize with certain other anticancer drugs. Aggressive hydration with intravenous saline infusion alone or with saline and mannitol or other diuretics appears to significantly reduce the incidence of nephrotoxicity.

Cisplatin has major antitumor activity in a broad range of solid tumors, including non-small cell and small cell lung cancer, esophageal and gastric cancer, head and neck cancer, and genitourinary cancers, particularly testicular, ovarian, and bladder cancer. When used in combination regimens with vinblastine and bleomycin or etoposide and bleomycin, cisplatin-based therapy has led to the cure of nonseminomatous testicular cancer.

Carboplatin is a second-generation platinum analog that exerts its cytotoxic effects exactly as cisplatin and has activity against the same spectrum of solid tumors. Its main dose-limiting toxicity is myelosuppression, and it has significantly less renal toxicity and gastrointestinal toxicity than cisplatin. Moreover, vigorous intravenously hydration is not required. As a result, carboplatin is now being used in place of cisplatin in combination chemotherapy.

Oxaliplatin is a third generation diaminocyclohexane platinum analog. Its mechanism of action is identical to that of cisplatin and carboplatin. However, it is not cross-resistant to cancer cells that are resistant to cisplatin or carboplatin on the basis of mismatch repair defects. This agent was recently approved for use as second-line therapy in metastatic colorectal cancer following treatment with the combination of fluorouracil-leucovorin and irinotecan, and it is now widely used as first-line therapy of this disease as well. Neurotoxicity is dose-limiting and characterized by a peripheral sensory neuropathy, often triggered or worsened upon exposure to cold. While this neurotoxicity is cumulative, it tends to be reversible—in contrast to cisplatin-induced neurotoxicity.

Clinical Uses of the Alkylating Agents

The alkylating agents are used in the treatment of a wide variety of hematologic and solid cancers, generally as part of a combination regimen. They are discussed along with various specific tumors (below).

Antimetabolites (Structural Analogs)

The development of drugs with actions on intermediary metabolism of proliferating cells has been important both clinically and conceptually. While biochemical properties unique to all cancer cells have yet to be discovered, neoplastic cells do have a number of quantitative differences in metabolism from normal cells that render them more susceptible to a number of antimetabolites or structural analogs. Many of these agents have been rationally designed and synthesized based on knowledge of cellular processes, and a few have been discovered as antibiotics.

Mechanisms of Action

The biochemical pathways that have thus far proved to be most vulnerable to antimetabolites have been those relating to nucleotide and nucleic acid synthesis. In a number of instances, when an enzyme is known to have a major effect on pathways leading to cell replication, inhibitors of the

reaction it catalyzes have proved to be useful anticancer drugs.

These drugs and their doses and toxicities are shown in Table 55–3. The principal drugs are discussed below.

Table 55–3. Antimetabolites: Dosages and Toxicities.		
Chemotherapeutic Agent	Single-Agent Dosage	Delayed Toxicity ¹
Capecitabine	1250 mg/m ² /bid orally for 14 days followed by 1 week of rest. Repeat every 3 weeks.	Diarrhea, hand-and-foot syndrome, ² myelosuppression, nausea and vomiting
Cladribine	0.09 mg/kg/d for 7 days by continuous IV infusion in sterile saline	Myelosuppression, nausea and vomiting, and immunosuppression
Cytarabine	100 mg/m ² /d for 5–10 days, either by continuous IV infusion or SC every 8 hours.	Nausea and vomiting, bone marrow depression, stomatitis, and cerebellar ataxia
Fludarabine	25 mg/m ² /d for 5 days every 28 days (administer IV over 30 minutes)	Myelosuppression, immunosuppression, fever, myalgias, and arthralgias
Fluorouracil	15 mg/kg/d IV for 5 days by 24-hour infusion; 15 mg/kg weekly IV	Nausea, mucositis, diarrhea, myelosuppression, hand and foot syndrome, and neurotoxicity
Gemcitabine	1000 mg/m ² IV weekly for up to 7 weeks followed by 1 week of rest	Nausea, vomiting, diarrhea, myelosuppression
Mercaptopurine	2.5 mg/kg/d orally	Myelosuppression, immunosuppression, and hepatotoxicity
Methotrexate	2.5–5 mg/d orally (Rheumatrex); 10 mg intrathecally (Folex) once or twice weekly	Mucositis, diarrhea, bone marrow depression with leukopenia and thrombocytopenia
Thioguanine	2 mg/kg/d orally	Myelosuppression, immunosuppression, and hepatotoxicity

¹These drugs do not cause acute toxicity.

²Hand and foot syndrome is a form of erythromelalgia manifested as tingling, numbness, pain, erythema, swelling, and increased pigmentation.

Methotrexate

Methotrexate (MTX) is a folic acid antagonist that binds to the active catalytic site of dihydrofolate reductase (DHFR), interfering with the synthesis of the reduced form that accepts one-carbon units. Lack of this cofactor interrupts the synthesis of thymidylate, purine nucleotides, and the amino acids serine and methionine, thereby interfering with the formation of DNA, RNA, and proteins. The enzyme binds methotrexate with high affinity, and at pH 6.0, virtually no dissociation of the enzyme-inhibitor complex occurs (inhibition constant about 1 nmol/L). At physiologic pH, reversible competitive kinetics occur (inhibition constant about 1 μ mol/L). Intracellular formation of polyglutamate derivatives appears to be important in the therapeutic action of methotrexate. The polyglutamates of methotrexate are selectively retained within cancer cells and have increased inhibitory effects on enzymes involved in folate metabolism, making them important determinants of the duration of action of methotrexate.

Drug Resistance

Tumor cell resistance to methotrexate has been attributed to (1) decreased drug transport, (2) decreased polyglutamate formation, (3) synthesis of increased levels of DHFR through gene amplification, and (4) altered DHFR with reduced affinity for methotrexate. Recent studies have also suggested that decreased accumulation of drug through activation of the multidrug resistance P170 glycoprotein transporter may also result in drug resistance.

Dosage & Toxicity

Methotrexate is administered by the intravenous, intrathecal, or oral route. Up to 90% of an oral dose is excreted in the urine within 12 hours. The drug is not subject to metabolism, and serum levels are therefore proportionate to dose as long as renal function and hydration status are adequate. Dosages and toxic effects are listed in Table 55–3. The effects of methotrexate can be reversed by administration of leucovorin (citrovorum factor). Leucovorin rescue has been used with accidental overdose or experimentally along with high-dose methotrexate therapy in a protocol intended to rescue normal cells while still leaving the tumor cells subject to its cytotoxic action.

Other Applications

Methotrexate is also used in the treatment of rheumatoid arthritis (Chapter 36: Nonsteroidal Anti-Inflammatory Drugs, Disease-Modifying Antirheumatic Drugs, Nonopioid Analgesics, & Drugs Used in Gout) and psoriasis.

Purine Antagonists

6-Thiopurines

Mercaptopurine (6-MP) was the first of the thiopurine series found useful as an anticancer drug. Like other thiopurines, it must be metabolized by hypoxanthine-guanine phosphoribosyl transferase (HGPRT) to the nucleotide form (6-thioinosinic acid), which in turn inhibits a number of the enzymes of purine nucleotide interconversion. Significant amounts of thioguanlylic acid and 6-methylmercaptopurine ribotide (MMPR) are also formed from 6-MP. These metabolites may also contribute to the action of the mercaptopurine. Mercaptopurine is used primarily in the treatment of childhood acute leukemia, and a closely related analog, azathioprine, is used as an immunosuppressive agent (see Chapter 56: Immunopharmacology).

Thioguanine (6-TG) inhibits several enzymes in the purine nucleotide pathway. A variety of metabolic lesions are associated with the cytotoxic action of the purinethiols. These include inhibition of purine nucleotide interconversion; decrease in intracellular levels of guanine nucleotides, which leads to inhibition of glycoprotein synthesis; interference with the formation of DNA and RNA; and incorporation of thiopurine nucleotides into both DNA and RNA. 6-TG has a synergistic action when used together with cytarabine in the treatment of adult acute leukemia.

Drug Resistance

Resistance to both 6-MP and 6-TG occurs most commonly by decrease in HGPRT activity; an alternative mechanism in acute leukemia involves elevation of levels of alkaline phosphatase, which results in dephosphorylation of thiopurine nucleotide and cellular loss of the resulting ribonucleoside.

Dosage & Toxicity

Mercaptopurine and thioguanine are both given orally (Table 55–3) and excreted mainly in the urine. However, 6-MP is converted to an inactive metabolite (6-thiouric acid) by an oxidation catalyzed by xanthine oxidase, whereas 6-TG requires deamination before it is metabolized by this enzyme. This factor is important because the purine analog allopurinol, a potent xanthine oxidase inhibitor, is frequently used with chemotherapy in hematologic cancers to prevent hyperuricemia after tumor cell lysis. It does this by blocking purine oxidation, allowing excretion of cellular purines that are relatively more soluble than uric acid. Nephrotoxicity and acute gout produced by excessive uric acid are thereby prevented. Simultaneous therapy with allopurinol and 6-MP results in excessive toxicity unless the dose of mercaptopurine is reduced to 25% of the usual level. This effect does not occur with 6-TG, which can be used in full doses with allopurinol.

Fludarabine Phosphate

Fludarabine phosphate (2-fluoro-arabinofuranosyladenine monophosphate) is rapidly dephosphorylated to 2-fluoro-arabinofuranosyladenine and then phosphorylated intracellularly by deoxycytidine kinase to the triphosphate. This metabolite interferes with DNA synthesis through inhibition of DNA polymerase- α and ribonucleotide reductase, and it also induces apoptosis. Fludarabine phosphate is used chiefly in the treatment of low-grade non-Hodgkin's lymphoma and chronic lymphocytic leukemia (CLL). Fludarabine phosphate is given parentally and is excreted primarily in the urine; its dose-limiting toxicity is myelosuppression.

Cladribine

Cladribine (2-chlorodeoxyadenosine) achieves high intracellular concentrations because of its resistance to adenosine deaminase; it is phosphorylated by deoxycytidine kinase and is incorporated into DNA. Cladribine causes DNA strand breaks (presumably through interference with DNA repair) and loss of NAD (through activation of poly[ADP-ribose]synthase). Cladribine is indicated for the treatment of hairy cell leukemia and is also used for CLL and low-grade non-Hodgkin's lymphoma. It is normally administered as a single continuous 7-day infusion; under these conditions, its toxicity usually consists of transient myelosuppression. In addition, it is an immunosuppressive agent, and a decrease in CD4 and CD8 cells, lasting for over 1 year, occurs in most patients.

Pyrimidine Antagonists

Fluorouracil

5-Fluorouracil (5-FU) is a prodrug and undergoes a complex series of biotransformation reactions to ribosyl and deoxyribosyl nucleotide metabolites. One of these metabolites, 5-fluoro-2'-deoxyuridine-5'-monophosphate (FdUMP), forms a covalently bound ternary complex with the enzyme thymidylate synthase and the reduced folate $N^{5,10}$ -methylenetetrahydrofolate, a reaction critical for the synthesis of thymidylate. This results in inhibition of DNA synthesis through "thymineless death." 5-FU is converted to 5-fluorouridine-5'-triphosphate (FUTP), which is then incorporated into RNA, where it interferes with RNA processing and mRNA translation. In

addition, 5-FU is converted to 5-fluorodeoxyuridine-5'-triphosphate (FdUTP), which can be incorporated into cellular DNA, resulting in inhibition of DNA synthesis and function. Thus, the cytotoxicity of fluorouracil is felt to be the result of effects on both DNA- and RNA-mediated events.

Fluorouracil is normally given intravenously (Table 55–3) and has a short metabolic half-life on the order of 15 minutes. It is not administered by the oral route because its bioavailability is erratic due to the high levels of the breakdown enzyme dihydropyrimidine dehydrogenase present in the gut mucosa. Floxuridine (5-fluoro-2'-deoxyuridine, FUDR) has an action similar to that of fluorouracil, and it is only used for hepatic artery infusions. A cream incorporating fluorouracil is used topically for treating basal cell cancers of the skin.

Fluorouracil is the most widely used agent for the treatment of colorectal cancer, both as adjuvant therapy as well as for advanced disease. In addition, it has activity against a wide variety of solid tumors, including cancers of the breast, stomach, pancreas, esophagus, liver, head and neck, and anus. Its major toxicities are listed in Table 55–3.

Capecitabine

Capecitabine is a fluoropyrimidine carbamate prodrug that has nearly 70–80% oral bioavailability. It undergoes extensive metabolism in the liver by the enzyme carboxylesterase to an intermediate, 5'-deoxy-5-fluorocytidine. This in turn is converted to 5'-deoxy-5-fluorouridine by the enzyme cytidine deaminase. The 5'-deoxy-5-fluorouridine metabolite is then hydrolyzed by thymidine phosphorylase to fluorouracil in the tumor. (The expression of thymidine phosphorylase is significantly higher in a broad range of solid tumors than in corresponding normal tissue.) Peak plasma levels are achieved in about 1.5 hours, and peak fluorouracil levels are reached at 2 hours after oral administration.

Capecitabine is used in the treatment of metastatic breast cancer as either a single agent or in combination with the taxane docetaxel. It has recently been approved for use in the treatment of metastatic colorectal cancer as monotherapy, and significant efforts are now directed at using this agent in combination with either irinotecan or oxaliplatin. The main toxicities of capecitabine are listed in Table 55–3. While myelosuppression, nausea and vomiting, and mucositis can be observed with this agent, the incidence is significantly less than that seen with intravenous fluorouracil.

Cytarabine

Cytarabine (cytosine arabinoside, ara-C) is an S phase-specific antimetabolite that is converted by deoxycytidine kinase to the 5'-mononucleotide (AraCMP). AraCMP is further metabolized to the triphosphate (AraCTP), which competitively inhibits DNA polymerase and results in blockade of DNA synthesis. Cytarabine is also incorporated into RNA and DNA. Incorporation into DNA leads to interference with chain elongation and defective ligation of fragments of newly synthesized

DNA. The cellular retention time for AraCTP appears to correlate with its lethality to malignant cells.

After intravenous administration (Table 55–3), the drug is cleared rapidly, with most being deaminated to an inactive form. The ratio of the anabolic enzyme deoxycytidine kinase to the inactivating catalyst cytidine deaminase is important in determining the cytotoxicity of cytarabine.

In view of cytarabine's S phase specificity, the drug is highly schedule-dependent and must be given either by continuous infusion or every 8–12 hours for 5–7 days. Its activity is limited almost entirely to treatment of acute myelogenous leukemia, for which it is a major drug. Adverse effects are listed in Table 55–3.

Gemcitabine

Gemcitabine is phosphorylated initially by the enzyme deoxycytidine kinase and then by other nucleoside kinases to the di- and triphosphate nucleotide forms, which then inhibit DNA synthesis. Inhibition is considered to result from two actions: inhibition of ribonucleotide reductase by gemcitabine diphosphate, which reduces the level of deoxyribonucleoside triphosphates required for the synthesis of DNA; and incorporation of gemcitabine triphosphate into DNA. Following incorporation of gemcitabine nucleotide, only one additional nucleotide can be added to the growing DNA strand, resulting in chain termination.

Gemcitabine was initially approved for use in pancreatic cancer but is now widely used in the treatment of non-small cell lung cancer and bladder cancer. Myelosuppression is the principal dose-limiting toxicity.

Plant Alkaloids

Vinblastine

Vinblastine is an alkaloid derived from *Vinca rosea*, the periwinkle plant. Its mechanism of action involves depolymerization of microtubules, which are an important part of the cytoskeleton and the mitotic spindle. The drug binds specifically to the microtubule protein tubulin in dimeric form; the drug-tubulin complex adds to the forming end of the microtubules to terminate assembly, and depolymerization of the microtubules then occurs. This results in mitotic arrest at metaphase, dissolution of the mitotic spindle, and interference with chromosome segregation. Toxicity includes nausea and vomiting, bone marrow suppression, and alopecia. It has clinical activity in the treatment of Hodgkin's disease, non-Hodgkin's lymphomas, breast cancer, and germ cell cancer. See clinical section below and Table 55–4.

Table 55–4. Natural Product Cancer Chemotherapy Drugs: Dosages and Toxicities.

Drug	Single-Agent Dosage	Acute Toxicity	Delayed Toxicity
Bleomycin	Up to 15 units/m ² IV twice weekly to a total dose of 200–250 units	Allergic reactions, fever, hypotension	Skin toxicity, pulmonary fibrosis, mucositis, alopecia
Dactinomycin (actinomycin D)	0.04 mg/kg IV weekly	Nausea and vomiting	Stomatitis, gastrointestinal tract upset, alopecia, bone marrow depression
Daunorubicin (daunomycin)	30–60 mg/m ² daily IV for 3 days, or 30–60 mg/m ² IV weekly	Nausea, fever, red urine (not hematuria)	Cardiotoxicity (see text), alopecia, bone marrow depression

Docetaxel	100 mg/m ² IV over 1 hour every 3 weeks	Hypersensitivity, rash	Neurotoxicity, fluid retention, neutropenia
Doxorubicin (Adriamycin)	60 mg/m ² daily IV for 3 days, or 30–60 mg/m ² IV weekly	Nausea, red urine (not hematuria)	Cardiotoxicity (see text), alopecia, bone marrow depression, stomatitis
Etoposide (VP-16)	50–100 mg/m ² daily for 5 days	Nausea, vomiting, hypotension	Alopecia, bone marrow depression
Idarubicin	12 mg/m ² IV daily for 3 days (with cytarabine)	Nausea and vomiting	Bone marrow depression, mucositis, cardiotoxicity
Irinotecan	125 mg/m ² IV once weekly for 4 weeks; repeat every 6 weeks or 300–350 mg/m ² IV every 3 weeks	Diarrhea, nausea, vomiting	Diarrhea, bone marrow depression, nausea and vomiting, liver function abnormalities
Mitomycin	20 mg/m ² IV every 6 weeks	Nausea	Thrombocytopenia, anemia, leukopenia, mucositis
Paclitaxel	130–170 mg/m ² IV over 3 or 24 hours every 3–4 weeks	Nausea, vomiting, hypotension, arrhythmias, hypersensitivity	Bone marrow depression, peripheral sensory neuropathy
Topotecan	1.5 mg/m ² IV for 5 days, repeat every 21 days for 4 courses	Nausea and vomiting	Bone marrow depression, arthralgias
Vinblastine	0.1–0.2 mg/kg IV weekly	Nausea and vomiting	Alopecia, loss of reflexes, bone marrow depression
Vincristine	1.5 mg/m ² IV (maximum: 2 mg weekly)	None	Areflexia, muscle weakness, peripheral neuritis, paralytic ileus, mild bone marrow depression, alopecia
Vinorelbine	30 mg/m ² IV weekly	Nausea and vomiting	Bone marrow depression, fatigue, constipation, hyporeflexia, paresthesias

Vincristine

Vincristine is also an alkaloid derivative of *Vinca rosea* and is closely related in structure to vinblastine. Its mechanism of action is considered to be identical to that of vinblastine in that it functions as a mitotic spindle poison leading to arrest of cells in the M phase of the cell cycle. Despite these similarities to vinblastine, vincristine has a strikingly different spectrum of clinical

activity and qualitatively different toxicities.

Vincristine has been effectively combined with prednisone for remission induction in acute lymphoblastic leukemia in children. It is also active in various hematologic malignancies such as Hodgkin's and non-Hodgkin's lymphoma and multiple myeloma and in several pediatric tumors including rhabdomyosarcoma, neuroblastoma, Ewing's sarcoma, and Wilms' tumor. The main dose-limiting toxicity is neurotoxicity, usually expressed as a peripheral sensory neuropathy, although autonomic nervous system dysfunction—with orthostatic hypotension, sphincter problems, and paralytic ileus—cranial nerve palsies, ataxia, seizures, and coma have been observed. While myelosuppression can occur, it is generally milder and much less significant than with vinblastine. The other potential side effect that can develop is the syndrome of inappropriate secretion of antidiuretic hormone (SIADH).

Vinorelbine

Vinorelbine is a semisynthetic vinca alkaloid whose mechanism of action is identical to that of vinblastine and vincristine, ie, inhibition of mitosis of cells in the M phase through inhibition of tubulin polymerization. Despite its similarities in mechanism of action, vinorelbine has activity in non-small cell lung cancer and in breast cancer. Myelosuppression with neutropenia is the dose-limiting toxicity, but nausea and vomiting, transient elevations in liver function tests, neurotoxicity, and SIADH are also reported.

Epipodophyllotoxins

Two compounds, **VP-16 (etoposide)** and a related drug, **VM-26 (teniposide)**, are semisynthetic derivatives of podophyllotoxin, which is extracted from the mayapple root (*Podophyllum peltatum*). Both an intravenous and an oral formulation of etoposide are approved for clinical use in the USA.

Etoposide and teniposide are similar in chemical structure and in their effects—they block cell division in the late S-G₂ phase of the cell cycle. Their primary mode of action involves inhibition of topoisomerase II, which results in DNA damage through strand breakage induced by the formation of a ternary complex of drug, DNA, and enzyme. The drugs are water-insoluble and need to be formulated in a Cremophor vehicle for clinical use. These agents are administered via the intravenous route (Table 55–4) and are rapidly and widely distributed throughout the body except for the brain. Up to 90–95% of drug is protein-bound, mainly to albumin. Dose reduction is required in the setting of renal dysfunction. Etoposide has clinical activity in germ cell cancer, small cell and non-small cell lung cancer, Hodgkin's and non-Hodgkin's lymphomas, and gastric cancer and as high-dose therapy in the transplant setting for breast cancer and lymphomas. Teniposide's use is limited to acute lymphoblastic leukemia.

Camptothecins

The camptothecins are natural products that are derived from the *Camptotheca acuminata* tree, and they inhibit the activity of topoisomerase I, the key enzyme responsible for cutting and religating single DNA strands. Inhibition of the enzyme results in DNA damage. **Topotecan** is indicated in the treatment of patients with advanced ovarian cancer who have failed platinum-based chemotherapy and is also approved as second-line therapy of small cell lung cancer. The main route of elimination is renal excretion, and for this reason caution must be exercised in patients with abnormal renal function, with dosage reduction being required.

Irinotecan is a prodrug that is converted mainly in the liver by the carboxylesterase enzyme to the

SN-38 metabolite, which is a potent inhibitor of topoisomerase I. In contrast to topotecan, irinotecan and SN-38 are mainly eliminated in bile and feces, and dose reduction is required in the setting of liver dysfunction. Irinotecan is indicated as second-line monotherapy in patients with metastatic colorectal cancer who have failed fluorouracil-based therapy and as first-line therapy when used in combination with fluorouracil and leucovorin. Myelosuppression and diarrhea are the two most common adverse events. There are two forms of diarrhea: an early form that occurs within 24 hours after administration and is felt to be a cholinergic event effectively treated with atropine, and a late form which usually occurs 3–10 days after treatment. The late diarrhea can be severe, leading to significant electrolyte imbalance and dehydration in some cases.

Taxanes

Paclitaxel is an alkaloid ester derived from the Western yew (*Taxus brevifolia*) and the European yew (*Taxus baccata*). The drug functions as a mitotic spindle poison through high-affinity binding to microtubules with enhancement of tubulin polymerization. This promotion of microtubule assembly by paclitaxel occurs in the absence of microtubule-associated proteins and guanosine triphosphate and results in inhibition of mitosis and cell division.

Paclitaxel has significant activity in a wide variety of solid tumors, including ovarian, advanced breast, non-small cell and small cell lung, head and neck, esophageal, prostate, and bladder cancer and AIDS-related Kaposi's sarcoma. It is metabolized extensively by the liver P450 system, and nearly 80% of the drug is excreted in feces. For this reason, dose reduction is required in the setting of liver dysfunction. The primary dose-limiting toxicities are listed in Table 55–4. Hypersensitivity reactions may be observed in up to 5% of patients, but the incidence can be reduced by premedication with dexamethasone, diphenhydramine, and an H₂ blocker.

Docetaxel is a semisynthetic taxane derived from the European yew tree. Its mechanism of action, metabolism, and elimination are identical to those of paclitaxel. It is approved for use as second-line therapy in advanced breast cancer and non-small cell lung cancer, and it also has major activity in head and neck cancer, small cell lung cancer, gastric cancer, advanced platinum-refractory ovarian cancer, and bladder cancer. Its major toxicities are listed in Table 55–4.

Antitumor Antibiotics

Screening of microbial products has led to the discovery of a number of growth inhibiting compounds that have proved to be clinically useful in cancer chemotherapy. Many of these antibiotics bind to DNA through intercalation between specific bases and block the synthesis of RNA, DNA, or both; cause DNA strand scission; and interfere with cell replication. All of the anticancer antibiotics now being used in clinical practice are products of various strains of the soil microbe *Streptomyces*. These include the anthracyclines, dactinomycin, bleomycin, and mitomycin.

Anthracyclines

The anthracycline antibiotics, isolated from *Streptomyces peucetius* var *caesius*, are among the most widely used cytotoxic anticancer drugs. Two congeners, **doxorubicin** and **daunorubicin**, are FDA-approved, and their structures are shown below. Several other anthracycline analogs have entered clinical practice, including idarubicin, epirubicin, and mitoxantrone. Daunorubicin was the first agent in this class to be isolated, and it is still used in the treatment of acute myeloid leukemia. Doxorubicin has a broad spectrum of clinical activity against hematologic malignancies as well as a wide range of solid tumors. The entire class of anthracyclines exert their cytotoxic action through four major mechanisms. These are (1) inhibition of topoisomerase II; (2) high-affinity binding to

DNA through intercalation, with consequent blockade of the synthesis of DNA and RNA, and DNA strand scission; (3) binding to cellular membranes to alter fluidity and ion transport; and (4) generation of semiquinone free radicals and oxygen free radicals through an enzyme-mediated reductive process. This latter mechanism has now been established as being the cause of the drug's cardiac toxicity.

In the clinical setting, anthracyclines are administered via the intravenous route (Table 55–4). The anthracyclines are metabolized extensively in the liver, with reduction and hydrolysis of the ring substituents. The hydroxylated metabolite is an active species, whereas the aglycone is inactive. Up to 50% of drug is eliminated in the feces via biliary excretion, and for this reason dose reduction is required in the setting of liver dysfunction. Although anthracyclines are usually administered on an every-3-week schedule, alternative schedules of administration such as low-dose weekly or 72–96 hour continuous infusions have been shown to yield equivalent clinical efficacy with reduced overall toxicity.

Doxorubicin is one of the most important anticancer drugs, with major clinical activity in carcinomas of the breast, endometrium, ovary, testicle, thyroid, stomach, bladder, liver, and lung; in soft tissue sarcomas; and in several childhood cancers, including neuroblastoma, Ewing's sarcoma, osteosarcoma, and rhabdomyosarcoma. It is also widely used in hematologic malignancies, including acute lymphoblastic leukemia, multiple myeloma, and Hodgkin's and non-Hodgkin's lymphomas. It is generally used in combination with other anticancer agents (eg, cyclophosphamide, cisplatin, and fluorouracil), and responses and remission duration tend to be improved with combination regimens as opposed to single-agent therapy. Daunorubicin has a far narrower spectrum of activity than doxorubicin. Daunorubicin has been mainly used for the treatment of acute myeloid leukemia, although there has been a shift in clinical practice toward using idarubicin, an analog of daunorubicin. Its efficacy in solid tumors appears to be limited.

Idarubicin is a semisynthetic anthracycline glycoside analog of daunorubicin and is approved for use in combination with cytarabine for induction therapy of acute myeloid leukemia. When combined with cytarabine, idarubicin appears to be more active than daunorubicin in producing complete remissions and in improving survival in patients with acute myelogenous leukemia.

Epirubicin is a doxorubicin analog whose mechanism of action is identical to that of all other anthracyclines. It was initially approved for use as a component of adjuvant therapy of early-stage,

node-positive breast cancer but is now also used for the treatment of metastatic breast cancer.

The main dose-limiting toxicity of all anthracyclines is myelosuppression, with neutropenia more commonly observed than thrombocytopenia. In some cases, mucositis is dose-limiting. Two forms of cardiotoxicity are observed. The acute form occurs within the first 2–3 days and presents as arrhythmias or conduction abnormalities, other electrocardiographic changes, pericarditis, and myocarditis. This form is usually transient and is asymptomatic in most cases. The chronic form results in a dose-dependent, dilated cardiomyopathy associated with heart failure. The chronic cardiac toxicity appears to result from increased production of free radicals within the myocardium. This effect is rarely seen at total doxorubicin dosages below 500–550 mg/m². Use of lower weekly doses or continuous infusions of doxorubicin appear to reduce the incidence of cardiac toxicity. In addition, treatment with the iron-chelating agent dexrazoxane (ICRF-187) is currently approved to prevent or reduce anthracycline-induced cardiotoxicity in women with metastatic breast cancer who have received a total cumulative dose of doxorubicin of 300 mg/m². All anthracyclines can produce "radiation recall reaction," with erythema and desquamation of the skin observed at sites of prior radiation therapy.

Mitoxantrone

Mitoxantrone (dihydroxyanthracenedione, DHAD) is an anthracene compound whose structure resembles the anthracycline ring. It binds to DNA to produce strand breakage and inhibits both DNA and RNA synthesis. It is currently used for treatment of advanced, hormone-refractory prostate cancer and low-grade non-Hodgkin's lymphoma. It is also indicated in breast cancer as well as in pediatric and adult acute myeloid leukemias. The plasma half-life of mitoxantrone in patients is approximately 75 hours, and it is predominantly excreted via the hepatobiliary route in feces. Myelosuppression with leukopenia is the dose-limiting toxicity, and mild nausea and vomiting, mucositis, and alopecia also occur. While the drug is felt to be less cardiotoxic than doxorubicin, both acute and chronic cardiac toxicity are reported. A blue discoloration of the fingernails, sclera, and urine can be observed up to 1–2 days after drug therapy.

Dactinomycin

Dactinomycin is an antitumor antibiotic isolated from a *Streptomyces* organism. It binds tightly to double-stranded DNA through intercalation between adjacent guanine-cytosine base pairs and inhibits all forms of DNA-dependent RNA synthesis, with ribosomal RNA formation being most sensitive to drug action.

Dactinomycin is mainly used to treat pediatric tumors such as Wilms' tumor, rhabdomyosarcoma, and Ewing's sarcoma, but it has activity also against germ cell tumors and gestational trophoblastic disease. Dactinomycin can also induce a "radiation recall reaction." See Table 55–4 for other toxicities.

Mitomycin

Mitomycin (mitomycin C) is an antibiotic isolated from *Streptomyces caespitosus*. It is an alkylating agent that undergoes metabolic activation through an enzyme-mediated reduction to generate an alkylating agent that cross-links DNA. Hypoxic tumor stem cells of solid tumors exist in an environment conducive to reductive reactions and are more sensitive to the cytotoxic actions of mitomycin than normal cells and oxygenated tumor cells. It is thought to be a CCNS alkylating agent, and it is the best available drug for use in combination with radiation therapy to attack hypoxic tumor cells. Its main clinical use is in the treatment of squamous cell cancer of the anus

along with fluorouracil and radiation therapy. In addition, it is used in combination chemotherapy for squamous cell carcinoma of the cervix and for adenocarcinomas of the stomach, pancreas, and lung. One special application of mitomycin has been in the intravesical treatment of superficial bladder cancer. Because virtually none of the agent is absorbed systemically, there is little or no systemic toxicity.

See Table 55–4 for common toxicities. The hemolytic-uremic syndrome, manifested as microangiopathic hemolytic anemia, thrombocytopenia, and renal failure, as well as occasional instances of interstitial pneumonitis have been reported.

Bleomycin

Bleomycin is a small peptide that contains a DNA-binding region and an iron-binding domain at opposite ends of the molecule. It acts by binding to DNA, which results in single-strand and double-strand breaks following free radical formation, and inhibition of DNA biosynthesis. The fragmentation of DNA is due to oxidation of a DNA-bleomycin-Fe(II) complex and leads to chromosomal aberrations. Bleomycin is a CCS drug that causes accumulation of cells in the G₂ phase of the cell cycle.

Bleomycin is indicated for the treatment of Hodgkin's and non-Hodgkin's lymphomas, germ cell tumor, head and neck cancer, and squamous cell cancer of the skin, cervix, and vulva. In addition, it can be used as a sclerosing agent for malignant pleural effusions and ascites. One advantage of this agent is that it can be given subcutaneously, intramuscularly, or intravenously (Table 55–4). Peak blood levels of bleomycin after intramuscular injection appear within 30–60 minutes. Intravenous injection of similar dosages yields higher peak concentrations and a terminal half-life of about 2.5 hours. Elimination of bleomycin is mainly via renal excretion; for this reason, dose modification is recommended in the setting of renal dysfunction.

Pulmonary toxicity is dose-limiting for bleomycin and usually presents as pneumonitis with cough, dyspnea, dry inspiratory crackles on physical examination, and infiltrates on chest x-ray. The incidence of this adverse event is increased in patients older than 70 years of age and with cumulative doses greater than 400 units. In rare cases, pulmonary toxicity can be fatal. Other toxicities are listed in Table 55–4.

Hormonal Agents

Steroid Hormones & Antisteroid Drugs

The relationship between hormones and hormone-dependent tumors was initially demonstrated in 1896 when Beatson showed that oophorectomy produced improvement in women with advanced breast cancer. Sex hormones and adrenocortical hormones are employed in the management of

several other types of cancer. Since sex hormones are actively involved in the stimulation and control of proliferation and function of certain tissues, including the mammary and prostate glands, cancers arising from these tissues may be inhibited or stimulated by appropriate changes in hormonal balance. Cancer of the breast and cancer of the prostate can be effectively treated with sex hormone therapy or ablation of appropriate endocrine organs.

Corticosteroids have been useful in the treatment of acute leukemia, lymphoma, multiple myeloma, and other hematologic malignancies as well as in advanced breast cancer. In addition, they are effective as supportive therapy in the management of cancer-related hypercalcemia. The steroid hormones and related agents most useful in cancer therapy are listed in Table 55–5.

Table 55–5. Hormonally Active Agents: Dosages and Toxicities.			
Drug	Usual Adult Dosage	Acute Toxicity	Delayed Toxicity
Antiandrogen			
Flutamide	250 mg/tid orally	Mild nausea	Hot flushes, transient elevations in liver function tests
Antiestrogen			
Tamoxifen	20 mg/d orally	Transient flare of tumor symptoms	Menopausal symptoms, fluid retention and edema, thromboembolic events, increased incidence of endometrial hyperplasia and cancer
Progestins			
Megestrol acetate	40 mg orally 4 times daily	None	Fluid retention
Adrenocorticosteroids			
Hydrocortisone	40–200 mg/d orally	None	Fluid retention, hypertension, diabetes, increased susceptibility to infection, moon facies
Prednisone	20–100 mg/d orally	None	
Gonadotropin-releasing hormone agonists			
Goserelin acetate	3.6 mg SC monthly	Transient flare of tumor symptoms, pain at injection site	Hot flushes, impotence, gynecomastia
Leuprolide	7.5 mg SC monthly	Transient flare of tumor symptoms, pain at injection site	Hot flushes, impotence, gynecomastia
Aromatase inhibitors			

Aminoglutethimide	250 mg orally twice daily and hydrocortisone 20 mg twice daily	Fatigue, mild nausea	Skin rash, adrenal insufficiency, myelosuppression
Anastrozole	1 mg orally daily	Mild nausea, headache	Fatigue, hot flushes, arthralgias
Exemestane	25 mg orally daily	Mild nausea, headache	Fatigue, hot flushes
Letrozole	2.5 mg orally daily	Mild nausea, headache	Fatigue, hot flushes, arthralgias

The mechanisms of action of steroid hormones on lymphoid, mammary, and prostatic cancer have been partially clarified. Specific cell surface receptors have been identified for estrogen, progesterone, corticosteroids, and androgens in neoplastic cells in these tissues. As in normal cells, steroid hormones also form an intracellular steroid-receptor complex that ultimately binds directly to nuclear proteins associated with DNA to activate transcription of a broad range of cellular genes involved in cell growth and proliferation (see Chapter 39: Adrenocorticosteroids & Adrenocortical Antagonists).

Most steroid-sensitive cancers express specific cell surface receptors. Prednisone-sensitive lymphomas, estrogen-sensitive breast cancers, and prostatic cancers express specific receptors for corticosteroids, estrogens, and androgens, respectively. It is now possible to assay tumor specimens for steroid receptor content and to identify which individual patients are likely to benefit from hormonal therapy. Measurement of the estrogen receptor (ER) and progesterone receptor (PR) proteins in breast cancer tissue is now standard clinical practice. ER or PR positivity predicts response to hormonal therapy, whereas patients whose tumors are ER-negative generally fail to respond to such treatment.

The sex hormones are used in the treatment of cancers of the breast, prostate, and endometrium. With replacement doses, estrogen can stimulate the growth of breast and endometrial cancer. Surprisingly, high-dose estrogen is useful therapeutically in metastatic breast cancer but has been largely replaced by antiestrogen therapy. In prostate cancer, androgens stimulate growth while estrogen administration results in suppression of androgen production. Drugs that reduce androgen secretion or block the effect of androgens at the receptor level are also effective in prostate cancer.

The toxicities of adrenocortical hormones are presented in Chapter 39: Adrenocorticosteroids & Adrenocortical Antagonists and those of estrogens and androgens in Chapter 40: The Gonadal Hormones & Inhibitors.

Estrogen & Androgen Inhibitors

The antiestrogen **tamoxifen** has proved to be extremely useful for the treatment of both early-stage and metastatic breast cancer. It is now approved as a chemopreventive agent in women at high risk for breast cancer. In addition, this hormonal agent has activity in endometrial cancer. Tamoxifen functions as a competitive partial agonist-inhibitor of estrogen and binds to the estrogen receptors of estrogen-sensitive tumors. However, tamoxifen has a tenfold lower affinity for ER than does estradiol, indicating the importance of ablation of endogenous estrogen for optimal antiestrogen effect. In addition to its direct antiestrogen effects on tumor cells, tamoxifen also suppresses serum levels of insulin-like growth factor-1 and up-regulates local production of transforming growth

factor-beta (TGF- β).

Tamoxifen is given orally and is rapidly and completely absorbed. High plasma levels of tamoxifen are obtained within 4–6 hours after oral administration, and the agent has a much longer biologic half-life than estradiol—on the order of 7–14 days. It is extensively metabolized by the liver P450 system, and the main metabolites also possess antitumor activity similar to that of the parent drug. Tamoxifen is well tolerated, and its side effects are generally quite mild (Table 55–5). **Flutamide** and **bicalutamide** are nonsteroidal antiandrogen agents that bind to the androgen receptor and inhibit androgen effects. They are administered orally and are rapidly and completely absorbed by the gastrointestinal tract. At present they are used in combination with radiation therapy for the treatment of early-stage prostate cancer and in the setting of metastatic prostate cancer. Toxicities are listed in Table 55–5.

Gonadotropin-Releasing Hormone Agonists

Leuprolide and **goserelin** are synthetic peptide analogs of naturally occurring gonadotropin-releasing hormone (GnRH, LHRH). They are described in further detail in Chapters 37 and 40. These analogs are more potent than the natural hormone and function as LHRH agonists. When given as depot preparations, these agents lead to a transient release of follicle-stimulating hormone (FSH) and luteinizing hormone (LH) followed by inhibition of the release of these gonadotropins. In men, this results in castration levels of testosterone after 2–4 weeks of therapy.

Leuprolide and goserelin are indicated in the treatment of advanced prostate cancer and more recently these agents have been incorporated as part of neoadjuvant therapy of early-stage prostate cancer. Leuprolide and goserelin are now formulated in long-acting depot forms, which allows for administration once every 3 months. The main side effects include hot flushes, impotence, and gynecomastia. Other toxicities are given in Table 55–5.

Aromatase Inhibitors

Aminoglutethimide is a nonsteroidal inhibitor of corticosteroid synthesis at the first step involving the conversion of cholesterol to pregnenolone; see Chapter 39: Adrenocorticosteroids & Adrenocortical Antagonists). Aminoglutethimide also inhibits the extra-adrenal synthesis of estrone and estradiol. Aside from its direct effects on adrenal steroidogenesis, aminoglutethimide is an inhibitor of an aromatase enzyme that converts the adrenal androgen androstenedione to estrone (Figure 40–2). This aromatization of an androgenic precursor into an estrogen occurs in body fat. Since estrogens promote the growth of breast cancer, estrogen synthesis in adipose tissue can be important in breast cancer growth in postmenopausal women.

Aminoglutethimide is primarily used in the treatment of metastatic breast cancer in women whose tumors express significant levels of estrogen or progesterone receptors. It also has activity in

advanced prostate cancer that is hormone-responsive. Aminoglutethimide is normally administered with hydrocortisone to prevent symptoms of adrenal insufficiency. Hydrocortisone is preferable to dexamethasone because the latter agent accelerates the rate of catabolism of aminoglutethimide. Adverse effects of aminoglutethimide are listed in Table 55–5.

Anastrozole is a selective nonsteroidal inhibitor of aromatase that has no inhibitory effect on adrenal glucocorticoid or mineralocorticoid synthesis. It is presently approved for first-line treatment of postmenopausal women with metastatic breast cancer that is ER-positive, for treatment of postmenopausal women with metastatic breast cancer that is ER-positive and has progressed while on tamoxifen therapy, and as adjuvant therapy of postmenopausal women with hormone-positive, early-stage breast cancer. **Letrozole** is a nonsteroidal competitive inhibitor of aromatase that is significantly more potent than aminoglutethimide and acts in the same way as anastrozole. It is also indicated for first-line treatment of postmenopausal women with hormone receptor-positive metastatic breast cancer and for second-line treatment of postmenopausal women with advanced breast cancer after progression on tamoxifen therapy. **Exemestane** is a steroidal hormonal agent that binds to and irreversibly inactivates aromatase. There appears to be a lack of cross-resistance between exemestane and nonsteroidal aromatase inhibitors. This agent is indicated for the treatment of advanced breast cancer in postmenopausal women whose disease has progressed on tamoxifen therapy. Each of these aromatase inhibitors exhibits a similar side effect profile (Table 55–5, see also Chapter 40: The Gonadal Hormones & Inhibitors).

Miscellaneous Anticancer Drugs

See Table 55–6.

Table 55–6. Miscellaneous Anticancer Drugs: Dosages and Toxicities.			
Drug	Usual Dosage	Acute Toxicity	Delayed Toxicity
Arsenic trioxide	0.15 mg/kg/d IV for 60 days as induction therapy; 0.15 mg/kg/d IV for 5 days per week for a total of 5 weeks as consolidation therapy	Headache and lightheadedness	Fatigue, cardiac dysrhythmias, fever, dyspnea, fluid retention and weight gain
Asparaginase	20,000 IU/m ² daily IV for 5–10 days	Nausea, fever, and allergic reactions	Hepatotoxicity, mental depression, pancreatitis
Imatinib	400–600 mg/d orally	Nausea and vomiting	Fluid retention with ankle and periorbital edema, diarrhea, myalgias
Hydroxyurea	300 mg/m ² orally for 5 days	Nausea and vomiting	Bone marrow depression
Mitotane	6–15 g/d orally	Nausea and vomiting	Diarrhea, lethargy, adrenal insufficiency, transient skin rash
Mitoxantrone	10–12 mg/m ² IV every 3–4 weeks	Nausea	Bone marrow depression, occasional cardiac toxicity, mild alopecia

Trastuzumab ¹	4 mg/kg IV loading dose; 2 mg/kg/wk as maintenance	Nausea and vomiting, infusion-related hypersensitivity reaction	Cardiomyopathy, myelosuppression, pulmonary toxicity
--------------------------	----------------------------------------------------	-----------------------------------------------------------------	------------------------------------------------------

¹This monoclonal antibody is described in Chapter 56: Immunopharmacology.

Imatinib

Imatinib (STI571) is an inhibitor of the tyrosine kinase domain of the Bcr-Abl oncoprotein and prevents the phosphorylation of the kinase substrate by ATP. It is indicated for the treatment of chronic myelogenous leukemia (CML), a pluripotent hematopoietic stem cell disorder characterized by the t(9:22) Philadelphia chromosomal translocation. This translocation results in the Bcr-Abl fusion protein, the causative agent in CML, and is present in up to 95% of patients with this disease. This agent inhibits other activated receptor tyrosine kinases for platelet-derived growth factor receptor (PDGFR), stem cell factor (SCF), and c-kit.

Imatinib is administered orally and is well absorbed; it is highly protein-bound in plasma. The drug is metabolized in the liver, and elimination of metabolites occurs mainly in feces via biliary excretion. This agent is approved for use as first-line therapy in chronic phase CML, in blast crisis, and as second-line therapy for chronic phase CML that has progressed on prior interferon- α therapy. Imatinib is effective also for treatment of gastrointestinal stromal tumors expressing the c-kit tyrosine kinase. Dosage and toxicities are listed in Table 55–6.

Asparaginase

Asparaginase (L-asparagine amidohydrolase) is an enzyme that is isolated from various bacteria for clinical use. The drug is used to treat childhood acute lymphocytic leukemia. It hydrolyzes circulating L-asparagine to aspartic acid and ammonia. Because tumor cells lack asparagine synthetase, they require an exogenous source of L-asparagine. Thus, depletion of L-asparagine results in effective inhibition of protein synthesis. In contrast, normal cells can synthesize L-asparagine and thus are less susceptible to the cytotoxic action of asparaginase. The main side effect of this agent is a hypersensitivity reaction manifested by fever, chills, nausea and vomiting, skin rash, and urticaria. Severe cases can present with bronchospasm, respiratory failure, and hypotension. Other toxicities include an increased risk of both clotting and bleeding as a result of alterations in various clotting factors, pancreatitis, and neurologic toxicity with lethargy, confusion, hallucinations, and coma.

Hydroxyurea

Hydroxyurea (HONHCONH₂) is an analog of urea whose mechanism of action involves the inhibition of DNA synthesis in the S phase by inhibiting the enzyme ribonucleotide reductase, resulting in depletion of deoxynucleoside triphosphate pools. The drug is administered orally and has nearly 100% oral bioavailability. It is mainly used in chronic myelogenous leukemia and treatment of the blast crisis of acute myeloid leukemia. However, it is also effective as an adjunct with radiation therapy for head and neck cancer and in treating essential thrombocytosis and polycythemia vera. Myelosuppression is the dose-limiting toxicity, but nausea and vomiting, mucositis and diarrhea, headache and increased lethargy, and a maculopapular skin rash with pruritus are also observed.

Mitotane

This drug (Figure 39–5) is a dichloro analog of the insecticide DDT that was first found to be adrenolytic in dogs. Subsequently, it was found to be useful in the treatment of an adrenocortical carcinoma, and it is labeled for this clinical indication. The drug produces tumor regression and reduces the excessive adrenal steroid secretion that often occurs with this malignancy. Toxicities are listed in Table 55–6.

Retinoic Acid Derivatives

All-*trans*-Retinoic acid (tretinoin) produces remissions in patients with acute promyelocytic leukemia (APL) through the induction of terminal differentiation, in which the leukemic promyelocytes lose their ability to proliferate. APL is associated with a t(15;17) chromosomal translocation, which disrupts the gene for the nuclear receptor- α for retinoic acid and fuses it to a gene called *PML*. This chimeric gene, which expresses aberrant forms of the retinoic acid receptor- α , is present in virtually all patients with promyelocytic leukemia and appears to be responsible for sensitivity to all-*trans*-retinoic acid. This agent is approved for use in APL following progression or relapse with anthracycline-based chemotherapy and for patients in whom anthracycline-based chemotherapy is contraindicated. However, a number of serious adverse events have been observed, and they include vitamin A toxicity manifesting as headache, fever, dry skin and mucous membranes, skin rash, pruritus, and conjunctivitis; retinoic acid syndrome with fever, leukocytosis, dyspnea, weight gain, diffuse pulmonary infiltrates, and pleural or pericardial effusions; increased serum cholesterol and triglyceride levels; central nervous system toxicity in the form of dizziness, anxiety, depression, confusion, and agitation; abdominal pain and diarrhea; and transient elevations in liver function tests. Finally, this retinoid has been shown to be teratogenic.

13-*cis*-Retinoic acid (isotretinoin) is used for the treatment of severe cystic acne (Chapter 62: Dermatologic Pharmacology). It also appears to have significant clinical activity as an adjuvant to prevent second primary tumors in patients with head and neck squamous cell carcinoma and may also have activity in the chemoprevention of non-small cell lung cancer. However, it remains an investigational agent for cancer chemotherapy in the USA, and further clinical studies are under way to confirm its true clinical benefit.

Arsenic Trioxide

Arsenic trioxide (As₂O₃) is used for induction of remission in patients with acute promyelocytic leukemia with the t(15;17) chromosomal translocation refractory to or relapsed following first-line therapy with all-*trans*-retinoic acid- and anthracycline-based chemotherapy. It functions by inducing differentiation through degradation of the chimeric PML/RAR- α protein. In addition, it induces apoptosis through a mitochondrion-dependent process, resulting in subsequent release of cytochrome C with caspase activation. This drug is administered via the intravenous route and it is widely distributed in the body. The main toxicities are fatigue, electrocardiographic changes with QT prolongation, arrhythmias, and a syndrome characterized by fever, dyspnea, skin rash, fluid retention, and weight gain.

Bone Marrow Growth Factors

Use of bone marrow-stimulating factors with chemotherapy can reduce the frequency and severity of neutropenic sepsis and other complications. Two recombinant bone marrow growth factors that stimulate neutrophil growth are available: granulocyte colony-stimulating factor (G-CSF, filgrastim; and pegfilgrastim, long-acting filgrastim) and granulocyte-macrophage colony-stimulating factor

(GM-CSF, sargramostim) (Chapter 33: Agents Used in Anemias; Hematopoietic Growth Factors). Both sargramostim and filgrastim can reduce the incidence of neutropenia and prevent the onset of infection when used as an adjunct to chemotherapy and can also shorten hospitalization after bone marrow transplantation. There are currently two colony-stimulating growth factors for red blood cells: darbopoetin alfa and erythropoietin. They are indicated for chemotherapy-induced anemia in patients with nonmyeloid cancer, as well as for anemia associated with chronic renal failure.

Amifostine

Amifostine (WR-2721) is an organic thiophosphate analog designed to produce preferential cytoprotection of normal tissues from cytotoxic therapies. The preferential cytoprotection is due to the activation of amifostine by membrane-bound alkaline phosphatase to the free thiol, WR-1065, the active form. This activation occurs to a greater extent in normal tissue sites than in tumor cells. The free thiol acts as a potent scavenger of free radicals and superoxide anions to inactivate the reactive species of cisplatin and radiation therapy. At present, this agent is approved to reduce the incidence of nephrotoxicity in ovarian cancer and non-small cell lung cancer in conjunction with cisplatin-based chemotherapy and to reduce the incidence of xerostomia in patients undergoing radiation therapy for head and neck cancer. Amifostine does not appear to adversely affect the antitumor activity of cisplatin or radiation therapy. Recent studies suggest that amifostine can reduce the incidence of pneumonitis and esophagitis secondary to combined modality therapy for non-small cell lung cancer, and there is also evidence that it can stimulate bone marrow growth in patients with marrow disorders such as the myelodysplastic syndrome.

Investigational Agents

Several of the drugs mentioned in the text remain investigational in the USA until their clinical efficacy and safety can be fully established. In specific instances where treatment with one of these agents seems warranted, it usually can be arranged through a compassionate use program either by contacting the pharmaceutical sponsor of the drug or by contacting the Division of Cancer Treatment of the National Cancer Institute and the Food and Drug Administration, which can provide further information and identify investigators who are authorized to administer these drugs. This status applies to gefitinib, a small molecule inhibitor of the tyrosine kinase domain of the epidermal growth factor (EGF) receptor; cetuximab, a chimeric monoclonal antibody directed specifically against the EGF receptor; pemetrexed, an inhibitor of thymidylate synthase, dihydrofolate reductase, and enzymes involved in de novo purine synthesis; suramin, an inhibitor of various growth factors including basic fibroblast growth factor; and several others.

Katzung PHARMACOLOGY, 9e > Section VIII. Chemotherapeutic Drugs > Chapter 55. Cancer Chemotherapy >

Clinical Pharmacology of Cancer Chemotherapeutic Drugs

A thorough knowledge of the kinetics of tumor cell proliferation along with an enhanced understanding of the pharmacology and mechanism of action of cancer chemotherapeutic agents is critically important in designing optimal regimens for patients with cancer (Table 55–7). The strategy for developing drug regimens requires a knowledge of the particular characteristics of specific tumors—eg, Is there a high growth fraction? Is there a high spontaneous cell death rate? Are most of the cells in G₀? Is a significant fraction of the tumor composed of hypoxic stem cells? Are their normal counterparts under hormonal control? Similarly, knowledge of the pharmacology of specific drugs is equally important—eg, Does the drug have a particular affinity for uptake by the tumor cells (streptozocin)? Are the tumor cells sensitive to the drug? Is the drug cell cycle-specific? Does the drug require activation in certain normal tissue such as the liver, or is it activated in the tumor tissue itself (capecitabine)? Similarly, for some tumor types, knowledge of receptor expression is important. For example, in patients with breast cancer, analysis of the tumor for expression of estrogen or progesterone receptors—or overexpression of HER-2 receptors—is important in guiding therapy. Knowledge of specific pathway abnormalities (eg, Ras pathway) for intracellular signaling may prove important for the next generation of anticancer drugs.

Table 55–7. Malignancies Responsive to Chemotherapy.

Diagnosis	Current Treatment of Choice	Other Valuable Agents
Acute lymphocytic leukemia	Induction: vincristine plus prednisone. Remission maintenance: mercaptopurine, methotrexate, and cyclophosphamide in various combinations	Asparaginase, daunorubicin, carmustine, doxorubicin, cytarabine, allopurinol, ¹ craniospinal radiotherapy
Acute myelocytic and myelomonocytic leukemia	Combination chemotherapy: cytarabine and mitoxantrone or daunorubicin or idarubicin	Methotrexate, thioguanine, mercaptopurine, allopurinol, ¹ mitoxantrone, azacitidine, ² amsacrine, ² etoposide
Chronic lymphocytic leukemia	Chlorambucil and prednisone (if indicated), fludarabine	Allopurinol, ¹ doxorubicin, cladribine
Chronic myelogenous leukemia	Imatinib, busulfan, or interferon, bone marrow transplantation (selected patients)	Vincristine, mercaptopurine, hydroxyurea, melphalan, interferon, allopurinol ¹
Hodgkin's disease (stages III and IV)	Combination chemotherapy: vinblastine, doxorubicin, dacarbazine, bleomycin	Lomustine, etoposide, ifosfamide, interferon, mechlorethamine, vincristine, procarbazine, prednisone
Non-Hodgkin's lymphoma	Combination chemotherapy: cyclophosphamide, doxorubicin, vincristine, prednisone	Bleomycin, lomustine, carmustine, etoposide, interferon, mitoxantrone, ifosfamide, rituximab
Multiple myeloma	Melphalan plus prednisone or multiagent combination chemotherapy	Cyclophosphamide, vincristine, carmustine, interferon, doxorubicin, epoetin alfa ¹

Macroglobulinemia	Chlorambucil or fludarabine	Prednisone
Polycythemia vera	Busulfan, chlorambucil, or cyclophosphamide	Radioactive phosphorus 32
Carcinoma of adrenal	Mitotane	Suramin ²
Carcinoma of breast	(1) Adjuvant chemotherapy or tamoxifen after primary breast surgery	Cyclophosphamide, doxorubicin, vincristine, methotrexate, fluorouracil, paclitaxel, mitoxantrone, prednisone, ¹ megestrol, androgens, ¹ aminoglutethimide, trastuzumab
	(2) Combination chemotherapy or hormonal manipulation for late recurrence	
Carcinoma of cervix	Radiation plus cisplatin (localized), cisplatin, carboplatin (metastatic)	Lomustine, cyclophosphamide, doxorubicin, methotrexate, mitomycin, bleomycin, vincristine, interferon, 13- <i>cis</i> -retinoic acid
Carcinoma of colon	Fluorouracil plus leucovorin plus irinotecan	Oxaliplatin
Carcinoma of endometrium	Progestins or tamoxifen	Doxorubicin, cisplatin, carboplatin
Carcinoma of lung	Cisplatin plus taxane	Methotrexate, vincristine, vinblastine, doxorubicin, mitomycin C
Carcinoma of ovary	Cisplatin or carboplatin plus paclitaxel	Cyclophosphamide, doxorubicin, melphalan, fluorouracil, vincristine, altretamine, bleomycin
Carcinoma of pancreas	Gemcitabine	Docetaxel, fluorouracil
Carcinoma of prostate	GnRH agonist plus androgen antagonist	Aminoglutethimide, doxorubicin, cisplatin, prednisone, ¹ estramustine, fluorouracil, progestins, suramin ²
Carcinoma of stomach	Fluorouracil plus cisplatin	Hydroxyurea, lomustine
Carcinoma of testis	Combination chemotherapy: cisplatin, bleomycin, and etoposide	Methotrexate, dactinomycin, plicamycin, vinblastine, doxorubicin, cyclophosphamide, etoposide, ifosfamide plus mesna ¹
Carcinoma of thyroid	Radioiodine (¹³¹ I), doxorubicin, cisplatin	Bleomycin, fluorouracil, melphalan
Carcinomas of head and neck	Fluorouracil plus cisplatin, cisplatin plus paclitaxel	Methotrexate, bleomycin, hydroxyurea, doxorubicin, vincristine, vinorelbine

Choriocarcinoma (trophoblastic neoplasms)	Methotrexate alone or etoposide and cisplatin	Vinblastine, mercaptopurine, chlorambucil, doxorubicin
Wilms' tumor	Vincristine plus dactinomycin after surgery and radiotherapy	Methotrexate, cyclophosphamide, doxorubicin
Neuroblastoma	Cyclophosphamide plus doxorubicin and vincristine	Dactinomycin, daunorubicin, cisplatin
Carcinoid	Doxorubicin plus cyclophosphamide, fluorouracil, octreotide	Interferon, dactinomycin, methysergide, ¹ streptozocin
Insulinoma	Streptozocin, interferon	Doxorubicin, fluorouracil, mitomycin, streptozocin
Osteogenic sarcoma	Doxorubicin, or methotrexate with leucovorin rescue initiated after surgery	Cyclophosphamide, dacarbazine, interferon, ifosfamide plus mesna ¹
Miscellaneous sarcomas	Doxorubicin plus dacarbazine	Methotrexate, dactinomycin, ifosfamide plus mesna, ¹ vincristine, vinblastine
Melanoma	Dacarbazine, cisplatin, temozolomide	Lomustine, hydroxyurea, mitomycin, dactinomycin, interferon, tamoxifen

¹Supportive agent, not oncolytic.

²Investigational agent. Treatment available through qualified investigators and centers authorized by National Cancer Institute and Cooperative Oncology Groups.

Drugs that affect cycling cells can often be used most effectively after treatment with a cell cycle-nonspecific agent (eg, alkylating agents); this principle has been tested in a few human tumors with increasing success. Similarly, recognition of true drug synergism (tumor cell kill by the drug combination greater than the additive effects of the individual drugs) or antagonism is important in the design of combination chemotherapeutic programs. The combination of cytarabine with an anthracycline in acute myelogenous leukemia and the use of vinblastine or etoposide along with cisplatin and bleomycin in testicular tumors are good examples of true drug synergism against cancer cells but not against normal tissues.

In general, it is preferable to use cytotoxic chemotherapeutic agents in intensive pulse courses every 3–4 weeks rather than to use continuous daily dosage schedules. This allows for maximum effects against neoplastic cell populations with complete hematologic and immunologic recovery between courses rather than leaving the patient continuously suppressed with cytotoxic therapy. This approach reduces adverse effects but does not reduce therapeutic efficacy.

The application of these principles is well illustrated in the current approach to the treatment of acute leukemia, lymphomas, Wilms' tumor, and testicular neoplasms.

Adjuvant Chemotherapy

One of the most important roles for effective cancer chemotherapy is as an adjuvant to initial or primary field treatment with other methods such as surgery or radiation therapy. Failures with primary field therapy are due principally to occult micrometastases outside the primary field. With the currently available treatment modalities, this form of combined-modality therapy appears to offer the greatest chance of curing patients with solid tumors.

Distant micrometastases are usually present in patients with one or more positive lymph nodes at the time of surgery (eg, in breast cancer) and in patients with tumors having a known propensity for early hematogenous spread (eg, osteogenic sarcoma, Wilms' tumor). The risk of recurrent or metastatic disease in such patients is extremely high (80%). Only systemic therapy can adequately attack micrometastases. Chemotherapy regimens that are at least moderately effective against advanced cancer may have curative potential (at the right dosage and schedule) when combined with primary therapy such as surgery. Several studies show that adjuvant chemotherapy prolongs both disease-free and overall survival in patients with osteogenic sarcoma, rhabdomyosarcoma, or breast cancer. Similar comments apply to the use of three cycles of combination chemotherapy (eg, MOPP) prior to total nodal radiation in stage IIB Hodgkin's disease.

In breast cancer, premenopausal women with positive lymph nodes at the time of mastectomy have benefited from combination chemotherapy. It has been established that several programs of cytotoxic chemotherapy achieve prolonged disease-free and overall survival times; this method of treatment has increased the cure rate in high-risk primary breast cancer. In general, regimens with at least three active drugs have been useful. The results produced by combination chemotherapy are superior to those produced by single agents because combination chemotherapy copes better with tumor cell heterogeneity and produces a greater tumor cell log kill. Full protocol doses of cytotoxic agents are required to maximize the likelihood of efficacy. Clinical trials have proved tamoxifen to be an effective adjuvant in postmenopausal women with positive estrogen receptor tests on the primary tumor. Because it is cytostatic rather than cytotoxic, adjuvant therapy with tamoxifen is usually administered for 5 years. A recent trial in women with node-negative disease showed no additional advantage with 10 years of tamoxifen therapy. Tamoxifen adjuvant chemotherapy is now standard in node-positive postmenopausal women with positive ER or PR tests on tumor specimens. Tamoxifen has also received regulatory approval for reducing the incidence of breast cancer in women who are at high risk for developing the disease.

Other applications of adjuvant chemotherapy include colorectal cancer, testicular cancer, head and neck cancer, and gynecologic neoplasms. In a recent large-scale trial in patients with primary melanoma at high risk of metastases, intensive administration of interferon alfa improved disease-free survival. Thus, adjuvant chemotherapy (with curative intent) should now be considered for patients who undergo primary surgical staging and therapy and are found to have a stage and histologic type of cancer with a high risk of micrometastasis. This policy is germane to those tumor types for which palliative chemotherapy has already been developed and has been shown to induce complete remissions in advanced stages of the disease. In each instance, the benefit:risk ratio must be closely examined.

Combined-modality therapy—radiation plus cisplatin—for localized carcinoma of the cervix has recently proved to achieve long-term survival rates superior to those reported with radiation alone.

Primary chemotherapy (prior to local surgery) is now extensively used in patients with osteogenic sarcoma and has facilitated limb-sparing procedures. Primary chemotherapy is also being evaluated in breast cancer to "downstage" patients prior to surgery.

The Leukemias

Acute Leukemia

Childhood Leukemia

Acute lymphoblastic leukemia (ALL) is the predominant form of leukemia in childhood, and it is the most common form of cancer in children. Children with this disease have a relatively good prognosis. A subset of patients with neoplastic lymphocytes expressing surface antigenic features of T lymphocytes have a poor prognosis (see Chapter 56: Immunopharmacology). A cytoplasmic enzyme expressed by normal thymocytes, terminal deoxycytidyl transferase (terminal transferase), is also expressed in many cases of ALL. T cell ALLs also express high levels of the enzyme adenosine deaminase (ADA). This led to interest in the use of the ADA inhibitor pentostatin (deoxycoformycin) for treatment of such T cell cases. Until 1948, the median length of survival in ALL was 3 months. With the advent of the folic acid antagonists, the length of survival was greatly increased. Subsequently, corticosteroids, mercaptopurine, cyclophosphamide, vincristine, daunorubicin, and asparaginase were all found to act against this disease. A combination of vincristine and prednisone plus other agents is currently used to induce remission. Over 90% of children enter complete remission with this therapy with only minimal toxicity. However, circulating leukemic cells often migrate to sanctuary sites located in the brain and testes. The value of prophylactic intrathecal methotrexate therapy for prevention of central nervous system leukemia (a major mechanism of relapse) has been clearly demonstrated. Intrathecal therapy with methotrexate should therefore be considered as a standard component of the induction regimen for children with ALL.

Adult Leukemia

Acute myelogenous leukemia (AML) is the most common leukemia seen in adults. The single most active agent for AML is cytarabine; however, it is best used in combination with an anthracycline, in which case complete remissions occur in about 70% of patients. Idarubicin has now replaced daunorubicin as the preferred anthracycline.

Patients often require intensive supportive care during the period of induction chemotherapy. Such care includes platelet transfusions to prevent bleeding, filgrastim to shorten periods of neutropenia, and antibiotics to combat infections. Younger patients (eg, < age 55) who are in complete remission and have an HLA-matched donor are candidates for allogeneic bone marrow transplantation. The transplant procedure is preceded by high-dose chemotherapy and total body irradiation followed by immunosuppression. This approach may cure up to 35–40% of eligible patients. Patients over age 60 respond less well to chemotherapy, primarily because their tolerance for aggressive therapy and their resistance to infection is lower.

Once remission of AML is achieved, consolidation chemotherapy is required to maintain a durable remission and to induce cure. The usual approach is to administer up to four courses of high-dose cytarabine.

Chronic Myelogenous Leukemia

Chronic myelogenous leukemia (CML) arises from a chromosomally abnormal hematopoietic stem cell in which a balanced translocation between the long arms of chromosomes 9 and 22, t(9:22), is observed in 90–95% of cases. This translocation results in expression of the Bcr-Abl fusion oncoprotein with a molecular weight of 210 kDa, which is constitutively expressed. The clinical symptoms and course are related to the white blood cell count and its rate of increase. Most patients with white cell counts over 50,000/ μ L should be treated. The goals of treatment are to reduce the

granulocytes to normal levels, to raise the hemoglobin concentration to normal, and to relieve disease-related symptoms. There has been a significant change in the management of this disease. Recently, the signal transduction inhibitor imatinib was approved for use as first-line therapy in previously untreated patients with chronic phase CML. Imatinib is also recommended in patients with chronic phase disease who have failed prior interferon alfa therapy. Nearly all patients treated with imatinib exhibit a complete hematologic response, and up to 40–50% of patients will show a complete cytogenetic response. The usual dose for chronic phase disease is 400 mg/d, and an advantage of this drug is that it is given orally. As described previously, this drug is extremely well tolerated and is associated with relatively minor side effects. Other treatment options include interferon alfa, busulfan, other oral alkylating agents, and hydroxyurea.

Chronic Lymphocytic Leukemia

Patients with early-stage chronic lymphocytic leukemia (CLL) have a relatively good prognosis, and therapy has not changed the course of the disease. However, in the setting of high-risk disease or in the presence of disease-related symptoms, treatment is indicated.

The purine nucleoside analog fludarabine is rapidly becoming the treatment of choice in CLL. Fludarabine can be given alone or used in combination with cyclophosphamide and with mitoxantrone and dexamethasone. The most commonly used single chemotherapeutic agent has been the alkylating agent chlorambucil. The dosage is usually 0.1 mg/kg/d, with monitoring of blood counts at weekly intervals. Chlorambucil is frequently combined with prednisone, although there is no clear evidence that the combination yields better response rates or survival compared with chlorambucil alone. Alternatively, cyclophosphamide can be given, usually in dosages of 1–2 g/m² every 3–4 weeks. In most cases, cyclophosphamide is given in combination with vincristine and prednisone (COP protocol), or it can also be given with these same drugs along with doxorubicin (CHOP).

Monoclonal antibody-targeted therapies are being more widely used in CLL, especially in relapsed or refractory disease. Alemtuzumab is a chimeric monoclonal antibody directed against the CD52 antigen and is approved for use in CLL that is refractory to alkylating agent or fludarabine therapy. Response rates up to 30–35% are observed, with disease stabilization in another 30% of patients. Rituximab is an anti-CD20 antibody that also has clinical activity in this setting.

The Lymphomas

Hodgkin's Disease

The treatment of Hodgkin's disease has undergone dramatic evolution over the last 30 years. Hodgkin's disease is now recognized as a B cell neoplasm in which the malignant Reed-Sternberg cells have rearranged *VH* genes. In addition, the Epstein-Barr virus genome has been identified in up to 80% of tumor specimens.

Complete staging evaluation is required before a definitive treatment plan can be made. For patients with stage I and stage IIA disease, there has been a significant change in the treatment approach. Initially, these patients were treated with extended-field radiation therapy. However, given the late effects of radiation therapy, which include hypothyroidism and an increased risk of secondary cancers and coronary artery disease, combined-modality therapy with a brief course of combination chemotherapy and involved field radiation therapy is now the recommended approach. The main advance for patients with advanced stage III and IV Hodgkin's disease came with the development of MOPP (mechlorethamine, vincristine, procarbazine, and prednisone) chemotherapy in the 1960s.

This regimen resulted initially in high complete response rates—on the order of 80–90%, with cures in up to 60% of patients. Over the past few years, the anthracycline-containing regimen ABVD (doxorubicin, bleomycin, vinblastine, and dacarbazine) has been shown to be more effective and less toxic than MOPP, especially with regard to the incidence of sterility and secondary malignancies. This regimen uses four cycles of ABVD. The Stanford group has developed an alternative regimen wherein a 12-week course of combination chemotherapy, termed Stanford V (doxorubicin, vinblastine, mechlorethamine, vincristine, bleomycin, etoposide, and prednisone) is followed by involved radiation therapy.

With all these regimens, over 80% of previously untreated patients with advanced Hodgkin's disease (stages III and IV) are expected to go into complete remission, with disappearance of all disease-related symptoms and objective evidence of disease. Approximately 50–60% of all patients with Hodgkin's disease are cured of their disease.

Non-Hodgkin's Lymphomas

Over the past 25 years, there has been a dramatic increase, by over 80%, in the incidence of non-Hodgkin's lymphoma. This is a heterogeneous disease, and the clinical characteristics of non-Hodgkin's lymphoma subsets are related to the underlying histopathologic features and the extent of disease involvement. In general, the nodular (or follicular) lymphomas have a far better prognosis, with a median survival up to 7 years, compared with the diffuse lymphomas, which have a median survival of about 1–2 years.

Combination chemotherapy is the treatment standard for patients with diffuse non-Hodgkin's lymphoma. The anthracycline-containing regimen CHOP (cyclophosphamide, doxorubicin, vincristine, and prednisone) has been considered the best treatment in terms of initial therapy. Recently, randomized phase III clinical studies have shown that the combination of CHOP with the anti-CD20 monoclonal antibody rituximab results in improved response rates, disease-free survival, and overall survival compared with CHOP chemotherapy alone.

The nodular follicular lymphomas are low-grade, indolent tumors that tend to present in an advanced stage and are usually confined to lymph nodes, bone marrow, and spleen. This form of non-Hodgkin's lymphomas, when presenting at an advanced stage, is considered incurable, and treatment is generally palliative. To date, there is no evidence that immediate treatment with combination chemotherapy offers clinical benefit over close observation and "watchful waiting" with initiation of chemotherapy at the time of disease symptoms.

Multiple Myeloma

This plasma cell malignancy is one of the models of neoplastic disease in humans because it arises from a single tumor stem cell, and the tumor cells produce a marker protein (myeloma immunoglobulin) that allows the total body burden of tumor cells to be quantified. Multiple myeloma principally involves the bone marrow and the surrounding bone, causing bone pain, lytic lesions, bone fractures, and anemia as well as an increased susceptibility to infection.

Most patients with multiple myeloma are symptomatic at the time of initial diagnosis and require treatment with cytotoxic chemotherapy. Treatment with the combination of the alkylating agent melphalan and prednisone (MP protocol) remains a standard regimen. About 40% of patients respond to the MP combination, and the median remission is on the order of 2–2.5 years. While a host of studies have investigated the efficacy of combination of multiple alkylating agents, none of these regimens have as yet been shown to be superior to MP.

Melphalan and other alkylating agents should be avoided in patients who are felt to be candidates for high-dose therapy with stem cell transplantation, as prior therapy will affect the success of stem cell harvesting. In this setting, the nonalkylator combination of vincristine, doxorubicin, and dexamethasone (VAD) has been used.

Thalidomide is now a well-established agent for treating refractory or relapsed disease, and about 30% of patients will achieve a response to this therapy. More recently, thalidomide has been used in combination with dexamethasone, and response rates on the order of 65% have been observed. Studies are now under way to directly compare VAD with the combination of thalidomide and dexamethasone. In some patients, especially those with poor performance status, single-agent pulse dexamethasone administered on a weekly basis can be effective in palliating symptoms.

Significant efforts are currently focused on developing novel agents for multiple myeloma. These include CC5013, a small molecule analog of thalidomide with immunomodulatory effects; the proteasome inhibitor PS341; and arsenic trioxide.

Breast Cancer

Stage I & Stage II Disease

The management of primary breast cancer has undergone a remarkable evolution as a result of major efforts at early diagnosis (through encouragement of self-examination as well as through the use of cancer detection centers) and the implementation of combined modality approaches incorporating systemic chemotherapy as an adjuvant to surgery and radiation therapy. Women with stage I disease (small primaries and negative axillary lymph node dissections) are currently treated with surgery alone, and they have an 80% chance of cure.

Women with node-positive disease have a high risk of both local and systemic recurrence. Thus, lymph node status directly indicates the risk of occult distant micrometastasis. In this situation, postoperative use of systemic cytotoxic chemotherapy with six cycles of cyclophosphamide-methotrexate-fluorouracil (CMF protocol) or of fluorouracil, doxorubicin, and cyclophosphamide (FAC) has been shown to significantly reduce the relapse rate and prolong survival. Alternative regimens with equivalent clinical benefit include four cycles of doxorubicin and cyclophosphamide and six cycles of fluorouracil, epirubicin, and cyclophosphamide (FEC). Each of these chemotherapy regimens has benefited women with stage II breast cancer with one to three involved lymph nodes. Women with four or more involved nodes have had limited benefit thus far from adjuvant chemotherapy. High-dose chemotherapy with autologous stem cell rescue and growth factor support is presently being evaluated in women with ten or more involved nodes. Long-term analysis has clearly shown improved survival rates in node-positive premenopausal women who have been treated aggressively with multiagent combination chemotherapy.

Tamoxifen is beneficial in postmenopausal women when used alone or when combined with cytotoxic chemotherapy. The present recommendation is to administer tamoxifen for 5 years of continuous therapy after surgical resection. Longer durations of tamoxifen therapy do not appear to add additional clinical benefit. Results from several randomized trials for breast cancer have established that adjuvant chemotherapy for premenopausal women and adjuvant tamoxifen for postmenopausal women are of benefit to women with stage I (node-negative) breast cancer. While this group of patients has the lowest overall risk of recurrence after surgery alone (about 35–50% over 15 years), this risk can be further reduced with adjuvant therapy.

Stage III & Stage IV Disease

The approach to women with advanced breast cancer remains a major problem, as current treatment options are only palliative. Combination chemotherapy, endocrine therapy, or a combination of both results in overall response rates of 40–50%, with only a 10–20% complete response rate. Breast cancers expressing estrogen receptors (ER) or progesterone receptors (PR), retain the intrinsic hormonal sensitivities of the normal breast—including the growth-stimulatory response to ovarian, adrenal, and pituitary hormones. Patients who show improvement with hormonal ablative procedures also respond to the addition of tamoxifen. The aromatase inhibitors anastrozole and letrozole have recently been approved as first-line therapy in women with advanced breast cancer whose tumors are hormone-receptor positive. In addition, these agents and exemestane are approved as second-line therapy following treatment with tamoxifen.

Patients with significant visceral involvement of the lung, liver, or brain and those with rapidly progressive disease rarely benefit from hormonal maneuvers, and initial systemic chemotherapy is indicated in such cases. For the 25–30% of breast cancer patients whose tumors express the HER-2/*neu* cell surface receptor, a humanized monoclonal anti-HER-2/*neu* antibody, trastuzumab, is available for therapeutic use alone or in combination chemotherapy.

Systemic Chemotherapy

About 50–60% of patients with metastatic disease respond to initial chemotherapy. A broad range of anticancer agents have activity in this disease, including the anthracyclines (doxorubicin, mitoxantrone, and epirubicin), the taxanes (docetaxel and paclitaxel), navelbine, capecitabine, gemcitabine, cyclophosphamide, methotrexate, and cisplatin. Doxorubicin and the taxanes are the most active cytotoxic drugs. Combination chemotherapy has been found to induce higher and more durable remissions in up to 50–80% of patients. Anthracycline-containing regimens including fluorouracil, doxorubicin, and cyclophosphamide or epirubicin, cyclophosphamide, and fluorouracil are now considered standard first-line regimens. With most combination regimens, partial remissions have a median duration of about 10 months and complete remissions have a duration of about 15 months. Unfortunately, only 10–20% of patients achieve complete remissions with any of these regimens, and as noted, complete remissions are usually not long-lasting. The addition of tamoxifen to combination chemotherapy yields only modest additional improvement.

Prostate Cancer

Prostate cancer was the second type of cancer shown to be responsive to hormonal manipulation. The treatment of choice for patients with advanced prostate cancer is elimination of testosterone production by the testes either through surgical or chemical castration. Bilateral orchiectomy or estrogen therapy in the form of diethylstilbestrol were previously used as first-line therapy. However, at present, the use of LHRH agonists—including leuprolide and goserelin agonists, alone or in combination with an antiandrogen (eg, flutamide, bicalutamide, or nilutamide)—has become the preferred approach. There appears to be no survival advantage of total androgen blockade using a combination of LHRH agonist and antiandrogen agent compared with single-agent therapy. Hormonal treatment reduces symptoms—especially bone pain—in 70–80% of patients and may cause a significant reduction in the PSA level, which is now widely accepted as a surrogate marker for response to treatment in prostate cancer. Although initial hormonal manipulation is able to control symptoms for up to 2 years, patients usually present with progressive disease. Second-line hormonal therapies include aminoglutethimide plus hydrocortisone, the antifungal agent ketoconazole plus hydrocortisone, or hydrocortisone alone.

Unfortunately, nearly all patients with advanced prostate cancer eventually become refractory to hormone therapy. A regimen of mitoxantrone and prednisone is approved in patients with hormone-

refractory prostate cancer since it provides effective palliation in those who experience significant bone pain. Estramustine is an antimicrotubule agent that produces an almost 20% response rate as a single agent. However, when used in combination with either etoposide or a taxane such as docetaxel or paclitaxel, response rates are more than doubled to 40–50%. To date, no combination regimen has resulted in improved survival benefit. For this reason, intense efforts are focused on identifying novel agents and treatment regimens for patients with hormone-refractory prostate cancer.

Gastrointestinal Cancers

Colorectal adenocarcinoma is the most common type of gastrointestinal malignancy. There are approximately 145,000 new cases diagnosed each year in the USA; worldwide, there are nearly one million cases diagnosed each year. At the time of initial presentation, only about 40–45% of cases are potentially curable with surgery. Patients presenting with high-risk stage II disease and stage III disease with involvement of regional lymph nodes are candidates for adjuvant chemotherapy with fluorouracil plus leucovorin and are generally treated for up to 6–8 months following surgical resection. Treatment with this combination regimen reduces the recurrence rate after surgery by 35% in these patients and clearly improves overall patient survival compared with surgery alone. For patients with rectal carcinoma, surgical adjuvant therapy with protracted intravenous infusion of fluorouracil along with pelvic irradiation provides a modest albeit significant improvement in both relapse-free and overall survival.

As a single agent, the topoisomerase I inhibitor irinotecan is approved as second-line therapy in patients who are no longer responding to fluorouracil. The combination of irinotecan, fluorouracil, and leucovorin (IFL protocol) when given either in a weekly bolus fashion or via a biweekly infusion schedule has now been shown to provide significant clinical benefit in terms of overall response rates, time to disease progression, and survival when compared with treatment with the combination of fluorouracil and leucovorin. Oxaliplatin has recently received approval in the USA for use in combination with a biweekly infusion schedule of fluorouracil and leucovorin as second-line therapy in patients who have failed the IFL regimen.

The incidence of gastric cancer, esophageal cancer, and pancreatic cancer is much lower than for colorectal cancer, but these malignancies are more aggressive. In most cases, they cannot be completely resected surgically, as most patients present with either locally advanced or metastatic disease at the time of their initial diagnosis. Fluorouracil-based chemotherapy has been the usual approach for gastroesophageal cancers. Recently, there has been a shift toward incorporating cisplatin-based regimens in combination with either the topoisomerase I inhibitor irinotecan or with one of the taxanes, paclitaxel or docetaxel, and response rates in the range of 40–50% are now being reported. In addition, neoadjuvant approaches with combination chemotherapy and radiation therapy prior to surgery appear to have some promise in selected patients. Although gemcitabine is approved for use as a single-agent in metastatic pancreas cancer, the overall response rate is less than 10%, with no complete responses. Intense efforts are now being placed on incorporating gemcitabine into various combination regimens and on identifying novel agents that target signal transduction pathways felt to be critical for the growth of pancreatic cancer.

Lung Cancer

Lung cancer can be divided into two main histopathologic subtypes, non-small cell and small cell. Non-small cell lung cancer (NSCLC) makes up about 75–80% of all cases of lung cancer, and this group includes adenocarcinoma, squamous cell cancer, and large cell cancer, while small cell lung cancer (SCLC) makes up the remaining 20–25%. When NSCLC is diagnosed in an advanced stage

with metastatic disease, the prognosis is extremely poor, with a median survival of about 8 months. It is clear that prevention (primarily through avoidance of cigarette smoking) and early detection remain the most important means of control. When diagnosed at an early stage, surgical resection can result in patient cure. However, in most cases, distant metastases have occurred at the time of diagnosis. In certain instances, radiation therapy can be offered for palliation of pain, airway obstruction, or bleeding and to treat patients whose performance status would not allow for more aggressive treatments.

Patients with small cell lung cancer (the most aggressive type) show the best responses to platinum-based combination regimens, including cisplatin and etoposide or cisplatin and irinotecan. The topoisomerase I inhibitor topotecan is used as second-line monotherapy in patients who have failed a platinum-based regimen.

Ovarian Cancer

In the majority of patients, this cancer remains occult and becomes symptomatic after it has already metastasized to the peritoneal cavity. At this stage, it usually presents with malignant ascites. It is important to accurately stage this cancer with laparoscopy, ultrasound, and CT scanning. Patients with stage I disease appear to benefit from whole-abdomen radiotherapy and may receive additional benefit from combination chemotherapy with cisplatin and cyclophosphamide.

Combination chemotherapy is the standard approach to stage III and stage IV disease. Randomized clinical studies have shown that the combination of paclitaxel and cisplatin provides survival benefit compared with the previous standard combination of cisplatin plus cyclophosphamide. More recently, several studies have shown that carboplatin and paclitaxel yields clinical results similar to what is achieved with the cisplatin plus paclitaxel combination; however, because of reduced toxicity and greater ease of administration, carboplatin plus paclitaxel has now become the treatment of choice. In patients who present with recurrent disease, the topoisomerase I inhibitor topotecan, the alkylating agent altretamine, and liposomal doxorubicin are used as single agent monotherapy.

Testicular Cancer

The introduction of platinum-based combination chemotherapy has made an impressive change in the treatment of patients with advanced testicular cancer. At present, chemotherapy is recommended for patients with stage IIC or stage III seminomas and nonseminomatous disease. Over 90% of patients respond to chemotherapy, and, depending upon the extent and severity of disease, complete remissions up to 70–80% are observed. Over 50% of patients achieving complete remission are cured with chemotherapy. In patients with good-risk features, three cycles of cisplatin, etoposide, and bleomycin (PEB protocol) or four cycles of cisplatin and etoposide give virtually identical results. In patients with high-risk disease, the combination of cisplatin, etoposide, and ifosfamide can be used as well as etoposide and bleomycin with high-dose cisplatin. Clinical studies are ongoing to determine the role of high-dose therapy and bone marrow transplantation in this setting.

Malignant Melanoma

Malignant melanoma is one of the most difficult neoplasms to treat because it is relatively resistant to drugs. Dacarbazine, temozolomide, and cisplatin are the most active cytotoxic agents for this disease. Biologic agents, including interferon alfa and interleukin-2 (IL-2), may have greater activity than traditional anticancer agents, and treatment with high-dose IL-2 has led to cures in a small subset of patients. Several clinical studies are actively investigating the combination of

biologic therapy with combination chemotherapy in what has been labeled biochemotherapy regimens. Thus far, overall response rates as well as complete response rates appear to be much higher with biochemotherapy regimens compared with chemotherapy alone. Unfortunately, treatment toxicity also seems to be increased. This approach remains investigational, and further studies are required to determine whether this approach can lead to improved patient survival.

Brain Cancer

Chemotherapy has only limited efficacy in the treatment of malignant gliomas. In general, the nitrosoureas, because of their ability to cross the blood-brain barrier, are the most active agents in this disease. Carmustine (BCNU) can be used a single agent, or lomustine (CCNU) can be used in combination with procarbazine and vincristine. In addition, the nonclassic alkylating agent temozolomide has activity in the setting of recurrent disease, and it is approved for this indication. The histopathologic subtype oligodendroglioma has now been shown to be especially chemosensitive, and the combination of procarbazine, lomustine, and vincristine (PCV protocol) is the treatment of choice for this disease.

Choriocarcinoma

This rare tumor arises from fetal trophoblastic tissue and was the first metastatic cancer cured with chemotherapy. Single-agent methotrexate produced complete regression of metastatic lesions, resulting in a high percentage of cures. At present, treatment with single-agent methotrexate or dactinomycin is recommended for low-risk disease, while intense combination regimens including methotrexate and leucovorin rescue, etoposide, dactinomycin, vincristine, and cyclophosphamide are recommended for intermediate or high-risk disease.

Evaluation of Clinical Response

Since cancer chemotherapy can induce clinical improvement, significant toxicity, or both, it is critically important to carefully assess the effects of treatment. The goal of therapy in most cancers is to palliate symptoms and to improve the overall quality of life.

Shrinkage in tumor size is a useful measure of clinical response, and this effect can be demonstrated by physical examination, chest film or other x-ray, or special scanning procedures such as bone scanning (breast, prostate cancer), CT scan, magnetic resonance imaging (MRI), or ultrasonography.

Another sign of therapeutic response is a significant decrease in the quantity of a tumor product or marker substance that reflects the amount of tumor in the body.

Normalization of organ function is another useful indicator of drug effectiveness. Examples of such improvement include the normalization of liver function (eg, increased serum albumin) in patients known to have liver metastases and improvement in neurologic findings in patients with cerebral metastases.

Finally, a valuable sign of clinical improvement is the general well-being of the patient. Although this finding is a combination of subjective and objective factors and may be subject to placebo effects, it nonetheless serves as an obvious and useful sign of clinical improvement and can be used to reassess some of the objective observations listed above. Factors to be considered in determining general well-being include improved appetite, weight gain, and improved performance status (eg, ambulatory versus bedridden).

Secondary Malignancies & Cancer Chemotherapy

The development of secondary malignancies is a late complication of some types of cancer chemotherapy. The most frequent secondary malignancy is acute myelogenous leukemia (AML). The alkylating agents, procarbazine, etoposide, and ionizing radiation are all considered to be leukemogenic. AML has been observed in up to 15% of patients with Hodgkin's disease who have received radiotherapy plus MOPP chemotherapy and in patients with multiple myeloma, ovarian carcinoma, or breast carcinoma treated with melphalan. The risk of AML is observed as early as 2–4 years after the initiation of chemotherapy and peaks at 5 and 9 years. With improvements in the clinical efficacy of various combination chemotherapy regimens resulting in prolonged survival and in some cases actual cure of cancer, the issue of how second cancers may affect long-term survival assumes greater importance. There is already evidence that certain alkylating agents (eg, cyclophosphamide) may be less carcinogenic than others (eg, melphalan). Systematic testing of the carcinogenicity of anticancer drugs in several animal models should allow less toxic agents to be identified and substituted for other more carcinogenic ones in chemotherapy regimens.

Preparations Available

CTL Cytotoxic T lymphocyte
DC Dendritic cell
DTH Delayed-type hypersensitivity
FKBP FK-binding protein
HAMA Human antimouse antibody
IFN Interferon
IL Interleukin
IGIV Immunoglobulin intravenous
LAK cell Lymphokine-activated killer cell
LFA Lymphocyte functional antigen
MAb Monoclonal antibody
MHC Major histocompatibility complex
MCP-1 Macrophage chemotactic protein-1
MIP-1 Macrophage inflammatory protein-1
NK cell Natural killer cell

PAF Platelet-activating factor
RA Rheumatoid arthritis
SCID Severe combined immunodeficiency disease
SLE Systemic lupus erythematosus
TCR T cell receptor
TGF- β Transforming growth factor- β
TH1, TH2 T helper cell types 1 and 2
TNF Tumor necrosis factor

General

Agents that suppress the immune system play an important role in the retention of organ or tissue grafts and in the treatment of certain diseases that arise from dysregulation of the immune response. While the details of the mechanisms of action of a number of these agents are still obscure, a knowledge of the elements of the immune system is useful in understanding their effects. Agents that augment the immune response or selectively alter the balance of various components of the immune system are also becoming important in the management of certain diseases such as cancer, AIDS, and autoimmune or inflammatory diseases. A growing number of other diseases (infections, cardiovascular diseases) may also be candidates for immune manipulation.

Immunopharmacology >

Elements of the Immune System

Normal Immune Responses

The immune system is designed to protect the host from invading pathogens and to eliminate disease. At its functioning best, the immune system is exquisitely responsive to invading pathogens while retaining the capacity to recognize "self" antigens to which it is tolerant. Protection from infection and disease is provided by the innate and the adaptive immune systems.

The Innate Immune System

The innate immune system is the first line of defense against an antigenic insult and includes physical (eg, skin), biochemical (eg, complement, lysozyme, interferons), and cellular components (neutrophils, monocytes, macrophages). An intact skin or mucosa is the first barrier to infection. When this barrier is breached, bacterial destruction is accomplished by lysozyme, which breaks the peptidoglycan cell wall, and by the split products arising from complement activation. These complement components (Figure 56–1) enhance macrophage and neutrophil phagocytosis by acting as opsonins (C3b), attracting immunocytes to inflammatory sites (C3a, C5a), and causing bacterial lysis via the generation of a membrane attack complex. During the inflammatory response triggered by infection, neutrophils and monocytes enter the tissue sites from the peripheral circulation. This influx is mediated by the release of chemokines (IL-8, MIP-1, MCP-1) from activated endothelial cells and immune cells (mostly macrophages) at the inflammatory site and is triggered by the adhesion of immune cells to ligands on the activated endothelial cell surface. If these mechanisms are successful, the invading pathogen is ingested, degraded, and eliminated, and disease is either prevented or is of short duration.

Figure 56-1.

Role of complement in innate immunity. Complement is made up of nine proteins (C1–C9), which are split into fragments during activation. **A:** Complement components (C3a, C5a) attract phagocytes (1) to inflammatory sites (2), where they ingest and degrade pathogens (3). **B:** Complement components C5b, C6, C7, C8, and C9 associate to form a membrane attack complex (MAC) that lyses bacteria, causing their destruction. **C:** Complement component C3b is an opsonin that coats bacteria (1) and facilitates their ingestion (2) and digestion (3) by phagocytes.

The Adaptive Immune System

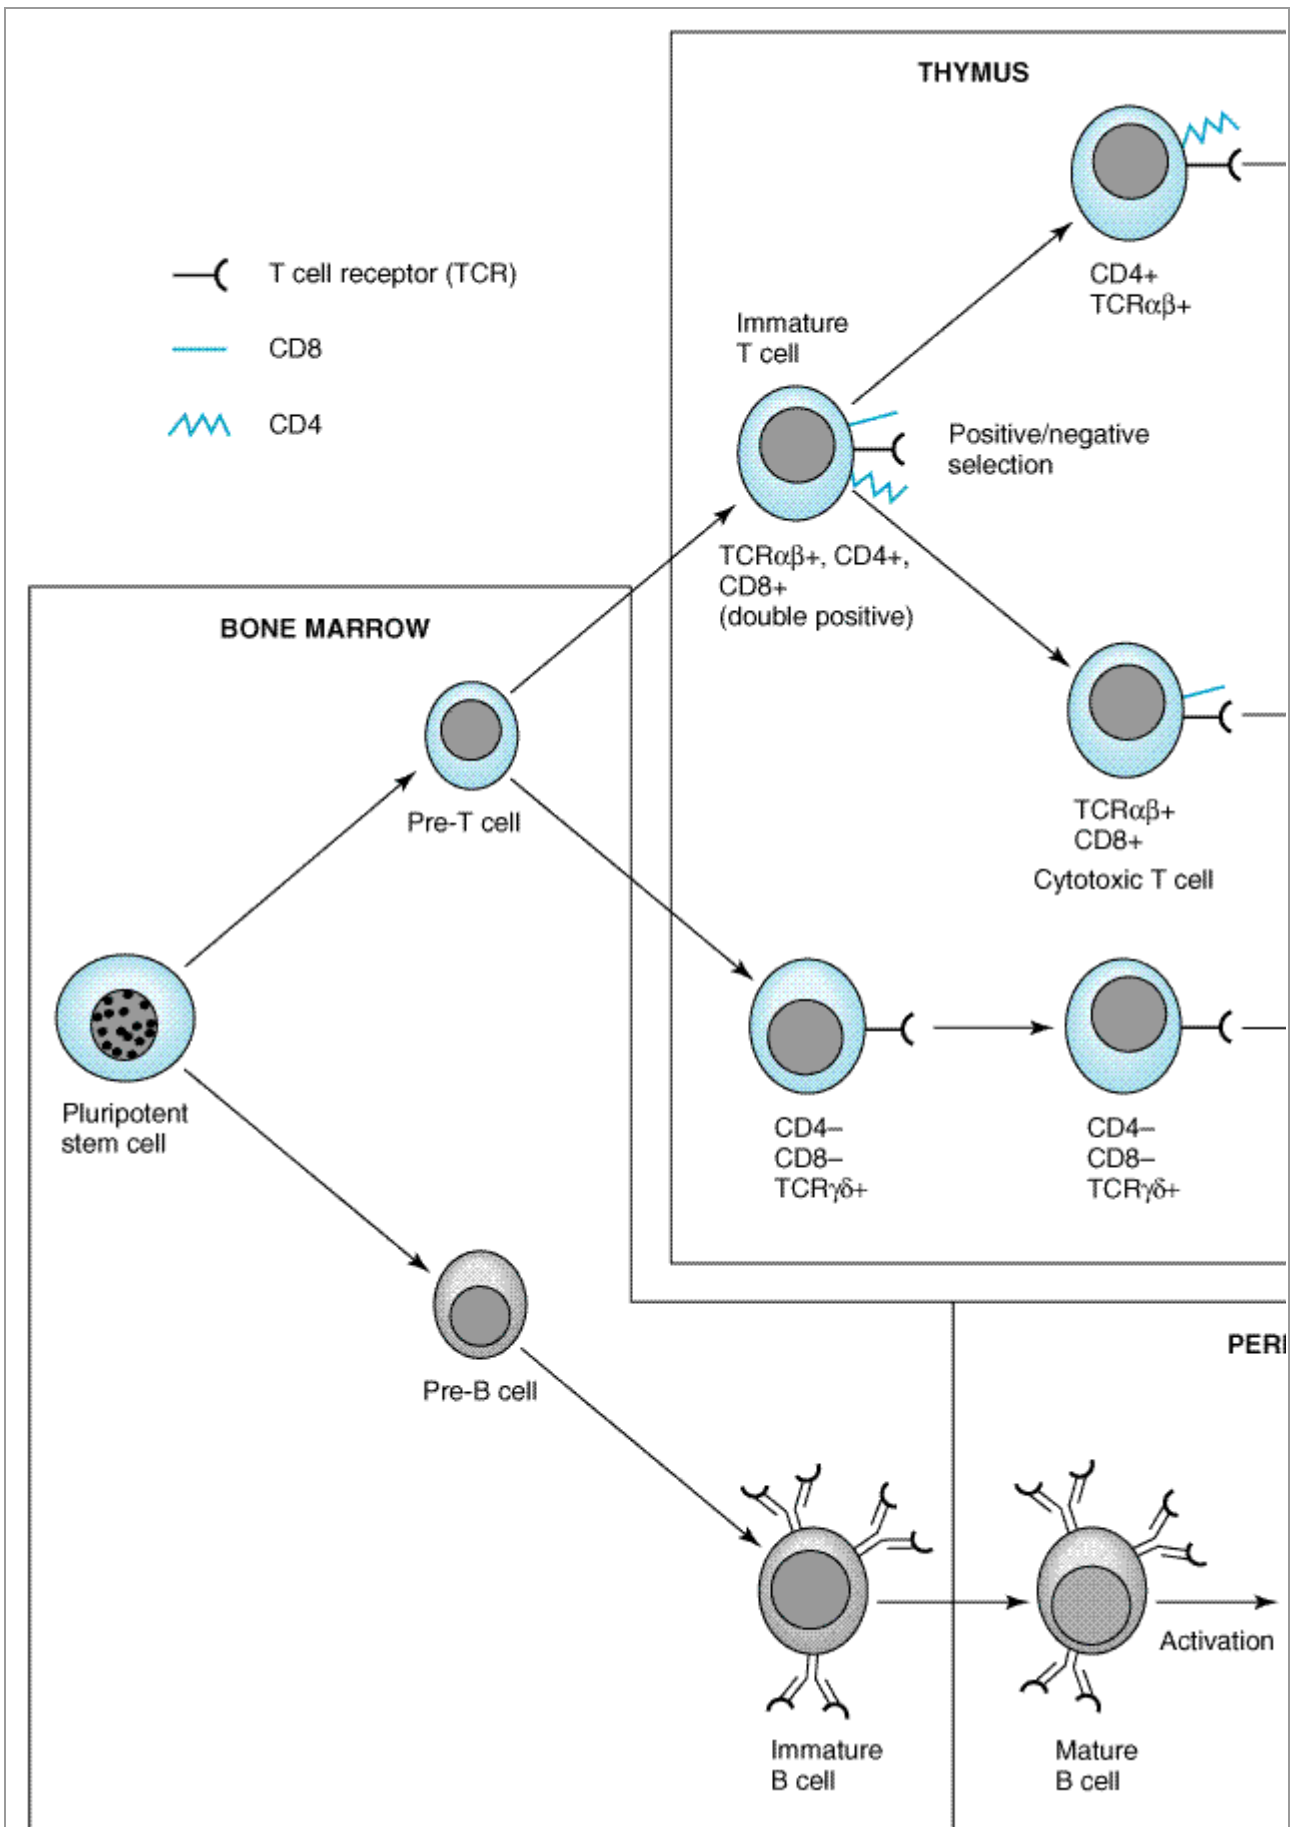

When the innate immune response is inadequate to cope with infection, the adaptive immune system is mobilized by cues from the innate response. The adaptive immune system has a number of characteristics that contribute to its success in eliminating pathogens. These include the ability (1) to respond to a variety of antigens, each in a specific manner; (2) to discriminate between

foreign ("nonself") antigens and self antigens of the host; and (3) to respond to a previously encountered antigen in a learned way by initiating a vigorous memory response. This adaptive response culminates in the production of **antibodies**, which are the effectors of **humoral immunity**; and the activation of **T lymphocytes**, which are the effectors of **cell-mediated immunity**.

The induction of specific immunity requires the participation of antigen-presenting cells (APCs), which include macrophages, dendritic cells, Langerhans cells, and B lymphocytes. These cells play pivotal roles in the immune response by enzymatically digesting protein antigens and presenting the derived peptides in association with class I and class II major histocompatibility complex (MHC) proteins to the T cell receptor (TCR) expressed on CD4 and CD8 T lymphocytes, respectively. At least two signals are necessary for the activation of CD4 and CD8 T cells. The first signal is delivered following engagement of the TCR with peptide-bound MHC molecules (see Figure 56–3 inset). In the absence of a second signal, the T cells become unresponsive (anergic) or undergo apoptosis. A second signal that involves ligation of costimulatory molecules (CD40, CD80, CD86) on the antigen-presenting cell to their respective ligands (CD40L for CD40, CD28 for CD80 and CD86) is required for T cell activation (see Figure 56–3 inset). Binding of CD80 or CD86 to CTLA-4 on activated T cells provides a negative feedback loop for regulating the immune response.

T lymphocytes develop and learn to recognize self and nonself in the thymus; those T cells that bind with high affinity to self antigens in the thymus undergo apoptosis (negative selection), while those that are capable of recognizing foreign antigens in the context of self MHC are retained and expanded (positive selection) (Figure 56–2) for export to the periphery (lymph nodes, spleen, mucosa-associated lymphoid tissue, peripheral blood), where they become activated after encountering MHC-presented peptides (Figure 56–3).

Figure 56–2.

Development of cells involved in cell-mediated and humoral immunity. Pluripotent stem cells

give rise to pre-T and pre-B lymphocytes in the bone marrow. Under the influence of thymic hormones, pre-T cells migrate to the fetal thymus, where they acquire the T cell receptor and undergo selection to become mature helper CD4 or cytotoxic CD8 T cells that are exported to the periphery. B lymphocytes develop in the bone marrow and differentiate into antibody-secreting plasma cells following encounter with specific antigens.

Figure 56-3.

Scheme of cellular interactions during the generation of cell-mediated and humoral immune responses (see text). The cell-mediated arm of the immune response involves the ingestion and digestion of antigen by APCs such as macrophages. The resulting processed peptides bound to class II MHC surface proteins are presented to T helper cells. TH cell activation is optimally achieved when costimulatory molecules (B7) and adhesion molecules (ICAM-1, LFA-3) and CD40-CD40 ligand on the APC are bound to their appropriate ligands on the T cell (see inset).

Activated TH cells secrete IL-2, which causes proliferation and activation of CTLs, and TH1 and TH2 cell subsets. TH1 cells also produce IFN- γ and TNF- β , which can directly activate macrophages and NK cells. The humoral response is triggered when B lymphocytes bind antigen via their surface immunoglobulin. They are then induced by TH2-derived IL-4 and IL-5 to proliferate and differentiate into memory cells and antibody-secreting plasma cells. Regulatory cytokines such as IFN- γ and IL-10 down-regulate TH2 and TH1 responses, respectively.

Studies using T cell clones have demonstrated the presence of two subsets of T helper lymphocytes (TH1 and TH2) based on the cytokines they secrete after activation. The TH1 subset characteristically produces interferon- γ (IFN- γ), interleukin-2 (IL-2), and tumor necrosis factor- β (TNF- β) and induces cell-mediated immunity by activation of macrophages, cytotoxic T cells (CTLs), and natural killer cells (NKs). The TH2 subset produces IL-4, IL-5, IL-6, and IL-10, which induce B cell proliferation and differentiation into antibody-secreting plasma cells. IL-10 produced by TH2 cells inhibits cytokine production by TH1 via the down-regulation of MHC expression by APCs. Conversely, IFN- γ produced by TH1 cells inhibits the proliferation of TH2 cells (Figure 56–3). Although these subsets have been well described in vitro, the nature of the antigenic challenge that elicits a TH1 or TH2 phenotype is less clear. Extracellular bacteria typically cause the elaboration of TH2 cytokines, culminating in the production of neutralizing or opsonic antibodies. In contrast, intracellular organisms (eg, mycobacterium species) elicit the production of TH1 cytokines, which lead to the activation of effector cells such as macrophages. A less well defined T cell subset (TH3) has been described that produces transforming growth factor- β (TGF- β), whose numerous functions include down-regulation of proliferation and differentiation of T lymphocytes.

Cytotoxic T lymphocytes (CTLs) recognize endogenously processed peptides presented by virus-infected cells or tumor cells. These peptides are usually nonapeptide (nine amino acid) fragments derived from virus or protein tumor antigens in the cytoplasm and are loaded onto MHC class I molecules (Figure 56–3, inset) in the endoplasmic reticulum. In contrast, MHC class II molecules present peptides (11–22 amino acids) that have been internalized from the extracellular environment and enzymatically digested foreign antigens to CD4 T helper cells. Upon activation, CTLs induce target cell death via lytic granule enzymes ("granzymes"), perforin, and the Fas-Fas ligand (Fas-FasL) apoptosis pathways. Nitric oxide may also be released, which inhibits cellular enzyme functions.

Natural killer (NK) cells are large granular lymphocyte-like cells that play an important role in innate immunity. Studies with monoclonal antisera originally suggested that NK cells may be of T cell or monocytic origin. More recent studies have shown that they may be derived from CD34 stem cells in the bone marrow that give rise to precursors of the NK cell lineage. NK cells are able to recognize and destroy tumor cells and pathogen-infected normal cells in vitro without prior stimulation. This activity is regulated by so-called "killer cell immunoglobulin-like receptors" (KIRs) on the NK cell surface that are specific for MHC class I molecules. When NK cells bind self MHC proteins (expressed on all nucleated cells), these receptors deliver inhibitory signals, preventing them from killing normal host cells. Tumor cells or virus-infected cells that have down-regulated MHC expression in order to avoid T cell destruction do not engage these KIRs. This results in activation of NK cells and subsequent destruction of the NK target cell. NK cells are also the main precursors of lymphokine-activated killer (LAK) cells. LAK cells are stimulated by high concentrations of IL-2 and are termed "promiscuous killers" because they can kill across MHC barriers and can also kill target cells that do not express MHC. As with CTL-mediated killing, NK cell killing involves the release of cytotoxic granules that induce programmed cell death of the target cell.

Natural killer T (NKT) cells are T cells that express T cell receptors as well as the NK1.1 receptors commonly found on NK cells. NKT cells recognize microbial lipid antigens presented by a unique class of MHC-like molecules known as CD1. They have been implicated in host defense against microbial agents, autoimmune diseases, and tumors.

B lymphocytes undergo selection in the bone marrow, during which self-reactive B lymphocytes are clonally deleted while B cell clones specific for foreign antigens are retained and expanded. The repertoire of antigen specificities by T cells is genetically determined and arises from T cell *receptor* gene rearrangement while the specificities of B cells arise from *immunoglobulin* gene rearrangement; for both types of cells, these determinations occur prior to encounters with antigen. Upon an encounter with antigen, a mature B cell binds the antigen, internalizes and processes it, and presents its peptide in the MHC class II to CD4 helper cells, which in turn secrete IL-4 and IL-5. These interleukins stimulate B cell proliferation and differentiation into memory B cells and antibody-secreting plasma cells. The primary antibody response consists mostly of IgM-class immunoglobulins. Subsequent antigenic stimulation results in a vigorous "booster" response accompanied by class (isotype) switching to produce IgG, IgA, and IgE antibodies with diverse effector functions. These antibodies also undergo affinity maturation, which allows the antibody to bind more efficiently to the antigen. With the passage of time, this results in accelerated elimination of microorganisms in subsequent infections. Antibodies mediate their functions by acting as opsonins to enhance phagocytosis and cellular cytotoxicity and by activating complement to elicit an inflammatory response and induce bacterial lysis (Figure 56–4).

Figure 56–4.

Antibody has multiple functions. The prototypical antibody consists of two heavy (H) and two light (L) chains, each subdivided into constant (C_L, C_H) and variable (V_L, V_H) domains. The structure is held together by intra- and interchain disulfide bridges. **A:** The complementarity-determining region (CDR) of the antigen-binding portion of the antibody engages the antigenic determinant (epitope) in a lock and key fashion. **B:** Antigen-antibody complexes activate complement to produce split complement components that cause bacterial lysis. **C:** The Fc portion of antibodies binds to Fc receptors on phagocytes (eg, macrophages, neutrophils) and facilitates uptake of bacteria (opsonization).

Abnormal Immune Responses

Whereas the normally functioning immune response can successfully neutralize toxins, inactivate

viruses, destroy transformed cells, and eliminate pathogens, inappropriate responses can lead to extensive tissue damage (hypersensitivity) or reactivity against self antigens (autoimmunity); conversely, impaired reactivity to appropriate targets (immunodeficiency) may occur.

Hypersensitivity

Hypersensitivity can be classified as immediate or delayed depending on the time required for clinical symptoms to become manifest following exposure of the host to the sensitizing antigen.

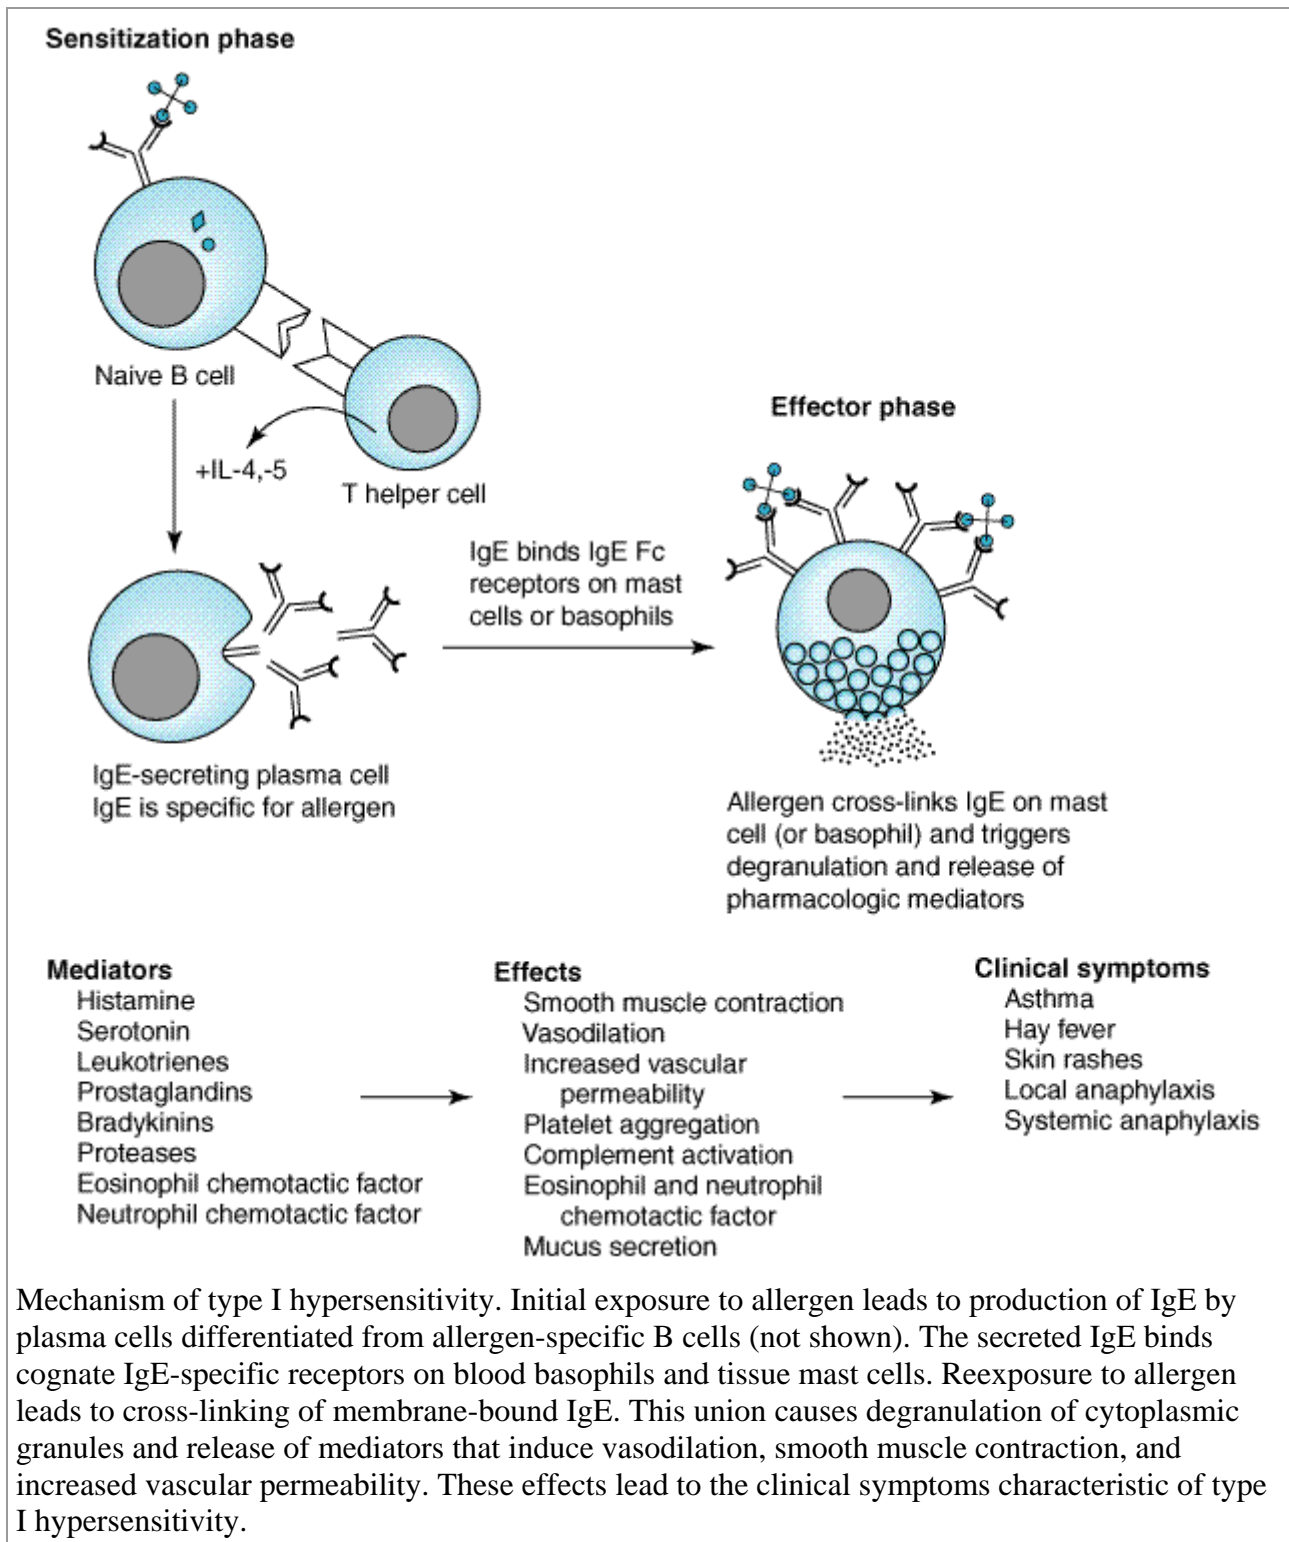

Immediate Hypersensitivity

Immediate hypersensitivity is antibody-mediated, with symptoms usually occurring within minutes or a few hours following the patient's encounter with antigen. Three categories of immediate hypersensitivity are recognized.

Type I

Type I hypersensitivity results from cross-linking of membrane-bound IgE on blood basophils or tissue mast cells by antigen. This cross-linking causes cells to degranulate, releasing substances such as histamine, leukotrienes, and eosinophil chemotactic factor that induce asthma, hay fever, or urticaria (hives) in affected individuals (Figure 56–5). A severe type I hypersensitivity reaction such as systemic anaphylaxis (eg, from insect envenomation, ingestion of certain foods, or drug hypersensitivity) requires immediate medical intervention.

Figure 56–5.

Type II

Type II hypersensitivity results from the formation of antigen-antibody complexes between foreign antigen and IgM or IgG immunoglobulins. One example of this type of hypersensitivity is a blood transfusion reaction that can occur if blood is not cross-matched properly. Preformed antibodies bind to red blood cell membrane antigens that activate the complement cascade, generating a membrane attack complex that destroys the transfused red blood cells. In hemolytic disease of the newborn, anti-Rh IgG antibodies produced by an Rh-negative mother cross the placenta, bind to red

blood cells of an Rh-positive fetus, and damage them. The disease can be prevented by the administration of anti-Rh antibodies to the mother 24–48 hours after delivery (see below). Type II hypersensitivity can also be drug-induced and occurs during the administration of penicillin to allergic patients. In these patients, penicillin binds to red blood cells or other host tissue to form a neoantigen that evokes production of antibodies capable of inducing complement-mediated red cell lysis. In some circumstances, subsequent administration of the drug can lead to systemic anaphylaxis (type I hypersensitivity).

Type III

Type III hypersensitivity is due to the presence of elevated levels of antigen-antibody complexes that cause tissue damage. The formation of these complexes, followed by deposition on basement membranes, activates complement to produce components with anaphylatoxic and chemotactic activities (C5a, C3a, C4a) that increase vascular permeability and recruit neutrophils to the site of complex deposition. Complex deposition and the action of lytic enzymes released by neutrophils can cause skin rashes, glomerulonephritis, and arthritis in these individuals.

Type IV: Delayed Type Hypersensitivity

Unlike immediate hypersensitivity, delayed-type hypersensitivity (DTH) is cell-mediated, and responses occur 2–3 days after exposure to the sensitizing antigen. Delayed-type hypersensitivity induces a local inflammatory response and causes tissue damage characterized by the influx of antigen-nonspecific inflammatory cells, especially macrophages and neutrophils. These cells are recruited under the influence of TH1-produced cytokines (Figure 56–6), which collectively induce extravasation and chemotaxis of circulating monocytes and neutrophils, induce myelopoiesis, and activate macrophages. The activated macrophages display increased phagocytic, microbicidal, and antigen-presenting functions and release copious amounts of digestive enzymes that contribute to the tissue damage associated with delayed-type hypersensitivity. Although widely considered to be deleterious, delayed-type hypersensitivity responses are very effective in eliminating infections caused by intracellular pathogens such as *M tuberculosis* and leishmania species. Tuberculosis exposure is determined using a DTH skin test.

Figure 56–6.

Autoimmunity

Autoimmune disease arises when the body mounts an immune response against itself as a result of failure to distinguish self tissues and cells from foreign (nonself) antigens. This phenomenon derives from the activation of self-reactive T and B lymphocytes that generate cell-mediated or humoral immune responses directed against self antigens. The pathologic consequences of this reactivity constitute different types of autoimmune diseases. Autoimmune diseases are highly complex due to MHC genetics, environmental conditions, infectious entities, and dysfunctional immune regulation. Examples of autoimmune diseases include rheumatoid arthritis, systemic lupus erythematosus, multiple sclerosis, and type 1 diabetes mellitus. In rheumatoid arthritis, IgM antibodies (rheumatoid factors) are produced that react with the Fc portion of IgG and may form immune complexes that activate the complement cascade, causing inflammation of the joints and kidneys. In systemic lupus erythematosus, antibodies are made against DNA, histones, red blood cells, platelets, and other cellular components. In multiple sclerosis and type 1 diabetes, cell-mediated autoimmune attack destroys myelin surrounding nerve cells and insulin-producing B cells of the pancreas, respectively. In type 1 diabetes, activated CD4 T_{DTH} cells that infiltrate the islets of Langerhans and recognize self islet B cell peptides are thought to produce cytokines which stimulate macrophages to produce lytic enzymes that destroy islet B cells. Autoantibodies directed against the islet B cell antigens are produced but probably do not contribute significantly to disease.

A number of mechanisms have been proposed to explain autoimmunity:

(1) Exposure of self-reactive T lymphocytes to antigens previously sequestered from the immune system (eg, lens protein, myelin basic protein).

(2) Molecular mimicry by invading pathogens, in which immune responses are directed at antigenic determinants on pathogens that share identical or similar epitopes with normal host tissue. This phenomenon occurs in rheumatic fever following *Streptococcus pyogenes* infection, in which heart damage is thought to arise from an immune response directed against streptococcal antigens shared with heart muscle. The suggested viral cause of autoimmune diseases has been ascribed to immune responses (both cell-mediated and humoral) directed against virus epitopes that mimic sequestered self antigens.

(3) Inappropriate expression of class II MHC molecules on the membranes of cells that normally do not express class II MHC (eg, islet B cells). Increased expression of MHC II may increase presentation of self peptides to T helper cells, which in turn induce CTL, T_{DTH}, and B lymphocyte cells that react against self antigens.

Immunodeficiency Diseases

Immunodeficiency diseases result from abnormalities in the immune system; the consequences of these abnormalities include increased susceptibility to infections and prolonged duration and severity of disease. Immunodeficiency diseases are either congenitally acquired or arise from extrinsic factors such as bacterial or viral infections or drug treatment. Affected individuals frequently succumb to infections caused by opportunistic organisms that have low pathogenicity for immunocompetent hosts. Examples of congenitally acquired immunodeficiency disease include X-linked agammaglobulinemia, DiGeorge's syndrome, and severe combined immunodeficiency disease (SCID) due to adenosine deaminase (ADA) deficiency. X-linked agammaglobulinemia is a disease affecting males that is characterized by a failure of immature B lymphocytes to mature into antibody-producing plasma cells. These individuals are susceptible to recurrent bacterial infections, though the cell-mediated responses directed against viruses and fungi are preserved. DiGeorge's syndrome is due to failure of the thymus to develop, resulting in diminished T cell responses (T_{DTH}, CTL). The ADA enzyme normally prevents the accumulation of toxic deoxy-ATP in cells. Deoxy-ATP is particularly toxic to lymphocytes and leads to death of T and B cells. Absence of the enzyme therefore results in SCID. Infusion of the purified enzyme (**pegademase**, from bovine sources) and transfer of ADA gene-modified lymphocytes have both been used successfully to treat this disease.

AIDS represents the classic example of immunodeficiency disease caused by extrinsic factors, in this instance the human immunodeficiency virus (HIV). This virus exhibits a strong tropism for CD4 helper T cells; these become depleted, giving rise to increased frequency of opportunistic infections and malignancies in infected individuals. This results from the failure of T helper cells to maintain the cytotoxic lymphocyte response. AIDS is also characterized by an imbalance in TH1 and TH2 cells, and the ratios of cells and their functions are skewed toward TH2. This results in a loss of cytotoxic lymphocyte activity and delayed hypersensitivity, with concurrent hypergammaglobulinemia.

The clinical conditions that arise when the immune system goes awry demonstrate the importance of immune regulation in ensuring the induction of a successful immune response specific for an invading pathogen without being injurious to the host.

Immunosuppressive agents have proved very useful in minimizing the occurrence or impact of deleterious effects of exaggerated or inappropriate immune responses. Unfortunately, these agents

also have the potential to cause disease and to increase the risk of infection and malignancies.

Tests of Immunocompetence

A wide variety of techniques have been used to test immunologic competence and drug-induced immune dysfunction. The simplest tests that can be used to detect the effects of immunosuppressive or immunostimulating agents include the following:

- (1) Delayed-type hypersensitivity testing with skin test antigens to detect the ability to respond to recall antigens, including antigens derived from common microbial pathogens such as candida. The Merieux skin test device is an effective approach to skin testing.
- (2) Measurement of serum immunoglobulins, serum complement, and specific antibodies to various natural and acquired antigens.
- (3) Serial measurements of antibody response after primary immunization or a secondary booster injection.
- (4) Total circulating lymphocyte count.
- (5) Measurement of the percentages of B cells, T cells, and subsets such as CD4, CD8, CD11a, and CD56 (eg, with monoclonal antibodies) that comprise the circulating blood lymphocyte count.
- (6) In vitro lymphocyte proliferative responses to mitogens such as phytohemagglutinin, concanavalin A, and pokeweed mitogen or to specific antigens of interest. The response may be measured by tritiated thymidine incorporation or by cytokine production (IFN- γ , IL-2, TNF, and others).
- (7) Mixed lymphocyte reaction, in which the lymphocytes of one individual are mixed with and proliferate in response to allogeneic lymphocytes of another individual.

Many of these tests are available through the pathology departments of major medical centers.

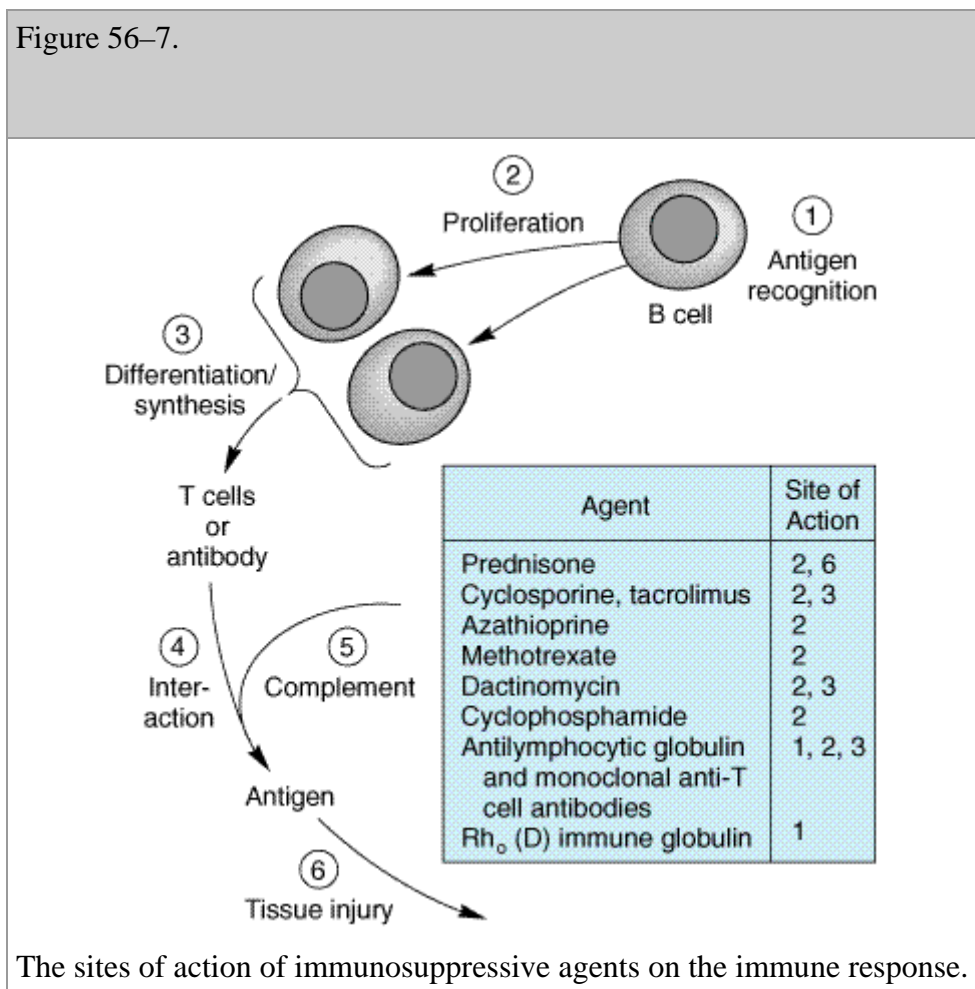

Immunosuppressive Agents

Glucocorticoids

Glucocorticoids were the first hormonal agents recognized as having lympholytic properties. Administration of a glucocorticoid (eg, prednisone, dexamethasone) reduces the size and lymphoid content of the lymph nodes and spleen, though it has essentially no toxic effect on proliferating myeloid or erythroid stem cells in the bone marrow. Glucocorticoids are thought to interfere with the cell cycle of activated lymphoid cells (Figure 56–7). The mechanism of their action is described in Chapter 39: Adrenocorticosteroids & Adrenocortical Antagonists. Glucocorticoids are quite cytotoxic to certain subsets of T cells, but their immunologic effects are probably due to their ability to modify cellular functions rather than to direct cytotoxicity. Glucocorticoids inhibit the production of inflammatory mediators, including PAF, leukotrienes, prostaglandins, histamine, and bradykinin. In monocytes and neutrophils, glucocorticoids cause diminished chemotaxis and impaired bactericidal and fungicidal activities but do not alter their phagocytic ability. Leukocyte distribution is also changed by glucocorticoids, which can cause lymphopenia (probably due to lymphoid tissue sequestration) and neutrophilia (due to demargination and impaired extravasation of neutrophils).

By inhibiting IL-1 production by monocytes, glucocorticoids also cause a decrease in IL-2 and IFN- γ production. Although cellular immunity is affected more than humoral immunity, the primary antibody response can be diminished—and, with continued use, previously established antibody responses are also decreased. Additionally, continuous administration of prednisone increases the fractional catabolic rate of IgG, the major class of antibody immunoglobulins, thus lowering the effective concentration of specific antibodies. Cutaneous delayed hypersensitivity is usually abrogated by glucocorticoid therapy.

Figure 56-7.

The sites of action of immunosuppressive agents on the immune response.

Glucocorticoids are used in a wide variety of conditions. It is thought that the immunosuppressive and anti-inflammatory properties of steroids account for their beneficial effects in diseases like idiopathic thrombocytopenic purpura and rheumatoid arthritis. Glucocorticoids modulate allergic reactions and are useful in the treatment of bronchial asthma or as premedication for other agents (eg, blood products, chemotherapy) that might cause undesirable immune responses. Steroids are first-line immunosuppressive therapy for both solid organ and hematopoietic stem cell transplant recipients. High doses, eg, 4 mg/kg/d of prednisone, can be used to treat organ rejection or graft-versus-host disease without fear of marrow toxicity.

The toxicity of high-dose, long-term glucocorticoid therapy can be severe and is discussed in Chapter 39: Adrenocorticosteroids & Adrenocortical Antagonists.

Cyclosporine

Cyclosporine is an immunosuppressive agent with efficacy in human organ transplantation, in the

treatment of graft-versus-host disease after hematopoietic stem cell transplantation, and in the treatment of selected autoimmune disorders. Patients in whom it is used as the only immunosuppressant or in combination with prednisone have similar graft survival rates and a lower incidence of rejection and infectious complications than patients treated with combinations of drugs such as azathioprine, prednisone, and antilymphocyte antibodies. The drug is a fat-soluble peptide antibiotic that appears to act at an early stage in the antigen receptor-induced differentiation of T cells and blocks their activation. Cyclosporine binds to cyclophilin, a member of a class of intracellular proteins called immunophilins. Cyclosporine and cyclophilin form a complex that inhibits a cytoplasmic phosphatase, calcineurin, that is necessary for the activation of a T cell-specific transcription factor. This transcription factor, NF-AT, is involved in the synthesis of interleukins (eg, IL-2) by activated T cells. In vitro studies have indicated that cyclosporine inhibits the gene transcription of IL-2, IL-3, IFN- γ , and other factors produced by antigen-stimulated T cells, but it does not block the effect of such factors on primed T cells nor does it block interaction with antigen.

Cyclosporine may be given orally or intravenously. Cyclosporine is slowly and incompletely absorbed (20–50%) after oral administration. It has an elimination half-life of 24 hours. The absorbed drug is almost totally metabolized and excreted in the bile. The dosage is based on a predetermined therapeutic blood level, measured as the trough level in steady state. Cyclosporine is metabolized primarily by P450 isoforms, and there is a potential for many drug interactions.

Toxicities are numerous and frequently include nephrotoxicity, hypertension, hyperglycemia, liver dysfunction, and hirsutism. A significant increase in the incidence of cholelithiasis has been observed in children treated with cyclosporine after heart transplantation. Cyclosporine causes very little bone marrow toxicity. While an increased incidence of lymphoma and other cancers (Kaposi's sarcoma, skin cancer) has been documented in transplant recipients receiving cyclosporine, other immunosuppressive agents may also predispose recipients to cancer. Some evidence suggests that tumors may arise after cyclosporine treatment because it induces TGF- β , which promotes tumor invasion and metastasis.

Cyclosporine may be effective without the simultaneous use of other immunosuppressive drugs in some patients, but in other patients it must be combined with them. It has been used successfully as the sole immunosuppressant for cadaveric transplants of the kidney, pancreas, and liver, and it has proved extremely useful in cardiac transplants as well. Low-dosage cyclosporine (7.5 mg/kg/d or less) has also proved useful in a variety of autoimmune disorders, including uveitis and rheumatoid arthritis. Cyclosporine may also have potential utility in the clinical management of other conditions, including psoriasis and asthma. In asthma it has been able to significantly improve the pulmonary function of some patients suffering from the disease and long-term glucocorticoid toxicity.

Cyclosporine is a major step in the direction of a more specific and selective agent that is effective against a subpopulation of lymphocytes. Its adverse effects are still considerable, though perhaps less severe than those of glucocorticoids and other cytotoxic agents used for immunosuppression. Its combination with newer agents is showing considerable efficacy in clinical and experimental settings where effective and less toxic immunosuppression is needed.

Tacrolimus (FK506)

Tacrolimus is an immunosuppressant macrolide antibiotic produced by *Streptomyces tsukubaensis*. It is not chemically related to cyclosporine, but their mechanisms of action are similar. Both drugs bind to cytoplasmic peptidyl-prolyl isomerases that are abundant in all tissues. While cyclosporine

binds to cyclophilin, tacrolimus binds to the immunophilin FK-binding protein (FKBP). Both complexes inhibit calcineurin, which is necessary for the activation of the T cell-specific transcription factor NF-AT.

On a weight basis, tacrolimus is 10–100 times more potent than cyclosporine in inhibiting immune responses. Tacrolimus is utilized for the same indications as cyclosporine, particularly in organ transplantation. Multicenter studies in the United States and in Europe indicate that both graft and patient survival are similar for the two drugs. Tacrolimus has been proved to be effective therapy for preventing rejection in solid-organ transplant patients even after failure of standard rejection therapy, including anti-T cell antibodies.

Tacrolimus can be administered orally or intravenously. After oral administration, peak concentrations are reached after 1–4 hours. The half-life of the intravenous form is approximately 9–12 hours. Like cyclosporine, tacrolimus is metabolized primarily by P450 enzymes in the liver, and there is a potential for drug interactions. The dosage is determined by trough blood level at steady state. Its toxic effects are similar to those of cyclosporine and include nephrotoxicity, neurotoxicity, hyperglycemia, hypertension, hyperkalemia, and gastrointestinal complaints.

Because of the effectiveness of systemic tacrolimus in some dermatologic diseases, a topical preparation is now available. Tacrolimus ointment is currently used in the therapy of atopic dermatitis and psoriasis.

Sirolimus

Sirolimus (rapamycin) is a newer agent, derived from *Streptomyces hygroscopicus*, that binds immunophilins and inhibits calcineurin, as do cyclosporine and tacrolimus. However, sirolimus does not block interleukin production by activated T cells but instead blocks the response of T cells to cytokines. In vitro, it antagonizes tacrolimus-induced T cell responses but seems to be synergistic with cyclosporine. Furthermore, it is a potent inhibitor of B cell proliferation and immunoglobulin production. Sirolimus also inhibits the mononuclear cell proliferative response to colony-stimulating factors and suppresses hematopoietic recovery after myelotoxic treatment in mice. Sirolimus has been used effectively alone or in combination with other immunosuppressants (cyclosporine, tacrolimus, and mycophenolate mofetil) in the preservation of solid organ allografts. Sirolimus is being investigated as therapy for steroid-refractory acute and chronic graft-versus-host disease in hematopoietic stem cell transplant recipients. Topical sirolimus is also used in some dermatologic disorders and, in combination with cyclosporine, in the management of uveoretinitis.

Toxicities of sirolimus can include profound myelosuppression (especially thrombocytopenia), hepatotoxicity, diarrhea, hypertriglyceridemia, and headache.

Interferons

The interferons (IFNs) are proteins that are currently grouped into three families: **IFN- α** , **IFN- β** , and **IFN- γ** . The IFN- α and IFN- β families comprise type I IFNs, ie, acid-stable proteins that act on the same receptor on target cells. Type I IFNs are usually induced by virus infections, with leukocytes producing IFN- α . Fibroblasts and epithelial cells produce IFN- β . IFN- γ , a type II IFN, is acid-labile and acts on a separate receptor on target cells. IFN- γ is usually the product of activated T lymphocytes.

IFNs interact with cell receptors to produce a wide variety of effects that depend on the cell and IFN types. IFNs, particularly IFN- γ , display immune enhancing properties, which include increased

antigen presentation and macrophage, natural killer cell, and cytotoxic T lymphocyte activation. IFNs also inhibit cell proliferation. In this respect, IFN- α and IFN- β are more potent than IFN- γ . Another striking IFN action is increased expression of MHC molecules on cell surfaces. While all three types of IFN induce MHC class I molecules, only IFN- γ induces class II expression. In glial cells, IFN- β antagonizes this effect and may, in fact, decrease antigen presentation within the nervous system.

In clinical practice, IFNs have been used mainly as therapeutic agents in cancers such as melanoma, renal cell carcinoma, and chronic myelogenous leukemia. Interferon- α , in combination with the antiviral drug ribavirin, is efficacious in the therapy of hepatitis C. Clinical trials of IFN- β in patients with multiple sclerosis have shown a favorable effect of this cytokine in relapsing-remitting multiple sclerosis. Patients treated with this cytokine had a reduced rate of exacerbations and less severe disease; they also showed fewer abnormalities on magnetic resonance imaging. Furthermore, these beneficial effects were accompanied by minimal side effects. IFN- β has therefore been approved for use in relapsing multiple sclerosis. The mechanism of cytokine action in multiple sclerosis still needs to be elucidated, and it remains to be determined whether the drug will benefit all patients with progressive disease.

Toxicities of interferons include fever, chills, malaise, myalgias, myelosuppression, headache, and depression.

Mycophenolate Mofetil

Mycophenolate mofetil is a semisynthetic derivative of mycophenolic acid, isolated from the mold *Penicillium glaucum*. In vitro, it inhibits a series of T and B lymphocyte responses, including mitogen and mixed lymphocyte responses. Its action involves inhibition of de novo synthesis of purines. Mycophenolate mofetil is hydrolyzed to mycophenolic acid, the active immunosuppressive moiety; it is synthesized and administered as mycophenolate mofetil to enhance bioavailability. Mycophenolate mofetil is used in solid organ transplant patients for refractory rejections and, in combination with prednisone, as an alternative to cyclosporine or tacrolimus in patients who do not tolerate those drugs. In a placebo-controlled multicenter study, its administration (at 2–3 g/d), along with tacrolimus and glucocorticoids, to recipients of cadaveric renal allografts significantly reduced acute rejection episodes. Mycophenolate mofetil is used to treat steroid-refractory graft-versus-host disease in hematopoietic stem cell transplant patients. It is in clinical trial in combination with tacrolimus as the primary immunosuppressant therapy after stem cell transplant. Newer immunosuppressant applications for mycophenolate mofetil include lupus nephritis, rheumatoid arthritis, and some dermatologic disorders. Mycophenolate mofetil is available in both oral and intravenous forms. The standard dose is one gram twice a day. Drug concentrations are measured in some centers, although the therapeutic range is not well established. Toxicities of mycophenolate mofetil include gastrointestinal disturbances (nausea and vomiting, diarrhea, abdominal pain) and myelosuppression (primarily neutropenia).

Thalidomide

Thalidomide is a sedative drug that was withdrawn from the market in the 1960s because of its disastrous teratogenic effects when used during pregnancy. Nevertheless, it has significant immunomodulatory actions and is currently in active use or in clinical trials for over 40 different conditions. Thalidomide inhibits angiogenesis and is anti-inflammatory and immunomodulatory. It inhibits TNF- α , reduces phagocytosis by neutrophils, increases production of IL-10, alters adhesion molecule expression, and enhances cell-mediated immunity via interactions with T cells. The complex actions of thalidomide continue to be studied as its clinical use evolves.

Thalidomide is currently used for the treatment of multiple myeloma, at initial diagnosis and for relapsed-refractory disease. Patients generally show signs of response within 2–3 months of starting the drug, and reported response rates range from 20% to 70% depending on the conditions and disease state. When combined with dexamethasone, the response rates in myeloma are 80% or more in some studies. Many patients have durable responses—up to 12–18 months. The success of thalidomide in myeloma has led to numerous clinical trials in other diseases such as myelodysplastic syndrome, acute myelogenous leukemia, and graft-versus-host disease, as well as in solid tumors like colon cancer, renal cell carcinoma, melanoma, and prostate cancer. The efficacy of thalidomide in these diseases is not yet known. Thalidomide has been used for many years in the treatment of some manifestations of leprosy and was recently reintroduced in the USA for erythema nodosum leprosum; it is also useful in management of the skin manifestations of lupus erythematosus.

The side effect profile of thalidomide is extensive. The most important toxicity is teratogenesis. Because of this effect, thalidomide use is closely regulated by the manufacturer. The regulatory program involves mandatory pregnancy testing and contraceptive measures that are acknowledged in writing by the patient and the prescribing physician. Pharmacists may dispense the drug in amounts sufficient for only 1 month of therapy and only with appropriate patient registries and consents.

Other adverse effects of thalidomide include peripheral neuropathy, constipation, rash, fatigue, hypothyroidism, and increased risk of deep vein thrombosis. Thrombosis is sufficiently frequent, particularly in the myeloma population, that most patients are placed on warfarin when thalidomide treatment is initiated.

Owing to thalidomide's serious toxicity profile, considerable effort has been expended in the development of analogs. Immunomodulatory derivatives of thalidomide are termed IMiDs. Some IMiDs are much more potent than thalidomide in regulating cytokines and affecting T cell proliferation. CC-5013 (Revimid) is an IMiD that in in vitro and animal studies has been shown to be similar to thalidomide in action but without the sedative effects or teratogenicity. CC-5013 is currently in phase I and II clinical trials for the treatment of myeloma, some myelodysplastic syndromes, and melanoma. Preliminary results show efficacy with decreased toxicity compared with thalidomide.

Another group of thalidomide analogs are called selective cytokine inhibitory drugs (SelCIDs). These agents are phosphodiesterase type 4 inhibitors with potent anti-TNF- α activity but no T cell costimulatory activity. Several SelCIDs are currently under investigation for clinical use.

Cytotoxic Agents

Azathioprine

Azathioprine is a derivative of mercaptopurine and, like the parent drug, functions as a structural analog or antimetabolite (Chapter 55: Cancer Chemotherapy). Although its action is presumably mediated by conversion to mercaptopurine, it has been more widely used than mercaptopurine for immunosuppression in humans. These agents represent prototypes of the antimetabolite group of cytotoxic immunosuppressive drugs, and many other agents that kill proliferative cells appear to work at a similar level in the immune response.

Azathioprine is well absorbed from the gastrointestinal tract and is metabolized primarily to mercaptopurine. Xanthine oxidase splits much of the active material to 6-thiouric acid prior to

excretion in the urine. After administration of azathioprine, small amounts of unchanged drug and mercaptopurine are also excreted by the kidney, and as much as a twofold increase in toxicity may occur in anephric or anuric patients. Since much of the drug's inactivation depends on xanthine oxidase, patients who are also receiving allopurinol (see Chapter 36: Nonsteroidal Anti-Inflammatory Drugs, Disease-Modifying Antirheumatic Drugs, Nonopioid Analgesics, & Drugs Used in Gout and Chapter 55: Cancer Chemotherapy) for control of hyperuricemia should have the dose of azathioprine reduced to one-fourth to one-third the usual amount to prevent excessive toxicity.

Azathioprine and mercaptopurine appear to produce immunosuppression by interfering with purine nucleic acid metabolism at steps that are required for the wave of lymphoid cell proliferation that follows antigenic stimulation. The purine analogs are thus cytotoxic agents that destroy stimulated lymphoid cells. Although continued messenger RNA synthesis is necessary for sustained antibody synthesis by plasma cells, these analogs appear to have less effect on this process than on nucleic acid synthesis in proliferating cells. Cellular immunity as well as primary and secondary serum antibody responses can be blocked by these cytotoxic agents.

Azathioprine

Azathioprine and mercaptopurine appear to be of definite benefit in maintaining renal allografts and may be of value in transplantation of other tissues. These antimetabolites have been used with some success in the management of acute glomerulonephritis and in the renal component of systemic lupus erythematosus. They have also proved useful in some cases of rheumatoid arthritis, Crohn's disease, and multiple sclerosis. The drugs have been of occasional use in prednisone-resistant antibody-mediated idiopathic thrombocytopenic purpura and autoimmune hemolytic anemias.

The chief toxic effect of azathioprine and mercaptopurine is bone marrow suppression, usually manifested as leukopenia, although anemia and thrombocytopenia may occur. Skin rashes, fever, nausea and vomiting, and sometimes diarrhea occur, with the gastrointestinal symptoms seen mainly at higher dosages. Hepatic dysfunction, manifested by very high serum alkaline phosphatase levels and mild jaundice, occurs occasionally, particularly in patients with preexisting hepatic dysfunction.

Leflunomide

Leflunomide is a prodrug of an inhibitor of pyrimidine synthesis rather than purine synthesis. It is orally active, and the active metabolite has a long half-life of several weeks. Thus, the drug should be started with a loading dose, but it can be taken once daily after reaching steady state. It is approved only for rheumatoid arthritis at present, though studies are under way combining

leflunomide with mycophenolate mofetil for a variety of autoimmune and inflammatory skin disorders.

Toxicities include elevation of liver enzymes with some risk of liver damage, renal impairment, and teratogenic effects. A low frequency of cardiovascular effects (angina, tachycardia) was reported in clinical trials of leflunomide.

Cyclophosphamide

The alkylating agent cyclophosphamide is one of the most efficacious immunosuppressive drugs available. Cyclophosphamide destroys proliferating lymphoid cells (see Chapter 55: Cancer Chemotherapy) but also appears to alkylate some resting cells. It has been observed that very large doses (eg, > 120 mg/kg intravenously over several days) may induce an apparent specific tolerance to a new antigen if the drug is administered simultaneously with—or shortly after—the antigen. In smaller doses, it has been very effective against autoimmune disorders (including systemic lupus erythematosus and multiple sclerosis) and in patients with autoimmune hemolytic anemia, antibody-induced pure red cell aplasia, and Wegener's granulomatosis.

Treatment with large doses of cyclophosphamide carries considerable risk of pancytopenia and hemorrhagic cystitis and therefore is generally combined with stem cell rescue (transplant) procedures. Although cyclophosphamide appears to induce tolerance for marrow or immune cell grafting, its use does not prevent the subsequent graft-versus-host disease syndrome, which may be serious or lethal if the donor is a poor histocompatibility match (despite the severe immunosuppression induced by high doses of cyclophosphamide). Other adverse effects of cyclophosphamide include nausea, vomiting, cardiac toxicity, and electrolyte disturbances.

Other Cytotoxic Agents

Other cytotoxic agents, including vincristine, methotrexate, and cytarabine (see Chapter 55: Cancer Chemotherapy), also have immunosuppressive properties. Methotrexate has been used extensively in rheumatoid arthritis (see Chapter 36: Nonsteroidal Anti-Inflammatory Drugs, Disease-Modifying Antirheumatic Drugs, Nonopioid Analgesics, & Drugs Used in Gout) and in the treatment of graft-versus-host disease. Although the other agents can be used for immunosuppression, they have not received as widespread use as the purine antagonists, and their indications for immunosuppression are less certain. The use of methotrexate (which can be given orally) appears reasonable in patients with idiosyncratic reactions to purine antagonists. The antibiotic dactinomycin has also been used with some success at the time of impending renal transplant rejection. Vincristine appears to be quite useful in idiopathic thrombocytopenic purpura refractory to prednisone. The related vinca alkaloid vinblastine has been shown to prevent mast cell degranulation in vitro by binding to microtubule units within the cell and to prevent release of histamine and other vasoactive compounds.

Antibodies As Immunosuppressive Agents

The development of hybridoma technology by Milstein and Kohler in 1975 revolutionized the antibody field and radically increased the purity and specificity of antibodies used in the clinic and for diagnostic tests in the laboratory. Hybridomas consist of antibody-forming cells fused to immortal plasmacytoma cells. Hybrid cells that are stable and produce the required antibody can be cloned for mass culture for antibody production. Large-scale fermentation facilities are now used for this purpose in the pharmaceutical industry.

More recently, molecular biology has been used to develop monoclonal antibodies that are specific for a single molecule. Combinatorial libraries of cDNAs encoding immunoglobulin heavy and light chains expressed on bacteriophage surfaces are screened against purified antigens. The result is an antibody fragment with specificity and high affinity for the antigen of interest. This technique has been used to develop antibodies specific for viruses (eg, HIV), bacterial proteins, and even tumor antigens. Several antibodies developed in this manner are in clinical trials.

Another genetic engineering technique involves "humanization" of murine monoclonal antibodies in order to increase the half-life of the antibody. Murine antibodies administered to human patients evoke production of antimouse antibodies (HAMAs), which clear the original murine protein very rapidly. Humanization involves replacing the murine Fc portion with a human Fc region while keeping the specificity intact. The procedure has been successful in reducing or preventing HAMA production for several drugs, including infliximab and etanercept, discussed below.

Antilymphocyte & Antithymocyte Antibodies

Antisera directed against lymphocytes have been prepared sporadically for over 100 years. With the advent of human organ transplantation as a therapeutic option, heterologous antilymphocyte globulin (ALG) took on new importance. ALG and antithymocyte globulin (ATG) are now in clinical use in many medical centers, especially in transplantation programs. The antiserum is usually obtained by immunization of large animals such as horses or sheep with human lymphoid cells.

Antilymphocyte antibody acts primarily on the small, long-lived peripheral lymphocytes that circulate between the blood and the lymph. With continued administration, "thymus-dependent" lymphocytes from the cuffs of lymphoid follicles are also depleted, as they normally participate in the recirculating pool. As a result of destruction or inactivation of the T cells, an impairment of delayed hypersensitivity and cellular immunity occurs while humoral antibody formation remains relatively intact. ALG and ATG are useful for suppressing certain major compartments (eg, T cells) of the immune system and play a definite role in the management of organ and bone marrow transplantation.

Monoclonal antibodies directed against specific antigens such as CD3, CD4, CD40, IL-2 receptor, and TNF (discussed below) much more selectively influence T cell subset function. The high specificity of these antibodies improves selectivity, reduces the toxicity of therapy, and alters the disease course in several different autoimmune disorders.

In the management of transplants, ALG and monoclonal antibodies can be used in the induction of immunosuppression, in the treatment of initial rejections, and in the treatment of steroid-resistant rejections. There has been some success in the use of ALG and ATG plus cyclosporine for recipient preparation for bone marrow transplantation. In this procedure, the recipient is treated with ALG or ATG in large doses for 7–10 days prior to transplantation of bone marrow cells from the donor. Residual ALG appears to destroy the T cells in the donor marrow graft, and the probability of severe graft-versus-host disease is reduced.

The adverse effects of ALG are mostly those associated with injection of a foreign protein obtained from heterologous serum. Local pain and erythema often occur at the injection site. Since the humoral antibody mechanism remains active, skin-reactive and precipitating antibodies may be formed against the foreign IgG. Similar reactions occur with monoclonal antibodies of murine origin, and reactions thought to be caused by the release of cytokines by T cells and monocytes have also been described.

Anaphylactic and serum sickness reactions to ALG and murine monoclonal antibodies have been observed and usually require cessation of therapy. Complexes of host antibodies with horse ALG may precipitate and localize in the glomeruli of the kidneys. Even more disturbing has been the development of histiocytic lymphomas in the buttock at the site of ALG injection. The incidence of lymphoma as well as other forms of cancer is increased in kidney transplant patients. It appears likely that part of the increased risk of cancer is related to the suppression of a normally potent defense system against oncogenic viruses or transformed cells. The preponderance of lymphoma in these cancer cases is thought to be related to the concurrence of chronic immune suppression with chronic low-level lymphocyte proliferation.

Monoclonal antibodies against T cell surface proteins are increasingly being used in the clinic for autoimmune disorders and in transplantation settings. Clinical studies have shown that the murine monoclonal antibody muromonab-CD3 (OKT3) directed against the CD3 molecule on the surface of human thymocytes and mature T cells can also be useful in the treatment of renal transplant rejection. In vitro, muromonab-CD3 blocks both killing by cytotoxic human T cells and several other T cell functions. In a prospective randomized multicenter trial with cadaveric renal transplants, use of muromonab-CD3 (along with lower doses of steroids or other immunosuppressive drugs) proved more effective at reversing acute rejection than did conventional steroid treatment. Muromonab-CD3 is now marketed for the treatment of renal allograft rejection crises. Several other monoclonal antibodies directed against surface markers on lymphocytes are approved for certain indications (see monoclonal antibody section below), while others are in various stages of development and clinical trials.

Immune Globulin Intravenous (IGIV)

A quite different approach to immunomodulation is the intravenous use of polyclonal human immunoglobulin. This immunoglobulin preparation is prepared from pools of thousands of healthy donors, and no specific antigen is the target of the therapeutic antibody. Rather, one expects that the pool of different antibodies will have a "normalizing" effect upon the patient's immune network.

IGIV in high doses (2 g/kg) has proved effective in a variety of different conditions ranging from asthma to autoimmune disorders. In patients with Kawasaki's disease, it has been shown to be safe and effective, reducing systemic inflammation and preventing coronary artery aneurysms. It has also brought about good clinical responses in subacute lupus erythematosus and refractory idiopathic thrombocytopenic purpura. Possible mechanisms of action of intravenous immunoglobulin include a reduction of helper T cells, increase of suppressor T cells, and a decrease in spontaneous immunoglobulin production and idiotypic-anti-idiotypic interactions with "pathologic antibodies." Though its precise mechanism of action is still controversial, IGIV brings undeniable clinical benefit to many patients with a variety of immune syndromes.

Rh₀(D) Immune Globulin Micro-Dose

One of the major advances in immunopharmacology was the development of a technique for preventing Rh hemolytic disease of the newborn. The technique is based on the observation that a *primary* antibody response to a foreign antigen can be blocked if specific antibody to that antigen is administered passively at the time of exposure to antigen. Rh₀(D) immune globulin is a concentrated (15%) solution of human IgG containing a higher titer of antibodies against the Rh₀(D) antigen of the red cell.

Sensitization of Rh-negative mothers to the D antigen usually occurs at the time of birth of an Rh₀(D)-positive or D^u-positive infant, when fetal red cells may leak into the mother's bloodstream.

Sensitization might also occur occasionally with miscarriages or ectopic pregnancies. In subsequent pregnancies, maternal antibody against Rh-positive cells is transferred to the fetus during the third trimester, leading to the development of erythroblastosis fetalis (hemolytic disease of the newborn).

If an injection of Rh_o(D) antibody is administered to the mother within 24–72 hours after the birth of an Rh-positive baby, the mother's own antibody response to the foreign Rh_o(D)-positive cells is suppressed because the baby's red cells are cleared from circulation before the mother can generate a B cell response against Rh_o(D). Therefore, she has no memory B cells that can activate upon subsequent pregnancies with an Rh_o(D)-positive fetus.

When the mother has been treated in this fashion, Rh hemolytic disease of the newborn has not been observed in subsequent pregnancies. For this prophylactic treatment to be successful, the mother must be Rh_o(D)-negative and D^u-negative and must not already be immunized to the Rh_o(D) factor. Treatment is also often advised for Rh-negative mothers who have had miscarriages, ectopic pregnancies, or abortions when the blood type of the fetus is unknown. *Note: Rh_o(D) immune globulin is administered to the mother and must not be given to the infant.*

The usual dose of Rh_o(D) immune globulin is 2 mL intramuscularly, containing approximately 300 μg anti-Rh_o(D) IgG. Adverse reactions are infrequent and consist of local discomfort at the injection site or, rarely, a slight temperature elevation.

Hyperimmune Immunoglobulins

Hyperimmune immunoglobulin preparations are IGIV preparations made from pools of selected human or animal donors with high-titer antibodies against particular agents of interest such as viruses or toxins (see also Appendix I). Various hyperimmune IGIVs are available for treatment of infections with respiratory syncytial virus, cytomegalovirus, varicella-zoster virus, human herpes virus 3, and hepatitis B virus and for patients with rabies, tetanus, and digoxin overdose. Intravenous administration of the hyperimmune globulins is a passive transfer of high-titer antibodies that either reduces risk or reduces the severity of infection. Rabies hyperimmune globulin is injected around the wound and given intravenously. Tetanus hyperimmune globulin is administered intravenously when indicated for prophylaxis. Rattlesnake and coral snake hyperimmune globulins (antivenins) are effective for North and South American rattlesnakes and some coral snakes (but not Arizona coral snake). Equine and ovine antivenins are available for rattlesnake envenomations, but only equine antivenin is available for coral snake bite.

Monoclonal Antibodies

Recent advances in the ability to manipulate the genes of immunoglobulins have resulted in development of a wide array of humanized and chimeric monoclonal antibodies directed against therapeutic targets. The only murine elements of humanized monoclonal antibodies are the complementarity-determining regions (CDRs) in the variable domains of immunoglobulin heavy and light chains. CDR loops are primarily responsible for the antigen-binding capacity of antibodies. Chimeric antibodies typically contain the antigen-binding murine variable regions and human constant regions. The following are brief descriptions of the engineered antibodies that have been approved by the FDA.

Trastuzumab is a recombinant DNA-derived, humanized monoclonal antibody that binds to the extracellular domain of the human epidermal growth factor receptor HER-2/*neu*. This antibody blocks the natural ligand from binding and down-regulates the receptor. Trastuzumab is approved for the treatment of metastatic breast cancer in patients whose tumors overexpress HER-2/*neu*. As a

single agent it induces remission in about 15–20% of patients; in combination with chemotherapy, it increases response rate and duration as well as 1-year survival. Trastuzumab is under investigation for other tumors that express HER-2.

Rituximab is a murine-human monoclonal IgG1 (human Fc) that binds to the CD20 molecule on normal and malignant B lymphocytes and is approved for the therapy of patients with relapsed or refractory low-grade or follicular B cell non-Hodgkin's lymphoma. The mechanism of action includes complement-mediated lysis, antibody-dependent cellular cytotoxicity, and induction of apoptosis in the malignant lymphoma cells. This drug appears to be synergistic with chemotherapy for lymphoma. **Ibritumomab tiuxetan** is an anti-CD20 murine monoclonal antibody labeled with either Yttrium-90 or Indium-111 approved for use in patients with relapsed or refractory low-grade, follicular, or B cell non-Hodgkin's lymphoma (NHL), including patients with rituximab-refractory follicular NHL. It is used in conjunction with rituximab in a two step therapeutic regimen.

Daclizumab is a humanized IgG1 that binds to CD25 (alpha subunit of IL-2 receptor). It functions as an IL-2 antagonist, blocking IL-2 from binding to activated lymphocytes, and is therefore immunosuppressive. It is indicated for prophylaxis of acute organ rejection in renal transplant patients and is usually used as part of an immunosuppressive regimen that also includes glucocorticoids and cyclosporine. Daclizumab is administered in doses of 1 mg/kg, the first 24 hours prior to transplant followed by four separate doses at 14-day intervals.

Basiliximab also binds to the IL-2 receptor alpha chain on activated lymphocytes but is a chimeric human-mouse IgG1. Its indication is identical to that of daclizumab; however, basiliximab is given in two bolus or intravenous infusions, the first administered no more than 2 hours prior to transplant and the second 4 days after the transplant procedure.

Abciximab is a Fab fragment of a murine-human monoclonal antibody that binds to the integrin GPIIb/IIIa receptor on activated platelets, inhibiting fibrinogen, Von Willebrand factor, and other adhesive molecules from binding to activated platelets and preventing their aggregation. See Chapter 34: Drugs Used in Disorders of Coagulation for additional details.

Palivizumab is a monoclonal antibody that binds to the fusion protein of respiratory syncytial virus, preventing infection in susceptible cells in the airways. Its use in neonates at risk for respiratory syncytial virus infection reduces the frequency of infection and hospitalization by about 50% (see Chapter 49: Antiviral Agents).

Infliximab, etanercept, and adalimumab are new biologic agents that bind TNF- α , a proinflammatory cytokine. Blocking TNF- α from binding to TNF receptors on inflammatory cell surfaces results in suppression of downstream inflammatory cytokines such as IL-1 and IL-6 and adhesion molecules involved in leukocyte activation and migration. Infliximab is a human-mouse chimeric IgG1 monoclonal antibody possessing human constant (Fc) regions and murine variable regions. In clinical trials in Crohn's disease, Infliximab reduced symptoms in 25% of patients who were refractory to all other agents. In clinical trials in rheumatoid arthritis, 52% of patients showed improvement of arthritic symptoms. Infliximab is currently approved for use in Crohn's disease of the colon and in rheumatoid arthritis. Toxicities of all three drugs include an increased incidence of lymphoma.

Etanercept is a dimeric fusion protein composed of human IgG1 constant regions (C_H2, C_H3, and hinge, not C_H1) fused to the TNF *receptor*. Etanercept binds to both TNF- α and TNF- β and appears to have effects similar to that of infliximab, ie, inhibition of TNF- α -mediated inflammation, but its half-life is shorter due to its physical form (fusion protein) and the route of injection

(subcutaneously, twice weekly). Etanercept is approved for adult rheumatoid arthritis, polyarticular course juvenile rheumatoid arthritis, and psoriatic arthritis. It may be used in combination with methotrexate.

Adalimumab is a completely human IgG1 that was generated using antibody-phage display technology. It is approved for use in rheumatoid arthritis. Like the other anti-TNF- α biologicals, adalimumab blocks the interaction of TNF- α with TNF receptors on cell surfaces; it does not bind TNF- β . Pharmacodynamic studies showed that administration of adalimumab reduced levels of C-reactive protein, erythrocyte sedimentation rate, serum IL-6, and matrix metalloproteinases MMP-1 and MMP-3. In vitro, adalimumab lyses cells expressing TNF- α in the presence of complement. Patients may self-administer single doses (40 mg/0.8 mL) of the antibody subcutaneously every other week. Adalimumab has a serum half-life of 2 weeks, which can be increased by 29–44% in patients who are also taking methotrexate.

Alefacept is an engineered protein consisting of the CD2-binding portion of LFA-3 fused to a human IgG1 Fc region (hinge, C_H1, and C_H2), approved for the treatment of plaque psoriasis. It inhibits activation of T cells by binding to cell surface CD2, inhibiting the normal CD2/LFA-3 interaction. Treatment of patients with alefacept also results in a dose-dependent reduction of circulating T cells overall and also in those that predominate in psoriatic plaques. Therefore, T cell numbers of patients receiving alefacept must be monitored and the drug discontinued if CD4 lymphocyte levels fall below 250 cells/ μ L. Dosing of 7.5 mg is once per week for 12 weeks as a bolus intravenous or intramuscular injection.

Alemtuzumab is a humanized IgG1 with a kappa chain that binds to CD52 found on normal and malignant B and T lymphocytes, NK cells, monocytes, macrophages, and a small population of granulocytes. Currently, alemtuzumab is approved for the treatment of B cell chronic lymphocytic leukemia in patients who have been treated with alkylating agents and have failed fludarabine therapy. Alemtuzumab appears to deplete leukemic and normal cells by direct antibody-dependent lysis. Patients receiving this antibody become lymphopenic and may also become neutropenic, anemic, and thrombocytopenic. As a result, patients should be closely monitored for opportunistic infections and hematologic toxicity. Partial response rates in clinical trials were between 21 and 31%.

Clinical Uses of Immunosuppressive Drugs

Immunosuppressive agents are commonly used in two clinical circumstances: transplantation and autoimmune disorders. The agents used differ somewhat for the specific disorders treated (see specific agents and Table 56–1), as do administration schedules. Because autoimmune disorders are very complex, optimal treatment schedules have yet to be established in many clinical situations.

Table 56–1. Clinical Uses of Immunosuppressive Agents.		
	Immunosuppressive Agents Used	Response
Autoimmune diseases		
Idiopathic thrombocytopenic purpura	Prednisone, ¹ vincristine, occasionally cyclophosphamide, mercaptopurine, or azathioprine; commonly high-dose gamma globulin, plasma immunoadsorption or plasma exchange	Usually good

Autoimmune hemolytic anemia	Prednisone, ¹ cyclophosphamide, chlorambucil, mercaptopurine, azathioprine, high-dose gamma globulin	Usually good
Acute glomerulonephritis	Prednisone, ¹ mercaptopurine, cyclophosphamide	Usually good
Acquired factor XIII antibodies	Cyclophosphamide plus factor XIII	Usually good
Autoreactive tissue disorders (autoimmune diseases) ²	Prednisone, cyclophosphamide, methotrexate, interferon alfa and interferon beta, azathioprine, cyclosporine, infliximab, etanercept, adalimumab	Often good, variable
Isoimmune disease		
Hemolytic disease of the newborn	Rh ₀ (D) immune globulin	Excellent
Organ transplantation		
Renal	Cyclosporine, azathioprine, prednisone, ALG, OKT3, tacrolimus, basiliximab, ³ daclizumab ³	Very good
Heart		Good
Liver	Cyclosporine, prednisone, azathioprine, tacrolimus	Fair
Bone marrow	Cyclosporine, cyclophosphamide, prednisone, methotrexate, ALG	Good

¹Drug of choice.

²Including systemic lupus erythematosus, rheumatoid arthritis, scleroderma, dermatomyositis, mixed tissue disorder, multiple sclerosis, Wegener's granulomatosis, chronic active hepatitis, lipoid nephrosis, inflammatory bowel disease.

³Basiliximab and daclizumab are approved for renal transplant only.

Solid Organ & Bone Marrow Transplantation

In organ transplantation, tissue typing—based on donor and recipient histocompatibility matching with the human leukocyte antigen (HLA) haplotype system—is required. Close histocompatibility matching reduces the likelihood of graft rejection and may also reduce the requirements for intensive immunosuppressive therapy. Prior to transplant, patients may receive an immunosuppressive regimen including antithymocyte globulin, muromonab-CD3, daclizumab, or basiliximab. Four types of rejection can occur in a solid organ transplant recipient: hyperacute, accelerated, acute, and chronic. Hyperacute rejection is due to preformed antibodies against the donor organ, such as anti-blood group antibodies. Hyperacute rejection occurs within hours after the transplant procedure and cannot be stopped with immunosuppressive drugs. It results in rapid necrosis and failure of the transplanted organ. Accelerated rejection is mediated by both antibodies and T cells, but it also cannot be stopped by immunosuppressive drugs. Acute rejection of an organ occurs within days to months and involves mainly cellular immunity. Reversal of acute rejection is usually possible with general immunosuppressive drugs such as azathioprine, mycophenolate mofetil, cyclosporine, tacrolimus, glucocorticoids, cyclophosphamide, methotrexate, or rapamycin.

Recently, biologicals such as anti-CD3 monoclonal antibody have been used to combat acute rejection. Chronic rejection usually occurs months or even years after transplantation. It is characterized by thickening and fibrosis of the vasculature of the transplanted organ, involving both cellular and humoral immunity. Chronic rejection is treated with the same drugs as those used for acute rejection.

Allogeneic hematopoietic stem cell transplantation is a well-established treatment for many malignant and nonmalignant diseases. An HLA-matched donor, usually a family member, is located; patients are conditioned with high-dose chemotherapy or radiation therapy (or both); and donor stem cells are then infused. The conditioning regimen is used not only to kill cancer cells in the case of malignant disease but also to totally suppress the immune system so that the patient does not reject the donor stem cells. As patients' blood counts recover (after reduction by the conditioning regimen), they develop a new immune system that is created from the donor stem cells. Rejection of donor stem cells is uncommon and can only be treated by infusion of more stem cells from the donor. Graft-versus-host disease, however, is very common, occurring in the majority of patients who receive an allogeneic transplant. Graft-versus-host disease occurs as donor T cells fail to recognize the patient's skin, liver, and gut (usually) as self and attack those tissues. Patients are immunosuppressed (cyclosporine, methotrexate, and others) early in their transplant course to help prevent graft-versus-host disease, but it usually occurs despite these medications. Acute graft-versus-host disease occurs within the first 100 days and is usually manifested as a skin rash, severe diarrhea, or hepatotoxicity. Additional medications are added, invariably starting with high-dose steroids and moving to additional drugs such as mycophenolate mofetil, rapamune, tacrolimus, daclizumab, and others, with variable success rates. Patients generally progress to chronic graft-versus-host disease (after 100 days) and require therapy for variable periods thereafter. Unlike solid organ transplantation, however, stem cell transplant patients generally are able to discontinue immunosuppressive drugs as the graft-versus-host disease resolves (generally 1–2 years after the transplant procedure).

Autoimmune Disorders

The effectiveness of immunosuppressive drugs in autoimmune disorders varies widely. Nonetheless, with immunosuppressive therapy, remissions can be obtained in many instances of autoimmune hemolytic anemia, idiopathic thrombocytopenic purpura, type 1 diabetes mellitus, Hashimoto's thyroiditis, and temporal arteritis. Apparent improvement is also often seen in patients with systemic lupus erythematosus, acute glomerulonephritis, acquired factor VIII inhibitors (antibodies), rheumatoid arthritis, inflammatory myopathy, scleroderma, and certain other autoimmune states.

Some cases of idiopathic aplastic anemia also appear to have an autoimmune basis. A recent series of aplastic anemia patients showed significant clinical improvement and prolonged survival when treated with ATG alone. Some prior cases treated with bone marrow transplantation after conditioning with cyclophosphamide, cyclosporine, or ALG have also shown prolonged improvement in blood counts even though there was evidence of graft rejection and recovery of recipient marrow function—again supporting an autoimmune basis for some cases of aplastic anemia. Another novel approach to control this condition is plasma immunoabsorption using protein A columns. This presumably removes the immunoreactive antibody, particularly in the form of immune complexes.

Immunosuppressive therapy is currently an option in chronic severe asthma, where cyclosporine seems to be an effective drug and rapamycin promises to be another alternative. Tacrolimus is currently under clinical investigation for the management of autoimmune chronic active hepatitis

and of multiple sclerosis, where IFN- β has a definitive role.

Immunomodulating Agents

The development of agents that modulate the immune response rather than suppress it has become an important area of pharmacology. The rationale underlying this research is that such drugs may increase the immune responsiveness of patients who have either selective or generalized immunodeficiency. The major potential uses are in immunodeficiency disorders, chronic infectious diseases, and cancer. At present, all but two of the immunostimulating or immunomodulating agents (BCG and levamisole) are classed as investigational drugs for this purpose. The AIDS epidemic has greatly increased interest in developing more effective immunomodulating drugs.

Cytokines

The cytokines are a large and heterogeneous group of proteins with diverse functions. Some are immunoregulatory proteins synthesized within lymphoreticular cells and play numerous interacting roles in the function of the immune system and in the control of hematopoiesis. The cytokines that have been clearly identified are summarized in Table 56–2. In most instances, cytokines mediate their effects via receptors on or in relevant target cells and appear to act in a manner similar to the mechanism of action of hormones. In other instances, cytokines may have antiproliferative, antimicrobial, and antitumor effects.

Cytokine	Properties
Interferon- α (IFN- α)	Antiviral, oncostatic, activates NK cells
Interferon- β (IFN- β)	Antiviral, oncostatic, activates NK cells
Interferon- γ (IFN- γ)	Antiviral, oncostatic, secreted by and activates or upregulates TH1 cells, NK cells, CTLs, and macrophages
Interleukin-1 (IL-1)	T cell activation, B cell proliferation and differentiation, HCF ¹
Interleukin-2 (IL-2)	T cell proliferation, TH1, NK, and LAK cell activation
Interleukin-3 (IL-3)	Hematopoietic precursor proliferation and differentiation
Interleukin-4 (IL-4)	TH2 and CTL activation, B cell proliferation
Interleukin-5 (IL-5)	Eosinophil proliferation, B cell proliferation and differentiation
Interleukin-6 (IL-6)	HCF, TH2, CTL, and B cell proliferation
Interleukin-7 (IL-7)	CTL, NK, LAK, and B cell proliferation, thymic precursor stimulation
Interleukin-8 (IL-8)	Neutrophil chemotaxis, proinflammatory
Interleukin-9 (IL-9)	T cell proliferation
Interleukin-10 (IL-10)	TH1 suppression, CTL activation, B cell proliferation
Interleukin-11 (IL-11)	Megakaryocyte proliferation, B cell differentiation
Interleukin-12 (IL-12)	TH1 and CTL proliferation and activation

Interleukin-13 (IL-13)	Macrophage function modulation, B cell proliferation
Interleukin-14 (IL-14)	B cell proliferation and differentiation
Interleukin-15 (IL-15)	TH1, CTL, and NK/LAK activation, expansion of T cell memory pools
Interleukin-16 (IL-16)	T lymphocyte chemotaxis, suppresses HIV replication
Interleukin-17 (IL-17)	Stromal cell cytokine production
Interleukin-18 (IL-18)	Induces TH1 responses
Interleukin-19 (IL-19)	Proinflammatory
Interleukin-20 (IL-20)	Promotes skin differentiation
Interleukin-21 (IL-21)	Proliferation of activated T cells, maturation of NK cells
Interleukin-22 (IL-22)	Regulator of TH2 cells
Interleukin-23 (IL-23)	Proliferation of TH1 memory cells
Interleukin-24 (IL-24)	Induces tumor apoptosis, induces TH1 responses
Tumor necrosis factor- α (TNF- α)	Oncostatic, macrophage activation, proinflammatory
Tumor necrosis factor- β (TNF- β)	Oncostatic, proinflammatory, chemotactic
Granulocyte colony stimulating factor	Granulocyte production
Granulocyte-macrophage colony stimulating factor	Granulocyte, monocyte, eosinophil production
Macrophage colony stimulating factor	Monocyte production, activation
Erythropoietin (EPO)	Red blood cell production
Thymopoietin (TPO)	Platelet production

¹Hematopoietic cofactor (HCF): Plays some role, but not the central role, in growth and differentiation of bone marrow derived cells.

The first group of cytokines discovered, the interferons, were followed by the colony-stimulating factors (CSFs, also discussed in Chapter 33: Agents Used in Anemias; Hematopoietic Growth Factors). The latter regulate the proliferation and differentiation of bone marrow progenitor cells. Most of the more recently discovered cytokines have been classified as interleukins and numbered in the order of their discovery. The identification of most interleukins and the production of highly purified cytokines of all types have been greatly facilitated by the development and pharmaceutical application of gene cloning techniques.

IFN- α is approved for the treatment of several neoplasms, including hairy cell leukemia, chronic myelogenous leukemia, malignant melanoma, and Kaposi's sarcoma, and for use in hepatitis B and C infections. It has also shown activity as an anticancer agent in renal cell carcinoma, carcinoid syndrome, and T cell leukemia. IFN- β is approved for use in relapsing-type multiple sclerosis. IFN- γ is approved for the treatment of chronic granulomatous disease and IL-2 for metastatic renal cell carcinoma and malignant melanoma. Numerous clinical investigations of the other cytokines, including IL-1, IL-3, IL-4, IL-6, IL-11, and IL-12, are now in progress. TNF- α has been extensively

tested in the therapy of various malignancies, but results have been disappointing. One exception is the use of intra-arterial high-dose TNF- α for malignant melanoma and soft tissue sarcoma of the extremities. In these settings, response rates greater than 80% have been noted.

Cytokines as adjuvants to vaccines have also been under clinical investigation. Interferons and IL-2 have shown some positive effects in the response of human subjects to hepatitis B vaccine. IL-12 and GM-CSF (sargramostim) have also shown adjuvant effects with vaccines. GM-CSF is of particular interest because it promotes recruitment of professional antigen-presenting cells such as dendritic cells required for priming naive antigen-specific T lymphocyte responses. There are some claims that GM-CSF can itself stimulate an antitumor immune response, resulting in tumor regression in melanoma and prostate cancer. However, recombinant cytokines are expensive drugs and may never reach wide use as vaccine adjuvants.

It is important to emphasize that cytokine interactions with target cells often result in the release of a cascade of different endogenous cytokines, which exert their effects sequentially or simultaneously. For example, IFN- γ exposure increases the number of cell surface receptors on target cells for TNF- α . Therapy with IL-2 induces the production of TNF- α , while therapy with IL-12 induces the production of IFN- γ .

Most cytokines (including TNF- α , IFN- γ , IL-2, G-CSF (filgrastim), and GM-CSF) have very short serum half-lives (minutes). The usual subcutaneous route of administration provides slower release into the circulation. Each cytokine has its own unique toxicity, but some toxicities are shared. Thus, IFN- α , IFN- β , IFN- γ , IL-2, and TNF- α all induce fever, flu-like symptoms, anorexia, fatigue, and malaise.

A more recent approach to immunomodulation involves the use of cytokine inhibitors for the treatment of inflammatory diseases and septic shock, conditions where cytokines such as IL-1 and TNF- α are involved in the pathogenesis. Now under investigation are anticytokine monoclonal antibodies, soluble cytokine receptors (both soluble IL-1 receptors and soluble TNF- α receptors occur naturally in humans), and the IL-1 receptor antagonist IL-1Ra (also a naturally occurring molecule that binds to IL-1 receptors but does not induce biologic responses). These molecules have shown efficacy in animal models of septic shock, experimental arthritis, immune complex-mediated colitis, and diabetes. Phase I clinical studies have demonstrated the safety of monoclonal anti-TNF- α and anti-IL-1Ra antibodies in human volunteers. Preliminary data from phase III studies with monoclonal anti-TNF- α antibodies suggest that these antibodies may be effective in the treatment of septic shock when bacteremia is present. Furthermore, results from a phase III study of IL-1Ra indicated that among high-risk patients, treatment with IL-1Ra improved survival significantly. Other clinical trials using IL-1Ra for the treatment of ulcerative colitis, rheumatoid arthritis, and myelogenous leukemia are also underway.

Levamisole

Levamisole was first synthesized for the treatment of parasitic infections. Later studies suggested that it increases the magnitude of delayed hypersensitivity or T cell-mediated immunity in humans. In immunodeficiency associated with Hodgkin's disease, levamisole has been noted to increase the number of T cells in vitro and to enhance skin test reactivity. Levamisole has also been widely tested in rheumatoid arthritis and found to have some efficacy. However, it has induced severe agranulocytosis (mainly in HLA-B27-positive patients), which required discontinuation of its use. The drug may also potentiate the action of fluorouracil (5-FU) in adjuvant therapy of colorectal cancer, and this combination has been approved for clinical use in the treatment of Dukes class C colorectal cancer after surgery. Its use in these cases reduces recurrences, and the mechanism

probably relates to macrophage activation and the killing of residual tumor cells by activated macrophages. However, based on recent results from several randomized clinical trials, the 5-FU-levamisole regimen is being replaced by 5-FU-leucovorin since the latter was more effective at increasing disease-free survival and decreasing overall mortality.

BCG (Bacille Calmette-Guérin) & Other Adjuvants

BCG is a viable strain of *Mycobacterium bovis* that has been used for immunization against tuberculosis. It has also been employed as a nonspecific adjuvant or immunostimulant in cancer therapy but has been successful only in intravesical therapy for superficial bladder cancer. BCG appears to act at least in part via activation of macrophages to make them more effective killer cells in concert with lymphoid cells in the cellular efferent limb of the immune response. Lipid extracts of BCG as well as nonviable preparations of *Corynebacterium parvum* may have similar nonspecific immunostimulant properties. A chemically defined derivative of the BCG cell wall, [Lys¹⁸]-muramyl dipeptide, has been licensed in Japan to enhance bone marrow recovery after cancer chemotherapy.

A variety of microbial products, including whole organisms and extracts, have been used in Japan as immunomodulators in standard cancer treatments. These have included **picibanil** (OK432), **lentinan**, and **pachymaran**. Clinical trials, usually historically controlled, showed a prolongation of remission and survival. These agents stimulate macrophages to release various cytokines, including IL-1, colony-stimulating factors, and TNF- α . TNF- α is released into the serum of BCG-treated animals after endotoxin challenge. TNF- α is also considered an important mediator of the hypotensive reaction observed in patients with endotoxic shock associated with gram-negative bacteremia.

Other Immunomodulators

Inosiplex (isoprinosine) has immunomodulating activities in various experimental and clinical settings. This agent increased natural killer cell cytotoxicity as well as T cell and monocyte functional activities. Inosiplex is approved in several European countries for the treatment of diverse immunodeficiency diseases but is not approved in the USA. Other synthetic drugs, including cyanoaziridine compounds (**azimexon**, **ciamexon**, and **imexon**) and **methylinosine monophosphate**, have been under investigation for the treatment of AIDS and neoplasia. Several sulfur-containing compounds have also been under investigation as immunomodulators. **Diethyl dithiocarbamate (DTC)** was found to reduce infections and slow progression in some patients with advanced HIV infection. The drug was not active in earlier stages of HIV infection and is not currently approved.

Thymosin consists of a group of protein hormones synthesized by the epithelioid component of the thymus. These proteins have been isolated and purified from bovine and human thymus glands. Thymosin, which has a molecular weight of approximately 10,000, appears to convey T cell specificity to uncommitted lymphoid stem cells. Smaller peptides and recombinant molecules such as thymosin- α 1, thymic humoral factor, and thymopentin, may have similar activity. Thymosin levels are high through normal childhood and early adulthood, begin to fall in the third to fourth decades, and are low in elderly people. Serum levels are also low in DiGeorge's syndrome of T cell deficiency. In vitro treatment of lymphocytes with thymosin increases the number of cells that manifest T cell surface markers and function. Mechanistically, thymosin is considered to induce the maturation of pre-T cells. The effects of fetal thymus transplantation in DiGeorge's syndrome are probably attributable to the action of thymosin.

While thymic hormones are licensed in Europe and Asia, their use has not been approved in the USA. Recent clinical trials have demonstrated some effectiveness of thymosin- α 1 plus IFN- α in treating hepatitis B and C.

Immunologic Reactions to Drugs & Drug Allergy

The basic immune mechanism and the ways in which it can be suppressed or stimulated by drugs have been discussed in foregoing sections of this chapter. Drugs also activate the immune system in undesirable ways manifested as adverse drug reactions. These reactions are generally lumped in a broad classification as "drug allergy." Indeed, many drug reactions such as those to penicillin, iodides, phenytoin, and sulfonamides are allergic in nature. These drug reactions are manifested as skin eruptions, edema, anaphylactoid reactions, glomerulonephritis, fever, and eosinophilia. The underlying mechanism of the allergic sensitization to drugs is IgE-mediated and occurs by sensitization and effector phases (see Figure 56–5).

Drug reactions mediated by immune responses may have different mechanisms. Thus, any of the four major types of hypersensitivity can be associated with allergic drug reactions:

Type I: IgE-mediated acute allergic reactions to stings, pollens, and drugs, including anaphylaxis, urticaria, and angioedema. IgE is fixed to tissue mast cells and blood basophils, and after interaction with antigen the cells release potent mediators.

Type II: Drugs often modify host proteins, thereby eliciting antibody responses to the modified protein. These allergic responses involve IgG or IgM in which the antibody becomes fixed to a host cell, which is then subject to complement-dependent lysis or to antibody-dependent cellular cytotoxicity (ADCC).

Type III: Drugs may cause serum sickness, which involves immune complexes containing IgG and is a multisystem complement-dependent vasculitis that may result in urticaria.

Type IV: Cell-mediated allergy is the mechanism involved in allergic contact dermatitis from topically applied drugs or induration of the skin at the site of an antigen injected intradermally.

In a number of drug reactions, several of these hypersensitivity reactions may present simultaneously. Some adverse reactions to drugs may be mistakenly classified as allergic or immune when they are actually genetic deficiency states or are idiosyncratic and not mediated by immune mechanisms (eg, hemolysis due to primaquine in glucose-6-phosphate dehydrogenase deficiency, or aplastic anemia due to chloramphenicol).

Immediate (Type I) Drug Allergy

Type I (immediate) allergy to certain drugs occurs when the drug, not capable of inducing an immune response by itself, covalently links to a host carrier protein (hapten). When this happens, the immune system detects the drug-hapten conjugate as "modified self" and responds by generating IgE antibodies specific for the drug-hapten. It is not known why some people mount an IgE response to a drug while others mount IgG responses. Under the influence of IL-4, IL-5, and IL-13 secreted by TH2 cells, B cells specific for the drug secrete IgE antibody. The mechanism for

IgE-mediated immediate hypersensitivity is diagrammed in Figure 56–5.

Fixation of the IgE antibody to high-affinity Fc receptors (Fc ϵ R) on blood basophils or their tissue equivalent (mast cells) sets the stage for an acute allergic reaction. The most important sites for mast cell distribution are skin, nasal epithelium, lung, and gastrointestinal tract. When the offending drug is reintroduced into the body, it binds and cross-links basophil and mast cell-surface IgE to signal release of the mediators (eg, histamine, leukotrienes; see Chapters 16 and 18) from granules. Mediator release is associated with a fall in intracellular cAMP within the mast cell. Many of the drugs that block mediator release appear to act through the cAMP mechanism (eg, catecholamines, glucocorticoids, theophylline), others block histamine release, and still others block histamine receptors. Other vasoactive substances such as kinins may also be generated during histamine release. These mediators initiate immediate vascular smooth muscle relaxation and increased vascular permeability, resulting in hypotension as well as bronchoconstriction.

Drug Treatment of Immediate Allergy

One can test an individual for possible sensitivity to a drug by a simple scratch test, ie, by applying an extremely dilute solution of the drug to the skin and making a scratch with the tip of a needle. If allergy is present, an immediate wheal (edema) and flare (increased blood flow) will often occur. However, skin tests may be negative in spite of marked hypersensitivity to a hapten or to a metabolic product of the drug, especially if the patient is taking steroids or antihistamines.

Drugs that modify allergic responses act at several links in this chain of events. Prednisone, which is often used in severe allergic reactions, is immunosuppressive and blocks proliferation of the IgE-producing clones and inhibits IL-4 production by helper T cells in the IgE response, since glucocorticoids are generally toxic to lymphocytes. In the efferent limb of the allergic response, isoproterenol, epinephrine, and theophylline reduce the release of mediators from mast cells and basophils and produce bronchodilation. Epinephrine causes both relaxation of bronchiolar smooth muscle and contraction of vascular muscle, relieving both bronchospasm and hypotension. The antihistamines competitively inhibit histamine, which would otherwise produce bronchoconstriction and increased capillary permeability in the end organ. Glucocorticoids may also act to reduce tissue injury and edema in the inflamed tissue as well as facilitating the actions of catecholamines in cells that may have become refractory to epinephrine or isoproterenol. Several agents directed toward the inhibition of leukotriene synthesis may be useful in acute allergic and inflammatory disorders (see Chapter 20: Drugs Used in Asthma).

Desensitization to Drugs

When reasonable alternatives are not available, certain drugs (eg, penicillin, insulin) must be used for life-threatening illnesses even in the presence of known allergic sensitivity. In such cases, desensitization can sometimes be accomplished by starting with very small doses of the drug and gradually increasing the dose over a period of hours or days to the full therapeutic range. This practice is hazardous and must be performed under direct medical supervision, as anaphylaxis may occur before desensitization has been achieved. It is thought that slow and progressive administration of the drug gradually binds all available IgE on mast cells, triggering a gradual release of granules. Once all of the IgE on the mast cell surfaces has been bound and the cells have been degranulated, the therapeutic doses of the offending drug may be given with minimal further immune reaction. Therefore, a patient is only "desensitized" during administration of the drug.

Autoimmune (Type II) Reactions to Drugs

Certain autoimmune syndromes can be induced by drugs. Examples of this phenomenon include systemic lupus erythematosus following hydralazine or procainamide therapy, "lupoid hepatitis" due to cathartic sensitivity, autoimmune hemolytic anemia resulting from methyldopa administration, thrombocytopenic purpura due to quinidine, and agranulocytosis due to a variety of drugs. As indicated in other chapters of this book, a number of drugs are associated with type I and type II reactions. In these drug-induced autoimmune states, IgG antibodies to tissue constituents or to the drug can be demonstrated. Immune mechanisms also appear to be involved in many additional cases of so-called idiopathic thrombocytopenic purpura, but it is more difficult to demonstrate the presence of specific antibodies. Blood platelets or granulocytes are sometimes innocent bystanders in an immunologic reaction to a drug but manage to be damaged or activated by antigen-antibody complexes or destroyed by the reticuloendothelial system, leading to the development of "idiopathic" thrombocytopenic purpura or agranulocytosis.

Fortunately, autoimmune reactions to drugs usually subside within several months after the offending drug is withdrawn. Immunosuppressive therapy is warranted only when the autoimmune response is unusually severe.

Serum Sickness & Vasculitic (Type III) Reactions

Immunologic reactions to drugs resulting in serum sickness are more common than immediate anaphylactic responses, but type II and type III hypersensitivities often overlap. The clinical features of serum sickness include urticarial and erythematous skin eruptions, arthralgia or arthritis, lymphadenopathy, peripheral edema, and fever. The reactions generally last 6–12 days and usually subside once the offending drug is eliminated. Antibodies of the IgM or IgG class are usually involved. The mechanism of tissue injury is immune complex formation and deposition on basement membranes (eg, lung, kidney), followed by complement activation and infiltration of leukocytes, causing tissue destruction. Glucocorticoids are useful in attenuating severe serum sickness reactions to drugs. In severe cases, plasmapheresis also removes the offending drug from circulation.

Immune vasculitis can also be induced by drugs. The sulfonamides, penicillin, thiouracil, anticonvulsants, and iodides have all been implicated in the initiation of hypersensitivity angiitis. Erythema multiforme is a relatively mild vasculitic skin disorder that may be secondary to drug hypersensitivity. Stevens-Johnson syndrome is probably a more severe form of this hypersensitivity reaction and consists of erythema multiforme, arthritis, nephritis, central nervous system abnormalities, and myocarditis. It has frequently been associated with sulfonamide therapy. Administration of nonhuman monoclonal or polyclonal antibodies such as rattlesnake antivenin may cause serum sickness.

Katzung PHARMACOLOGY, 9e > Section VIII. Chemotherapeutic Drugs > Chapter 56.
Immunopharmacology >

Preparations Available*

Abciximab (ReoPro)

Parenteral: 2 mg/mL solution for IV injection

Adalimumab (Humira)

Parenteral: 40 mg/vial for IV injection

Alefacept (Amivive)

Parenteral: 7.5, 15 mg for IV injection

Alemtuzumab (Campath)

Parenteral: 30 mg/3 mL vial for IV injection

Anti-Thymocyte Globulin (Thymoglobulin)

Parenteral: 25 mg/vial for IV injection

Azathioprine (generic, Imuran)

Oral: 50 mg tablets

Parenteral: 100 mg/vial for IV injection

Basiliximab (Simulect)

Parenteral: 20 mg powder for IV injection

BCG (Bacillus Calmette-Guérin) (Tice BCG)

Parenteral: 30 mg, 1×10^8 organism/vial for percutaneous vaccination

Cyclophosphamide (Cytosan, Neosar)

Oral: 25, 50 mg tablets

Parenteral: 100 mg/mL for injection

Cyclosporine (Sandimmune, Neoral, SangCya)

Oral: 25, 50, 100 mg capsules; 100 mg/mL solution

Parenteral: 50 mg/mL for IV administration

Daclizumab (Zenapax)

Parenteral: 25 mg/5 mL vial for IV infusion

Etanercept (Enbrel)

Parenteral: 25 mg lyophilized powder for subcutaneous injection

Gemtuzumab (Mylotarg)

Parenteral: 5 mg powder for injection

Glatiramer (Copaxone)

Parenteral: 20 mg for SC injection

Ibritumomab tiuxetan (Cevalin)

Parenteral: 3.2 mg/2 mL for injection

Immune Globulin Intravenous (IGIV) (Gamimune, Gammagard, Iveegam, Polygam, others)

Parenteral: 5, 10% solutions; 2.5, 5, 6, 10, 12 g powder for injection

Infliximab (Remicade)

Parenteral: 100 mg lyophilized powder for IV injection

Interferon alfa-2a (Roferon-A)

Parenteral: 3–36 million units in vials or prefilled single-use syringes

Interferon alfa-2b (Intron-A)

Parenteral: 3–50 million units in vials or multidose pens

Interferon beta-1a (Avonex, Rebif)

Parenteral: 22, 33, 44 µg powder for IV injection

Interferon beta-1b (Betaseron)

Parenteral: 0.3 mg powder for SC injection

Interferon gamma-1b (Actimmune)

Parenteral: 100 µg vials

Interleukin-2, IL-2, aldesleukin (Proleukin)

Parenteral: 22 million unit vials

Leflunomide (Arava)

Oral: 10, 20, 100 mg tablets

Levamisole (Ergamisol)

Oral: 50 mg tablets

Lymphocyte immune globulin (Atgam)

Parenteral: 50 mg/mL for injection (in 5 mL ampules)

Methylprednisolone sodium succinate (Solu-Medrol, others)

Parenteral: 40, 125, 500, 1000, 2000 mg powder for injection

Muromonab-CD3 [OKT3] (Orthoclone OKT3)

Parenteral: 5 mg/5 mL ampule for injection

Mycophenolate mofetil (CellCept)

Oral: 250 mg capsules; 500 mg tablets; 200 mg powder for suspension

Parenteral: 500 mg powder for injection

Pegademase Bovine (Adagen)

Parenteral: 250 units/mL for IM injection

Note: Pegademase is bovine adenosine deaminase

Peginterferon alfa-2a (Pegasys)

Parenteral: 180 µg/mL

Peginterferon alfa-2b (PEG-Intron)

Parenteral: 50, 80, 120, 150 µg/0.5 mL

Prednisone (generic)

Oral: 1, 2.5, 10, 20, 50 mg tablets; 1, 5 mg/mL solution

Rh₀(D) Immune Globulin Micro-dose (BayRho-D, BayRho-D Mini-Dose, MICRhoGAM, RhoGam, WinRho)

Parenteral: in single-dose and micro-dose vials

Rituximab (Rituxan)

Parenteral: 10 mg/mL for IV infusion

Sirolimus (Rapamune)

Oral: 1 mg tablets; 1 mg/mL solution

Tacrolimus [FK506] (Prograf)

Oral: 0.5, 1, 5 mg capsules

Parenteral: 5 mg/mL

Topical (Protopic): 0.03%, 0.1% ointment

Thalidomide (Thalomid)

Oral: 50 mg capsules

Note: Thalidomide is labeled for use only in erythema nodosum leprosum in the USA.

Trastuzumab (Herceptin)

Parenteral: 440 mg powder for IV infusion

* Several drugs discussed in this chapter are available as orphan drugs but are not listed here. Other drugs not listed here will be found in other chapters.

Section IX. Toxicology

Chapter 57. Introduction to Toxicology: Occupational & Environmental

Katzung PHARMACOLOGY, 9e > Section IX. Toxicology > Chapter 57. Introduction to Toxicology: Occupational & Environmental >

General

Humans live in a chemical environment and inhale, ingest, or absorb from the skin many of these chemicals. Toxicology is concerned with the deleterious effects of these chemical agents on all living systems. In the biomedical area, however, the toxicologist is primarily concerned with adverse effects in humans resulting from exposure to drugs and other chemicals as well as the demonstration of safety or hazard associated with their use.

Occupational Toxicology

Occupational toxicology deals with the chemicals found in the workplace. The major emphasis of occupational toxicology is to identify the agents of concern, define the conditions leading to their safe use, and prevent absorption of harmful amounts. Guidelines have been elaborated to establish safe ambient air concentrations for many chemicals found in the workplace. The American Conference of Governmental Industrial Hygienists periodically prepares lists of recommended **threshold limit values (TLVs)** for about 600 such chemicals (Doull, 2001). These guidelines are reevaluated as new information becomes available.

Environmental Toxicology

Environmental toxicology deals with the potentially deleterious impact of chemicals, present as pollutants of the environment, to living organisms. The term **environment** includes all the surroundings of an individual organism, but particularly the air, soil, and water. While humans are considered a target species of particular interest, other terrestrial and aquatic species are of considerable importance as potential biologic targets.

Air pollution is a product of industrialization, technologic development, and increased urbanization. Humans may also be exposed to chemicals used in the agricultural environment as pesticides or in food processing that may persist as residues or ingredients in food products. The Food and Agriculture Organization and the World Health Organization (FAO/WHO) Joint Expert Commission on Food Additives adopted the term **acceptable daily intake (ADI)** to denote the daily intake of a chemical which, during an entire lifetime, appears to be without appreciable risk. These guidelines are reevaluated as new information becomes available.

Ecotoxicology

Ecotoxicology is concerned with the toxic effects of chemical and physical agents on populations and communities of living organisms within defined ecosystems; it includes the transfer pathways of those agents and their interactions with the environment. Traditional toxicology is concerned with toxic effects on individual organisms; ecotoxicology is concerned with the impact on populations of living organisms or on ecosystems. It is possible that an environmental event, while exerting severe effects on *individual* organisms, may have no important impact on populations or on

an ecosystem. Thus, the terms "environmental toxicology" and "ecotoxicology" are not interchangeable.

Toxicologic Terms & Definitions

Hazard & Risk

Hazard is *the ability of a chemical agent to cause injury in a given situation or setting*; the conditions of use and exposure are primary considerations. To assess hazard, one needs to have knowledge about both the inherent toxicity of the substance and the amounts to which individuals are liable to be exposed. Humans can safely use potentially toxic substances when the necessary conditions minimizing absorption are established and respected.

Risk is defined as *the expected frequency of the occurrence of an undesirable effect* arising from exposure to a chemical or physical agent. Estimation of risk makes use of dose-response data and extrapolation from the observed relationships to the expected responses at doses occurring in actual exposure situations. The quality and suitability of the biologic data used in such estimates are major limiting factors.

Routes of Exposure

The route of entry for chemicals into the body differs in different exposure situations. In the industrial setting, inhalation is the major route of entry. The transdermal route is also quite important, but oral ingestion is a relatively minor route. Consequently, preventive measures are largely designed to eliminate absorption by inhalation or by topical contact. Atmospheric pollutants gain entry by inhalation, whereas for pollutants of water and soil, oral ingestion is the principal route of exposure for humans.

Duration of Exposure

Toxic reactions may differ qualitatively depending on the duration of the exposure. A single exposure—or multiple exposures occurring over 1 or 2 days—represents **acute exposure**. Multiple exposures continuing over a longer period of time represent a **chronic exposure**. In the occupational setting, both acute (eg, accidental discharge) and chronic (eg, repetitive handling of a chemical) exposures may occur, whereas with chemicals found in the environment (eg, pollutants in ground water), chronic exposure is more likely.

Environmental Considerations

Certain chemical and physical characteristics are known to be important for estimating the potential hazard involved for environmental toxicants. In addition to information regarding effects on different organisms, knowledge about the following properties is essential to predict the environmental impact: The **degradability** of the substance; its **mobility** through air, water, and soil; whether or not **bioaccumulation** occurs; and its transport and **biomagnification** through food chains. (See Bioaccumulation & Biomagnification.) Chemicals that are poorly degraded (by abiotic or biotic pathways) exhibit *environmental persistence* and thus can accumulate. Lipophilic substances tend to bioaccumulate in body fat, resulting in tissue residues. When the toxicant is incorporated into the food chain, biomagnification occurs as one species feeds upon others and concentrates the chemical. The pollutants that have the widest environmental impact are poorly degradable; are relatively mobile in air, water, and soil; exhibit bioaccumulation; and also exhibit biomagnification.

Bioaccumulation & Biomagnification

If the intake of a long-lasting contaminant by an organism exceeds the latter's ability to metabolize or excrete the substance, the chemical accumulates within the tissues of the organism. This is called **bioaccumulation**.

Although the concentration of a contaminant may be virtually undetectable in water, it may be magnified hundreds or thousands of times as the contaminant passes up the food chain. This is called **biomagnification**.

The biomagnification of PCBs in the Great Lakes of North America is illustrated by the following residue values available from *Environment Canada*, a report published by the Canadian government, and other sources.

Thus, the biomagnification for this substance in the food chain, beginning with phytoplankton and ending with the herring gull, is nearly 50,000-fold. Domesticated animals and humans may eat fish from the Great Lakes, resulting in PCB residues in these species as well.

Source	PCB Concentration (ppm) ¹	Concentration Relative to Phytoplankton
Phytoplankton	0.0025	1
Zooplankton	0.123	49.2
Rainbow smelt	1.04	416
Lake trout	4.83	1,932
Herring gull	124	49,600

¹Sources: *Environment Canada, The State of Canada's Environment*, 1991. Government of Canada, Ottawa, and other publications.

Specific Chemicals

Air Pollutants

Five major substances account for about 98% of air pollution: carbon monoxide (about 52%), sulfur oxides (about 14%), hydrocarbons (about 14%), nitrogen oxides (about 14%), and particulate matter (about 4%). The sources of these chemicals include transportation, industry, generation of electric power, space heating, and refuse disposal. Sulfur dioxide and smoke resulting from incomplete combustion of coal have been associated with acute adverse effects, particularly among the elderly and individuals with preexisting cardiac or respiratory disease. Ambient air pollution has been implicated as a contributing factor in bronchitis, obstructive ventilatory disease, pulmonary emphysema, bronchial asthma, and lung cancer.

Carbon Monoxide

Carbon monoxide (CO) is a colorless, tasteless, odorless, and nonirritating gas, a byproduct of incomplete combustion. The average concentration of CO in the atmosphere is about 0.1 ppm; in

heavy traffic, the concentration may exceed 100 ppm. The recommended 1999–2000 threshold limit values (TLV-TWA and TLV-STEL) are shown in Table 57–1.

Table 57–1. Threshold Limit Values (TLV) of Some Common Air Pollutants and Solvents.		
Compound	TLV (ppm)	
	TWA ¹	STEL ²
Benzene	0.5	2.5
Carbon monoxide	25	NA
Carbon tetrachloride	5	10
Chloroform	10	NA
Nitrogen dioxide	3	5
Ozone	0.05	NA
Sulfur dioxide	2	5
Tetrachloroethylene	25	100
Toluene	50	NA
1,1,1-Trichloroethane	350	450
Trichloroethylene	50	100

Note: NA = none assigned.)

¹TLV-TWA is the concentration for a normal 8-hour workday or 40-hour workweek to which workers may be repeatedly exposed without adverse effects.

²TLV-STEL is the maximum concentration that should not be exceeded at any time during a 15-minute exposure period.

Mechanism of Action

CO combines reversibly with the oxygen-binding sites of hemoglobin and has an affinity for hemoglobin that is about 220 times that of oxygen. The product formed, carboxyhemoglobin, cannot transport oxygen. Furthermore, the presence of carboxyhemoglobin interferes with the dissociation of oxygen from the remaining oxyhemoglobin, thus reducing the transfer of oxygen to tissues. The brain and the heart are the organs most affected. Normal nonsmoking adults have carboxyhemoglobin levels of less than 1% saturation (1% of total hemoglobin is in the form of carboxyhemoglobin); this level has been attributed to the endogenous formation of CO from heme catabolism. Smokers may exhibit 5–10% saturation, depending on their smoking habits. An individual breathing air containing 0.1% CO (1000 ppm) would have a carboxyhemoglobin level of about 50%.

Clinical Effects

The principal signs of CO intoxication are those of hypoxia and progress in the following sequence: (1) psychomotor impairment; (2) headache and tightness in the temporal area; (3) confusion and loss of visual acuity; (4) tachycardia, tachypnea, syncope, and coma; and (5) deep coma, convulsions, shock, and respiratory failure. There is great variability in individual responses to a given carboxyhemoglobin concentration. Carboxyhemoglobin levels below 15% rarely produce symptoms; collapse and syncope may appear around 40%; above 60%, death may ensue. Prolonged hypoxia and posthypoxic unconsciousness can result in irreversible damage to the brain and the myocardium. The clinical effects may be aggravated by heavy labor, high altitudes, and high ambient temperatures. The presence of cardiovascular disease is considered to increase the risks associated with CO exposure. Delayed neuropsychiatric impairment can occur after poisoning, and the resolution of behavioral consequences can be slow. While CO intoxication is usually thought of as a form of acute toxicity, there is some evidence that chronic exposure to low levels may lead to undesirable effects, including the development of atherosclerotic coronary disease in cigarette smokers. However, convincing experimental evidence is lacking. The fetus may be quite susceptible to the effects of CO exposure.

Treatment

In cases of acute intoxication, removal of the individual from the exposure source and maintenance of respiration is essential, followed by administration of oxygen—the specific antagonist to CO—within the limits of oxygen toxicity. With room air at 1 atm, the elimination half-time of CO is about 320 minutes; with 100% oxygen, the half-time is about 80 minutes; and with hyperbaric oxygen (2–3 atm), the half-time can be reduced to about 20 minutes.

Sulfur Dioxide

Sulfur dioxide (SO₂) is a colorless, irritant gas generated primarily by the combustion of sulfur-containing fossil fuels. The 1999–2000 threshold limit values are given in Table 57–1.

Mechanism of Action

On contact with moist membranes, SO₂ forms sulfurous acid, which is responsible for its severe irritant effects on the eyes, mucous membranes, and skin. It is estimated that approximately 90% of inhaled SO₂ is absorbed in the upper respiratory tract, the site of its principal effect. The inhalation of SO₂ causes bronchial constriction; altered smooth muscle tone and parasympathetic reflexes appear to be involved in this reaction. Exposure to 5 ppm for 10 minutes leads to increased resistance to airflow in most humans. Exposures to 5–10 ppm are reported to cause severe bronchospasm; 10–20% of the healthy young adult population is estimated to be reactive to even lower concentrations. The phenomenon of adaptation to irritating concentrations is a recognized occurrence in workers. Asthmatic individuals are especially sensitive to SO₂.

Clinical Effects & Treatment

The signs and symptoms of intoxication include irritation of the eyes, nose, and throat and reflex bronchoconstriction. If severe exposure has occurred, delayed onset pulmonary edema may be observed. Cumulative effects from chronic low-level exposure to SO₂ are not striking, particularly in humans. Chronic exposure, however, has been associated with aggravation of chronic cardiopulmonary disease. Treatment is not specific for SO₂ but depends on therapeutic maneuvers utilized in the treatment of irritation of the respiratory tract.

Nitrogen Oxides

Nitrogen dioxide (NO₂) is a brownish irritant gas sometimes associated with fires. It is formed also from fresh silage; exposure of farmers to NO₂ in the confines of a silo can lead to **silo-filler's disease**. The 1999–2000 threshold limit values are shown in Table 57–1.

Mechanism of Action

NO₂ is a deep lung irritant capable of producing pulmonary edema. The type I cells of the alveoli appear to be the cells chiefly affected on acute exposure. Exposure to 25 ppm is irritating to some individuals; 50 ppm is moderately irritating to the eyes and nose. Exposure for 1 hour to 50 ppm can cause pulmonary edema and perhaps subacute or chronic pulmonary lesions; 100 ppm can cause pulmonary edema and death.

Clinical Effects & Treatment

The signs and symptoms of acute exposure to NO₂ include irritation of the eyes and nose, cough, mucoid or frothy sputum production, dyspnea, and chest pain. Pulmonary edema may appear within 1–2 hours. In some individuals, the clinical signs may subside in about 2 weeks; the patient may then pass into a second stage of abruptly increasing severity, including recurring pulmonary edema and fibrotic destruction of terminal bronchioles (bronchiolitis obliterans). Chronic exposure of laboratory animals to 10–25 ppm NO₂ has resulted in emphysematous changes; thus, chronic effects in humans are of concern. There is no specific treatment for acute intoxication by NO₂; therapeutic measures for the management of deep lung irritation and noncardiogenic pulmonary edema are employed. These measures include maintenance of gas exchange with adequate oxygenation and alveolar ventilation. Drug therapy may include bronchodilators, sedatives, and antibiotics.

Ozone

Ozone (O₃) is a bluish irritant gas that occurs normally in the earth's atmosphere, where it is an important absorbent of ultraviolet light. In the workplace, it can occur around high-voltage electrical equipment and around ozone-producing devices used for air and water purification. It is also an important oxidant found in polluted urban air. The effect of low ambient levels of ozone on admission to Ontario, Canada, hospitals for respiratory problems revealed a near-linear gradient between exposure (1-hour level, 20–100 ppb) and response. See Table 57–1 for 1999–2000 threshold limit values.

Clinical Effects & Treatment

O₃ is an irritant of mucous membranes. Mild exposure produces upper respiratory tract irritation. Severe exposure can cause deep lung irritation, with pulmonary edema when inhaled at sufficient concentrations. Ozone penetration in the lung depends on tidal volume; consequently, exercise can increase the amount of ozone reaching the distal lung. Some of the effects of O₃ resemble those seen with radiation, suggesting that O₃ toxicity may result from the formation of reactive free radicals. The gas causes shallow, rapid breathing and a decrease in pulmonary compliance. Enhanced sensitivity of the lung to bronchoconstrictors is also observed. Exposure around 0.1 ppm for 10–30 minutes causes irritation and dryness of the throat; above 0.1 ppm, one finds changes in visual acuity, substernal pain, and dyspnea. Pulmonary function is impaired at concentrations exceeding 0.8 ppm. Airway hyperresponsiveness and airway inflammation have been observed in humans.

Animal studies indicate that the response of the lung to O₃ is a dynamic one. The morphologic and biochemical changes are the result of both direct injury and secondary responses to the initial

damage. Long-term exposure in animals results in morphologic and functional pulmonary changes. Chronic bronchitis, bronchiolitis, fibrosis, and emphysematous changes have been reported in a variety of species exposed to concentrations above 1 ppm. There is no specific treatment for acute O₃ intoxication. Management depends on therapeutic measures utilized for deep lung irritation and noncardiogenic pulmonary edema (see Nitrogen Oxides, above.)

Solvents

Halogenated Aliphatic Hydrocarbons

These agents find wide use as industrial solvents, degreasing agents, and cleaning agents. The substances include carbon tetrachloride, chloroform, trichloroethylene, tetrachloroethylene (perchloroethylene), and 1,1,1-trichloroethane (methyl chloroform). See Table 57–1 for recommended threshold limit values.

Mechanism of Action & Clinical Effects

In laboratory animals, the halogenated hydrocarbons cause central nervous system depression, liver injury, kidney injury, and some degree of cardiotoxicity. These substances are depressants of the central nervous system in humans, though their relative potencies vary considerably; chloroform is the most potent and was widely used as an anesthetic agent. Chronic exposure to tetrachloroethylene can cause impaired memory and peripheral neuropathy. In 1994, evidence was presented suggesting that 1,1,1-trichloroethane used in some degreasing operations may be associated with peripheral neuropathy. This proposed association requires confirmation because of the widespread use of this agent. Hepatotoxicity is also a common toxic effect that can occur in humans after acute or chronic exposures, the severity of the lesion being dependent on the amount absorbed. Carbon tetrachloride is the most potent of the series in this regard. Nephrotoxicity can occur in humans exposed to carbon tetrachloride, chloroform, and trichloroethylene. With chloroform, carbon tetrachloride, trichloroethylene, and tetrachloroethylene, carcinogenicity has been observed in lifetime exposure studies performed in rats or mice. The potential effects of low-level, long-term exposures in humans, however, are yet to be determined. Data indicate that the margin of safety for humans is very large with respect to the potential carcinogenic effect of household exposure to chloroform or environmentally relevant concentrations of trichloroethylene.

Treatment

There is no specific treatment for acute intoxication resulting from exposure to halogenated hydrocarbons. Management depends upon the organ system involved.

Aromatic Hydrocarbons

Benzene is widely used for its solvent properties and as an intermediate in the synthesis of other chemicals. The 1999–2000 recommended threshold limit values are given in Table 57–1. The acute toxic effect of benzene is depression of the central nervous system. Exposure to 7500 ppm for 30 minutes can be fatal. Exposure to concentrations larger than 3000 ppm may cause euphoria, nausea, locomotor problems, and coma; vertigo, drowsiness, headache, and nausea may occur at concentrations ranging from 250 to 500 ppm. No specific treatment exists for the acute toxic effect of benzene.

Chronic exposure to benzene can result in very serious toxic effects, the most significant being an insidious and unpredictable injury to the bone marrow; aplastic anemia, leukopenia, pancytopenia,

or thrombocytopenia may occur. Bone marrow cells in early stages of development appear to be most sensitive to benzene. The early symptoms of chronic benzene intoxication may be rather vague (headache, fatigue, and loss of appetite). Epidemiologic data suggest an association between chronic benzene exposure and an increased incidence of leukemia in workers.

Toluene (methylbenzene) does not possess the myelotoxic properties of benzene, nor has it been associated with leukemia. It is, however, a central nervous system depressant. See Table 57–1 for the threshold limit values. Exposure to 800 ppm can lead to severe fatigue and ataxia; 10,000 ppm can produce rapid loss of consciousness. Chronic effects of long-term toluene exposure are unclear because human studies indicating behavioral effects usually concern exposures to several solvents, not toluene alone. In limited occupational studies, however, metabolic interactions and modification of toluene's effects have not been observed in workers also exposed to other solvents.

Insecticides

Chlorinated Hydrocarbon Insecticides

These agents are usually classified in four groups: DDT (chlorophenothane) and its analogs, benzene hexachlorides, cyclodienes, and toxaphenes (Table 57–2). They are aryl, carbocyclic, or heterocyclic compounds containing chlorine substituents. The individual compounds differ widely in their biotransformation and capacity for storage in tissues; toxicity and storage are not always correlated. They can be absorbed through the skin as well as by inhalation or oral ingestion. There are, however, important quantitative differences between the various derivatives; DDT in solution is poorly absorbed through the skin, whereas dieldrin absorption from the skin is very efficient.

Table 57–2. Chlorinated Hydrocarbon Insecticides.

Chemical Class	Compounds	Toxicity Rating ¹	ADI ²
DDT and analogs	Dichlorodiphenyltrichloroethane (DDT)	4	0.005
	Methoxychlor	3	0.1
	Tetrachlorodiphenylethane (TDE)	3	—
Benzene hexachlorides	Benzene hexachloride (BHC; hexachlorocyclohexane)	4	0.008
	Lindane	4	0.008
Cyclodienes	Aldrin	5	0.0001
	Chlordane	4	0.0005
	Dieldrin	5	0.0001
	Heptachlor	4	0.0001
Toxaphenes	Toxaphene (camphechlor)	4	—

¹Toxicity rating: Probable human oral lethal dosage for class 3 = 500–5000 mg/kg, class 4 = 50–500 mg/kg, and class 5 = 5–50 mg/kg. (See Gosselin et al, 1984.)

²ADI = acceptable daily intake (mg/kg/d).

Human Toxicology

The acute toxic properties of the chlorinated hydrocarbon insecticides in humans are qualitatively similar. These agents interfere with inactivation of the sodium channel in excitable membranes and cause rapid repetitive firing in most neurons. Calcium ion transport is also inhibited. These events affect repolarization and enhance the excitability of neurons. The major effect is central nervous stimulation. With DDT, tremor may be the first manifestation, possibly continuing on to convulsions, whereas with the other compounds convulsions often appear as the first sign of intoxication. There is no specific treatment for the acute intoxicated state, management being symptomatic.

Chronic administration of some of these agents to laboratory animals over long periods has resulted in enhanced tumorigenicity; there is no agreement regarding the potential carcinogenic properties of these substances, and extrapolation of these observations to humans is controversial. Evidence of carcinogenic effects in humans has not been established. In a large epidemiologic study, no relationship was observed between the risk of breast cancer and serum levels of DDE, the major metabolite of DDT. A case-control study conducted to investigate the relation between DDE and DDT breast adipose tissue levels and breast cancer risk yielded results that did not support a positive association.

Environmental Toxicology

The chlorinated hydrocarbon insecticides are considered persistent chemicals (Jorgenson, 2001). Degradation is quite slow when compared to other insecticides, and bioaccumulation, particularly in aquatic ecosystems, is well documented. Their mobility in soil depends on the composition of the soil; the presence of organic matter favors the adsorption of these chemicals onto the soil, whereas adsorption is poor in sandy soils. Once adsorbed, they do not readily desorb.

Because of their environmental impact, use of the chlorinated hydrocarbon insecticides has been largely curtailed in North America and Europe. Some of them are still used, however, in equatorial countries.

Organophosphorus Insecticides

These agents, some of which are listed in Table 57–3, are utilized to combat a large variety of pests. They are useful pesticides when in direct contact with insects or when used as **plant systemics**, where the agent is translocated within the plant and exerts its effects on insects that feed on the plant. Some of these agents are used in human and veterinary medicine as local or systemic antiparasitics (Chapter 54: Clinical Pharmacology of the Anthelmintic Drugs). The compounds are absorbed by the skin as well as by the respiratory and gastrointestinal tracts. Biotransformation is rapid, particularly when compared with the rates observed with the chlorinated hydrocarbon insecticides. Current and suggested human inhalation occupational exposure limits for 30 organophosphate pesticides have been reviewed (Storm et al, 2000).

Table 57–3. Organophosphorus Insecticides.

Compound	Toxicity Rating ¹	ADI ²
Azinphos-methyl	5	0.005
Chlorfenvinphos	—	0.002
Diazinon	4	0.002
Dichlorvos	—	0.004
Dimethoate	4	0.01
Fenitrothion	—	0.005
Leptophos	—	—
Malathion	4	0.02
Parathion	6	0.005
Parathion-methyl	5	0.02
Trichlorfon	4	0.01

¹Toxicity rating: Probable human oral lethal dosage for class 4 = 50–500 mg/kg, class 5 = 5–50 mg/kg, and class 6 = \leq 5 mg/kg. (See Gosselin et al, 1984.)

²ADI = acceptable daily intake (mg/kg/d).

Human Toxicology

In mammals as well as insects, the major effect of these agents is inhibition of acetylcholinesterase through phosphorylation of the esteratic site. The signs and symptoms that characterize acute intoxication are due to inhibition of this enzyme and accumulation of acetylcholine; some of the agents also possess direct cholinergic activity. These effects and their treatment are described in Chapters 7 and 8 in this book and in Steenland et al, 1994. Altered neurologic and cognitive function, as well as psychological symptoms of variable duration, have been associated with exposure to high concentrations of these insecticides (Ecobichon, 1994). Furthermore, there is some indication of an association of low arylesterase activity with neurologic symptom complexes in Gulf War veterans (Haley et al, 1999).

In addition to—and independently of—inhibition of acetylcholinesterase, some of these agents are capable of phosphorylating another enzyme present in neural tissue, the so-called **neuropathy target esterase**. This results in development of a delayed neurotoxicity characterized by polyneuropathy, associated with paralysis and axonal degeneration (organophosphorus ester-induced delayed polyneuropathy; OPIDP); hens are particularly sensitive to these properties and have proved very useful for studying the pathogenesis of the lesion and for identifying potentially neurotoxic organophosphorus derivatives. In humans, neurotoxicity has been observed with **triorthocresyl phosphate (TOCP)**, a noninsecticidal organophosphorus compound, and is thought to occur with the insecticides dichlorvos, trichlorfon, leptophos, methamidophos, mipafox, and trichloronat. The polyneuropathy usually begins with burning and tingling sensations, particularly in the feet, with motor weakness following a few days later. Sensory and motor difficulties may extend to the legs and hands. Gait is affected, and ataxia may be present. There is no specific treatment for this form of delayed neurotoxicity.

Environmental Toxicology

Organophosphorus insecticides are not considered to be persistent pesticides because they are relatively unstable and break down in the environment. As a class they are considered to have a small impact on the environment in spite of their acute effects on organisms.

Carbamate Insecticides

These compounds (Table 57–4) inhibit acetylcholinesterase by carbamoylation of the esteratic site. Thus, they possess the toxic properties associated with inhibition of this enzyme as described for the organophosphorus insecticides. The effects and treatment are described in Chapters 7 and 8. The clinical effects due to carbamates are of shorter duration than those observed with organophosphorus compounds. The range between the doses that cause minor intoxication and those which result in lethality is larger with carbamates than that observed with the organophosphorus agents. Spontaneous reactivation of cholinesterase is more rapid after inhibition by the carbamates. While the clinical approach to carbamate poisoning is similar to that for organophosphates, the use of pralidoxime is not recommended.

Table 57–4. Carbamate Insecticides.

Compound	Toxicity Rating ¹	ADI ²
Aldicarb	6	0.005
Aminocarb	5	—
Carbaryl	4	0.01
Carbofuran	5	0.01
Dimetan	4	—
Dimetilan	4	—
Isolan	5	—
Methomyl	5	—
Propoxur	4	0.02
Pyramat	4	—
Pyrolan	5	—
Zectran	5	—

¹Toxicity rating: Probable human oral lethal dosage for class 4 = 50–500 mg/kg, class 5 = 5–50 mg/kg, and class 6 = \leq 5 mg/kg. (See Gosselin et al, 1984.)

²ADI = acceptable daily intake (mg/kg/d).

The carbamate insecticides are considered to be nonpersistent pesticides and are thought to exert only a small impact on the environment.

Botanical Insecticides

Insecticides derived from natural sources include **nicotine, rotenone, and pyrethrum**. Nicotine is obtained from the dried leaves of *Nicotiana tabacum* and *Nicotiana rustica*. It is rapidly absorbed from mucosal surfaces; the free alkaloid, but not the salt, is readily absorbed from the skin. Nicotine reacts with the acetylcholine receptor of the postsynaptic membrane (sympathetic and parasympathetic ganglia, neuromuscular junction), resulting in depolarization of the membrane. Toxic doses cause stimulation rapidly followed by blockade of transmission. These actions are described in Chapter 7: Cholinoceptor-Activating & Cholinesterase-Inhibiting Drugs. Treatment is directed toward maintenance of vital signs and suppression of convulsions.

Rotenone (Figure 57–1) is obtained from *Derris elliptica*, *Derris mallaccensis*, *Lonchocarpus utilis*, and *Lonchocarpus urucu*. The oral ingestion of rotenone produces gastrointestinal irritation. Conjunctivitis, dermatitis, pharyngitis, and rhinitis can also occur. Treatment is symptomatic.

2,4-Dichlorophenoxyacetic acid

Rotenone

2,4,5-Trichlorophenoxyacetic acid

Pyrethrin I

Chemical structures of selected herbicides and pesticides.

Pyrethrum consists of six known insecticidal esters: pyrethrin I (Figure 57–1), pyrethrin II, cinerin I, cinerin II, jasmolin I, and jasmolin II. Synthetic pyrethroids account for about 30% of worldwide insecticide usage. Pyrethrum may be absorbed after inhalation or ingestion; absorption from the skin is not significant. The esters are extensively biotransformed. Pyrethrum insecticides are not highly toxic to mammals. When absorbed in sufficient quantities, the major site of toxic action is the central nervous system; excitation, convulsions, and tetanic paralysis can occur. Voltage-sensitive sodium, calcium, and chloride channels are considered targets, as well as peripheral-type

benzodiazepine receptors. Treatment is with anticonvulsants. The most frequent injury reported in humans results from the allergenic properties of the substance, especially contact dermatitis. Cutaneous paresthesias have been observed in workers spraying synthetic pyrethroids. Severe occupational exposures to synthetic pyrethroids in China resulted in marked effects on the central nervous system, including convulsions.

Herbicides

Chlorophenoxy Herbicides

2,4-Dichlorophenoxyacetic acid (2,4-D), 2,4,5-trichlorophenoxyacetic acid (2,4,5-T), and their salts and esters are the major compounds of interest as herbicides used for the destruction of weeds (Figure 57–1). They have been assigned toxicity ratings of 4 or 3, respectively, which place the probable human lethal dosages at 50–500 or 500–5000 mg/kg, respectively (Gosselin et al, 1984).

In humans, 2,4-D in large doses can cause coma and generalized muscle hypotonia. Rarely, muscle weakness and marked myotonia may persist for several weeks. With 2,4,5-T, coma may occur, but the muscular dysfunction is less evident. In laboratory animals, signs of liver and kidney dysfunction have also been reported. There is limited evidence that occupational exposure to phenoxy herbicides is associated with an increased risk of non-Hodgkin's lymphoma; the evidence for soft-tissue sarcoma, however, is considered equivocal.

The toxicologic profile for these agents, particularly that of 2,4,5-T, has been confusing because of the presence of chemical contaminants (**dioxins**) produced during the manufacturing process (see below). 2,3,7,8-Tetrachlorodibenzo-*p*-dioxin (TCDD) is the most important of these contaminants.

Bipyridyl Herbicides

Paraquat is the most important agent of this class (Figure 57–1). Its mechanism of action is said to be similar in plants and animals and involves single-electron reduction of the herbicide to free radical species. It has been given a toxicity rating of 4, which places the probable human lethal dosage at 50–500 mg/kg. A number of lethal human intoxications (accidental or suicidal) have been reported. Paraquat accumulates slowly in the lung by an active process and causes lung edema, alveolitis, and progressive fibrosis.

In humans, the first signs and symptoms after oral exposure are attributable to gastrointestinal irritation (hematemesis and bloody stools). Within a few days, however, delayed toxicity occurs, with respiratory distress and the development of congestive hemorrhagic pulmonary edema accompanied by widespread cellular proliferation. Hepatic, renal, or myocardial involvement may also be evident. The interval between ingestion and death may be several weeks. Because of the delayed pulmonary toxicity, prompt removal of paraquat from the digestive tract is important. Gastric lavage, the use of cathartics, and the use of adsorbents to prevent further absorption have all been advocated; after absorption, treatment is successful in fewer than 50% of cases. Oxygen should be used cautiously to combat dyspnea or cyanosis, as it may aggravate the pulmonary lesions. Patients require prolonged observation, because the proliferative phase begins 1–2 weeks after ingestion.

Environmental Pollutants

Polychlorinated Biphenyls

The **polychlorinated biphenyls (PCBs, coplanar biphenyls)** have been used in a large variety of applications as dielectric and heat transfer fluids, plasticizers, wax extenders, and flame retardants. Their industrial use and manufacture in the USA was terminated by 1977. Unfortunately, they persist in the environment. The products used commercially were actually mixtures of PCB isomers and homologs containing 12–68% chlorine. These chemicals are highly stable and highly lipophilic, poorly metabolized, and very resistant to environmental degradation; they bioaccumulate in food chains. Food is the major source of PCB residues in humans.

A serious exposure to PCBs—lasting several months—occurred in Japan in 1968 as a result of cooking oil contamination with PCB-containing transfer medium (Yusho disease). Possible effects on the fetus and on the development of the offspring of poisoned women were reported. It is now known that the contaminated cooking oil contained not only PCBs but also polychlorinated dibenzofurans (PCDFs) and polychlorinated quaterphenyls (PCQs). Consequently, the effects that were initially attributed to the presence of PCBs are now thought to have been largely caused by the other contaminants. Workers occupationally exposed to PCBs have exhibited the following clinical signs: dermatologic problems (chloracne, folliculitis, erythema, dryness, rash, hyperkeratosis, hyperpigmentation), some hepatic involvement, and elevated plasma triglycerides.

The effects of PCBs alone on reproduction and development, as well as their carcinogenic effects, have yet to be established in humans—whether workers or the general population—even though some subjects have been exposed to very high levels of PCBs. Some adverse behavioral effects in infants are reported to have been observed in two studies involving subjects from the general population, but the adverse effects observed in the two studies were dissimilar; furthermore, there are a number of uncertainties about the exposure assessments in both studies (Kimbrough, 1995). An association between prenatal exposure to PCBs and deficits in childhood intellectual function was described for children born to mothers who had eaten large quantities of contaminated fish (Jacobson & Jacobson, 2002). The bulk of the evidence from human studies indicates that PCBs pose little hazard to human health except in situations where food is contaminated with high concentrations of these congeners.

The **polychlorinated dibenzo-*p*-dioxins (PCDDs)**, or **dioxins**, have been mentioned above as a group of congeners of which the most important is **2,3,7,8-tetrachlorodibenzo-*p*-dioxin (TCDD)**. In addition, there is a larger group of dioxin-like compounds, including certain **polychlorinated dibenzofurans (PCDFs)** and **coplanar biphenyls**. While PCBs were used commercially, PCDDs and PCDFs are unwanted by-products that appear in the environment as contaminants because of improperly controlled combustion processes. PCDD and PCDF contamination of the global environment is considered to represent a contemporary problem produced by human activities. Like PCBs, these chemicals are very stable and highly lipophilic. They are poorly metabolized and very resistant to environmental degradation.

In laboratory animals, TCDD administered in suitable doses has produced a wide variety of toxic effects, including a wasting syndrome (severe weight loss accompanied by reduction of muscle mass and adipose tissue), thymic atrophy, epidermal changes, hepatotoxicity, immunotoxicity, effects on reproduction and development, teratogenicity, and carcinogenicity. Fortunately, most of these actions have not been observed in humans. The effects observed in workers involved in the manufacture of 2,4,5-T (and therefore presumably exposed to TCDD) consisted primarily of contact dermatitis and chloracne. In severely TCDD-intoxicated patients, only discrete chloracne may be present.

The presence of TCDD in 2,4,5-T is believed to be largely responsible also for other human toxicities associated with the herbicide. There is some epidemiologic evidence indicating an

association between occupational exposure to the phenoxy herbicides and an excess incidence of non-Hodgkin's lymphoma. The evidence of an association of increased soft tissue sarcomas with herbicides themselves, however, is considered equivocal. On the other hand, the TCDD contaminant in these herbicides may play a role in soft tissue sarcomas.

"Endocrine Disruptors"

The potential hazardous effects of some chemicals found in the environment are receiving considerable attention because of their estrogen-like or antiandrogenic properties. These so-called endocrine disruptors that mimic, enhance, or inhibit a hormonal action include a number of plant constituents (phytoestrogens) and some mycoestrogens as well as industrial chemicals, particularly persistent organochlorine agents like DDT and PCBs. In vitro assays alone are unreliable for regulatory purposes, and animal studies are considered indispensable. Modified endocrine responses in some reptiles and marine invertebrates have been observed. In humans, however, a causal relationship between exposure to a specific environmental agent and an adverse health effect due to endocrine modulation has not been established. At present, the evidence is not considered compelling.

Chapter 58. Heavy Metal Intoxication & Chelators

Heavy Metal Intoxication & Chelators: Introduction

Some metals such as iron are essential for life, while others such as lead are present in all organisms but serve no useful biologic purpose. Some of the oldest diseases of humans can be traced to heavy metal poisoning associated with metal mining, refining, and use. Even with the present recognition of the hazards of heavy metals, the incidence of intoxication remains significant and the need for preventive strategies and effective therapy remains high. When intoxication occurs, chelator molecules (from *chela* "claw") may be used to bind the metal and facilitate its excretion from the body. Chelator drugs are discussed in the second part of this chapter.

Toxicology of Heavy Metals

Lead

Lead poisoning is one of the oldest occupational and environmental diseases in the world. Despite its recognized hazards, lead continues to have widespread commercial application. Environmental lead exposure, ubiquitous by virtue of the anthropogenic distribution of lead to air, water, and food, has declined considerably in the past 2 decades as a result of diminished use of lead in gasoline and other applications. While these public health measures, together with improved workplace conditions, have decreased the incidence of serious overt lead poisoning, there remains considerable concern over the effects of low-level lead exposure. Extensive evidence indicates that lead may have subtle subclinical adverse effects on neurocognitive function and on blood pressure at blood lead concentrations once considered "normal" or "safe." Lead serves no useful purpose in the human body. In key target organs such as the developing central nervous system, no safe threshold of lead exposure has been established.

Pharmacokinetics

Inorganic lead is slowly but consistently absorbed via the respiratory and gastrointestinal tracts. Inorganic lead is poorly absorbed through the skin, but organic lead compounds, eg, leaded antiknock gasoline, are well absorbed by this route. Absorption of lead dust via the respiratory tract is the most common cause of industrial poisoning. The intestinal tract is the primary route of entry in nonindustrial exposure (Table 58–1). Absorption via the gastrointestinal tract varies with the nature of the lead compound, but in general, adults absorb about 10% of the ingested amount while young children absorb up to 50%. Low dietary calcium, iron deficiency, and ingestion on an empty stomach have all been associated with increased lead absorption.

Table 58–1. Toxicology of Selected Arsenic, Lead, and Mercury Compounds.

	Form Entering Body	Major Route of Absorption	Distribution	Major Clinical Effects	Key Aspects of Mechanism	Metabolism and Elimination
Arsenic	Inorganic arsenic salts	Gastrointestinal, respiratory (all mucosal surfaces), skin	Predominantly soft tissues (highest in liver, kidney). Avidly bound in skin, hair, nails	Cardiovascular: shock, arrhythmias. CNS: encephalopathy, peripheral neuropathy. Gastroenteritis; pancytopenia; cancer (many sites)	Inhibits enzymes via sulfhydryl binding; interferes with oxidative phosphorylation	Methylation. Renal (major); sweat and feces (minor)
Lead	Inorganic lead oxides and salts	Gastrointestinal, respiratory	Soft tissues; redistributed to skeleton (> 90% of adult body burden)	CNS deficits; peripheral neuropathy; anemia; nephropathy; hypertension (?)	Inhibits enzymes; interferes with essential cations; alters membrane structure	Renal (major); breast milk (minor)
	Organic (tetraethyl lead)	Skin, gastrointestinal, respiratory	Soft tissues, especially liver, CNS	Encephalopathy	Hepatic dealkylation (fast) → trialkylmetabolites (slow) → dissociation to lead	Urine and feces (major); sweat (minor)
Mercury	Elemental mercury	Respiratory tract	Soft tissues, especially kidney, CNS	CNS: behavioral (erethism); gingivostomatitis; peripheral neuropathy; acrodynia; pneumonitis (high-dose)	Inhibits enzymes; alters membranes	Elemental Hg converted to Hg ²⁺ . Urine (major); feces (minor)

Inorganic : Hg ⁺ (less toxic); Hg ²⁺ (more toxic)	Gastrointestina l, skin (minor)	Soft tissues, especially kidney	Acute tubular necrosis; gastroenteritis; CNS effects (rare)	Inhibits enzymes; alters membranes	Urine	
Organic: alkyl, aryl	Gastrointestina l, skin, respiratory (minor)	Soft tissues	CNS effects, birth defects	Inhibits enzymes; alters neuronal structure	Deacylatio n. Fecal (alkyl, major); urine (Hg ²⁺ after deacylation , minor)	

Once absorbed from the respiratory or gastrointestinal tract, lead is bound to erythrocytes and widely distributed initially to soft tissues such as the bone marrow, brain, kidney, liver, muscle, and gonads; then to the subperiosteal surface of bone; and later to bone matrix. Lead also crosses the placenta and poses a potential hazard to the fetus. The kinetics of lead clearance from the body follows a multi-compartment model, composed predominantly of the blood and soft tissues, with a half-life of 1–2 months; and the skeleton, with a half-life of years to decades. Approximately 70% of the lead that is eliminated appears in the urine, with lesser amounts excreted through the bile, skin, hair, nails, sweat, and breast milk. The fraction not undergoing prompt excretion, approximately half of the absorbed lead, may be incorporated into the skeleton, the repository of more than 90% of the body lead burden in most adults. In patients with high bone lead burdens, slow release from the skeleton may elevate blood lead concentrations for years after exposure ceases; and pathologic high bone turnover states such as hyperthyroidism or prolonged immobilization may result in frank lead intoxication. The lead burden in bone has been quantitated using noninvasive x-ray fluorescence, a technique that may provide the best measure of long-term, cumulative lead absorption.

Pharmacodynamics

Lead exerts multisystemic toxic effects through at least three mechanisms: by inhibiting enzyme activity, sometimes as a consequence of binding to sulfhydryl groups; by interfering with the action of essential cations, particularly calcium, iron, and zinc; and by altering the structure of cell membranes and receptors.

Nervous System

The developing central nervous system of the fetus and young child is the most sensitive target organ for lead's toxic effect. Epidemiologic studies suggest that blood lead concentrations less than 5 µg/dL may result in subclinical deficits in neurocognitive function in lead-exposed young children, with no demonstrable threshold for a "no effect" level (Canfield et al, 2003). Hearing acuity may also be diminished. Adults are less sensitive to the CNS effects of lead, but at blood lead

concentrations in excess of 30 $\mu\text{g}/\text{dL}$, behavioral, constitutional, and neurocognitive effects may gradually emerge, producing signs and symptoms such as irritability, fatigue, decreased libido, anorexia, sleep disturbance, impaired visual-motor coordination, and slowed reaction time. Headache, arthralgias, and myalgias are also frequent complaints. Tremor occurs but is less common. Lead encephalopathy, usually occurring at blood lead concentrations in excess of 100 $\mu\text{g}/\text{dL}$, is typically accompanied by increased intracranial pressure and may produce ataxia, stupor, coma, convulsions, and death. There is wide interindividual variation in the magnitude of lead exposure required to cause overt lead-related signs and symptoms.

Peripheral neuropathy may appear after chronic high-dose lead exposure, usually following months to years of blood lead concentrations in excess of 100 $\mu\text{g}/\text{dL}$. Predominantly motor in character, the neuropathy may present clinically with painless weakness of the extensors, particularly in the upper extremity, resulting in classic wrist-drop. Preclinical signs of lead-induced peripheral nerve dysfunction may be detectable by electrodiagnostic testing.

Blood

Lead can induce an anemia that may be either normocytic or microcytic and hypochromic. Lead interferes with heme synthesis by blocking the incorporation of iron into protoporphyrin IX and by inhibiting the function of enzymes in the heme synthesis pathway, including aminolevulinic acid dehydratase and ferrochelatase. Within 2–8 weeks after an elevation in blood lead concentration (generally to 30–50 $\mu\text{g}/\text{dL}$ or greater), increases in heme precursors, notably free erythrocyte protoporphyrin or its zinc chelate, zinc protoporphyrin, may be detectable in whole blood. Lead also contributes to anemia by increasing erythrocyte membrane fragility and decreasing red cell survival time. Frank hemolysis may occur with high exposure. The presence of basophilic stippling on the peripheral blood smear, thought to be a consequence of lead inhibition of the enzyme 3',5'-pyrimidine nucleotidase, is sometimes a suggestive—albeit insensitive and nonspecific—diagnostic clue to the presence of lead intoxication.

Kidneys

Chronic high-dose lead exposure, usually associated with months to years of blood lead concentrations in excess of 80 $\mu\text{g}/\text{dL}$, may result in renal interstitial fibrosis and nephrosclerosis. Lead nephropathy may have a latency period of years. Lead may alter uric acid excretion by the kidney, resulting in recurrent bouts of gouty arthritis ("saturnine gout"). Acute high-dose lead exposure sometimes produces transient azotemia, possibly as a consequence of intrarenal vasoconstriction.

Reproductive Organs

High-dose lead exposure is a recognized risk factor for stillbirth or spontaneous abortion. Epidemiologic studies of the impact of low-level lead exposure on reproductive outcome such as low birth weight, preterm delivery, or spontaneous abortion have yielded mixed results. However, a well-designed nested case-control study recently detected an odds ratio for spontaneous abortion of 1.8 (95% CI 1.1–3.1) for every 5 $\mu\text{g}/\text{dL}$ increase in maternal blood lead across an approximate range of 5–20 $\mu\text{g}/\text{dL}$ (Borja-Aburto et al, 1999). In males, blood lead concentrations in excess of 40 $\mu\text{g}/\text{dL}$ have been associated with diminished or aberrant sperm production.

Gastrointestinal Tract

Moderate lead poisoning may cause loss of appetite, constipation, and, less commonly, diarrhea. At high dosage, intermittent bouts of severe colicky abdominal pain ("lead colic") may occur. The mechanism of lead colic is unclear but is believed to involve spasmodic contraction of the smooth muscles of the intestinal wall. In heavily exposed individuals with poor dental hygiene, the reaction of circulating lead with sulfur ions released by microbial action may produce dark deposits of lead sulfide at the gingival margin ("gingival lead lines"). Although frequently mentioned as a diagnostic clue, this is a far from universal sign of lead exposure.

Cardiovascular System

Epidemiologic, experimental, and in vitro mechanistic data indicate that lead exposure elevates blood pressure in susceptible individuals. In populations with environmental or occupational lead exposure, blood lead concentration is linked with increases in systolic and diastolic blood pressure. Studies of middle-aged and elderly men and women have identified cumulative lead exposure to be an independent risk factor for hypertension (Korrick et al, 1999). Lead can also elevate blood pressure in experimental animals, an effect that may be caused by interaction with calcium-mediated constriction of vascular smooth muscle.

Major Forms of Lead Intoxication

Inorganic Lead Poisoning

See Table 58–1.

Acute

Acute inorganic lead poisoning is uncommon today. It usually results from industrial inhalation of large quantities of lead oxide fumes or, in small children, from ingestion of a large oral dose of lead in lead-based paints or contaminated food or drink. The onset of severe symptoms usually requires several days or weeks of recurrent exposure and presents with signs and symptoms of encephalopathy or colic. Evidence of hemolytic anemia (or anemia with basophilic stippling if exposure has been subacute) and elevated hepatic aminotransferases may be present. The diagnosis of acute inorganic lead poisoning may be difficult, and depending on the presenting symptoms, the condition has sometimes been mistaken for appendicitis, peptic ulcer, pancreatitis, or infectious meningitis. Subacute presentation, featuring headache, fatigue, intermittent abdominal cramps, myalgias, and arthralgias, has often been mistaken for a flu-like viral illness and may not come to medical attention. When there has been recent ingestion of lead-containing paint chips, glazes, or weights, radiopacities may be visible on abdominal radiographs.

Chronic

The patient with chronic lead intoxication usually presents with multisystemic findings, including constitutional complaints of anorexia, fatigue, and malaise; neurologic complaints, including headache, difficulty in concentrating, irritability or depressed mood; weakness, arthralgias or myalgias; and gastrointestinal symptoms. Lead poisoning should be strongly suspected in any patient presenting with headache, abdominal pain, and anemia; and less commonly with motor neuropathy, gout, and renal insufficiency. Chronic lead intoxication should be considered in any child with neurocognitive deficits, growth retardation, or developmental delay.

The diagnosis is best confirmed by measuring lead in whole blood. Although this test reflects lead currently circulating in blood and soft tissues and is not a reliable marker of either recent or

cumulative lead exposure, most patients with lead-related disease will have blood lead concentrations above the normal range. Average background blood lead concentrations in North America and Europe have declined considerably in recent decades, and the geometric mean blood lead concentration in the United States in 1999–2000 was estimated to be 1.66 $\mu\text{g}/\text{dL}$ (CDC, 2003). Although predominantly a research tool, the concentration of lead in bone assessed by noninvasive K x-ray fluorescence measurement of lead in bone has been correlated with long-term cumulative lead exposure, and its relationship to numerous lead-related disorders is a subject of ongoing investigation. Measurement of lead excretion in the urine following a single dose of a chelating agent (sometimes called a "chelation challenge test") primarily reflects the lead content of soft tissues and may not be a reliable marker of long-term lead exposure, remote past exposure, or skeletal lead burden.

Organolead Poisoning

Poisoning from organolead compounds is now very rare, in large part due to the worldwide phase-out of tetraethyl and tetramethyl lead as antiknock additives in gasoline. However, organolead compounds such as lead stearate or lead naphthenate are still used in certain commercial processes. Because of their volatility or lipid solubility, organolead compounds tend to be well absorbed through either the respiratory tract or the skin. Organolead compounds predominantly target the central nervous system, producing dose-dependent effects that may include neurocognitive deficits, insomnia, delirium, hallucinations, tremor, convulsions, and death.

Treatment

Inorganic Lead Poisoning

Treatment of inorganic lead poisoning involves immediate termination of exposure, supportive care, and the judicious use of chelation therapy. (Chelation is discussed further later in this chapter.) Lead encephalopathy is a medical emergency that requires intensive supportive care. Cerebral edema may improve with corticosteroids and mannitol, and anticonvulsants may be required to treat seizures. Radiopacities on abdominal radiographs may suggest the presence of retained lead objects requiring gastrointestinal decontamination. Adequate urine flow should be maintained, but overhydration should be avoided. Intravenous edetate calcium disodium (CaNa_2EDTA) is administered at a dosage of 1000–1500 $\text{mg}/\text{m}^2/\text{d}$ (approximately 30–50 $\text{mg}/\text{kg}/\text{d}$) by continuous infusion for up to 5 days. Some clinicians advocate that chelation treatment for lead encephalopathy be initiated with an intramuscular injection of dimercaprol, followed in 4 hours by concurrent administration of dimercaprol and EDTA. Parenteral chelation is limited to 5 or fewer days, at which time oral treatment with another chelator, succimer, may be instituted. In symptomatic lead intoxication without encephalopathy, treatment may sometimes be initiated with succimer. The end point for chelation is usually resolution of symptoms or return of the blood lead concentration to the premorbid range. In patients with chronic exposure, cessation of chelation may be followed by an upward rebound in blood lead concentration as the lead reequilibrates from bone lead stores.

While most clinicians support chelation for symptomatic patients with elevated blood lead concentrations, the decision to chelate asymptomatic subjects is more controversial. Since 1991, the CDC has recommended chelation for all children with blood lead concentrations of 45 $\mu\text{g}/\text{dL}$ or greater. However, a recent randomized, double-blind, placebo-controlled clinical trial of succimer in children with blood lead concentrations between 25 $\mu\text{g}/\text{dL}$ and 44 $\mu\text{g}/\text{dL}$ found no benefit on neurocognitive function or long-term blood lead reduction (Rogan et al, 2001). Prophylactic use of chelating agents in the workplace should never be a substitute for reduction or prevention of excessive exposure.

Organic Lead Poisoning

Initial treatment consists of decontaminating the skin and preventing further exposure. Treatment of seizures requires appropriate use of anticonvulsants. Empiric chelation may be attempted if high blood lead concentrations are present.

Arsenic

Arsenic is a naturally occurring element in the earth's crust with a long history of use as a constituent of commercial and industrial products, as a component in pharmaceuticals, and as an agent of deliberate poisoning. Recent commercial applications of arsenic include its use in the manufacture of semiconductors, wood preservatives, herbicides, cotton desiccants, nonferrous alloys, glass, insecticides, and veterinary pharmaceuticals. In some regions of the world, groundwater may contain high levels of arsenic that has leached from natural mineral deposits. Arsenic in drinking water in the Ganges delta of India and Bangladesh is now recognized as one of the world's most pressing environmental health problems. Arsine, a hydride gas with potent hemolytic effects, is manufactured predominantly for use in the semiconductor industry but may also be generated accidentally when arsenic-containing ores come in contact with acidic solutions.

It is of historical interest that Fowler's solution, which contains 1% potassium arsenite, was widely used as a medicine for many conditions from the eighteenth century through the mid twentieth century. Organic arsenicals were the first pharmaceutical antibiotics* and were widely used for the first half of the twentieth century until supplanted by penicillin and other more effective and less toxic agents.

* Paul Ehrlich's "magic bullet" for syphilis (arsphenamine; Salvarsan) was an arsenical.

Other organoarsenicals, most notably lewisite (dichloro[2-chlorovinyl]arsine), were developed in the early twentieth century as chemical warfare agents. Arsenic trioxide was reintroduced into the United States Pharmacopeia in 2000 as an orphan drug for the treatment of relapsed acute promyelocytic leukemia (Chapter 55: Cancer Chemotherapy).

Pharmacokinetics

Soluble arsenic compounds are well absorbed through the respiratory and gastrointestinal tracts (Table 58–1). Percutaneous absorption is limited but may be clinically significant after heavy exposure to concentrated arsenic reagents. Most of the absorbed inorganic arsenic undergoes methylation, mainly in the liver, to monomethylarsonic acid and dimethylarsinic acid, which are excreted, along with residual inorganic arsenic, in the urine. When chronic daily absorption is less than 1000 μg of soluble inorganic arsenic, approximately two thirds of the absorbed dose is excreted in the urine. After massive ingestions, the elimination half-life is prolonged. Inhalation of arsenic compounds of low solubility may result in prolonged retention in the lung and may not be reflected by urinary arsenic excretion. Arsenic binds to sulfhydryl groups present in keratinized tissue, and following cessation of exposure, hair, nails, and skin may contain elevated levels after urine values have returned to normal. However, arsenic present in hair and nails as a result of external deposition may be indistinguishable from that incorporated after internal absorption.

Pharmacodynamics

Arsenic compounds are believed to exert their toxic effects by several modes of action. Interference with enzymatic function may result from sulfhydryl group binding by trivalent arsenic or by

substitution for phosphate. Inorganic arsenic or its metabolites may induce oxidative stress, alter gene expression, and interfere with cell signal transduction. Although on a molar basis trivalent arsenic (As^{3+} , arsenite) is generally two to ten times more acutely toxic than pentavalent arsenic (As^{5+} , arsenate), *in vivo* interconversion is known to occur, and the full spectrum of arsenic toxicity has occurred after sufficient exposure to either form. Arsine gas is oxidized *in vivo* and exerts a potent hemolytic effect associated with alteration of ion flux across the erythrocyte membrane; however, it also disrupts cellular respiration in other tissues. Arsenic is a recognized human carcinogen and has been associated with cancer of the lung, skin, and bladder (National Research Council, 2001). Marine organisms may contain large amounts of a well-absorbed trimethylated organoarsenic, arsenobetaine, as well as a variety of arsenosugars. Arsenobetaine exerts no known toxic effects when ingested by mammals and is excreted in the urine unchanged; arsenosugars are partially metabolized to dimethylarsinic acid.

Major Forms of Arsenic Intoxication

Acute Inorganic Arsenic Poisoning

Within minutes to hours after exposure to high doses (tens to hundreds of milligrams) of soluble inorganic arsenic compounds, many systems are affected. Initial gastrointestinal signs and symptoms include nausea, vomiting, diarrhea, and abdominal pain. Diffuse capillary leak, combined with gastrointestinal fluid loss, may result in hypotension, shock, and death. Cardiopulmonary toxicity, including congestive cardiomyopathy, cardiogenic or noncardiogenic pulmonary edema, and ventricular arrhythmias, may occur promptly or after a delay of several days. Pancytopenia usually develops within a week, and basophilic stippling of erythrocytes may be present soon after. Central nervous system effects, including delirium, encephalopathy, and coma, may occur within the first few days of intoxication. An ascending sensorimotor peripheral neuropathy may begin to develop after a delay of 2–6 weeks. This neuropathy may ultimately involve the proximal musculature and result in neuromuscular respiratory failure. Months after an episode of acute poisoning, transverse white striae (Aldrich-Mees lines) may be visible in the nails.

Acute inorganic arsenic poisoning should be considered in an individual presenting with abrupt onset of gastroenteritis in combination with hypotension and metabolic acidosis. The diagnosis may be confirmed by demonstration of elevated amounts of inorganic arsenic and its metabolites in the urine (typically in the range of several thousand micrograms in the first 2–3 days following acute symptomatic poisoning). Arsenic disappears rapidly from the blood, and except in anuric patients, blood arsenic levels should not be used for diagnostic purposes. Treatment is based on appropriate gut decontamination, intensive supportive care, and prompt chelation with unithiol, 3–5 mg/kg intravenously every 4–6 hours, or dimercaprol, 3–5 mg/kg intramuscularly every 4–6 hours. In animal studies, the efficacy of chelation has been highest when it is administered within minutes to hours after arsenic exposure; therefore, if diagnostic suspicion is high, treatment should not be withheld for the several days to weeks often required to obtain laboratory confirmation. Succimer has also been effective in animal models and has a higher therapeutic index than dimercaprol. However, because it is available in the United States only for oral administration, its use may not be advisable in the initial treatment of acute arsenic poisoning, when severe gastroenteritis and splanchnic edema may limit absorption by this route.

Chronic Inorganic Arsenic Poisoning

Chronic inorganic arsenic poisoning also results in multisystemic signs and symptoms. Overt noncarcinogenic effects may be evident after chronic absorption of more than 500–1000 $\mu\text{g}/\text{d}$. The time to appearance of symptoms will vary with dose and interindividual tolerances. Constitutional

symptoms of fatigue, weight loss, and weakness may be present, along with anemia, nonspecific gastrointestinal complaints, and a sensorimotor peripheral neuropathy, particularly featuring a stocking-glove pattern of dysesthesia. Skin changes—among the most characteristic effects—typically develop after years of exposure and include a "raindrop" pattern of hyperpigmentation, and hyperkeratoses involving the palms and soles. Peripheral vascular disease and noncirrhotic portal hypertension may also occur. Epidemiologic studies suggest a possible link to hypertension and diabetes. Cancer of the lung, skin, bladder, and possibly other sites, may appear years after exposure to doses of arsenic that are not high enough to elicit other acute or chronic effects.

The diagnosis of chronic arsenic poisoning involves integration of the clinical findings with confirmation of exposure. Urinary levels of total arsenic, usually less than 50 $\mu\text{g}/24\text{ h}$, may return to normal within days to weeks after exposure ceases. Because it may contain large amounts of nontoxic organoarsenic, all seafood should be avoided for at least 3 days prior to submission of a urine sample for diagnostic purposes. The arsenic content of hair and nails (normally less than 1 ppm) may sometimes reveal past elevated exposure, but results should be interpreted cautiously in view of the potential for external contamination.

Arsine Gas Poisoning

Arsine gas poisoning produces a distinctive pattern of intoxication dominated by profound hemolytic effects. After a latent period that may range from 2 hours to 24 hours postinhalation (depending on the magnitude of exposure), massive intravascular hemolysis may occur. Initial symptoms may include malaise, headache, dyspnea, weakness, nausea, vomiting, abdominal pain, jaundice, and hemoglobinuria. Oliguric renal failure, a consequence of hemoglobin deposition in the renal tubules, often appears within 1–3 days. In massive exposures, lethal effects on cellular respiration may occur before renal failure develops. Urinary arsenic levels are elevated but will seldom be available to confirm the diagnosis during the critical period of illness. Intensive supportive care—including exchange transfusion, vigorous hydration, and, in the case of acute renal failure, hemodialysis—is the mainstay of therapy. Currently available chelating agents have not been demonstrated to be of clinical value in arsine poisoning.

Mercury

Metallic mercury as "quicksilver"—the only metal that is liquid under ordinary conditions—has attracted scholarly and scientific interest from antiquity. In early times it was recognized that the mining of mercury was hazardous to health. As industrial use of mercury became common during the past 200 years, new forms of toxicity were recognized that were found to be associated with various transformations of the metal. In the early 1950s, a mysterious epidemic of birth defects and neurologic disease occurred in the Japanese fishing village of Minamata. The causative agent was determined to be methylmercury in contaminated seafood, traced to industrial discharges into the bay from a nearby factory. In addition to elemental mercury and alkylmercury (including methylmercury), other key mercurials include inorganic mercury salts and aryl mercury compounds, each of which exerts a relatively unique pattern of clinical toxicity.

Mercury is mined predominantly as HgS in cinnabar ore and is then converted commercially to a variety of chemical forms. Key industrial and commercial applications of mercury are found in the electrolytic production of chlorine and caustic soda; the manufacture of electrical equipment, thermometers, and other instruments; paint and pigment production; dental amalgam; and gold refining. Use in pharmaceuticals and in biocides has declined substantially in recent years, but occasional use in antiseptics and folk medicines is still encountered. Environmental exposure to mercury from the burning of fossil fuels—or the bioaccumulation of methylmercury in fish—

remains a concern in some regions of the world. Low-level exposure to mercury released from dental amalgam fillings occurs, but no evidence of toxicity from this source has been demonstrated.

Pharmacokinetics

The absorption of mercury varies considerably depending on the chemical form of the metal. Elemental mercury is quite volatile and can be absorbed from the lungs (Table 58–1). It is poorly absorbed from the intact gastrointestinal tract. Inhaled mercury is the primary source of occupational exposure. Organic short-chain alkylmercury compounds are volatile and potentially harmful by inhalation as well as by ingestion. Percutaneous absorption of all types of mercurials is limited but may be of clinical concern when there is heavy exposure. After absorption, mercury is distributed to the tissues within a few hours, with the highest concentration occurring in the kidney. Inorganic mercury is excreted through the urine and the feces. Excretion of inorganic mercury follows a multicomponent model: most is excreted within days to weeks, but a fraction may be retained in the kidneys and brain for years. Methylmercury undergoes biliary excretion and enterohepatic circulation, with 90% eventually excreted in the feces. Mercury binds to sulfhydryl groups in keratinized tissue, and, as with lead and arsenic, traces appear in the hair and nails.

Major Forms of Mercury Intoxication

Mercury interacts with sulfhydryl groups *in vivo*, inhibiting enzymes and altering cell membranes. The pattern of clinical intoxication from mercury depends to a great extent on the chemical form of the metal and the route and severity of exposure.

Acute

Acute inhalation of elemental mercury vapors may cause chemical pneumonitis and noncardiogenic pulmonary edema. Acute gingivostomatitis may occur, and neurologic sequelae (see below) may also ensue. Acute ingestion of inorganic mercury salts, such as mercuric chloride, can result in a corrosive, potentially life-threatening hemorrhagic gastroenteritis followed within hours to days by acute tubular necrosis and oliguric renal failure.

Chronic

Chronic poisoning from inhalation of mercury vapor results in a classic triad of tremor, neuropsychiatric disturbance, and gingivostomatitis. The tremor usually begins as a fine intention tremor of the hands, but the face may also be involved, and progression to choreiform movements of the limbs may occur. Neuropsychiatric manifestations, including memory loss, fatigue, insomnia, and anorexia, are common. There may be an insidious change in mood to shyness, withdrawal, and depression along with explosive anger or blushing (a behavioral pattern referred to as **erethism**). Recent studies suggest that low-dose exposure may produce subclinical neurologic effects. Gingivostomatitis, sometimes accompanied by loosening of the teeth, may be reported after high-dose exposure. Evidence of peripheral nerve damage may be detected on electrodiagnostic testing, but overt peripheral neuropathy is rare. Acrodynia is an uncommon idiosyncratic reaction to subacute or chronic mercury exposure and occurs mainly in children. It is characterized by painful erythema of the extremities and may be associated with hypertension, diaphoresis, anorexia, insomnia, irritability or apathy, and a miliarial rash.

Methylmercury intoxication affects mainly the central nervous system and results in paresthesias, ataxia, hearing impairment, dysarthria, and progressive constriction of the visual fields. Signs and symptoms may first appear several weeks or months after exposure begins. Methylmercury is a

reproductive toxin. High-dose prenatal exposure to methylmercury may produce mental retardation and a cerebral palsy-like syndrome in the offspring. Low-level prenatal exposures have been associated with a risk of subclinical neurodevelopmental deficits (National Research Council, 2000). Dimethylmercury is a rarely encountered but extremely neurotoxic form of organomercury that may be lethal in small quantities.

The diagnosis of mercury intoxication involves integration of the history and physical findings with confirmatory laboratory testing or other evidence of exposure. In the absence of occupational exposure, the urine mercury concentration is usually less than 5 $\mu\text{g/L}$, and whole blood mercury is less than 5 $\mu\text{g/L}$ (CDC, 2003). In 1990, the Biological Exposure Index (BEI) Committee of the American Conference of Governmental Industrial Hygienists (ACGIH) recommended that workplace exposures should result in urinary mercury concentrations less than 35 μg per gram of creatinine and end-of-workweek whole blood mercury concentrations less than 15 $\mu\text{g/L}$.

Treatment

Acute Exposure

In addition to intensive supportive care, prompt chelation with oral or intravenous unithiol, intramuscular dimercaprol, or oral succimer may be of value in diminishing nephrotoxicity after acute exposure to inorganic mercury salts. Vigorous hydration may help to maintain urine output, but if acute renal failure ensues, days to weeks of hemodialysis may be necessary. Because the efficacy of chelation declines with time since exposure, treatment should not be delayed until the onset of oliguria or other major systemic effects.

Chronic Exposure

Unithiol and succimer increase urine mercury excretion following acute or chronic elemental mercury inhalation, but the impact of such treatment on clinical outcome is unknown. Dimercaprol has been shown to redistribute mercury to the central nervous system from other tissue sites, and since the brain is a key target organ, dimercaprol should not be used in treatment of exposure to elemental or organic mercury. Limited data suggest that succimer, unithiol, and *N*-acetyl-L-cysteine (NAC) may enhance body clearance of methylmercury.

Pharmacology of Chelators

Chelating agents are drugs used to prevent or reverse the toxic effects of a heavy metal on an enzyme or other cellular target, or to accelerate the elimination of the metal from the body. Chelating agents are usually flexible molecules with two or more electronegative groups that form stable coordinate-covalent bonds with a cationic metal atom. In some cases, eg, succimer, the parent compound may require *in vivo* biotransformation to become an active complexing agent. The chelator-metal complexes formed are excreted by the body. Edetate (ethylenediaminetetraacetate, Figure 58–1) is an important example.

Figure 58–1.

Salt and chelate formation with edetate (ethylenediaminetetraacetate; EDTA). **A:** In a solution of the disodium salt of EDTA, the sodium and hydrogen ions are chemically and biologically available. **B:** In solutions of calcium disodium edetate, calcium is bound by coordinate-covalent bonds with nitrogens as well as by the usual ionic bonds. Calcium ions are effectively removed from solution. **C:** In the lead-edetate chelate, lead is incorporated into five heterocyclic rings. (Modified and reproduced, with permission, from Meyers FH, Jawetz E, Goldfiel A: *Review of Medical Pharmacology*, 7th ed. Originally published by Lange Medical Publications. McGraw-Hill, 1980.)

The efficiency of the chelator is partly determined by the number of ligands available for metal binding. The greater the number of these ligands, the more stable the metal-chelator complex. Depending on the number of metal-ligand bonds, the complex may be referred to as mono-, bi-, or polydentate. The chelating ligands include functional groups such as -OH , -SH , and -NH , which

can donate electrons for coordination with the metal. Such bonding effectively prevents interaction of the metal with similar functional groups of enzymes or other proteins, coenzymes, cellular nucleophiles, and membranes.

In addition to removing the target metal that is exerting toxic effects on the body, some chelating agents (such as calcium EDTA used for lead intoxication) may enhance the excretion of essential cations such as zinc or copper. However, this side effect is seldom of clinical significance during the limited time frame that characterizes most courses of therapeutic chelation.

In some cases, the metal-mobilizing effect of a therapeutic chelating agent may not only enhance that metal's excretion—a desired effect—but may also redistribute some of the metal to other vital organs. This has been demonstrated for dimercaprol, which redistributes mercury and arsenic to brain while also enhancing urinary mercury and arsenic excretion. Although several chelating agents have the capacity to mobilize cadmium, their tendency to redistribute cadmium to the kidney and increase nephrotoxicity has negated their therapeutic value in cadmium intoxication.

In most cases, the capacity of chelating agents to prevent or reduce the adverse effects of toxic metals appears to be greatest when they are administered very soon after an acute metal exposure. Use of chelating agents days to weeks after an acute metal exposure ends—or their use in the treatment of chronic metal intoxication—may still be associated with increased metal excretion. However, at that point, the capacity of such enhanced excretion to mitigate the pathologic effect of the metal exposure may be reduced.

The most important chelating agents currently in use in the United States are described below.

Dimercaprol (2,3-Dimercaptopropanol, BAL)

Dimercaprol (Figure 58–2), an oily, colorless liquid with a strong mercaptan-like odor, was developed in Great Britain during World War II as a therapeutic antidote against poisoning by the arsenic-containing warfare agent lewisite. It thus became known as British anti-Lewisite, or BAL. Because aqueous solutions of dimercaprol are unstable and oxidize readily, it is dispensed in 10% solution in peanut oil and must be administered by intramuscular injection, which is often painful.

Figure 58–2.

Ferroxamine

Dimercaprol

(2, 3-dimercaptopropanol)

Succimer

(DMSA)

Penicillamine

Chemical structures of several chelators. Ferroxamine (ferrioxamine) without the chelated iron is deferoxamine. It is represented here to show the functional groups; the iron is actually held in a caged system. The structures of the in vivo metal-chelator complexes for dimercaprol, succimer, penicillamine, and unithiol (not shown), are not known and may involve the formation of mixed disulfides with amino acids. (Modified and reproduced, with permission, from Meyers FH, Jawetz E, Goldfien A: *Review of Medical Pharmacology*, 7th ed. McGraw-Hill, 1980.)

In animal models, dimercaprol prevents and reverses arsenic-induced inhibition of sulfhydryl-containing enzymes and, if given soon after exposure, may protect against the lethal effects of inorganic and organic arsenicals. Human data indicate that it can increase the rate of excretion of arsenic and lead and may offer therapeutic benefit in the treatment of acute intoxication by arsenic, lead, and mercury.

Indications & Toxicity

Dimercaprol is FDA-approved as single-agent treatment of acute poisoning by arsenic and inorganic or elemental mercury and for the treatment of severe lead poisoning when used in conjunction with edetate calcium disodium (EDTA; see below). Although studies of its metabolism in humans are limited, intramuscularly administered dimercaprol appears to be readily absorbed, metabolized, and excreted by the kidney within 4–8 hours. Animal models indicate that it may also undergo biliary excretion, but the role of this excretory route in humans and other details of its biotransformation are uncertain.

When used in therapeutic doses, dimercaprol is associated with a high incidence of adverse effects, including hypertension, tachycardia, nausea, vomiting, lacrimation, salivation, fever (particularly in children), and pain at the injection site. Its use has also been associated with thrombocytopenia and increased prothrombin time—factors that may limit intramuscular injection because of the risk of hematoma formation at the injection site. Despite its protective effects in acutely intoxicated

animals, dimercaprol may redistribute arsenic and mercury to the central nervous system, and it is not advocated for treatment of chronic poisoning. Water-soluble analogs of dimercaprol—unithiol and succimer—have higher therapeutic indices and have replaced dimercaprol in many settings.

Succimer (Dimercaptosuccinic Acid, DMSA)

Succimer is a water-soluble analog of dimercaprol, and like that agent it has been shown in animal studies to prevent and reverse metal-induced inhibition of sulfhydryl-containing enzymes and to protect against the acute lethal effects of arsenic. In humans, treatment with succimer is associated with an increase in urinary lead excretion and a decrease in blood lead concentration. It may also decrease the mercury content of the kidney, a key target organ of inorganic mercury salts. In the United States, succimer is formulated exclusively for oral use, but intravenous formulations have been used successfully elsewhere. It is absorbed rapidly but somewhat variably after oral administration. Peak blood levels occur at approximately 3 hours. The drug binds *in vivo* to the amino acid cysteine to form 1:1 and 1:2 mixed disulfides, possibly in the kidney, and it may be these complexes that are the active chelating moieties. The elimination half-time of transformed succimer is approximately 2–4 hours.

Indications & Toxicity

Succimer is currently FDA-approved for the treatment of children with blood lead concentrations greater than 45 $\mu\text{g}/\text{dL}$, but it is also commonly used in adults. The usual dosage is 10 mg/kg orally three times a day. Oral administration of succimer is comparable to parenteral EDTA in reducing blood lead concentration and has supplanted EDTA in outpatient treatment of patients capable of absorbing the oral drug. However, despite the demonstrated capacity of both succimer and EDTA to enhance lead elimination, their value in reversing established lead toxicity or in otherwise improving therapeutic outcome has yet to be established by a placebo-controlled clinical trial. Based on its protective effects against arsenic in animals and its ability to mobilize mercury from the kidney, succimer has also been used in the treatment of arsenic and mercury poisoning. Succimer has been well tolerated in limited clinical trials. It has a negligible impact on body stores of calcium, iron, and magnesium. It induces a mild increase in urinary excretion of zinc that is of minor or no clinical significance. Gastrointestinal disturbances, including anorexia, nausea, vomiting, and diarrhea, are the most common side effects, occurring in less than 10% of patients. Rashes, sometimes requiring discontinuation of the medication, have been reported in less than 5% of patients. Mild, reversible increases in liver aminotransferases have been noted in 6–10% of patients, and isolated cases of mild to moderate neutropenia have been reported.

Edetate Calcium Disodium (Ethylenediaminetetraacetic Acid [EDTA])

Ethylenediaminetetraacetic acid (Figure 58–1) is an efficient chelator of many divalent and trivalent metals *in vitro*. The drug is administered as a calcium disodium salt to prevent potentially life-threatening depletion of calcium.

EDTA penetrates cell membranes relatively poorly and therefore chelates extracellular metal ions much more effectively than intracellular ions.

The highly polar ionic character of EDTA limits its oral absorption. Moreover, oral administration may increase lead absorption from the gut. Consequently, EDTA should be administered by intravenous infusion. In patients with normal renal function, EDTA is rapidly excreted by glomerular filtration, with 50% of an injected dose appearing in the urine within 1 hour. EDTA mobilizes lead from soft tissues, causing a marked increase in urinary lead excretion and a

corresponding decline in blood lead concentration. In patients with renal insufficiency, excretion of the drug—and its metal-mobilizing effects—may be delayed.

Indications & Toxicity

Edetate calcium disodium is indicated chiefly for the chelation of lead, but it may also have utility in poisoning by zinc, manganese, and certain heavy radionuclides. In spite of repeated claims in the alternative medicine literature, EDTA has no demonstrated utility in the treatment of atherosclerotic cardiovascular disease.

Because the drug and the mobilized metals are excreted via the urine, the drug is contraindicated in anuric patients. Nephrotoxicity from EDTA has been reported, but in most cases this can be prevented by maintenance of adequate urine flow, avoidance of excessive doses, and limitation of a treatment course to 5 or fewer consecutive days. EDTA may result in temporary zinc depletion that is of uncertain clinical significance. An experimental analog of EDTA, calcium disodium diethylenetriaminepentaacetic acid (DTPA), has been used for removal ("decorporation") of uranium, plutonium, and other heavy radioisotopes from the body.

Unithiol (Dimercaptopropanesulfonic Acid, DMPS)

Unithiol, a dimercapto chelating agent that is a water-soluble analog of dimercaprol, has been available in the official formularies of Russia and other former Soviet countries since 1958 and in Germany since 1976. It has been legally available from compounding pharmacists in the United States since 1999. Unithiol can be administered orally and intravenously. Bioavailability by the oral route is approximately 50%, with peak blood levels occurring in approximately 3.7 hours. Over 80% of an intravenous dose is excreted in the urine, mainly as cyclic DMPS sulfides. The elimination half-time for total unithiol (parent drug and its transformation products) is approximately 20 hours. Unithiol exhibits protective effects against the toxic action of mercury and arsenic in animal models, and it increases the excretion of mercury, arsenic, and lead in humans.

Indications & Toxicity

Unithiol has no FDA-approved indications, but experimental studies and its pharmacologic and pharmacodynamic profile suggest that intravenous unithiol offers advantages over intramuscular dimercaprol or oral succimer in the initial treatment of severe acute poisoning by inorganic mercury or arsenic. Aqueous preparations of unithiol (usually 50 mg/mL in sterile water) can be administered at a dose of 3–5 mg/kg every 4 hours by slow intravenous infusion over 20 minutes. If a few days of treatment are accompanied by stabilization of the patient's cardiovascular and gastrointestinal status, it may be possible to change to oral administration at a dose of 4–8 mg/kg every 6–8 hours. Oral unithiol may also be considered as an alternative to oral succimer in the treatment of lead intoxication.

Unithiol has been reported to have a low overall incidence of adverse effects (< 4%). Self-limited dermatologic reactions (drug exanthems or urticaria) are the most commonly reported adverse effects, though isolated cases of major allergic reactions, including erythema multiforme and Stevens-Johnson syndrome, have been reported. Because rapid intravenous infusion may cause vasodilation and hypotension, unithiol should be infused slowly over an interval of 15–20 minutes.

Penicillamine (D-Dimethylcysteine)

Penicillamine (Figure 58–2) is a white crystalline, water-soluble derivative of penicillin. D-Penicillamine is less toxic than the L isomer and consequently is the preferred therapeutic form. Penicillamine is readily absorbed from the gut and is resistant to metabolic degradation.

Indications & Toxicity

Penicillamine is used chiefly for treatment of poisoning with copper or to prevent copper accumulation, as in Wilson's disease (hepatolenticular degeneration). It is also used occasionally in the treatment of severe rheumatoid arthritis (Chapter 36: Nonsteroidal Anti-Inflammatory Drugs, Disease-Modifying Antirheumatic Drugs, Nonopioid Analgesics, & Drugs Used in Gout). Its ability to increase urinary excretion of lead and mercury had occasioned its use as outpatient treatment for intoxication with these metals, but succimer, with its stronger metal-mobilizing capacity and lower side effect profile, has generally replaced penicillamine for these purposes.

Adverse effects have been seen in up to one third of patients receiving penicillamine. Hypersensitivity reactions include rash, pruritus, and drug fever, and the drug should be used with extreme caution, if at all, in patients with a history of penicillin allergy. Nephrotoxicity with proteinuria has also been reported, and protracted use of the drug may result in renal insufficiency. Pancytopenia has been associated with prolonged drug intake. Pyridoxine deficiency is a frequent toxic effect of other forms of the drug but is rarely seen with the D form. An acetylated derivative, *N*-acetylpenicillamine, has been used experimentally in mercury poisoning and may have superior metal-mobilizing capacity, but it is not commercially available.

Deferoxamine

Deferoxamine is isolated from *Streptomyces pilosus*. It binds iron avidly but essential trace metals poorly. Furthermore, while competing for loosely bound iron in iron-carrying proteins (hemosiderin and ferritin), it fails to compete for biologically chelated iron, as in microsomal and mitochondrial cytochromes and hemoproteins. Consequently, it is the chelator of choice for iron poisoning (Chapters 33 and 59). Deferoxamine plus hemodialysis may also be useful in the treatment of aluminum toxicity in renal failure. Deferoxamine is poorly absorbed when administered orally and may increase iron absorption when given by this route. It should therefore be administered intramuscularly or, preferably, intravenously. It is believed to be metabolized, but the pathways are unknown. The iron-chelator complex is excreted in the urine, often turning the urine an orange-red color.

Rapid intravenous administration may result in hypotension. Adverse idiosyncratic responses such as flushing, abdominal discomfort, and rash have also been observed. Pulmonary complications (eg, acute respiratory distress syndrome) have been reported in some patients undergoing deferoxamine infusions lasting longer than 24 hours, and neurotoxicity and increased susceptibility to certain infections (eg, with *Yersinia enterocolitica*) have been described after long-term therapy of iron overload conditions (eg, thalassemia major).

Preparations Available

Deferoxamine (Desferal)

Parenteral: Powder to reconstitute, 500 mg/vial

Dimercaprol (BAL in Oil)

Parenteral: 100 mg/mL for IM injection

Edetate calcium [calcium EDTA] (Calcium Disodium Versenate)

Parenteral: 200 mg/mL for injection

Penicillamine (Cuprimine, Depen)

Oral: 125, 250 mg capsules; 250 mg tablets

Succimer (Chemet)

Oral: 100 mg capsules

Unithiol (Dimaval)

Bulk powder available for compounding as oral capsules, or for infusion (50 mg/mL).

Chapter 59. Management of the Poisoned Patient

Management of the Poisoned Patient: Introduction

Over a million cases of acute poisoning occur in the USA each year, although only a small fraction are fatal. Most deaths are due to intentional suicidal overdose by an adolescent or adult. Childhood deaths due to accidental ingestion of a drug or toxic household product have been markedly reduced in the past 30 years as a result of safety packaging and effective poisoning prevention education.

Even with a serious exposure, poisoning is rarely fatal if the victim receives prompt medical attention and good supportive care. Careful management of respiratory failure, hypotension, seizures, and thermoregulatory disturbances has resulted in improved survival of patients who reach the hospital alive.

This chapter reviews the basic principles of poisoning, initial management and specialized treatment of poisoning including methods of increasing the elimination of drugs and toxins.

Toxicokinetics & Toxicodynamics

The term "toxicokinetics" denotes the absorption, distribution, excretion, and metabolism of toxins, toxic doses of therapeutic agents, and their metabolites. The term "toxicodynamics" is used to denote the injurious effects of these substances on vital function. Although there are many similarities between the pharmacokinetics and toxicokinetics of most substances, there are also important differences. The same caution applies to pharmacodynamics and toxicodynamics.

Special Aspects of Toxicokinetics

Volume of Distribution

The volume of distribution (V_d) is defined as the apparent volume into which a substance is distributed (see Chapter 3: Pharmacokinetics & Pharmacodynamics: Rational Dosing & the Time Course of Drug Action). A large V_d implies that the drug is not readily accessible to measures aimed at purifying the blood, such as hemodialysis. Examples of drugs with large volumes of distribution (> 5 L/kg) include antidepressants, antipsychotics, antimalarials, narcotics, propranolol, and verapamil. Drugs with relatively small volumes of distribution (< 1 L/kg) include salicylate, phenobarbital, lithium, valproic acid, warfarin, and phenytoin (see Table 3–1).

Clearance

Clearance is a measure of the volume of plasma that is cleared of drug per unit time (see Chapter 3: Pharmacokinetics & Pharmacodynamics: Rational Dosing & the Time Course of Drug Action). For most drugs the total clearance is the sum of clearances by excretion by the kidneys and metabolism by the liver. In planning detoxification strategy, it is important to know the contribution of each organ to total clearance. For example, if a drug is 95% cleared by liver metabolism and only 5% cleared by renal excretion, even a dramatic increase in urinary concentration of the poison will have little effect on overall elimination.

Overdosage of a drug can alter the usual pharmacokinetic processes, and this must be considered when applying kinetics to poisoned patients. For example, dissolution of tablets or gastric emptying time may be slowed so that absorption and peak toxic effects are delayed. Drugs may injure the epithelial barrier of the gastrointestinal tract and thereby increase absorption. If the capacity of the liver to metabolize a drug is exceeded, more drug will be delivered to the circulation. With a dramatic increase in the concentration of drug in the blood, protein-binding capacity may be exceeded, resulting in an increased fraction of free drug and greater toxic effect. At normal dosage, most drugs are eliminated at a rate proportionate to the plasma concentration (first-order kinetics). If the plasma concentration is very high and normal metabolism is saturated, the rate of elimination may become fixed (zero-order kinetics). This change in kinetics may markedly prolong the apparent serum half-life and increase toxicity.

Special Aspects of Toxicodynamics

The general dose-response principles described in Chapter 2: Drug Receptors & Pharmacodynamics are relevant when estimating the potential severity of an intoxication. When considering quantal dose-response data, both the therapeutic index and the overlap of therapeutic and toxic response curves must be considered. For instance, two drugs may have the same therapeutic index but unequal safe dosing ranges if the slopes of their dose-response curves are not the same. For some drugs, eg, sedative-hypnotics, the major toxic effect is a direct extension of the therapeutic action, as shown by their graded dose-response curve (see Figure 22–1). In the case of a drug with a linear dose-response curve (drug A), lethal effects may occur at ten times the normal therapeutic dose. In contrast, a drug with a curve that reaches a plateau (drug B) may not be lethal at 100 times the normal dose.

For many drugs, at least part of the toxic effect may be quite different from the therapeutic action. For example, intoxication with drugs that have atropine-like effects (eg, tricyclic antidepressants) will reduce sweating, making it more difficult to dissipate heat. In tricyclic antidepressant intoxication, there may also be increased muscular activity or seizures; the body's production of heat is thus enhanced, and lethal hyperpyrexia may result. Overdoses of drugs that depress the cardiovascular system, eg, β -blockers or calcium channel blockers, can profoundly alter not only cardiac function but all functions that are dependent on blood flow. These include renal and hepatic elimination of the toxin and any other drugs that may be given.

Approach to the Poisoned Patient

How Does the Poisoned Patient Die?

An understanding of common mechanisms of death due to poisoning can help prepare the physician to treat patients effectively. Many toxins depress the central nervous system (CNS), resulting in obtundation or coma. Comatose patients frequently lose their airway protective reflexes and their respiratory drive. Thus, they may die as a result of airway obstruction by the flaccid tongue, aspiration of gastric contents into the tracheobronchial tree, or respiratory arrest. These are the most common causes of death due to overdoses of narcotics, barbiturates, alcohol, and other sedative-hypnotic drugs.

Cardiovascular toxicity is also frequently encountered in poisoning. Hypotension may be due to depression of cardiac contractility; hypovolemia resulting from vomiting, diarrhea, or fluid sequestration; peripheral vascular collapse due to blockade of α -adrenoceptor-mediated vascular tone; or cardiac arrhythmias. Hypothermia or hyperthermia due to exposure as well as the temperature-dysregulating effects of many drugs can also produce hypotension. Lethal arrhythmias such as ventricular tachycardia and fibrillation can occur with overdoses of many cardioactive drugs such as ephedrine, amphetamines, cocaine, tricyclic antidepressants, digitalis, and theophylline.

Cellular hypoxia may occur in spite of adequate ventilation and oxygen administration when poisoning is due to cyanide, hydrogen sulfide, carbon monoxide, and other poisons that interfere with transport or utilization of oxygen. In such patients, cellular hypoxia is evident by the development of tachycardia, hypotension, severe lactic acidosis, and signs of ischemia on the ECG.

Seizures, muscular hyperactivity, and rigidity may result in death. Seizures may cause pulmonary aspiration, hypoxia, and brain damage. Hyperthermia may result from sustained muscular hyperactivity and can lead to muscle breakdown and myoglobinuria, renal failure, lactic acidosis, and hyperkalemia. Drugs and poisons that often cause seizures include antidepressants, theophylline, isoniazid (INH), diphenhydramine, antipsychotics, cocaine, and amphetamines.

Other organ system damage may occur after poisoning, and is sometimes delayed in onset. Paraquat attacks lung tissue, resulting in pulmonary fibrosis, beginning several days after ingestion. Massive hepatic necrosis due to poisoning by acetaminophen or certain mushrooms results in hepatic encephalopathy and death 48–72 hours or longer after ingestion.

Finally, some patients may die before hospitalization because the behavioral effects of the ingested drug may result in traumatic injury. Intoxication with alcohol and other sedative-hypnotic drugs is a frequent contributing factor to motor vehicle accidents. Patients under the influence of hallucinogens such as phencyclidine (PCP) or LSD may die in fights or falls from high places.

Initial Management of the Poisoned Patient

The initial management of a patient with coma, seizures, or otherwise altered mental status should follow the same approach regardless of the poison involved. Attempting to make a specific toxicologic diagnosis only delays the application of supportive measures that form the basis ("ABCDs") of poisoning treatment.

First, the **airway** should be cleared of vomitus or any other obstruction and an oral airway or endotracheal tube inserted if needed. For many patients, simple positioning in the lateral decubitus position is sufficient to move the flaccid tongue out of the airway. **Breathing** should be assessed by observation and oximetry and, if in doubt, by measuring arterial blood gases. Patients with respiratory insufficiency should be intubated and mechanically ventilated. The **circulation** should be assessed by continuous monitoring of pulse rate, blood pressure, urinary output, and evaluation of peripheral perfusion. An intravenous line should be placed and blood drawn for serum glucose and other routine determinations.

At this point, every patient with altered mental status should receive a challenge with concentrated **dextrose**, unless a rapid bedside blood sugar test demonstrates that the patient is not hypoglycemic. Adults are given 25 g (50 mL of 50% dextrose solution) intravenously, children 0.5 g/kg (2 mL/kg of 25% dextrose). Hypoglycemic patients may appear to be intoxicated, and there is no rapid and reliable way to distinguish them from poisoned patients. Alcoholic or malnourished patients should also receive 100 mg of thiamine intramuscularly or in the intravenous infusion solution at this time to prevent Wernicke's syndrome.

The opioid antagonist naloxone may be given in a dose of 0.4–2 mg intravenously. Naloxone will reverse respiratory and CNS depression due to all varieties of opioid drugs (see Chapter 31: Opioid Analgesics & Antagonists). It is useful to remember that these drugs cause death primarily by respiratory depression; therefore, if airway and breathing assistance have already been instituted, naloxone may not be necessary. Larger doses of naloxone may be needed for patients with overdose involving propoxyphene, codeine, and some other opioids. The benzodiazepine antagonist flumazenil (see Chapter 22: Sedative-Hypnotic Drugs) may be of value in patients with suspected benzodiazepine overdose, but it should not be used if there is a history of tricyclic antidepressant overdose or a seizure disorder, as it can induce convulsions in such patients.

History & Physical Examination

Once the essential initial "ABCD" interventions have been instituted, one can begin a more detailed evaluation to make a specific diagnosis. This includes gathering any available history and performing a toxicologically oriented physical examination. Other causes of coma or seizures such as head trauma, meningitis, or metabolic abnormalities should be looked for and treated. (See Common Toxic Syndromes.)

History

Oral statements about the amount and even the type of drug ingested in toxic emergencies may be unreliable. Even so, family members, police, and fire department or paramedical personnel should be asked to describe the environment in which the toxic emergency occurred and should bring to the emergency department any syringes, empty bottles, household products, or over-the-counter medications in the immediate vicinity of the possibly poisoned patient.

Physical Examination

A brief examination should be performed, emphasizing those areas most likely to give clues to the toxicologic diagnosis. These include vital signs, eyes and mouth, skin, abdomen, and nervous system.

Vital Signs

Careful evaluation of vital signs (blood pressure, pulse, respirations, and temperature) is essential in all toxicologic emergencies. Hypertension and tachycardia are typical with amphetamines, cocaine, and antimuscarinic (anticholinergic) drugs. Hypotension and bradycardia are characteristic features of overdose with calcium channel blockers, β -blockers, clonidine, and sedative-hypnotics. Hypotension with tachycardia is common with tricyclic antidepressants, phenothiazines, vasodilators, and theophylline. Rapid respirations are typical of salicylates, carbon monoxide, and other toxins that produce metabolic acidosis or cellular asphyxia. Hyperthermia may be associated with sympathomimetics, anticholinergics, salicylates, and drugs producing seizures or muscular rigidity. Hypothermia can be caused by any CNS-depressant drug, especially when accompanied by exposure to a cold environment.

Eyes

The eyes are a valuable source of toxicologic information. Constriction of the pupils (miosis) is typical of opioids, clonidine, phenothiazines, and cholinesterase inhibitors (eg, organophosphate insecticides), and deep coma due to sedative drugs. Dilation of the pupils (mydriasis) is common with amphetamines, cocaine, LSD, and atropine and other anticholinergic drugs. Horizontal nystagmus is characteristic of intoxication with phenytoin, alcohol, barbiturates, and other sedative drugs. The presence of both vertical and horizontal nystagmus is strongly suggestive of phencyclidine poisoning. Ptosis and ophthalmoplegia are characteristic features of botulism.

Mouth

The mouth may show signs of burns due to corrosive substances, or soot from smoke inhalation. Typical odors of alcohol, hydrocarbon solvents, or ammonia may be noted. Poisoning due to cyanide can be recognized by some examiners as an odor like bitter almonds.

Skin

The skin often appears flushed, hot, and dry in poisoning with atropine and other antimuscarinics. Excessive sweating occurs with organophosphates, nicotine, and sympathomimetic drugs. Cyanosis may be caused by hypoxemia or by methemoglobinemia. Icterus may suggest hepatic necrosis due to acetaminophen or *Amanita phalloides* mushroom poisoning.

Abdomen

Abdominal examination may reveal ileus, which is typical of poisoning with antimuscarinic, opioid, and sedative drugs. Hyperactive bowel sounds, abdominal cramping, and diarrhea are common in poisoning with organophosphates, iron, arsenic, theophylline, and *A phalloides*.

Nervous System

A careful neurologic examination is essential. Focal seizures or motor deficits suggest a structural lesion (such as intracranial hemorrhage due to trauma) rather than toxic or metabolic encephalopathy. Nystagmus, dysarthria, and ataxia are typical of phenytoin, carbamazepine, alcohol, and other sedative intoxication. Twitching and muscular hyperactivity are common with atropine and other anticholinergic agents, and cocaine and other sympathomimetic drugs. Muscular rigidity can be caused by haloperidol and other antipsychotic agents and by strychnine. Seizures are often caused by overdose with antidepressants (especially tricyclic antidepressants and bupropion), cocaine, amphetamines, theophylline, isoniazid, and diphenhydramine. Flaccid coma with absent

reflexes and even an isoelectric EEG may be seen with deep coma due to opioid or sedative-hypnotic intoxication and may be mistaken for brain death.

Laboratory & Imaging Procedures

Arterial Blood Gases

Hypoventilation will result in an elevated PCO₂ (hypercapnia) and a low PO₂ (hypoxia). The PO₂ may also be low with aspiration pneumonia or drug-induced pulmonary edema. Poor tissue oxygenation due to hypoxia, hypotension, or cyanide poisoning will result in metabolic acidosis. The PO₂ measures only oxygen dissolved in the plasma and not total blood oxygen content or oxyhemoglobin saturation, and may appear normal in patients with severe carbon monoxide poisoning. Pulse oximetry may also give falsely normal results in carbon monoxide intoxication.

Electrolytes

Sodium, potassium, chloride, and bicarbonate should be measured. The anion gap is then calculated by subtracting the measured anions from cations:

$$\text{Anion gap} = (\text{Na}^+ + \text{K}^+) - (\text{HCO}_3^- + \text{Cl}^-)$$

It is normally no greater than 12–16 meq/L. A larger-than-expected anion gap is caused by the presence of unmeasured anions accompanying metabolic acidosis. This may occur with numerous conditions, such as diabetic ketoacidosis, renal failure, or shock-induced lactic acidosis. Drugs that may induce an elevated anion gap metabolic acidosis (Table 59–1) include aspirin, metformin, methanol, ethylene glycol, isoniazid, and iron.

Table 59–1. Examples of Drug-Induced Anion Gap Acidosis.	
Type of Elevation of the Anion Gap	Agents
Organic acid metabolites	Methanol, ethylene glycol, diethylene glycol
Lactic acidosis	Cyanide, carbon monoxide, ibuprofen, isoniazid, metformin, salicylates, valproic acid; any drug-induced seizures, hypoxia, or hypotension

Note: The normal anion gap calculated from $(\text{Na}^+ + \text{K}^+) - (\text{HCO}_3^- + \text{Cl}^-)$ is 12–16 meq/L; calculated from $(\text{Na}^+) - (\text{HCO}_3^- + \text{Cl}^-)$, it is 8–12 meq/L.

Alterations in the serum potassium level are hazardous because they may result in cardiac arrhythmias. Drugs that may cause hyperkalemia despite normal renal function include potassium itself, β-blockers, digitalis glycosides, potassium-sparing diuretics, and fluoride. Drugs associated with hypokalemia include barium, β-agonists, caffeine, theophylline, and thiazide and loop diuretics.

Renal Function Tests

Some toxins have direct nephrotoxic effects; in other cases, renal failure is due to shock or myoglobinuria. Blood urea nitrogen and creatinine levels should be measured and urinalysis performed. Elevated serum creatine kinase (CK) and myoglobin in the urine suggest muscle necrosis due to seizures or muscular rigidity. Oxalate crystals in the urine suggest ethylene glycol poisoning.

Serum Osmolality

The calculated serum osmolality is dependent mainly on the serum sodium and glucose and the blood urea nitrogen and can be estimated from the following formula:

$$2 \times \text{Na}^+ (\text{meq/L}) + \frac{\text{Glucose (mg/dL)}}{18} + \frac{\text{BUN (mg/dL)}}{3}$$

This calculated value is normally 280–290 mosm/L. Ethanol and other alcohols may contribute significantly to the measured serum osmolality but, since they are not included in the calculation, cause an osmolar gap:

$$\text{Osmolar gap} = \text{Measured osmolality} - \text{Calculated osmolality}$$

Table 59–2 lists the concentration and expected contribution to the serum osmolality in ethanol, methanol, ethylene glycol, and isopropanol poisonings.

Table 59–2. Some Substances That Cause an Osmolar Gap.		
Substance ¹	Serum Level (mg/dL)	Corresponding Osmolar Gap (mosm/kg)
Ethanol	350	75
Methanol	80	25
Ethylene glycol	200	35
Isopropanol	350	60

¹ Other substances that can increase the osmolar gap include acetone, mannitol, and magnesium.

Note: Most laboratories use the freezing point method of determining osmolality. However, if the vaporization point method is used, the alcohols may be driven off and their contribution to osmolality will be lost.

Electrocardiogram

Widening of the QRS complex duration to greater than 100 milliseconds is typical of tricyclic antidepressant and quinidine overdoses (Figure 59–1). The QT_c interval may be prolonged to more than 440 milliseconds in many poisonings, including quinidine, tricyclic antidepressants, several newer antidepressants and antipsychotics, lithium, and arsenic (see also <http://www.torsades.org/>). Variable atrioventricular (AV) block and a variety of atrial and ventricular arrhythmias are common

with poisoning by digoxin and other cardiac glycosides. Hypoxemia due to carbon monoxide poisoning may result in ischemic changes on the ECG.

Figure 59–1.

Changes in the ECG in tricyclic antidepressant overdose. **A:** Slowed intraventricular conduction results in prolonged QRS interval (0.18 s; normal, 0.08 s). **B:** and **C:** Supraventricular tachycardia with progressive widening of QRS complexes mimics ventricular tachycardia. (Reproduced, with permission, from Benowitz NL, Goldschlager N: Cardiac disturbances in the toxicologic patient. In: Haddad LM, Winchester JF [editors]. *Clinical Management of Poisoning and Drug Overdose*. WB Saunders, 1983.)

Imaging Findings

A plain film of the abdomen may be useful because some tablets, particularly iron and potassium, may be radiopaque. Chest x-ray may reveal aspiration pneumonia, hydrocarbon pneumonia, or pulmonary edema. When head trauma is suspected, a CT scan is recommended.

Toxicology Screening Tests

It is a common misconception that a broad toxicology "screen" is the best way to diagnose and manage an acute poisoning. However, comprehensive toxicology screening is time-consuming, expensive, and often unreliable. Moreover, many highly toxic drugs such as calcium channel blockers, β -blockers, and isoniazid are not included in the screening process. The clinical examination of the patient and selected routine laboratory tests are usually sufficient to generate a tentative diagnosis and an appropriate treatment plan. While screening tests may be helpful in confirming a suspected intoxication or for ruling out intoxication as a cause of apparent brain death, they should not delay needed treatment.

When a specific antidote or other treatment is under consideration, quantitative laboratory testing may be indicated. For example, determination of the acetaminophen serum level is useful in assessing the need for antidotal therapy with acetylcysteine. Serum levels of theophylline,

carbamazepine, lithium, salicylates, valproic acid, and other drugs may indicate the need for hemodialysis (Table 59–3).

Table 59–3. Indications for Hemodialysis (HD) and Hemoperfusion (HP) in Drug Poisoning.	
Intoxicating Drug	Intervention
Intervention may be indicated depending on degree of intoxication or blood concentration	
Carbamazepine	HP
Ethchlorvynol	HP
Ethylene glycol	HD
Lithium	HD
Methanol	HD
Meprobamate	HP
Metformin	HD
Phenobarbital	HP
Procainamide	HD or HP
Salicylate	HD
Theophylline	HP or HD
Valproic acid	HD
Intervention not indicated (ineffective)	
Amphetamines	
Antidepressants	
Antipsychotics	
Benzodiazepines	
Calcium channel blockers	
Digoxin	
Metoprolol	
Opioids	
Propranolol	
Quinidine	
Many other drugs and poisons	

Decontamination

Decontamination procedures should be undertaken simultaneously with initial stabilization, diagnostic assessment, and laboratory evaluation. Decontamination involves removing toxins from the skin or gastrointestinal tract.

Skin

Contaminated clothing should be completely removed and double-bagged to prevent illness in health care providers and for possible laboratory analysis. Wash contaminated skin with soap and water.

Gastrointestinal Tract

There remains controversy regarding the efficacy of gut emptying by emesis or gastric lavage, especially when treatment is initiated more than 1 hour after ingestion. For most ingestions, clinical toxicologists recommend simple administration of activated charcoal to bind ingested poisons in the gut before they can be absorbed. In unusual circumstances, induced emesis or gastric lavage may also be used.

Emesis

Emesis can be induced with *ippecac syrup* (never *extract* of ipecac), and this method is sometimes used to treat childhood ingestions at home under telephone supervision of a physician or poison control center personnel. Ipecac should not be used if the suspected intoxicant is a corrosive agent, a petroleum distillate, or a rapidly acting convulsant. Previously popular methods of inducing emesis such as fingertip stimulation of the pharynx, salt water, and apomorphine are ineffective or dangerous and should not be used.

Gastric Lavage

If the patient is awake or if the airway is protected by an endotracheal tube, gastric lavage may be performed using an orogastric or nasogastric tube. As large a tube as possible should be used. Lavage solutions (usually 0.9% saline) should be at body temperature to prevent hypothermia.

Activated Charcoal

Owing to its large surface area, activated charcoal can adsorb many drugs and poisons. It is most effective if given in a ratio of at least 10:1 of charcoal to estimated dose of toxin by weight. Charcoal does not bind iron, lithium, or potassium, and it binds alcohols and cyanide only poorly. It does not appear to be useful in poisoning due to corrosive mineral acids and alkali. Recent studies suggest that oral activated charcoal given alone may be just as effective as gut emptying followed by charcoal. Also, other studies have shown that repeated doses of oral activated charcoal may enhance systemic elimination of some drugs (including carbamazepine, dapsone, and theophylline) by a mechanism referred to as "gut dialysis."

Cathartics

Administration of a cathartic (laxative) agent may hasten removal of toxins from the gastrointestinal tract and reduce absorption, although no controlled studies have been done. Whole bowel irrigation with a balanced polyethylene glycol-electrolyte solution (GoLYTELY, CoLyte) can enhance gut decontamination after ingestion of iron tablets, enteric-coated medicines, illicit drug-filled packets, and foreign bodies. The solution is administered at 1–2 L/h (500 mL/h in children) for several hours until the rectal effluent is clear.

Specific Antidotes

There is a popular misconception that there is an antidote for every poison. Actually, selective antidotes are available for only a few classes of toxins. The major antidotes and their characteristics are listed in Table 59–4.

Table 59–4. Examples of Specific Antidotes.		
Antidote	Poison(s)	Comments
Acetylcysteine (Mucomyst)	Acetaminophen	Best results if given within 8–10 hours of overdose. Follow liver function tests and acetaminophen blood levels. Acetylcysteine is given orally in the USA. Intravenous acetylcysteine has been used successfully in Europe and is under trial in the USA.
Atropine	Anticholinesterases: organophosphates, carbamates	A test dose of 1–2 mg (for children, 0.05 mg/kg) is given IV and repeated until symptoms of atropinism appear (tachycardia, dilated pupils, ileus). Dose may be repeated every 10–15 minutes, with decrease of secretions as therapeutic end point.
Bicarbonate, sodium	Membrane-depressant cardiotoxic drugs (tricyclic antidepressants, quinidine, etc)	1–2 mEq/kg IV bolus usually reverses cardiotoxic effects (wide QRS, hypotension). Give cautiously in heart failure (avoid sodium overload).
Calcium	Fluoride; calcium channel blockers	Large doses may be needed in severe calcium channel blocker overdose. Start with 15 mg/kg IV.
Deferoxamine	Iron salts	If poisoning is severe, give 15 mg/kg/h IV. Urine may become pink. 100 mg of deferoxamine binds 8.5 mg of iron.
Digoxin antibodies	Digoxin and related cardiac glycosides	One vial binds 0.5 mg digoxin; indications include serious arrhythmias, hyperkalemia.
Esmolol	Theophylline, caffeine, metaproterenol	Short-acting β -blocker reverses β_1 -induced tachycardia and (possibly) β_2 -induced vasodilation. Infuse 25–50 μ g/kg/min IV.
Ethanol	Methanol, ethylene glycol	Ethanol therapy can be started before laboratory diagnosis is confirmed. A loading dose is calculated so as to give a blood level of at least 100 mg/dL (42 g/70 kg in adults).
Flumazenil	Benzodiazepines	Adult dose is 0.2 mg IV, repeated as necessary to a maximum of 3 mg. <i>Do not give to patients with seizures, benzodiazepine dependence, or tricyclic overdose.</i>
Fomepizole	Methanol, ethylene glycol	More convenient and easier to use than ethanol. Loading dose 15 mg/kg; repeat every 12 hours.

Glucagon	β-blockers	5–10 mg IV bolus may reverse hypotension and bradycardia that was resistant to β-agonist drugs. May cause vomiting.
Naloxone	Narcotic drugs, other opioid derivatives	A specific antagonist of opioids; 1–2 mg initially by IV, IM, or subcutaneous injection. Larger doses may be needed to reverse the effects of overdose with propoxyphene, codeine, or fentanyl derivatives. Duration of action (2–3 hours) may be significantly shorter than that of the opioid being antagonized.
Oxygen	Carbon monoxide	Give 100% by high-flow nonrebreathing mask; use of hyperbaric chamber is controversial.
Physostigmine	Suggested for antimuscarinic anticholinergic agents; not for tricyclic antidepressants	Adult dose is 0.5–1 mg IV slowly. The effects are transient (30–60 minutes), and the lowest effective dose may be repeated when symptoms return. May cause bradycardia, increased bronchial secretions, seizures. Have atropine ready to reverse excess effects. <i>Do not use for tricyclic antidepressant overdose.</i>
Pralidoxime (2-PAM)	Organophosphate cholinesterase inhibitors	Adult dose is 1 g IV, which should be repeated every 3–4 hours as needed or preferably as a constant infusion of 250–400 mg/h. Pediatric dose is approximately 250 mg. No proved benefit in carbamate poisoning.

Methods of Enhancing Elimination of Toxins

After appropriate diagnostic and decontamination procedures and administration of antidotes, it is important to consider whether measures for enhancing elimination, such as hemodialysis or urinary alkalization, can improve clinical outcome. Table 59–3 lists intoxications requiring immediate dialysis, those in which it is used only if supportive measures fail, and those for which dialysis is not indicated.

Dialysis Procedures

See Table 59–3.

Peritoneal Dialysis

This is a relatively simple and available technique but is inefficient in removing most drugs.

Hemodialysis

Hemodialysis is more efficient than peritoneal dialysis and has been well studied. It assists in correction of fluid and electrolyte imbalance and may also enhance removal of toxic metabolites (eg, formate in methanol poisoning, oxalate and glycolate in ethylene glycol poisoning). The efficiency of both peritoneal dialysis and hemodialysis is a function of the molecular weight, water solubility, protein binding, endogenous clearance, and distribution in the body of the specific toxin.

Hemodialysis is especially useful in overdose cases in which fluid and electrolyte imbalances are present (eg, salicylate intoxication).

Hemoperfusion

Blood is pumped from the patient via a venous catheter through a column of adsorbent material and then recirculated to the patient. Hemoperfusion does not improve fluid and electrolyte balance. However, it does remove many high-molecular-weight toxins that have poor water solubility because the perfusion cartridge has a large surface area for adsorption that is directly perfused with the blood and is not impeded by a membrane. The rate-limiting factors in removal of toxins by hemoperfusion are the affinity of the charcoal or adsorbent resin for the drug, the rate of blood flow through the cartridge, and the rate of equilibration of the drug from the peripheral tissues to the blood. Hemoperfusion may enhance whole body clearance of salicylate, phenytoin, ethchlorvynol, phenobarbital, theophylline, and carbamazepine.

Forced Diuresis and Urinary pH Manipulation

Previously popular but of unproved value, forced diuresis may cause volume overload and electrolyte abnormalities and is not recommended. Renal elimination of a few toxins can be enhanced by alteration of urinary pH. For example, urinary alkalinization is useful in cases of salicylate overdose. Acidification may increase the urine concentration of drugs such as phencyclidine and amphetamines but is not advised because it may worsen renal complications from rhabdomyolysis, which often accompanies the intoxication.

Common Toxic Syndromes

Acetaminophen

Acetaminophen is one of the drugs most commonly involved in suicide attempts and accidental poisonings, both as the sole agent and in combination with other drugs. Acute ingestion of more than 150–200 mg/kg (children) or 7 g total (adults) is considered potentially toxic. A highly toxic metabolite is produced in the liver (see Figure 4–4).

Initially, the patient is asymptomatic or has mild gastrointestinal upset (nausea, vomiting). After 24–36 hours, evidence of liver injury appears, with elevated aminotransferase levels and hypoprothrombinemia. In severe cases, fulminant liver failure occurs, leading to hepatic encephalopathy and death. Renal failure may also occur.

The severity of poisoning is estimated from a serum acetaminophen concentration measurement. If the level is greater than 150–200 mg/L approximately 4 hours after ingestion, the patient is at risk for liver injury. (Chronic alcoholics or patients taking drugs that enhance P450 production of toxic metabolites are at risk with lower levels, perhaps as low as 100 mg/L at 4 hours.) The antidote acetylcysteine acts as a glutathione substitute, binding the toxic metabolite as it is being produced. It is most effective when given early and should be started within 8–10 hours if possible. A liver transplant may be required for patients with fulminant hepatic failure.

Amphetamines & Other Stimulants

Stimulant drugs commonly abused in the USA include methamphetamine ("crank," "crystal"), methylenedioxymethamphetamine (MDMA, "ecstasy"), and cocaine ("crack") as well as legal substances such as pseudoephedrine (Sudafed) and ephedrine (as such and in the herbal agent *Ma-*

huang) (see Chapter 32: Drugs of Abuse). Caffeine is often added to dietary supplements sold as "metabolic enhancers" or "fat-burners" and is also found combined with pseudoephedrine or ephedrine in pills sold as amphetamine substitutes.

At the doses usually used by stimulant abusers, euphoria and wakefulness are accompanied by a sense of power and well-being. At higher doses, restlessness, agitation, and acute psychosis may occur, accompanied by hypertension and tachycardia. Prolonged muscular hyperactivity can cause dehydration and eventually, hypotension. Seizures and muscle activity may contribute to hyperthermia and rhabdomyolysis. Body temperatures as high as 42°C have been recorded. Hyperthermia can cause brain damage, hypotension, coagulopathy, and renal failure.

Treatment includes general supportive measures as outlined earlier. There is no specific antidote. Seizures and hyperthermia are the most dangerous manifestations and must be treated aggressively. Seizures are usually managed with intravenous benzodiazepines (eg, lorazepam). Temperature is reduced by removing clothing, spraying with tepid water, and encouraging evaporative cooling with fanning. For very high body temperatures (eg, > 40–41°C), neuromuscular paralysis is used to abolish muscle activity quickly.

Anticholinergic Agents

A large number of prescription and nonprescription drugs, as well as a variety of plants and mushrooms, can inhibit the effects of acetylcholine. Many drugs used for other purposes (eg, antihistamines) also have anticholinergic effects. Many of them have other potentially toxic actions as well—eg, antihistamines such as diphenhydramine can cause seizures; tricyclic antidepressants, which have anticholinergic, quinidine-like, and α -blocking effects, can cause severe cardiovascular toxicity.

The classic anticholinergic syndrome is remembered as "red as a beet" (skin flushed), "hot as a hare" (hyperthermia), "dry as a bone" (dry mucous membranes, no sweating), "blind as a bat" (blurred vision), and "mad as a hatter" (confusion, delirium). Patients usually have sinus tachycardia, and the pupils are usually dilated (see Chapter 8: Cholinergic-Blocking Drugs). There may be agitated delirium or coma. Muscle twitching is common, but seizures are unusual unless the patient has ingested an antihistamine or a tricyclic antidepressant. Urinary retention is common, especially in older men.

Treatment is largely supportive. Agitated patients may require sedation with a benzodiazepine or an antipsychotic agent (eg, haloperidol). The specific antidote for peripheral and central anticholinergic syndrome is physostigmine, which has a prompt and dramatic effect and is especially useful for patients who are very agitated. It is given in small intravenous doses (0.5–1 mg), with careful monitoring, because it can cause bradycardia and seizures if given too rapidly. Physostigmine should not be given to a patient with suspected tricyclic antidepressant overdose because it can aggravate cardiotoxicity, resulting in heart block or asystole. Catheterization may be needed to prevent excessive distention of the bladder.

Antidepressants

Tricyclic antidepressants (eg, amitriptyline, desipramine, doxepin, many others; see Chapter 30: Antidepressant Agents) are among the most common prescription drugs involved in life-threatening drug overdose. Ingestion of more than 1 g of a tricyclic (or about 15–20 mg/kg) is considered potentially lethal.

Tricyclic antidepressants are competitive antagonists at muscarinic cholinergic receptors, and anticholinergic findings (tachycardia, dilated pupils, dry mouth) are common even at moderate doses. The tricyclics are also strong α -blockers, which can lead to vasodilation. Centrally mediated agitation and seizures may be followed by depression and hypotension. Most importantly, the tricyclics have quinidine-like depressant effects that cause slowed conduction with a wide QRS interval and depressed cardiac contractility. This cardiac toxicity may result in serious arrhythmias (Figure 59–1), including ventricular conduction block and ventricular tachycardia.

Treatment of tricyclic antidepressant overdose includes general supportive care as outlined earlier. Endotracheal intubation should be carried out and ventilation assisted as needed. Intravenous fluids are given for hypotension, and dopamine or norepinephrine is added if needed. Because of blockade of catecholamine reuptake, nerve endings may be depleted of norepinephrine, and dopamine may be relatively ineffective; therefore, many toxicologists recommend norepinephrine as the initial drug of choice for tricyclic-induced hypotension. The antidote for quinidine-like cardiac toxicity (manifested by a wide QRS complex) is sodium bicarbonate: a bolus of 50–100 meq (or 1–2 meq/kg) provides a rapid increase in extracellular sodium that helps overcome sodium channel blockade. *Do not use physostigmine!* Although this agent does effectively reverse anticholinergic symptoms, it can aggravate depression of cardiac conduction and can cause seizures.

Monoamine oxidase inhibitors (eg, tranylcypromine, phenelzine) are a group of older antidepressants that are occasionally used for resistant depression. They can cause severe hypertensive reactions when interacting foods or drugs are taken (see Chapter 9: Adrenoceptor-Activating & Other Sympathomimetic Drugs); and they can interact with the selective serotonin reuptake inhibitors (SSRIs).

Newer antidepressants (eg, fluoxetine, paroxetine, citalopram, venlafaxine) are mostly selective serotonin reuptake inhibitors and are generally safer than the tricyclic antidepressants and monoamine oxidase inhibitors, although they can cause seizures. Bupropion (not an SSRI) has caused seizures even in therapeutic doses. Some antidepressants have been associated with QT prolongation and torsade de pointes arrhythmia. The SSRIs may interact with each other or especially with monoamine oxidase inhibitors to cause the **serotonin syndrome**, characterized by agitation, muscle hyperactivity, and hyperthermia.

Antipsychotics

Antipsychotic drugs include the older phenothiazines and butyrophenones, as well as newer atypical drugs. All of these can cause CNS depression, seizures, and hypotension. Some can cause QT prolongation. The potent dopamine D₂ blockers are also associated with parkinsonian-like movement disorders (dystonic reactions) and in rare cases with the neuroleptic malignant syndrome, characterized by "lead-pipe" rigidity, hyperthermia, and autonomic instability (see Chapter 29: Antipsychotic Agents & Lithium).

Aspirin (Salicylate)

Salicylate poisoning (see Chapter 36: Nonsteroidal Anti-Inflammatory Drugs, Disease-Modifying Antirheumatic Drugs, Nonopioid Analgesics, & Drugs Used in Gout) is a much less common cause of childhood poisoning deaths since the introduction of child-resistant containers and the reduced use of children's aspirin. It still accounts for numerous suicidal and accidental poisonings. Acute ingestion of more than 200 mg/kg is likely to produce intoxication. Poisoning can also result from chronic overmedication; this occurs most commonly in elderly patients using salicylates for chronic

pain who become confused about their dosing. Poisoning causes uncoupling of oxidative phosphorylation and disruption of normal cellular metabolism.

The first sign of salicylate toxicity is often hyperventilation and respiratory alkalosis due to medullary stimulation (see Figure 36–4). Metabolic acidosis follows, and an increased anion gap results from accumulation of lactate as well as excretion of bicarbonate by the kidney to compensate for respiratory alkalosis. Arterial blood gas testing often reveals this mixed respiratory alkalosis and metabolic acidosis. Body temperature may be elevated due to uncoupling of oxidative phosphorylation. Severe hyperthermia may occur in serious cases. Vomiting and hyperpnea as well as hyperthermia contribute to fluid loss and dehydration. With very severe poisoning, profound metabolic acidosis, seizures, coma, pulmonary edema, and cardiovascular collapse may occur. Absorption of salicylate and signs of toxicity may be delayed after very large overdoses or ingestion of enteric-coated tablets.

General supportive care as described earlier is essential. After massive aspirin ingestions (eg, more than 100 tablets), aggressive gut decontamination is advisable, including gastric lavage, repeated doses of activated charcoal, and consideration of whole bowel irrigation. Intravenous fluids are used to replace fluid losses caused by tachypnea, vomiting, and fever. For moderate intoxications, intravenous sodium bicarbonate is given to alkalinize the urine and promote salicylate excretion by trapping the salicylate in its ionized, polar form. For severe poisoning (eg, patients with severe acidosis, coma, and serum salicylate level > 100 mg/dL), emergency hemodialysis is performed to remove the salicylate more quickly and restore acid-base balance and fluid status.

Beta Blockers

In overdose, these drugs block both β_1 - and β_2 -adrenoceptors—ie, selectivity, if any, is lost at high dosage. The most toxic β -blocker is propranolol. As little as two to three times the therapeutic dose can cause serious toxicity. This may be because propranolol has additional properties: At high doses it may cause sodium channel blocking effects similar to those seen with quinidine-like drugs, and it is lipophilic, allowing it to enter the CNS (see Chapter 10: Adrenoceptor Antagonist Drugs).

Bradycardia and hypotension are the most common manifestations of toxicity. Agents with partial agonist activity (eg, pindolol) can cause tachycardia and hypertension. Seizures and cardiac conduction block (wide QRS complex) may be seen with propranolol overdose.

General supportive care should be provided as outlined earlier. The usual measures used to raise the blood pressure and heart rate, such as intravenous fluids, β -agonist drugs, and atropine, are generally ineffective. Glucagon is a useful antidote that—like β -agonists—acts on cardiac cells to raise intracellular cAMP but does so through stimulation of glucagon receptors rather than β -adrenoceptors. It can improve heart rate and blood pressure when given in high doses (5–20 mg intravenously).

Calcium Channel Blockers

Calcium antagonists can cause serious toxicity or death with relatively small overdoses. These channel blockers depress sinus node automaticity and slow AV node conduction (see Chapter 12: Vasodilators & the Treatment of Angina Pectoris). They also reduce cardiac output and blood pressure. Serious hypotension is mainly seen with nifedipine and related dihydropyridines, but in severe overdose all of the listed cardiovascular effects can occur with any of the calcium channel blockers.

Treatment requires general supportive care as outlined earlier. Since most ingested calcium antagonists are in a sustained-release form, it may be possible to expel them before they are completely absorbed; initiate whole bowel irrigation and oral activated charcoal as soon as possible, before calcium antagonist-induced ileus intervenes. Calcium, given intravenously in doses of 2–10 g, is a useful antidote for depressed cardiac contractility but less effective for nodal block or peripheral vascular collapse.

Carbon Monoxide & Other Toxic Gases

Carbon monoxide (CO) is a colorless, odorless gas that is ubiquitous because it is created whenever carbon-containing materials are burned (see Table 57–1). Carbon monoxide poisoning is the leading cause of death due to poisoning in the USA. Most cases occur in victims of fires, but accidental and suicidal exposures are also common. Diagnosis and treatment of carbon monoxide poisoning are described in Chapter 57: Introduction to Toxicology: Occupational & Environmental. Many other toxic gases are produced in fires or released in industrial accidents (Table 59–5).

Gas	Mechanism of Toxicity	Clinical Features and Treatment
Irritant gases (eg, chlorine, ammonia, sulfur dioxide, nitrogen oxides)	Corrosive effect on upper and lower airways	Cough, stridor, wheezing, pneumonia Treatment: Humidified oxygen, bronchodilators
Carbon monoxide	Binds to hemoglobin, reducing oxygen delivery to tissues	Headache, dizziness, nausea, vomiting, seizures, coma Treatment: 100% oxygen
Cyanide	Binds to cytochrome, blocks cellular oxygen use	Headache, nausea, vomiting, syncope, seizures, coma Treatment: CN antidote kit consists of nitrites to induce methemoglobinemia (which binds CN) and thiosulfate (which hastens conversion of CN to less toxic thiocyanate)
Hydrogen sulfide	Similar to cyanide	Similar to cyanide. Smell of rotten eggs Treatment: No specific antidote
Oxidizing agents (eg, nitrogen oxides)	Can cause methemoglobinemia	Dyspnea, cyanosis (due to brown color of methemoglobin), syncope, seizures, coma Treatment: Methylene blue (which hastens conversion back to normal hemoglobin)

Cholinesterase Inhibitors

Organophosphate and carbamate cholinesterase inhibitors (see Chapter 7: Cholinergic-Activating & Cholinesterase-Inhibiting Drugs) are widely used to kill insects and other pests. Most cases of serious organophosphate or carbamate poisoning result from intentional ingestion by a suicidal person, but poisoning has also occurred at work (pesticide application or packaging) or, rarely, as a

result of food contamination or terrorist attack (eg, release of the chemical warfare nerve agent sarin in the Tokyo subway system in 1995).

Stimulation of muscarinic receptors causes abdominal cramps, diarrhea, excessive salivation, sweating, urinary frequency, and increased bronchial secretions (see Chapter 6: Introduction to Autonomic Pharmacology and Chapter 7: Cholinoceptor-Activating & Cholinesterase-Inhibiting Drugs). Stimulation of nicotinic receptors causes generalized ganglionic activation, which can lead to hypertension and either tachycardia or bradycardia. Muscle twitching and fasciculations may progress to weakness and respiratory muscle paralysis. CNS effects include agitation, confusion, and seizures. The mnemonic DUMBELS (diarrhea, urination, miosis and muscle weakness, bronchospasm, excitation, lacrimation, and seizures, sweating, and salivation) helps recall the common findings. Blood testing may be used to document depressed activity of red blood cell (acetylcholinesterase) and plasma (butyrylcholinesterase) enzymes, which provide an indirect estimate of synaptic cholinesterase activity.

General supportive care should be provided as outlined above. Extra precautions should be taken to ensure that rescuers and health care providers are not poisoned by exposure to contaminated clothing or skin. This is especially critical for the most potent substances such as parathion or nerve gas agents. Antidotal treatment consists of atropine and pralidoxime (see Chapter 8: Cholinoceptor-Blocking Drugs). Atropine is an effective competitive inhibitor at muscarinic sites but has no effect at nicotinic sites. Pralidoxime given early enough is capable of restoring the cholinesterase activity and is active at both muscarinic and nicotinic sites.

Digoxin

Digitalis and other cardiac glycosides are found in many plants (see Chapter 13: Drugs Used in Heart Failure) and in the skin of some toads. Toxicity may occur as a result of acute overdose or from accumulation of digoxin in a patient with renal insufficiency or one taking a drug that interferes with digoxin elimination. Patients receiving long-term digoxin treatment are often also taking diuretics, which can lead to electrolyte depletion (especially potassium).

Vomiting is common in patients with digitalis overdose. Hyperkalemia may be caused by acute digitalis overdose or severe poisoning, while hypokalemia may be present in patients as a result of long-term diuretic treatment. (Digitalis does not cause hypokalemia.) A variety of cardiac rhythm disturbances may occur, including sinus bradycardia, AV block, atrial tachycardia with block, accelerated junctional rhythm, premature ventricular beats, bidirectional ventricular tachycardia, and other ventricular arrhythmias.

General supportive care should be provided as outlined earlier. Atropine is often effective for bradycardia or AV block. Lidocaine is sometimes effective for arrhythmias. *Administration of calcium should be avoided because it may precipitate lethal arrhythmias.* Cardioversion should be used only for ventricular fibrillation. The use of digoxin antibodies (see Chapter 13: Drugs Used in Heart Failure) has revolutionized the treatment of digoxin toxicity; they should be administered intravenously in the dosage indicated in the package insert. Symptoms usually improve within 30–60 minutes after antibody administration. Digoxin antibodies may also be tried in cases of poisoning by other cardiac glycosides (eg, digitoxin, oleander), although larger doses may be needed due to incomplete cross-reactivity.

Ethanol & Sedative-Hypnotic Drugs

Overdosage with ethanol and sedative-hypnotic drugs (eg, benzodiazepines, barbiturates, γ -hydroxybutyrate [GHB], carisoprodol [Soma]; see Chapter 22: Sedative-Hypnotic Drugs and Chapter 23: The Alcohols) occurs frequently because of their common availability and use.

Patients with ethanol or sedative-hypnotic overdose may be euphoric and rowdy ("drunk") or in a state of stupor or coma ("dead drunk"). Comatose patients often have depressed respiratory drive. Depression of protective airway reflexes may result in aspiration of gastric contents. Hypothermia may be present because of environmental exposure and depressed shivering. Ethanol blood levels greater than 300 mg/dL usually cause deep coma, but regular users are often tolerant to the effects of ethanol and may be ambulatory despite even higher levels. Patients with GHB overdose are often deeply comatose for 3–4 hours and then awaken fully in a matter of minutes.

General supportive care should be provided. With careful attention to protecting the airway (including endotracheal intubation) and assisting ventilation, most patients will recover as the drug effects wear off. Hypotension usually responds to body warming (if cold), intravenous fluids and, if needed, dopamine. Patients with isolated benzodiazepine overdose may awaken after intravenous flumazenil, a benzodiazepine antagonist. However, this drug is not widely used as empiric therapy for drug overdose because it may precipitate seizures in patients who are addicted to benzodiazepines or who have ingested a convulsant drug (eg, a tricyclic antidepressant). There are no antidotes for ethanol, barbiturates, or most other sedative-hypnotics. Hemoperfusion is occasionally used for very severe phenobarbital poisoning.

Ethylene Glycol & Methanol

These alcohols are important toxins because of their metabolism to highly toxic organic acids (see Chapter 23: The Alcohols). They are capable of causing CNS depression and a drunken state similar to ethanol overdose. However, their products of metabolism—formic acid (from methanol) or hippuric, oxalic, and glycolic acids (from ethylene glycol)—cause a severe metabolic acidosis and can lead to coma and blindness (in the case of formic acid) or renal failure (from oxalic acid and glycolic acid). Initially, the patient appears drunk, but after a delay of up to several hours, a severe anion gap metabolic acidosis becomes apparent, accompanied by hyperventilation and altered mental status. Patients with methanol poisoning may complain of severe visual disturbances, eg, "like being in a snowstorm."

Metabolism of ethylene glycol and methanol to their toxic products can be blocked by inhibiting the enzyme alcohol dehydrogenase with a competing drug. Ethanol is metabolized preferentially by alcohol dehydrogenase, so ethanol can be given orally or intravenously (5% pharmaceutical grade) to a level of approximately 100 mg/dL. Alternatively, the antidote fomepizole—an effective blocker of alcohol dehydrogenase that does not induce ethanol intoxication—can be used.

Iron & Other Metals

Iron is widely used in over-the-counter vitamin preparations and is a leading cause of childhood poisoning deaths. As few as 10–12 prenatal multivitamins with iron may cause serious illness in a small child. Poisoning with other metals (lead, mercury, arsenic) is also important, especially in industry. See Chapter 33: Agents Used in Anemias; Hematopoietic Growth Factors and Chapter 58: Heavy Metal Intoxication & Chelators for detailed discussions of poisoning by iron and other metals.

Opioids

Opioids (opium, morphine, heroin, meperidine, methadone, etc) are common drugs of abuse (see Chapter 31: Opioid Analgesics & Antagonists and Chapter 32: Drugs of Abuse), and overdose is a frequent result of using the poorly standardized preparations sold on the street. See Chapter 31: Opioid Analgesics & Antagonists for a detailed discussion of opioid overdose and its treatment.

Rattlesnake Envenomation

In the USA, rattlesnakes are the most common venomous reptiles. Bites are rarely fatal, and 20% do not involve envenomation. However, about 60% of bites cause significant morbidity due to the destructive digestive enzymes found in the venom. Evidence of rattlesnake envenomation includes severe pain, swelling, bruising, hemorrhagic bleb formation, and obvious fang marks. Systemic effects include nausea, vomiting, muscle fasciculations, tingling and metallic taste in the mouth, shock, and systemic coagulopathy with prolonged clotting time and reduced platelet count.

Studies have shown that emergency field remedies such as incision and suction, tourniquets, and ice packs are far more damaging than useful. Avoidance of unnecessary motion, on the other hand, does help to limit the spread of the venom. Definitive therapy relies on intravenous antivenin and should be started as soon as possible.

Theophylline

Although it has been largely replaced by inhaled β -agonists, theophylline continues to be used for the treatment of bronchospasm by some patients with asthma and bronchitis (see Chapter 20: Drugs Used in Asthma). A dose of 20–30 tablets can cause serious or fatal poisoning. Chronic or subacute theophylline poisoning can also occur as a result of accidental overmedication or use of a drug that interferes with theophylline metabolism (eg, cimetidine, ciprofloxacin, erythromycin; see Chapter 4: Drug Biotransformation).

In addition to sinus tachycardia and tremor, vomiting is common after overdose. Hypotension, tachycardia, hypokalemia, and hyperglycemia may occur, probably due to β_2 -adrenergic activation. The cause of this activation is not fully understood, but the effects can be ameliorated by the use of β -blockers (see below). Cardiac arrhythmias include atrial tachycardias, premature ventricular contractions, and ventricular tachycardia. In severe poisoning (eg, acute overdose with serum level > 100 mg/L), seizures often occur and are usually resistant to common anticonvulsants. Toxicity may be delayed in onset for many hours after ingestion of sustained-release tablet formulations.

General supportive care should be provided. Aggressive gut decontamination should be carried out using repeated doses of activated charcoal and whole bowel irrigation. Propranolol or other β -blockers (eg, esmolol) are useful antidotes for β -mediated hypotension and tachycardia. Phenobarbital is preferred over phenytoin for convulsions; most anticonvulsants are ineffective. Hemodialysis is indicated for serum concentrations > 100 mg/L and for intractable seizures in patients with lower levels.

Section X. Special Topics

Special Aspects of Perinatal & Pediatric Pharmacology: Introduction

* Supported by a grant from The Canadian Institutes for Health Research.

The effects of drugs on the fetus and newborn infant are based on the general principles set forth in Chapters 1–4 of this book. However, the physiologic contexts in which these pharmacologic laws operate are different in pregnant women and in rapidly maturing infants. At present, the special pharmacokinetic factors operative in these patients are beginning to be understood, whereas information regarding pharmacodynamic differences (eg, receptor characteristics and responses) is still incomplete. This chapter presents basic principles of pharmacology in the special context of perinatal and pediatric therapeutics.

Katzung PHARMACOLOGY, 9e > Section X. Special Topics > Chapter 60. Special Aspects of Perinatal & Pediatric Pharmacology* >

Drug Therapy in Pregnancy

Pharmacokinetics

Most drugs taken by pregnant women can cross the placenta and expose the developing embryo and fetus to their pharmacologic and teratogenic effects. Critical factors affecting placental drug transfer and drug effects on the fetus include the following: (1) the physicochemical properties of the drug; (2) the rate at which the drug crosses the placenta and the amount of drug reaching the fetus; (3) the duration of exposure to the drug; (4) distribution characteristics in different fetal tissues; (5) the stage of placental and fetal development at the time of exposure to the drug; (6) the effects of drugs used in combination.

Lipid Solubility

As is true also of other biologic membranes, drug passage across the placenta is dependent on lipid solubility and the degree of drug ionization. Lipophilic drugs tend to diffuse readily across the placenta and enter the fetal circulation. For example, thiopental, a drug commonly used for cesarean sections, crosses the placenta almost immediately and can produce sedation or apnea in the newborn infant. Highly ionized drugs such as succinylcholine and tubocurarine, also used for cesarean sections, cross the placenta slowly and achieve very low concentrations in the fetus. Impermeability of the placenta to polar compounds is relative rather than absolute. If high enough maternal-fetal concentration gradients are achieved, polar compounds cross the placenta in measurable amounts. Salicylate, which is almost completely ionized at physiologic pH, crosses the placenta rapidly. This occurs because the small amount of salicylate that is not ionized is highly lipid-soluble.

Molecular Size

The molecular weight of the drug also influences the rate of transfer and the amount of drug transferred across the placenta. Drugs with molecular weights of 250–500 can cross the placenta easily, depending upon their lipid solubility and degree of ionization; those with molecular weights

of 500–1000 cross the placenta with more difficulty; and those with molecular weights greater than 1000 cross very poorly. An important clinical application of this property is the choice of heparin as an anticoagulant in pregnant women. Because it is a very large (and polar) molecule, heparin is unable to cross the placenta. Unlike warfarin, which is teratogenic and should be avoided during the first trimester and even beyond (as the brain continues to develop), heparin may be safely given to pregnant women who need anticoagulation. Yet the placenta contains drug transporters, which can carry to the fetus larger molecules. For example, a variety of maternal antibodies cross the placenta and may cause fetal morbidity, as in Rh incompatibility.

Placental Transporters

During the last decade, increasing numbers of drug transporters have been identified in the placenta, with substantial effects of drug transfer to the fetus. For example, the P-glycoprotein transporter encoded by the *MDR1* gene pumps back into the maternal circulation a variety of drugs, including cancer drugs (eg, vinblastine, doxorubicin) and other agents (eg, digoxin). Inhibition of this transporter may cause drug accumulation in the fetus.

Protein Binding

The degree to which a drug is bound to plasma proteins (particularly albumin) may also affect the rate of transfer and the amount transferred. However, if a compound is very lipid-soluble (eg, some anesthetic gases), it will not be affected greatly by protein binding. Transfer of these more lipid-soluble drugs and their overall rates of equilibration are more dependent on (and proportionate to) placental blood flow. This is because very lipid-soluble drugs diffuse across placental membranes so rapidly that their overall rates of equilibration do not depend on the free drug concentrations becoming equal on both sides. If a drug is poorly lipid-soluble and is ionized, its transfer is slow and will probably be impeded by its binding to maternal plasma proteins. Differential protein binding is also important since some drugs exhibit greater protein binding in maternal plasma than in fetal plasma because of a lower binding affinity of fetal proteins. This has been shown for sulfonamides, barbiturates, phenytoin, and local anesthetic agents.

Placental and Fetal Drug Metabolism

Two mechanisms help protect the fetus from drugs in the maternal circulation: (1) The placenta itself plays a role both as a semipermeable barrier and as a site of metabolism of some drugs passing through it. Several different types of aromatic oxidation reactions (eg, hydroxylation, N-dealkylation, demethylation) have been shown to occur in placental tissue. Pentobarbital is oxidized in this way. Conversely, it is possible that the metabolic capacity of the placenta may lead to creation of toxic metabolites, and the placenta may therefore augment toxicity (eg, ethanol, benzpyrenes). (2) Drugs that have crossed the placenta enter the fetal circulation via the umbilical vein. About 40–60% of umbilical venous blood flow enters the fetal liver; the remainder bypasses the liver and enters the general fetal circulation. A drug that enters the liver may be partially metabolized there before it enters the fetal circulation. In addition, a large proportion of drug present in the umbilical artery (returning to the placenta) may be shunted through the placenta back to the umbilical vein and into the liver again. It should be noted that metabolites of some drugs may be more active than the parent compound and may affect the fetus adversely.

Pharmacodynamics

Maternal Drug Actions

The effects of drugs on the reproductive tissues (breast, uterus, etc) of the pregnant woman are sometimes altered by the endocrine environment appropriate for the stage of pregnancy. Drug effects on other maternal tissues (heart, lungs, kidneys, central nervous system, etc) are not changed significantly by pregnancy, though the physiologic context (cardiac output, renal blood flow, etc) may be altered and may require the use of drugs that are not needed by the same woman when she is not pregnant. For example, cardiac glycosides and diuretics may be needed for heart failure precipitated by the increased cardiac workload of pregnancy, or insulin may be required for control of blood glucose in pregnancy-induced diabetes.

Therapeutic Drug Actions in the Fetus

Fetal therapeutics is an emerging area in perinatal pharmacology. This involves drug administration to the pregnant woman with the fetus as the target of the drug. At present, corticosteroids are used to stimulate fetal lung maturation when preterm birth is expected. Phenobarbital, when given to pregnant women near term, can induce fetal hepatic enzymes responsible for the glucuronidation of bilirubin, and the incidence of jaundice is lower in newborns when mothers are given phenobarbital than when phenobarbital is not used. Before phototherapy became the preferred mode of therapy for neonatal indirect hyperbilirubinemia, phenobarbital was used for this indication. Administration of phenobarbital to the mother was suggested recently as a means of decreasing the risk of intracranial bleeding in preterm infants. However, large randomized studies failed to confirm this effect. Antiarrhythmic drugs have also been given to mothers for treatment of fetal cardiac arrhythmias. Although their efficacy has not yet been established by controlled studies, digoxin, flecainide, procainamide, verapamil, and other antiarrhythmic agents have been shown to be effective in case series. During the last decade it has been shown that maternal use of zidovudine decreases by two thirds transmission of HIV from the mother to the fetus, and use of combinations of three antiretroviral agents can eliminate fetal infection almost entirely (Chapter 49: Antiviral Agents).

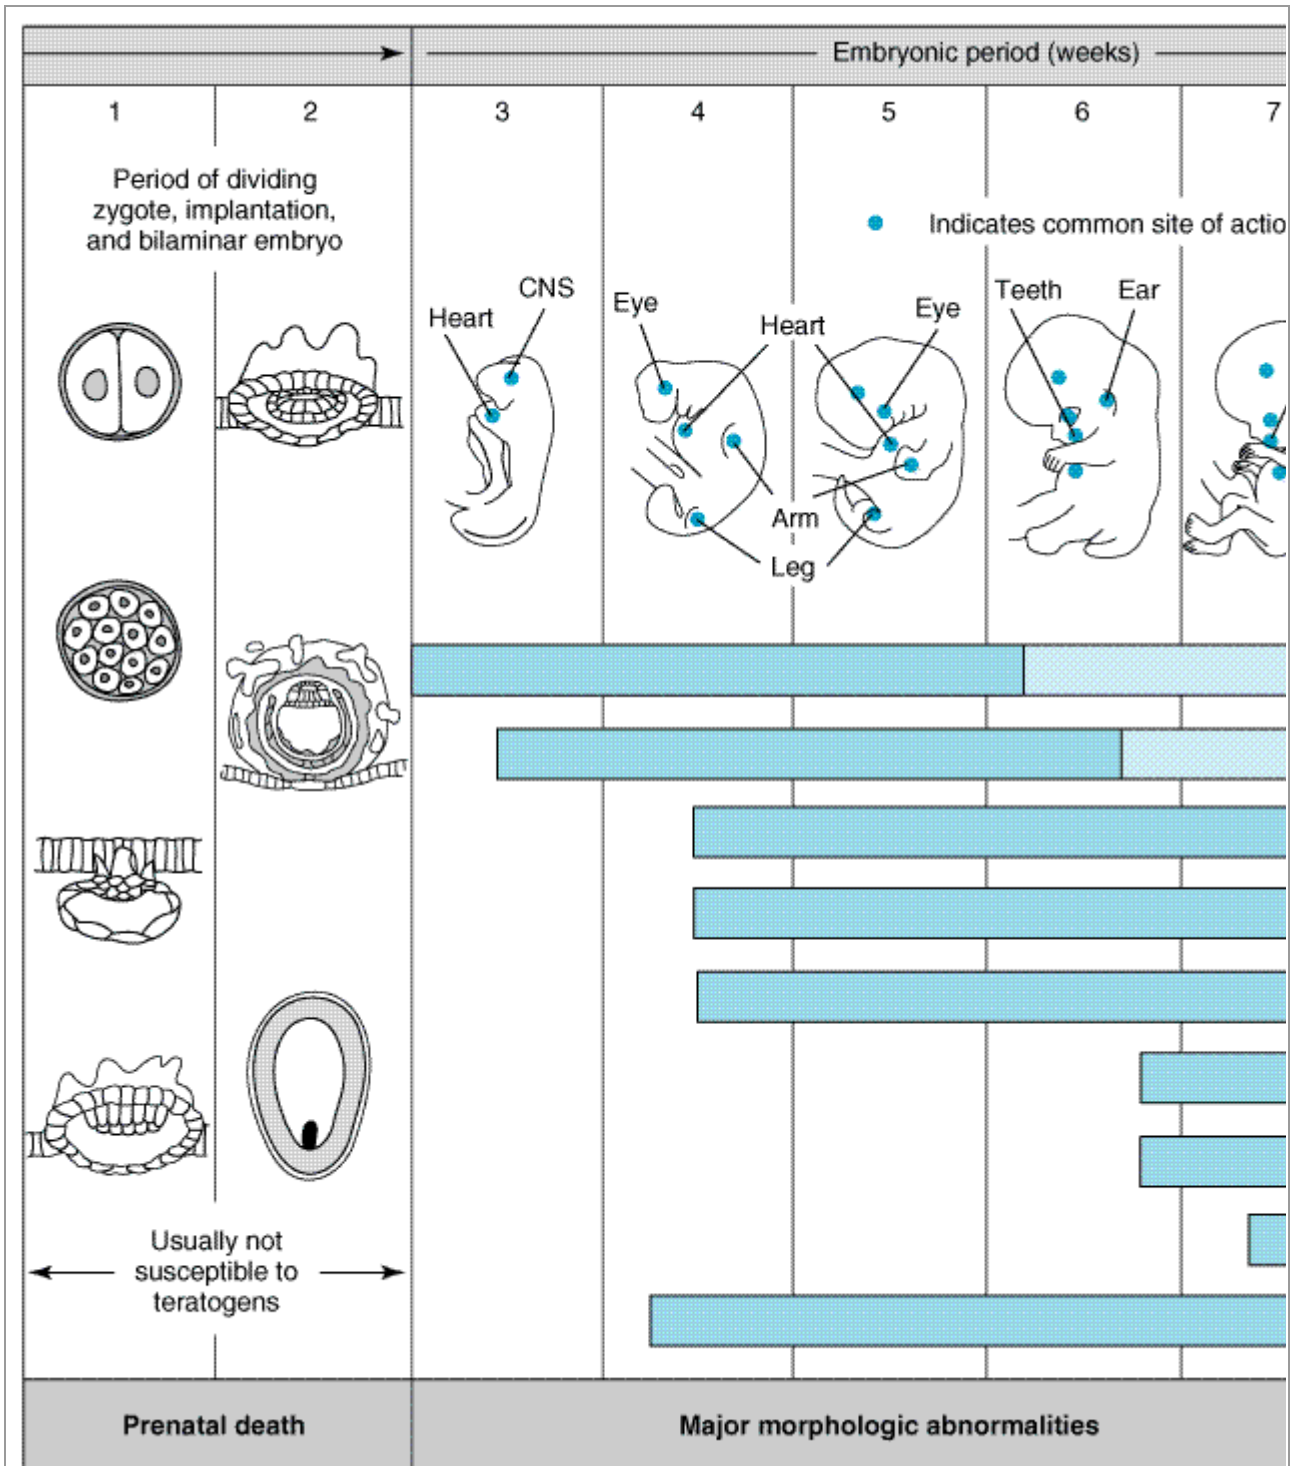

Predictable Toxic Drug Actions in the Fetus

Chronic use of opioids by the mother may produce dependence in the fetus and newborn. This dependence may be manifested after delivery as a neonatal withdrawal syndrome. A less well understood fetal drug toxicity is caused by the use of angiotensin-converting enzyme inhibitors during pregnancy. These drugs can result in significant and irreversible renal damage in the fetus and are therefore contraindicated in pregnant women. Adverse effects may also be delayed, as in the case of female fetuses exposed to diethylstilbestrol, who may be at increased risk for adenocarcinoma of the vagina after puberty.

Teratogenic Drug Actions

A single intrauterine exposure to a drug can affect the fetal structures undergoing rapid development at the time of exposure. Thalidomide is an example of a drug that may profoundly affect the development of the limbs after only brief exposure. This exposure, however, must be at a critical time in the development of the limbs. The thalidomide phocomelia risk occurs during the fourth through the seventh weeks of gestation because it is during this time that the arms and legs develop (Figure 60–1).

Figure 60–1.

Schematic diagram of critical periods of human development. (Reproduced, with permission, from Moore KL: *The Developing Human: Clinically Oriented Embryology*, 4th ed. Saunders, 1988.)

Teratogenic Mechanisms

The mechanisms by which different drugs produce teratogenic effects are poorly understood and are probably multifactorial. For example, drugs may have a direct effect on maternal tissues with secondary or indirect effects on fetal tissues. Drugs may interfere with the passage of oxygen or nutrients through the placenta and therefore have effects on the most rapidly metabolizing tissues of the fetus. Finally, drugs may have important direct actions on the processes of differentiation in developing tissues. For example, vitamin A (retinol) has been shown to have important

differentiation-directing actions in normal tissues. Several vitamin A analogs (isotretinoin, etretinate) are powerful teratogens, suggesting that they alter the normal processes of differentiation. Finally, deficiency of a critical substance appears to play a role in some types of abnormalities. For example, folic acid supplementation during pregnancy appears to reduce the incidence of neural tube defects (eg, spina bifida).

Continued exposure to a teratogen may produce cumulative effects or may affect several organs going through varying stages of development. Chronic consumption of high doses of ethanol during pregnancy, particularly during the first and second trimesters, may result in the fetal alcohol syndrome (Chapter 23: The Alcohols). In this syndrome, the central nervous system, growth, and facial development may be affected.

Defining a Teratogen

To be considered teratogenic, a candidate substance or process should (1) result in a characteristic set of malformations, indicating selectivity for certain target organs; (2) exert its effects at a particular stage of fetal development, ie, during the limited time period of organogenesis of the target organs (Figure 60–1); and (3) show a dose-dependent incidence. Some drugs with known teratogenic or other adverse effects in pregnancy are listed in Table 60–1.

Drug	Trimester	Effect
ACE inhibitors	All, especially second and third	Renal damage
Aminopterin	First	Multiple gross anomalies
Amphetamines	All	Suspected abnormal developmental patterns, decreased school performance
Androgens	Second and third	Masculinization of female fetus
Antidepressants, tricyclic	Third	Neonatal withdrawal symptoms have been reported in a few cases with clomipramine, desipramine, and imipramine
Barbiturates	All	Chronic use can lead to neonatal dependence. Cognitive loss has been described.
Busulfan	All	Various congenital malformations; low birth weight
Carbamazepine	First	Neural tube defects
Chlorpropamide	All	Prolonged symptomatic neonatal hypoglycemia
Clomipramine	Third	Neonatal lethargy, hypotonia, cyanosis, hypothermia
Cocaine	All	Increased risk of spontaneous abortion, abruptio placentae, and premature labor; neonatal cerebral infarction, abnormal development, and decreased school performance
Cyclophosphamide	First	Various congenital malformations

Cytarabine	First, second	Various congenital malformations
Diazepam	All	Chronic use may lead to neonatal dependence and increase risk for oral cleft
Diethylstilbestrol	All	Vaginal adenosis, clear cell vaginal adenocarcinoma
Ethanol	All	Risk of fetal alcohol syndrome and alcohol-related neurodevelopmental defects
Etretinate	All	High risk of multiple congenital malformations
Heroin	All	Chronic use leads to neonatal dependence
Iodide	All	Congenital goiter, hypothyroidism
Isotretinoin	All	Extremely high risk of CNS, face, ear, and other malformations
Lithium	First	Ebstein's anomaly
Methadone	All	Chronic use leads to neonatal dependence
Methotrexate	First	Multiple congenital malformations
Methylthiouracil	All	Hypothyroidism
Metronidazole	First	May be mutagenic (from animal studies; there is no evidence for mutagenic or teratogenic effects in humans)
Organic solvents	First	Multiple malformations and effects on brain development
Misoprostol	First	Möbius sequence
Penicillamine	First	Cutis laxa, other congenital malformations
Phencyclidine	All	Abnormal neurologic examination, poor suck reflex and feeding
Phenytoin	All	Fetal hydantoin syndrome
Propylthiouracil	All	Congenital goiter
Streptomycin	All	Eighth nerve toxicity described in a few cases
Smoking (constituents of tobacco smoke)	All	Intrauterine growth retardation; prematurity; sudden infant death syndrome; perinatal complications
Tamoxifen	All	Increased risk of spontaneous abortion or fetal damage
Tetracycline	All	Discoloration and defects of teeth
Thalidomide	First	Phocomelia (shortened or absent long bones of the limbs) and many internal malformations
Trimethadione	All	Multiple congenital anomalies
Valproic acid	All	Neural tube defects
Warfarin	First	Hypoplastic nasal bridge, chondrodysplasia
	Second	CNS malformations
	Third	Risk of bleeding. Discontinue use 1 month before delivery.

Counseling Women About Teratogenic Risk

Since the thalidomide disaster, medicine has been practiced as if every drug were a potential human teratogen when, in fact, fewer than 30 such drugs have been identified, with hundreds of agents proved safe for the unborn. Owing to high levels of anxiety among pregnant women—and because half of the pregnancies in North America are unplanned—every year many thousands of women need counseling about fetal exposure to drugs, chemicals, and radiation. In the Motherisk program in Toronto, thousands of women are counseled every month, and the ability of appropriate counseling to prevent unnecessary abortions has been documented. Clinicians who wish to provide such counsel to pregnant women must ensure that their information is up to date and evidence-based and that the woman understands that the baseline teratogenic risk in pregnancy (ie, the risk of a neonatal abnormality in the absence of any known teratogenic exposure) is about 3%. It is also critical to address the maternal-fetal risks of the untreated condition. Recent studies show serious morbidity in women who discontinued SSRI therapy for depression in pregnancy.

Katzung PHARMACOLOGY, 9e > Section X. Special Topics > Chapter 60. Special Aspects of Perinatal & Pediatric Pharmacology* >

Drug Therapy in Infants & Children

Physiologic processes that influence pharmacokinetic variables in the infant change significantly in the first year of life, particularly during the first few months. Therefore, special attention must be paid to pharmacokinetics in this age group. Pharmacodynamic differences between pediatric and other patients have not been explored in great detail and are probably small except for those specific target tissues that mature at birth or immediately thereafter (eg, the ductus arteriosus).

Drug Absorption

Drug absorption in infants and children follows the same general principles as in adults. Unique factors that influence drug absorption include blood flow at the site of administration, as determined by the physiologic status of the infant or child; and, for orally administered drugs, gastrointestinal function, which changes rapidly during the first few days after birth. Age after birth also influences the regulation of drug absorption.

Blood Flow at the Site of Administration

Absorption after intramuscular or subcutaneous injection depends mainly, in neonates as in adults, on the rate of blood flow to the muscle or subcutaneous area injected. Physiologic conditions that might reduce blood flow to these areas are cardiovascular shock, vasoconstriction due to sympathomimetic agents, and heart failure. However, sick preterm infants requiring intramuscular injections may have very little muscle mass. This is further complicated by diminished peripheral perfusion to these areas. In such cases, absorption becomes irregular and difficult to predict, because the drug may remain in the muscle and be absorbed more slowly than expected. If perfusion suddenly improves, there can be a sudden and unpredictable increase in the amount of drug entering the circulation, resulting in high and potentially toxic concentrations of drug. Examples of drugs especially hazardous in such situations are cardiac glycosides, aminoglycoside antibiotics, and anticonvulsants.

Gastrointestinal Function

Significant biochemical and physiologic changes occur in the neonatal gastrointestinal tract shortly

after birth. In full-term infants, gastric acid secretion begins soon after birth and increases gradually over several hours. In preterm infants, the secretion of gastric acid occurs more slowly, with the highest concentrations appearing on the fourth day of life. Therefore, drugs that are partially or totally inactivated by the low pH of gastric contents should not be administered orally.

Gastric emptying time is prolonged (up to 6 or 8 hours) in the first day or so after delivery. Therefore, drugs that are absorbed primarily in the stomach may be absorbed more completely than anticipated. In the case of drugs absorbed in the small intestine, therapeutic effect may be delayed. Peristalsis in the neonate is irregular and may be slow. The amount of drug absorbed in the small intestine may therefore be unpredictable; more than the usual amount of drug may be absorbed if peristalsis is slowed, and this could result in potential toxicity from an otherwise standard dose. Table 60–2 summarizes data on oral bioavailability of various drugs in neonates as opposed to older children and adults. An increase in peristalsis, as in diarrheal conditions, tends to decrease the extent of absorption, since contact time with the large absorptive surface of the intestine is decreased.

Table 60–2. Oral Drug Absorption (Bioavailability) of Various Drugs in the Neonate Compared with Older Children and Adults.

Drug	Oral Absorption
Acetaminophen	Decreased
Ampicillin	Increased
Diazepam	Normal
Digoxin	Normal
Penicillin G	Increased
Phenobarbital	Decreased
Phenytoin	Decreased
Sulfonamides	Normal

Gastrointestinal enzyme activities tend to be lower in the newborn than in the adult. Activities of α -amylase and other pancreatic enzymes in the duodenum are low in infants up to 4 months of age. Neonates also have low concentrations of bile acids and lipase, which may decrease the absorption of lipid-soluble drugs.

Drug Distribution

As body composition changes with development, the distribution volumes of drugs are also changed. The neonate has a higher percentage of its body weight in the form of water (70–75%) than does the adult (50–60%). Differences can also be observed between the full-term neonate (70% of body weight as water) and the small preterm neonate (85% of body weight as water). Similarly, extracellular water is 40% of body weight in the neonate, compared with 20% in the adult. Most neonates will experience diuresis in the first 24–48 hours of life. Since many drugs are distributed throughout the extracellular water space, the size (volume) of the extracellular water compartment may be important in determining the concentration of drug at receptor sites. This is especially important for water-soluble drugs (such as aminoglycosides) and less crucial for lipid-soluble

agents.

Preterm infants have much less fat than full-term infants. Total body fat in preterm infants is about 1% of total body weight, compared with 15% in full-term neonates. Therefore, organs that generally accumulate high concentrations of lipid-soluble drugs in adults and older children may accumulate smaller amounts of these agents in less mature infants.

Another major factor determining drug distribution is drug binding to plasma proteins. Albumin is the plasma protein with the greatest binding capacity. In general, protein binding of drugs is reduced in the neonate. This has been seen with local anesthetic drugs, diazepam, phenytoin, ampicillin, and phenobarbital. Therefore, the concentration of free (unbound) drug in plasma is increased initially. Because the free drug exerts the pharmacologic effect, this can result in greater drug effect or toxicity despite a normal or even low plasma concentration of total drug (bound plus unbound). Consider a therapeutic dose of a drug (eg, diazepam) given to a patient. The concentration of total drug in the plasma is 300 $\mu\text{g/L}$. If the drug is 98% protein-bound in an older child or adult, then 6 $\mu\text{g/L}$ is the concentration of free drug. Assume that this concentration of free drug produces the desired effect in the patient without producing toxicity. However, if this drug is given to a preterm infant in a dosage adjusted for body weight and it produces a total drug concentration of 300 $\mu\text{g/L}$ —and protein binding is only 90%—then the free drug concentration will be 30 $\mu\text{g/L}$, or five times higher. Although the higher free concentration may result in faster elimination (Chapter 3: Pharmacokinetics & Pharmacodynamics: Rational Dosing & the Time Course of Drug Action), this concentration may be quite toxic initially.

Some drugs compete with serum bilirubin for binding to albumin. Drugs given to a neonate with jaundice can displace bilirubin from albumin. Because of the greater permeability of the neonatal blood-brain barrier, substantial amounts of bilirubin may enter the brain and cause kernicterus. This was in fact observed when sulfonamide antibiotics were given to preterm neonates as prophylaxis against sepsis. Conversely, as the serum bilirubin rises for physiologic reasons or because of a blood group incompatibility, bilirubin can displace a drug from albumin and substantially raise the free drug concentration. This may occur without altering the total drug concentration and would result in greater therapeutic effect or toxicity at normal concentrations. This has been shown to happen with phenytoin.

Drug Metabolism

The metabolism of most drugs occurs in the liver (Chapter 4: Drug Biotransformation). The drug-metabolizing activities of the cytochrome P450-dependent mixed-function oxidases and the conjugating enzymes are substantially lower (50–70% of adult values) in early neonatal life than later. The point in development at which enzymatic activity is maximal depends upon the specific enzyme system in question. Glucuronide formation reaches adult values (per kilogram body weight) between the third and fourth years of life. Because of the neonate's decreased ability to metabolize drugs, many drugs have slow clearance rates and prolonged elimination half-lives. If drug doses and dosing schedules are not altered appropriately, this immaturity predisposes the neonate to adverse effects from drugs that are metabolized by the liver. Table 60–3 demonstrates how neonatal and adult drug elimination half-lives can differ and how the half-lives of phenobarbital and phenytoin decrease as the neonate grows older. The process of maturation must be considered when administering drugs to this age group, especially in the case of drugs administered over long periods.

Table 60–3. Approximate Elimination Half-Lives of Various Drugs in Neonates and Adults.

Drug	Neonatal Age	Neonates $t_{1/2}$ (hours)	Adults $t_{1/2}$ (hours)
Acetaminophen		2.25	0.9–2.2
Diazepam		25–100	40–50
Digoxin		60–70	30–60
Phenobarbital	0–5 days	200	64–140
	5–15 days	100	
	1–30 months	50	
Phenytoin	0–2 days	80	12–18
	3–14 days	18	
	14–50 days	6	
Salicylate		4.5–11	10–15
Theophylline	Neonate	13–26	10–15
	Child	3–4	

Another consideration for the neonate is whether or not the mother was receiving drugs (such as phenobarbital) that can induce early maturation of fetal hepatic enzymes. In this case, the ability of the neonate to metabolize certain drugs will be greater than expected, and one may see less therapeutic effect and lower plasma drug concentrations when the usual neonatal dose is given.

Drug Excretion

The glomerular filtration rate is much lower in newborns than in older infants, children, or adults, and this limitation persists during the first few days of life. Calculated on the basis of surface area, glomerular filtration in the neonate is only 30–40% of the adult value. The glomerular filtration rate is even lower in neonates born before 34 weeks of gestation. Function improves substantially during the first week of life. At the end of the first week, the glomerular filtration rate and renal plasma flow have increased 50% from the first day. By the end of the third week, glomerular filtration is 50–60% of the adult value; by 6–12 months, it reaches adult values (per unit surface area). Therefore, drugs that depend on renal function for elimination are cleared from the body very slowly in the first weeks of life.

Penicillins, for example, are cleared by preterm infants at 17% of the adult rate based on comparable surface area and 34% of the adult rate when adjusted for body weight. The dosage of ampicillin for a neonate less than 7 days old is 50–100 mg/kg/d in two doses at 12-hour intervals. The dosage for a neonate over 7 days old is 100–200 mg/kg/d in three doses at 8-hour intervals. A decreased rate of renal elimination in the neonate has also been observed with aminoglycoside antibiotics (kanamycin, gentamicin, neomycin, and streptomycin). The dosage of gentamicin for a neonate less than 7 days old is 5 mg/kg/d in two doses at 12-hour intervals. The dosage for a neonate over 7 days old is 7.5 mg/kg/d in three doses at 8-hour intervals. Total body clearance of digoxin is directly dependent upon adequate renal function, and accumulation of digoxin can occur when glomerular filtration is decreased. Since renal function in a sick infant may not improve at the predicted rate during the first weeks and months of life, appropriate adjustments in dosage and dosing schedules may be very difficult. In this situation, adjustments are best made on the basis of

plasma drug concentrations determined at intervals throughout the course of therapy.

While great focus is naturally concentrated on the neonate, it is important to remember that toddlers may have shorter elimination half-lives of drugs than older children and adults, due probably to increased renal elimination and metabolism. For example, the dose per kilogram of digoxin is much higher in toddlers than in adults. The mechanisms for these developmental changes are still poorly understood.

Special Pharmacodynamic Features in the Neonate

The appropriate use of drugs has made possible the survival of neonates with severe abnormalities who would otherwise die within days or weeks after birth. For example, administration of indomethacin (Chapter 35: Agents Used in Hyperlipidemia) causes the rapid closure of a patent ductus arteriosus, which would otherwise require surgical closure in an infant with a normal heart. Infusion of prostaglandin E₁, on the other hand, causes the ductus to remain open, which can be life-saving in an infant with transposition of the great vessels or tetralogy of Fallot (Chapter 18: The Eicosanoids: Prostaglandins, Thromboxanes, Leukotrienes, & Related Compounds). An unexpected effect of such PGE₁ infusion has recently been described. The drug caused antral hyperplasia with gastric outlet obstruction as a clinical manifestation in 6 of 74 infants who received it. This phenomenon appears to be dose-dependent.

Katzung PHARMACOLOGY, 9e > Section X. Special Topics > Chapter 60. Special Aspects of Perinatal & Pediatric Pharmacology * >

Pediatric Dosage Forms & Compliance

The form in which a drug is manufactured and the way in which the parent dispenses the drug to the child determine the actual dose administered. Many drugs prepared for children are in the form of elixirs or suspensions. **Elixirs** are alcoholic solutions in which the drug molecules are dissolved and evenly distributed. No shaking is required, and unless some of the vehicle has evaporated, the first dose from the bottle and the last dose should contain equivalent amounts of drug. **Suspensions** contain undissolved particles of drug that must be distributed throughout the vehicle by shaking. If shaking is not thorough each time a dose is given, the first doses from the bottle may contain less drug than the last doses, with the result that less than the expected plasma concentration or effect of the drug may be achieved early in the course of therapy. Conversely, toxicity may occur late in the course of therapy, when it is not expected. This uneven distribution is a potential cause of inefficacy or toxicity in children taking phenytoin suspensions. It is thus essential that the prescriber know the form in which the drug will be dispensed and provide proper instructions to the pharmacist and patient or parent.

Compliance may be more difficult to achieve in pediatric practice than otherwise, since it involves not only the parent's conscientious effort to follow directions but also such practical matters as measuring errors, spilling, and spitting out. For example, the measured volume of "teaspoons" ranges from 2.5 to 7.8 mL. The parents should obtain a calibrated medicine spoon or syringe from the pharmacy. These devices improve the accuracy of dose measurements and simplify administration of drugs to children.

When evaluating compliance, it is often helpful to ask if an attempt has been made to give a further dose after the child has spilled half of what was offered. The parents may not always be able to say with confidence how much of a dose the child actually received. The parents must be told whether or not to wake the baby for its every-6-hour dose day or night. These matters should be discussed

and made clear, and no assumptions should be made about what the parents may or may not do. Noncompliance frequently occurs when antibiotics are prescribed to treat otitis media or urinary tract infections and the child feels well after 4 or 5 days of therapy. The parents may not feel there is any reason to continue giving the medicine even though it was prescribed for 10 or 14 days. This common situation should be anticipated so the parents can be told why it is important to continue giving the medicine for the prescribed period even if the child seems to be "cured."

Practical and convenient dosage forms and dosing schedules should be chosen to the extent possible. The easier it is to administer and take the medicine and the easier the dosing schedule is to follow, the more likely it is that compliance will be achieved.

Consistent with their ability to comprehend and cooperate, children should also be given some responsibility for their own health care and for taking medications. This should be discussed in appropriate terms both with the child and with the parents. Possible adverse effects and drug interactions with over-the-counter medicines or foods should also be discussed. Whenever a drug does not achieve its therapeutic effect, the possibility of noncompliance should be considered. There is ample evidence that in such cases parents' or children's reports may be grossly inaccurate. Random pill counts and measurement of serum concentrations may help disclose noncompliance. The use of computerized pill containers, which record each lid opening, has been shown to be very effective in measuring compliance.

Because many pediatric doses are calculated—eg, using body weight—rather than simply read from a list, major dosing errors may result from incorrect calculations. Typically, tenfold errors due to incorrect placement of the decimal point have been described. In the case of digoxin, for example, an intended dose of 0.1 mL containing 5 μ g of drug, when replaced by 1.0 mL—which is still a small volume—can result in fatal overdosage. A good rule for avoiding such "decimal point" errors is to use a leading "0" plus decimal point when dealing with doses less than "1" and to avoid using a zero after a decimal point (see Chapter 66: Rational Prescribing & Prescription Writing).

Drug Use during Lactation

Despite the fact that most drugs are excreted into breast milk in amounts too small to adversely affect neonatal health, thousands of women taking medications do not breast-feed because of misperception of risk. Unfortunately, physicians contribute heavily to this bias. It is important to remember that formula feeding is associated with higher morbidity and mortality in all socioeconomic groups.

Most drugs administered to lactating women are detectable in breast milk. Fortunately, the concentration of drugs achieved in breast milk is usually low (Table 60–4). Therefore, the total amount the infant would receive in a day is substantially less than what would be considered a "therapeutic dose." If the nursing mother must take medications and the drug is a relatively safe one, she should optimally take it 30–60 minutes after nursing and 3–4 hours before the next feeding. This allows time for many drugs to be cleared from the mother's blood, and the concentrations in breast milk will be relatively low. Drugs for which no data are available on safety during lactation should be avoided or breast-feeding discontinued while they are being given.

Table 60–4. Drugs Often Used during Lactation and Possible Effects on the Nursing Infant.

Drug	Effect on Infant	Comments
Ampicillin	Minimal	No significant adverse effects; possible occurrence of diarrhea or allergic sensitization.
Aspirin	Minimal	Occasional doses probably safe; high doses may produce significant concentration in breast milk, but infant dose is nevertheless low.
Caffeine	Minimal	Caffeine intake in moderation is safe; concentration in breast milk is about 1% of that in maternal blood.
Chloral hydrate	Significant	May cause drowsiness if infant is fed at peak concentration in milk.
Chloramphenicol	Significant	Concentrations too low to cause gray baby syndrome; possibility of bone marrow suppression does exist; recommend not taking chloramphenicol while breast-feeding.
Chlorothiazide	Minimal	No adverse effects reported.
Chlorpromazine	Minimal	Appears insignificant.
Codeine	Minimal	No adverse effects reported.
Diazepam	Significant	May cause sedation in breast-fed infants; clinical monitoring recommended.
Dicumarol	Minimal	No adverse side effects reported; may wish to follow infant's prothrombin time.
Digoxin	Minimal	Insignificant quantities enter breast milk.
Ethanol	Moderate	Large amounts consumed by mother can produce alcohol effects in infant. Calculate "time to zero" concentration to schedule consumption or breast-feeding (see Chapter 23: The Alcohols).
Heroin	Significant	Enters breast milk and can prolong neonatal narcotic dependence.
Iodine (radioactive)	Significant	Enters milk in quantities sufficient to cause thyroid suppression in infant.
Isoniazid (INH)	Minimal	Milk concentrations equal maternal plasma concentrations. Possibility of pyridoxine deficiency developing in the infant.
Kanamycin	Minimal	No adverse effects reported.
Lithium	Significant	Breast-feeding with caution; levels can be measured in milk.
Methadone	Significant	(See heroin.) Under close physician supervision, breast-feeding can be continued. Signs of opioid withdrawal in the infant may occur if mother stops taking methadone or stops breast feeding abruptly.
Oral contraceptives	Minimal	May suppress lactation in high doses.
Penicillin	Minimal	Very low concentrations in breast milk.
Phenobarbital	Moderate	Hypnotic doses can cause sedation in the infant. Close monitoring

		of infant.
Phenytoin	Moderate	Amounts entering breast milk are not sufficient to cause adverse effects in infant.
Prednisone	Moderate	Low maternal doses (5 mg/d) probably safe. Doses two or more times physiologic amounts (> 15 mg/d) should probably be avoided.
Propranolol	Minimal	Very small amounts enter breast milk.
Propylthiouracil	Significant	May suppress thyroid function in infant.
Spirolactone	Minimal	Very small amounts enter breast milk.
Tetracycline	Moderate	Possibility of permanent staining of developing teeth in the infant. Should be avoided during lactation.
Theophylline	Moderate	Can enter breast milk in moderate quantities but not likely to produce significant effects.
Thyroxine	Minimal	No adverse effects in therapeutic doses.
Tolbutamide	Minimal	Low concentrations in breast milk.
Warfarin	Minimal	Very small quantities found in breast milk.

Most antibiotics taken by nursing mothers can be detected in breast milk. Tetracycline concentrations in breast milk are approximately 70% of maternal serum concentrations and present a risk of permanent tooth staining in the infant. Isoniazid rapidly reaches equilibrium between breast milk and maternal blood. The concentrations achieved in breast milk are high enough so that signs of pyridoxine deficiency may occur in the infant if the mother is not given pyridoxine supplements.

Most sedatives and hypnotics achieve concentrations in breast milk sufficient to produce a pharmacologic effect in some infants. Barbiturates taken in hypnotic doses by the mother can produce lethargy, sedation, and poor suck reflexes in the infant. Chloral hydrate can produce sedation if the infant is fed at peak milk concentrations. Diazepam can have a sedative effect on the nursing infant, but, most importantly, its long half-life can result in significant drug accumulation.

Opioids such as heroin, methadone, and morphine enter breast milk in quantities potentially sufficient to prolong the state of neonatal narcotic dependence if the drug was taken chronically by the mother during pregnancy. If conditions are well controlled and there is a good relationship between the mother and the physician, an infant could be breast-fed while the mother is taking methadone. She should not, however, stop taking the drug abruptly; the infant can be tapered off the methadone as the mother's dose is tapered. The infant should be watched for signs of narcotic withdrawal.

Minimal use of alcohol by the mother has not been reported to harm nursing infants. Excessive amounts of alcohol, however, can produce alcohol effects in the infant. Nicotine concentrations in the breast milk of smoking mothers are low and do not produce effects in the infant. Very small amounts of caffeine are excreted in the breast milk of coffee-drinking mothers.

Lithium enters breast milk in concentrations equal to those in maternal serum. Clearance of this drug is almost completely dependent upon renal elimination, and women who are receiving lithium may expose the baby to relatively large amounts of the drug.

Radioactive substances such as iodinated ^{125}I albumin and radioiodine can cause thyroid suppression in infants and may increase the risk of subsequent thyroid cancer as much as tenfold. Breast-feeding is contraindicated after large doses and should be withheld for days to weeks after small doses. Similarly, breast-feeding should be avoided in mothers receiving cancer chemotherapy or being treated with cytotoxic or immune-modulating agents for collagen diseases such as lupus erythematosus or after an organ transplant.

Katzung PHARMACOLOGY, 9e > Section X. Special Topics > Chapter 60. Special Aspects of Perinatal & Pediatric Pharmacology * >

Pediatric Drug Dosage

Because of differences in pharmacokinetics in infants and children, simple proportionate reduction in the adult dose may not be adequate to determine a safe and effective pediatric dose. The most reliable pediatric dose information is usually that provided by the manufacturer in the package insert. However, such information is not available for the majority of products even when studies have been published in the medical literature—reflecting the reluctance of manufacturers to label their products for children. Recently, the Food & Drug Administration has moved toward more explicit expectations that manufacturers test their new products in infants and children. In the absence of explicit pediatric dose recommendations, an approximation can be made by any of several methods based on age, weight, or surface area. These rules are not precise and should not be used if the manufacturer provides a pediatric dose. Most drugs approved for use in children have recommended pediatric doses, generally stated as milligrams per kilogram or per pound. However, most drugs in the common formularies, eg, *Physicians' Desk Reference*, are still not specifically approved for children. This is due to lack of interest by manufacturers because the pediatric market for drugs is relatively small. When pediatric doses are calculated (either from one of the methods set forth below or from a manufacturer's dose), the pediatric dose should never exceed the adult dose.

Surface Area

Calculations of dosage based on age or weight (see below) are conservative and tend to underestimate the required dose. Doses based on surface area (Table 60–5) are more likely to be adequate.

Table 60–5. Determination of Drug Dosage from Surface Area.1				
Weight		Approximate Age	Surface Area (m ²)	Percent of Adult Dose
(kg)	(lb)			
3	6.6	Newborn	0.2	12
6	13.2	3 months	0.3	18
10	22	1 year	0.45	28
20	44	5.5 years	0.8	48
30	66	9 years	1	60
40	88	12 years	1.3	78

50	110	14 years	1.5	90
60	132	Adult	1.7	102
70	154	Adult	1.76	103

Reproduced, with permission, from Silver HK, Kempe CH, Bruyn HB: *Handbook of Pediatrics*, 14th ed. Originally published by Lange Medical Publications. Copyright © 1983 by the McGraw-Hill Companies, Inc.

¹ For example, if adult dose is 1 mg/kg, dose for 3-month-old infant would be 2 mg/kg (18% of 70 mg/6 kg).

Age (Young's rule):

$$\text{Dose} = \text{Adult dose} \times \frac{\text{Age (years)}}{\text{Age} + 12}$$

Weight (somewhat more precise is Clark's rule):

$$\text{Dose} = \text{Adult dose} \times \frac{\text{Weight (kg)}}{70}$$

or

$$\text{Dose} = \text{Adult dose} \times \frac{\text{Weight (lb)}}{150}$$

In spite of these approximations, only by conducting studies in children can safe and effective doses for a given age group and condition be determined.

Chapter 61. Special Aspects of Geriatric Pharmacology

Katzung PHARMACOLOGY, 9e > Section X. Special Topics > Chapter 61. Special Aspects of Geriatric Pharmacology >

Special Aspects of Geriatric Pharmacology: Introduction

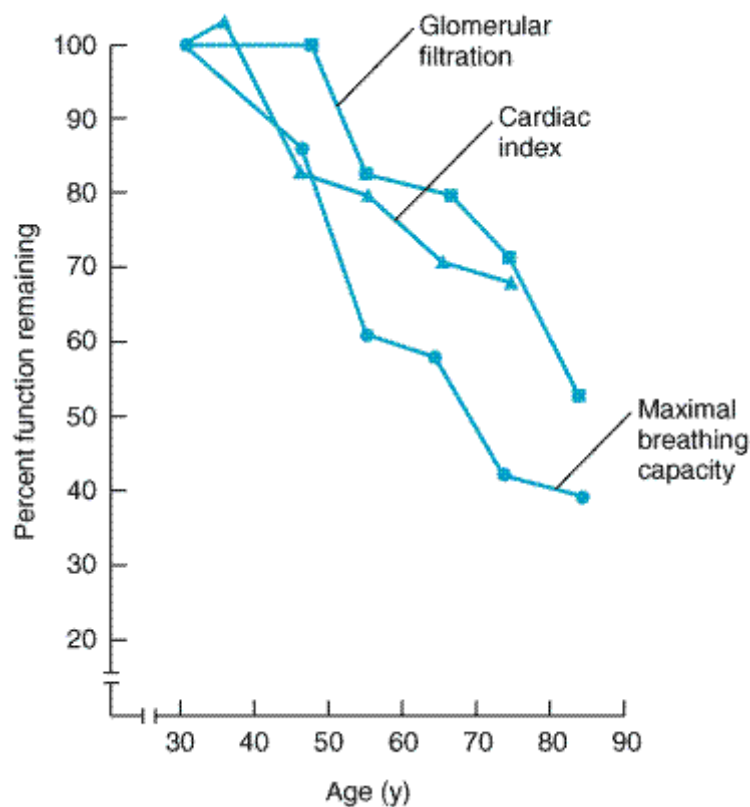

Society often classifies everyone over 65 as "elderly," but most authorities consider the field of geriatrics to apply to persons over 75—even though this too is an arbitrary definition. Furthermore, chronologic age is only one determinant of the changes pertinent to drug therapy that occur in older people. Important changes in responses to some drugs occur with increasing age in many individuals. For other drugs, age-related changes are minimal, especially in the "healthy old." Drug usage patterns also change as a result of the increasing incidence of disease with age and the tendency to prescribe heavily for patients in nursing homes. General changes in the lives of older people have significant effects on the way drugs are used. Among these changes are the increased incidence with advancing age of multiple diseases, nutritional problems, reduced financial resources, and—in some patients—decreased dosing compliance for a variety of reasons. The health practitioner thus should be aware of the changes in pharmacologic responses that may occur in

older people and how to deal with these changes.

Pharmacologic Changes Associated with Aging

In the general population, measurements of functional capacity of most of the major organ systems show a decline beginning in young adulthood and continuing throughout life. As shown in Figure 61-1, there is no "middle-age plateau" but rather a linear decrease beginning no later than age 45. However, these data reflect the mean and do not apply to every person above a certain age; approximately one third of healthy subjects have no age-related decrease in, for example, creatinine clearance up to the age of 75. Thus, the elderly do not lose specific functions at an accelerated rate compared with young and middle-aged adults but rather accumulate more deficiencies with the passage of time. Some of these changes result in altered pharmacokinetics. For the pharmacologist and the clinician, the most important of these is the decrease in renal function. Other changes and concurrent diseases may alter the pharmacodynamic characteristics of particular drugs in certain patients.

Figure 61-1.

Effect of age on some physiologic functions. (Modified and reproduced, with permission, from Kohn RR: *Principles of Mammalian Aging*. Prentice-Hall, 1978.)

Pharmacokinetic Changes

Absorption

There is little evidence that there is any major alteration in drug absorption with age. However, conditions associated with age may alter the rate at which some drugs are absorbed. Such conditions

include altered nutritional habits, greater consumption of nonprescription drugs (eg, antacids, laxatives), and changes in gastric emptying, which is often slower in older persons.

Distribution

Compared to young adults, the elderly have reduced lean body mass, reduced total and percentage body water, and an increase in fat as a percentage of body mass. Some of these changes are shown in Table 61–1. There is usually a decrease in serum albumin, which binds many drugs, especially weak acids. There may be a concurrent *increase* in serum orosomucoid (α -acid glycoprotein), a protein that binds many basic drugs. Thus, the ratio of bound to free drug may be significantly altered. As explained in Chapter 3: Pharmacokinetics & Pharmacodynamics: Rational Dosing & the Time Course of Drug Action, these changes may alter the appropriate loading dose of a drug. However, since both the clearance and the effects of drugs are related to the free concentration, the steady state effects of a maintenance dosage regimen should not be altered by these factors alone. For example, the loading dose of digoxin in an elderly patient with heart failure should be reduced (if used at all) because of the decreased apparent volume of distribution. The maintenance dose may have to be reduced because of reduced clearance of the drug.

Variable	Young Adults (20–30 years)	Older Adults (60–80 years)
Body water (% of body weight)	61	53
Lean body mass (% of body weight)	19	12
Body fat (% of body weight)	26–33 (women)	38–45
	18–20 (men)	36–38
Serum albumin (g/dL)	4.7	3.8
Kidney weight (% of young adult)	(100)	80
Hepatic blood flow (% of young adult)	(100)	55–60

Metabolism

The capacity of the liver to metabolize drugs does not appear to decline consistently with age for all drugs. Animal studies and some clinical studies have suggested that certain drugs are metabolized more slowly; some of these drugs are listed in Table 61–2. The greatest changes are in phase I reactions, ie, those carried out by the microsomal mixed-function oxidase system; there are much smaller changes in the ability of the liver to carry out conjugation (phase II) reactions (see Chapter 4: Drug Biotransformation). Some of these changes may be caused by decreased liver blood flow (Table 61–1), an important variable in the clearance of drugs that have a high hepatic extraction ratio. In addition, there is a decline with age of the liver's ability to recover from injury, eg, that caused by alcohol or viral hepatitis. Therefore, a history of recent liver disease in an older person should lead to caution in dosing with drugs that are cleared primarily by the liver, even after apparently complete recovery from the hepatic insult. Finally, malnutrition and diseases that affect hepatic function—eg, heart failure—are more common in the elderly. Heart failure may dramatically alter the ability of the liver to metabolize drugs and may also reduce hepatic blood

flow. Similarly, severe nutritional deficiencies, which occur more often in old age, may impair hepatic function.

Table 61–2. Effects of Age on Hepatic Clearance of Some Drugs.	
Age-Related Decrease in Hepatic Clearance Found	No Age-Related Difference Found
Alprazolam	Ethanol
Barbiturates	Isoniazid
Carbenoxolone	Lidocaine
Chlordiazepoxide	Lorazepam
Chlormethiazole	Nitrazepam
Clobazam	Oxazepam
Desmethyldiazepam	Prazosin
Diazepam	Salicylate
Flurazepam	Warfarin
Imipramine	
Meperidine	
Nortriptyline	
Phenylbutazone	
Propranolol	
Quinidine, quinine	
Theophylline	
Tolbutamide	

Elimination

Because the kidney is the major organ for clearance of drugs from the body, the age-related decline of renal functional capacity referred to above is very important. The decline in creatinine clearance occurs in about two thirds of the population. It is important to note that this decline is not reflected in an equivalent rise in serum creatinine because the production of creatinine is also reduced as muscle mass declines with age. The practical result of this change is marked prolongation of the half-life of many drugs and the possibility of accumulation to toxic levels if dosage is not reduced in size or frequency. Dosing recommendations for the elderly often include an allowance for reduced renal clearance. If only the young adult dosage is known for a drug that requires renal clearance, a rough correction can be made by using the Cockcroft-Gault formula (Cockcroft et al, 1976), which is applicable to patients from age 40 through age 80:

$$\text{Creatinine clearance (mL/min)} = \frac{(140 - \text{Age}) \times (\text{Weight in kg})}{72 \times \text{Serum creatinine in mg/dL}}$$

For women, the result should be multiplied by 0.85. It must be emphasized that this estimate is, at best, a *population* estimate and may not apply to a particular patient (Goldberg et al, 1987). If the patient has normal renal function (up to one third of patients), a dose corrected on the basis of this estimate will be too low—but a low dose is initially desirable if one is uncertain of the renal function in any patient. If a precise measure is needed, a standard 12- or 24-hour creatinine clearance determination should be done. As indicated above, nutritional changes alter pharmacokinetic parameters. A patient who is severely dehydrated (not uncommon in patients with stroke or other motor impairment) may have an additional marked reduction in renal drug clearance that is completely reversible by rehydration.

The lungs are important for the excretion of volatile drugs. As a result of reduced respiratory capacity (Figure 61–1) and the increased incidence of active pulmonary disease in the elderly, the use of inhalation anesthesia is less common and parenteral agents more common in this age group. (See Chapter 25: General Anesthetics.)

Pharmacodynamic Changes

It was long believed that geriatric patients were much more "sensitive" to the action of many drugs, implying a change in the pharmacodynamic interaction of the drugs with their receptors. It is now recognized that many—perhaps most—of these apparent changes result from altered pharmacokinetics or diminished homeostatic responses. Clinical studies have supported the idea that the elderly are more sensitive to *some* sedative-hypnotics and analgesics. In addition, there are some data from animal studies that suggest actual changes with age in the characteristics or numbers of a few receptors. The most extensive studies show a decrease in responsiveness to β -adrenoceptor stimulants. Other examples are discussed below.

Certain homeostatic control mechanisms appear to be blunted in the elderly. Since homeostatic responses are often important components of the total response to a drug, these physiologic alterations may change the pattern or intensity of drug response. In the cardiovascular system, the cardiac output increment required by mild or moderate exercise is successfully provided to at least age 75 (in individuals without obvious cardiac disease), but the increase is the result primarily of increased stroke volume in the elderly and not tachycardia, as in young adults. Average blood pressure goes up with age (in most Western countries), but the incidence of symptomatic orthostatic hypotension also increases markedly. It is thus particularly important to check for orthostatic hypotension on every visit. Similarly, the average 2-hour postprandial blood sugar increases by about 1 mg/dL for each year of age above 50. Temperature regulation is also impaired, and hypothermia is poorly tolerated in the elderly.

Behavioral & Lifestyle Changes

Major changes in the conditions of daily life accompany the aging process and impact health. Some of these (eg, forgetting to take one's pills) are the result of cognitive changes associated with vascular or other pathology. Others relate to economic stresses associated with greatly reduced income and possibly, increased expenses due to illness. One of the most important changes is the loss of a spouse.

Katzung PHARMACOLOGY, 9e > Section X. Special Topics > Chapter 61. Special Aspects of Geriatric Pharmacology >

Major Drug Groups

Central Nervous System Drugs

Sedative-Hypnotics

The half-lives of many benzodiazepines and barbiturates increase 50–150% between age 30 and age 70. Much of this change occurs during the decade from 60 to 70. For many of the benzodiazepines, both the parent molecule and its metabolites (produced in the liver) are pharmacologically active (see Chapter 22: Sedative-Hypnotic Drugs). The age-related decline in renal function and liver disease, if present, both contribute to the reduction in elimination of these compounds. In addition, an increased volume of distribution has been reported for some of these drugs. Lorazepam and oxazepam may be less affected by these changes than the other benzodiazepines. In addition to these pharmacokinetic factors, it is generally believed that the elderly vary more in their sensitivity to the sedative-hypnotic drugs on a pharmacodynamic basis as well. Among the toxicities of these drugs, ataxia and other aspects of motor impairment should be particularly watched for in order to avoid accidents.

Analgesics

The opioid analgesics show variable changes in pharmacokinetics with age. However, the elderly are often markedly more sensitive to the respiratory effects of these agents because of age-related changes in respiratory function. Therefore, this group of drugs should be used with caution until the sensitivity of the particular patient has been evaluated, and the patient should then be dosed appropriately for full effect. Unfortunately, studies show that opioids are consistently *underutilized* in patients who require strong analgesics for chronic painful conditions such as cancer. There is no justification for underutilization of these drugs, especially in the care of the elderly, and good pain management plans are readily available (Ashburn et al, 1993; Schug et al, 1992).

Antipsychotic & Antidepressant Drugs

The antipsychotic agents (phenothiazines and haloperidol) have been very heavily used (and probably misused) in the management of a variety of psychiatric diseases in the elderly. There is no doubt that they are useful in the management of schizophrenia in old age, and they are probably useful also in the treatment of some symptoms associated with delirium, dementia, agitation, combativeness, and a paranoid syndrome that appears in some geriatric patients. However, they are not fully satisfactory in these geriatric conditions, and dosage should not be increased on the assumption that full control is possible. There is no evidence that these drugs have any beneficial effects in Alzheimer's dementia, and on theoretical grounds the antimuscarinic effects of the phenothiazines might be expected to worsen memory impairment and intellectual dysfunction (see below). Much of the apparent improvement in agitated and combative patients may simply reflect the sedative effects of the drugs. When a sedative antipsychotic is desired, a phenothiazine such as thioridazine is appropriate. If sedation is to be avoided, haloperidol is more appropriate. The latter drug has increased extrapyramidal toxicity, however, and should be avoided in patients with preexisting extrapyramidal disease. The phenothiazines, especially older drugs such as chlorpromazine, often induce orthostatic hypotension in young adults because of their α -adrenoceptor-blocking effects. They are even more prone to do so in the elderly.

Because of increased responsiveness to all these drugs, dosage should usually be started at a fraction of that used in young adults. The half-lives of some phenothiazines are increased in the geriatric population. Thioridazine's half-life, for example, is more than doubled. Plasma protein binding of fluphenazine is reduced, which results in an increase of the free drug:total drug ratio.

Lithium is often used in the treatment of mania in the aged. Because it is cleared by the kidneys, dosages must be adjusted appropriately. Concurrent use of thiazide diuretics reduces the clearance of lithium and should be accompanied by further reduction in dosage and more frequent measurement of lithium blood levels.

Psychiatric depression is thought to be underdiagnosed and undertreated in the elderly. The suicide rate in the over-65 age group (twice the national average) supports this view. Unfortunately, the apathy, flat affect, and social withdrawal of major depression may be mistaken for senile dementia. Clinical evidence suggests that the elderly are as responsive to the antidepressants (of all types) as younger patients but are more likely to experience toxic effects. This factor along with the reduced clearance of some of these drugs underlines the importance of careful dosing and strict attention to the appearance of toxic effects. If a tricyclic antidepressant is to be used, a drug with reduced antimuscarinic effects should be selected, eg, nortriptyline or desipramine (see Table 30–3). To minimize autonomic effects, a selective serotonin reuptake inhibitor may be chosen.

Drugs Used in Alzheimer's Disease

Alzheimer's disease is characterized by progressive impairment of memory and cognitive functions and may lead to a completely vegetative state and early death. The biochemical defects responsible for these changes have not been identified, but in addition to evidence for abnormalities of neuronal lipoprotein processing, there is much evidence for a marked decrease in choline acetyltransferase and other markers of cholinergic neuron activity and for changes in brain glutamate, dopamine, norepinephrine, serotonin, and somatostatin activity. Eventually, cholinergic and perhaps other neurons die or are destroyed. Patients with Alzheimer's disease are often exquisitely sensitive to the central nervous system toxicities of drugs with antimuscarinic effects.

Many methods of treatment of Alzheimer's disease have been explored. Most attention has been focused on the cholinomimetic drugs because of the evidence for loss of cholinergic neurons noted above. MAO type B inhibition with selegiline (L-deprenyl) has been suggested to have some beneficial effects. "Ampakines," substances that facilitate synaptic activity at glutamate AMPA (see Chapter 21: Introduction to the Pharmacology of CNS Drugs) receptors and nerve growth factors, are also under intense study. So-called cerebral vasodilators are ineffective.

Tacrine (tetrahydroaminoacridine, THA), a long-acting cholinesterase inhibitor and muscarinic modulator, has been extensively studied. Tacrine is orally active, enters the central nervous system readily, and has a duration of effect of 6–8 hours. Tacrine blocks both acetylcholinesterase and butyrylcholinesterase and has complex inhibitory effects on M₁ and M₂ cholinergic receptors. It is also a weak nicotinic blocker. The drug apparently increases the release of acetylcholine from cholinergic nerve endings as well. Finally, tacrine may inhibit MAO, decrease the release of GABA, and increase the release of norepinephrine, dopamine, and serotonin from nerve endings. Tacrine causes cholinomimetic adverse effects, including nausea and vomiting, and significant hepatic toxicity. The latter is manifested by a reversible increase in serum AST or ALT levels of sufficient magnitude to require dose reduction or withdrawal in 40–50% of patients. Hepatocellular necrosis with jaundice has been reported.

Donepezil, rivastigmine, and galantamine are newer cholinesterase inhibitors with adequate penetration into the CNS and a spectrum of action more limited to indirect cholinomimetic effects than tacrine's. The cholinesterase inhibitors should be used with caution in patients receiving other drugs that inhibit cytochrome P450 enzymes (eg, ketoconazole, quinidine; see Chapter 4: Drug Biotransformation).

According to several double-blind trials, these drugs can improve cognitive measures in some patients with Alzheimer's disease. Very tentative evidence suggests that they may even reduce morbidity from other diseases and prolong life slightly. Preparations available are listed in Chapter 7: Cholinoceptor-Activating & Cholinesterase-Inhibiting Drugs. More effective and less toxic drugs are urgently needed for the treatment of Alzheimer's disease.

Cardiovascular Drugs

Antihypertensive Drugs

As noted previously, blood pressure, especially systolic pressure, increases with age in Western countries and in most cultures in which salt intake is high. In women, the increase is especially marked after age 50. The high frequency and sometimes benign course of this form of late-onset systolic hypertension encouraged a conservative approach to its treatment in the past. It is now clear, however, that uncontrolled hypertension leads to the same sequelae in the elderly as in younger individuals. Most clinicians believe that hypertension should be treated vigorously in the elderly.

The basic principles of therapy are not different in the geriatric age group from those described in Chapter 11: Antihypertensive Agents, but the usual cautions regarding altered pharmacokinetics and sensitivity apply. Because of its safety, nondrug therapy (weight reduction in the obese and salt restriction) should be encouraged. Thiazides are a reasonable first step in drug therapy. The hypokalemia, hyperglycemia, and hyperuricemia caused by these agents are more relevant in the elderly because of the higher incidence in these patients of arrhythmias, type 2 diabetes, and gout. Thus, use of low antihypertensive doses—rather than maximum diuretic doses—is important. Calcium channel blockers are effective and safe if titrated to the appropriate response. They are especially useful if the patient also has atherosclerotic angina (Chapter 12: Vasodilators & the Treatment of Angina Pectoris). Beta blockers are potentially hazardous in patients with obstructive airway disease and are considered less useful than calcium channel blockers in the older patient unless heart failure is present. ACE inhibitors are also considered less useful in the elderly unless heart failure or diabetes is present. The most powerful drugs, such as guanethidine and minoxidil, are rarely needed. Every patient receiving antihypertensive drugs should be checked regularly for orthostatic hypotension because of the danger of cerebral ischemia and falls.

Positive Inotropic Agents

Heart failure is a common and particularly lethal disease in the elderly. Fear of this condition may be one reason why physicians overuse cardiac glycosides in this age group. The toxic effects of this drug group are particularly dangerous in the geriatric population, since the elderly are more susceptible to arrhythmias. The clearance of digoxin is usually decreased in the older age group, and while the volume of distribution is often decreased as well, the half-life of this drug may be increased by 50% or more. Because the drug is cleared mostly by the kidneys, renal function must be considered in designing a dosage regimen. There is no evidence that there is any increase in pharmacodynamic sensitivity to the therapeutic effects of the cardiac glycosides; in fact, animal studies suggest a possible decrease in therapeutic sensitivity. On the other hand, as noted above, there is probably an increase in sensitivity to the toxic arrhythmogenic actions. Hypokalemia, hypomagnesemia, hypoxemia (from pulmonary disease), and coronary atherosclerosis all contribute to the high incidence of digitalis-induced arrhythmias in geriatric patients. The less common toxicities of digitalis such as delirium, visual changes, and endocrine abnormalities (see Chapter 13: Drugs Used in Heart Failure) also occur more often in the elderly than in younger patients.

Antiarrhythmic Agents

The treatment of arrhythmias in the elderly is particularly challenging because of the lack of good hemodynamic reserve, the frequency of electrolyte disturbances, and the high incidence of severe coronary disease. The clearances of quinidine and procainamide decrease and their half-lives increase with age. Disopyramide should probably be avoided in the geriatric population because its major toxicities—antimuscarinic action, leading to voiding problems in men; and negative inotropic cardiac effects, leading to heart failure—are particularly undesirable in these patients. The clearance of lidocaine appears to be little changed, but the half-life is increased in the elderly. Although this observation implies an increase in the volume of distribution, it has been recommended that the loading dose of this drug be reduced in geriatric patients because of their greater sensitivity to its toxic effects.

Recent evidence indicates that many patients with atrial fibrillation—a very common arrhythmia in the elderly—do as well with simple control of ventricular rate as with conversion to normal sinus rhythm. Of course, measures should be taken to reduce the risk of thromboembolism in chronic atrial fibrillation (aspirin or anticoagulant drugs).

Antimicrobial Drugs

Several age-related changes contribute to the high incidence of infections in geriatric patients. There appears to be a reduction in host defenses in the elderly; this is manifested in the increase in both serious infections and cancer. This may reflect an alteration in T lymphocyte function. In the lungs, a major age- and tobacco-dependent decrease in mucociliary clearance significantly increases susceptibility to infection. In the urinary tract, the incidence of serious infection is greatly increased by urinary retention and catheterization in men.

Since 1940, the antimicrobial drugs have contributed more to the prolongation of life than any other drug group because they can compensate to some extent for this deterioration in natural defenses. The basic principles of therapy of the elderly with these agents are no different from those applicable in younger patients and have been presented in Chapter 51: Clinical Use of Antimicrobial Agents. The major pharmacokinetic changes relate to decreased renal function; because most of the β -lactam, aminoglycoside, and fluoroquinolone antibiotics are excreted by this route, important changes in half-life may be expected. This is particularly important in the case of the aminoglycosides, because they cause concentration- and time-dependent toxicity in the kidney and in other organs. For gentamicin, kanamycin, and netilmicin, the half-lives are more than doubled. According to one study, the increase may not be so marked for tobramycin.

Anti-Inflammatory Drugs

Osteoarthritis is a very common disease of the elderly. Rheumatoid arthritis is less exclusively a geriatric problem, but the same drug therapy is usually applicable. The basic principles laid down in Chapter 36: Nonsteroidal Anti-Inflammatory Drugs, Disease-Modifying Antirheumatic Drugs, Nonopioid Analgesics, & Drugs Used in Gout and the properties of the anti-inflammatory drugs described there apply fully here.

The nonsteroidal anti-inflammatory agents must be used with special care in the geriatric patient because they cause toxicities to which the elderly are very susceptible. In the case of aspirin, the most important of these is gastrointestinal irritation and bleeding. In the case of the newer NSAIDs, the most important is renal damage, which may be irreversible. Because they are cleared primarily by the kidneys, these drugs will accumulate more rapidly in the geriatric patient and especially in

the patient whose renal function is already compromised beyond the average range for his or her age. A vicious circle is easily set up in which cumulation of the NSAID causes more renal damage, which causes more cumulation. There is no evidence that the COX-2-selective NSAIDs are safer with regard to renal function. Elderly patients receiving high doses of any NSAID should be carefully monitored for changes in renal function.

Corticosteroids are extremely useful in elderly patients who cannot tolerate full doses of NSAIDs. However, they consistently cause a dose- and duration-related osteoporosis, an especially hazardous toxic effect in the elderly. It is not certain whether this drug-induced effect can be reduced by increased calcium and vitamin D intake, but it would seem prudent to consider these agents (and bisphosphonates if osteoporosis is already present) and to encourage frequent exercise in any patient taking corticosteroids.

Katzung PHARMACOLOGY, 9e > Section X. Special Topics > Chapter 61. Special Aspects of Geriatric Pharmacology >

Adverse Drug Reactions in the Elderly

The positive relationship between number of drugs taken and the incidence of adverse reactions to them has been well documented. In long-term care facilities, which have a high population of the elderly, the average number of prescriptions per patient varies between 6 and 8. Studies have shown that the percentage of patients with adverse reactions increases from about 10% when a single drug is being taken to nearly 100% when ten drugs are taken. Thus, it may be expected that about half of patients in long-term care facilities will have recognized or unrecognized reactions at some time. The overall incidence of drug reactions in geriatric patients is estimated to be at least twice that in the younger population. Reasons for this high incidence undoubtedly include errors in prescribing on the part of the practitioner and errors in drug usage by the patient.

Practitioner errors sometimes occur because the physician does not appreciate the importance of changes in pharmacokinetics with age and age-related diseases. Some errors occur because the practitioner is unaware of incompatible drugs prescribed by other practitioners for the same patient. For example, cimetidine, a drug heavily prescribed to the elderly, causes a much higher incidence of untoward effects (eg, confusion, slurred speech) in the geriatric population than in younger patients. It also inhibits the hepatic metabolism of many drugs, including phenytoin, warfarin, β -blockers, and other agents. A patient who has been taking one of the latter agents without untoward effect may develop markedly elevated blood levels and severe toxicity if cimetidine is added to the regimen without adjustment of dosage of the other drugs. Additional examples of drugs that inhibit liver microsomal enzymes and lead to adverse reactions are described in Chapter 4: Drug Biotransformation and Appendix II.

Patient errors may result from noncompliance for reasons described below. In addition, they often result from use of nonprescription drugs taken without the knowledge of the physician. As noted in Chapters 64 and 65, many OTC agents and herbal medications contain "hidden ingredients" with potent pharmacologic effects. For example, many antihistamines have significant sedative effects and are inherently more hazardous in patients with impaired cognitive function. Similarly, their antimuscarinic action may precipitate urinary retention in the geriatric male or glaucoma in a patient with a narrow anterior chamber angle. If the patient is also taking a metabolism inhibitor such as cimetidine, the probability of an adverse reaction is greatly increased. A patient taking a herbal medication containing ginkgo is more likely to experience bleeding while taking low doses of aspirin.

Practical Aspects of Geriatric Pharmacology

The quality of life in elderly patients can be greatly improved and life span can be prolonged by the intelligent use of drugs. However, there are several practical obstacles to compliance that the prescriber must recognize.

The expense of drugs can be a major disincentive in patients receiving marginal retirement incomes who are not covered or inadequately covered by health insurance. The prescriber must be aware of the cost of the prescription and of cheaper alternative therapies. For example, the monthly cost of arthritis therapy with newer NSAIDs may exceed \$100, while that for generic aspirin is about \$5 and for ibuprofen, an older NSAID, about \$20.

Noncompliance may result from forgetfulness or confusion, especially if the patient has several prescriptions and different dosing intervals. A survey carried out in 1986 showed that the population over 65 years of age accounted for 32% of drugs prescribed in the USA though these patients represented only 11–12% of the population at that time. Since the prescriptions are often written by several different practitioners, there is usually no attempt to design "integrated" regimens that use drugs with similar dosing intervals for the conditions being treated. Patients may forget instructions regarding the need to complete a fixed duration of therapy when a course of anti-infective drug is being given. The disappearance of symptoms is often regarded as the best reason to halt drug taking, especially if the prescription was expensive.

Noncompliance may also be deliberate. A decision not to take a drug may be based on prior experience with it. There may be excellent reasons for such "intelligent" noncompliance, and the practitioner should try to elicit them. Such efforts may also improve compliance with alternative drugs, because enlisting the patient as a participant in therapeutic decisions tends to increase the motivation to succeed.

Some errors in drug taking are caused by physical disabilities. Arthritis, tremor, and visual problems may all contribute. Liquid medications that are to be measured out "by the spoonful" are especially inappropriate for patients with any type of tremor or motor disability. The use of a pediatric dosing syringe may be helpful in such cases. Because of decreased production of saliva, older patients often have difficulty swallowing large tablets. "Childproof" containers are often "patient-proof" if the patient has arthritis. Cataracts and macular degeneration occur in a large number of patients over 70; therefore, labels on prescription bottles should be large enough for the patient with diminished vision to read, or color-coded if the patient can see but can no longer read.

Drug therapy has considerable potential for both helpful and harmful effects in the geriatric patient. The balance may be tipped in the right direction by adherence to a few principles:

- (1) Take a careful drug history. The disease to be treated may be drug-induced, or drugs being taken may lead to interactions with drugs to be prescribed.
- (2) Prescribe only for a specific and rational indication. Do not prescribe omeprazole for "dyspepsia."
- (3) Define the goal of drug therapy. Then start with small doses and titrate to the response desired. Wait at least three half-lives (adjusted for age) before increasing the dose. If the

expected response does not occur at the normal adult dosage, check blood levels. If the expected response does not occur at the appropriate blood level, switch to a different drug.

(4) Maintain a high index of suspicion regarding drug reactions and interactions. Know what other drugs the patient is taking.

(5) Simplify the regimen as much as possible. When multiple drugs are prescribed, try to use drugs that can be taken at the same time of day. Whenever possible, reduce the number of drugs being taken.

Chapter 62. Dermatologic Pharmacology

Katzung PHARMACOLOGY, 9e > Section X. Special Topics > Chapter 62. Dermatologic Pharmacology >

Dermatologic Pharmacology: Introduction

The skin offers a number of special opportunities to the therapist. For example, the topical route of administration is especially appropriate for diseases of the skin, though some dermatologic diseases respond as well or better to drugs administered systemically.

The general pharmacokinetic principles governing the use of drugs applied to the skin are the same as those involved in other routes of drug administration (Chapter 1: Introduction and Chapter 3: Pharmacokinetics & Pharmacodynamics: Rational Dosing & the Time Course of Drug Action). However, human skin, though often depicted as a simple three-layered structure, is a complex series of diffusion barriers. Quantitation of the flux of drugs and drug vehicles through these barriers is the basis of pharmacokinetic analysis of dermatologic therapy; techniques for making such measurements are rapidly increasing in number and sensitivity.

Major variables that determine pharmacologic response to drugs applied to the skin include the following:

(1) Regional variation in drug penetration: For example, the scrotum, face, axilla, and scalp are far more permeable than the forearm and may require less drug for equivalent effect.

(2) Concentration gradient: Increasing the concentration gradient increases the mass of drug transferred per unit time, just as in the case of diffusion across other barriers (Chapter 1: Introduction). Thus, resistance to topical corticosteroids can sometimes be overcome by use of higher concentrations of drug.

(3) Dosing schedule: Because of its physical properties, the skin acts as a reservoir for many drugs. As a result, the "local half-life" may be long enough to permit once-daily application of drugs with short systemic half-lives. For example, once-daily application of corticosteroids appears to be just as effective as multiple applications in many conditions.

(4) Vehicles and occlusion: An appropriate vehicle maximizes the ability of the drug to penetrate the outer layers of the skin. In addition, through their physical properties (moistening

or drying effects), vehicles may themselves have important therapeutic effects. Occlusion (application of a plastic wrap to hold the drug and its vehicle in close contact with the skin) is extremely effective in maximizing efficacy.

Katzung PHARMACOLOGY, 9e > Section X. Special Topics > Chapter 62. Dermatologic Pharmacology >

Dermatologic Vehicles

Topical medications usually consist of active ingredients incorporated in a vehicle that facilitates cutaneous application. Important considerations in selection of a vehicle include the solubility of the active agent in the vehicle; the rate of release of the agent from the vehicle; the ability of the vehicle to hydrate the stratum corneum, thus enhancing penetration; the stability of the therapeutic agent in the vehicle; and interactions, chemical and physical, of the vehicle, stratum corneum, and active agent.

Depending upon the vehicle, dermatologic formulations may be classified as tinctures, wet dressings, lotions, gels, aerosols, powders, pastes, creams, and ointments. The ability of the vehicle to retard evaporation from the surface of the skin increases in this series, being least in tinctures and wet dressings and greatest in ointments. In general, acute inflammation with oozing, vesiculation, and crusting is best treated with drying preparations such as tinctures, wet dressings, and lotions, while chronic inflammation with xerosis, scaling, and lichenification is best treated with more lubricating preparations such as creams and ointments. Tinctures, lotions, gels, and aerosols are convenient for application to the scalp and hairy areas. Emulsified vanishing type creams may be used in intertriginous areas without causing maceration.

Emulsifying agents are used to provide homogeneous, stable preparations when mixtures of immiscible liquids such as oil-in-water creams are compounded. Some patients develop irritation from these agents. Substituting a preparation that does not contain them or using one containing a lower concentration may resolve the problem.

Katzung PHARMACOLOGY, 9e > Section X. Special Topics > Chapter 62. Dermatologic Pharmacology >

Antibacterial Agents

Topical Antibacterial Preparations

Topical antibacterial agents may be useful in preventing infections in clean wounds, in the early treatment of infected dermatoses and wounds, in reducing colonization of the nares by staphylococci, in axillary deodorization, and in the management of acne vulgaris. The efficacy of antibiotics in these topical applications is not uniform. The general pharmacology of the antimicrobial drugs is discussed in Chapter 43: Beta-Lactam Antibiotics & Other Inhibitors of Cell Wall Synthesis, Chapter 44: Chloramphenicol, Tetracyclines, Macrolides, Clindamycin, & Streptogramins, Chapter 45: Aminoglycosides & Spectinomycin, Chapter 46: Sulfonamides, Trimethoprim, & Quinolones, Chapter 47: Antimycobacterial Drugs, Chapter 48: Antifungal Agents, Chapter 49: Antiviral Agents, Chapter 50: Miscellaneous Antimicrobial Agents; Disinfectants, Antiseptics, & Sterilants, and Chapter 51: Clinical Use of Antimicrobial Agents.

Numerous topical anti-infectives contain corticosteroids in addition to antibiotics. There is no

convincing evidence that topical corticosteroids inhibit the antibacterial effect of antibiotics when the two are incorporated in the same preparation. In the treatment of secondarily infected dermatoses, which are usually colonized with streptococci, staphylococci, or both, combination therapy may prove superior to corticosteroid therapy alone. Antibiotic-corticosteroid combinations may be useful in treating diaper dermatitis, otitis externa, and impetiginized eczema.

The selection of a particular antibiotic depends of course upon the diagnosis and, when appropriate, *in vitro* culture and sensitivity studies of clinical samples. The pathogens isolated from most infected dermatoses are group A beta-hemolytic streptococci, *Staphylococcus aureus*, or both. The pathogens present in surgical wounds will be those resident in the environment. Information about regional patterns of drug resistance is therefore important in selecting a therapeutic agent. Prepackaged topical antibacterial preparations that contain multiple antibiotics are available in fixed dosages well above the therapeutic threshold. These formulations offer the advantages of efficacy in mixed infections, broader coverage for infections due to undetermined pathogens, and delayed microbial resistance to any single component antibiotic.

Bacitracin & Gramicidin

Bacitracin and gramicidin are peptide antibiotics, active against gram-positive organisms such as streptococci, pneumococci, and staphylococci. In addition, most anaerobic cocci, neisseriae, tetanus bacilli, and diphtheria bacilli are sensitive. Bacitracin is compounded in an ointment base alone or in combination with neomycin, polymyxin B, or both. The use of bacitracin in the anterior nares may temporarily decrease colonization by pathogenic staphylococci. Microbial resistance may develop following prolonged use. Bacitracin-induced contact urticaria syndrome, including anaphylaxis, occurs rarely. Allergic contact dermatitis occurs frequently. Bacitracin is poorly absorbed through the skin, so systemic toxicity is rare.

Gramicidin is available only for topical use, in combination with other antibiotics such as neomycin, polymyxin, bacitracin, and nystatin. Systemic toxicity limits this drug to topical use. The incidence of sensitization following topical application is exceedingly low in therapeutic concentrations.

Mupirocin

Mupirocin (pseudomonic acid A) is structurally unrelated to other currently available topical antibacterial agents. Most gram-positive aerobic bacteria, including methicillin-resistant *S aureus*, are sensitive to mupirocin. It is effective in the treatment of impetigo caused by *S aureus* and group A beta-hemolytic streptococci.

Intranasal (Bactroban Nasal ointment) use for eliminating nasal carriage of *S aureus* may be associated with irritation of mucous membranes caused by the polyethylene glycol vehicle. Mupirocin is not appreciably absorbed systemically after topical application to intact skin.

Polymyxin B Sulfate

Polymyxin B is a peptide antibiotic effective against gram-negative organisms, including *Pseudomonas aeruginosa*, *Escherichia coli*, enterobacter, and klebsiella. Most strains of proteus and serratia are resistant, as are all gram-positive organisms. Topical preparations may be compounded in either a solution or ointment base. Numerous prepackaged antibiotic combinations containing polymyxin B are available. Detectable serum concentrations are difficult to achieve from topical application, but the total daily dose applied to denuded skin or open wounds should not

exceed 200 mg in order to reduce the likelihood of neurotoxicity and nephrotoxicity. Hypersensitivity to topically applied polymyxin B sulfate is uncommon.

Neomycin & Gentamicin

Neomycin and gentamicin are aminoglycoside antibiotics active against gram-negative organisms, including *E coli*, proteus, klebsiella, and enterobacter. Gentamicin generally shows greater activity against *P aeruginosa* than neomycin. Gentamicin is also more active against staphylococci and group A beta-hemolytic streptococci. Widespread topical use of gentamicin, especially in a hospital environment, should be avoided to slow the appearance of gentamicin-resistant organisms.

Neomycin is available in numerous topical formulations, both alone and in combination with polymyxin, bacitracin, and other antibiotics. It is also available as a sterile powder for topical use. Gentamicin is available as an ointment or cream.

Topical application of neomycin rarely results in detectable serum concentrations. However, in the case of gentamicin, serum concentrations of 1–18 µg/mL are possible if the drug is applied in a water-miscible preparation to large areas of denuded skin, as in burned patients. Both drugs are water-soluble and are excreted primarily in the urine. Renal failure may permit the accumulation of these antibiotics, with possible nephrotoxicity, neurotoxicity, and ototoxicity.

Neomycin frequently causes sensitization, particularly if applied to eczematous dermatoses or if compounded in an ointment vehicle. When sensitization occurs, cross-sensitivity to streptomycin, kanamycin, paromomycin, and gentamicin is possible.

Topical Antibiotics in Acne

Several systemic antibiotics that have traditionally been used in the treatment of acne vulgaris have been shown to be effective when applied topically. Currently, four antibiotics are so utilized: clindamycin phosphate, erythromycin base, metronidazole, and sulfacetamide. The effectiveness of topical therapy is less than that achieved by systemic administration of the same antibiotic. Therefore, topical therapy is generally suitable in mild to moderate cases of inflammatory acne.

Clindamycin

Clindamycin has in vitro activity against *Propionibacterium acnes*; this has been postulated as the mechanism of its beneficial effect in acne therapy. Approximately 10% of an applied dose is absorbed, and rare cases of bloody diarrhea and pseudomembranous colitis have been reported following topical application. The hydroalcoholic vehicle may cause drying and irritation of the skin, with complaints of burning and stinging. The water-based gel and lotion formulations are well tolerated and less likely to cause irritation. Allergic contact dermatitis is uncommon. Clindamycin is also available in a fixed-combination topical gel with benzoyl peroxide (BenzaClin).

Erythromycin

In topical preparations, the base of erythromycin rather than a salt is used to facilitate penetration. Although the mechanism of action of topical erythromycin in inflammatory acne vulgaris is unknown, it is presumed to be due to its inhibitory effects on *P acnes*. One of the possible complications of topical therapy is the development of antibiotic-resistant strains of organisms, including staphylococci. If this occurs in association with a clinical infection, topical erythromycin should be discontinued and appropriate systemic antibiotic therapy started. Adverse local reactions

to erythromycin solution may include a burning sensation at the time of application and drying and irritation of the skin. The topical water-based gel is less drying and may be better-tolerated. Allergic hypersensitivity appears to be uncommon. Erythromycin is also available in a fixed combination preparation with benzoyl peroxide (Benzamycin) for topical treatment of acne vulgaris.

Metronidazole

Topical metronidazole is effective in the treatment of acne rosacea. The mechanism of action is unknown, but it may relate to the inhibitory effects of metronidazole on *Demodex brevis* or as an anti-inflammatory agent by direct effect on neutrophil cellular function. Oral metronidazole had been shown to be a carcinogen in susceptible rodent species, and topical use during pregnancy and by nursing mothers and children is therefore not recommended. (See Chapter 53: Antiprotozoal Drugs for a more detailed discussion.)

Adverse local effects of the water-based gel formulation (MetroGel) include dryness, burning, and stinging. Less drying formulations may be better-tolerated (MetroCream, MetroLotion, and Noritate cream). Caution should be exercised when applying metronidazole near the eyes to avoid excessive tearing.

Sodium Sulfacetamide

Topical sulfacetamide is available alone as a 10% lotion (Klaron) and as a 10% wash (Ovace), and in several preparations in combination with sulfur for the treatment of acne vulgaris and acne rosacea. The mechanism of action is thought to be due to inhibition of *P. acnes* by competitive inhibition of *p*-aminobenzoic acid utilization. Approximately 4% of topically applied sulfacetamide is absorbed percutaneously, and its use is therefore contraindicated in patients having a known hypersensitivity to sulfonamides.

Katzung PHARMACOLOGY, 9e > Section X. Special Topics > Chapter 62. Dermatologic Pharmacology >

Antifungal Agents

The treatment of superficial fungal infections caused by dermatophytic fungi may be accomplished (1) with topical antifungal agents, eg, clotrimazole, miconazole, econazole, ketoconazole, oxiconazole, sulconazole, ciclopirox olamine, naftifine, terbinafine, and tolnaftate; or (2) with orally administered agents, ie, griseofulvin, terbinafine, ketoconazole, fluconazole, and itraconazole. Superficial infections caused by candida species may be treated with topical applications of clotrimazole, miconazole, econazole, ketoconazole, oxiconazole, ciclopirox olamine, nystatin, or amphotericin B. Chronic generalized mucocutaneous candidiasis is responsive to long-term therapy with oral ketoconazole.

Topical Antifungal Preparations

Topical Azole Derivatives

The imidazoles, which currently include clotrimazole, econazole, ketoconazole, miconazole, oxiconazole, and sulconazole, have a wide range of activity against dermatophytes (epidermophyton, microsporum, and trichophyton) and yeasts, including *Candida albicans* and *Pityrosporum orbiculare*, the cause of tinea versicolor.

Miconazole (Monistat, Micatin) is available for topical application as a cream or lotion and as vaginal cream or suppositories for use in vulvovaginal candidiasis. Clotrimazole (Lotrimin, Mycelex) is available for topical application to the skin as a cream or lotion and as vaginal cream and tablets for use in vulvovaginal candidiasis. Econazole (Spectazole) is available as a cream for topical application. Oxiconazole (Oxistat) is available as a cream and lotion for topical use. Ketoconazole (Nizoral) is available as a cream for topical treatment of dermatophytosis and candidiasis and as a shampoo for the treatment of seborrheic dermatitis. Sulconazole (Exelderm) is available as a cream or solution. Topical antifungal-corticosteroid fixed combinations have recently been introduced on the basis of providing more rapid symptomatic improvement than an antifungal agent alone. Clotrimazole-betamethasone dipropionate cream (Lotrisone) is one such example.

Once- or twice-daily application to the affected area will generally result in clearing of superficial dermatophyte infections in 2–3 weeks, although the medication should be continued until eradication of the organism is confirmed. Paronychia and intertriginous candidiasis can be treated effectively by any of these agents when applied three or four times daily. Seborrheic dermatitis should be treated with twice-daily applications of ketoconazole until clinical clearing is obtained.

Adverse local reactions to the imidazoles may include stinging, pruritus, erythema, and local irritation. Allergic contact dermatitis appears to be uncommon.

Ciclopirox Olamine

Ciclopirox olamine is a synthetic broad-spectrum antimycotic agent with inhibitory activity against dermatophytes, candida species, and *P orbiculare*. This agent appears to inhibit the uptake of precursors of macromolecular synthesis; the site of action is probably the cell membrane.

Pharmacokinetic studies indicate that 1–2% of the dose is absorbed when applied as a solution on the back under an occlusive dressing. Ciclopirox olamine is available as a 1% cream and lotion (Loprox) for the topical treatment of dermatomycosis, candidiasis, and tinea versicolor. The incidence of adverse reactions has been low. Pruritus and worsening of clinical disease have been reported. The potential for delayed allergic contact hypersensitivity appears small.

Topical 8% ciclopirox olamine (Penlac nail lacquer) has been approved for the treatment of mild to moderate onychomycosis of fingernails and toenails. Although well tolerated with minimal side effects, the overall cure rates in clinical trials are less than 12%.

Naftifine

Naftifine hydrochloride is an allylamine that is highly active against dermatophytes but less active against yeasts. The antifungal activity derives from selective inhibition of squalene epoxidase, a key enzyme for the synthesis of ergosterol.

Naftifine (Naftin) is available as a 1% cream and gel for the topical treatment of dermatophytosis, to be applied on a twice-daily dosing schedule. Adverse reactions include local irritation, burning sensation, and erythema. Contact with mucous membranes should be avoided.

Terbinafine

Terbinafine (Lamisil) is an allylamine with activity similar to that of naftifine hydrochloride. It is available as a 1% cream and solution for the topical treatment of dermatophyte infections. Treatment should be for a minimum of 1 week and should not exceed 4 weeks. Clinical

improvement may continue for 2–4 weeks following cessation of therapy. Reported adverse reactions include local irritation with erythema, dryness, and stinging. Contact with eyes and mucous membranes should be avoided.

Butenafine

Butenafine hydrochloride (Mentax) is a benzylamine that is structurally related to the allylamines. As with the allylamines, butenafine inhibits the epoxidation of squalene, thus blocking the synthesis of ergosterol, an essential component of the fungal cell membranes. Butenafine is available as a 1% cream to be applied once daily for the treatment of superficial dermatophytosis.

Tolnaftate

Tolnaftate is a synthetic antifungal compound that is effective topically against dermatophyte infections caused by epidermophyton, microsporum, and trichophyton. It is also active against *P orbiculare* but not against candida.

Tolnaftate (Aftate, Tinactin) is available as a cream, solution, powder, or powder aerosol for application twice daily to infected areas. Recurrences following cessation of therapy are common, and infections of the palms, soles, and nails are usually unresponsive to tolnaftate alone. The powder or powder aerosol may be used chronically following initial treatment in patients susceptible to tinea infections. Tolnaftate is generally well tolerated and rarely causes irritation or allergic contact sensitization.

Nystatin & Amphotericin B

Nystatin and amphotericin B are useful in the topical therapy of *C albicans* infections but ineffective against dermatophytes. Nystatin is limited to topical treatment of cutaneous and mucosal candida infections because of its narrow spectrum and negligible absorption from the gastrointestinal tract following oral administration. Amphotericin B has a broader antifungal spectrum and is used intravenously in the treatment of many systemic mycoses (Chapter 48: Antifungal Agents) and to a lesser extent in the treatment of cutaneous candida infections.

The recommended dosage for topical preparations of nystatin in treating paronychia and intertriginous candidiasis is application two or three times a day. Oral candidiasis (thrush) is treated by holding 5 mL (infants, 2 mL) of nystatin oral suspension in the mouth for several minutes four times daily before swallowing. An alternative therapy for thrush is to retain a vaginal tablet in the mouth until dissolved four times daily. Recurrent or recalcitrant perianal, vaginal, vulvar, and diaper area candidiasis may respond to oral nystatin, 0.5–1 million units in adults (100,000 units in children) four times daily in addition to local therapy. Vulvovaginal candidiasis may be treated by insertion of 1 vaginal tablet twice daily for 14 days, then nightly for an additional 14–21 days.

Amphotericin B (Fungizone) is available for topical use in cream and lotion form. The recommended dosage in the treatment of paronychia and intertriginous candidiasis is application two to four times daily to the affected area.

Adverse effects associated with oral administration of nystatin include mild nausea, diarrhea, and occasional vomiting. Topical application is nonirritating, and allergic contact hypersensitivity is exceedingly uncommon. Topical amphotericin B is well tolerated and only occasionally locally irritating. Hypersensitivity is very rare. The drug may cause a temporary yellow staining of the skin,

especially when the cream vehicle is used.

Oral Antifungal Agents

Griseofulvin

Griseofulvin is effective orally against dermatophyte infections caused by epidermophyton, microsporum, and trichophyton. It is ineffective against candida and *P orbiculare*.

Griseofulvin's antifungal activity has been attributed to inhibition of hyphal cell wall synthesis, effects on nucleic acid synthesis, and inhibition of mitosis. Griseofulvin interferes with microtubules of the mitotic spindle and with cytoplasmic microtubules. The destruction of cytoplasmic microtubules may result in impaired processing of newly synthesized cell wall constituents at the growing tips of hyphae. Griseofulvin is active only against growing cells.

Following the oral administration of 1 g of micronized griseofulvin, peak serum levels of 1.5–2 μ g/mL are obtained in 4–8 hours. The drug can be detected in the stratum corneum 4–8 hours following oral administration, with the highest concentration in the outermost layers and the lowest in the base. Reducing the particle size of the medication greatly increases absorption of the drug. Formulations that contain the smallest particle size are labeled "ultramicrozoned." Ultramicrozoned griseofulvin achieves bioequivalent plasma levels with half the dose of micronized drug. In addition, solubilizing griseofulvin in polyethylene glycol enhances absorption even further. Micronized griseofulvin is available as 250 mg and 500 mg tablets, and ultramicrozoned drug is available as 125 mg, 165 mg, 250 mg, and 330 mg tablets and as 250 mg capsules.

The usual adult dosage of the micronized ("microsize") form of the drug is 500 mg daily in single or divided doses with meals; occasionally, 1 g/d is indicated in the treatment of recalcitrant infections. The pediatric dosage is 10 mg/kg of body weight daily in single or divided doses with meals. An oral suspension is available for use in children.

Griseofulvin is most effective in treating tinea infections of the scalp and glabrous (nonhairy) skin. In general, infections of the scalp respond to treatment in 4–6 weeks, and infections of glabrous skin will respond in 3–4 weeks. Dermatophyte infections of the nails respond only to prolonged administration of griseofulvin. Fingernails may respond to 6 months of therapy, whereas toenails are quite recalcitrant to treatment and may require 8–18 months of therapy; relapse almost invariably occurs.

Adverse effects seen with griseofulvin therapy include headaches, nausea, vomiting, diarrhea, photosensitivity, peripheral neuritis, and occasionally mental confusion. Griseofulvin is derived from a penicillium mold, and cross-sensitivity with penicillin may occur. It is contraindicated in patients with porphyria or hepatic failure or those who have had hypersensitivity reactions to it in the past. Its safety in pregnant patients has not been established. Leukopenia and proteinuria have occasionally been reported. Therefore, in patients undergoing prolonged therapy, routine evaluation of the hepatic, renal, and hematopoietic systems is advisable. Coumarin anticoagulant activity may be altered by griseofulvin, and anticoagulant dosage may require adjustment.

Oral Azole Derivatives

Azole derivatives currently available for oral treatment of systemic mycosis include fluconazole (Diflucan), itraconazole (Sporonax), and ketoconazole (Nizoral). As discussed in Chapter 48: Antifungal Agents, imidazole derivatives act by affecting the permeability of the cell membrane of

sensitive cells through alterations of the biosynthesis of lipids, especially sterols, in the fungal cell.

Ketoconazole was the first imidazole derivative used for oral treatment of systemic mycoses. Patients with chronic mucocutaneous candidiasis respond well to a once-daily dose of 200 mg of ketoconazole, with a median clearing time of 16 weeks. Most patients require long-term maintenance therapy. Variable results have been reported in treatment of chromomycosis.

Ketoconazole has been shown to be quite effective in the therapy of cutaneous infections caused by epidermophyton, microsporum, and trichophyton species. Infections of the glabrous skin often respond within 2–3 weeks to a once-daily oral dose of 200 mg. Palmar-plantar skin is slower to respond, often taking 4–6 weeks at a dosage of 200 mg twice daily. Infections of the hair and nails may take even longer before resolving with low cure rates noted for tinea capitis. Tinea versicolor is very responsive to short courses of a once-daily dose of 200 mg.

Nausea or pruritus has been noted in approximately 3% of patients taking ketoconazole. More significant side effects include gynecomastia, elevations of hepatic enzyme levels, and hepatitis. Caution is advised when using ketoconazole in patients with a history of hepatitis. Routine evaluation of hepatic function is advisable for patients on prolonged therapy.

The newer azole derivatives for oral therapy include fluconazole and itraconazole. Fluconazole is well absorbed following oral administration, with a plasma half-life of 30 hours. In view of this long half-life, daily doses of 100 mg are sufficient to treat mucocutaneous candidiasis; alternate-day doses are sufficient for dermatophyte infections. The plasma half-life of itraconazole is similar to fluconazole, with detectable therapeutic concentrations remaining in the stratum corneum for up to 28 days following termination of therapy. Itraconazole has been demonstrated to be effective for the treatment of onychomycosis in a dosage of 200 mg daily taken with food to ensure maximum absorption for 3 consecutive months. Recent reports of heart failure in patients receiving itraconazole for onychomycosis have resulted in recommendations that it not be given for treatment of onychomycosis in patients with ventricular dysfunction. Additionally, routine evaluation of hepatic function is recommended for patients receiving itraconazole for onychomycosis.

Administration of oral azoles with midazolam or triazolam has resulted in elevated plasma concentrations and may potentiate and prolong hypnotic and sedative effects of these agents. Administration with HMG-CoA reductase inhibitors has been shown to cause a significant risk of rhabdomyolysis. *Therefore, administration of the oral azoles with midazolam, triazolam, or HMG-CoA inhibitors is contraindicated.*

Terbinafine

Terbinafine (Lamisil) is an allylamine antifungal agent that has been shown to be quite effective for the treatment of onychomycosis. Recommended oral dosing consists of 250 mg daily for 6 weeks for fingernail infections and 12 weeks for toenail infections. Recent reports of serious hepatic toxicity, including liver failure and death, have led to recommendations that patients receiving terbinafine for onychomycosis be monitored closely with periodic laboratory evaluations for possible hepatic dysfunction.

Katzung PHARMACOLOGY, 9e > Section X. Special Topics > Chapter 62. Dermatologic Pharmacology >

Topical Antiviral Agents

Acyclovir, Valacyclovir, Penciclovir, & Famciclovir

Acyclovir, valacyclovir, penciclovir, and famciclovir are synthetic guanine analogs with inhibitory activity against members of the herpesvirus family, including herpes simplex types 1 and 2. As explained in Chapter 49: Antiviral Agents, these guanine derivatives are phosphorylated preferentially by herpes simplex virus-coded thymidine kinase, and, following further phosphorylation, the resultant triphosphate interferes with herpesvirus DNA polymerase and viral DNA replication. Indications and usage of oral and parenteral acyclovir, valacyclovir, and famciclovir in the treatment of cutaneous infections are discussed in Chapter 49: Antiviral Agents.

Topical acyclovir (Zovirax) is available as a 5% ointment for application to primary cutaneous herpes simplex infections and to limited mucocutaneous herpes simplex virus infections in immunocompromised patients. In primary infections, the use of topical acyclovir shortens the duration of viral shedding and may decrease healing time. In localized, limited mucocutaneous infections in immunocompromised patients, its use may be associated with a decrease in the duration of viral shedding.

Topical penciclovir (Denavir) is available as a 1% cream for the treatment of recurrent orolabial herpes simplex virus infection in immunocompetent adults. Application of penciclovir within 1 hour after appearance of the first sign or symptom of a recurrence and repeat application every 2 hours while awake for 4 days shortens viral shedding and reduces time to healing by approximately 1 day. Adverse local reactions to acyclovir and penciclovir may include pruritus and mild pain with transient stinging or burning.

Katzung PHARMACOLOGY, 9e > Section X. Special Topics > Chapter 62. Dermatologic Pharmacology >

Immunomodulators

Imiquimod

Imiquimod (Aldara) is an immunomodulator approved for the treatment of external genital and perianal warts in adults. The precise mechanism of its action is not fully understood but is thought to be related to imiquimod's ability to stimulate peripheral mononuclear cells to release interferon- α and to stimulate macrophages to produce interleukins-1, -6, -8, and tumor necrosis factor- α . Imiquimod should be applied to the wart tissue 3 times per week and left on the skin for 6–10 hours prior to washing off with mild soap and water. Treatment should be continued until eradication of the warts is accomplished, but not for more than a total of 16 weeks. Percutaneous absorption is minimal, with less than 0.9% absorbed following a single-dose application. Adverse side effects consist of local inflammatory reactions, including pruritus, erythema, and superficial erosion.

Tacrolimus & Pimecrolimus

Tacrolimus (Protopic) and pimecrolimus (Elidel) are macrolide immunosuppressants that have been shown to be of significant benefit in the treatment of atopic dermatitis. Both agents inhibit T lymphocyte activation and prevent the release of inflammatory cytokines and mediators from mast cells in vitro after stimulation by antigen-IgE complexes. Tacrolimus is available as 0.03% and 0.1% ointments, and pimecrolimus is available as a 1% cream. Both are indicated for short-term and intermittent long-term therapy for mild to moderate atopic dermatitis. Tacrolimus 0.03% ointment and pimecrolimus 1% cream are approved for use in children over 2 years of age, while all strengths are approved for adult use. Recommended dosing of both agents is twice-daily application to

affected skin until clearing is noted. Neither medication should be used with occlusive dressings. The most common side effect of both drugs is a burning sensation in the applied area that improves with continued use.

Katzung PHARMACOLOGY, 9e > Section X. Special Topics > Chapter 62. Dermatologic Pharmacology >

Ectoparasiticides

Lindane (Hexachlorocyclohexane)

The gamma isomer of hexachlorocyclohexane was commonly called gamma benzene hexachloride, which was a misnomer, since no benzene ring is present in this compound. Lindane is an effective pediculicide and scabicide.

Percutaneous absorption studies using a solution of lindane in acetone have shown that almost 10% of a dose applied to the forearm is absorbed, to be subsequently excreted in the urine over a 5-day period. Serum levels following the application of a commercial lindane lotion reach maximum at 6 hours and decline thereafter with a half-life of 24 hours. After absorption, lindane is concentrated in fatty tissues, including the brain.

Lindane (Kwell, etc) is available as a shampoo or lotion. For pediculosis capitis or pubis, one application of 30 mL of shampoo is worked into a lather and left on the scalp or genital area for 5 minutes and then rinsed off. No additional application is indicated unless living lice are present 1 week after treatment. Then reapplication may be required. Recent concerns about the toxicity of lindane have altered treatment guidelines for its use in scabies; the current recommendation calls for a single application to the entire body from the neck down, left on for 8–12 hours, and then washed off. Patients should be retreated only if active mites can be demonstrated, and never within 1 week of initial treatment.

Much controversy exists about the possible systemic toxicities of topically applied lindane used for medical purposes. Concerns about neurotoxicity and hematotoxicity have resulted in warnings that lindane should be used with caution in infants, children, and pregnant women. The current USA package insert recommends that it not be used as a scabicide in premature infants and in patients with known seizure disorders. The risk of adverse systemic reactions to lindane appears to be minimal when it is used properly and according to directions in adult patients. However, local irritation may occur, and contact with the eyes and mucous membranes should be avoided.

Crotamiton

Crotamiton, *N*-ethyl-*o*-crotonotoluidide, is a scabicide with some antipruritic properties. Its mechanism of action is not known, and studies on percutaneous absorption have not been published.

Crotamiton (Eurax) is available as a cream or lotion. Suggested guidelines for scabies treatment call for two applications to the entire body from the chin down at 24-hour intervals, with a cleansing bath 48 hours after the last application. Crotamiton is an effective agent that can be used as an alternative to lindane. Allergic contact hypersensitivity and primary irritation may occur, necessitating discontinuance of therapy. Application to acutely inflamed skin or to the eyes or mucous membranes should be avoided.

Sulfur

Sulfur has a long history of use as a scabicide. Although it is nonirritating, it has an unpleasant odor, is staining, and is thus disagreeable to use. It has been replaced by more aesthetic and effective scabicides in recent years, but it remains a possible alternative drug for use in infants and pregnant women. The usual formulation is 5% precipitated sulfur in petrolatum.

Permethrin

Permethrin is neurotoxic to *Pediculus humanus*, *Pthirus pubis*, and *Sarcoptes scabiei*. Less than 2% of an applied dose is absorbed percutaneously. Residual drug persists up to 10 days following application.

It is recommended that permethrin 1% cream rinse (Nix) be applied undiluted to affected areas of pediculosis for 10 minutes and then rinsed off with warm water. For the treatment of scabies, a single application of 5% cream (Elimite) is applied to the body from the neck down, left on for 8–14 hours, and then washed off. Adverse reactions to permethrin include transient burning, stinging, and pruritus. Cross-sensitization to pyrethrins or chrysanthemums may occur.

Malathion

Malathion is an organophosphate cholinesterase inhibitor that is hydrolyzed by plasma carboxylesterases much faster in humans than in insects, thereby providing a therapeutic advantage in treating pediculosis (Chapter 7: Cholinoceptor-Activating & Cholinesterase-Inhibiting Drugs). Malathion is available as a 0.5% lotion (Ovide) that should be applied to the hair when dry and the hair then combed to remove nits and lice after 4–6 hours.

Katzung PHARMACOLOGY, 9e > Section X. Special Topics > Chapter 62. Dermatologic Pharmacology >

Agents Affecting Pigmentation

Hydroquinone & Monobenzene

Hydroquinone and monobenzene (Benoquin), the monobenzyl ether of hydroquinone, are used to reduce hyperpigmentation of the skin. Topical hydroquinone usually results in temporary lightening, whereas monobenzene causes irreversible depigmentation.

The mechanism of action of these compounds appears to involve inhibition of the enzyme tyrosinase, thus interfering with the biosynthesis of melanin. In addition, monobenzene may be toxic to melanocytes, resulting in permanent depigmentation. Some percutaneous absorption of these compounds takes place, because monobenzene may cause hypopigmentation at sites distant from the area of application. Both hydroquinone and monobenzene may cause local irritation. Allergic sensitization to these compounds does occur, and a prescription combination of hydroquinone, fluocinolone acetonide, and retinoic acid (Tri-Luma) is more effective than hydroquinone alone.

Trioxsalen & Methoxsalen

Trioxsalen and methoxsalen are psoralens used for the *repigmentation* of depigmented macules of vitiligo. With the recent development of high-intensity long-wave ultraviolet fluorescent lamps,

photo-chemotherapy with oral methoxsalen for psoriasis and with oral trioxsalen for vitiligo has been under intensive investigation.

Psoralens must be photoactivated by long-wave-length ultraviolet light in the range of 320–400 nm (UVA) to produce a beneficial effect. Psoralens intercalate with DNA and, with subsequent UVA irradiation, cyclobutane adducts are formed with pyrimidine bases. Both monofunctional and bifunctional adducts may be formed, the latter causing interstrand cross-links. These DNA photoproducts may inhibit DNA synthesis. The major long-term risks of psoralen photochemotherapy are cataracts and skin cancer.

Katzung PHARMACOLOGY, 9e > Section X. Special Topics > Chapter 62. Dermatologic Pharmacology >

Sunscreens

Topical medications useful in protecting against sunlight contain either chemical compounds that absorb ultraviolet light, called sunscreens; or opaque materials such as titanium dioxide that reflect light, called sunshades. The three classes of chemical compounds most commonly used in sunscreens are *p*-aminobenzoic acid (PABA) and its esters, the benzophenones, and the dibenzoylmethanes.

Most sunscreen preparations are designed to absorb ultraviolet light in B ultraviolet wavelength range from 280 to 320 nm, which is the range responsible for most of the erythema and tanning associated with sun exposure. Chronic exposure to light in this range induces aging of the skin and photocarcinogenesis. Para-aminobenzoic acid and its esters are the most effective available absorbers in the B region.

The benzophenones include oxybenzone, dioxybenzone, and sulisobenzene. These compounds provide a broader spectrum of absorption from 250 to 360 nm, but their effectiveness in the UVB erythema range is less than that of *p*-aminobenzoic acid. The dibenzoylmethanes include Parasol and Eusolex. These compounds absorb wavelengths throughout the longer ultraviolet A range, 320 nm to 400 nm, with maximum absorption at 360 nm. Patients particularly sensitive to ultraviolet A wavelengths include individuals with polymorphous light eruption, cutaneous lupus erythematosus, and drug-induced photosensitivity. In these patients, dibenzoylmethane-containing sunscreen may provide superior photoprotection.

The protection factor (PF) of a given sunscreen is a measure of its effectiveness in absorbing erythrogenic ultraviolet light. It is determined by measuring the minimal erythema dose (MED) with and without the sunscreen in a group of normal people. The ratio of the minimal erythema dose with sunscreen to the minimal erythema dose without sunscreen is the protection factor. Fair-skinned individuals who sunburn easily are advised to use a product with a protection factor of 15 or greater.

Katzung PHARMACOLOGY, 9e > Section X. Special Topics > Chapter 62. Dermatologic Pharmacology >

Acne Preparations

Retinoic Acid & Derivatives

Retinoic acid, also known as tretinoin or *all-trans*-retinoic acid, is the acid form of vitamin A. It is an effective topical treatment for acne vulgaris. Several analogs of vitamin A, eg, 13-*cis*-retinoic acid (isotretinoin), have been shown to be effective in various dermatologic diseases when given *orally*. Vitamin A alcohol is the physiologic form of vitamin A. The topical therapeutic agent, retinoic acid, is formed by the oxidation of the alcohol group, with all four double bonds in the side chain in the *trans* configuration as shown.

Retinoic acid

Retinoic acid is insoluble in water but soluble in many organic solvents. It is susceptible to oxidation and ester formation, particularly when exposed to light. Topically applied retinoic acid remains chiefly in the epidermis, with less than 10% absorption into the circulation. The small quantities of retinoic acid absorbed following topical application are metabolized by the liver and excreted in bile and urine.

Retinoic acid has several effects on epithelial tissues. It stabilizes lysosomes, increases ribonucleic acid polymerase activity, increases prostaglandin E₂, cAMP, and cGMP levels, and increases the incorporation of thymidine into DNA. Its action in acne has been attributed to decreased cohesion between epidermal cells and increased epidermal cell turnover. This is thought to result in the expulsion of open comedones and the transformation of closed comedones into open ones.

Topical retinoic acid is applied initially in a concentration sufficient to induce slight erythema with mild peeling. The concentration or frequency of application may be decreased if too much irritation is produced. Topical retinoic acid should be applied to dry skin only, and care should be taken to avoid contact with the corners of the nose, eyes, mouth, and mucous membranes. During the first 4–6 weeks of therapy, comedones not previously evident may appear and give the impression that the acne has been aggravated by the retinoic acid. However, with continued therapy, the lesions will clear, and in 8–12 weeks optimal clinical improvement should occur. A timed-release formulation of tretinoin containing microspheres (Retin-A Micro) delivers the medication over time and may be less irritating for sensitive patients.

The effects of tretinoin on keratinization and desquamation offer benefits for patients with photodamaged skin. Prolonged use of tretinoin promotes dermal collagen synthesis, new blood vessel formation, and thickening of the epidermis, which helps diminish fine lines and wrinkles. A specially formulated moisturizing 0.05% cream (Renova) is marketed for this purpose.

The most common adverse effects of topical retinoic acid are erythema and dryness that occur in the first few weeks of use, but these can be expected to resolve with continued therapy. Animal studies suggest that this drug may increase the tumorigenic potential of ultraviolet radiation. In light of this, patients using retinoic acid should be advised to avoid or minimize sun exposure and use a protective sunscreen. Allergic contact dermatitis to topical retinoic acid is rare.

Adapalene (Differin) is a derivative of naphthoic acid that resembles retinoic acid in structure and effects. It is applied as a 0.1% gel once daily. Unlike tretinoin, adapalene is photochemically stable and shows little decrease in efficacy when used in combination with benzoyl peroxide. Adapalene is

less irritating than tretinoin and is most effective in patients with mild to moderate acne vulgaris.

Tazarotene (Tazorac) is an acetylenic retinoid that is available as a 0.1% gel and cream for the treatment of mild to moderately severe facial acne. Topical tazarotene should be used by women of childbearing age only after contraceptive counseling. It is recommended that tazarotene should not be used by pregnant women.

Isotretinoin

Isotretinoin (Accutane) is a synthetic retinoid currently restricted to the treatment of severe cystic acne that is recalcitrant to standard therapies. The precise mechanism of action of isotretinoin in cystic acne is not known, although it appears to act by inhibiting sebaceous gland size and function. The drug is well absorbed, extensively bound to plasma albumin, and has an elimination half-life of 10–20 hours.

Most cystic acne patients respond to 1–2 mg/kg, given orally in two divided doses daily for 4–5 months. If severe cystic acne persists following this initial treatment, after a period of 2 months, a second course of therapy may be initiated. Common adverse effects resemble hypervitaminosis A and include dryness and itching of the skin and mucous membranes. Less common side effects are headache, corneal opacities, pseudotumor cerebri, inflammatory bowel disease, anorexia, alopecia, and muscle and joint pains. These effects are all reversible on discontinuance of therapy. Skeletal hyperostosis has been observed in patients receiving isotretinoin with premature closure of epiphyses noted in children treated with this medication. Lipid abnormalities (triglycerides, HDL) are frequent; their clinical relevance is unknown at present.

Teratogenicity is a significant risk in patients taking isotretinoin; therefore, women of childbearing potential *must* use an effective form of contraception for at least 1 month before, throughout isotretinoin therapy, and for one or more menstrual cycles following discontinuance of treatment. A serum pregnancy test *must* be obtained within 2 weeks before starting therapy in these patients, and therapy should be initiated only on the second or third day of the next normal menstrual period.

Benzoyl Peroxide

Benzoyl peroxide is an effective topical agent in the treatment of acne vulgaris. It penetrates the stratum corneum or follicular openings unchanged and is converted metabolically to benzoic acid within the epidermis and dermis. Less than 5% of an applied dose is absorbed from the skin in an 8-hour period.

It has been postulated that the mechanism of action of benzoyl peroxide in acne is related to its antimicrobial activity against *P. acnes* and to its peeling and comedolytic effects.

To decrease the likelihood of irritation, application should be limited to a low concentration (2.5%) once daily for the first week of therapy and increased in frequency and strength if the preparation is well tolerated. Fixed-combination formulations of 5% benzoyl peroxide with 3% erythromycin base (Benzamycin) or 1% clindamycin (BenzaClin) appear to be more effective than individual agents alone.

Benzoyl peroxide is a potent contact sensitizer in experimental studies, and this adverse effect may occur in up to 1% of acne patients. Care should be taken to avoid contact with the eyes and mucous membranes. Benzoyl peroxide is an oxidant and may rarely cause bleaching of the hair or colored

fabrics.

Azelaic Acid

Azelaic acid (Azelex) is a straight-chain saturated dicarboxylic acid that has been demonstrated to be effective in the treatment of acne vulgaris. Its mechanism of action has not been fully determined, but preliminary studies demonstrate antimicrobial activity against *P. acnes* as well as an *in vitro* inhibitory effect on the conversion of testosterone to dihydrotestosterone. Initial therapy is begun with once-daily applications of the 20% cream to the affected areas for 1 week and twice daily thereafter. Most patients will experience mild irritation with redness and dryness of the skin during the first week of treatment. Clinical improvement is noted in 6–8 weeks of continuous therapy.

Katzung PHARMACOLOGY, 9e > Section X. Special Topics > Chapter 62. Dermatologic Pharmacology >

Drugs for Psoriasis

Acitretin

Acitretin (Soriatane), a metabolite of the aromatic retinoid etretinate, is quite effective in the treatment of psoriasis, especially pustular forms. It is given orally at a dosage of 25–50 mg/d. Adverse effects attributable to acitretin therapy are similar to those seen with isotretinoin and resemble hypervitaminosis A. Elevations in cholesterol and triglycerides may be noted with acitretin, and hepatotoxicity with liver enzyme elevations has been reported. Acitretin is more teratogenic than isotretinoin in the animal species studied to date, which is of special concern in view of the drug's prolonged elimination time of over 3 months after chronic administration. In cases where etretinate is formed by concomitant administration of acitretin and ethanol, etretinate may be found in plasma and subcutaneous fat for many years.

Acitretin must not be used by women who are pregnant or may become pregnant while undergoing treatment or at any time for at least 3 years after treatment is discontinued. Ethanol must be strictly avoided during treatment with acitretin and for 2 months after discontinuing therapy. Patients must not donate blood during treatment and for 3 years after acitretin is stopped.

Tazarotene

Tazarotene (Tazorac) is an acetylenic retinoid prodrug that is hydrolyzed to its active form by an esterase. The active metabolite, tazarotenic acid, binds to retinoic acid receptors, resulting in modified gene expression. The precise mechanism of action in psoriasis is unknown but may relate to both anti-inflammatory and antiproliferative actions. Tazarotene is absorbed percutaneously, and teratogenic systemic concentrations may be achieved if applied to more than 20% of total body surface area. Women of childbearing potential must therefore be advised of the risk prior to initiating therapy, and adequate birth control measures must be utilized while on therapy.

Treatment of psoriasis should be limited to once-daily application not to exceed 20% of total body surface area. Adverse local effects include a burning or stinging sensation (sensory irritation) and peeling, erythema, and localized edema of the skin (irritant dermatitis). Potentiation of photosensitizing medication may occur, and patients should be cautioned to minimize sunlight exposure and to use sunscreens and protective clothing.

Calcipotriene

Calcipotriene (Dovonex) is a synthetic vitamin D₃ derivative that has been shown to be effective in the treatment of plaque type psoriasis vulgaris of moderate severity. Approximately 6% of the topically applied 0.005% ointment is absorbed through psoriatic plaques, resulting in a transient elevation of serum calcium in fewer than 1% of subjects treated in clinical trials. Improvement of psoriasis was generally noted following 2 weeks of therapy, with continued improvement for up to 8 weeks of treatment. Fewer than 10% of patients demonstrate total clearing while on calcipotriene as single-agent therapy. Adverse effects include burning, itching, and mild irritation, with dryness and erythema of the treatment area. Care should be taken to avoid facial contact, which may cause ocular irritation.

Katzung PHARMACOLOGY, 9e > Section X. Special Topics > Chapter 62. Dermatologic Pharmacology >

Anti-Inflammatory Agents

Topical Corticosteroids

The remarkable efficacy of topical corticosteroids in the treatment of inflammatory dermatoses was noted soon after the introduction of hydrocortisone in 1952. Subsequently, numerous analogs have been developed that offer extensive choices of potencies, concentrations, and vehicles. The therapeutic effectiveness of topical corticosteroids is based primarily on their anti-inflammatory activity. Definitive explanations of the effects of corticosteroids on endogenous mediators of inflammation such as histamine, kinins, lysosomal enzymes, prostaglandins, and leukotrienes await further experimental clarification. The antimetabolic effects of corticosteroids on human epidermis may account for an additional mechanism of action in psoriasis and other dermatologic diseases associated with increased cell turnover. The general pharmacology of these endocrine agents is discussed in Chapter 39: Adrenocorticosteroids & Adrenocortical Antagonists.

Chemistry & Pharmacokinetics

The original topical glucocorticosteroid was hydrocortisone, the natural glucocorticosteroid of the adrenal cortex. The 9 α -fluoro derivative of hydrocortisone was active topically, but its salt-retaining properties made it undesirable even for topical use. Prednisolone and methylprednisolone are as active topically as hydrocortisone. The 9 α -fluorinated steroids dexamethasone and betamethasone subsequently developed did not have any advantage over hydrocortisone. However, triamcinolone and fluocinolone, the acetonide derivatives of the fluorinated steroids, have a distinct advantage in topical therapy. Similarly, betamethasone is not very active topically, but attaching a 5-carbon valerate chain to the 17-hydroxyl position results in a compound over 300 times as active as hydrocortisone for topical use. Fluocinonide is the 21-acetate derivative of fluocinolone acetonide; the addition of the 21-acetate enhances the topical activity about fivefold. Fluorination of the steroid is not required for high potency; hydrocortisone valerate and butyrate have activity similar to that of triamcinolone acetonide.

Corticosteroids are only minimally absorbed following application to normal skin; for example, approximately 1% of a dose of hydrocortisone solution applied to the ventral forearm is absorbed. Long-term occlusion with an impermeable film such as plastic wrap is an effective method of enhancing penetration, yielding a tenfold increase in absorption. There is a marked regional anatomic variation in corticosteroid penetration. Compared with the absorption from the forearm, hydrocortisone is absorbed 0.14 times as well through the plantar foot arch, 0.83 times as well

through the palm, 3.5 times as well through the scalp, 6 times as well through the forehead, 9 times as well through vulvar skin, and 42 times as well through scrotal skin. Penetration is increased severalfold in the inflamed skin of atopic dermatitis; and in severe exfoliative diseases, such as erythrodermic psoriasis, there appears to be little barrier to penetration.

Experimental studies on the percutaneous absorption of hydrocortisone fail to reveal a significant increase in absorption when applied on a repetitive basis compared to a single dose, and a single daily application may be effective in most conditions. Ointment bases tend to give better activity to the corticosteroid than do cream or lotion vehicles. Increasing the concentration of a corticosteroid increases the penetration but not to the same degree. For example, approximately 1% of a 0.25% hydrocortisone solution is absorbed from the forearm. A tenfold increase in concentration causes only a fourfold increase in absorption. Solubility of the corticosteroid in the vehicle is a significant determinant of the percutaneous absorption of a topical steroid. Marked increases in efficacy are noted when optimized vehicles are used, as demonstrated by newer formulations of betamethasone dipropionate and diflorasone diacetate.

Table 62–1 groups topical corticosteroid formulations according to approximate relative efficacy. Table 62–2 lists major dermatologic diseases in order of their responsiveness to these drugs. In the first group of diseases, low- to medium-efficacy corticosteroid preparations often produce clinical remission. In the second group, it is often necessary to use high-efficacy preparations, occlusion therapy, or both. Once a remission has been achieved, every effort should be made to maintain the patient with a low-efficacy corticosteroid.

Lowest efficacy	
0.25–2.5%	Hydrocortisone
0.25%	Methylprednisolone acetate (Medrol)
0.1%	Dexamethasone ¹ (Decaderm)
1.0%	Methylprednisolone acetate (Medrol)
0.5%	Prednisolone (MetiDerm)
0.2%	Betamethasone ¹ (Celestone)
Low efficacy	
0.01%	Fluocinolone acetonide ¹ (Fluonid, Synalar)
0.01%	Betamethasone valerate ¹ (Valisone)
0.025%	Fluorometholone ¹ (Oxylone)
0.05%	Alclometasone dipropionate (Aclovate)
0.025%	Triamcinolone acetonide ¹ (Aristocort, Kenalog, Triacet)
0.1%	Clocortolone pivalate ¹ (Cloderm)

0.03%	Flumethasone pivalate ¹ (Locorten)
Intermediate efficacy	
0.2%	Hydrocortisone valerate (Westcort)
0.1%	Mometasone furoate (Elocon)
0.1%	Hydrocortisone butyrate (Locoid)
0.1%	Hydrocortisone probutate (Pandel)
0.025%	Betamethasone benzoate ¹ (Uticort)
0.025%	Flurandrenolide ¹ (Cordran)
0.1%	Betamethasone valerate ¹ (Valisone)
0.1%	Prednicarbate (Dermatop)
0.05%	Fluticasone propionate (Cutivate)

0.25%	Desoximetasone ¹ (Topicort)
0.5%	Triamcinolone acetonide ¹
0.2%	Fluocinolone acetonide ¹ (Synalar-HP)
0.05%	Diflorasone diacetate ¹ (Florone, Maxiflor)

0.1%	Halcinonide ¹ (Halog)
Highest efficacy	
0.05%	Betamethasone dipropionate in optimized vehicle (Diprolene) ¹
0.05%	Diflorasone diacetate ¹ in optimized vehicle (Psorcon)
0.05%	Halobetasol propionate ¹ (Ultravate)
0.05%	Clobetasol propionate ¹ (Temovate)
¹ Fluorinated steroids.	

The limited penetration of topical corticosteroids can be overcome in certain clinical circumstances by the intralesional injection of relatively insoluble corticosteroids, eg, triamcinolone acetonide, triamcinolone diacetate, triamcinolone hexacetonide, and betamethasone acetate-phosphate. When these agents are injected into the lesion, measurable amounts remain in place and are gradually released for 3–4 weeks. This form of therapy is often effective for the lesions listed in Table 62–2 that are generally unresponsive to topical corticosteroids. The dosage of the triamcinolone salts should be limited to 1 mg per treatment site, ie, 0.1 mL of 10 mg/mL suspension, to decrease the incidence of local atrophy (see below).

Table 62–2. Dermatologic Disorders Responsive to Topical Corticosteroids Ranked in Order of Sensitivity.	
Very responsive	
Atopic dermatitis	
Seborrheic dermatitis	
Lichen simplex chronicus	
Pruritus ani	
Later phase of allergic contact dermatitis	
Later phase of irritant dermatitis	
Nummular eczematous dermatitis	
Stasis dermatitis	
Psoriasis, especially of genitalia and face	
Less responsive	
Discoid lupus erythematosus	
Psoriasis of palms and soles	
Necrobiosis lipoidica diabetorum	

Sarcoidosis
Lichen striatus
Pemphigus
Familial benign pemphigus
Vitiligo
Granuloma annulare
Least responsive: intralesional injection required
Keloids
Hypertrophic scars
Hypertrophic lichen planus
Alopecia areata
Acne cysts
Prurigo nodularis
Chondrodermatitis nodularis chronica helioides

Adverse Effects

All absorbable topical corticosteroids possess the potential to suppress the pituitary-adrenal axis (Chapter 39: Adrenocorticosteroids & Adrenocortical Antagonists). Although most patients with pituitary-adrenal axis suppression demonstrate only a laboratory test abnormality, cases of severely impaired stress response can occur. Iatrogenic Cushing's syndrome may occur as a result of protracted use of topical corticosteroids in large quantities. Applying potent corticosteroids to extensive areas of the body for prolonged periods, with or without occlusion, increases the likelihood of systemic side effects. Fewer of these factors are required to produce adverse systemic effects in children, and growth retardation is of particular concern in the pediatric age group.

Adverse local effects of topical corticosteroids include the following: atrophy, which may present as depressed, shiny, often wrinkled "cigarette paper"-appearing skin with prominent telangiectases and a tendency to develop purpura and ecchymosis; steroid rosacea, with persistent erythema, telangiectatic vessels, pustules, and papules in central facial distribution; perioral dermatitis, steroid acne, alterations of cutaneous infections, hypopigmentation, hypertrichosis, and increased intraocular pressure; and allergic contact dermatitis. The latter may be confirmed by patch testing with high concentrations of corticosteroids, ie, 1% in petrolatum, because topical corticosteroids are not irritating. Screening for allergic contact dermatitis potential is performed with tixocortol pivalate, budesonide, and hydrocortisone valerate or butyrate. Topical corticosteroids are contraindicated in individuals who demonstrate hypersensitivity to them. Some sensitized subjects develop a generalized flare when dosed with ACTH or oral prednisone.

Alefacept

Alefacept (Amevive) is an immunosuppressive dimeric fusion protein that consists of the extracellular CD2-binding portion of the human leukocyte function antigen-3 linked to the Fc portion of human IgG1. Alefacept interferes with lymphocyte activation, which plays a role in the pathophysiology of psoriasis, resulting in a reduction in subsets of CD2 T lymphocytes and circulating total CD4 and CD8 T lymphocyte counts. Alefacept is indicated for the treatment of

adult patients with moderate to severe chronic plaque psoriasis. The recommended dosage is 7.5 mg given once weekly as an intravenous bolus or 15 mg once weekly as an intramuscular injection for a 12-week course of treatment. Patients should have CD4 lymphocyte counts monitored weekly while on alefacept, and dosing should be withheld if CD4 counts are below 250 cells/ μ L. The drug should be discontinued if the counts remain below 250 cells/ μ L for 1 month. Alefacept is an immunosuppressive agent and should not be administered to patients with clinically significant infection. Because of the possibility of an increased risk of malignancy, it should not be administered to patients with a history of systemic malignancy.

Tar Compounds

Tar preparations are used mainly in the treatment of psoriasis, dermatitis, and lichen simplex chronicus. The phenolic constituents endow these compounds with antipruritic properties, making them particularly valuable in the treatment of chronic lichenified dermatitis. Acute dermatitis with vesiculation and oozing may be irritated by even weak tar preparations, which should be avoided. However, in the subacute and chronic stages of dermatitis and psoriasis, these preparations are quite useful and offer an alternative to the use of topical corticosteroids.

The most common adverse reaction to coal tar compounds is an irritant folliculitis, necessitating discontinuance of therapy to the affected areas for a period of 3–5 days. Phototoxicity and allergic contact dermatitis may also occur. Tar preparations should be avoided in patients who have previously exhibited sensitivity to them.

Katzung PHARMACOLOGY, 9e > Section X. Special Topics > Chapter 62. Dermatologic Pharmacology >

Keratolytic & Destructive Agents

Salicylic Acid

Salicylic acid was chemically synthesized in 1860 and has been extensively used in dermatologic therapy as a keratolytic agent. It is a white powder quite soluble in alcohol but only slightly soluble in water.

Salicylic acid

The mechanism by which salicylic acid produces its keratolytic and other therapeutic effects is poorly understood. The drug may solubilize cell surface proteins that keep the stratum corneum intact, thereby resulting in desquamation of keratotic debris. Salicylic acid is keratolytic in concentrations of 3–6%. In concentrations greater than 6%, it can be destructive to tissues.

Salicylism and death have occurred following topical application. In an adult, 1 g of a topically applied 6% salicylic acid preparation will raise the serum salicylate level not more than 0.5 mg/dL of plasma; the threshold for toxicity is 30–50 mg/dL. Higher serum levels are possible in children,

who are therefore at a greater risk to develop salicylism. In cases of severe intoxication, hemodialysis is the treatment of choice (see Chapter 59: Management of the Poisoned Patient). It is advisable to limit both the total amount of salicylic acid applied and the frequency of application. Urticarial, anaphylactic, and erythema multiforme reactions may occur in patients allergic to salicylates. Topical use may be associated with local irritation, acute inflammation, and even ulceration with the use of high concentrations of salicylic acid. Particular care must be exercised when using the drug on the extremities of diabetics or patients with peripheral vascular disease.

Propylene Glycol

Propylene glycol is extensively used in topical preparations because it is an excellent vehicle for organic compounds. Propylene glycol has recently been used alone as a keratolytic agent in 40–70% concentrations, with plastic occlusion, or in gel with 6% salicylic acid.

Only minimal amounts of a topically applied dose are absorbed through normal stratum corneum. Percutaneously absorbed propylene glycol is oxidized by the liver to lactic acid and pyruvic acid, with subsequent utilization in general body metabolism. Approximately 12–45% of the absorbed agent is excreted unchanged in the urine.

Propylene glycol is an effective keratolytic agent for the removal of hyperkeratotic debris. Propylene glycol is also an effective humectant and increases the water content of the stratum corneum. The hygroscopic characteristics of the agent may help it to develop an osmotic gradient through the stratum corneum, thereby increasing hydration of the outermost layers by drawing water out from the inner layers of the skin.

Propylene glycol is used under polyethylene occlusion or with 6% salicylic acid for the treatment of ichthyosis, palmar and plantar keratodermas, psoriasis, pityriasis rubra pilaris, keratosis pilaris, and hypertrophic lichen planus.

In concentrations greater than 10%, propylene glycol may act as an irritant in some patients; those with eczematous dermatitis may be more sensitive. Allergic contact dermatitis occurs with propylene glycol, and a 4% aqueous propylene glycol solution is recommended for the purpose of patch testing.

Urea

Urea in a compatible cream vehicle or ointment base has a softening and moisturizing effect on the stratum corneum. It has the ability to make creams and lotions feel less greasy, and this has been utilized in dermatologic preparations to decrease the oily feel of a preparation that otherwise might feel unpleasant. It is a white crystalline powder with a slight ammonia odor when moist.

Urea is absorbed percutaneously, although the precise amount absorbed is not well documented. It is distributed predominantly in the extracellular space and excreted in urine. Urea is a natural product of metabolism, and systemic toxicities with topical application do not occur.

Urea allegedly increases the water content of the stratum corneum, presumably as a result of the hygroscopic characteristics of this naturally occurring molecule. Urea is also keratolytic. The mechanism of action appears to involve alterations in prekeratin and keratin, leading to increased solubilization. In addition, urea may break hydrogen bonds that keep the stratum corneum intact.

As a humectant, urea is used in concentrations of 2–20% in creams and lotions. As a keratolytic

agent, it is used in 20% concentration in diseases such as ichthyosis vulgaris, hyperkeratosis of palms and soles, xerosis, and keratosis pilaris. Concentrations of 30–50% applied to the nail plate have been useful in softening the nail prior to avulsion.

Podophyllum Resin & Podofilox

Podophyllum resin, an alcoholic extract of *Podophyllum peltatum*, commonly known as mandrake root or May apple, is used in the treatment of condyloma acuminatum and other verrucae. It is a mixture of podophyllotoxin, alpha and beta peltatin, desoxypodophyllotoxin, dehydropodophyllotoxin, and other compounds. It is soluble in alcohol, ether, chloroform, and compound tincture of benzoin.

Percutaneous absorption of podophyllum resin occurs, particularly in intertriginous areas and from applications to large moist condylomas. It is soluble in lipids and therefore is distributed widely throughout the body, including the central nervous system.

The major use of podophyllum resin is in the treatment of condyloma acuminatum.

Podophyllotoxin and its derivatives are active cytotoxic agents with specific affinity for the microtubule protein of the mitotic spindle. Normal assembly of the spindle is prevented, and epidermal mitoses are arrested in metaphase. A 25% concentration of podophyllum resin in compound tincture of benzoin is recommended for the treatment of condyloma acuminatum. Application should be restricted to wart tissue only, to limit the total amount of medication used and to prevent severe erosive changes in adjacent tissue. In treating cases of large condylomas, it is advisable to limit application to sections of the affected area to minimize systemic absorption. The patient is instructed to wash off the preparation 2–3 hours after the initial application, since the irritant reaction is variable. Depending on the individual patient's reaction, this period can be extended to 6–8 hours on subsequent applications. If three to five applications have not resulted in significant resolution, other methods of treatment should be considered.

Toxic symptoms associated with excessively large applications include nausea, vomiting, alterations in sensorium, muscle weakness, neuropathy with diminished tendon reflexes, coma, and even death. Local irritation is common, and inadvertent contact with the eye may cause severe conjunctivitis. Use during pregnancy is contraindicated in view of possible cytotoxic effects on the fetus.

Pure podophyllotoxin (podofilox) is approved for use as a 0.5% podophyllotoxin preparation (Condylox) for application by the patient in the treatment of genital condylomas. The low concentration of podofilox significantly reduces the potential for systemic toxicity. Most men with penile warts may be treated with less than 70 μ L per application. At this dose, podofilox is not routinely detected in the serum. Treatment is self administered in treatment cycles of twice-daily application for 3 consecutive days followed by a 4-day drug-free period. Local adverse effects include inflammation, erosions, burning pain, and itching.

Fluorouracil

Fluorouracil is a fluorinated pyrimidine antimetabolite that resembles uracil, with a fluorine atom substituted for the 5-methyl group. Its systemic pharmacology is described in Chapter 55: Cancer Chemotherapy. Fluorouracil is used topically for the treatment of multiple actinic keratoses..

Approximately 6% of a topically applied dose is absorbed—an amount insufficient to produce adverse systemic effects. Most of the absorbed drug is metabolized and excreted as carbon dioxide,

urea, and α -fluoro- β -alanine. A small percentage is eliminated unchanged in the urine. Fluorouracil inhibits thymidylate synthetase activity, interfering with the synthesis of deoxyribonucleic acid and to a lesser extent ribonucleic acid. These effects are most marked in atypical, rapidly proliferating cells.

The response to treatment begins with erythema and progresses through vesiculation, erosion, superficial ulceration, necrosis, and finally reepithelialization. Fluorouracil should be continued until the inflammatory reaction reaches the ulceration and necrosis stage, usually in 3–4 weeks, at which time treatment should be terminated. The healing process may continue for 1–2 months after therapy is discontinued. Local adverse reactions may include pain, pruritus, a burning sensation, tenderness, and residual postinflammatory hyperpigmentation. Excessive exposure to sunlight during treatment may increase the intensity of the reaction and should be avoided. Allergic contact dermatitis to fluorouracil has been reported, and its use is contraindicated in patients with known hypersensitivity.

Trials demonstrated similar effectiveness of 10% masoprocol cream (Actinex), but usage has been limited because of frequency of allergic contact dermatitis.

Aminolevulinic Acid

Aminolevulinic acid (ALA) is an endogenous precursor of photosensitizing porphyrin metabolites. When exogenous ALA is provided to the cell through topical applications, protoporphyrin IX (PpIX) accumulates in the cell. When exposed to light of appropriate wavelength and energy, the accumulated PpIX produces a photodynamic reaction resulting in the formation of cytotoxic superoxide and hydroxyl radicals. Photosensitization of actinic keratoses using ALA (Levulan Kerastick) and illumination with a blue light photodynamic therapy illuminator (BLU-U) is the basis for ALA photodynamic therapy.

Treatment consists of applying ALA 20% topical solution to individual actinic keratoses followed by blue light photodynamic illumination 14–18 hours later. Transient stinging or burning at the treatment site occurs during the period of light exposure. Patients *must* avoid exposure to sunlight or bright indoor lights for at least 40 hours after ALA application. Redness, swelling, and crusting of the actinic keratoses will occur and gradually resolve over a 3- to 4-week time course.

Katzung PHARMACOLOGY, 9e > Section X. Special Topics > Chapter 62. Dermatologic Pharmacology >

Antipruritic Agents

Doxepin

Topical doxepin hydrochloride 5% cream (Zonalon) may provide significant antipruritic activity when utilized in the treatment of pruritus associated with atopic dermatitis or lichen simplex chronicus. The precise mechanism of action is unknown but may relate to the potent H₁ and H₂-receptor antagonist properties of dibenzoxepin tricyclic compounds. Percutaneous absorption is variable and may result in significant drowsiness in some patients. In view of the anticholinergic effect of doxepin, topical use is contraindicated in patients with untreated narrow-angle glaucoma or a tendency to urinary retention.

Plasma levels of doxepin similar to those achieved during oral therapy may be obtained with topical application; the usual drug interactions associated with tricyclic antidepressants may occur.

Therefore, MAO inhibitors must be discontinued at least 2 weeks prior to the initiation of doxepin cream. Topical application of the cream should be performed four times daily for up to 8 days of therapy. The safety and efficacy of chronic dosing has not been established. Adverse local effects include marked burning and stinging of the treatment site which may necessitate discontinuation of the cream in some patients. Allergic contact dermatitis appears to be frequent, and patients should be monitored for symptoms of hypersensitivity.

Pramoxine

Pramoxine hydrochloride is a topical anesthetic that can provide temporary relief from pruritus associated with mild eczematous dermatoses. Pramoxine is available as a 1% cream, lotion, or gel and in combination with hydrocortisone acetate. Application to the affected area two to four times daily may provide short-term relief of pruritus. Local adverse effects include transient burning and stinging. Care should be exercised to avoid contact with the eyes.

Katzung PHARMACOLOGY, 9e > Section X. Special Topics > Chapter 62. Dermatologic Pharmacology >

Trichogenic & Antitrichogenic Agents

Minoxidil

Topical minoxidil (Rogaine) is effective in reversing the progressive miniaturization of terminal scalp hairs associated with androgenic alopecia. Vertex balding is more responsive to therapy than frontal balding. The mechanism of action of minoxidil on hair follicles is unknown. Chronic dosing studies have demonstrated that the effect of minoxidil is not permanent, and cessation of treatment will lead to hair loss in 4–6 months. Percutaneous absorption of minoxidil in normal scalp is minimal, but possible systemic effects on blood pressure (Chapter 11: Antihypertensive Agents) should be monitored in patients with cardiac disease.

Finasteride

Finasteride (Propecia) is a 5 α -reductase inhibitor that blocks the conversion of testosterone to dihydrotestosterone, the androgen responsible for androgenic alopecia in genetically predisposed men. Oral finasteride, 1 mg/d, promotes hair growth and prevents further hair loss in a significant proportion of men with androgenic alopecia. Treatment for at least 3–6 months is necessary to see increased hair growth or prevent further hair loss. Continued treatment with finasteride is necessary to sustain benefit. Reported side effects include decreased libido, ejaculation disorders, and erectile dysfunction, which resolve in most men who remain on therapy and in all men who discontinue finasteride.

There are no data to support the use of finasteride in women with androgenic alopecia. Pregnant women should not be exposed to finasteride either by use or by handling crushed tablets because of the risk of hypospadias developing in a male fetus.

Eflornithine

Eflornithine (Vaniqa) is an irreversible inhibitor of ornithine decarboxylase that catalyzes the rate-limiting step in the biosynthesis of polyamines. Polyamines are required for cell division and differentiation, and inhibition of ornithine decarboxylase affects the rate of hair growth. Eflornithine has been shown to be effective in reducing facial hair growth in approximately 30% of women

when applied twice daily for 6 months of therapy. Hair growth was observed to return to pretreatment levels 8 weeks after discontinuation. Local adverse effects include stinging, burning, and folliculitis.

Katzung PHARMACOLOGY, 9e > Section X. Special Topics > Chapter 62. Dermatologic Pharmacology >

Antineoplastic Agents

Alitretinoin (Panretin) is a topical formulation of 9-*cis*-retinoic acid which is approved for the treatment of cutaneous lesions in patients with AIDS-related Kaposi's sarcoma. Localized reactions may include intense erythema, edema, and vesiculation necessitating discontinuation of therapy. Patients who are applying alitretinoin should not concurrently use products containing deet, a common component of insect repellent products.

Bexarotene (Targretin) is a member of a subclass of retinoids that selectively binds and activates retinoid X receptor subtypes. It is available both in an oral formulation and as a topical gel for the treatment of cutaneous T cell lymphoma. Teratogenicity is a significant risk for both systemic and topical treatment with bexarotene, and women of childbearing potential must avoid becoming pregnant throughout therapy and for at least 1 month following discontinuation of the drug.

Katzung PHARMACOLOGY, 9e > Section X. Special Topics > Chapter 62. Dermatologic Pharmacology >

Antiseborrhea Agents

Table 62–3 lists topical formulations for the treatment of seborrheic dermatitis. These are of variable efficacy and may necessitate concomitant treatment with topical corticosteroids for severe cases.

Table 62–3. Antiseborrhea Agents.
Betamethasone valerate foam (Luxiq)
Chloroxine shampoo (Capitrol)
Coal tar shampoo (Ionil-T, Pentrax, Theraplex-T, T-Gel)
Fluocinolone acetonide shampoo (FS Shampoo)
Ketoconazole shampoo (Nizoral)
Selenium sulfide shampoo (Selsun, Exsel)
Zinc pyrithione shampoo (DHS-Zinc, Theraplex-Z)

Interferon	Melanoma, viral warts	See also Chapter 56: Immunopharmacology.
Mycophenolate mofetil	Bullous disease	See also Chapter 56: Immunopharmacology.
Thalidomide	Erythema nodosum leprosum	See also Chapter 47: Antimycobacterial Drugs and Chapter 56: Immunopharmacology.

Chapter 63. Drugs Used in the Treatment of Gastrointestinal Diseases

Drugs Used in the Treatment of Gastrointestinal Diseases: Introduction

Many of the drug groups discussed elsewhere in this book have important applications in the treatment of diseases of the gastrointestinal tract and other organs. Other groups are used almost exclusively for their effects on the gut; these are discussed below according to their therapeutic uses.

Katzung PHARMACOLOGY, 9e > Section X. Special Topics > Chapter 63. Drugs Used in the Treatment of Gastrointestinal Diseases >

Drugs Used in Acid-Peptic Diseases

Acid-peptic diseases include gastroesophageal reflux, peptic ulcer (gastric and duodenal), and stress-related mucosal injury. In all these conditions, mucosal erosions or ulceration arise when the caustic effects of aggressive factors (acid, pepsin, bile) overwhelm the defensive factors of the gastrointestinal mucosa (mucus and bicarbonate secretion, prostaglandins, blood flow, and the processes of restitution and regeneration after cellular injury). Over 99% of peptic ulcers are caused by infection with the bacterium *Helicobacter pylori* or by use of nonsteroidal anti-inflammatory drugs (NSAIDs). Drugs used in the treatment of acid-peptic disorders may be divided into two classes: agents that reduce intragastric acidity and agents that promote mucosal defense.

Agents That Reduce Intragastric Acidity

Physiology of Acid Secretion

The parietal cell contains receptors for gastrin, histamine (H₂), and acetylcholine (muscarinic, M₃) (Figure 63–1). When acetylcholine or gastrin bind to the parietal cell receptors, they cause an increase in cytosolic calcium, which in turn stimulates protein kinases that stimulate acid secretion from a H⁺/K⁺ ATPase (the proton pump) on the canalicular surface.

Figure 63–1.

In close proximity to the parietal cells are gut endocrine cells called enterochromaffin-like (ECL) cells. ECL cells have receptors for gastrin and acetylcholine and are the major source for histamine release. Histamine binds to the H₂ receptor on the parietal cell, resulting in activation of adenylyl cyclase, which increases intracellular cyclic adenosine monophosphate (cAMP). cAMP activates protein kinases that stimulate acid secretion by the H⁺/K⁺ ATPase. In humans, it is believed that the major effect of gastrin upon acid secretion is mediated indirectly through the release of histamine from ECL cells rather than through direct parietal cell stimulation.

Antacids

Antacids have been used for centuries in the treatment of patients with dyspepsia and acid-peptic disorders. They were the mainstay of treatment for acid-peptic disorders until the advent of H₂-receptor antagonists and proton pump inhibitors. They continue to be used commonly by patients as nonprescription remedies for the intermittent treatment of heartburn and dyspepsia.

Antacids are weak bases that react with gastric hydrochloric acid to form a salt and water. Although their principle mechanism of action is reduction of intragastric acidity, they may also promote mucosal defense mechanisms through stimulation of mucosal prostaglandin production. After a meal, approximately 45 meq/h of hydrochloric acid is secreted. A single dose of 156 meq of antacid

given 1 hour after a meal effectively neutralizes gastric acid for up to 2 hours. However, the acid-neutralization capacity among different proprietary formulations of antacids is highly variable, depending on their rate of dissolution (tablet versus liquid), water solubility, rate of reaction with acid, and rate of gastric emptying.

Sodium bicarbonate (eg, baking soda, Alka Seltzer) reacts rapidly with HCl to produce carbon dioxide and NaCl. Formation of carbon dioxide results in gastric distention and belching. Unreacted alkali is readily absorbed, potentially causing metabolic alkalosis when given in high doses or to patients with renal insufficiency. Sodium chloride absorption may exacerbate fluid retention in patients with heart failure, hypertension, and renal insufficiency.

Calcium carbonate (eg, Tums, Os-Cal) is less soluble and reacts more slowly than sodium bicarbonate with HCl to form carbon dioxide and CaCl₂. Like sodium bicarbonate, calcium carbonate may cause belching or metabolic alkalosis. Calcium carbonate is used for a number of other indications apart from its antacid properties (see Chapter 42: Agents That Affect Bone Mineral Homeostasis). Excessive doses of either sodium bicarbonate or calcium carbonate with calcium-containing dairy products can lead to hypercalcemia, renal insufficiency, and metabolic alkalosis (milk-alkali syndrome).

Formulations containing **magnesium hydroxide** or **aluminum hydroxide** react slowly with HCl to form magnesium chloride or aluminum chloride and water. Because no gas is generated, belching does not occur. Metabolic alkalosis is also uncommon because of the efficiency of the neutralization reaction. Because unabsorbed magnesium salts may cause an osmotic diarrhea and aluminum salts may cause constipation, these agents are commonly administered together in proprietary formulations (eg, Gelusil, Maalox, Mylanta) to minimize the impact upon bowel function. Both magnesium and aluminum are absorbed and excreted by the kidneys. Hence, patients with renal insufficiency should not take these agents long-term.

All antacids may affect the absorption of other medications by binding the drug (reducing its absorption) or by increasing intragastric pH that affects the drug's dissolution or solubility (especially weakly basic or acidic drugs). Hence, antacids should not be given within 2 hours of doses of tetracyclines, fluoroquinolones, itraconazole, and iron.

H₂-Receptor Antagonists

From their introduction in the 1970s until the early 1990s, H₂-receptor antagonists (commonly referred to as H₂-blockers) were the most commonly prescribed drugs in the world (see Clinical Uses). With the recognition of the role of *H pylori* in ulcer disease (which may be treated with appropriate antibacterial therapy) and the advent of proton pump inhibitors, the use of prescription H₂-blockers has declined markedly.

Chemistry & Pharmacokinetics

Four H₂ antagonists are in clinical use: **cimetidine**, **ranitidine**, **famotidine**, and **nizatidine** (Figure 63–2). All four agents are rapidly absorbed from the intestine. Cimetidine, ranitidine, and famotidine undergo first-pass hepatic metabolism resulting in a bioavailability of approximately 50%. Nizatidine has little first-pass metabolism and a bioavailability of almost 100%. The serum half-lives of the four agents range from 1.1–4 hours; however, duration of action depends on the dose given (Table 63–1). H₂ antagonists are cleared by a combination of hepatic metabolism, glomerular filtration, and renal tubular secretion. Dose reduction is required in patients with moderate to severe renal (and possibly severe hepatic) insufficiency. In the elderly, there is a

decline of up to 50% in drug clearance as well as a significant reduction in volume of distribution.

Figure 63–2.

H₂ receptor-blocking drugs.

Table 63–1. Clinical Comparisons of H₂ Receptor Blockers.

Drug	Relative Potency	Dose to Achieve > 50% Acid Inhibition for 10 Hours	Usual Dose for Acute Duodenal or Gastric Ulcer	Usual Dose for Gastroesophageal Reflux Disease	Usual Dose for Prevention of Stress-Related Bleeding
Cimetidine	1	400–800 mg	800 mg HS or 400 mg bid	800 mg bid	50 mg/h continuous infusion
Ranitidine	4–10x	150 mg	300 mg HS or 150 mg bid	150 mg bid	6.25 mg/h continuous infusion or 50 mg IV every 6–8 h

Nizatidine	4–10x	150 mg	300 mg HS or 150 mg bid	150 mg bid	Not available
Famotidine	20–50x	20 mg	40 mg HS or 20 mg bid	20 mg bid	20 mg IV every 12 h

Pharmacodynamics

The H₂ antagonists exhibit competitive inhibition at the parietal cell H₂ receptor, and suppress basal and meal-stimulated acid secretion in a linear, dose-dependent manner. They are highly selective and do not affect H₁ or H₃ receptors. The volume of gastric secretion and concentration of pepsin are also reduced (Figure 63–3).

Figure 63–3.

Effects of ranitidine on hypersecretion of pepsin and acid secretion in a patient. Gastric contents were collected by gastric tube for two 6-hour periods. Pepsin is quantitated as thousands of units and acid as millimoles per 30 minutes. During the first period, intravenous saline (placebo) injections were made at 40-minute intervals. During the second period, increasing intravenous ranitidine doses were given at 40-minute intervals as shown by the arrows. Ranitidine had a marked and long-lasting effect on acid secretion and a shorter but significant effect on pepsin production. (Modified and reproduced, with permission, from Danilewith M et al: Ranitidine suppression of gastric hypersecretion resistant to cimetidine. *N Engl J Med* 1982;306:20.)

H₂ antagonists reduce acid secretion stimulated by histamine as well as by gastrin and cholinomimetic agents through two mechanisms. First, histamine released from ECL cells by gastrin or vagal stimulation is blocked from binding to the parietal cell H₂ receptor. Second, direct stimulation of the parietal cell by gastrin or acetylcholine results in diminished acid secretion in the presence of H₂ receptor blockade. It appears that reduced parietal cell cAMP levels attenuate the intracellular activation of protein kinases by gastrin or acetylcholine.

The potencies of the four H₂-receptor antagonists vary over a 50-fold range (Table 63–1). When given in usual prescription doses however, all of the H₂ antagonists inhibit 60–70% of total 24-hour acid secretion. H₂ antagonists are especially effective at inhibiting nocturnal acid secretion (which depends largely on histamine) but have a modest impact on meal-stimulated acid secretion (which is stimulated by gastrin and acetylcholine as well as histamine). Thus, they block more than 90% of nocturnal acid but only 60–80% of daytime acid secretion. Therefore, nocturnal and fasting intragastric pH is raised to 4–5 but the impact upon the daytime, meal-stimulated pH profile is less. Recommended prescription doses maintain greater than 50% acid inhibition for 10 hours; hence, these drugs are commonly given twice daily. At doses available in over-the-counter formulations, the duration of acid inhibition is less than 6 hours.

Clinical Uses

H₂-receptor antagonists continue to be prescribed commonly. However, due to their superior acid inhibition and safety profile, proton pump inhibitors (see below) are steadily replacing H₂ antagonists for most clinical indications.

Gastroesophageal Reflux Disease (GERD)

Patients with infrequent heartburn or dyspepsia (fewer than 3 times per week) may take either antacids or intermittent H₂ antagonists. Because antacids provide rapid acid neutralization, they afford faster symptom relief than H₂ antagonists. However, the effect of antacids is short-lived (1–2 hours) compared with H₂ antagonists (6–10 hours). H₂ antagonists may be taken prophylactically before meals in an effort to reduce the likelihood of heartburn. Frequent heartburn is better treated with twice daily H₂ antagonists; this regimen provides effective symptom control in 50–75% of people (Table 63–1). In patients with erosive esophagitis (approximately half of patients with GERD), H₂ antagonists afford healing in less than 50% of patients. Although higher doses of H₂ antagonists increase healing rates, proton pump inhibitors are preferred.

Peptic Ulcer Disease

Proton pump inhibitors have largely replaced H₂ antagonists in the treatment of peptic ulcer disease. Nocturnal acid suppression affords effective ulcer healing in the majority of patients with uncomplicated gastric and duodenal ulcers. Hence, all the agents may be administered once daily at bedtime for acute, uncomplicated ulcers, resulting in ulcer healing rates greater than 80–90% after 6–8 weeks of therapy. For patients with acute peptic ulcers caused by *H pylori*, H₂ antagonists no longer play a significant therapeutic role. For the minority of patients in whom *H pylori* cannot be successfully eradicated, H₂ antagonists may be given daily at bedtime in half of the usual ulcer therapeutic dose in order to prevent ulcer recurrence (eg, ranitidine 150 mg, famotidine 20 mg). For patients with ulcers caused by aspirin or other NSAIDs, H₂ antagonists provide rapid ulcer healing so long as the NSAID is discontinued. If the NSAID must be continued for clinical reasons despite active ulceration, a proton pump inhibitor should be given to promote ulcer healing.

Nonulcer Dyspepsia

H₂ antagonists are commonly used as over-the-counter agents and prescription agents for treatment of intermittent dyspepsia not caused by peptic ulcer. However, benefit compared with placebo has never been convincingly demonstrated.

Prevention of Bleeding from Stress-Related Gastritis

H₂-receptor antagonists significantly reduce the incidence of bleeding from stress-related gastritis in seriously ill patients in the intensive care unit. H₂ antagonists are given intravenously, either as intermittent injections or continuous infusions. For maximal efficacy, the pH of gastric aspirates should be measured and the doses titrated to achieve a gastric pH \geq 4.

Adverse Effects

H₂ antagonists are extremely safe drugs. Side effects occur in fewer than 3% of patients and include diarrhea, headache, fatigue, myalgias, and constipation.

Central Nervous System

Mental status changes (confusion, hallucinations, agitation) may occur with administration of intravenous H₂ antagonists, especially in patients in the intensive care unit who are elderly or who have renal or hepatic dysfunction. These events may be more common with cimetidine. Mental status changes rarely occur in ambulatory patients.

Endocrine Effects

Cimetidine inhibits binding of dihydrotestosterone to androgen receptors, inhibits metabolism of estradiol, and increases serum prolactin levels. When used long-term or in high doses, it may cause gynecomastia or impotence in men and galactorrhea in women. These effects are specific to cimetidine and do not occur with the other H₂ antagonists.

Pregnancy and Nursing Mothers

Although there are no known harmful effects on the fetus, these agents cross the placenta. Therefore, they should not be administered to pregnant women unless absolutely necessary. The H₂ antagonists are secreted into breast milk and may therefore affect nursing infants.

Other Effects

H₂ antagonists may rarely cause blood dyscrasias. Blockade of cardiac H₂ receptors may cause bradycardia but this is rarely of clinical significance. Rapid intravenous infusion may cause bradycardia and hypotension through blockade of cardiac H₂ receptors; therefore, intravenous injection should be given over 30 minutes. H₂ antagonists rarely cause reversible abnormalities in liver chemistry.

Drug Interactions

Cimetidine interferes with several important hepatic cytochrome P450 drug metabolism pathways, including those catalyzed by CYP1A2, CYP2C9, CYP2D6, and CYP3A4 (see Chapter 4: Drug Biotransformation). Hence, the half-lives of drugs metabolized by these pathways may be prolonged. These drugs include warfarin, theophylline, phenytoin, lidocaine, quinidine, propranolol, labetalol, metoprolol, tricyclic antidepressants, several benzodiazepines, calcium channel blockers, sulfonyleureas, metronidazole, and ethanol. It is best to avoid cimetidine in patients using these drugs. Ranitidine binds 4–10 times less avidly than cimetidine to cytochrome P450. Negligible interaction occurs with nizatidine and famotidine.

H₂ antagonists compete with certain drugs (such as procainamide) for renal tubular secretion. All of these agents except famotidine inhibit gastric first-pass metabolism of ethanol (especially in

women). Although the importance of this is debated, increased bioavailability of ethanol could lead to increased blood ethanol levels.

Proton Pump Inhibitors (PPI)

Since their introduction in the late 1980s, these efficacious acid inhibitory agents have rapidly assumed the major role for the treatment of acid-peptic disorders. They are now among the most widely selling drugs worldwide due to their outstanding efficacy and safety.

Chemistry & Pharmacokinetics

Five proton pump inhibitors are available for clinical use: **omeprazole**, **lansoprazole**, **rabeprazole**, **pantoprazole**, and **esomeprazole**. All are substituted benzimidazoles that resemble H₂ antagonists in structure (Figure 63–4) but have a completely different mechanism of action. Omeprazole is a racemic mixture of R- and S-isomers. Esomeprazole is the S-isomer of omeprazole. All agents are available in oral formulations. Pantoprazole is also available in an intravenous formulation.

Figure 63–4.

Molecular structure of the proton pump inhibitors: omeprazole, lansoprazole, pantoprazole, and the sodium salt of rabeprazole. Omeprazole and esomeprazole have the same chemical structure (see text).

Proton pump inhibitors are administered as inactive prodrugs. To protect the acid-labile prodrug from rapid destruction within the gastric lumen, they are formulated as acid-resistant enteric-coated

microgranules mixed with apple juice or applesauce. After passing through the stomach into the alkaline intestinal lumen, the enteric coatings dissolve and the prodrug is absorbed. These prodrugs are lipophilic weak bases (pK_a 4–5) and therefore diffuse readily across lipid membranes into acidified compartments (such as the parietal cell canaliculus). Within the acidified compartment the prodrug rapidly becomes protonated and is concentrated > 1000-fold within the parietal cell canaliculus. There, it rapidly undergoes a molecular conversion to the active, reactive thiophilic sulfonamide cation. The sulfonamide reacts with the H^+/K^+ ATPase, forms a covalent disulfide linkage, and irreversibly inactivates the enzyme.

The pharmacokinetics of available proton pump inhibitors are shown in Table 63–2. Their bioavailability is decreased approximately 50% by food; hence, the drugs should be administered on an empty stomach. In a fasting state, only 10% of proton pumps are actively secreting acid and susceptible to inhibition. Proton pump inhibitors should be administered approximately 1 hour before a meal (usually breakfast or dinner), so that the peak serum concentration coincides with the maximal activity of proton pump secretion. The drugs have a short serum half-life of about 1.5 hours; however, the duration of acid inhibition lasts up to 24 hours due to the irreversible inactivation of the proton pump. At least 18 hours are required for synthesis of new H^+/K^+ ATPase pump molecules. Because not all proton pumps are inactivated with the first dose of medication, up to 3–4 days of daily medication are required before the full acid-inhibiting potential is reached. Similarly, after stopping the drug, it takes 3–4 days for full acid secretion to return.

Table 63–2. Pharmacokinetics of Proton Pump Inhibitors.

Drug	Bioavailability	Half-Life (h)	T_{max} (h) ¹	AUC (mg x h/L) ¹
Omeprazole	40–65%	0.5–1	1–3.5	0.2–1.2
Esomeprazole	50–89%	1.2	1.5	4.2 (20 mg dose)
				12.6 (40 mg dose)
Lansoprazole	80–90%	1.5	1–1.7	1.7–5
Pantoprazole	77%	1.9	2.0–4.0	2–5
Rabeprazole	52%	0.7–2.0	2.0–5.0	0.8

¹ T_{max} , time of maximum concentration; AUC, area under the curve.

Proton pump inhibitors undergo rapid first-pass and systemic hepatic metabolism and have negligible renal clearance. Dose reduction is not needed for patients with renal insufficiency or mild to moderate liver disease but should be considered in patients with severe liver impairment (Table 63–3). Although other proton pumps exist in the body, the H^+/K^+ ATPase appears to exist only in the parietal cell and is distinct structurally and functionally from other H^+ transporting enzymes.

Table 63–3. Clinical Comparisons of Proton Pump Inhibitors.

Agent	Usual Dosage for Peptic Ulcer or GERD ¹	Maintenance Therapy
-------	----------------------------------------------------	---------------------

Esomeprazole	20–40 mg qd	20 mg qd
Lansoprazole	30 mg qd	15 mg qd
Omeprazole	20 mg qd	20 mg qd
Pantoprazole	40 mg qd	40 mg qd
Rabeprazole	20 mg qd	20 mg qd

¹GERD, gastroesophageal reflux disease.

The intravenous formulation of pantoprazole has similar characteristics to the oral drugs. When given to a fasting patient, intravenous pantoprazole inactivates acid pumps that are actively secreting but has no effect on pumps in quiescent, nonsecreting vesicles. Because the half-life of a single injection of the intravenous formulation is short, acid secretion returns several hours later as pumps move from the tubulo-vesicles to the canalicular surface. Thus, in order to provide maximal inhibition, intravenous pantoprazole must be given over 24–48 hours as a continuous infusion or as repeated bolus injections. The optimal dosing of intravenous pantoprazole to achieve maximal blockade is not yet established.

Pharmacodynamics

From a pharmacokinetic perspective, proton pump inhibitors are ideal drugs: they have a short serum half-life, they are concentrated and activated near their site of action, and they have a long duration of action. In contrast to H₂ antagonists, proton pump inhibitors inhibit both fasting and meal-stimulated secretion because they block the final common pathway of acid secretion, the proton pump. In standard doses, proton pump inhibitors inhibit 90–98% of 24-hour acid secretion. In patients receiving long-term therapy with proton pump inhibitors, the median 24-hour intragastric pH varies from 3.6 to 4.9 (esomeprazole 40 mg); the mean number of hours the pH is higher than 4 varies from 10.5 hours to 16.8.

Clinical Uses

Gastroesophageal Reflux Disease (GERD)

Proton pump inhibitors are the most effective agents for the treatment of nonerosive and erosive reflux disease, esophageal complications of reflux disease (peptic stricture or Barrett's esophagus), and extraesophageal manifestations of reflux disease. Once-daily dosing provides effective symptom relief and tissue healing in 85–90% of patients; up to 15% of patients require twice daily dosing.

Symptoms of erosive esophagitis recur in over 80% of patients within 6 months after discontinuation of a proton pump inhibitor. For this reason, long-term daily maintenance therapy with a full-dose or half-dose proton pump inhibitor often is needed, particularly for patients with erosive esophagitis or esophageal complications.

In current clinical practice, many patients with symptomatic gastroesophageal reflux are treated empirically with medications without prior endoscopy, ie, without knowledge of whether the patient has erosive or nonerosive reflux disease. Empiric treatment with proton pump inhibitors provides sustained symptomatic relief in 70–80% of patients, compared with 50–60% with H₂ antagonists. Due to recent cost reductions, proton pump inhibitors are increasingly being used as first-line

therapy for patients with symptomatic GERD.

Sustained acid suppression with twice-daily proton pump inhibitors for at least 3 months is used to treat extraesophageal complications of reflux disease (asthma, chronic cough, laryngitis, and noncardiac chest pain).

Peptic Ulcer Disease

Compared with H₂ antagonists, proton pump inhibitors afford more rapid symptom relief and faster ulcer healing for duodenal ulcers and, to a lesser extent, gastric ulcers. All of the pump inhibitors heal more than 90% of duodenal ulcers within 4 weeks and a similar percentage of gastric ulcers within 6–8 weeks.

H Pylori–Associated Ulcers

For *H pylori*–associated ulcers, there are two therapeutic goals: heal the ulcer and eradicate the organism. The most effective regimens for *H pylori* eradication are combinations of two antibiotics and a proton pump inhibitor. Proton pump inhibitors promote eradication of *H pylori* through several mechanisms: direct antimicrobial properties (minor) and—by raising intragastric pH—lowering the minimal inhibitory concentrations of antibiotics against *H pylori*. The best treatment regimen consists of a 10–14 day regimen of "triple therapy": a proton pump inhibitor twice daily, clarithromycin 500 mg twice daily, and amoxicillin 1 g twice daily. For patients who are allergic to penicillin, metronidazole 500 mg twice daily should be substituted for amoxicillin. After completion of triple therapy, the proton pump inhibitor should be continued once daily for a total of 4–6 weeks to ensure complete ulcer healing.

NSAID-Associated Ulcers

For patients with ulcers caused by aspirin or other NSAIDs, either H₂ antagonists or proton pump inhibitors provide rapid ulcer healing so long as the NSAID is discontinued; continued use of the NSAID impairs ulcer healing. Treatment with a once daily proton pump inhibitor promotes ulcer healing despite continued NSAID therapy.

Proton pump inhibitors are also given to prevent ulcer complications from NSAIDs. Asymptomatic peptic ulceration develops in 10–20% of people taking frequent NSAIDs, and ulcer-related complications (bleeding, perforation) develop in 1–2% of persons per year. Proton pump inhibitors taken once daily are effective in reducing the incidence of ulcers and ulcer complications in patients taking aspirin or other NSAIDs.

Prevention of Rebleeding from Peptic Ulcers

In patients with acute gastrointestinal bleeding due to peptic ulcers, the risk of rebleeding from ulcers that have a visible vessel or adherent clot is increased. Ulcer rebleeding is reduced significantly with use of proton pump inhibitors administered for 3–5 days either as high-dose oral therapy (eg, omeprazole 40 mg orally twice daily) or as a continuous intravenous infusion. The optimal dosing for intravenous pantoprazole is under investigation.

Nonulcer Dyspepsia

Proton pump inhibitors have modest efficacy for treatment of nonulcer dyspepsia, benefiting 10–20% more patients than placebo. Despite their increasing use for this indication, superiority to H₂

antagonists (or even placebo) has not been conclusively demonstrated.

Prevention of Stress Gastritis

Intravenous proton pump inhibitors increasingly are being used in critically ill patients to reduce the incidence of stress-related mucosal bleeding despite a lack of any controlled trials demonstrating their efficacy. In the absence of trials that establish efficacy and optimal dosing for proton pump inhibitors, intravenous H₂ antagonists remain the preferred drugs for this indication.

Gastrinoma and Other Hypersecretory Conditions

Patients with isolated gastrinomas are best treated with surgical resection. In patients with metastatic or unresectable gastrinomas, massive acid hypersecretion results in peptic ulceration, erosive esophagitis, and malabsorption. Previously, these patients required vagotomy and extraordinarily high doses of H₂ antagonists, which resulted in suboptimal acid suppression. With proton pump inhibitors, excellent acid suppression can be achieved in all patients. Dosage is titrated to reduce basal acid output to less than 5–10 meq/h. Typical doses of omeprazole are 60–120 mg/d.

Adverse Effects

General

Proton pump inhibitors are extremely safe. Diarrhea, headache, and abdominal pain are reported in 1–5% of patients, although the frequency of these events is only slightly increased compared with placebo. Proton pump inhibitors do not have teratogenicity in animal models; however, safety during pregnancy has not been established.

Nutrition

Acid is important in releasing vitamin B₁₂ from food. A minor reduction in oral cyanocobalamin absorption occurs during proton pump inhibition, potentially leading to subnormal B₁₂ levels with prolonged therapy. Acid also promotes absorption of food-bound minerals (iron, calcium, zinc); however, no mineral deficiencies have been reported with proton pump inhibitor therapy.

Enteric Infections

Gastric acid is an important barrier to colonization and infection of the stomach and intestine from ingested bacteria. Hypochlorhydria from any cause increases the risk for enteric infections (eg, salmonella, shigella). A small increased risk of enteric infections may exist in patients taking proton pump inhibitors, especially when traveling in underdeveloped countries.

Potential Problems Due to Increased Serum Gastrin

Gastrin levels are regulated by a feedback loop. During meals, intraluminal food proteins stimulate gastrin release from antral G-cells. The rise in serum gastrin stimulates parietal cell acid secretion. Increased intragastric acidity stimulates antral D-cells to release somatostatin, which binds to receptors on adjacent antral G-cells, turning off further gastrin release. Acid suppression alters this feedback inhibition so that gastrin levels rise two- to four-fold in patients taking proton pump inhibitors. In approximately 3%, gastrin levels exceed 500 pg/mL (normal < 100 pg/mL). Upon stopping the drug, the levels normalize.

The rise in serum gastrin levels in patients receiving long-term therapy with proton pump inhibitors has raised two theoretical concerns. First, gastrin is a trophic hormone that stimulates hyperplasia of ECL cells. Hypergastrinemia due to gastrinoma (Zollinger-Ellison syndrome) or atrophic gastritis is associated with the development of gastric carcinoids in up to 3% of patients. In female rats given proton pump inhibitors for prolonged periods, gastric carcinoid tumors developed in areas of ECL hyperplasia. Although humans who take proton pump inhibitors for a long time may exhibit ECL hyperplasia in response to hypergastrinemia, carcinoid tumor formation has not been documented. Second, hypergastrinemia increases the proliferative rate of colonic mucosa, potentially promoting carcinogenesis. In humans, hypergastrinemia caused by vagotomy, atrophic gastritis, or Zollinger-Ellison syndrome has not been associated with increased colon cancer risk. At present, routine monitoring of serum gastrin levels is not recommended in patients receiving prolonged proton pump inhibitor therapy.

Potential Problems Due to Decreased Gastric Acidity

As noted above, gastric acid serves as an important barrier to bacterial colonization of the stomach and small intestine. Increases in gastric bacterial concentrations are detected in patients taking proton pump inhibitors. An increase in nitrate-reductase positive strains could theoretically increase carcinogenic nitrites and N-nitrosamines. However, most studies do not demonstrate this.

Among patients infected with *H pylori*, long-term acid suppression leads to increased chronic inflammation in the gastric body and decreased inflammation in the antrum. Concerns have been raised that increased gastric inflammation may accelerate gastric gland atrophy (atrophic gastritis) and intestinal metaplasia—known risk factors for gastric adenocarcinoma. A special US Food and Drug Administration Gastrointestinal Advisory Committee concluded that there is no evidence that prolonged proton pump inhibitor therapy produces the kind of atrophic gastritis (multifocal atrophic gastritis) or intestinal metaplasia that is associated with increased risk of adenocarcinoma. Routine testing for *H pylori* is no longer recommended in patients who require long-term proton pump inhibitor therapy.

Drug Interactions

Decreased gastric acidity may alter absorption of drugs for which intragastric acidity affects drug bioavailability, eg, ketoconazole and digoxin. All proton pump inhibitors are metabolized by hepatic P450 cytochromes, including CYP2C19 and CYP3A4. Omeprazole may inhibit the metabolism of coumadin, diazepam, and phenytoin. Esomeprazole also may decrease metabolism of diazepam. Lansoprazole may enhance clearance of theophylline. However, clinically significant interactions with these drugs are rare. Rabeprazole and pantoprazole have no significant drug interactions.

Mucosal Protective Agents

The gastroduodenal mucosa has evolved a number of defense mechanisms to protect itself against the noxious effects of acid and pepsin. Both mucus and epithelial cell-cell tight junctions restrict back diffusion of acid and pepsin. Epithelial bicarbonate secretion establishes a pH gradient within the mucous layer in which the pH ranges from 7 at the mucosal surface to 1–2 in the gastric lumen. Blood flow carries bicarbonate and vital nutrients to surface cells. Areas of injured epithelium are quickly repaired by restitution, a process in which migration of cells from gland neck cells seals small erosions to reestablish intact epithelium. Mucosal prostaglandins appear to be important in stimulating mucus and bicarbonate secretion and mucosal blood flow. A number of agents that potentiate these mucosal defensive mechanisms are available for the prevention and treatment of

acid-peptic disorders.

Sucralfate

Chemistry & Pharmacokinetics

Sucralfate is a salt of sucrose complexed to sulfated aluminum hydroxide. In water or acidic solutions it forms a viscous, tenacious paste that binds selectively to ulcers or erosions for up to 6 hours. Sucralfate has limited solubility, breaking down into sucrose sulfate (strongly negatively charged) and an aluminum salt. Less than 3% of intact drug and 0.01% of aluminum is absorbed from the intestinal tract; the remainder is excreted in the feces.

Pharmacodynamics

A variety of beneficial effects have been attributed to sucralfate, but the precise mechanism of action is unclear. It is believed that the negatively charged sucrose sulfate binds to positively charged proteins in the base of ulcers or erosion, forming a physical barrier that restricts further caustic damage and stimulates mucosal prostaglandin and bicarbonate secretion. It may also bind epithelial growth factor and fibroblast growth factor, enhancing mucosal repair.

Clinical Uses

Sucralfate is administered in a dosage of 1 g four times daily on an empty stomach (at least 1 hour before meals). At present, its clinical uses are limited. It has been shown to be effective for the healing of duodenal ulcers, but with the advent of more effective agents (proton pump inhibitors), it is seldom used for this indication. In critically ill patients hospitalized in the intensive care unit, sucralfate is effective for the prevention of bleeding from stress-related gastritis. It is still unclear which is the preferred agent for this indication: sucralfate (administered as a slurry through a nasogastric tube), intravenous H₂ antagonists, or intravenous proton pump inhibitors. Some clinicians administer sucralfate to patients taking NSAIDs who are experiencing dyspepsia. It is not an effective agent in preventing or healing NSAID-induced ulcers.

Adverse Effects

Because it is not absorbed, sucralfate is virtually devoid of systemic side effects. Constipation occurs in 2% due to the aluminum salt. Because a small amount of aluminum is absorbed, it should not be used for prolonged periods in patients with renal insufficiency.

Drug Interactions

Sucralfate may bind to other medications, impairing their absorption.

Prostaglandin Analogs

Chemistry & Pharmacokinetics

The human gastrointestinal mucosa synthesizes a number of prostaglandins (see Chapter 18: The Eicosanoids: Prostaglandins, Thromboxanes, Leukotrienes, & Related Compounds), however the primary ones are prostaglandins E and F. **Misoprostol**, a methyl analog of PGE₁, has been approved for gastrointestinal conditions. Following oral administration, it is rapidly absorbed and metabolized to a metabolically active free acid. The serum half-life is less than 30 minutes; hence, it

must be administered 3–4 times daily. It is excreted in the urine, however dose reduction is not needed in patients with renal insufficiency.

Pharmacodynamics

Misoprostol has both acid inhibitory and mucosal protective properties. It is believed to stimulate mucus and bicarbonate secretion and enhance mucosal blood flow. In addition, it binds to a prostaglandin receptor on parietal cells, reducing histamine-stimulated cAMP production and causing modest acid inhibition. Prostaglandins have a variety of other actions, including stimulation of intestinal electrolyte and fluid secretion, intestinal motility and uterine contractions.

Clinical Uses

Peptic ulcers develop in approximately 10–20% of patients who receive long-term NSAID therapy (see Proton Pump Inhibitors, above). Misoprostol reduces the incidence of NSAID-induced ulcers to less than 3% and the incidence of ulcer complications by 50%. It is approved for prevention of NSAID-induced ulcers in high-risk patients; however, it has never achieved widespread use due to its high side effect profile and need for multiple daily dosing. As discussed, proton pump inhibitors may be as effective and better tolerated than misoprostol for this indication. Cyclooxygenase-2-selective NSAIDs, which may have less gastrointestinal toxicity (see Chapter 36: Nonsteroidal Anti-Inflammatory Drugs, Disease-Modifying Antirheumatic Drugs, Nonopioid Analgesics, & Drugs Used in Gout), offer another option for patients at high-risk for NSAID-induced complications.

Adverse Effects & Drug Interactions

Diarrhea and cramping abdominal pain occurs in 10–20% of patients. Because misoprostol stimulates uterine contractions (see Chapter 18: The Eicosanoids: Prostaglandins, Thromboxanes, Leukotrienes, & Related Compounds), it should not be used during pregnancy or in women of childbearing potential unless they have a negative serum pregnancy test and are compliant with effective contraceptive measures. No significant drug interactions are reported.

Colloidal Bismuth Compounds

Chemistry & Pharmacokinetics

The only bismuth compound available in the USA is **bismuth subsalicylate**, a nonprescription formulation containing bismuth and salicylate. In other countries, **bismuth subcitrate** and **bismuth dinitrate** are also available. Bismuth subsalicylate undergoes rapid dissociation within the stomach, allowing absorption of salicylate. Over 99% of the bismuth appears in the stool. Although minimal (< 1%) bismuth is absorbed, it is stored in many tissues and has slow renal excretion. Salicylate (like aspirin) is readily absorbed and excreted in the urine.

Pharmacodynamics

Like sucralfate, bismuth probably coats ulcers and erosions, creating a protective layer against acid and pepsin. It may also stimulate prostaglandin, mucus, and bicarbonate secretion. Bismuth subsalicylate reduces stool frequency and liquidity in acute infectious diarrhea, due to salicylate inhibition of intestinal prostaglandin and chloride secretion. Bismuth has direct antimicrobial effects and binds enterotoxins, accounting for its benefit in preventing and treating traveler's diarrhea. Bismuth compounds have direct antimicrobial activity against *H pylori*.

Clinical Uses

In spite of the lack of comparative trials, nonprescription bismuth compounds are widely used by patients for the nonspecific treatment of dyspepsia and acute diarrhea. Bismuth subsalicylate also is used for the prevention of traveler's diarrhea (30 mL or 2 tablets four times daily)

Bismuth compounds have been used in multidrug regimens for the eradication of *H pylori* infection. In the USA, a "triple therapy" regimen has been used, consisting of bismuth subsalicylate (2 tablets; 262 mg each), tetracycline (500 mg), and metronidazole (250 mg), each taken four times daily for 14 days. Because of the need for four-times daily dosing and the high side effect profile, this regimen is no longer used as first-line therapy for *H pylori* eradication (see Proton Pump Inhibitors above). For patients with resistant infections, "quadruple therapy" consisting of a proton pump inhibitor twice daily in addition to the three-drug bismuth-based regimen four times daily for 14 days is highly effective. In Europe, bismuth subcitrate is used instead of bismuth subsalicylate, and treatment for 7–10 days may be sufficient.

Adverse Effects

All bismuth formulations have an excellent safety profile. Bismuth causes blackening of the stool, which may be confused with gastrointestinal bleeding. Liquid formulations may cause harmless darkening of the tongue. Bismuth agents should be used for only short periods and should be avoided in patients with renal insufficiency. Prolonged usage of some bismuth compounds may rarely lead to bismuth toxicity resulting in encephalopathy (ataxia, headaches, confusion, seizures). However, such toxicity is not reported with bismuth subsalicylate or bismuth citrate. High dosages of bismuth subsalicylate may lead to salicylate toxicity.

Katzung PHARMACOLOGY, 9e > Section X. Special Topics > Chapter 63. Drugs Used in the Treatment of Gastrointestinal Diseases >

Drugs Stimulating Gastrointestinal Motility

Drugs that can selectively stimulate gut motor function (**prokinetic** agents) have significant potential clinical usefulness. Agents that increase lower esophageal sphincter pressures may be useful for GERD. Drugs that improve gastric emptying may be helpful for gastroparesis and postsurgical gastric emptying delay. Agents that stimulate the small intestine may be beneficial for postoperative ileus or chronic intestinal pseudo-obstruction. Finally, agents that enhance colonic transit may be useful in the treatment of constipation. Unfortunately, only a limited number of agents are available for clinical use at this time.

Physiology of the Enteric Nervous System

The enteric nervous system (see Chapter 6: Introduction to Autonomic Pharmacology) is composed of interconnected networks of ganglion cells and nerve fibers mainly located in the submucosa (submucosal plexus) and between the circular and longitudinal muscle layers (myenteric plexus). These networks give rise to nerve fibers that connect with the mucosa and deep muscle. Although extrinsic sympathetic and parasympathetic nerves project onto the submucosal and myenteric plexuses, the enteric nervous system can independently regulate gastrointestinal motility and secretion. Afferent fibers present in the mucosa and muscularis connect to cell bodies in the plexuses that mediate local reflexes.

Myenteric plexus interneurons containing **calcitonin gene related peptide (CGRP)** may be important in controlling the peristaltic reflex, promoting release of excitatory mediators proximally and inhibitory mediators distally. Excitatory muscle activity (contraction) is promoted by enteric interneurons and motor neurons that release **acetylcholine, serotonin, and substance P**. Inhibition of muscle activity and relaxation is promoted by enteric motor neurons that release **vasoactive intestinal peptide, nitric oxide, and ATP**. **Motilin** may stimulate excitatory neurons or muscle cells directly. **Dopamine** acts as an inhibitory neurotransmitter in the gastrointestinal tract, decreasing the intensity of esophageal and gastric contractions.

Although there are at least 14 serotonin (5-HT) receptor subtypes, drug development for gastrointestinal applications to date has focused on **5-HT₃ receptor antagonists** and **5-HT₄ receptor agonists**. These agents—which have effects upon gastrointestinal motility and visceral afferent sensation—are discussed under Drugs Used for the Treatment of Irritable Bowel Syndrome and Antiemetics. Other drugs acting on 5-HT receptors are discussed in Chapter 16: Histamine, Serotonin, & the Ergot Alkaloids, Chapter 29: Antipsychotic Agents & Lithium, and Chapter 30: Antidepressant Agents.

Cholinomimetic Agents

Cholinomimetic agonists such as **bethanechol** stimulate muscarinic M₃ receptors on muscle cells and at myenteric plexus synapses (see Chapter 7: Cholinoceptor-Activating & Cholinesterase-Inhibiting Drugs). Bethanechol was used in the past for the treatment of GERD and gastroparesis. Due to multiple cholinergic side effects and the advent of newer agents, it is now seldom used. The acetylcholinesterase inhibitor **neostigmine** can enhance gastric, small intestine, and colonic emptying. Intravenous neostigmine (2 mg) has enjoyed a resurgence in clinical usage for the treatment of hospitalized patients with acute large bowel distention (known as acute colonic pseudo-obstruction or Ogilvie's syndrome), resulting in prompt colonic evacuation of flatus and feces in the majority of patients. Cholinergic side effects include excessive salivation, nausea, vomiting, diarrhea, and bradycardia.

Metoclopramide, Domperidone, & Cisapride

Metoclopramide and **cisapride** are substituted benzamides and **domperidone** is a butyrophenone. The primary prokinetic mechanism of action of all three agents is mediated through cholinergic stimulation. In addition to agonist activity at 5-HT₄ receptors on enteric neurons, which promotes release of acetylcholine, cisapride exhibits some antagonist activity at 5-HT₃ receptors. Metoclopramide and domperidone (but not cisapride) are dopamine D₂ receptor antagonists. Within the gastrointestinal tract dopamine receptor antagonism may potentiate cholinergic smooth muscle stimulation. Metoclopramide and domperidone also block dopamine D₂ receptors in the chemoreceptor trigger zone of the medulla (area postrema), resulting in potent anti-nausea and antiemetic action.

These agents increase esophageal peristaltic amplitude, increase lower esophageal sphincter (LES) pressure, and enhance gastric emptying. Cisapride also enhances small bowel and colonic motility.

Clinical Uses

Gastroesophageal Reflux Disease (GERD)

Metoclopramide is available for clinical use in the USA; domperidone is available in many other

countries. Cisapride was removed from the United States market by the manufacturer due to cardiac arrhythmias and is now available only for compassionate use. All three agents are used for the treatment of symptomatic GERD but none are effective for treatment of erosive esophagitis. Due to the superior efficacy and safety of antisecretory agents for treatment of heartburn, prokinetic agents are used mainly in combination with antisecretory agents for treatment of regurgitation or refractory heartburn.

Impaired Gastric Emptying

All three agents have been widely used for the treatment of patients with delayed gastric emptying due to postsurgical disorders (vagotomy, antrectomy) and diabetic gastroparesis. Metoclopramide is sometimes administered in hospitalized patients to promote advancement of nasogastric feeding tubes from the stomach into the duodenum.

Nonulcer Dyspepsia

These agents lead to symptomatic improvement in a small number of patients with chronic dyspepsia.

Prevention of Vomiting

Due to their potent antiemetic action, metoclopramide and domperidone are used for the prevention and treatment of emesis (see Antiemetic Agents).

Postpartum Lactation Stimulation

Domperidone is sometimes recommended to promote postpartum lactation (see also Adverse Effects).

Adverse Effects

The most common adverse effects of **metoclopramide** involve the central nervous system. Restlessness, drowsiness, insomnia, anxiety, and agitation occur in 10–20% of patients, especially the elderly. Extrapyramidal effects (dystonias, akathisia, parkinsonian features) due to central dopamine receptor blockade occur acutely in 25% of patients given high doses and in 5% of patients receiving long-term therapy. Tardive dyskinesia, sometime irreversible, has developed in patients treated for a prolonged period with metoclopramide. For this reason, long-term use should be avoided unless absolutely necessary, especially in the elderly. Elevated prolactin levels (caused by both metoclopramide and domperidone) can cause galactorrhea, gynecomastia, impotence, and menstrual disorders.

Domperidone is extremely well tolerated. Because it does not cross the blood-brain barrier to a significant degree, neuropsychiatric and extrapyramidal side effects are rare.

Due to prokinetic effects in the colon, abdominal cramps and diarrhea occur in up to 15% of patients taking **cisapride**; however significant problems are unusual. In addition, cisapride is metabolized by the hepatic cytochrome P450 CYP3A4 enzyme. When coadministered with drugs that inhibit this enzyme (such as ketoconazole, fluconazole, macrolide antibiotics, and HIV protease inhibitors), significant increases in serum levels of cisapride may occur that rarely lead to QT prolongation on the ECG and serious cardiac arrhythmias. For this reason, cisapride was removed

from the market by the manufacturer.

Macrolides

Macrolide antibiotics such as erythromycin directly stimulate motilin receptors on gastrointestinal smooth muscle and promote the onset of a migrating motor complex. Intravenous erythromycin (3 mg/kg) is beneficial in some patients with gastroparesis; however, tolerance rapidly develops. Specific motilin agonists are under investigation.

Katzung PHARMACOLOGY, 9e > Section X. Special Topics > Chapter 63. Drugs Used in the Treatment of Gastrointestinal Diseases >

Laxatives

The overwhelming majority of people do not need laxatives, yet they are self-prescribed by a large portion of the population. For most people, intermittent constipation is best prevented with a high fiber diet, adequate fluid intake, regular exercise, and the heeding of nature's call. Patients not responding to dietary changes or fiber supplements should undergo medical evaluation prior to the initiation of long-term laxative treatment. Laxatives may be classified by their major mechanism of action, but many work through more than one mechanism.

Bulk-Forming Laxatives

Bulk-forming laxatives are indigestible, hydrophilic colloids that absorb water, forming a bulky, emollient gel that distends the colon and promotes peristalsis. Common preparations include natural plant products (**psyllium, methylcellulose**) and synthetic fibers (**polycarbophil**). Bacterial digestion of plant fibers within the colon may lead to increased bloating and flatus.

Stool Surfactant Agents (Softeners)

These agents soften stool material, permitting water and lipids to penetrate. They may be administered orally or rectally. Common agents include **docusate** (oral or enema) or **glycerin suppository**. In hospitalized patients, docusate is commonly prescribed to prevent constipation and minimize straining. **Mineral oil** is a clear, viscous oil that lubricates fecal material, retarding water absorption from the stool. It is used to prevent and treat fecal impaction in young children and debilitated adults. It is not palatable but may be mixed with juices. Aspiration can result in a severe lipid pneumonitis. Long-term use can impair absorption of fat-soluble vitamins (A, D, E, K).

Osmotic Laxatives

The colon can neither concentrate nor dilute fecal fluid: fecal water is isotonic throughout the colon. Osmotic laxatives are soluble but nonabsorbable compounds that result in increased stool liquidity due to an obligate increase in fecal fluid.

Nonabsorbable Sugars or Salts

These agents may be used for the treatment of acute constipation or the prevention of chronic constipation. **Magnesium oxide (milk of magnesia)** is a commonly used osmotic laxative. It should not be used for prolonged periods in patients with renal insufficiency due to risk of hypermagnesemia. **Sorbitol** and **lactulose** are nonabsorbable sugars that can be used to prevent or

treat chronic constipation. These sugars are metabolized by colonic bacteria, producing severe flatus and cramps.

High doses of osmotically active agents produce prompt bowel evacuation (purgation) within 1–3 hours. The rapid movement of water into the distal small bowel and colon leads to a high volume of liquid stool followed by rapid relief of constipation. The most commonly used **purgatives** are **magnesium citrate** and **sodium phosphate**. These hyperosmolar agents may lead to intravascular volume depletion and electrolyte fluctuations; hence they should not be used in patients who are frail, elderly, have renal insufficiency, or have significant cardiac disease.

Balanced Polyethylene Glycol

Lavage solutions containing **polyethylene glycol (PEG)** are used for complete colonic cleansing prior to gastrointestinal endoscopic procedures. These balanced, isotonic solutions contain an inert, nonabsorbable, osmotically active sugar (PEG) with sodium sulfate, sodium chloride, sodium bicarbonate, and potassium chloride. The solution is designed so that no significant intravascular fluid or electrolyte shifts occur. Therefore, they are safe for all patients. The solution should be ingested rapidly (4 L over 2 hours) to promote bowel cleansing. For treatment or prevention of chronic constipation, smaller doses of PEG powder may be mixed with water or juices (17 g/8 oz) and ingested daily. In contrast to sorbitol or lactulose, PEG does not produce significant cramps or flatus.

Stimulant Laxatives

Stimulant laxatives (cathartics) induce bowel movements through a number of poorly understood mechanisms. These include direct stimulation of the enteric nervous system and colonic electrolyte and fluid secretion. There has been concern that long-term use of cathartics could lead to dependency and destruction of the myenteric plexus, resulting in colonic atony and dilation. More recent research suggests that long-term use of these agents probably is safe in most patients. Cathartics may be required on a long-term basis, especially in patients who are neurologically impaired and in bed-bound patients in long-term care facilities.

Anthraquinone Derivatives

Aloe, senna, and cascara occur naturally in plants. These laxatives are poorly absorbed and after hydrolysis in the colon, produce a bowel movement in 6–12 hours when given orally and within 2 hours when given rectally. Chronic use leads to a characteristic brown pigmentation of the colon known as "melanosis coli." There has been some concern that these agents may be carcinogenic, but epidemiologic studies do not suggest a relationship to colorectal cancer.

Diphenylmethane Derivatives

Due to concerns about possible cardiac toxicity, these agents (eg, phenolphthalein) were recently removed from the market.

Castor Oil

This oil is a potent stimulant laxative. It is hydrolyzed in the upper small intestine to ricinoleic acid, a local irritant that stimulates intestinal motility. Formerly used as a purgative to clean the colon before procedures, it is now seldom used.

Antidiarrheal Agents

Antidiarrheal agents may be used safely in patients with mild to moderate acute diarrhea. However, they should not be used in patients with bloody diarrhea, high fever, or systemic toxicity because of the risk of worsening the underlying condition. They should be discontinued in patients whose diarrhea is worsening despite therapy. Antidiarrheals are also used to control chronic diarrhea caused by such conditions as irritable bowel syndrome (IBS) or inflammatory bowel disease (IBD).

Opioid Agonists

Opioids have significant constipating effects (see Chapter 31: Opioid Analgesics & Antagonists). They increase colonic phasic segmenting activity through inhibition of presynaptic cholinergic nerves in the submucosal and myenteric plexuses and lead to increased colonic transit time and fecal water absorption. They also decrease mass colonic movements and the gastrocolic reflex. Although all opioids have antidiarrheal effects, central nervous system effects and potential for addiction limit the usefulness of most. **Loperamide** is a nonprescription opioid agonist that does not cross the blood-brain barrier and has no analgesic properties or potential for addiction. Tolerance to long-term use has not been reported. It is typically administered in doses of 2 mg taken one to four times daily. **Diphenoxylate** is another opioid agonist that has no analgesic properties in standard doses; however, higher doses have central nervous system effects and prolonged use can lead to opioid dependence. Commercial preparations commonly contain small amounts of atropine to discourage overdose (2.5 mg diphenoxylate with 0.025 mg atropine). The anticholinergic properties of atropine may contribute to the antidiarrheal action.

Colloidal Bismuth Compounds

See Mucosal Protective Agents.

Kaolin & Pectin

Kaolin is a naturally occurring hydrated magnesium aluminum silicate (attapulgate), and pectin is an indigestible carbohydrate derived from apples. Both appear to act as absorbents of bacteria, toxins, and fluid, thereby decreasing stool liquidity and number. They may be useful in acute diarrhea but are seldom used on a chronic basis. A common commercial preparation is Kaopectate. The usual dose is 1.2–1.5 g after each loose bowel movement (maximum: 9 g/d). Kaolin-pectin formulations are not absorbed and have no significant side effects except constipation. They should not be taken within 2 hours of other medications (to which they may bind).

Bile Salt Binding Resins

Conjugated bile salts are normally absorbed in the terminal ileum. Disease of the terminal ileum (eg, Crohn's disease) or surgical resection leads to malabsorption of bile salts, which may cause colonic secretory diarrhea. The bile salt binding resins **cholestyramine** or **colestipol** may decrease diarrhea caused by excess fecal bile acids (see Chapter 35: Agents Used in Hyperlipidemia). The usual dose is 4–5 g one to three times daily before meals. Side effects include bloating, flatulence, constipation, and fecal impaction. In patients with diminished circulating bile acid pools, further removal of bile acids may lead to an exacerbation of fat malabsorption. These agents bind a number

of drugs and reduce their absorption; hence, they should not be given within 2 hours of other drugs.

Octreotide

Somatostatin is a 14 amino acid peptide that is released in the gastrointestinal tract and pancreas from paracrine cells, D-cells, and enteric nerves as well as from the hypothalamus (see Chapter 37: Hypothalamic & Pituitary Hormones). It is a key regulatory peptide that has myriad physiologic effects:

1. It inhibits the secretion of numerous hormones, including gastrin, cholecystokinin, glucagon, growth hormone, insulin, secretin, pancreatic polypeptide, vasoactive intestinal peptide, and 5-HT₃.
2. It reduces intestinal fluid secretion and pancreatic secretion.
3. It slows gastrointestinal motility and inhibits gallbladder contraction.
4. It induces direct contraction of vascular smooth muscle, leading to a reduction of portal and splanchnic blood flow.
5. It inhibits secretion of some anterior pituitary hormones.

The clinical usefulness of somatostatin is limited by its short half-life in the circulation (3 minutes) when it is administered by intravenous injection. **Octreotide** is a synthetic octapeptide with actions similar to somatostatin. When administered intravenously, it has a serum half-life of 1.5 hours. It also may be administered by subcutaneous injection, resulting in a 6- to 12-hour duration of action. A longer-acting formulation is available for once-monthly depot intramuscular injection.

Clinical Uses

Inhibition of Endocrine Tumor Effects

Two gastrointestinal neuroendocrine tumors (carcinoid, VIPoma) cause secretory diarrhea and systemic symptoms such as flushing and wheezing. For patients with advanced symptomatic tumors that cannot be completely removed by surgery, octreotide decreases secretory diarrhea and systemic symptoms through inhibition of hormonal secretion and may slow tumor progression.

Other Causes of Diarrhea

Octreotide inhibits intestinal secretion and has dose-related effects on bowel motility. In low doses (50 µg subcutaneously) it stimulates motility, whereas at higher doses (eg, 100–250 µg subcutaneously), it inhibits motility. Octreotide is effective in higher doses for the treatment of diarrhea due to vagotomy or dumping syndrome as well as for diarrhea caused by short bowel syndrome or AIDS. Octreotide has been used in low doses (50 µg subcutaneously) to stimulate small bowel motility in patients with small bowel bacterial overgrowth or intestinal pseudo-obstruction secondary to scleroderma.

Other Uses

Because it inhibits pancreatic secretion, octreotide may be of value in patients with pancreatic fistula. The role of octreotide in the treatment of pituitary tumors (eg, acromegaly) is discussed in

Chapter 37: Hypothalamic & Pituitary Hormones. Octreotide is sometimes used in gastrointestinal bleeding (see below).

Adverse Effects

Impaired pancreatic secretion may cause steatorrhea, which can lead to fat-soluble vitamin deficiency. Alterations in gastrointestinal motility cause nausea, abdominal pain, flatulence, and diarrhea. Due to inhibition of gallbladder contractility and alterations in fat absorption, long-term use can cause formation of sludge or gallstones in over half of patients, which rarely results in the development of acute cholecystitis. Because octreotide alters the balance between insulin, glucagon, and growth hormone, hyperglycemia or, less frequently, hypoglycemia (usually mild) can occur. Prolonged treatment with octreotide may result in hypothyroidism. Octreotide also can cause bradycardia.

Katzung PHARMACOLOGY, 9e > Section X. Special Topics > Chapter 63. Drugs Used in the Treatment of Gastrointestinal Diseases >

Drugs Used for the Treatment of Irritable Bowel Syndrome (IBS)

Irritable bowel syndrome is an idiopathic chronic, relapsing disorder characterized by abdominal discomfort (pain, bloating, distention, or cramps) in association with alterations in bowel habits (diarrhea, constipation, or both). With episodes of abdominal pain or discomfort, patients note a change in the frequency or consistency of their bowel movements.

Pharmacologic therapies for irritable bowel syndrome are directed at relieving abdominal pain and discomfort and improving bowel function. For patients with predominant diarrhea, antidiarrheal agents, especially loperamide, are helpful in reducing stool frequency and fecal urgency. For patients with predominant constipation, fiber supplements may lead to softening of stools and reduced straining; however, increased gas production may exacerbate bloating and abdominal discomfort. Consequently, osmotic laxatives, especially milk of magnesia, are commonly used to soften stools and promote increased stool frequency.

For the treatment of chronic abdominal pain, low doses of tricyclic antidepressants (eg, amitriptyline or desipramine 10–25 mg/d) appear to be helpful (see Chapter 30: Antidepressant Agents). At these doses, these agents have no effect on mood but may alter central processing of visceral afferent information. The anticholinergic properties of these agents also may have effects on gastrointestinal motility and secretion, reducing stool frequency and liquidity of stools. Finally, tricyclic antidepressants may alter receptors for enteric neurotransmitters such as serotonin, affecting visceral afferent sensation.

Several other agents are available that are specifically intended for the treatment of irritable bowel syndrome.

Antispasmodics (Anticholinergics)

Some agents are promoted as providing relief of abdominal pain or discomfort through "antispasmodic" actions. However, small or large bowel spasm has not been found to be an important factor in symptom causation in patients with irritable bowel syndrome. These agents work primarily through anticholinergic activities. Commonly used medications in this class include **dicyclomine** (Bentyl) and **hyoscyamine** (Levsin). These drugs inhibit muscarinic cholinergic receptors in the enteric plexus and on smooth muscle. Efficacy of these agents for relief of abdominal symptoms has

never been convincingly demonstrated. At low doses, they have minimal autonomic effects. However, at higher doses they exhibit significant anticholinergic side effects including dry mouth, visual disturbances, urinary retention, and constipation. For these reasons, these drugs are infrequently used.

Serotonin 5-HT₃ Receptor Antagonists

Inhibition of 5-HT₃ receptors in the gastrointestinal tract results in modulation of visceral afferent pain sensation and intestinal motility. **Alosetron** is a 5-HT₃ antagonist that has been approved for the treatment of patients with severe irritable bowel syndrome with diarrhea (Figure 63–5). Three other 5-HT₃ antagonists (ondansetron, granisetron, dolasetron) have been approved for the prevention and treatment of nausea and vomiting (see Antiemetics); however, their efficacy in the treatment of irritable bowel syndrome has not been determined. The relative differences between these 5-HT₃ antagonists that determine their pharmacodynamic effects have not been well studied.

Figure 63–5.

Pharmacokinetics & Pharmacodynamics

Alosetron is a highly potent and specific antagonist of the 5-HT₃ receptor. It is rapidly absorbed from the gastrointestinal tract with a bioavailability of 50–60% and has a plasma half-life of 1.5 hours but a much longer duration of effect. It undergoes extensive hepatic cytochrome P450 metabolism with renal excretion of most metabolites.

Alosetron blocks 5-HT₃ receptors on enteric afferent neurons, inhibiting distention-induced sensory and motor reflex activation. Blockade of central 5-HT₃ receptors also reduces central response to visceral stimulation. 5-HT₃ receptor blockade on enteric cholinergic neurons inhibits colonic motility, especially in the left colon, increasing total colonic transit time. Alosetron binds with higher affinity and dissociates more slowly from 5-HT₃ receptors than other 5-HT₃ antagonists, which may account for its long duration of action.

Clinical Uses

Alosetron currently is approved for the treatment of women with severe irritable bowel syndrome in whom diarrhea is the predominant symptom ("diarrhea-predominant IBS"). Efficacy in men has not been established. In a dosage of 1 mg once or twice daily, it reduces IBS-related lower abdominal pain, cramps, urgency, and diarrhea. Approximately 50–60% of patients report adequate relief of pain and discomfort compared with 30–40% of patients treated with placebo. It also leads to a reduction in the mean number of bowel movements per day and improvement in stool consistency. This agent has not been evaluated for the treatment of other causes of diarrhea.

Adverse Events

In contrast to the excellent safety profile of other 5-HT₃ receptor antagonists, alosetron is associated with rare but serious gastrointestinal toxicity. Constipation occurs in up to 30% of patients with diarrhea-predominant IBS, requiring discontinuation of the drug in 10%. Serious complications of constipation requiring hospitalization or surgery have occurred in 1 of every 1000 patients. Episodes of ischemic colitis—some fatal—have been reported in up to 3 of every 1000 patients. Given the seriousness of these adverse events, alosetron is restricted to women with severe diarrhea-predominant IBS who have not responded to conventional therapies and who have been educated about the relative risks and benefits.

Drug Interactions

Despite being metabolized by a number of CYP enzymes, alosetron does not appear to have clinically significant interactions with other drugs.

Serotonin 5-HT₄ Receptor Agonist

Pharmacokinetics & Pharmacodynamics

Tegaserod is a partial serotonin 5-HT₄ agonist that resembles serotonin in structure. Although it binds with high affinity to 5-HT₄ receptors, it has no appreciable binding to 5-HT₃ (unlike cisapride) or dopamine receptors (unlike metoclopramide or domperidone). Tegaserod has a bioavailability of only 10%. It should be taken before meals because food further reduces bioavailability by 50%. The drug is metabolized both by gastric acid-catalyzed hydrolysis and hepatic glucuronidation. Approximately 66% of drug is excreted unchanged in the feces and 33% as a metabolite in the urine. It should not be given to patients with severe hepatic or renal impairment.

Research with tegaserod suggests that stimulation of 5-HT₄ receptors on mucosal afferent nerve fibers triggers the release of neurotransmitters from the submucosal and myenteric plexuses, including calcitonin gene-related peptide, that stimulate the peristaltic reflex. These neurotransmitters stimulate proximal bowel contraction (via acetylcholine and substance P) and distal bowel relaxation (via nitric oxide and vasoactive intestinal peptide). Thus, tegaserod binding to mucosal 5-HT₄ receptors promotes gastric emptying and enhances small and large bowel transit. Stimulation of 5-HT₄ receptors activates cAMP-dependent chloride secretion from the colon, leading to increased stool liquidity. In animal models, stimulation of 5-HT₄ receptors appears to modulate visceral afferent sensation of bloating and distention.

Clinical Uses

Tegaserod was recently approved for the treatment of patients with irritable bowel syndrome with

predominant constipation. Controlled studies have demonstrated a modest improvement in patient global satisfaction and a reduction in severity of pain and bloating in patients treated with tegaserod 6 mg twice daily compared with placebo. Tegaserod also increases the number of bowel movements per week and reduces the hardness of stools. The role of tegaserod in the treatment of other gastrointestinal motility disorders such as nonulcer dyspepsia, gastroparesis, and chronic constipation is under investigation.

Adverse Effects

Tegaserod appears to be an extremely safe agent. Diarrhea occurs in 9% of patients within the first few days of treatment, but resolves in the majority of patients. Less than 2% of patients discontinue the drug because of diarrhea. Although it is stated that the drug does not cross the blood-brain barrier (and does not affect central serotonin receptors), headache may occur.

Drug Interactions

Tegaserod has no known effects on cytochrome P450 enzymes and no known drug interactions. Unlike cisapride, tegaserod does not inhibit cardiac repolarization and does not prolong the QT interval.

Katzung PHARMACOLOGY, 9e > Section X. Special Topics > Chapter 63. Drugs Used in the Treatment of Gastrointestinal Diseases >

Antiemetic Agents

Nausea and vomiting may be manifestations of a wide variety of conditions, including adverse effects from medications; systemic disorders or infections; pregnancy; vestibular dysfunction; central nervous system infection or increased pressure; peritonitis; hepatobiliary disorders; radiation or chemotherapy; and gastrointestinal obstruction, dysmotility, or infections.

Pathophysiology

The brainstem vomiting center is located in the lateral medullary reticular formation and coordinates the complex act of vomiting through interactions with cranial nerves VIII and X and neural networks in the nucleus tractus solitarius that control respiratory, salivatory, and vasomotor centers. High concentrations of muscarinic, histamine H₁, and serotonin 5-HT₃ receptors have been identified in the vomiting center.

There are five sources of afferent input to the vomiting center:

1. The chemoreceptor trigger zone is located in the fourth ventricle in the area postrema. This is outside the blood-brain barrier and is accessible to emetogenic stimuli in the blood or cerebrospinal fluid. The chemoreceptor trigger zone is rich in dopamine D₂ receptors, serotonin 5-HT₃ receptors, and opioid receptors.
2. The vestibular system is important in motion sickness via cranial nerve VIII. It is rich in muscarinic and histamine H₁ receptors.
3. Irritation of the pharynx, innervated by the vagus nerve, provokes a prominent gag and retch

response.

4. Vagal and enteric afferents in the mucosa of the gastrointestinal tract are rich in 5-HT₃ receptors. Irritation of the gastrointestinal mucosa by chemotherapy, radiation therapy, distention, or acute infectious gastroenteritis leads to release of mucosal serotonin and activation of these receptors, which stimulate vagal afferent input to the vomiting center and chemoreceptor trigger zone.

5. The central nervous system plays a role in vomiting due to psychiatric disorders, stress, and anticipatory vomiting prior to chemotherapy.

Identification of the different neurotransmitters involved with emesis has allowed development of a diverse group of antiemetic agents that have affinity for various receptors. Combinations of antiemetic agents with different mechanisms of action are often used, especially in patients with vomiting due to chemotherapeutic agents.

Serotonin 5-HT₃ Antagonists

Pharmacokinetics & Pharmacodynamics

Selective 5-HT₃ receptor antagonists have potent antiemetic properties that are mediated mainly through peripheral 5-HT₃ receptor blockade on intestinal vagal afferents. In addition, central 5-HT₃ receptor blockade in the vomiting center and chemoreceptor trigger zone probably plays an important role. The antiemetic action of these agents is restricted to emesis attributable to vagal stimulation; other emetic stimuli such as motion sickness are poorly controlled.

Three agents are available: **ondansetron**, **granisetron**, and **dolasetron**. The drugs have a long serum half-life of 4–9 hours and may be administered once or twice daily by oral or intravenous routes. The drugs undergo extensive hepatic metabolism and are eliminated by renal and hepatic excretion. However, dose reduction is not required in geriatric patients or patients with renal insufficiency. For patients with hepatic insufficiency, dose reduction may be required with ondansetron.

These agents do not exhibit dopamine receptor or muscarinic receptor antagonism. They do not have effects on esophageal or gastric motility but may slow colonic transit.

Clinical Uses

Chemotherapy-Induced Nausea and Vomiting

5-HT₃ receptor antagonists are the primary agents for the prevention and treatment of chemotherapy induced nausea and emesis. The drugs are most effective when given by intravenous injection 30 minutes prior to administration of chemotherapy in the following doses: ondansetron 32 mg, granisetron 10 µg/kg, and dolasetron 1.8 mg/kg. These doses may be repeated every 24 hours. For less emetogenic regimens, oral administration may be effective in the following regimens: ondansetron 8 mg every 8–12 hours, granisetron 2 mg/d, and dolasetron 100 mg/d. Clinical studies suggest that the efficacy of 5-HT₃ receptor antagonists is enhanced by administration of dexamethasone 6–10 mg every 6 hours for two to four doses. Other antiemetics may also be used in combination with 5-HT₃ receptor antagonists to prevent emesis or to treat delayed emesis; these include phenothiazines or metoclopramide (for dopaminergic blockade), and benzodiazepines.

Postoperative and Post-Radiation Nausea and Vomiting

5-HT₃ receptor antagonists are used to prevent or treat postoperative nausea and vomiting. Due to side effects and increased restrictions on use of other antiemetic agents, 5-HT₃ receptor antagonists are increasingly used for this indication. They are also effective in the prevention and treatment of nausea and vomiting in patients undergoing radiation therapy to the whole body or abdomen.

Other Indications

The efficacy of 5-HT₃ receptor antagonists for the treatment of nausea and vomiting due to acute or chronic medical illness or acute gastroenteritis has not been evaluated.

Adverse Effects

These 5-HT₃ receptor antagonists are well-tolerated agents with excellent safety profiles. The most commonly reported side effects are headache, dizziness, and constipation. All three agents cause a small but statistically significant prolongation of the QT interval, but this is most pronounced with dolasetron. Although cardiac arrhythmias have not been linked to use of dolasetron, it should not be administered to patients with prolonged QT or in conjunction with other medications that may prolong the QT interval.

Drug Interactions

No significant drug interactions have been reported. All three agents undergo some metabolism by the hepatic cytochrome P450 system but they do not appear to affect the metabolism of other drugs metabolized by these enzyme systems. However, other drugs may reduce hepatic clearance of the 5-HT₃ receptor antagonists, altering their half-life.

Phenothiazines & Butyrophenones

Phenothiazines are antipsychotic agents that can be used for their potent antiemetic and sedative properties (see Chapter 29: Antipsychotic Agents & Lithium). The antiemetic properties of phenothiazines are mediated through inhibition of dopamine and muscarinic receptors. Sedative properties are due to their antihistamine activity. The agents most commonly used as antiemetics are **prochlorperazine**, **promethazine**, and **thiethylperazine**.

Antipsychotic butyrophenones also possess antiemetic properties due to their central dopaminergic blockade (see Chapter 29: Antipsychotic Agents & Lithium). The main agent used is **droperidol**, which can be given by intramuscular or intravenous injection. In antiemetic doses, droperidol is extremely sedating. Until recently, it was used extensively for postoperative nausea and vomiting, in conjunction with opiates and benzodiazepines for sedation for surgical and endoscopic procedures, for neuroleptanalgesia, and for induction and maintenance of general anesthesia. Extrapyramidal side effects and hypotension may occur. Droperidol may prolong the QT interval, rarely resulting in fatal episodes of ventricular tachycardia including torsade de pointes. Therefore, droperidol should not be used in patients with QT prolongation and should only be used in patients who have not responded adequately to alternative agents.

Substituted Benzamides

Substituted benzamides include **metoclopramide** and **trimethobenzamide**. Their primary mechanism of antiemetic action is believed to be dopamine-receptor blockade. Trimethobenzamide

also has weak antihistaminic activity. For prevention and treatment of nausea and vomiting, metoclopramide may be given in the relatively high dosage of 10–20 mg orally or intravenously every 6 hours. The usual dose of trimethobenzamide is 250 mg orally, 200 mg rectally, or 200 mg by intramuscular injection. As discussed previously, the principal side effects of these central dopamine antagonists are extrapyramidal: restlessness, dystonias, and parkinsonian symptoms.

H₁ Antihistamines & Anticholinergics

The pharmacology of anticholinergic agents is discussed in Chapter 8: Cholinergic-Blocking Drugs and of H₁ antihistaminic agents in Chapter 16: Histamine, Serotonin, & the Ergot Alkaloids. As single agents, these drugs have weak antiemetic activity, although they are particularly useful for the prevention or treatment of motion sickness. Their use may be limited by sedation, dizziness, sedation, confusion, dry mouth, cycloplegia, and urinary retention. **Diphenhydramine** and one of its salts, **dimenhydrinate**, are first-generation histamine H₁ antagonists that have significant anticholinergic properties. Because of its sedating properties, diphenhydramine is commonly used in conjunction with other antiemetics for treatment of emesis due to chemotherapy. **Meclizine** is an H₁ antihistaminic agent with minimal anticholinergic properties that also has less sedation. It is used for the prevention of motion sickness and treatment of vertigo due to labyrinth dysfunction.

Hyoscine (scopolamine), a prototypic muscarinic receptor antagonist, is one of the best agents for the prevention of motion sickness. However, it has a very high incidence of anticholinergic effects when given orally or parenterally. It is better tolerated as a transdermal patch. Superiority to dimenhydrinate has not been proved.

Benzodiazepines

Benzodiazepines such as lorazepam or diazepam are used prior to the initiation of chemotherapy to reduce anticipatory vomiting or vomiting caused by anxiety. The pharmacology of these agents is presented in Chapter 22: Sedative-Hypnotic Drugs.

Cannabinoids

Dronabinol is Δ^9 -tetrahydrocannabinol, the major psychoactive chemical in marijuana (see Chapter 32: Drugs of Abuse). After oral ingestion, the drug is almost completely absorbed but undergoes significant first-pass hepatic metabolism. It undergoes hepatic metabolism and its metabolites are excreted slowly over days to weeks in the feces and urine. Like crude marijuana, dronabinol is a psychoactive agent that is used medically as an appetite stimulant and as an antiemetic, but the mechanisms for these effects are not understood. For the prevention of chemotherapy-induced nausea and vomiting, it is usually administered in conjunction with other antiemetic agents. Combination therapy with phenothiazines provides synergistic antiemetic action and appears to attenuate the adverse effects of both agents. Dronabinol is usually administered in a dosage of 5 mg/m² prior to chemotherapy and every 2–4 hours as needed. Adverse effects include euphoria, dysphoria, sedation, hallucinations, dry mouth, and increased appetite. It has some autonomic effects that may result in tachycardia, conjunctival injection, and orthostatic hypotension. Dronabinol has no significant drug-drug interactions but may potentiate the clinical effects of other psychoactive agents.

Corticosteroids

Corticosteroids (dexamethasone, methylprednisolone) have antiemetic properties, but the basis for these effects is unknown. These agents are commonly used in combination with other agents in the

treatment of chemotherapy-induced vomiting. The pharmacology of this class of drugs is discussed in Chapter 39: Adrenocorticosteroids & Adrenocortical Antagonists.

Katzung PHARMACOLOGY, 9e > Section X. Special Topics > Chapter 63. Drugs Used in the Treatment of Gastrointestinal Diseases >

Drugs Used to Treat Inflammatory Bowel Disease (IBD)

Inflammatory bowel disease comprises two distinct disorders: ulcerative colitis and Crohn's disease. The etiology and pathogenesis of these disorders remains unknown. For this reason, pharmacologic treatment of inflammatory bowel disorders often involves drugs that belong to different therapeutic classes and have different but nonspecific mechanisms of anti-inflammatory action.

Aminosalicylates

Chemistry & Formulations

Drugs that contain **5-aminosalicylic acid (5-ASA)** have been used successfully for decades in the treatment of inflammatory bowel diseases. 5-ASA differs from salicylic acid only by the addition of an amino group at the 5 (meta) position. Aminosalicylates are believed to work topically (not systemically) in areas of diseased gastrointestinal mucosa. Up to 80% of unformulated, aqueous 5-ASA is absorbed from the small intestine and does not reach the distal small bowel or colon in appreciable quantities. To overcome the rapid absorption of 5-ASA from the proximal small intestine, a number of formulations have been designed to deliver 5-ASA to various distal segments of the small bowel or the colon. These include **sulfasalazine, olsalazine, balsalazide**, and various forms of **mesalamine**.

Azo Compounds

Sulfasalazine, balsalazide, and olsalazine contain 5-ASA bound by an azo (N=N) bond to an inert compound or to another 5-ASA molecule (Figure 63–6). In sulfasalazine, 5-ASA is bound to sulfapyridine; in balsalazide, 5-ASA is bound to 4-aminobenzoyl-B-alanine; and in olsalazine, two 5-ASA molecules are bound together. The azo structure markedly reduces absorption of the parent drug from the small intestine. In the terminal ileum and colon, resident bacteria cleave the azo bond by means of an azoreductase enzyme, releasing the active 5-ASA. Consequently, high concentrations of active drug are made available in the terminal ileum or colon.

Figure 63–6.

Mesalamine Compounds

A number of proprietary formulations have been designed that package 5-ASA in various ways in order to deliver it to different segments of the small or large bowel. These 5-ASA formulations are known generically as **mesalamine**. **Pentasa** is a mesalamine formulation that contains time-release microgranules that release 5-ASA throughout the small intestine. **Asacol** has 5-ASA coated in a pH-sensitive resin that dissolves at pH 7 (the pH of the distal ileum and proximal colon). 5-ASA also may be delivered in high concentrations to the rectum and sigmoid colon by means of enema formulations (**Rowasa**) or suppositories (**Canasa**).

Pharmacokinetics & Pharmacodynamics

Although unformulated 5-ASA is readily absorbed from the small intestine, absorption of 5-ASA from the colon is extremely low. In contrast, approximately 20–30% of 5-ASA from oral mesalamine formulations is systemically absorbed in the small intestine. Absorbed 5-ASA undergoes N-acetylation in the gut epithelium and liver to a metabolite that does not possess significant anti-inflammatory activity. The acetylated metabolite is excreted by the kidneys.

Of the azo compounds, 10% of sulfasalazine and less than 1% of balsalazide are absorbed as native compounds. After azoreductase breakdown of sulfasalazine, over 85% of the carrier molecule sulfapyridine is systemically absorbed from the colon. Sulfapyridine undergoes hepatic metabolism (including acetylation) followed by renal excretion. By contrast, after azoreductase breakdown of balsalazide, over 70% of the carrier peptide is recovered intact in the feces and only a small amount

of systemic absorption occurs.

The mechanism of action of 5-ASA is not certain. The primary action of salicylate and other NSAIDs is due to blockade of prostaglandin synthesis by inhibition of cyclooxygenase. However, the aminosalicylates have variable effects on prostaglandin production. It is believed that 5-ASA modulates inflammatory mediators derived from both the cyclooxygenase and lipoxygenase pathways. Other potential mechanisms of action of the 5-ASA drugs relate to their ability to interfere with the production of inflammatory cytokines. 5-ASA inhibits the activity of nuclear factor- κ B (NF- κ B), an important transcription factor for proinflammatory cytokines. 5-ASA may also inhibit cellular functions of natural killer cells, mucosal lymphocytes, and macrophages, and it may scavenge reactive oxygen metabolites.

Clinical Uses

5-ASA drugs induce and maintain remission in ulcerative colitis and are considered to be the first-line agents for treatment of mild to moderate active ulcerative colitis. Their efficacy in Crohn's disease is not as well established, although many clinicians use 5-ASA agents as first-line therapy for mild to moderate disease involving the colon or distal ileum.

The effectiveness of 5-ASA therapy depends in part on achieving high drug concentration at the site of active disease. Thus, 5-ASA suppositories or enemas are useful in patients with ulcerative colitis or Crohn's disease confined to the rectum (proctitis) or distal colon (proctosigmoiditis). In patients with ulcerative colitis or Crohn's colitis that extends to the proximal colon, both the azo compounds and mesalamine formulations are useful. For the treatment of Crohn's disease involving the small bowel, mesalamine compounds, which release 5-ASA in the small intestine, have a theoretic advantage over the azo compounds.

Adverse Effects

Sulfasalazine has a high incidence of adverse effects, most of which are attributable to systemic effects of the sulfapyridine molecule. Slow acetylators of sulfapyridine have more frequent and more severe adverse effects than fast acetylators. Up to 40% of patients cannot tolerate therapeutic doses of sulfasalazine. The most common problems are dose-related and include nausea, gastrointestinal upset, headaches, arthralgias, myalgias, bone marrow suppression, and malaise. Hypersensitivity to sulfapyridine (or, rarely, 5-ASA) results in fever, exfoliative dermatitis, pancreatitis, pneumonitis, hemolytic anemia, pericarditis, or hepatitis. Sulfasalazine has also been associated with oligospermia, which reverses upon discontinuation of the drug. Sulfasalazine impairs folate absorption and processing; hence, dietary supplementation with 1 mg/d folic acid is recommended.

In contrast to sulfasalazine, other aminosalicylate formulations are well tolerated. In most clinical trials, the frequency of drug adverse events is similar to patients treated with placebo. For unclear reasons, olsalazine may stimulate a secretory diarrhea—which should not be confused with active inflammatory bowel disease—in 10% of patients. Rare hypersensitivity reactions may occur with all aminosalicylates but are much less common than with sulfasalazine. Careful studies have documented subtle changes indicative of renal tubular damage in patients receiving high doses of aminosalicylates. Rare cases of interstitial nephritis are reported, particularly in association with high doses of mesalamine formulations; this may be attributable to the higher serum 5-ASA levels attained with these drugs. Sulfasalazine and other aminosalicylates rarely cause worsening of colitis, which may be misinterpreted as refractory colitis.

Glucocorticoids

Pharmacokinetics & Pharmacodynamics

In gastrointestinal practice, prednisone and prednisolone are the most commonly used oral glucocorticoids. These drugs have an intermediate duration of biologic activity allowing once daily dosing.

Hydrocortisone enemas, foam, or suppositories are used to maximize colonic tissue effects and minimize systemic absorption via topical treatment of active inflammatory bowel disease in the rectum and sigmoid colon. Absorption of hydrocortisone is reduced with rectal administration, although 15–30% of the administered dosage is absorbed.

Budesonide is a potent synthetic analog of prednisolone that has high affinity for the glucocorticoid receptor but is subject to rapid first-pass hepatic metabolism (in part by CYP3A4) resulting in low oral bioavailability. A controlled-release oral formulation of budesonide (Entocort) is now available that releases the drug in the distal ileum and colon where it is absorbed. The bioavailability of controlled-release budesonide capsules is approximately 10%.

As in other tissues, glucocorticoids inhibit production of inflammatory cytokines (TNF- α , IL-1) and chemokines (IL-8); reduce expression of inflammatory cell adhesion molecules; and inhibit gene transcription of nitric oxide synthase, phospholipase A₂, cyclooxygenase-2, and NF- κ B.

Clinical Uses

Glucocorticoids are commonly used in the treatment of patients with moderate to severe active inflammatory bowel disease. Active disease is commonly treated with an initial oral dosage of 40–60 mg/d of prednisone or prednisolone. Higher doses have not been shown to be more efficacious but have significantly greater adverse effects. Once a patient responds to initial therapy (usually within 1–2 weeks), the dosage is tapered to minimize development of adverse effects. In severely ill patients, the drugs are usually administered intravenously.

For the treatment of inflammatory bowel disease involving the rectum or sigmoid colon, rectally administered glucocorticoids are preferred because of their lower systemic absorption.

Oral controlled-release budesonide (9 mg/d) is increasingly used in the treatment of active mild to moderate Crohn's disease involving the ileum and proximal colon. It appears to be slightly less effective than prednisolone in achieving clinical remission, but has significantly less adverse systemic effects.

Corticosteroids are not useful to maintain disease remission. Other medications such as aminosalicylates or immunosuppressive agents should be used for this purpose.

Adverse Effects

Side effects of glucocorticoids are reviewed in Chapter 39: Adrenocorticosteroids & Adrenocortical Antagonists.

Purine Analogs: Azathioprine & 6-Mercaptopurine

Pharmacokinetics & Pharmacodynamics

Azathioprine and 6-mercaptopurine are purine antimetabolites that have immunosuppressive properties (see Chapter 55: Cancer Chemotherapy and Chapter 56: Immunopharmacology).

Azathioprine and 6-mercaptopurine have a serum half-life of less than 2 hours; however, the active metabolites, 6-thioguanine nucleotides, are concentrated in cells resulting in a prolonged half-life of days. The prolonged kinetics of 6-thioguanine nucleotide results in a median delay of 17 weeks before onset of therapeutic benefit from oral azathioprine or 6-mercaptopurine is observed in patients with inflammatory bowel disease.

The molecular basis for the therapeutic effects of the purine analogs is unknown. Intracellular 6-thioguanine causes inhibition of purine nucleotide metabolism and DNA synthesis and repair, resulting in inhibition of cell division and proliferation.

Clinical Uses

Azathioprine and 6-mercaptopurine are important agents in the induction and maintenance of remission of ulcerative colitis and Crohn's disease. After 3–6 months of treatment, 50–60% of patients with active disease achieve remission. These agents help maintain remission in up to 80% of patients. Among patients who depend on long-term glucocorticoid therapy to control active disease, purine analogs allow dose reduction or elimination of steroids in the majority.

Adverse Effects

Dose-related toxicities of azathioprine or 6-mercaptopurine include nausea, vomiting, bone marrow depression (leading to leukopenia, macrocytosis, anemia, or thrombocytopenia), and hepatic toxicity. Routine laboratory monitoring with complete blood count and liver function tests is required. Leukopenia or elevations in liver chemistries usually respond to medication dose reduction. Severe leukopenia may predispose to opportunistic infections; leukopenia may respond to therapy with granulocyte stimulating factor. Hypersensitivity reactions to azathioprine or 6-mercaptopurine occur in 5% of patients. These include fever, rash, pancreatitis, diarrhea, and hepatitis.

Although there appears to be an increased risk of lymphoma in transplant recipients receiving long-term 6-mercaptopurine or azathioprine therapy, it is unclear whether the risk is increased among patients with inflammatory bowel disease. These drugs cross the placenta; however, there are many reports of successful pregnancies in women taking these agents, and the risk of teratogenicity appears to be small.

Drug Interactions

Allopurinol markedly reduces metabolism of the purine analogs, potentially leading to severe leukopenia. The dose of 6-mercaptopurine or azathioprine should be reduced by at least half in patients taking allopurinol.

Methotrexate

Pharmacokinetics & Pharmacodynamics

Methotrexate is another antimetabolite that has beneficial effects in a number of chronic inflammatory diseases, including Crohn's disease and rheumatoid arthritis (see Chapter 36: Nonsteroidal Anti-Inflammatory Drugs, Disease-Modifying Antirheumatic Drugs, Nonopioid

Analgesics, & Drugs Used in Gout), and in cancer (see Chapter 55: Cancer Chemotherapy). Methotrexate may be given orally, subcutaneously, and intramuscularly. Reported oral bioavailability is 50–90% at doses used in chronic inflammatory diseases. Intramuscular and subcutaneous methotrexate exhibit nearly complete bioavailability.

The principal mechanism of action is inhibition of dihydrofolate reductase, an enzyme important in the production of thymidine and purines. At the high doses used for chemotherapy, methotrexate inhibits cellular proliferation. However, at the low doses used in the treatment of inflammatory bowel disease (12–25 mg/wk), the antiproliferative effects may not be evident. Methotrexate shares structural homology with interleukin-1 and may interfere with its inflammatory actions. It may also stimulate increased release of adenosine, an endogenous anti-inflammatory autacoid. Methotrexate may also stimulate apoptosis and death of activated T lymphocytes.

Clinical Uses

Methotrexate is used to induce and maintain remission in patients with Crohn's disease. Its efficacy in ulcerative colitis is uncertain. To induce remission, patients are treated with 15–25 mg of methotrexate once weekly by subcutaneous injection. If a satisfactory response is achieved within 8–12 weeks, the dose is reduced to 15 mg/wk.

Adverse Effects

At higher dosage, methotrexate may cause bone marrow depression, megaloblastic anemia, alopecia, and mucositis. At the doses used in the treatment of inflammatory bowel disease, these events are uncommon but warrant dose reduction if they do occur. Folate supplementation reduces the risk of these events without impairing the anti-inflammatory action.

In patients with psoriasis treated with methotrexate, hepatic damage is common; however, among patients with inflammatory bowel disease and rheumatoid arthritis, the risk is significantly lower. Renal insufficiency may increase risk of hepatic accumulation and toxicity.

Anti-TNF-Alpha Therapy

Pharmacokinetics & Pharmacodynamics

A dysregulation of the TH1 T cell response is present in inflammatory bowel disease, especially Crohn's disease. One of the key proinflammatory cytokines in the TH1 response is TNF- α . **Infliximab** is a chimeric mouse-human monoclonal antibody to human TNF- α . It consists of human IgG1 constant regions, human κ light chains and transplanted monoclonal murine variable regions that have a high affinity for TNF- α . The molecule is 25% murine and 75% human.

Infliximab is administered as an intravenous infusion. The plasma concentration is linearly proportionate to dose and its elimination follows first-order kinetics. At therapeutic doses of 5–10 mg/kg, the half-life of infliximab is approximately 8–10 days, resulting in plasma disappearance of antibodies over 8–12 weeks.

The biologic activity of TNF- α is mediated by binding of soluble or membrane-bound TNF- α trimers to cell-surface TNF- α receptors. Infliximab binds to soluble TNF- α trimers with high affinity, preventing the cytokine from binding to its receptors. Serum TNF- α concentrations may actually increase because binding to infliximab slows TNF- α clearance. Infliximab also binds to membrane-bound TNF- α and neutralizes its activity. Furthermore, the Fc portion of human IgG1

region of infliximab promotes complement activation and antibody-mediated cellular cytotoxicity of inflammatory cells.

Clinical Uses

Infliximab leads to symptomatic improvement in two thirds and disease remission in one third of patients with moderately severe or fistulizing Crohn's disease, including patients who have been dependent on glucocorticoids or who have not responded to 6-mercaptopurine or methotrexate. The median time to clinical response is 2 weeks. Infliximab induction therapy is generally given in a dosage of 5 mg/kg at 0, 2, and 6 weeks. Patients who respond may be treated with repeat infusions every 6–12 weeks to maintain remission with or without other therapies.

Adverse Effects

The most important adverse effect of infliximab therapy is infection due to suppression of the TH1 inflammatory response. Reactivation of latent tuberculosis, with dissemination, has occurred. Before administering infliximab, all patients must undergo purified protein derivative (PPD) testing; prophylactic therapy for tuberculosis is warranted for patients with positive test results. Other infections include pneumonia, sepsis, pneumocystosis, and listeriosis.

Infliximab infusions result in acute adverse infusion reactions in > 10% of patients, but discontinuation of the infusion is required in only 1%. Early reactions include fever, chills, pruritus, urticaria, or cardiopulmonary symptoms that include chest pain, dyspnea, or hemodynamic instability. Infusion reactions are more common with the second or subsequent infusions than with the first. Reactions may be reduced with prophylactic administration of acetaminophen and diphenhydramine.

An antibody directed at the murine epitope of infliximab may develop in patients. A delayed infusion reaction, which occurs 1–2 weeks after infusion, develops in approximately 5% patients who are re-treated with infliximab. Delayed infusion reaction is more common in patients with circulating anti-infliximab antibodies (20–30% of those getting multiple infusions) than in those without the antibodies. These reactions consist of myalgia; arthralgia; fever; rash; urticaria; and facial, hand, and lip edema. Delayed reactions respond to symptomatic treatment with antihistamines or corticosteroids. Positive antinuclear antibodies (ANA) and anti-dsDNA develop in a small number of patients. Development of a lupus-like syndrome has been reported that resolved after discontinuation of the drug.

Several malignancies have developed in patients who were treated with infliximab. However, the observed rates may be similar to those expected in patients with inflammatory bowel disease.

Katzung PHARMACOLOGY, 9e > Section X. Special Topics > Chapter 63. Drugs Used in the Treatment of Gastrointestinal Diseases >

Pancreatic Enzyme Supplements

Exocrine pancreatic insufficiency is most commonly caused by cystic fibrosis, chronic pancreatitis, or pancreatic resection. When secretion of pancreatic enzymes falls below 10% of normal, fat and protein maldigestion occur which can lead to steatorrhea, azotorrhea, vitamin malabsorption, and weight loss. Pancreatic enzyme supplements, which contain a mixture of amylase, lipase, and proteases, are the mainstay of treatment for pancreatic enzyme insufficiency. Two major types of preparations in use are **pancreatin** and **pancrelipase**. Pancreatin is an alcohol-derived extract of

hog pancreas with relatively low concentrations of lipase and proteolytic enzymes, whereas pancrelipase is an enriched preparation. On a per weight basis, pancrelipase has approximately 12 times the lipolytic activity and more than 4 times the proteolytic activity of pancreatin. Consequently, pancreatin is no longer in common clinical use. Only pancrelipase will be discussed here.

Pancrelipase is available in both nonenteric-coated and enteric-coated preparations. Pancrelipase enzymes are rapidly and permanently inactivated by gastric acids. Therefore, nonenteric-coated preparations (eg, Cotazym, Viokase) should be given concomitantly with acid suppression therapy (proton pump inhibitor or H₂ antagonist) in order to reduce acid-mediated destruction within the stomach. Encapsulated formulations contain acid-resistant microspheres (Creon) or microtablets (Pancrease, Ultrase). Enteric-coated formulations are more commonly used because they do not require concomitant acid suppression therapy.

Pancrelipase preparations are administered with each meal and snack. Formulations are available in sizes containing varying amounts of lipase, amylase, and protease. However, manufacturers' listings of enzyme content do not always reflect true enzymatic activity. Dosing should be individualized according to the age and weight of the patient, the degree of pancreatic insufficiency, and the amount of dietary fat intake. Therapy is initiated at a dose that provides 30,000 units of lipase activity in the prandial and postprandial period—a level that is sufficient to reduce steatorrhea to a clinically insignificant level in most cases. Suboptimal response to enteric-coated formulations may be due to poor mixing of granules with food and/or slow dissolution and release of enzymes. Gradual increase of dose, change to a different formulation, or addition of acid suppression therapy may improve response.

Pancreatic enzyme supplements are well-tolerated. The capsules should be swallowed, not chewed, as pancreatic enzymes may cause oropharyngeal mucositis. Excessive doses may cause diarrhea and abdominal pain. The high purine content of pancreas extracts may lead to hyperuricosuria and renal stones. Several cases of colonic strictures were reported in patients with cystic fibrosis receiving high doses of pancrelipase with high lipase activity. These high dose formulations have since been removed from the market.

Bile Acid Therapy for Gallstones

Ursodiol (ursodeoxycholic acid) is a naturally occurring bile acid that makes up less than 5% of the circulating bile salt pool in humans and a much higher percentage in bears. After oral administration, it is absorbed, conjugated in the liver with glycine or taurine, and excreted in the bile. Conjugated ursodiol undergoes extensive enterohepatic recirculation. The serum half-life is approximately 100 hours. With long-term daily administration, ursodiol constitutes 30–50% of the circulating bile acid pool. A small amount of unabsorbed conjugated or unconjugated ursodiol passes into the colon where it is either excreted or undergoes dehydroxylation by colonic bacteria to lithocholic acid, a substance with potential hepatic toxicity.

Pharmacodynamics

Ursodiol is used for the dissolution of cholesterol gallstones. The solubility of cholesterol in bile is determined by the relative proportions of bile acids, lecithin, and cholesterol. Although prolonged ursodiol therapy expands the bile acid pool, this does not appear to be the principal mechanism of

action for dissolution of gallstones. Ursodiol decreases the cholesterol content of bile by reducing hepatic cholesterol secretion. Ursodiol also appears to stabilize hepatocyte canalicular membranes, possibly through a reduction in the concentration of other endogenous bile acids or through inhibition of immune-mediated hepatocyte destruction.

Clinical Use

Ursodiol is used for dissolution of small cholesterol gallstones in patients with symptomatic gallbladder disease who refuse cholecystectomy or who are poor surgical candidates. At a dosage of 10 mg/kg/d for 12–24 months, dissolution occurs in up to half of patients with small (< 5–10 mm) noncalcified gallstones. It is also effective for the prevention of gallstones in obese patients undergoing rapid weight loss therapy. Several trials demonstrate that ursodiol 13–15 mg/kg/d is helpful for patients with early-stage primary biliary cirrhosis, reducing liver function abnormalities and improving liver histology.

Adverse Effects

Ursodiol is practically free of serious adverse effects. Bile salt-induced diarrhea is uncommon. Unlike its predecessor, chenodeoxycholate, ursodiol has not been associated with hepatotoxicity.

Drugs Used to Treat Variceal Hemorrhage

Portal hypertension most commonly occurs as a consequence of chronic liver disease. Portal hypertension is caused by increased blood flow within the portal venous system and increased resistance to portal flow within the liver. Splanchnic blood flow is increased in patients with cirrhosis due to low arteriolar resistance that is mediated by increased circulating vasodilators and decreased vascular sensitivity to vasoconstrictors. Intrahepatic resistance to blood flow is increased in cirrhosis due to fixed fibrosis within the spaces of Disse and hepatic veins as well as reversible vasoconstriction of hepatic sinusoids and venules. Among the consequence of portal hypertension are ascites, hepatic encephalopathy, and the development of portosystemic collaterals—especially gastric or esophageal varices. Varices can rupture, leading to massive upper gastrointestinal bleeding.

Several drugs are available that reduce portal pressures. These may be used in the short term for the treatment of active variceal hemorrhage or long term to reduce the risk of hemorrhage.

Somatostatin & Octreotide

The pharmacology of octreotide is discussed above. In patients with cirrhosis and portal hypertension, intravenous somatostatin (250 µg/h) or octreotide (50 µg/h) reduces portal blood flow and variceal pressures; however, the mechanism by which they do so is poorly understood. They do not appear to induce direct contraction of vascular smooth muscle. Their activity may be mediated through inhibition of release of glucagon and other gut neuropeptides that alter mesenteric blood flow. Although data from clinical trials are conflicting, these agents are probably effective in promoting initial hemostasis from bleeding esophageal varices. They are generally administered for 3–5 days.

Vasopressin & Terlipressin

Vasopressin (antidiuretic hormone) is a polypeptide hormone secreted by the hypothalamus and stored in the posterior pituitary. Its pharmacology is discussed in Chapters 17 and 37. Although its primary physiologic role is to maintain serum osmolality, it is also a potent arterial vasoconstrictor. When administered intravenously by continuous infusion, it causes splanchnic arterial vasoconstriction that leads to reduced splanchnic perfusion and lowered portal venous pressures. Prior to the advent of octreotide, vasopressin was commonly used to treat acute variceal hemorrhage. However, because of its high side effect profile, it is no longer used for this purpose. However, for patients with acute gastrointestinal bleeding from small bowel or large bowel vascular ectasias or diverticulosis, vasopressin may be infused into one of the branches of the superior or inferior mesenteric artery through an angiographically placed catheter to promote vasospasm. Side effects with systemic vasopressin are common. Systemic and peripheral vasoconstriction can lead to hypertension, myocardial ischemia or infarction, or mesenteric infarction. These may be reduced by coadministration of nitroglycerin, which may further reduce portal venous pressures (by reducing portohepatic vascular resistance) and may also reduce the coronary and peripheral vascular vasospasm caused by vasopressin. Other common adverse effects are nausea, abdominal cramps and diarrhea (due to intestinal hyperactivity). Furthermore, the antidiuretic effects of vasopressin promote retention of free fluid which can lead to hyponatremia, fluid retention, and pulmonary edema.

Terlipressin is a vasopressin analog that appears to have similar efficacy to vasopressin with fewer adverse effects. This agent is undergoing clinical testing in the USA.

Beta-Receptor Blocking Drugs

The pharmacology of these agents is discussed in Chapter 10: Adrenoceptor Antagonist Drugs. Beta-receptor antagonists reduce portal venous pressures via a decrease in portal venous inflow. This decrease is due to a decrease in cardiac output (β_1 blockade) and to splanchnic vasoconstriction (β_2 blockade) caused by the unopposed effect of systemic catecholamines on α -receptors. Thus, nonselective β -blockers such as propranolol and nadolol are more effective than selective β_1 blockers in reducing portal pressures. Among patients with cirrhosis and esophageal varices who have not previously had an episode of variceal hemorrhage, the incidence of bleeding among patient treated with nonselective β -blockers is 15% compared with 25% in control groups. Among patients with a history of variceal hemorrhage, the likelihood of recurrent hemorrhage is 80% within 2 years. Nonselective β -blockers significantly reduce the rate of recurrent bleeding, although a reduction in mortality is unproved.

Katzung PHARMACOLOGY, 9e > Section X. Special Topics > Chapter 63. Drugs Used in the Treatment of Gastrointestinal Diseases >

Preparations Available

Antacids

Aluminum hydroxide gel* (Amphojel, ALternaGEL, others)

Oral: 300, 500, 600 mg tablets; 400, 500 mg capsules; 320, 450, 675 mg/5 mL suspension

Calcium carbonate* (Tums, others)

Oral: 350, 420, 500, 600, 650, 750, 1000, 1250 mg chewable tablets; 1250 mg/5 mL suspension

Combination aluminum hydroxide and magnesium hydroxide preparations* (Maalox, Mylanta, Gaviscon, Gelusil, others)

Oral: 400 to 800 mg combined hydroxides per tablet, capsule, or 5 mL suspension

H₂ Histamine Receptor Blockers

Cimetidine (generic, Tagamet, Tagamet HB*)

Oral: 100*, 200, 300, 400, 800 mg tablets; 300 mg/5 mL liquid

Parenteral: 300 mg/2 mL, 300 mg/50 mL for injection

Famotidine (generic, Pepcid, Pepcid AC*)

Oral: 10 mg tablets*, gelcaps*; 20, 40 mg tablets; powder to reconstitute for 40 mg/5 mL suspension

Parenteral: 10 mg/mL for injection

Nizatidine (Axid, Axid AR*)

Oral: 75 mg tablets*; 150, 300 mg capsules

Ranitidine (generic, Zantac, Zantac 75*)

Oral: 75*, 150, 300 mg tablets; 150 mg effervescent tablets; 150, 300 mg capsules; 15 mg/mL syrup

Parenteral: 1.0, 25 mg/mL for injection

Selected Anticholinergic Drugs

Atropine (generic)

Oral: 0.4 mg tablets

Parenteral: 0.05, 0.1, 0.3, 0.4, 0.5, 0.8, 1 mg/mL for injection

Belladonna alkaloids tincture (generic)

Oral: 0.27–0.33 mg/mL liquid

Dicyclomine (generic, Bentyl, others)

Oral: 10, 20 mg capsules; 20 mg tablets; 10 mg/5 mL syrup

Parenteral: 10 mg/mL for injection

Glycopyrrolate (generic, Robinul)

Oral: 1, 2 mg tablets

Parenteral: 0.2 mg/mL for injection

***l*-Hyoscyamine** (Anaspaz, others)

Oral: 0.125, 0.15 mg tablets; 0.375 mg timed-release capsules; 0.125 mg/5 mL oral elixir and solution

Parenteral: 0.5 mg/mL for injection

Methscopolamine (Pamine)

Oral: 2.5 mg tablets

Propantheline (generic, Pro-Banthine)

Oral: 7.5, 15 mg tablets

Scopolamine (generic)

Oral: 0.4 mg tablets

Parenteral: 0.3, 0.4, 0.86, 1 mg/mL for injection

Tridihexethyl (Pathilon)

Oral: 25 mg tablets

Proton Pump Inhibitors

Esomeprazole (Nexium)

Oral: 20, 40 mg delayed-release capsules

Omeprazole (Prilosec)

Oral: 10, 20, 40 mg delayed-release capsules

Lansoprazole (Prevacid)

Oral: 15, 30 mg delayed-release capsules; 15, 30 mg enteric-coated granules for oral suspension

Pantoprazole (Protonix)

Oral: 20, 40 mg delayed release tablets

Parenteral: 40 mg/vial powder for IV injection

Rabeprazole (Aciphex)

Oral: 20 mg delayed-release tablets

Mucosal Protective Agents

Misoprostol (Cytotec)

Oral: 100, 200 µg tablets

Sucralfate (generic, Carafate)

Oral: 1 g tablets; 1 g/10 mL suspension

Digestive Enzymes

Pancrelipase (Cotazym, Pancrease, Viokase, others)

Oral: Capsules, tablets, or powder containing lipase, protease, and amylase activity. See manufacturers' literature for details.

Drugs for Motility Disorders & Selected Antiemetics

Alosetron (Lotronex)

Oral: 1 mg tablets

Cisapride (Propulsid)

Available in the USA only from the manufacturer, 877-795-4247

Dolasetron (Anzemet)

Oral: 50, 100 mg tablets

Parenteral: 20 mg/mL for injection

Dronabinol (Marinol)

Oral: 2.5, 5, 10 mg capsules

Granisetron (Kytril)

Oral: 1 mg tablets

Parenteral: 1 mg/mL for injection

Metoclopramide (generic, Reglan, others)

Oral: 5, 10 mg tablets; 5 mg/5 mL syrup, 10 mg/mL concentrated solution

Parenteral: 5 mg/mL for injection

Ondansetron (Zofran)

Oral: 4, 8, 24 mg tablets; 4 mg/5 mL solution

Parenteral: 2 mg/mL for IV injection

Prochlorperazine (Compazine)

Oral: 5, 10, 25 mg tablets; 10, 15, 30 mg capsules; 1 mg/mL solution

Rectal: 2.5, 5, 25 mg suppositories

Parenteral: 5 mg/mL for injection

Tegaserod (Zelnorm)

Oral: 2, 6 mg tablets

Selected Anti-Inflammatory Drugs Used in Gastrointestinal Disease

Balsalazide (Colazal)

Oral: 750 mg capsules

Budesonide (Entocort)

Oral: 3 mg capsules

Hydrocortisone (Cortenema, Cortifoam)

Rectal: 100 mg/60 mL unit retention enema; 90 mg/applicatorful intrarectal foam

Mesalamine (5-ASA)

Oral: Asacol: 400 mg delayed-release tablets; Pentasa: 250 mg controlled-release capsules

Rectal: Rowasa: 4 g/60 mL suspension; 500 mg suppositories

Methylprednisolone (Medrol Enpack)

Rectal: 40 mg/bottle retention enema

Olsalazine (Dipentum)

Oral: 250 mg capsules

Sulfasalazine (generic, Azulfidine, others)

Oral: 500 mg tablets and enteric-coated tablets

Infliximab (Remicade)

Parenteral: 100 mg powder for injection

Selected Antidiarrheal Drugs

Bismuth subsalicylate* (Pepto-Bismol, others)

Oral: 262 mg caplets, chewable tablets; 130, 262, 524 mg/15 mL suspension

Difenoxin (Motofen)

Oral: 1 mg (with 0.025 mg atropine sulfate) tablets

Diphenoxylate (generic, Lomotil, others)

Oral: 2.5 mg (with 0.025 mg atropine sulfate) tablets and liquid

Kaolin/pectin* (generic, Kaopectate, others)

Oral (typical): 5.85 g kaolin and 260 mg pectin per 30 mL suspension

Loperamide* (generic, Imodium, others)

Oral: 2 mg tablets, capsules; 1 mg/5 mL liquid

Selected Laxative Drugs*

Bisacodyl (generic, Dulcolax, others)

Oral: 5 mg enteric-coated tablets

Rectal: 10 mg suppositories

Cascara sagrada (generic)

Oral: 325 mg tablets; 5 mL per dose fluid extract (approximately 18% alcohol)

Castor oil (generic, others)

Oral: liquid or liquid emulsion

Docusate (generic, Colace, others)

Oral: 50, 100, 250 mg capsules; 100 mg tablets; 20, 50, 60, 150 mg/15 mL syrup

Glycerin liquid (Fleet BabyLax)

Rectal liquid: 4 mL per applicator

Glycerin suppository (generic, Sani-Supp)

Lactulose (Chronulac, Cephulac)

Oral: 10 g/15 mL syrup

Magnesium hydroxide [milk of magnesia, Epsom Salt] (generic)

Oral: 400, 800 mg/5 mL aqueous suspension

Methylcellulose

Oral: bulk powder

Mineral oil (generic, others)

Oral: liquid or emulsion

Polycarbophil (Equalactin, Mitrolan, FiberCon, Fiber-Lax)

Oral: 500, 625 mg tablets; 500 mg chewable tablets

Polyethylene glycol electrolyte solution (CoLyte, GoLYTELY, others)

Oral: Powder for oral solution, makes one gallon (approximately 4 L)

Psyllium (generic, Serutan, Metamucil, others)

Oral: 3.3, 3.4, 3.5, 4.03, 6 g psyllium granules or powder per packet

Senna (Senokot, Ex-Lax, others)

Oral: 8.6, 15, 17, 25 mg tablets; 8.8, 15 mg/mL liquid

Drugs That Dissolve Gallstones

Monoctanoin (Moctanin)

Parenteral: 120 mL bottle for bile duct perfusion

Ursodiol (Actigall)

Oral: 300 mg (Actigall) capsules

*Over-the-counter formulations.

Chapter 64. Therapeutic & Toxic Potential of Over-the-Counter Agents

Katzung PHARMACOLOGY, 9e > Section X. Special Topics > Chapter 64. Therapeutic & Toxic Potential of Over-the-Counter Agents >

Therapeutic & Toxic Potential of Over-the-Counter Agents

In the USA, drugs are divided by law into two classes: those restricted to sale by prescription only and those for which directions for safe use by the public can be written. The latter category constitutes the nonprescription or over-the-counter (OTC) drugs. In 2001, the American public spent approximately \$18 billion on over 125,000 OTC products to medicate themselves for ailments ranging from acne to warts. These products contain approximately 1000 active ingredients in various forms and combinations.

It is apparent that many OTC drugs are no more than "me too" products advertised to the public in ways that suggest that there are significant differences between them. For example, there are over 100 different systemic analgesic products, almost all of which contain aspirin, acetaminophen, nonsteroidal anti-inflammatory drugs (NSAIDs) such as ibuprofen, or a combination of these agents as primary ingredients. They are made different from one another by the addition of questionable ingredients such as caffeine or antihistamines; by brand names chosen to suggest a specific use or strength ("women's," "migraine," "arthritis," "maximum"); or by special dosage formulations (enteric-coated tablets, gels, liquids, sustained-release products, powders, seltzers). There is a price attached to all of these features, and in most cases a less expensive generic product can be equally effective. It is probably safe to assume that the public is generally overwhelmed and confused by the wide array of products presented and will probably use those that are most heavily advertised.

Since 1972, the Food and Drug Administration (FDA) has been engaged in a methodical review of OTC ingredients for both safety and efficacy. There have been two major outcomes of this review: (1) Ingredients designated as ineffective or unsafe for their claimed therapeutic use are being eliminated from OTC product formulations (eg, antimuscarinic agents have been eliminated from OTC sleep aids); and (2) Agents previously available by prescription only have been made available for OTC use because they were judged by the review panel to be generally safe and effective for consumer use without medical supervision (Table 64–1). Since the appointment of the Nonprescription Drugs Advisory Committee in 1993, the rate of switches from prescription to OTC status has accelerated. Indeed, more than 700 OTC products contain ingredients and dosages that were available only by prescription less than 30 years ago. Some agents such as docosanol and the nicotine polacrilex lozenge have bypassed the prescription route altogether and have been released directly to the OTC market. Other OTC ingredients previously available in low doses only are now available in higher-strength formulations. Examples of other prescription drugs currently under consideration for OTC reclassification include cyclobenzaprine, sucralfate, non-sedating antihistamines (cetirizine, fexofenadine), and topical penciclovir. The prescription to OTC reclassification process is very rigorous, and many agents have not been approved for OTC use. For example, the cholesterol-lowering agents cholestyramine, lovastatin, and pravastatin were denied OTC status on the basis that these agents could not be used safely and effectively in an OTC setting. The advisory committee believed that diagnosis and ongoing management by a health care provider was necessary for the management of hyperlipidemia, a chronic, asymptomatic condition with

potentially life-threatening consequences. In a similar recommendation, oral acyclovir for OTC use in the treatment of recurrent genital herpes was not approved because of concerns about misdiagnosis and inappropriate use leading to increased viral resistance.

Table 64–1. Selected Agents Switched from Prescription to Otc Status by the Food and Drug Administration.

Ingredient	Indication	Year Ingredient First Switched	Single-Ingredient Product Examples
Systemic agents			
Brompheniramine	Antihistamine	1976	Dimetapp ¹
Chlorpheniramine	Antihistamine	1976	Chlor-Trimeton
Cimetidine	Acid reducer	1995	Tagamet HB
Clemastine	Antihistamine	1992	Tavist Allergy
Dexbrompheniramine	Antihistamine	1982	Drixoral Cold & Allergy ²
Diphenhydramine	Antihistamine, sleep aid	1981	Benadryl Allergy, Sominex, Nytol
Doxylamine	Sleep aid, antihistamine	1978	Unisom
Famotidine	Acid reducer	1995	Pepcid AC
Ibuprofen	Analgesic, antipyretic	1984	Advil, Motrin IB, Nuprin
Ketoprofen	Analgesic, antipyretic	1995	Orudis KT
Loperamide	Antidiarrheal	1988	Imodium A-D
Loratadine	Antihistamine	2002	Claritin, Alavert
Naproxen sodium	Analgesic, antipyretic	1994	Aleve
Nicotine polacrilex (gum)	Smoking cessation	1996	Nicorette
Nicotine transdermal system	Smoking cessation	1996	Nicotrol, Nicoderm CQ
Nizatidine	Acid reducer	1996	Axid AR
Omeprazole	Acid reducer	2003	Prilosec OTC
Phenylpropanolamine	Nasal decongestant	1981	Not applicable ³
Pseudoephedrine	Nasal decongestant	1976	Sudafed
Pyrantel pamoate	Anthelmintic (pinworm)	1986	Pin-X, Antiminth
Ranitidine	Acid reducer	1995	Zantac 75
Tripolidine	Antihistamine	1982	Actifed ⁴

Topical agents			
Butenafine	Antifungal (topical)	2001	Lotrimin Ultra
Butoconazole	Antifungal (vaginal)	1995	Femstat-3, Mycelex-3
Clotrimazole	Antifungal (topical)	1989	Lotrimin AF, Mycelex
Clotrimazole	Antifungal (vaginal)	1990	Gyne-Lotrimin, Mycelex-7, Gyne-Lotrimin-3
Cromolyn	Nasal antiallergy	1997	Nasalcrom
Hydrocortisone	Antipruritic	1979	Cortaid, Cortizone
Ketoconazole	Dandruff shampoo	1997	Nizoral AD
Miconazole	Antifungal (topical)	1982	Micatin
Miconazole	Antifungal (vaginal)	1991	Monistat-7, Monistat-3
Minoxidil	Hair growth stimulant	1996	Rogaine Regular and Extra Strength For Men, Rogaine For Women
Naphazoline/antazoline	Ophthalmic decongestant-antihistamine	1994	Vasocon A
Naphazoline/pheniramine	Ophthalmic decongestant-antihistamine	1994	Naphcon A, Opcon A, Ocuhist
Oxymetazoline	Nasal decongestant	1976	Neo-Synephrine 12 Hour, Afrin 12 Hour
Permethrin	Pediculicide (head lice)	1990	Nix
Terbinafine	Antifungal (topical)	1999	Lamisil AT
Tioconazole	Antifungal (vaginal)	1997	Vagistat-1
Xylometazoline	Nasal decongestant	1976	Otrivin

¹No single ingredient product available (brompheniramine/pseudoephedrine combination).

²No single ingredient product available (dextbrompheniramine/pseudoephedrine combination).

³Products containing phenylpropanolamine were withdrawn from the US market in 2000 based on reports of an increased risk of hemorrhagic stroke in patients using this agent.

⁴No single ingredient product available (triprolidine/pseudoephedrine combination).

There are three reasons why it is essential for clinicians to be familiar with this class of products. First, many OTC medications are effective in treating common ailments, and it is important to be able to help the patient select a safe, effective product. Because managed care practices encourage clinicians to limit the cost of drugs they prescribe, many will begin to recommend effective OTC treatments to their patients, since these drugs are rarely paid for by the insurance plan. (See Table

medical conditions or interact with prescription medications. (See Appendix II, Drug Interactions.) Finally, the misuse or abuse of OTC products may actually produce significant medical complications. Phenylpropanolamine, for example, a sympathomimetic previously found in many cold, allergy, and weight control products, was withdrawn from the United States market by the FDA in 2000 based on reports that the drug increased the risk of hemorrhagic stroke. A general awareness of these products and their formulations will enable clinicians to more fully appreciate the potential for OTC drug-related problems in their patients.

Table 64–2. Ingredients of Known Efficacy for Selected Over-the-Counter (OTC) Classes.

OTC Category	Ingredient and Usual Adult Dosage	Product Examples	Comments
Acid reducers, H ₂ antagonists	Cimetidine, 200 mg once or twice daily	Tagamet HB	These products have been approved at lower than prescription doses for the relief of "heartburn, acid indigestion, and sour stomach." They should not be taken for longer than 2 weeks and are not recommended for children under 12 years of age.
	Famotidine, 10 mg once or twice daily	Pepcid AC	
	Nizatidine, 75 mg once or twice daily	Axid AR	
	Ranitidine, 75 mg once or twice daily	Zantac 75	
Acid reducers, proton pump inhibitors	Omeprazole magnesium, 20.6 mg once daily for 14 days	Prilosec OTC	Omeprazole is the first proton pump inhibitor approved for the treatment of frequent heartburn in adults with symptoms of heartburn 2 or more days per week. The product should not be taken for more than 14 days or more often than every 4 months unless directed by a physician. Omeprazole magnesium 20.6 mg is equivalent to 20 mg of omeprazole (prescription strength).
Acne preparations	Benzoyl peroxide, 2.5%, 5%, 10%	Clearasil, Fostex, Oxy-5, Oxy-10, various generic	One of the most effective acne preparations. Apply sparingly once or twice daily. Decrease dose if excessive skin irritation occurs.
Allergy and "cold" preparations	Chlorpheniramine, 4 mg every 4–6 hours; 8–12 mg (extended release) every 8–12 hours	Chlor-Trimeton Allergy 4 Hour, Chlor-Trimeton Allergy 12 Hour, various generic	Antihistamines alone relieve most symptoms associated with allergic rhinitis or hay fever. Chlorpheniramine, brompheniramine, and clemastine cause less
	Brompheniramine, 4	Dimetane Extentabs,	

	mg every 4–6 hours; 12 mg (extended release) every 12 hours	Dimetapp Allergy, various generic	drowsiness than diphenhydramine and doxylamine. Loratadine, a second-generation antihistamine, was recently approved for OTC use; therapeutically comparable to first-generation agents but with a much lower incidence of sedation. Occasionally, symptoms unrelieved by the antihistamine respond to the addition of a sympathomimetic.
	Clemastine 1.34 mg every 12 hours	Tavist Allergy	
	Diphenhydramine, 25–50 mg every 6–8 hours	Benadryl Allergy, various generic	
	Loratadine (10 mg) every 24 hours	Alavert, Claritin	
	Chlorpheniramine (2–4 mg) with pseudoephedrine (30–60 mg) every 4–6 hours	Allerest Maximum Strength, Sudafed Cold & Allergy, various generic	
	Diphenhydramine (25 mg) with pseudoephedrin (60 mg) every 4–6 hours	Benadryl Allergy/Sinus, various generic	
	Loratadine (10 mg with pseudoephedrine (240 mg) every 24 hours	Claritin-D 24 Hour	
	Triprolidine (2.5 mg) with pseudoephedrine (60 mg) every 4–6 hours	Actifed, various generic	
Analgesics and antipyretics	Acetaminophen, 325–650 mg every 4–6 hours	Panadol, Tylenol, various generic	There are numerous product modifications, including the addition of antacids and

			certain individuals (see text). Use of OTC products containing aspirin, other salicylates, acetaminophen, ibuprofen, naproxen, or ketoprofen may increase the risk of hepatotoxicity and gastrointestinal hemorrhage in individuals who consume three or more alcoholic drinks daily.
Antacids	Magnesium hydroxide and aluminum hydroxide alone or in combination; calcium carbonate, dosage varies; consult product labeling	Amphojel, Maalox, Milk of Magnesia, Mylanta, Tums, various generic	Combinations of magnesium and aluminum hydroxide are less likely to cause constipation or diarrhea and offer high neutralizing capacity. Some preparations include simethicone, an antiflatulent to relieve symptoms of bloating and pressure.
Anthelmintics (pinworm infection)	Pyrantel pamoate, 11 mg/kg (maximum: 1 g)	Antiminth, Pin-X, Reese's Pinworm	Treat all members of the household. Consult physician for children under age 2 years or under 25 lb. Undergarments, pajamas and linens should be washed daily until the infection is resolved.
Antidiarrheal agents	Attapulgate, 1200 mg after each loose bowel movement up to 7 doses daily	Donnagel, Kaopectate, Parepectolin, various generic	Antidiarrheals should not be used if diarrhea is accompanied by fever > 101°F or if blood or mucus is present in stool.
	Bismuth subsalicylate, 524 mg every 30–60 minutes as needed up to 8 doses daily	Pepto-Bismol, various generic	Bismuth salts can cause dark discoloration of the tongue and stools. Salicylates are absorbed and can cause tinnitus if coadministered with aspirin.
	Loperamide, 4 mg initially, then 2 mg after each loose stool, not to exceed 8 mg daily	Imodium A-D	A synthetic opioid that acts on intestinal smooth muscle to decrease motility allowing for absorption of water and electrolytes. Poorly penetrates the CNS and has a lower risk of side effects compared to diphenoxylate or opiates. Not considered a controlled substance.

Antifungal topical preparations	Butenafine, 1% (cream) apply to affected areas once daily	Lotrimin Ultra	Effective for the treatment of tinea pedis (athlete's foot), tinea cruris (jock itch), and tinea corporis (ringworm). Clotrimazole and miconazole also effective against <i>Candida albicans</i> .
	Clotrimazole, 1% (cream, lotion, solution), apply to affected areas twice daily	Lotrimin AF Cream/Lotion/Solution, Mycelex OTC	
	Miconazole, 2% (cream, powder, solution), apply to affected areas twice daily	Lotrimin AF Powder/Spray, Micatin, Zeasorb-AF	
	Terbinafine, 1% (cream), apply to affected areas once or twice daily	Lamisil AT	
	Tolnaftate, 1% (cream, powder, solution), apply to affected areas twice daily	Aftate, Tinactin, Ting, various generic	
	Undecylenic acid, 10–25% (powder, spray powder, cream, liquid) apply to affected areas twice daily	Cruex, Desenex, various generic	
	Antifungal vaginal preparations	Butoconazole, 2% cream, one applicatorful intravaginally at bedtime for 3 consecutive days	
Clotrimazole (1%, 2% vaginal cream, 100 mg, 200 mg tablet); see comments for dosage		Gyne-Lotrimin, Mycelex-7, Gyne-Lotrimin-3, various generic	Insert one applicatorful (1%) or one tablet (100 mg) intravaginally at bedtime for 7 consecutive days. Alternatively: Insert one applicatorful (2%) or one tablet (200 mg), intravaginally at bedtime for 3 consecutive days.
Miconazole (2%, 4% vaginal cream; 100 mg, 200 mg vaginal suppositories); see comments for dosage		Monistat-7, Monistat-3	Insert one applicatorful intravaginally at bedtime for 7 consecutive days (2%) or 3 consecutive days (4%). Alternatively: insert one

			suppository intravaginally at bedtime for 7 consecutive days (100 mg) or 3 consecutive days (200 mg).
	Tioconazole, 6.5% vaginal ointment, one applicatorful intravaginally at bedtime (single-dose)	Monistat-1, Vagistat-1	
Anti-inflammatory topical preparations	Hydrocortisone, 0.5% (cream, ointment, lotion), 1% (cream ointment, lotion, spray)	Anusol HC, Cortaid, Cortizone-5, Cortizone-10, various generic	Used to temporarily relieve itching and inflammation associated with minor rashes due to contact or allergic dermatitides, insect bites, and hemorrhoids. Apply sparingly to affected areas two to four times daily.
Antiseborrheal agents	Coal tar, 0.5-15% shampoo, dosage varies; consult product labeling	Denorex, Ionil T Plus, Tegrin, Zetar, various generic	Tar derivatives inhibit epidermal proliferation and may possess antipruritic and antimicrobial activity.
	Ketoconazole, 1% shampoo, apply every 3-4 days	Nizoral A-D	Synthetic azole antifungal agent with activity versus <i>Pityrosporum ovale</i> , a fungus that may cause seborrhea and dandruff. Massage over entire scalp for 3 minutes. Rinse thoroughly and repeat application.
	Pyrithione zinc, 1-2% shampoo, apply once or twice weekly	Denorex, Head & Shoulders, Sebulon, various generic	Both selenium sulfide and zinc pyrithione are cytostatic agents that decrease epidermal turnover rates. Massage into wet scalp for 2-3 minutes. Rinse thoroughly and repeat application. Selenium sulfide can be irritating to the eyes and skin.
	Selenium sulfide, 1% shampoo, apply once or twice weekly	Head & Shoulders Intensive Treatment, Selsun Blue, various generic	
Antitussives	Codeine, 10-20 mg every 4-6 hours (with guaifenesin)	Robitussin A-C, Guiatuss AC, various generic	Acts centrally to increase the cough threshold. In doses required for cough suppression, the addictive liability associated with codeine is low. Many codeine-containing antitussive combinations are schedule V narcotics, and OTC sale is restricted in some states.

	Dextromethorphan, 10–20 mg every 4 hours or 30 mg every 6–8 hours	Benylin Adult Formula Cough, Hold DM, Vicks 44 Cough Relief, various generic	Dextromethorphan is a nonopioid congener of levorphanol without analgesic or addictive properties. Often is used with antihistamines, decongestants, and expectorants in combination products.
Decongestants, topical	Oxymetazoline, 0.05% nasal solution, 2–3 sprays per nostril every 10–12 hours	Afrin, Dristan 12 Hour Nasal, Neo-Synephrine 12 Hour, various generic	Topical sympathomimetics are effective for the temporary acute management of rhinorrhea associated with common colds and allergies. Long-acting agents (oxymetazoline and xylometazoline) are generally preferred, though phenylephrine is equally effective. Topical decongestants should not be used for longer than 3 days to prevent rebound nasal congestion.
	Phenylephrine (0.125%, 0.25%, 0.5%, 1%), nasal solution, 2–3 sprays/drops per nostril every 3–4 hours	Neo-Synephrine, various generic	
	Xylometazoline (0.05%, 0.1%), nasal solution, 2–3 sprays/drops per nostril every 8–10 hours	Otrivin	
Decongestants, systemic	Phenylephrine, 10 mg every 4 hours	Novahistine Elixir, various generic combination products	Oral decongestants have a prolonged duration of action but may cause more systemic effects, including nervousness, excitability, restlessness, and insomnia. Also available in antihistamine, antitussive, expectorant, and analgesic combination products. Phenylephrine is unpredictably absorbed from the gastrointestinal tract.
	Pseudoephedrine, 60 mg every 4–6 hours or 120 mg (extended release) every 12 hours	Sudafed, various generic	
Expectorants	Guaifenesin, 100–400 mg every 4 hours	Robitussin, various generic	The only OTC expectorant recognized as safe and effective by the FDA. Often used with antihistamines, decongestants, and antitussives in combination products.
Hair growth stimulants	Minoxidil, 2%, 5% solution, apply 1 mL to affected areas of scalp twice daily.	Rogaine for Men, Rogaine for Women, Rogaine Extra Strength for Men	Minoxidil appears to directly stimulate hair follicles resulting in increased hair thickness and reduced hair loss. Treatment for four

			months or longer may be necessary to achieve visible results. If new hair growth is observed, continued treatment is necessary as hair density returns to pretreatment levels within months following drug discontinuation.
Laxatives	Bulk formers: Polycarbophil, psyllium and methylcellulose preparations. Dosage varies; consult product labeling	Citrucel, Equalactin, Konsyl, Metamucil, Perdiem, various generic	The safest laxatives for chronic use include the bulk formers and stool softeners. Saline laxatives and stimulants may be used acutely but not chronically (see text). Bulk formers hold water and expand in stool, promoting peristalsis.
	Stool softeners: Docusate sodium, 50–500 mg daily. Docusate calcium, 240 mg daily	Colace, Surfak, various generic	Soften fecal material via detergent action that allows water to penetrate stool.
	Stimulant laxatives: Bisacodyl, 5–15 mg daily. Senna: dosage varies, consult product labeling	Correctol, Dulcolax, Ex-Lax, Senokot, various generic	Stimulant laxative actions include direct irritation of intestinal mucosa or stimulation of the myenteric plexus, resulting in peristalsis. These agents may also cause alteration of fluid and electrolyte absorption, resulting in luminal fluid accumulation and bowel evacuation.
Pediculicides (head lice)	Permethrin 1%	Nix	Instructions for use varies; consult product labeling. Avoid contact with eyes. Comb out nits. Linens, pajamas, combs, and brushes should be washed daily until the infestation is eliminated. Repeat application 7 days later if live nits are still visible.
	Pyrethrins (0.3%) combined with piperonyl butoxide (3–4%)	A-200, RID	
Sleep aids	Diphenhydramine, 25–50 mg at bedtime	Compoz, Nytol, Sominex, various generic	Diphenhydramine and doxylamine are

			may be indicative of a serious underlying condition requiring medical attention, patients should consult a physician if insomnia persists continuously for longer than 2 weeks.
Smoking cessation aids	Nicotine (transdermal patch), dosage varies; consult product labeling	Nicoderm CQ, Nicotrol, various generic	Nicotine replacement products in combination with behavioral support approximately double abstinence rates compared to placebo. Review directions for use carefully, since product strengths vary and self-titration and tapering may be necessary.
	Nicotine polacrilex gum or lozenge; dosage varies; consult product labeling	Nicorette, Commit, various generic	

Table 64–2 lists examples of OTC products that may be used effectively to treat common medical problems. The selection of one ingredient over another may be important in patients with certain medical conditions or in patients taking other medications. These are discussed in detail in other chapters. The recommendations listed in Table 64–2 are based upon the efficacy of the ingredients and on the principles set forth in the following paragraphs.

- (1) Select the product that is simplest in formulation with regard to ingredients and dosage form. In general, single-ingredient products are preferred. Although some combination products contain effective doses of all ingredients, others contain therapeutic doses of some ingredients and subtherapeutic doses of others. Furthermore, there may be differing durations of action among the ingredients, and there is always a possibility that the clinician or patient will be unaware of the presence of certain active ingredients in the product. Acetaminophen, for example, is present in many cough and cold preparations; a patient unaware of this may take separate doses of analgesic in addition to that contained in the cold preparation, potentially leading to toxicity.
- (2) Select a product that contains a therapeutically effective dose.
- (3) Carefully read the product labeling to determine which ingredients are appropriate based on the patient's symptoms and underlying health conditions and whatever is known about the medications the patient is already taking.
- (4) Recommend a generic product if one is available.
- (5) Be wary of "gimmicks" or advertising claims of specific superiority over similar products.
- (6) For children, the dose, dosage form, and palatability of the product will be prime considerations.

Certain ingredients in OTC products should be avoided or used with caution in selected patients

patient is taking. Many of the more potent OTC ingredients are hidden in products where their presence would not ordinarily be expected (Table 64–3). While most OTC medications are clearly labeled with the specific ingredients contained in the product, many products do not presently conform to the new FDA-mandated standardized OTC medication labeling requirements that are being phased in through 2005. Lack of awareness of the ingredients present in OTC products and the belief by many physicians that OTC products are ineffective and harmless may cause diagnostic confusion and perhaps interfere with therapy. For example, innumerable OTC products, including analgesics and allergy, cough, and cold preparations, contain sympathomimetics. These agents should be avoided or used cautiously by type 1 diabetics and patients with hypertension, angina, or hyperthyroidism. Aspirin should not be used in children and adolescents for viral infections (with or without fever) because of an increased risk of Reye's syndrome. Aspirin and other NSAIDs should be avoided by individuals with active peptic ulcer disease, certain platelet disorders, and patients taking oral anticoagulants. Cimetidine, an H₂-receptor antagonist, is a well-known inhibitor of hepatic drug metabolism and can increase the blood levels and toxicity of drugs such as phenytoin, theophylline, and warfarin.

Table 64–3. Hidden Ingredients in Over-the-Counter (OTC) Products.

Hidden Drug or Drug Class	OTC Class Containing Drug	Product Examples
Alcohol (percent ethanol)	Cough syrups, cold preparations	Cheracol Plus (5%)
		Comtrex Multi-Symptom Cold & Cough Relief (10%)
		Vicks 44M (10%)
		Vicks NyQuil Liquid (10%)
	Mouthwashes	Cepacol Mouthwash (14%)
		Listerine (27%) Scope (15%)
Antihistamines	Analgesics	Aspirin Free Anacin PM
		Aspirin Free Excedrin PM
		Extra Strength Bayer PM
		Percogesic Extra Strength
		Tylenol PM
		Tylenol Severe Allergy
	Menstrual products	Midol PM
		Maximum Strength Midol Menstrual
		Maximum Strength Midol PMS
		Maximum Strength Multi-Symptom Pamprin
		Menstrual Relief
		Premsyn PMS
	Sleep aids	Compoz

		Nytol
		Sominex
		Twilite Caplets
		Unisom
Aspirin and other salicylates	Antidiarrheals	Pepto-Bismol (bismuth subsalicylate)
	Cold/allergy preparations	Alka-Seltzer Plus Cold & Cough Liqui-Gels
		BC Allergy Sinus Cold Powder
Caffeine	Analgesics	Alka-Seltzer Morning Relief
		Anacin
		Cope
		Excedrin Extra Strength
		Excedrin Migraine
		Goody's Extra Strength Fast Relief
		Goody's Extra Strength Headache Powder
		Vanquish
	Menstrual products	Maximum Strength Midol Menstrual
	Stimulants	Lucidex
		NoDoz
		Vivarin
	Local anesthetics (usually benzocaine)	Antitussives/Lozenges
Spec T Sore Throat/Cough Suppressant		
Vicks Chloraseptic Lozenges		
Dermatologic preparations		Americaine
		Bactine
		Dermoplast
		Lanacane
		Solarcaine
Hemorrhoidal products		Americaine
		Anusol Ointment
		Medicone
		Tronolane
Toothache, cold sore, and teething products		(Many)
		Anbesol
		Baby Orajel
		Kank-A

		Orabase B
		Zilactin-B
Sodium (mg/tablet or mg/5 mL or as stated)	Analgesics	Alka-Seltzer Original Effervescent Tablet (568)
		Alka-Seltzer Extra Strength Effervescent Tablet (588)
		Bromo-Seltzer Granules (959/pre-measured packet)
	Antacids	Alka-Seltzer Original Effervescent Tablet (568)
		Alka-Seltzer Extra Strength Effervescent Tablet (588)
		Alka-Seltzer Gold (299)
		Alka-Seltzer Heartburn Relief (569)
		Bromo-Seltzer Granules (959/pre-measured packet)
		Citrocarbonate Effervescent Granules (780/ teaspoon)
	Laxatives	Fleets Enema (4,439 mg, of which 275–400 mg/enema is absorbed)
		Fleet Phospho-Soda (554/teaspoon)
	Sympathomimetics	Analgesics
Sinarest No Drowsiness		
Sine-Aid Sinus Headache Tablets		
Sinutab		
Tylenol Flu Day Non-Drowsy		
Tylenol Sinus Day Non-Drowsy		
Asthma products		Bronkaid Dual Action
		Primatene
Cold/allergy preparations		(Many)
		Advil Cold and Sinus
		Alka-Seltzer Plus
		Comtrex Maximum Strength Day and Night Flu
		Contac Severe Cold and Flu
		Dimetapp Cold & Allergy
		PediaCare Cold & Allergy
		Motrin Cold & Flu
		Sudafed
		TheraFlu Severe Cold & Congestion

		Triaminic Chest Congestion
		Vicks 44M
		Vicks DayQuil
		Vicks NyQuil
	Cough preparations	(Many)
		PediaCare Long Lasting Cough Plus Cold
		Robitussin PM Cold & Cough
		Robitussin Maximum Strength Cough & Cold
		Triaminic Cough
		Vicks 44D
	Hemorrhoidal products	Hem-Prep
		Pazo Hemorrhoid Ointment
		Preparation H
	Sore throat products	Spec-T Sore Throat/Decongestant

Overuse or misuse of OTC products may induce significant medical problems. A prime example is rebound congestion from the regular use of decongestant nasal sprays for more than 3 days. The improper and chronic use of some antacids (eg, aluminum hydroxide) may cause constipation and even impaction in elderly people, as well as hypophosphatemia. Laxative abuse can result in abdominal cramping and fluid and electrolyte disturbances. Insomnia, nervousness, and restlessness can result from the use of sympathomimetics or caffeine hidden in many OTC products (Table 64–3). The chronic systemic use of some analgesics containing large amounts of caffeine may produce rebound headaches, and long-term use of analgesics has been associated with interstitial nephritis. Recent evidence suggests that use of OTC products containing aspirin, other salicylates, acetaminophen, ibuprofen, naproxen, or ketoprofen may increase the risk of hepatotoxicity and gastrointestinal hemorrhage in individuals who consume three or more alcoholic drinks daily. Furthermore, acute ingestion of large amounts of aspirin or acetaminophen by adults or children can cause serious toxicity. Antihistamines may cause sedation or drowsiness, especially when taken concurrently with sedative-hypnotics, tranquilizers, alcohol, or other central nervous system depressants. Finally, antihistamines, local anesthetics, antimicrobial agents, counterirritants, *p*-aminobenzoic acid (PABA) and preservatives contained in a myriad of OTC topical and vaginal products may induce allergic reactions.

There are three major drug information sources for OTC products. *Handbook of Nonprescription Drugs* is the most comprehensive resource for OTC medications; it evaluates ingredients contained in major OTC drug classes and lists the ingredients included in many OTC products. *Nonprescription Drug Therapy* is a loose-leaf reference, updated quarterly, that provides detailed OTC product information and patient counseling instructions. *Physicians' Desk Reference for Nonprescription Drugs*, a compendium of manufacturers' information regarding OTC products, is published annually but is somewhat incomplete with regard to the number of products included and the consistency of information provided. Any health care provider who seeks more specific information regarding OTC products may find the references useful.

Chapter 65. Botanicals ("Herbal Medications") & Nutritional Supplements

Botanicals ("Herbal Medications") & Nutritional Supplements: Introduction

The medical use of botanicals in their natural and unprocessed form undoubtedly began when the first intelligent animals noticed that certain food plants altered particular body functions. Much information exists about the historical use and effectiveness of botanical products. Unfortunately, the quality of this information is extremely variable. One of the most complete compendiums of clinical recommendations regarding the use of botanicals is the *Report of the German Commission E* (a committee that sets standards for herbal medications in that country; Blumenthal, 2000). Interest in the endocrine effects and possible nutritional benefits of certain purified chemicals such as [dehydroepiandrosterone](#), [melatonin](#), high-dose vitamins, and minerals has led to a parallel development of consumer demand for such substances. These substances, together with the botanicals, constitute a substantial source of profits for those who exploit the concept of "alternative medicine."

The alternative medicinal substances are distinguished from similar botanical substances used in traditional medicine ([morphine](#), digitalis, [atropine](#), etc) by virtue of being available without a prescription and, unlike over-the-counter medications, being legally considered dietary supplements rather than drugs (thus avoiding conventional FDA oversight). Among the purified chemicals, [dehydroepiandrosterone](#) and [melatonin](#) are of significant pharmacologic interest.

This chapter provides an evidence-based approach to the pharmacology and clinical efficacy of several of the commonly used and commercially available botanicals and dietary supplements. [Ephedrine](#), the active principle in Ma-huang, is discussed in [Chapter 9: Adrenoceptor-Activating & Other Sympathomimetic Drugs](#).

Regulatory Factors

Dietary supplements (which include vitamins, minerals, cofactors, herbal medications, and amino acids) are not considered over-the-counter drugs in the USA but rather food supplements. In 1994, the United States Congress, influenced by growing "consumerism" as well as strong manufacturer lobbying efforts, passed the Dietary Supplement and Health Education Act (DSHEA). This landmark act prevented adequate FDA oversight of these substances. Thus, DSHEA has allowed a variety of substances with pharmacologic activity—if classified as dietary supplements—to be sold without a prescription or any FDA review of efficacy or safety prior to product marketing. Dietary supplements are governed under Current Good Manufacturing Practice in Manufacturing, Packaging or Holding Human Food (CGMP) regulations. Although administered by the FDA, CGMP regulations are often inadequate to ensure product purity, potency, and other variables such as accurate product identification and appropriate botanical harvesting. Therefore, much of the criticism regarding the dietary supplement industry involves a lack of product purity and variations in potency.

In 1999, the FDA announced labeling recommendations for dietary supplements marketed in the USA. These recommendations were not mandated; some manufacturers, however, have adopted them in an effort to increase sales. According to these recommendations, the term "dietary

supplement" should be included in the product label name. A "Supplement Facts Panel" similar to the "Nutrition Facts Panels" found on processed foods was also recommended. According to these new labeling recommendations, up to 14 "inactive" ingredients can be listed.

Katzung PHARMACOLOGY, 9e > Section X. Special Topics > Chapter 65. Botanicals ("Herbal Medications") & Nutritional Supplements >

Clinical Aspects of the Use of Botanicals

Many United States consumers have embraced the use of botanicals and other supplements as a "natural" approach to their health care. Unfortunately, misconceptions regarding safety and efficacy of the agents are common, and the fact that a substance can be called "natural" of course does not guarantee its safety. In fact, these products can be adulterated, misbranded, or contaminated either intentionally or unintentionally in a variety of ways. Furthermore, the doses recommended for active botanical substances may be much higher than those considered clinically safe. For example, the doses recommended for several Ma-huang preparations contain three to five times the medically recommended daily dose of the active ingredient, ephedrine—doses that impose significant risks for patients with cardiovascular disease.

Adverse effects have been documented for a variety of botanical medications. Unfortunately, chemical analysis is rarely performed on the products involved. This leads to uncertainty about whether the primary herb or an adulterant caused the adverse effect. In some cases, the chemical constituents of the herb can clearly lead to toxicity. Some of the herbs that should be used cautiously or not at all, based on the severity of their reported effects, are listed in Table 65–1.

Table 65–1. Botanical Supplements and Some Associated Risks.			
Commercial Name, Scientific Name, Plant Parts	Intended Use	Toxic Agents, Effects	Comments
Comfrey <i>Symphytum</i> species Leaves and roots	Internal digestive aid, topical for wound healing	Pyrrolizidine alkaloids, hepatotoxicity	Avoid internal ingestion: topical use should be limited to 4–6 weeks
Coltsfoot <i>Tussilago farfara</i> Leaves, flower	Upper respiratory tract infections	Pyrrolizidine alkaloids, hepatotoxicity	Avoid ingestion of any parts of plant; leaves may be used topically for anti-inflammatory effects for up to 4–6 weeks
Germander <i>Teucrium chamaedrys</i> Leaves, tops	Diet aid	Hepatotoxicity	Avoid

Borage <i>Borago officinalis</i> Tops, leaves	Anti-inflammatory, diuretic	Pyrrolizidine alkaloids, hepatotoxicity	Avoid
Chaparral <i>Larrea tridentata</i> Twigs, leaves	Anti-infective, antioxidant, anticancer	Hepatotoxicity	Avoid
Sassafras <i>Sassafras albidum</i> Root bark	Blood thinner	Safrole oil, hepatocarcinogen in animals	Avoid
Aconite Aconitum species	Analgesic	Alkaloid, cardiac and central nervous system effects	Avoid
Pennyroyal <i>Mentha pulegium</i> or <i>Hedeoma pulegioides</i> Extract	Digestive aid, induction of menstrual flow, abortifacient	Pulegone and pulegone metabolite, liver failure, renal failure	Avoid
Poke root <i>Phytolacca americana</i>	Antirheumatic	Hemorrhagic gastritis	Avoid
Jin Bu Huan	Analgesic; sedative	Hepatotoxicity	Avoid
Ephedra, Ma huang Ephedra species	Diet aid; stimulant; bronchodilator	Central nervous system toxicity, cardiac toxicity	Avoid in patients at risk for stroke, myocardial infarction, uncontrolled blood pressure, seizures, general anxiety disorder
Royal jelly <i>Apis mellifera</i> (honeybee)	Tonic	Bronchospasm, anaphylaxis	Avoid in patients with chronic allergies or respiratory diseases; asthma, chronic obstructive pulmonary disease, emphysema, atopy

Katzung PHARMACOLOGY, 9e > Section X. Special Topics > Chapter 65. Botanicals ("Herbal Medications") & Nutritional Supplements > Botanical Substances >

Echinacea (*Echinacea Purpurea*)

Chemistry

The three most widely used species of Echinacea are *Echinacea purpurea*, *E pallida*, and *E angustifolia*. The chemical constituents include flavonoids, lipophilic constituents (eg, alkamides,

polyacetylenes), water-soluble polysaccharides, and water-soluble caffeoyl conjugates (eg, echinacoside, chicoric acid, caffeic acid). Within any marketed Echinacea formulation, the relative amounts of these components are dependent upon the species used, the method of manufacture, and the plant parts used. The German Commission E has approved two formulations for clinical use: the fresh pressed juice of aerial parts of *E purpurea* and the alcoholic root extract of *E pallida*. While the active constituents of Echinacea are not completely known, chicoric acid, alkamide, and polysaccharides are most often noted as having immune-modulating properties. Commercial formulations, however, are not standardized for any particular constituent.

Pharmacologic Effects

Immune Modulation

The effect of Echinacea on the immune system is controversial. Human studies using commercially marketed formulations of Echinacea have shown increased phagocytosis but not immunostimulation. In vitro, however, *E purpurea* juice increased production of interleukin-1, -6, -10, and tumor necrosis factor- α by human phagocytes. Enhanced natural killer cell activity and antibody-dependent cellular toxicity was also observed with *E purpurea* extract in cell lines from both healthy and immunocompromised patients. Studies using the isolated purified polysaccharides from Echinacea have also shown cytokine activation. The latter compounds, however, are unlikely to accurately reproduce the activity of the entire extract.

Anti-Inflammatory Effects

Certain Echinacea constituents have demonstrated anti-inflammatory properties in vitro. Inhibition of cyclooxygenase and 5-lipoxygenase may be involved. In animals, application of Echinacea prior to application of a topical irritant reduced both paw and ear edema. There are too few clinical trials in humans to warrant the use of Echinacea in wound healing.

Antibacterial, Antifungal, Antiviral, and Antioxidant Effects

Some in vitro studies have reported weak antibacterial, antifungal, antiviral, and antioxidant activity with Echinacea constituents. The applicability of these findings to clinical trials is discussed below.

Clinical Trials

Echinacea is most often used to enhance immune function in individuals who have colds and other respiratory tract infections. Systematic reviews and cold treatment trials generally report favorable results for Echinacea in reducing symptoms or time to recovery if the agent was administered within the first 24 hours of a cold. To date, however, most of these trials have contained multiple variables (eg, formulation, dose, duration) that make it difficult to make a clear therapeutic recommendation or ensure reproducible outcomes. At best, symptoms and duration may be reduced by about 25–30%. Echinacea has also been evaluated as a prophylactic agent in the prevention of upper respiratory tract infection. These trials have generally been less favorable and have reported no effect.

Echinacea has been used investigationaly to enhance hematologic recovery following chemotherapy. It has also been used as an adjunct in the treatment of urinary tract and vaginal fungal infections. These indications require further research before they can be accepted in clinical practice. Echinacea is ineffective in treating recurrent genital herpes.

Adverse Effects

Flu-like symptoms (eg, fever, shivering, headache, vomiting) have been reported following the intravenous use of Echinacea extracts. Adverse effects with oral commercial formulations are minimal and most often include unpleasant taste, gastrointestinal upset, or central nervous system effects (eg, headache, dizziness). Allergic reactions such as rash, acute asthma, and anaphylaxis have been infrequently reported.

Drug Interactions & Precautions

Until the role of Echinacea in immune modulation is better defined, this agent should be avoided in patients with immune deficiency disorders (eg, AIDS, cancer), autoimmune disorders (eg, multiple sclerosis, rheumatoid arthritis), patients with tuberculosis, and patients using immunosuppressant medications (eg, organ transplant recipients). The German Commission E recommends limiting the chronic use of Echinacea to no more than 8 weeks. While there are no reported drug interactions for Echinacea, some preparations have a high alcohol content and should not be used with medications known to cause a disulfiram-like reaction.

Dosage

Dried *Echinacea pallida* root extract (1:5 tincture, 50% ethanol) is given at a dosage of 900 mg/d. *E. purpurea* freshly pressed juice is given at a dosage of 6–9 mL/d in divided doses two to five times daily. Echinacea is generally taken at the first sign of a cold.

Katzung PHARMACOLOGY, 9e > Section X. Special Topics > Chapter 65. Botanicals ("Herbal Medications") & Nutritional Supplements > Botanical Substances >

Feverfew (Tanacetum Parthenium)

Chemistry

Feverfew contains flavonoid glycosides, monoterpenes (eg, camphor, other pinene derivatives), and sesquiterpene lactones. The most prevalent sesquiterpene is parthenolide, which is primarily found in the seeds and leaves of the plant, with concentrations ranging from 1% to 3%.

Feverfew products should be standardized to contain no less than 0.2% parthenolide since this agent is considered to be one of the primary active constituents. It is likely, however, that other constituents also contribute to the overall biologic activity. Parthenolide content in commercially marketed formulations can vary depending on growing conditions, manufacturing process, and duration of storage. Some commercial dried leaf formulations contain no parthenolide, due to polymerization with prolonged storage.

Pharmacologic Effects

Migraine Headache

Feverfew is most often used as a prophylactic remedy for migraine headache. This action has been related to the serotonin hypothesis for migraine causation (see also Chapter 16: Histamine, Serotonin, & the Ergot Alkaloids). In vitro, feverfew and parthenolide inhibit platelet aggregation and serotonin release from platelets.

Anti-Inflammatory Effects

Feverfew has been used as an anti-inflammatory agent to treat rheumatoid arthritis. In vitro inhibition of prostaglandin, thromboxane, and leukotriene B₄ synthesis as well as cytokine (TNF- α and IL-1) expression have been reported.

Other Actions

Additional in vitro effects of feverfew include inhibition of histamine release from mast cells and granular components from leukocytes; inhibition of smooth muscle contraction; cytotoxic effects on human tumor cell lines; and antimicrobial effects against gram-positive bacteria, yeasts, and filamentous fungi.

Clinical Trials

Migraine

The use of feverfew as a prophylactic remedy for migraine headache is extensively described in the anecdotal literature. Unfortunately, most of the reported formal trials used small samples and had variable outcomes.

In a recent systematic review, three of four randomized, double-blind, placebo-controlled trials reported a positive effect. In these studies, the feverfew group generally had significant reductions in headache frequency, severity, and nausea compared with placebo. Feverfew products were standardized to contain 0.2–0.66% parthenolide, dosing ranged from 50 mg/d to 143 mg/d, and study durations from 1 month to 6 months. In contrast to studies reporting beneficial effects, which used freeze-dried or air-dried whole feverfew leaves, trials using an ethanol extract of feverfew leaves (standardized to 0.35% parthenolide) and a special extract showed no prophylactic benefit. Since one of these formulations contained 0.35% parthenolide, this may indicate that other chemical constituents necessary for biologic activity were absent from the ethanol formulation.

Overall, the benefits of feverfew in the prevention of migraine headache are weakly substantiated. Additional research is required to establish its place in therapy.

Arthritis

The use of feverfew in rheumatoid arthritis has been poorly studied. A double blind, placebo-controlled trial in 41 patients failed to find a significant benefit of feverfew over placebo at 6 weeks. Until further clinical trials are conducted, feverfew should not be recommended as a treatment for rheumatoid arthritis.

Adverse Effects

Mouth ulcers and gastrointestinal upset are the most common side effects associated with the use of feverfew. In a survey of 300 feverfew users, 11.3% reported mouth ulcers. External contact dermatitis may also occur. A rebound syndrome, consisting of nervousness, tension headache, insomnia, and joint stiffness has been reported in some patients who abruptly discontinued using feverfew.

Drug Interactions, Precautions, & Dosing

Patients taking anticoagulant and antiplatelet drugs should use feverfew cautiously, because the herb may inhibit platelet aggregation.

Recommended dosing of feverfew is two or three fresh leaves daily or up to 125 mg/d of the dried leaf formulation. Long-term effects of feverfew are unknown, as clinical studies typically lasted only 4–6 months or less.

Garlic (*Allium Sativum*)

Chemistry

The pharmacologic activity of garlic involves a variety of organosulfur compounds. The most notable of these is allicin, which is responsible for the characteristic garlic odor.

Pharmacologic Effects

Cardiovascular Effects

In vitro, allicin and related compounds inhibit HMG-CoA reductase, which is involved in cholesterol biosynthesis (see Chapter 35: Agents Used in Hyperlipidemia). Several clinical trials have investigated the lipid-lowering potential of garlic. Some have shown significant reductions in cholesterol and others no effect. The most recent meta-analysis suggested a minor (5%) reduction of total cholesterol that was insignificant when dietary controls were in place.

Clinical trials report antiplatelet effects following garlic ingestion and mixed effects on fibrinolytic activity. These effects in combination with antioxidant effects and reductions in total cholesterol may be beneficial in patients with atherosclerosis. In preliminary trials involving atherosclerotic patients, significant reductions in plaque volume were observed for patients taking garlic versus placebo.

Garlic constituents may affect blood vessel elasticity and blood pressure. Proposed mechanisms include opening of potassium channels in vascular smooth muscle, stimulation of nitric oxide synthesis, and inhibition of angiotensin-converting enzyme. Epidemiologic studies suggest that individuals chronically consuming low doses of garlic (averaging 460 mg/d) may have reductions in aortic stiffness. A meta-analysis of garlic's antihypertensive properties revealed a mild effect with a 7.7 mm Hg decrease in systolic pressure and a 5 mm Hg decrease in diastolic pressure.

Endocrine Effects

The effect of garlic on glucose homeostasis is controversial. Certain organosulfur constituents in garlic have demonstrated hypoglycemic effects in nondiabetic animal models. There has been no effect, however, in animal models or humans with diabetes.

Antimicrobial Effects

In vitro, allicin has demonstrated activity against gram-positive and gram-negative bacteria as well as fungi (*Candida albicans*), protozoa (*Entamoeba histolytica*), and certain viruses. The primary mechanism involves the inhibition of thiol-containing enzymes needed by these microbes. The

antimicrobial effect of garlic has not been extensively studied in clinical trials. Given the availability of effective prescription antimicrobials, the usefulness of garlic in this area appears limited.

Antineoplastic Effects

In vitro, garlic inhibits procarcinogens for colon, esophageal, lung, breast, and stomach cancer, probably by detoxification of carcinogens and reduced carcinogen activation. The evidence for anticarcinogenic properties in vivo is largely epidemiologic. For example, certain populations with high dietary garlic consumption appear to have a reduced incidence of stomach cancer.

Adverse Effects

Following oral ingestion, adverse effects may include nausea (6%), hypotension (1.3%), allergy (1.1%), and bleeding (rare). Breath odor has been reported with an incidence of 20–40% at recommended doses using enteric-coated formulations. Contact dermatitis may occur with the handling of raw garlic.

Drug Interactions & Precautions

Because of reported antiplatelet effects, patients using anticoagulating medications (eg, warfarin, aspirin, ibuprofen) should use garlic cautiously. Additional monitoring of blood pressure and signs and symptoms of bleeding is warranted. Garlic may reduce the bioavailability of saquinavir, an antiviral protease inhibitor, but it does not appear to affect the bioavailability of ritonavir.

Dosage

Products should be standardized to contain 1.3% alliin (the allicin precursor) or have an alliin-generating potential of 0.6%. Enteric-coated formulations are recommended to minimize degradation of the active substances. A daily dose of 600–900 mg/d of powdered garlic is most common. This is equivalent to one clove of raw garlic (2–4 g) per day.

Katzung PHARMACOLOGY, 9e > Section X. Special Topics > Chapter 65. Botanicals ("Herbal Medications") & Nutritional Supplements > Botanical Substances >

Ginkgo (Ginkgo Biloba)

Chemistry

Ginkgo biloba extract is prepared from the leaves of the ginkgo tree. The most common formulation is prepared by concentrating 50 parts of the crude leaf to prepare one part of extract. The active constituents in ginkgo are flavone glycosides and terpenoids (ie, ginkgolides A, B, C, J, and bilobalide).

Pharmacologic Effects

Cardiovascular Effects

In animal models and some human studies, ginkgo has been shown to increase blood flow and reduce blood viscosity. Enhancement of endogenous nitric oxide (Chapter 19: Nitric Oxide, Donors,

& Inhibitors) may be involved. A meta-analysis suggested that ginkgo was more effective than placebo and possibly comparable to pentoxifylline (Chapter 20: Drugs Used in Asthma) in relieving symptoms of intermittent claudication.

Metabolic Effects

Antioxidant and radical-scavenging properties have been observed for the flavonoid fraction of ginkgo as well as some of the terpene constituents. In vitro, ginkgo has demonstrated superoxide dismutase-like activity and superoxide anion and hydroxyl radical-scavenging properties. It has also demonstrated a protective effect in limiting free radical formation in animal models of ischemic injury and in reducing markers of oxidative stress in patients undergoing coronary artery bypass surgery.

Central Nervous System Effects

In aged animal models, chronic administration of ginkgo for 3–4 weeks led to modifications in central nervous system receptors and neurotransmitters. Receptor densities increased for muscarinic, α_2 , and 5-HT_{1a} receptors and decreased for β -adrenoceptors. Increased serum levels of acetylcholine and norepinephrine and enhanced synaptosomal reuptake of serotonin have also been reported. Additional mechanisms that may be involved include reversible inhibition of MAO-A and MAO-B, reduced corticosterone synthesis, inhibition of amyloid-beta fibril formation, and enhanced GABA levels.

Ginkgo is frequently used to treat "cerebral insufficiency" and dementia of the Alzheimer type. The term "cerebral insufficiency," however, includes a variety of manifestations ranging from poor concentration and confusion to anxiety and depression as well as physical complaints such as hearing loss and headache. For this reason, studies evaluating "cerebral insufficiency" tend to be more inclusive and difficult to assess than trials evaluating dementia. A systematic review and meta-analysis agree that ginkgo is significantly better than placebo at improving symptoms of dementia, but the clinical relevance of these improvements is questionable and amounts to an improvement of approximately 3% in cognition. The duration of the largest of these studies was 1 year. Recent studies on the effects of ginkgo for memory enhancement in healthy nondemented elderly adults did not show a benefit with 6 weeks of use. Ginkgo is currently under investigation as a prophylactic agent for dementia of the Alzheimer type.

Miscellaneous Effects

Various ginkgolides, particularly ginkgolide B, have platelet-activating factor (PAF) antagonist properties. This action could explain some antiplatelet and anti-inflammatory effects of these substances.

Ginkgo has also been studied for its effects in allergic and asthmatic bronchoconstriction, erectile dysfunction, tinnitus and hearing loss, short-term memory loss in healthy nonelderly adults, and macular degeneration. A systematic review of randomized controlled trials for chronic tinnitus suggests an improvement with up to 3 months of use. In all of these miscellaneous conditions, with the exception of tinnitus, the evidence is insufficient to warrant clinical use at this time.

Adverse Effects

Adverse effects have been reported with a frequency comparable to that of placebo. These include nausea, headache, stomach upset, diarrhea, allergy, anxiety, and insomnia. A few case reports noted

bleeding complications in patients using ginkgo. In two of these cases, the patients were also using either aspirin or warfarin.

Drug Interactions & Precautions

Ginkgo may have antiplatelet properties and should not be used in combination with other antiplatelet or anticoagulant medications. A case report of an enhanced sedative effect was reported when ginkgo was combined with trazodone. Seizures have been reported as a toxic effect of ginkgo, most likely related to seed contamination in the leaf formulations. Ginkgo seeds are epileptogenic. Ginkgo formulations should be avoided in individuals with preexisting seizure disorders.

Dosage

Ginkgo biloba dried leaf extract should be standardized to contain 24% flavone glycosides and 6% terpene lactones. Products should be concentrated to a 50:1 ratio. The daily dose ranges from 120–240 mg of the dried extract in two or three divided doses. Onset of effect may require 2–4 weeks.

Katzung PHARMACOLOGY, 9e > Section X. Special Topics > Chapter 65. Botanicals ("Herbal Medications") & Nutritional Supplements > Botanical Substances >

Ginseng

Chemistry

Ginseng botanical preparations may be derived from any of several species of the genus *Panax*. Of these, crude preparations or extracts of *Panax ginseng*, the Chinese or Korean variety, and *Panax quinquefolium*, the American variety, are most often available to consumers in the United States. The active principles appear to be a dozen or more triterpenoid saponin glycosides called ginsenosides or panaxosides. It is recommended that commercial *Panax ginseng* formulations be standardized to contain 7% ginsenosides.

Other plant materials are commonly sold under the name ginseng but are not from *Panax* species. These include Siberian ginseng (*Eleutherococcus senticosus*) and Brazilian ginseng (*Pfaffia paniculata*). Of these, Siberian ginseng is more widely available in the United States. Siberian ginseng contains eleutherosides but no ginsenosides. Currently, there is no recommended standardization for eleutheroside content in Siberian ginseng products.

Pharmacology

An extensive literature exists on the potential pharmacologic effects of ginsenosides. Unfortunately, the studies differ widely in the species of *Panax* used, the ginsenosides studied, the degree of purification applied to the extracts, the animal species studied, and the measurements used to evaluate the responses. Some of the more commonly reported beneficial pharmacologic effects include modulation of immune function, ergogenic ("energizing") activity, nootropic ("mind-enhancing") activity, vasoregulatory effects, anti-inflammatory effects, antistress activity, analgesia, antiplatelet activity, improved glucose homeostasis, and anticancer properties.

Clinical Trials

Ginseng is most often used to help improve physical and mental performance. Unfortunately, the clinical trials are of small sample size and report either an improvement in mental function and

physical performance or no effect. Some randomized controlled trials evaluating "quality of life" and enhancement of immune function have claimed significant benefits with *P. ginseng*. American ginseng appears to lower postprandial glucose indices in subjects with and without diabetes. Some epidemiologic trials suggest a reduction in several types of cancer with *P. ginseng*. Systematic reviews, however, have generally failed to find conclusive evidence for the use of *P. ginseng* for any particular condition. Until better clinical studies are published, no recommendation can be made regarding the use of ginseng.

Adverse Effects

A variety of adverse effects have been reported. Weak estrogenic properties may cause the vaginal bleeding and mastalgia reported by some patients. Central nervous system stimulation (eg, insomnia, nervousness) and hypertension have been reported in patients using high doses (more than 3 g/d) of *Panax ginseng*. Methylxanthines found in the ginseng plant may contribute to this effect. The German Commission E lists high blood pressure as a contraindication to the use of Siberian ginseng but not *Panax ginseng*.

Drug Interactions & Precautions

Irritability, sleeplessness, and manic behavior have been reported in psychiatric patients using ginseng in combination with other medications (phenelzine, lithium, neuroleptics). Ginseng should be used cautiously in patients taking any psychiatric, estrogenic, or hypoglycemic medications. Ginseng has antiplatelet properties and should not be used in combination with warfarin. Similar to echinacea, cytokine stimulation has been observed for both *P. ginseng* and *P. quinquefolium*, necessitating cautious use in individuals who are immunocompromised, are taking immune stimulants or suppressants, or have autoimmune disorders.

Dosing

The German Commission E recommends 1–2 g/d of crude *P. ginseng* root or its equivalent. Two hundred milligrams of ginseng extract is equivalent to 1 g of the crude root. Ginsana has been used as a standardized extract in some clinical trials and is available in the United States. Dosing for Siberian ginseng is 2–3 g/d of the crude root.

Katzung PHARMACOLOGY, 9e > Section X. Special Topics > Chapter 65. Botanicals ("Herbal Medications") & Nutritional Supplements > Botanical Substances >

Kava (*Piper Methysticum*)

Kava is an extract derived from the root of the pepper plant, *Piper methysticum* Forster. Kava has been used as a ceremonial drink for many centuries in Polynesia, Melanesia, and Micronesia. In many parts of the world, kava is used for its relaxing properties in the same way as alcohol is used in Western societies.

Chemistry

Extracts of the kava root contain both lipophilic and hydrophilic components. The active constituents of kava are referred to as kavalactones or kavapyrones. The active enolides and dienolides are thought to be kawain (kavain), methysticin, and yangonin.

Pharmacologic Effects

Central Nervous System Effects

The mechanism of action of kava on the central nervous system is not known. Since kava shares similar central nervous system effects with the benzodiazepines, GABA receptors were thought to be involved. In vitro, kavalactones have been shown to bind readily to GABA_A receptors located in the hypothalamus and amygdala, areas thought to be largely responsible for emotion and memory rather than cognition and movement. However, kavalactones do not compete with flunitrazepam or diazepam for benzodiazepine binding sites. Kava may also increase the number of GABA-binding sites.

Other suggested mechanisms include reduced excitatory neurotransmission by decreasing the release of glutamate, inhibition of norepinephrine uptake, reversible MAO-B inhibition, or dopamine antagonism.

Kava has also been shown to have mild anticonvulsant properties in animals, possibly involving voltage-dependent sodium channels.

Research is needed to assess reported analgesic effects in humans. Animal data suggest that opioid receptors are not involved in the actions of kava.

Antiplatelet Effects

One of the kavalactones, kavain, has in vitro cyclooxygenase-inhibiting activity. The potential for antiplatelet and anti-inflammatory effects needs further study.

Clinical Trials

Anxiety

Kava is most often used as a sedative-hypnotic to treat anxiety. The substance has been evaluated in Europe and in the USA for the treatment of anxiety in several placebo-controlled studies. Most of these trials have shown significant improvements in anxiety symptoms in patients with moderate to severe anxiety within 8 weeks after starting treatment. In one study, kava was compared with oxazepam, a benzodiazepine. Similar reductions in anxiolytic effects and fewer adverse effects were reported for the kava group. Kava appears to have a slow onset of action for the treatment of anxiety symptoms, most patients responding only after 4–8 weeks. Kava should not be used to treat acute symptoms of anxiety or panic attacks.

Adverse Effects

In most patients, kava's adverse effects are mild at recommended doses. These effects include tingling in the mouth and gastrointestinal upset. Kava does not seem to impair memory or cognitive function to the same degree as benzodiazepines.

Kava can cause central nervous system effects such as sedation, euphoria, and visual and auditory changes. Ataxia, muscle weakness, paresthesias, and even ascending paralysis have also been reported with excessive kava doses. Clinical evidence suggests that kava does not induce physiologic dependence, though it may lead to psychological dependence. Reactions resembling dopaminergic antagonism have been reported. All patients were using kava at recommended doses

and experienced dystonic extrapyramidal reactions.

Kava has been shown to alter uterine tone in vitro and should be avoided during pregnancy. Kavalactones are soluble and excreted into breast milk. Women who are nursing should avoid kava.

An ichthyosiform skin rash has been seen when kava is taken at very high doses chronically. It is associated with facial swelling and photosensitivity. Exfoliation on the palms of the hands and soles of the feet, forearms, back, and shins has also been described. Sebaceous gland skin eruptions have been reported, with lymphocytic infiltrates on biopsy. Kava dermatopathy is reversible on cessation of consumption.

Since 1999, eleven cases of kava-induced hepatitis have been reported in the USA, Germany, and Switzerland. Various kava products were used at varying doses (60–240 mg/d). Liver biopsies revealed hepatic necrosis requiring liver transplants. As a result, kava products have been removed from the market in Canada, Germany, Switzerland, and Australia.

Drug Interactions

Kava predictably potentiates the effects of other central nervous system depressants such as alcohol and possibly barbiturates. Combining kava with alcohol may result in additive or greater impairment of cognitive performance. Impaired motor function can also occur when kava is combined with central nervous system depressants. One case has been reported of a patient who combined alprazolam with kava and presented in a semicomatose state. Kavalactones inhibit cytochrome P450 isozymes, particularly 3A4, 2C9, 2C19, 2D6, and 1A2. Alprazolam is primarily metabolized by CYP3A4. A decrease in levodopa effectiveness was reported in one patient with Parkinson's disease. The use of kava with dopamine agonists or antagonists should be avoided.

Dosage

Fifty to 70 milligrams of purified kavalactones three times daily appears to be the optimal anti-anxiety dosage. This is equivalent to 100–250 mg of dried kava root extract three times daily. As a hypnotic, 180–210 mg of kavalactones may be taken 30 minutes to 1 hour before bedtime. Until more is known about the risk of kava-induced hepatotoxicity and drug interactions, kava is not recommended for use. If patients insist on using kava, use should be limited to 3 months or less to minimize the potential for dependence and hepatotoxicity.

Katzung PHARMACOLOGY, 9e > Section X. Special Topics > Chapter 65. Botanicals ("Herbal Medications") & Nutritional Supplements > Botanical Substances >

Milk Thistle (*Silybum Marianum*)

Chemistry

The fruit and seeds of the milk thistle plant contain a lipophilic mixture of flavonolignans known as silymarin. Silymarin comprises 2–3% of the dried herb and is composed of three primary isomers, silybin (also known as silybinin or silibinin), silychristin (silichristin), and silydianin (silidianin). Silybin is the most prevalent and potent of the three isomers and accounts for about 50% of the silymarin complex. Products should be standardized to contain 70–80% silymarin.

Pharmacologic Effects

Liver Disease

In animal models, milk thistle limits hepatic injury associated with a variety of toxins, including Amanita mushrooms, galactosamine, carbon tetrachloride, acetaminophen, radiation, cold ischemia, and ethanol. In vitro studies and some in vivo studies demonstrate that silymarin reduces lipid peroxidation, scavenges free radicals, and enhances glutathione and superoxide dismutase levels. This may contribute to membrane stabilization and reduce toxin entry.

Milk thistle may have anti-inflammatory properties. In vitro, silybin strongly and noncompetitively inhibits lipoxygenase and leukotriene formation. On the other hand, concentrations required to inhibit thromboxane and prostaglandin formation in vivo probably exceed dosing capabilities. Inhibition of leukocyte migration has also been observed in vivo and may be a factor when acute inflammation is present.

One of the most unusual mechanisms claimed for milk thistle involves an increase in RNA polymerase I activity in nonmalignant hepatocytes but not in hepatoma or other malignant cell lines. By increasing this enzyme's activity, enhanced protein synthesis and cellular regeneration may occur in diseased but not malignant cells. Milk thistle may have a role in hepatic fibrosis. In an animal model of cirrhosis, it reduced collagen accumulation, and in an in vitro model it reduced expression of the profibrogenic cytokine TGF- β .

It has been suggested that milk thistle may be beneficial in the management of hypercholesterolemia and gallstones. A small trial in humans showed a reduction in bile saturation index and biliary cholesterol concentration. The latter may reflect a reduction in liver cholesterol synthesis. To date, however, there is insufficient evidence to warrant the use of milk thistle for either of these disorders.

Chemotherapeutic Effects

Preliminary in vitro and mouse studies have been carried out with skin, breast, and prostate cancer cell lines. In murine models of skin cancer, milk thistle reduced tumor initiation and promotion. It also inhibited cell growth and proliferation by inducing a G₁ cell cycle arrest in cultured human breast and prostate cancer cell lines. However, the use of milk thistle in the treatment of cancer has not yet been adequately studied and should not be recommended to patients.

Clinical Trials

Milk thistle has been used to treat acute and chronic viral hepatitis, alcoholic liver disease, and toxin-induced liver injury in human patients. Milk thistle has most often been studied in the treatment of alcoholic hepatitis and cirrhosis. In both of these disorders, outcomes have been mixed and reports include significant reductions in markers of liver dysfunction and in mortality, as well as no effect. In acute viral hepatitis, studies have generally involved small sample sizes and have shown mixed outcomes of improved liver function (eg, aminotransferase values, bilirubin, prothrombin time) or no effect. Studies in chronic viral hepatitis and toxin-induced injury have also been of small size but have reported mostly favorable results. Parenteral silybin is marketed and used in Europe as an antidote in *Amanita phalloides* mushroom poisoning, based on favorable outcomes reported in case-control studies.

Overall, milk thistle may be effective in improving survival and liver function in a variety of conditions, but additional well-designed clinical trials are needed to confirm these findings.

Adverse Effects

Milk thistle has rarely been reported to cause adverse effects. Loose stools associated with increased bile secretion may occur at high doses.

Drug Interactions, Precautions, & Dosing

There are no reported drug-drug interactions or precautions for milk thistle. Recommended dosage is 200–400 mg/d, calculated as silybin, in three divided doses.

St. John's Wort (*Hypericum Perforatum*)

Chemistry

St. John's wort, also known as hypericum, contains a variety of constituents that may contribute to its pharmacologic activity. Hypericin, a marker of standardization for currently marketed products, was thought to be the primary antidepressant constituent. Recent attention has focused on hyperforin, but a combination of several compounds is probably involved. Commercial formulations are usually prepared by soaking the dried chopped flowers in methanol to create a hydroalcoholic extract that is then dried.

Pharmacologic Effects

Anti-Depressant Action

The hypericin fraction was initially reported to have MAO-A and -B inhibitor properties. Later studies found that the concentration required for this inhibition was higher than that which could be achieved with recommended dosages. In vitro studies using the commercially formulated hydroalcoholic extract have shown inhibition of serotonin, norepinephrine, and dopamine reuptake. While the hypericin constituent did not show reuptake inhibition for any of these systems, a concentrated hyperforin extract did. Chronic administration of the commercial extract has also been shown to significantly down-regulate the expression of cortical β -adrenoceptors and up-regulate the expression of serotonin receptors in a rodent model.

Other effects observed in vitro include opioid sigma receptor binding using the hypericin fraction and GABA receptor binding using the commercial extract. Interleukin-6 production is also reduced in the presence of the extract.

A number of clinical trials have shown St. John's wort to be more efficacious than placebo and just as efficacious as some prescription antidepressants for mild to moderate depression. It does not appear to be effective, however, for more severe depression. Most trials used doses of St. John's wort ranging from 300 mg/d to 1000 mg/d and lasted 4–8 weeks.

Antiviral and Anticarcinogenic Effects

The hypericin constituent of St. John's wort is photolabile and can be activated by exposure to certain wavelengths of visible or UVA light. Parenteral formulations of hypericin (photoactivated just before administration) have been used investigatively to treat HIV infection (given

intravenously) and basal and squamous cell carcinoma (given by intralesional injection). In vitro, photoactivated hypericin inhibits a variety of enveloped and nonenveloped viruses as well as the growth of cells in some neoplastic tissues. Inhibition of protein kinase C and of singlet oxygen radical generation have been proposed as possible mechanisms. The latter could inhibit cell growth or cause cell apoptosis. These studies were carried out using the isolated hypericin constituent of St. John's wort; the usual hydroalcoholic extract of St. John's wort has not been studied for these indications and should not be recommended for patients with viral illness or cancer.

Adverse Effects

Photosensitization has been reported, and patients should be instructed to wear sunscreen while using this product. Hypomania, mania, and autonomic arousal have also been reported in patients using St. John's wort.

Drug Interactions & Precautions

Inhibition of reuptake of various amine transmitters has been highlighted as a potential mechanism of action for St. John's wort. Drugs with similar mechanisms (ie, antidepressants, stimulants) should be used cautiously or avoided in patients using St. John's wort due to the risk of serotonin syndrome or MAO crisis (see Chapters 30 and 59). This herb may induce hepatic CYP enzymes and the P-glycoprotein drug transporter. This has led to case reports of subtherapeutic levels of digoxin, birth control drugs (and subsequent pregnancy), cyclosporine, HIV protease and nonnucleoside reverse transcriptase inhibitors, warfarin, irinotecan, theophylline, and anticonvulsants.

Dosage

The most common commercial formulation of St. John's wort is the dried hydroalcoholic extract. Products are currently standardized to contain 0.3% hypericin. This may change to reflect the new results implicating hyperforin, which should be 2–5%. The recommended dosing for mild to moderate depression is 900 mg of the dried extract per day in three divided doses. Onset of effect may take 2–4 weeks. Long-term benefits beyond 8 weeks have not been sufficiently studied.

Saw Palmetto (*Serenoa Repens* or *Sabal Serrulata*)

Chemistry

The active constituents in saw palmetto berries are not well defined. Phytosterols (eg, β -sitosterol), aliphatic alcohols, polyphenolic compounds, and flavonoids are all present. Marketed preparations are lipophilic extracts that contain 85–95% fatty acids and sterols.

Pharmacologic Effects

Saw palmetto is most often used in the treatment of benign prostatic hyperplasia. Enzymatic conversion of testosterone to dihydrotestosterone (DHT) by 5 α -reductase is inhibited by saw palmetto in vitro. This effect is similar to that of finasteride, which is also used to treat the disorder (Chapter 40: The Gonadal Hormones & Inhibitors). In vitro, saw palmetto also inhibits the binding of DHT to androgen receptors. Additional effects that have been observed in vitro include inhibition of prostatic growth factors, blockade of α_1 -adrenoceptors, and inhibition of inflammatory mediators

produced by the 5-lipoxygenase pathway.

The clinical pharmacology of saw palmetto is not well defined. One week of treatment in healthy volunteers failed to influence 5 α -reductase activity, DHT concentration, or testosterone concentration. Six months of treatment in patients with benign prostatic hyperplasia also failed to affect prostate-specific antigen (PSA) levels, a marker that is typically reduced by enzymatic inhibition of 5 α -reductase. In contrast, other researchers have reported a reduction in epidermal growth factor, DHT levels, and estrogen expression after three months of treatment in patients with benign prostatic hyperplasia. The largest clinical trial to date compared saw palmetto, 320 mg/d, with finasteride, 5 mg/d, in 1098 patients. At 6 months, overall symptom score, quality of life, and peak urinary flow were significantly improved for both groups. Finasteride was significantly better at reducing prostate volume (18% versus 6%, respectively). Adverse effects were comparable in both groups except for a significantly greater degree of sexual dysfunction in patients receiving finasteride versus saw palmetto. Shortcomings in the latter trial included lack of placebo control and failure to extend the study duration beyond 6 months.

In a systematic review of seven double-blind placebo-controlled trials, saw palmetto was found to be significantly more effective than placebo in reducing nocturnal urinary frequency (33–74% versus 13–39%, respectively), in reducing daytime urinary frequency (11–43% versus 1–29%, respectively), and in increasing peak urinary flow (26–50% versus 2–35%, respectively). A recent meta-analysis of randomized controlled trials also indicated a therapeutic advantage of saw palmetto over placebo in improving urologic symptoms and flow measures.

Small comparative trials of saw palmetto versus α -blockers showed greater symptomatic improvement with α -blockers.

Adverse Effects

In the largest clinical trial conducted to date, adverse events reported with an incidence of 1–3% included hypertension, decreased libido, abdominal pain, impotence, back pain, urinary retention, and headache. In another large-scale trial, gastrointestinal upset was the most common side effect.

Drug Interactions, Precautions, & Dosing

No drug-drug interactions have been reported for saw palmetto. Patients should be instructed that it may take 4–6 weeks for onset of clinical effects. Recommended dosing of a standardized dried extract (containing 85–95% fatty acids and sterols) is 160 mg orally twice daily. The efficacy of saw palmetto in benign prostatic hyperplasia beyond 6 months has not been established.

Katzung PHARMACOLOGY, 9e > Section X. Special Topics > Chapter 65. Botanicals ("Herbal Medications") & Nutritional Supplements > Purified Nutritional Supplements >

Dehydroepiandrosterone

Dehydroepiandrosterone (DHEA) is a precursor hormone secreted by the adrenal cortex and to a lesser extent by the central nervous system (Chapter 40: The Gonadal Hormones & Inhibitors). It is readily converted to androstenedione, testosterone, and androsterone. In peripheral tissues, aromatase converts DHEA to estradiol. In the plasma, DHEA is converted to DHEA sulfate (DHEAS).

Although no specific physiologic function has been attributed to DHEA or DHEAS, the

relationships between their endogenous levels and various diseases have been widely studied. Exogenous DHEA supplementation has been advocated for a variety of indications, including relief of age-related disorders, promotion of weight loss, reduction of heart disease risk, prevention of a variety of cancers, and strengthening of the immune system.

Clinical Uses

Weight Loss

Only a few poorly designed studies have assessed the effects of DHEA supplements in facilitating weight loss. Each of these studies employed a very small sample size and varying measures of weight loss. The effects of DHEA on weight loss are therefore uncertain. Until more is known, DHEA should not be recommended as a weight loss agent.

Cardiovascular Disease

DHEA may affect the synthesis of cholesterol and other lipids involved in atherogenesis. Many studies have assessed the relationship between endogenous DHEA levels and the risk for developing cardiovascular disease. Both high and low DHEA levels have been associated with increased risk of cardiovascular morbidity in men. In postmenopausal women, cardiovascular morbidity was greater in women with high DHEAS levels.

Hypercholesterolemia

The effects on cholesterol values in the few studies reported to date have been modest and variable. Thus, the role of DHEA in hypercholesterolemia in men and women has not been determined. According to existing information, endogenous levels of DHEA do not correlate with cholesterol regulation or synthesis. DHEA supplementation might have a role in decreasing HDL cholesterol in postmenopausal women since DHEA is converted to estradiol and to a lesser extent testosterone. These proposed effects need to be assessed using adequate study design.

Aging

Because DHEA and DHEAS levels decline with age, DHEA has been advocated as replacement therapy to prevent age-associated changes (especially in sexual function in men) and diseases. DHEA has demonstrated some antioxidant effects. The extent to which DHEA may decrease free radical formation, however, requires further study.

A low DHEA dose is adequate to increase DHEAS levels to those of a 20- or 30-year-old individual, and some evidence suggests that DHEA replacement dosing increases mean free testosterone levels in elderly men (by 5–10% after DHEA initiation, remaining slightly elevated for 2–3 months). The clinical significance of this effect is not known.

There is insufficient evidence at present to recommend DHEA in preventing any age-associated diseases.

Alzheimer's Disease

The role of DHEA supplementation in Alzheimer's disease remains controversial. Some research suggests that low endogenous DHEA and DHEAS levels correlate with dementia, while other reports are negative. Research is continuing to assess the effects of DHEA supplementation on

dementia and Alzheimer's disease.

Treatment of HIV Infection and AIDS

Early studies in mice demonstrated that DHEA supplementation afforded protection against certain virus infections. Furthermore, DHEA affected T lymphocytes by increasing IL-2 production and decreasing IL-4, IL-5, and IL-6 release. The effect of DHEA supplementation on HIV disease progression has therefore been assessed in both men and women. Women reported improvements in energy, cognitive and physical functioning, emotional well-being, and health perception. Modest increases in body weight and CD4 cell counts were seen in women receiving DHEA. No patients displayed a statistically significant decline in viral load. Although male subjects reported improvements in well being, changes in CD4 cell counts were not observed.

Systemic Lupus Erythematosus (SLE)

SLE is associated with low levels of endogenous DHEA and DHEAS in women. In one study, patients receiving DHEA for 6 months had fewer lupus flares and improved global assessment scores of disease activity as measured by retrospective medical record review. Adverse effects included acne, hirsutism, menstrual alterations, emotional changes, and weight gain. In another study, statistically significant improvements were observed in the SLE disease activity index during the first 3 months of therapy. However, nearly 60% of patients discontinued DHEA supplementation prior to the 1-year study completion. Reasons for discontinuation included lack of efficacy (30%) and androgenic side effects (14%).

Diabetes

Early evidence suggested that DHEA might be used to ameliorate insulin resistance in patients with diabetes. DHEA and DHEAS levels appear to decline in a variety of disease states characterized by insulin resistance or states associated with hyperinsulinism such as hypertension, obesity, and type 2 diabetes mellitus. These relationships have prompted the promotion of DHEA as a regulator of blood glucose levels. However, a role for DHEA in regulating blood glucose and the management of diabetes has not been adequately demonstrated. Until more information is available, patients with diabetes should not rely on DHEA to help control blood glucose.

Adverse Effects & Risks of DHEA & DHEAS Use

Benign Prostatic Hyperplasia and Prostate Cancer

The effects of DHEA on the prostate are still unknown. However, since DHEA supplementation can increase mean testosterone levels, it might contribute to increased prostate cell growth, and worsening of prostate cancer must be considered. Because the ultimate effects are unknown, patients with benign prostatic hyperplasia should avoid using DHEA. If a patient uses DHEA therapy, he should be closely monitored for signs and symptoms of prostate disease.

Other Cancers

DHEA supplementation can increase production of gonadal hormones. Therefore, DHEA should be avoided by patients with any type of hormone-dependent cancer.

Endocrine Effects

Endocrine adverse effects depend on gender and DHEA dose. DHEA is a precursor of gonadal hormones, and it appears to be preferentially converted to the hormone present in lowest quantities. In premenopausal women, DHEA is converted mainly to testosterone and minimally to estrogen. In men, conversion favors increased production of estrogen and to a lesser extent testosterone. Women therefore may complain of masculinizing effects such as hirsutism, acne, and deepening of the voice. Men may experience gynecomastia and breast tenderness.

Reports of euphoria or an increased sense of well-being are also common and may be related to increased release of corticosteroid congeners. DHEA has also been reported to cause mania and cardiac arrhythmias. Although these reports are rare, patients at risk for these effects should avoid taking DHEA.

Drug Interactions

Drug-drug interactions have not been systematically studied for DHEA. It is unknown whether DHEA interacts with over-the-counter medicine or prescription drugs.

Dosage

Replacement dosage sufficient to maintain DHEA levels at young adult values varies with gender and the individual. Approximately 25–50 mg daily is adequate for women, whereas 25–100 mg may be required for men. Adverse effects appear to be uncommon at these doses. Doses greater than 100 mg daily have been used to increase androgens and other hormones. Doses of 1600 mg daily have resulted in significant adverse effects, often requiring drug discontinuation.

Katzung PHARMACOLOGY, 9e > Section X. Special Topics > Chapter 65. Botanicals ("Herbal Medications") & Nutritional Supplements > Purified Nutritional Supplements >

Melatonin

Melatonin, a serotonin derivative produced by the pineal gland and some other tissues (see also Chapter 16: Histamine, Serotonin, & the Ergot Alkaloids), is believed to be responsible for regulating sleep-wake cycles. Melatonin release coincides with darkness; it typically begins around 9 PM and lasts until about 4 AM. Melatonin release is suppressed by daylight. Melatonin has also been studied for a number of other functions, including contraception, protection against endogenous oxidants, prevention of aging, and treatment of depression, HIV infection, and a variety of cancers. Currently, melatonin is most often administered to induce sleep and to prevent jet lag.

Pharmacologic Effects & Clinical Uses

Jet Lag

Jet lag, a disturbance of the sleep-wake cycle, occurs when there is a disparity between the external time and the traveler's endogenous circadian clock (internal time). The internal time regulates not only daily sleep rhythms but also body temperature and many metabolic systems. The synchronization of the circadian clock relies on light as the most potent "zeitgeber" (time giver).

Jet lag is especially common among frequent travelers and airplane cabin crews. Typical symptoms of jet lag may include daytime drowsiness, insomnia, frequent awakenings, and gastrointestinal upset. Clinical studies with administration of melatonin have reported subjective reduction in daytime fatigue, improved mood, and a quicker recovery time (return to normal sleep patterns,

energy, and alertness). Unfortunately, many of these studies were characterized by inconsistencies in dosing, duration of therapy, and time of drug administration. In addition to melatonin, maximizing exposure to daylight on arrival at the new destination can aid in resetting the internal clock.

Insomnia

Melatonin has been studied in the treatment of various sleep disorders, including insomnia and delayed sleep-phase syndrome. Melatonin has been shown to improve sleep onset, duration, and quality when administered to healthy volunteers, suggesting a pharmacologic hypnotic effect. Melatonin has also been shown to increase rapid-eye-movement (REM) sleep.

Clinical studies in patients with sleep disorders have shown that oral melatonin supplementation may alter sleep architecture. Subjective improvements in sleep quality and improvements in sleep onset and sleep duration have been reported. However, the significance of these findings is impaired by many study limitations.

Patients over 65 years of age tend to suffer from sleep maintenance insomnia; melatonin serum levels have been reported to be low in these patients. Elderly patients with sleep maintenance insomnia who received immediate-release and sustained-release melatonin had improved sleep onset time. They did not, however, experience an improvement in sleep maintenance or total sleep time.

Female Reproductive Function

Melatonin receptors have been identified in granulosa cell membranes, and significant amounts of melatonin have been detected in ovarian follicular fluid. Melatonin has been associated with midcycle suppression of luteinizing hormone surge and secretion. This may result in partial inhibition of ovulation. Nightly doses of melatonin (75–300 mg) given with a progestin through days 1–21 of the menstrual cycle resulted in lower mean LH levels. Therefore, melatonin should not be used by women who are pregnant or attempting to conceive. Furthermore, melatonin supplementation may decrease prolactin release in women and therefore should be used cautiously or not at all while nursing.

Male Reproductive Function

In healthy men, chronic melatonin administration (≈ 6 months) decreased sperm quality, possibly by aromatase inhibition in the testes. Until more is known, melatonin should not be used by couples who are actively trying to conceive.

Adverse Effects

Melatonin appears to be well tolerated and is often used in preference to over-the-counter "sleep-aid" drugs. Although melatonin is associated with few adverse effects, some next-day drowsiness has been reported as well as tachycardia, depression, vivid dreams, and headache. Sporadic case reports of movement disorders and psychoses have also appeared.

Drug Interactions

Melatonin drug interactions have not been formally studied. Various studies, however, suggest that melatonin concentrations are altered by a variety of drugs, including NSAIDs, antidepressants, β -

adrenoceptor agonists and antagonists, scopolamine, and sodium valproate. The relevance of these effects is unknown.

Dosage

Jet Lag

The optimal timing and dose of melatonin have not been established. Current information suggests 5–8 mg of the immediate-release formulation given on the evening of departure and for 1–3 nights after arrival at the new destination. Exposure to daylight at the new time zone is also important to regulate the sleep-wake cycle.

Insomnia

Doses of 0.3–10 mg of the immediate-release formulation orally given once nightly have been tried. The lowest effective dose should be used first and may be repeated in 30 minutes up to a maximum of 10–20 mg. Sustained-release formulations may be used but currently do not offer any notable advantages over the immediate-release formulations. Sustained-release formulations are also more costly.

Chapter 66. Rational Prescribing & Prescription Writing

Rational Prescribing

Like any other process in medicine, writing a prescription should be based on a series of rational steps.

(1) Make a specific diagnosis: Prescriptions based merely on a desire to satisfy the patient's psychological need for some type of therapy are often unsatisfactory and may result in adverse effects. A specific diagnosis, even if it is tentative, is required to move to the next step. In a 35-year-old woman with symmetric joint stiffness, pain, and inflammation that are worse in the morning and not associated with a history of infection, a diagnosis of rheumatoid arthritis would be considered. This diagnosis and the reasoning underlying it should be shared with the patient.

(2) Consider the pathophysiologic implications of the diagnosis: If the disorder is well understood, the prescriber is in a much better position to offer effective therapy. For example, increasing knowledge about the mediators of inflammation makes possible more effective use of NSAIDs and other agents used in rheumatoid arthritis. The patient should be provided with the appropriate level and amount of information about the pathophysiology. Many disease-oriented public and private agencies (eg, American Heart Association, American Cancer Society, Arthritis Foundation) provide information sheets suitable for patients.

(3) Select a specific therapeutic objective: A therapeutic objective should be chosen for each of the pathophysiologic processes defined in the preceding step. In a patient with rheumatoid arthritis, relief of pain by reduction of the inflammatory process is one of the major therapeutic goals that identifies the drug groups which will be considered. Arresting the course of the disease process in rheumatoid arthritis is a different therapeutic goal that might lead to consideration of other drug groups and prescriptions.

(4) Select a drug of choice: One or more drug groups will be suggested by each of the therapeutic goals specified in the preceding step. Selection of a drug of choice from among these groups will follow from a consideration of the specific characteristics of the patient and the clinical presentation. For certain drugs, characteristics such as age, other diseases, and other drugs being taken are extremely important in determining the most suitable drug for management of the present complaint. In the example of the patient with probable rheumatoid arthritis, it would be important to know whether she has a history of aspirin intolerance or ulcer disease, whether the cost of medication is an especially important factor, and whether there is a need for once-daily dosing. Based on this information, a drug would probably be selected from the nonsteroidal anti-inflammatory group. If the patient is intolerant of aspirin and does not have ulcer disease but does have a need for low-cost treatment, ibuprofen would be a rational choice.

(5) Determine the appropriate dosing regimen: The dosing regimen is determined primarily by the pharmacokinetics of the drug in that patient. If the patient is known to have disease of the organs required for elimination of the drug selected, adjustment of the "average" regimen will be needed. For a drug such as ibuprofen, which is eliminated mainly by the kidneys, renal function should be assessed. If renal function is normal, the half-life of ibuprofen (about 2 hours) requires administration three or four times daily. The dose suggested in drug handbooks and the manufacturer's literature is 400–800 mg four times daily.

(6) Devise a plan for monitoring the drug's action and determine an end point for therapy:

The prescriber should be able to describe to the patient the kinds of drug effects that will be monitored and in what way, including laboratory tests (if necessary) and signs and symptoms that the patient should report. For conditions that call for a limited course of therapy (eg, most infections), the duration of therapy should be made clear so that the patient will not stop taking the drug prematurely and will understand why the prescription probably need not be renewed. For the patient with rheumatoid arthritis, the need for prolonged—perhaps indefinite—therapy should be explained. The prescriber should also specify any changes in the patient's condition that would call for changes in therapy. For example, in the patient with rheumatoid arthritis, development of gastrointestinal bleeding would require an immediate change in drug therapy and a prompt workup of the bleeding. Major toxicities that require immediate attention should be explained clearly to the patient.

(7) Plan a program of patient education: The prescriber and other members of the health team should be prepared to repeat, extend, and reinforce the information transmitted to the patient as often as necessary. The more toxic the drug prescribed, the greater the importance of this educational program. The importance of informing and involving the patient in each of the above steps must be recognized, as shown by experience with teratogenic drugs (see Chapter 60: Special Aspects of Perinatal & Pediatric Pharmacology; Shulman, 1989).

The Prescription

While a prescription can be written on any piece of paper (as long as all of the legal elements are present), it usually takes a specific form. A typical printed prescription form for outpatients is shown in Figure 66–1.

Figure 66–1.

① JOHN B. DOE, MD 1234 SOUTH NORTHEAST DR ③ WEST CITY, CA 94999 (234) 555-6789 ④	
FOR: ⑥	DATE: ⑤
ADDRESS: ⑦	
Rx ⑧ (DRUG NAME AND STRENGTH) (QUANTITY) ⑩	
SIG: ⑪	
REFILL	TIMES
OR UNTIL ⑫	
NO CHILDPROOF CONTAINER	⑬
WARNING: ⑭	⑮, MD
	AD1234567 ⑯
	STATE LICENSE NO. ⑰

Common form of outpatient prescription. Circled numbers are explained in the text.

In the hospital setting, drugs are prescribed on a particular page of the patient's hospital chart called the **physician's order sheet (POS)** or **chart order**. The contents of that prescription are specified in the medical staff rules by the hospital's Pharmacy and Therapeutics Committee. The patient's name is typed or written on the form; therefore, the orders consist of the name and strength of the medication, the dose, the route and frequency of administration, the date, other pertinent information, and the signature of the prescriber. The duration of therapy or the number of doses is often not specified; therefore, medications are continued until the prescriber discontinues the order or until it is terminated as a matter of policy routine, eg, a stop order policy.

A typical chart order might be as follows:

11/13/03
10:30 a.m.
(1) Ampicillin 500 mg IV q6h x 5 days
(2) Aspirin 0.6 g per rectum q6h prn temp over 101
[Signed] Janet B. Doe, MD

Thus, the elements of the hospital chart order are equivalent to the central elements (5, 8–11, 15) of the outpatient prescription.

Elements of the Prescription

The first four elements (see circled numerals in Figure 66–1) of the outpatient prescription establish the identity of the prescriber: name, license classification (ie, professional degree), address, and office telephone number. Before dispensing a prescription, the pharmacist must establish the prescriber's bona fides and should be able to contact the prescriber by telephone if any questions arise. Element [5] is the date the prescription was written. It should be near the top of the prescription form or at the beginning (left margin) of the chart order. Since the order has legal significance and usually has some temporal relationship to the date of the patient-prescriber interview, a pharmacist should refuse to fill a prescription without verification by telephone if too much time has elapsed since its writing.

Elements [6] and [7] identify the patient by name and address. The patient's name and full address should be clearly spelled out.

The body of the prescription contains the elements [8] to [11] that specify the medication, the strength and quantity to be dispensed, the dosage, and complete directions for use. When writing the drug name (element [8]), either the brand name (proprietary name) or generic name (nonproprietary name) may be used. Reasons for using one or the other are discussed below. The strength of the medication (element [9]) should be written in metric units. However, the prescriber should be familiar with both systems now in use: apothecary and metric. For practical purposes, the following approximate conversions are useful:

1 grain (gr) = 0.065 grams (g), often rounded to 60 milligrams (mg)

15 gr = 1 g

1 ounce (oz) by volume = 30 milliliters (mL)

1 teaspoonful (tsp) = 5 mL

1 tablespoonful (tbsp) = 15 mL

1 quart (qt) = 1000 mL

1 minim = 1 drop (gtt)

20 drops = 1 mL

2.2 pounds (lb) = 1 kilogram (kg)

The strength of a solution is usually expressed as the quantity of solute in sufficient solvent to make 100 mL; for instance, 20% potassium chloride solution is 20 grams of KCl per deciliter (g/dL). Both the concentration and the volume should be explicitly written out.

The quantity of medication prescribed should reflect the anticipated duration of therapy, the cost, the need for continued contact with the clinic or physician, the potential for abuse, and the potential for toxicity or overdose. Consideration should be given also to the standard sizes in which the product is available and whether this is the initial prescription of the drug or a repeat prescription or refill. If 10 days of therapy are required to effectively cure a streptococcal infection, an appropriate quantity for the full course should be prescribed. Birth control pills are often prescribed for 1 year or until the next examination is due; however, some patients may not be able to afford a year's supply at one time; therefore, a 3-month supply might be ordered, with refill instructions to renew three times or for 1 year (element [12]). Finally, when first prescribing medications that are to be used for the treatment of a chronic disease, the initial quantity should be small, with refills for larger quantities. The purpose of beginning treatment with a small quantity of drug is to reduce the cost if the patient cannot tolerate it. Once it is determined that intolerance is not a problem, a larger quantity purchased less frequently is sometimes less expensive.

The directions for use (element [11]) must be both drug-specific and patient-specific. The simpler the directions, the better; and the fewer the number of doses (and drugs) per day, the better. Patient

noncompliance (failure to adhere to the drug regimen) is a major cause of treatment failure. To help patients remember to take their medications, prescribers often give an instruction that medications be taken at or around mealtimes and at bedtime. However, it is important to inquire about the patient's eating habits and other lifestyle patterns, since many patients do not eat three regularly spaced meals a day—especially if they are sick or dieting.

The instructions on how and when to take medications, the duration of therapy, and the purpose of the medication must be explained to each patient by the physician and by the pharmacist. (Neither should assume that the other will do it.) Furthermore, the drug name, the purpose for which it is given, and the duration of therapy should be written on each label so that the drug may be identified easily in case of overdose. An instruction to "take as directed" may save the time it takes to write the orders out but often leads to noncompliance, patient confusion, and medication error. The directions for use must be clear and concise to avoid toxicity and to obtain the greatest benefits from therapy.

Although directions for use are no longer written in Latin, many Latin apothecary abbreviations (and some others included below) are still in use. Knowledge of these abbreviations is essential for the dispensing pharmacist and often useful for the prescriber. Some of the abbreviations still used are listed in Table 66–1.

Table 66–1. Abbreviations Used in Prescriptions and Chart Orders.

ABBREVIATION	EXPLANATION
ā	before
ac	before meals
agit	shake, stir
Aq	water
Aq dest	distilled water
bid	twice a day
ċ	with
cap	capsule
D5W, D ₅ W	dextrose 5% in water
dil	dissolve, dilute
disp, dis	dispense
elix	elixir
ext	extract
g	gram
gr	grain
gtt	drops
h	hour
hs	at bedtime

IA	intra-arterial
IM	intramuscular
IV	intravenous
IVPB	IV piggyback
kg	kilogram
mEq, meq	milliequivalent
mg	milligram
mcg, μ g (do not use)	microgram (always write out "microgram")
no	number
non rep	do not repeat
OD	right eye
OS, OL	left eye
OTC	over-the-counter
OU	both eyes
\bar{p}	after
pc	after meals
PO	by mouth
PR	per rectum
prn	when needed
q	every
qam, om	every morning
qd	every day
qh, q1h	every hour
q2h, q3h, etc	every 2 hours, every 3 hours, etc
qhs	every night at bedtime
qid	four times a day
qod	every other day
qs	sufficient quantity
rept, repet	may be repeated
Rx	take
\bar{s}	without
SC, SQ	subcutaneous
Sig, S	label
sos	if needed
$\bar{s}\bar{s}$, ss	one-half
stat	at once
sup, supp	suppository

susp	suspension
tab	tablet
tbsp, T (do not use)	tablespoon (always write out "15 mL")
tid	three times a day
tr, tinct	tincture
tsp (do not use)	teaspoon (always write out "5 mL")
U (do not use)	units (always write out "units")
vag	vaginal
i, ii, iii, iv, etc	one, two, three, four, etc
℥(do not use)	dram (in fluid measure, 3.7 mL)
℥̄(do not use)	ounce (in fluid measure, 29.6 mL)
Note: It is always safer to write out the direction without abbreviating.	

Elements [12] to [14] of the prescription include refill information, waiver of the requirement for childproof containers, and additional labeling instructions (eg, warnings such as "may cause drowsiness," "do not drink alcohol"). Pharmacists put the name of the medication on the label unless directed otherwise by the prescriber, and some medications have the name of the drug stamped or imprinted on the tablet or capsule. Pharmacists must place the expiration date for the drug on the label. If the patient or prescriber does not request waiver of childproof containers, the pharmacist or dispenser must place the medication in such a container. Pharmacists may not refill a prescription medication without authorization from the prescriber. Prescribers may grant authorization to renew prescriptions at the time of writing the prescription or over the telephone. Elements [15] to [17] are the prescriber's signature and other identification data.

Prescribing Errors

All prescription orders should be legible, unambiguous, dated (and timed in the case of a chart order), and signed clearly for optimal communication between prescriber, pharmacist, and nurse. Furthermore, a good prescription or chart order should contain sufficient information to permit the pharmacist or nurse to discover possible errors before the drug is dispensed or administered.

Several types of prescribing errors are particularly common. These include errors involving omission of needed information; poor writing perhaps leading to errors of drug dose or timing; and prescription of drugs that are inappropriate for the specific situation.

Omission of Information

Errors of omission are common in hospital orders and may include instructions to "resume pre-op meds," which assumes that a full and accurate record of the "pre-op meds" is available; "continue present IV fluids," which fails to state exactly what fluids are to be given, in what volume, and over what time period; or "continue eye drops," which omits mention of which eye is to be treated as well as the drug, concentration, and frequency of administration. Chart orders may also fail to

discontinue a prior medication when a new one is begun; may fail to state whether a regular or long-acting form is to be used; may fail to specify a strength or notation for long-acting forms; or may authorize "as-needed" (prn) use that fails to state what conditions will justify the need.

Poor Prescription Writing

Poor prescription writing is traditionally exemplified by illegible handwriting. However, other types of poor writing are common and often more dangerous. One of the most important is the misplaced or ambiguous decimal point. Thus ".1" is easily misread as "1," a tenfold overdose, if the decimal point is not unmistakably clear. This danger is easily avoided by always preceding the decimal point with a zero. On the other hand, appending an unnecessary zero after a decimal point increases the risk of a tenfold overdose, because "1.0 mg" is easily misread as "10 mg," whereas "1 mg" is not. The slash or virgule ("/") was traditionally used as a substitute for a decimal point. This should be abandoned because it is too easily misread as the numeral "1." Similarly, the abbreviation "U" for units should never be used because "10U" is easily misread as "100"; the word "units" should *always* be written out. Doses in micrograms should *always* have this unit written out because the abbreviated form ("µg") is very easily misread as "mg," a 1000-fold overdose! Orders for drugs specifying only the number of dosage units and not the total dose required should not be filled if more than one size dosage unit exists for that drug. For example, ordering "one ampule of furosemide" is unacceptable because furosemide is available in ampules that contain 20, 40, or 100 mg of the drug. The abbreviation "OD" should be used (if at all) only to mean "the right eye"; it has been used for "every day" and has caused inappropriate administration of drugs into the eye. Similarly, "Q.D." or "QD" should not be used because it is often read as "QID," resulting in four daily doses instead of one. Acronyms such as "ASA" (aspirin), "5-ASA" (5-aminosalicylic acid), "6MP" (6-mercaptopurine), etc, should not be used; drug names should be written out. Unclear handwriting can be lethal when drugs with similar names but very different effects are available, eg, acetazolamide and acetohexamide, methotrexate and metolazone. In this situation, errors are best avoided by noting the indication for the drug in the body of the prescription, eg, "acetazolamide, for glaucoma."

Inappropriate Drug Prescriptions

Prescribing an inappropriate drug for a particular patient results from failure to recognize contraindications imposed by other diseases the patient may have, failure to obtain information about other drugs the patient is taking (including over-the-counter drugs), or failure to recognize possible physicochemical incompatibilities between drugs that may react with each other. Contraindications to drugs in the presence of other diseases or pharmacokinetic characteristics are listed in the discussions of the drugs described in this book. The manufacturer's package insert usually contains similar information. Some of the important drug interactions are listed in Appendix II of this book as well as in package inserts.

Physicochemical incompatibilities are of particular concern when parenteral administration is planned. For example, when calcium and phosphate ion concentrations are excessively high in a total parenteral nutrition (TPN) solution, precipitation will occur. Similarly, the simultaneous administration of antacids or products high in metal content may compromise the absorption of many drugs in the intestine, eg, tetracyclines. The package insert and the *Handbook on Injectable Drugs* (Trissel 2003) are good sources for this information.

Compliance

Compliance (sometimes called "adherence") is the extent to which patients follow treatment instructions. There are four types of noncompliance leading to medication errors.

- (1) The patient fails to obtain the medication. Some studies suggest that one third of patients never have their prescriptions filled. Some patients leave the hospital without obtaining their discharge medications, while others leave the hospital without having their prehospitalization medications resumed. Some patients cannot afford the medications prescribed.
- (2) The patient fails to take the medication as prescribed. Examples include wrong dosage, wrong frequency of administration, improper timing or sequencing of administration, wrong route or technique of administration, or taking medication for the wrong purpose. This usually results from inadequate communication between the patient and the prescriber and the pharmacist.
- (3) The patient prematurely discontinues the medication. This can occur, for instance, if the patient incorrectly assumes that the medication is no longer needed because the bottle is empty or symptomatic improvement has occurred.
- (4) The patient (or another person) takes medication inappropriately. For example, the patient may share a medication with others for any of several reasons.

Several factors encourage noncompliance. Some diseases cause no symptoms (eg, hypertension); patients with these diseases therefore have no symptoms to remind them to take their medications. Patients with very painful conditions, such as arthritis, may continually change medications in hope of finding a better one. Characteristics of the therapy itself can limit the degree of compliance; patients taking a drug once a day are much more likely to be compliant than those taking a drug four times a day. Various patient factors also play a role in compliance. Patients living alone are much less likely to be compliant than married patients of the same age. Packaging may also be a deterrent to compliance—elderly arthritic patients often have difficulty opening their medication containers. Lack of transportation as well as various social or personal beliefs about the use of medications are likewise barriers to compliance.

Strategies for improving compliance include enhanced communication between the patient and health care team members; assessment of personal, social, and economic conditions (often reflected in the patient's lifestyle); development of a routine for taking medications (eg, at mealtimes if the patient has regular meals); and provision of systems to assist taking medications (ie, containers that separate drug doses by day of the week, or medication alarm clocks that remind patients to take their medications); and mailing of refill reminders by the pharmacist to patients taking drugs chronically. The patient who is likely to discontinue a medication because of a perceived drug-related problem should receive instruction and education about how to monitor and understand the effects of the medication. Compliance can often be improved by enlisting the patient's active participation in the treatment.

Katzung PHARMACOLOGY, 9e > Section X. Special Topics > Chapter 66. Rational Prescribing & Prescription Writing >

Legal Factors (USA)

The United States government recognizes two classes of drugs: (1) over-the-counter (OTC) drugs and (2) those that require a prescription from a licensed prescriber (Rx Only). OTC drugs are those that can be safely self-administered by the layman for self-limiting conditions and for which appropriate labels can be written for lay comprehension. Half of all drug doses consumed by the American public are OTC drugs.

Physicians, dentists, podiatrists, and veterinarians—and, in some states, specialized pharmacists, nurses, physician's assistants, and optometrists—are granted authority to prescribe dangerous drugs (those bearing the federal legend statement, "Rx Only") on the basis of their training in diagnosis and treatment (see Who May Prescribe?). Pharmacists are authorized to dispense prescriptions pursuant to a prescriber's order provided that the medication order is appropriate and rational for the patient. Nurses are authorized to administer medications to patients subject to a prescriber's order.

Prescription drugs are controlled by the United States Food and Drug Administration as described in Chapter 5: Basic & Clinical Evaluation of New Drugs. The federal legend statement as well as the package insert are part of the packaging requirements for all prescription drugs. The package insert is the official brochure setting forth the indications, contraindications, warnings, and dosing for the drug.

The prescriber, by writing and signing a prescription order, controls who may obtain prescription drugs. The pharmacist may purchase these drugs, but they may be dispensed only on the order of a legally qualified prescriber. Thus, a "prescription" is actually three things: the physician's order in the patient's chart, the written order to which the pharmacist refers when dispensing, and the patient's medication container with a label affixed.

While the federal government controls the drugs and their labeling and distribution, the state legislatures control who may prescribe drugs through their licensing boards, eg, the Board of Medical Examiners. Prescribers must pass examinations, pay fees, and—in the case of some states and some professions—meet other requirements for relicensure such as continuing education. If these requirements are met, the prescriber is licensed to order dispensing of drugs.

The federal government and the states further impose special restrictions on drugs according to their perceived potential for abuse (Table 66–3). Such drugs include opioids, hallucinogens, stimulants, depressants, and anabolic steroids (see Chapter 32: Drugs of Abuse). Special requirements must be met when these drugs are to be prescribed. The Controlled Drug Act requires prescribers and dispensers to register with the Drug Enforcement Agency (DEA), pay a fee, receive a personal registration number, and keep records of all controlled drugs prescribed or dispensed. Every time a controlled drug is prescribed, a valid DEA number must appear on the prescription blank.

Table 66–3. Classification of Controlled Substances.

Schedule	Potential for Abuse	Other Comments
I	High	No accepted medical use; lack of accepted safety as drug.
II	High	Current accepted medical use. Abuse may lead to psychologic or physical dependence.
III	Less than I or II	Current accepted medical use. Moderate or low potential for physical dependence and high potential for psychologic dependence.

IV	Less than III	Current accepted medical use. Limited potential for dependence.
V	Less than IV	Current accepted medical use. Limited dependence possible.

Prescriptions for substances with a high potential for abuse (schedule II) cannot be refilled. Prescriptions for schedule III, IV, and V drugs can be refilled, but there is a five-refill maximum, and in no case may the prescription be refilled after 6 months from the date of writing. Schedule II drug prescriptions may not be transmitted over the telephone, and some states require a special state-issued prescription blank. These restrictive prescribing laws are intended to limit the amount of drugs of abuse that are made available to the public.

Unfortunately, the inconvenience occasioned by these laws—and an unwarranted fear by medical professionals themselves regarding the risk of patient tolerance and addiction—continues to hamper adequate treatment of patients with terminal conditions. This has been shown to be particularly true in children and elderly patients with cancer. *There is no excuse for inadequate treatment of pain in a terminal patient; not only is addiction irrelevant in such a patient, it is actually uncommon in patients who are being treated for pain* (see Chapter 31: Opioid Analgesics & Antagonists). Some states have recognized the underutilization of pain medications in the treatment of pain associated with chronic and terminal conditions. California, for example, has enacted an "intractable pain treatment" act that reduces the difficulty of renewing prescriptions for opioids. Under the provisions of this act, upon receipt of a copy of the order from the prescriber, eg, by fax, a pharmacist may write a "triplicate" prescription* for a Schedule II substance for a patient under hospice care or living in a skilled nursing facility or in cases where the patient is expected to live less than 6 months; the word "exemption" with regulatory code number is written on a typical prescription, thus providing easier access for the terminally ill.

* The "triplicate" is the special California prescription form required for Schedule II substances.

Labeled & Unlabeled Uses of Drugs

In the USA, the FDA approves a drug only for the specific uses proposed and documented by the manufacturer in its New Drug Application (NDA; see Chapter 5: Basic & Clinical Evaluation of New Drugs). These approved (labeled) uses or indications are set forth in the package insert that accompanies the drug. For a variety of reasons, these labeled indications may not include all the conditions in which the drug might be useful. Therefore, a clinician may wish to prescribe the agent for some other, unapproved (unlabeled) clinical condition, often on the basis of adequate or even compelling scientific evidence. Federal laws governing FDA regulations and drug use place no restrictions on such unapproved use.‡

‡"Once a product has been approved for marketing, a physician may prescribe it for uses or in treatment regimens or patient populations that are not included in the approved labeling. Such 'unapproved' or, more precisely, 'unlabeled' uses may be appropriate and rational in certain circumstances, and may, in fact, reflect approaches to drug therapy that have been extensively reported in medical literature."—FDA Drug Bull 1982;12:4.

Even if the patient suffers injury from the drug, its use for an unlabeled purpose does not in itself constitute "malpractice." However, the courts may consider the package insert labeling as a complete listing of the indications for which the drug is considered safe unless the clinician can show that other use is considered safe by competent expert testimony.

Who May Prescribe?*

The right to prescribe drugs and much of the legal responsibility for any harm that derives from the prescription were largely limited to just two groups in the past: physicians and osteopaths. In recent years, this power has diffused and now includes—in a number of states and in varying degrees—pharmacists, nurse practitioners, physician's assistants, and optometrists (see Table 66–2). This development began with the growth of a sense of independence within different health professions and was actively promoted by their professional societies. The more recent development of large health maintenance organizations has greatly strengthened the movement because it offers these extremely powerful economic bodies a way to reduce their expenses.

State	Pharmacists	Nurse Practitioners	Physician's Assistants	Optometrists
California	Yes, under protocol; ¹ must be trained in clinical practice	Yes ²	Yes, under protocol ¹	Yes; limited to certain drug classes
Florida	Yes, according to state formulary; protocol not required	Yes ²	Yes ²	Yes; limited to certain drug classes
Michigan	Yes, under protocol; must be specially qualified by education, training, or experience	Yes; do not need physician supervision	Yes ²	Yes; limited to certain drug classes
Mississippi	Yes, under protocol in an institutional setting	Yes, ² under narrowly specified conditions	No	Yes; limited to certain drug classes
Nevada	Yes, under protocol, within a licensed medical facility	Yes ²	Yes ²	Yes; limited to certain drug classes
New Mexico	Yes, under protocol, must be "pharmacist clinician"	Yes; do not need physician supervision	Yes ²	Yes; limited to certain drug classes
North Dakota	Yes, under protocol in an institutional setting	Yes; do not need physician supervision	Yes	Yes; limited to certain drug classes
Oregon	Yes, under guidelines set by the state board	Yes; do not need physician supervision	Yes ²	Yes; limited to certain drug classes
Texas	Yes, under protocol set for a particular patient in an	Yes; do not need physician	Yes	Yes; limited to certain drug

	institutional setting	supervision		classes
Washington	Yes, under guidelines set by the state board	Yes; do not need physician supervision	Yes ²	Yes; limited to certain drug classes

¹Under protocol: see Who May Prescribe.

²In collaboration with or under the supervision of a physician.

For example, under a plan of pharmacist care, a patient diagnosed as asthmatic by a physician might be referred to a pharmacist for coordination and follow-up of therapy. The pharmacist would be responsible for generating a problem list, prescribing and dispensing the appropriate drugs after consultation with the physician, educating the patient with regard to his or her disease and medications, and then following the patient's responses to the medications by means of appropriate tests (peak airflow metering, etc).

The primary organizations controlling the privilege of prescribing in the USA are the state boards, under the powers delegated to them by the state legislatures. As indicated in Table 66–2, many state boards have attempted to reserve some measure of the primary responsibility for prescribing to physicians by requiring that the ancillary professional work with or under a physician according to a specific "protocol." In the state of California, this protocol must include a statement of the training, supervision, and documentation requirements of the arrangement and must specify referral requirements, limitations to the list of drugs that may be prescribed (ie, a formulary), and a method of evaluation by the supervising physician. The protocol must be in writing and must be periodically updated (An Explanation of the Scope of RN Practice, 1994).

* This Section Prepared with the Assistance of Ronda Malone, PharmD.

Socioeconomic Factors

Generic Prescribing

Prescribing by generic name offers the pharmacist flexibility in selecting the particular drug product to fill the order and the patient a potential savings if there is price competition. The brand name of a popular sedative is, for example, Valium by Roche. The generic (public nonproprietary) name of the same chemical substance adopted by United States Adopted Names (USAN) and approved by the Food and Drug Administration (FDA) is diazepam. All diazepam drug products in the USA meet the pharmaceutical standards expressed in *United States Pharmacopeia (USP)*. However, there are several manufacturers, and prices vary greatly. For some drugs in common use, the difference in cost between the trade-named product and generic products varies from less than twofold to more than 100-fold.

In most states and in many hospitals, pharmacists have the option of supplying a generically equivalent drug product even if a proprietary name has been specified in the order. If the physician wants a particular brand of drug product dispensed, handwritten instruction to "dispense as written" or words of similar meaning are required. Some government-subsidized health care programs and many third-party insurance payers require that pharmacists dispense the cheapest generically equivalent product in the inventory. However, the principles of drug product selection by private

pharmacists do not permit substituting one therapeutic agent for another (therapeutic substitution)—ie, dispensing trichlormethiazide for hydrochlorothiazide would not be permitted without the prescriber's permission even though these two diuretics may be considered pharmacodynamically equivalent. Pharmacists within managed care organizations may follow different policies; see below.

It should not be assumed that every generic drug product is as satisfactory as the trade-named product, though most generics are satisfactory. Bioavailability—the effective absorption of the drug product—varies between manufacturers and sometimes between different lots of a drug produced by the same manufacturer. In the case of a very small number of drugs, which usually have a low therapeutic index, poor solubility, or a high ratio of inert ingredients to active drug content, a specific manufacturer's product may give more consistent results. In the case of life-threatening diseases, the advantages of generic substitution are probably outweighed by the clinical urgency so that the prescription should be filled as written.

In an effort to codify bioequivalence information, the FDA publishes *Approved Drug Products With Therapeutic Equivalence Evaluations*, with monthly supplements, commonly called "the Orange Book." The book contains listings of multisource products in one of two categories: Products coded "A" are considered bioequivalent to all other versions of that product with a similar "A" coding. Products not considered bioequivalent are coded "B." Of the approximately 8000 products listed, 90% are coded "A."

Mandatory drug product selection on the basis of price is common practice in the USA as third-party payers (insurance companies, health maintenance organizations, etc) enforce money-saving regulations. If outside a managed care organization, the prescriber can sometimes override these controls by writing "dispense as written" on a prescription that calls for a brand-named product. However, in such cases, the patient may have to pay the difference between the dispensed product and the cheaper one.

Within most managed care organizations, formulary controls have been put in place that force the selection of less expensive medications whenever they are available. In a managed care environment, the prescriber often selects the drug group rather than a specific agent, and the pharmacist dispenses the formulary drug from that group. For example, if a prescriber in such an organization decides that a patient needs a thiazide diuretic, the pharmacist will automatically dispense the single thiazide diuretic carried on the organization's formulary.

Other Cost Factors

The private pharmacy bases its charges on the cost of the drug plus a fee for providing a professional service. Each time a prescription is dispensed, there is a fee. The prescriber controls the frequency of filling prescriptions by authorizing refills and specifying the quantity to be dispensed. Thus, the prescriber can save the patient money by prescribing standard sizes (so that drugs do not have to be repackaged) and, when chronic treatment is involved, by ordering the largest quantity consistent with safety, expense, and third-party plan. Optimal prescribing for cost savings often involves consultation between the prescriber and the pharmacist. Because of continuing increases in the wholesale prices of drugs in the USA, prescription costs have risen dramatically over the past 3 decades (see The Cost of Prescriptions).

The Cost of Prescriptions

The cost of prescriptions has risen dramatically in the last several decades. The average price for a single prescription in the USA in 2003 was more than \$50.00. This rise is occasioned by new technology, marketing costs, and stockholder expectations. The pharmaceutical industry typically posts double-digit profits annually while the retail business sector shows a 3% profit. The cost to the patient for many new drugs like "statins" exceeds \$1000 per year. Pharmaceuticals are the highest out-of-pocket health-related cost for the health sector because many other health care services are covered by health insurance whereas prescriptions are often not.

These high drug costs have caused payers and consumers alike to seek alternative sources or to ask the government to subsidize personal pharmaceutical needs. Because the Canadian government has done a better job in controlling drug prices, their prices are less than those in the United States. This fact has caused a number of United States citizens to purchase their drugs "off-shore" for "personal use" in quantities up to a 3-month supply—at substantial savings. However, there is no assurance that these drugs are what they are purported to be or that they will be delivered in a timely manner—or that there is a traditional doctor-pharmacist-patient relationship and the safeguards that such a relationship offers. Pharmacists and physicians are asking the question: Why can't we purchase drugs at "off-shore" prices and thus lower the overall cost to the patients? The Veterans Administration system for controlling costs through bulk purchases of drugs and serious negotiation of prices with manufacturers shows that it is possible.

Appendix I: Vaccines, Immune Globulins, & Other Complex Biologic Products

Vaccines, Immune Globulins, & Other Complex Biologic Products: Introduction

Vaccines and related biologic products constitute an important group of agents that bridge the disciplines of microbiology, infectious diseases, immunology, and immunopharmacology. A listing of the most important preparations is provided here. The reader who requires more complete information is referred to the sources listed at the end of this appendix.

Katzung PHARMACOLOGY, 9e > Section X. Special Topics > Appendix I: Vaccines, Immune Globulins, & Other Complex Biologic Products >

Active Immunization

Active immunization consists of the administration of antigen to the host to induce formation of antibodies and cell-mediated immunity. Immunization is practiced to induce protection against many infectious agents and may utilize either inactivated (killed) materials or live attenuated agents (Table I–1). Desirable features of the ideal immunogen include complete prevention of disease, prevention of the carrier state, production of prolonged immunity with a minimum of immunizations, absence of toxicity, and suitability for mass immunization (eg, cheap and easy to administer). Active immunization is generally preferable to passive immunization—in most cases because higher antibody levels are sustained for longer periods of time, requiring less frequent immunization, and in some cases because of the development of concurrent cell-mediated immunity. However, active immunization requires time to develop and is therefore generally inactive at the time of a specific exposure (eg, for parenteral exposure to hepatitis B, concurrent hepatitis B IgG [passive antibodies] and active immunization are given to prevent illness).

Table I–1. Materials Commonly Used for Active Immunization in the United States.¹

Vaccine	Type of Agent	Route of Administration	Primary Immunization	Booster ²	Indications
Diphtheria-tetanus-acellular pertussis (DTaP)	Toxoids and inactivated bacterial components	Intramuscular	See Table I–2		For all children
<i>Haemophilus influenzae</i> type b conjugate (Hib)	Bacterial polysaccharide conjugated to protein	Intramuscular	One dose (see Table I–2 for childhood schedule)	Not recommended	1. For all children 2. Asplenia and

					other at-risk conditions
Hepatitis A	Inactivated virus	Intramuscular	One dose (administer at least 2–4 weeks before travel to endemic areas)	At 6–12 months for long-term immunity	<ol style="list-style-type: none"> 1. Travelers to hepatitis A endemic areas 2. Homosexual and bisexual men 3. Illicit drug users 4. Chronic liver disease or clotting factor disorders 5. Persons with occupational risk for infection 6. Persons living in, or relocating to, endemic

					<p>areas</p> <p>7. Household and sexual contacts of individuals with acute hepatitis A</p>
Hepatitis B	Inactive viral antigen, recombinant	Intramuscular (subcutaneous injection is acceptable in individuals with bleeding disorders)	Three doses at 0, 1, and 6 months (see Table I-2 for childhood schedule)	Not routinely recommended	<p>1. For all infants</p> <p>2. Preadolescents, adolescents, and young adults</p> <p>3. Persons with occupational, lifestyle, or environmental risk</p> <p>4. Hemophiliacs</p> <p>5. Hemodialysis patients</p> <p>6. Postexposure proph</p>

					ylaxis
Influenza	Inactivated virus or viral components	Intramuscular	One dose (children ≥ 12 years of age should receive split virus vaccine only; children < 9 who are receiving influenza vaccine for the first time should receive two doses administered at least 1 month apart)	Yearly with current vaccine	<ol style="list-style-type: none"> 1. Adults ≥ 50 years of age 2. Persons with high risk conditions (eg, asthma) 3. Health care workers and others in contact with high-risk groups 4. Residents of nursing homes and other residential chronic care facilities
Measles	Live virus	Subcutaneous	Two doses at least 1 month apart	None	<ol style="list-style-type: none"> 1. Adults and adolescents born after 1956

					without a history of measles or live virus vaccination on or after their first birthday 2. Postexposure prophylaxis in unimmunized persons
Measles-mumps-rubella (MMR)	Live virus	Subcutaneous	See Table I-2	None	For all children
Menningococcal vaccine	Bacterial polysaccharides of serotypes A/C/Y/W-135	Subcutaneous	One dose	Every 3 to 5 years if there is continuing high risk of exposure	1. Military recruits 2. Travelers to areas with epidemic meningococcal disease 3. Individuals

					with asplenia, complement deficiency, or properdin deficiency 4. Control of outbreaks in closed or semi-closed populations 5. College freshmen who live in dormitories
Mumps	Live virus	Subcutaneous	One dose	None	Adults born after 1956 without a history of mumps or live virus vaccination on or after their first birthday
Pneumococcal vaccine	Bacterial polysaccharides of 23 serotypes	Intramuscular or subcutaneous	One dose	Repeat after 5 years in patients at high risk	1. Adults ≥65 years of age 2. Persons at

					increased risk for pneumococcal disease or its complications
Poliovirus vaccine, inactivated (IPV)	Inactivated viruses of all three serotypes	Subcutaneous	See Table I-2 for childhood schedule. Adults: Two doses 4 to 8 weeks apart, and a third dose 6 to 12 months after the second	One-time booster dose for adults at increased risk of exposure	<ol style="list-style-type: none"> For all children Previously unvaccinated adults at increased risk for occupational or travel exposure to polioviruses
Rabies	Inactivated virus	Intramuscular (IM) or intradermal (ID)	<p>Preexposure: Three doses (IM or ID) at days 0, 7, and 21 or 28</p> <p>Postexposure: Five-doses (IM only) at days 0, 3, 7, 14, and 28</p>	Serologic testing every 6 months to 2 years in persons at high risk	<ol style="list-style-type: none"> Preexposure prophylaxis in persons at risk for contact with rabies

					virus 2. Postexposure prophylaxis (administer with rabies immune globulin)
Rubella	Live virus	Subcutaneous	One or two doses (at least 28 days apart)	None	Adults born after 1956 without a history of rubella or live virus vaccination on or after their first birthday
Tetanus-diphtheria (Td or DT) ³	Toxoids	Intramuscular	Two doses 4–8 weeks apart, and a third dose 6–12 months after the second	Every 10 years	1. All adults who have not been immunized as children 2. Postexposure prophylaxis if > 5 years has passed since last dose
Typhoid, Ty21a oral	Live bacteria	Oral	Four doses administered every	Four doses every 5	Risk of exposure to

			other day	years	typhoid fever
Typhoid, Vi capsular polysaccharide	Bacterial polysaccharide	Intramuscular	One dose	Every 2 years	Risk of exposure to typhoid fever
Varicella	Live virus	Subcutaneous	Two doses 4–8 weeks apart in persons past their 13th birthday (see Table I–2 for childhood schedule)	Unknown	<ol style="list-style-type: none"> 1. For all children 2. Persons (at high risk for exposure) past their 13th birthday without a history of varicella infection or immunization 3. Postexposure prophylaxis in susceptible persons
Yellow Fever	Live virus	Subcutaneous	One dose 10 days to 10 years before travel	Every 10 years	<ol style="list-style-type: none"> 1. Laboratory personnel who may be

					exposed to yellow fever virus 2. Travelers to areas where yellow fever occurs
--	--	--	--	--	-------------------------------------------------------------------------------

¹ Dosages for the specific product, including variations for age, are best obtained from the manufacturer's package insert. Does not include all combination products.

² One dose unless otherwise indicated.

³ Td = Tetanus and diphtheria toxoids for use in persons ≥ 7 years of age (contains less diphtheria toxoid than DPT and DT). DT = Tetanus and diphtheria toxoids for use in persons < 7 years of age (contains the same amount of diphtheria toxoid as DPT).

Current recommendations for routine active immunization of children are given in Table I-2.

Table I-2. Recommended Routine Childhood Immunization Schedule. ¹		
Age	Immunization	Comments
Birth to 2 months	Hepatitis B vaccine (HBV)	Infants born to seronegative mothers: Administration should begin at birth, with the second dose administered at least 4 weeks after the first dose.
		Infants born to seropositive mothers: Should receive the first dose within 12 hours after birth (with hepatitis B immune globulin), the second dose at 1–2 months of age, and the third dose at 6 months of age.
2 months	Diphtheria and tetanus toxoids and acellular pertussis vaccine (DTaP), inactivated poliovirus vaccine (IPV), <i>Haemophilus influenzae</i> type b conjugate vaccine (Hib) ² pneumococcal conjugate vaccine (PCV)	
1–4 months	HBV	The second dose should be given at least 4 weeks after the first dose.

4 months	DTaP, Hib ² , IPV, PCV	
6 months	DTaP, Hib ² , PCV	
6–18 months	HBV, IPV	The third dose of HBV should be given at least 16 weeks after the first dose and at least 8 weeks after the second dose, but not before age 6 months.
6–23 months	Influenza, split virus vaccine	Two doses \geq 1 month apart are recommended for children \leq 9 years who are receiving influenza vaccine for the first time.
12–15 months	Measles-mumps-rubella vaccine (MMR), Hib ² , PCV	
12–18 months	DTaP at 15–18 months, varicella vaccine	DTaP may be given as early as age 12 months. Varicella vaccine is recommended at any visit after the first birthday for susceptible children. Susceptible children \geq 13 years of age should receive two doses given at least 4 weeks apart.
4–6 years	DTaP IPV, MMR	The second dose of MMR should be routinely administered at 4–6 years of age but may be given during any visit if at least 4 weeks have elapsed since administration of the first dose. The second dose should be given no later than age 11–12 years.
11–12 years	Diphtheria and tetanus toxoids (Td)	Vaccination is recommended if at least 5 years has elapsed since administration of the last dose of DTaP. Routine booster doses of Td should be given every 10 years thereafter.

¹Adapted from MMWR Morb Mortal Wkly Rep 2002;31:31.

²Three Hib conjugate vaccines are available for use: (a) oligosaccharide conjugate Hib vaccine (HbOC), (b) polyribosylribitol phosphate-tetanus toxoid conjugate (PRP-T), and (c) *Haemophilus influenzae* type b conjugate vaccine (meningococcal protein conjugate) (PRP-OMP). Children immunized with PRP-OMP at 2 and 4 months of age do not require a dose at 6 months of age.

Katzung PHARMACOLOGY, 9e > Section X. Special Topics > Appendix I: Vaccines, Immune Globulins, & Other Complex Biologic Products >

Passive Immunization

Passive immunization consists of transfer of immunity to a host using preformed immunologic products. From a practical standpoint, only immunoglobulins have been utilized for passive immunization, since passive administration of cellular components of the immune system has been technically difficult and associated with graft-versus-host reactions. Products of the cellular immune system (eg, interferons) have also been used in the therapy of a wide variety of hematologic and

infectious diseases (Chapter 56: Immunopharmacology).

Passive immunization with antibodies may be accomplished with either animal or human immunoglobulins in varying degrees of purity. These may contain relatively high titers of antibodies directed against a specific antigen or, as is true for pooled immune globulin, may simply contain antibodies found in most of the population. Passive immunization is useful for (1) individuals unable to form antibodies (eg, congenital agammaglobulinemia); (2) prevention of disease when time does not permit active immunization (eg, postexposure); (3) for treatment of certain diseases normally prevented by immunization (eg, tetanus); and (4) for treatment of conditions for which active immunization is unavailable or impractical (eg, snakebite).

Complications from administration of *human* immunoglobulins are rare. The injections may be moderately painful and rarely a sterile abscess may occur at the injection site. Transient hypotension and pruritus occasionally occur with the administration of IGIV products, but generally are mild. Individuals with certain immunoglobulin deficiency states (IgA deficiency, etc) may occasionally develop hypersensitivity reactions to immune globulin that may limit therapy. Conventional immune globulin contains aggregates of IgG; it will cause severe reactions if given intravenously. However, if the passively administered antibodies are derived from *animal* sera, hypersensitivity reactions ranging from anaphylaxis to serum sickness may occur. Highly purified immunoglobulins, especially from rodents or lagomorphs are the least likely to cause reactions. To avoid anaphylactic reactions, tests for hypersensitivity to the animal serum must be performed. If an alternative preparation is not available and administration of the specific antibody is deemed essential, desensitization can be carried out.

Antibodies derived from human serum not only avoid the risk of hypersensitivity reactions but also have a much longer half-life in humans (about 23 days for IgG antibodies) than those from animal sources (5–7 days or less). Consequently, much smaller doses of human antibody can be administered to provide therapeutic concentrations for several weeks. These advantages point to the desirability of using human antibodies for passive protection whenever possible. Materials available for passive immunization are summarized in Table I–3.

Indication	Product	Dosage	Comments
Black widow spider bite	Antivenin (<i>Latrodectus mactans</i>), equine	One vial (6000 units) IV or IM.	For persons with hypertensive cardiovascular disease or age < 16 or > 60 years.
Bone marrow transplantation	Immune globulin (intravenous) ²	500 mg/kg IV on days 7 and 2 prior to transplantation and then once weekly through day 90 after transplantation.	Prophylaxis to decrease the risk of infection, interstitial pneumonia, and acute graft-versus-host disease in adults undergoing bone marrow transplantation.
Botulism	Botulism antitoxin (trivalent, types	Consult the CDC. ³	Treatment and prophylaxis of botulism. Available from the CDC. ³ Ten to 20

	A, B, and E), equine		percent incidence of serum reactions.
Chronic lymphocytic leukemia (CLL)	Immune globulin (intravenous) ³	Initial dose of 400 mg/kg IV every 3–4 weeks. Dosage should be adjusted upward if bacterial infections occur.	CLL patients with hypogammaglobulinemia and a history of at least one serious bacterial infection.
Cytomegalovirus (CMV)	Cytomegalovirus immune globulin (intravenous)	Consult the manufacturer's dosing recommendations.	Prophylaxis of CMV infection in bone marrow, kidney, liver, lung, pancreas, heart transplant recipients.
Diphtheria	Diphtheria antitoxin, equine	20,000–120,000 units IV or IM depending on the severity and duration of illness.	Early treatment of respiratory diphtheria. Available from the CDC. ³ Anaphylactic reactions in $\approx 7\%$ of adults and serum reactions in $\approx 5\text{--}10\%$ of adults.
Hepatitis A	Immune globulin (intramuscular)	Preexposure prophylaxis: 0.02 mL/kg IM for anticipated risk of ≤ 3 months, 0.06 mL/kg for anticipated risk of > 3 months, repeated every 4–6 months for continued exposure. Postexposure: 0.02 mL/kg IM as soon as possible after exposure up to 2 weeks.	Preexposure and postexposure hepatitis A prophylaxis. The availability of hepatitis A vaccine has greatly reduced the need for preexposure prophylaxis.
Hepatitis B	Hepatitis B immune globulin (HBIG)	0.06 mL/kg IM as soon as possible after exposure up to 1 week for percutaneous exposure or 2 weeks for sexual exposure. 0.5 mL IM within 12 hours after birth for perinatal exposure.	Postexposure prophylaxis in nonimmune persons following percutaneous, mucosal, sexual, or perinatal exposure. Hepatitis B vaccine should also be administered.
HIV-infected children	Immune globulin (intravenous) ²	400 mg/kg IV every 28 days.	HIV-infected children with recurrent serious bacterial infections or hypogammaglobulinemia.
Kawasaki disease	Immune globulin (intravenous) ²	400 mg/kg IV daily for 4 consecutive days within 4 days after the onset of illness. A	Effective in the prevention of coronary aneurysms. For use in patients who

		single dose of 2 g/kg IV over 10 hours is also effective.	meet strict criteria for Kawasaki disease.
Measles	Immune globulin (intramuscular)	Normal hosts: 0.25 mL/kg IM. Immunocompromised hosts: 0.5 mL/kg IM (maximum 15 mL for all patients).	Postexposure prophylaxis (within 6 days after exposure) in nonimmune contacts of acute cases.
Idiopathic thrombocytopenic purpura (ITP)	Immune globulin (intravenous) ²	Consult the manufacturer's dosing recommendations for the specific product being used.	Response in children with ITP is greater than in adults. Corticosteroids are the treatment of choice in adults, except for severe pregnancy-associated ITP.
Primary immunodeficiency disorders	Immune globulin (intravenous) ²	Consult the manufacturer's dosing recommendations for the specific product being used.	Primary immunodeficiency disorders include specific antibody deficiencies (eg, X-linked agammaglobulinemia) and combined deficiencies (eg, severe combined immunodeficiencies).
Rabies	Rabies immune globulin	20 IU/kg. The full dose should be infiltrated around the wound and any remaining volume should be given IM at an anatomic site distant from vaccine administration.	Postexposure rabies prophylaxis in persons not previously immunized with rabies vaccine. Must be combined with rabies vaccine.
Respiratory syncytial virus (RSV)	Palivizumab	15 mg/kg IM once prior to the beginning of the RSV season and once monthly until the end of the season.	For use in infants and children younger than 24 months with chronic lung disease or a history of premature birth (\leq 35 weeks' gestation).
	RSV immune globulin	750 mg/kg IV once prior to the beginning of the RSV season and once monthly until the end of the season.	As for palivizumab. Palivizumab is preferred for selected high-risk children, but RSV-IGIV may be preferred for selected high-risk children.
Rubella	Immune globulin (intramuscular)	0.55 mL/kg IM.	Nonimmune pregnant women exposed to rubella who will not consider therapeutic abortion. Administration does not prevent rubella in the fetus of an exposed mother.

Snake bite (coral snake)	Antivenin (<i>Micrurus fulvius</i>), equine	At least 3–5 vials (30–50 mL) IV initially within 4 hours after the bite. Additional doses may be required.	Neutralizes venom of eastern coral snake and Texas coral snake. Serum sickness occurs in almost all patients who receive > 7 vials.
Snake bite (pit vipers)	Antivenin (Crotalidae) polyvalent, equine	The entire dose should be given within 4 hours after the bite by the IV or IM route (1 vial = 10 mL): Minimal envenomation: 2–4 vials Moderate envenomation: 5–9 vials Severe envenomation: 10–15 vials Additional doses may be required.	Neutralizes the venom of rattlesnakes, copperheads, cottonmouths, water moccasins, and tropical and Asiatic crotalids. Serum sickness occurs in almost all patients who receive > 7 vials.
Tetanus	Tetanus immune globulin	Postexposure prophylaxis: 250 units IM. For severe wounds or when there has been a delay in administration, 500 units is recommended. Treatment: 3000–6000 units IM.	Treatment of tetanus and postexposure prophylaxis of nonclean, nonminor wounds in inadequately immunized persons (less than two doses of tetanus toxoid or less than three doses if wound is more than 24 hours old).
Vaccinia	Vaccinia immune globulin	Consult the CDC. ³	Treatment of severe reactions to vaccinia vaccination, including eczema vaccinatum, vaccinia necrosum, and ocular vaccinia. Available from the CDC. ³
Varicella	Varicella-zoster immune globulin	Weight (kg): Dose (units) ≤10: 125 IM 10.1–20: 250 IM 20.1–30: 375 IM 30.1–40: 500 IM > 40: 625 IM	Postexposure prophylaxis (preferably within 48 hours but no later than within 96 hours after exposure) in susceptible immunocompromised hosts, selected pregnant women, and perinatally exposed newborns.

¹Passive immunotherapy or immunoprophylaxis should always be administered as soon as possible after exposure. Prior to the administration of animal sera, patients should be questioned and tested for hypersensitivity.

²See the following references for an analysis of additional uses of intravenously administered immune globulin: Ratko TA et al: Recommendations for off-label use of intravenously administered immunoglobulin preparations. JAMA 1995;273:1865; and Dalakas MC: Intravenous immune globulin therapy for neurologic diseases. Ann Intern Med 1997;126:721.

³Centers for Disease Control and Prevention, 404-639-3670 during weekday business hours; 404-639-2888 during nights,

weekends, and holidays (emergency requests only).

Legal Liability for Untoward Reactions

It is the physician's responsibility to inform the patient of the risk of immunization and to employ vaccines and antisera in an appropriate manner. This may require skin testing to assess the risk of an untoward reaction. Some of the risks described above are, however, currently unavoidable; on the balance, the patient and society are clearly better off accepting the risks for routinely administered immunogens (eg, influenza and tetanus vaccines).

Manufacturers should be held legally accountable for failure to adhere to existing standards for production of biologicals. However, in the present litigious atmosphere of the United States, the filing of large liability claims by the statistically inevitable victims of good public health practice has caused many manufacturers to abandon efforts to develop and produce low-profit but medically valuable therapeutic agents such as vaccines. Since the use and sale of these products are subject to careful review and approval by government bodies such as the Surgeon General's Advisory Committee on Immunization Practices and the Food and Drug Administration, "strict product liability" (liability without fault) may be an inappropriate legal standard to apply when rare reactions to biologicals, produced and administered according to government guidelines, are involved.

Recommended Immunization of Adults for Travel

Every adult, whether traveling or not, should be immunized with tetanus toxoid and should also be fully immunized against poliomyelitis, measles (for those born after 1956), and diphtheria. In addition, every traveler must fulfill the immunization requirements of the health authorities of the countries to be visited. These are listed in *Health Information for International Travel*, available from the Superintendent of Documents, United States Government Printing Office, Washington, DC 20402. A useful website is <http://www.cdc.gov/travel/vaccinat.htm>. *The Medical Letter on Drugs and Therapeutics* also offers periodically updated recommendations for international travelers (see issue of April 15, 2002). Immunizations received in preparation for travel should be recorded on the International Certificate of Immunization. **Note:** Smallpox vaccination is not recommended or required for travel in any country.

Appendix II: Important Drug Interactions & Their Mechanisms

Katzung PHARMACOLOGY, 9e > Section X. Special Topics > Appendix II: Important Drug Interactions & Their Mechanisms >

Important Drug Interactions & Their Mechanisms: Introduction

One of the factors that can alter the response to drugs is the concurrent administration of other drugs. There are several mechanisms by which drugs may interact, but most can be categorized as pharmacokinetic (absorption, distribution, metabolism, excretion), pharmacodynamic, or combined interactions. Knowledge of the mechanism by which a given drug interaction occurs is often clinically useful, since the mechanism may influence both the time course and the methods of circumventing the interaction. Some important drug interactions occur as a result of two or more mechanisms.

Pharmacokinetic Mechanisms

The gastrointestinal absorption of drugs may be affected by concurrent use of other agents that (1) have a large surface area upon which the drug can be adsorbed, (2) bind or chelate, (3) alter gastric pH, (4) alter gastrointestinal motility, or (5) affect transport proteins such as P-glycoprotein. One must distinguish between effects on adsorption rate and effects on extent of absorption. A reduction in only the absorption rate of a drug is seldom clinically important, whereas a reduction in the extent of absorption will be clinically important if it results in subtherapeutic serum levels.

The mechanisms by which drug interactions alter drug distribution include (1) competition for plasma protein binding, (2) displacement from tissue binding sites, and (3) alterations in local tissue barriers, eg, P-glycoprotein inhibition in the blood-brain barrier. Although competition for plasma protein binding can increase the free concentration (and thus the effect) of the displaced drug in plasma, the increase will be transient owing to a compensatory increase in drug disposition. The clinical importance of protein binding displacement has been overemphasized; current evidence suggests that such interactions are unlikely to result in adverse effects. Displacement from tissue binding sites would tend to transiently increase the blood concentration of the displaced drug.

The metabolism of drugs can be stimulated or inhibited by concurrent therapy. Induction (stimulation) of cytochrome P450 isozymes in the liver and small intestine can be caused by drugs such as barbiturates, carbamazepine, efavirenz, glutethimide, nevirapine, phenytoin, primidone, rifampin, and rifabutin. Enzyme inducers can also increase the activity of phase II metabolism such as glucuronidation. Enzyme induction does not take place quickly; maximal effects usually occur after 7–10 days and require an equal or longer time to dissipate after the enzyme inducer is stopped. Rifampin, however, may produce enzyme induction after only a few doses. Inhibition of metabolism generally takes place more quickly than enzyme induction and may begin as soon as sufficient tissue concentration of the inhibitor is achieved. However, if the half-life of the affected drug is long, it may take a week or more to reach a new steady-state serum level. Drugs that may inhibit cytochrome P450 metabolism of other drugs include allopurinol, amiodarone, androgens, chloramphenicol, cimetidine, ciprofloxacin, clarithromycin, cyclosporine, delavirdine, diltiazem, disulfiram, enoxacin, erythromycin, fluconazole, fluoxetine, fluvoxamine, grapefruit juice, indinavir, isoniazid, itraconazole, ketoconazole, metronidazole, mexiletine, miconazole, nefazodone, omeprazole, paroxetine, phenylbutazone, propoxyphene, quinidine, ritonavir, sulfonamides, verapamil, zafirlukast, and zileuton.

The renal excretion of active drug can also be affected by concurrent drug therapy. The renal excretion of certain drugs that are weak acids or weak bases may be influenced by other drugs that

affect urinary pH. This is due to changes in ionization of the drug, as described in Chapter 1: Introduction under Ionization of Weak Acids and Weak Bases; the Henderson-Hasselbalch Equation. For some drugs, active secretion into the renal tubules is an important elimination pathway. The ABC transporter P-glycoprotein is involved in active tubular secretion of some drugs, and inhibition of this transporter can inhibit renal elimination with attendant increase in serum drug concentrations.

Pharmacodynamic Mechanisms

When drugs with similar pharmacologic effects are administered concurrently, an additive or synergistic response is usually seen. The two drugs may or may not act on the same receptor to produce such effects. Conversely, drugs with opposing pharmacologic effects may reduce the response to one or both drugs. Pharmacodynamic drug interactions are relatively common in clinical practice, but adverse effects can usually be minimized if one understands the pharmacology of the drugs involved. In this way, the interactions can be anticipated and appropriate countermeasures taken.

Combined Toxicity

The combined use of two or more drugs, each of which has toxic effects on the same organ, can greatly increase the likelihood of organ damage. For example, concurrent administration of two nephrotoxic drugs can produce kidney damage even though the dose of either drug alone may have been insufficient to produce toxicity. Furthermore, some drugs can enhance the organ toxicity of another drug even though the enhancing drug has no intrinsic toxic effect on that organ.

Katzung PHARMACOLOGY, 9e > Section X. Special Topics > Appendix II: Important Drug Interactions & Their Mechanisms >

Predictability of Drug Interactions

The designations listed in Table II–1 will be used here to *estimate* the predictability of the drug interactions. These estimates are intended to indicate simply whether or not the interaction will occur and do not always mean that the interaction is likely to produce an adverse effect. Whether the interaction occurs and produces an adverse effect or not depends upon (1) the presence or absence of factors that predispose to the adverse effects of the drug interaction (diseases, organ function, dose of drugs, etc) and (2) awareness on the part of the prescriber, so that appropriate monitoring can be ordered or preventive measures taken.

Table II–1. Important Drug Interactions.

HP = Highly predictable. Interaction occurs in almost all patients receiving the interacting combination.

P = Predictable. Interaction occurs in most patients receiving the combination.

NP = Not predictable. Interaction occurs only in some patients receiving the combination.

NE = Not established. Insufficient data available on which to base estimate of predictability.

Drug or Drug Group	Properties Promoting Drug Interaction	Clinically Documented Interactions
--------------------	---------------------------------------	------------------------------------

Alcohol	Chronic alcoholism results in enzyme induction. Acute alcoholic intoxication tends to inhibit drug metabolism (whether person is alcoholic or not). Severe alcohol-induced hepatic dysfunction may inhibit ability to metabolize drugs. Disulfiram-like reaction in the presence of certain drugs. Additive central nervous system depression with other central nervous system depressants.	<p>Acetaminophen: [NE] Increased formation of hepatotoxic acetaminophen metabolites (in chronic alcoholics).</p> <p>Acitretin: [P] Increased conversion of acitretin to etretinate (teratogenic).</p> <p>Anticoagulants, oral: [NE] Increased hypoprothrombinemic effect with acute alcohol intoxication.</p> <p>Central nervous system depressants: [HP] Additive or synergistic central nervous system depression.</p> <p>Insulin: [NE] Acute alcohol intake may increase hypoglycemic effect of insulin (especially in fasting patients).</p> <p><i>Drugs that may produce a disulfiram-like reaction:</i></p> <p>Cephalosporins: [NP] Disulfiram-like reactions noted with cefamandole, cefoperazone, cefotetan, and moxalactam.</p> <p>Chloral hydrate: [NP] Mechanism not established.</p> <p>Disulfiram: [HP] Inhibits aldehyde dehydrogenase.</p> <p>Metronidazole: [NP] Mechanism not established.</p> <p>Sulfonylureas: [NE] Chlorpropamide is most likely to produce a disulfiram-like reaction; acute alcohol intake may increase hypoglycemic effect (especially in fasting patients).</p>
Allopurinol	Inhibits hepatic drug-metabolizing enzymes.	<p>Anticoagulants, oral: [NP] Increased hypoprothrombinemic effect.</p> <p>Azathioprine: [P] Decreased azathioprine detoxification resulting in increased azathioprine toxicity.</p> <p>Mercaptopurine: [P] Decreased mercaptopurine metabolism resulting in increased mercaptopurine toxicity.</p>
Antacids	Antacids may adsorb drugs in gastrointestinal tract, thus reducing	Digoxin: [NP] Decreased gastrointestinal absorption of digoxin.

	<p>intestine more quickly. Some antacids (eg, magnesium hydroxide with aluminum hydroxide) alkalinize the urine somewhat, thus altering excretion of drugs sensitive to urinary pH.</p>	<p>Itraconazole: [P] Reduced gastrointestinal absorption of itraconazole due to increased pH (itraconazole requires acid for absorption).</p> <p>Ketoconazole: [P] Reduced gastrointestinal absorption of ketoconazole due to increased pH (ketoconazole requires acid for absorption).</p> <p>Quinolones: [HP] Decreased gastrointestinal absorption of ciprofloxacin, norfloxacin, enoxacin (and probably other quinolones).</p> <p>Salicylates: [P] Increased renal clearance of salicylates due to increased urine pH; occurs only with large doses of salicylates.</p> <p>Sodium polystyrene sulfonate: [NE] Binds antacid cation in gut, resulting in metabolic alkalosis.</p> <p>Tetracyclines: [HP] Decreased gastrointestinal absorption of tetracyclines.</p> <p>Thyroxine: [NP] Reduced gastrointestinal absorption of thyroxine.</p>
<p>Anticoagulants, oral</p>	<p>Metabolism inducible. Susceptible to inhibition of metabolism by CYP2C9. Highly bound to plasma proteins. Anticoagulation response altered by drugs that affect clotting factor synthesis or catabolism.</p>	<p><i>Drugs that may increase anticoagulant effect:</i></p> <p>Amiodarone: [P] Inhibits anticoagulant metabolism.</p> <p>Anabolic steroids: [P] Alter clotting factor disposition?</p> <p>Chloramphenicol: [NE] Decreased dicumarol metabolism (probably also warfarin).</p> <p>Cimetidine: [HP] Decreased warfarin metabolism.</p> <p>Ciprofloxacin: [NP] Decreased anticoagulant metabolism?</p> <p>Clofibrate: [P] Mechanism not established.</p> <p>Danazol: [NE] Impaired synthesis of clotting factors?</p> <p>Dextrothyroxine: [P] Enhances</p>

clotting factor catabolism?

Disulfiram: [P] Decreased warfarin metabolism.

Erythromycin: [NP] Probably inhibits anticoagulant metabolism.

Fluconazole: [P] Decreased warfarin metabolism.

Gemfibrozil: [NE] Mechanism not established.

Lovastatin: [NE] Probably decreased anticoagulant metabolism.

Metronidazole: [P] Decreased warfarin metabolism.

Miconazole: [NE] Decreased warfarin metabolism.

Nonsteroidal anti-inflammatory drugs: [P] Inhibition of platelet function, gastric erosions; some agents increase hypoprothrombinemic response (unlikely with diclofenac, ibuprofen, or naproxen).

Propafenone: [NE] Probably decreased anticoagulant metabolism.

Quinidine: [NP] Additive hypoprothrombinemia.

Salicylates: [HP] Platelet inhibition with aspirin but not with other salicylates; [P] large doses have hypoprothrombinemic effect.

Sulfinpyrazone: [NE] Inhibits warfarin metabolism.

Sulfonamides: [NE] Inhibit warfarin metabolism; displace protein binding.

Thyroid hormones: [P] Enhance clotting factor catabolism.

Trimethoprim-sulfamethoxazole: [P] Inhibits warfarin metabolism; displaces from protein binding.

See also Alcohol; Allopurinol.

Drugs that may decrease anticoagulant effect:

Aminoglutethimide: [P] Enzyme induction.

Barbiturates: [P] Enzyme induction.

		<p>Carbamazepine: [P] Enzyme induction.</p> <p>Cholestyramine: [P] Reduces absorption of anticoagulant.</p> <p>Glutethimide: [P] Enzyme induction.</p> <p>Nafcillin: [NE] Enzyme induction.</p> <p>Phenytoin: [NE] Enzyme induction; anticoagulant effect may increase transiently at start of phenytoin therapy due to protein-binding displacement.</p> <p>Primidone: [P] Enzyme induction.</p> <p>Rifabutin: [P] Enzyme induction.</p> <p>Rifampin: [P] Enzyme induction.</p> <p>St. John's wort: [NE] Enzyme induction.</p> <p><i>Effects of anticoagulants on other drugs:</i></p> <p>Hypoglycemics, oral: [P] Dicumarol inhibits hepatic metabolism of tolbutamide and chlorpropamide.</p> <p>Phenytoin: [P] Dicumarol inhibits metabolism of phenytoin.</p>
<p>Antidepressants, tricyclic and heterocyclic</p>	<p>Inhibition of amine uptake into postganglionic adrenergic neuron. Antimuscarinic effects may be additive with other antimuscarinic drugs. Metabolism inducible. Susceptible to inhibition of metabolism by CYP2D6 and other CYP450 enzymes.</p>	<p>Barbiturates: [P] Increased antidepressant metabolism.</p> <p>Carbamazepine: [NE] Enhanced metabolism of antidepressants.</p> <p>Cimetidine: [P] Decreased antidepressant metabolism.</p> <p>Clonidine: [P] Decreased clonidine antihypertensive effect.</p> <p>Guanadrel: [P] Decreased uptake of guanadrel into sites of action.</p> <p>Guanethidine: [P] Decreased uptake of guanethidine into sites of action.</p> <p>Monoamine oxidase inhibitors: [NP] Some cases of excitation, hyperpyrexia, mania, and convulsions, especially with serotonergic antidepressants such as clomipramine and imipramine, but many patients have received combination without ill effects.</p> <p>Quinidine: [NE] Decreased antidepressant metabolism.</p>

		<p>Rifampin: [P] Increased antidepressant metabolism.</p> <p>Selective serotonin reuptake inhibitors (SSRIs): [P] Fluoxetine and paroxetine inhibit CYP2D6 and decrease metabolism of antidepressants metabolized by this enzyme (eg, desipramine). Citalopram, sertraline, and fluvoxamine are only weak inhibitors of CYP2D6, but fluvoxamine inhibits CYP1A2 and CYP3A4 and thus can inhibit the metabolism of antidepressants metabolized by these enzymes.</p> <p>Sympathomimetics: [P] Increased pressor response to norepinephrine, epinephrine, and phenylephrine.</p>
Azole antifungals	<p>Inhibition of CYP3A4 (itraconazole = ketoconazole > voriconazole > fluconazole). Inhibition of CYP2C9 (fluconazole, voriconazole). Susceptible to enzyme inducers (itraconazole, ketoconazole, voriconazole). Gastrointestinal absorption pH-dependent (itraconazole, ketoconazole). Inhibition of P-glycoprotein (itraconazole, ketoconazole).</p>	<p>Barbiturates: [P] Increased metabolism of itraconazole, ketoconazole, voriconazole.</p> <p>Calcium channel blockers: [P] Decreased calcium channel blocker metabolism.</p> <p>Carbamazepine: [P] Decreased carbamazepine metabolism.</p> <p>H₂-receptor antagonists: [NE] Decreased absorption of itraconazole and ketoconazole.</p> <p>Cisapride: [NP] Decreased metabolism of cisapride; possible ventricular arrhythmias.</p> <p>Cyclosporine: [P] Decreased metabolism of cyclosporine.</p> <p>Digoxin: [NE] Increased gastrointestinal absorption and decreased renal excretion of digoxin with itraconazole and ketoconazole.</p> <p>HMG CoA reductase inhibitors: Decreased metabolism of lovastatin, simvastatin, and, to a lesser extent, atorvastatin.</p> <p>Phenytoin: [P] Decreased metabolism of phenytoin with fluconazole and probably voriconazole.</p> <p>Pimozide: [NE] Decreased pimozide metabolism.</p>

		<p>Proton pump inhibitors: [P] Decreased absorption of itraconazole and ketoconazole.</p> <p>Rifampin: [P] Increased metabolism of itraconazole, ketoconazole, and voriconazole.</p> <p><i>See also</i> Antacids; Anticoagulants, oral.</p>
Barbiturates	Induction of hepatic microsomal drug-metabolizing enzymes. Additive central nervous system depression with other central nervous system depressants.	<p>Beta-adrenoceptor blockers: [P] Increased β-blocker metabolism.</p> <p>Calcium channel blockers: [P] Increased calcium channel blocker metabolism.</p> <p>Central nervous system depressants: [HP] Additive central nervous system depression.</p> <p>Corticosteroids: [P] Increased corticosteroid metabolism.</p> <p>Cyclosporine: [NE] Increased cyclosporine metabolism.</p> <p>Delavirdine: [P] Increased delavirdine metabolism.</p> <p>Doxycycline: [P] Increased doxycycline metabolism.</p> <p>Estrogens: [P] Increased estrogen metabolism.</p> <p>Methadone: [NE] Increased methadone metabolism.</p> <p>Phenothiazine: [P] Increased phenothiazine metabolism.</p> <p>Protease inhibitors: [NE] Increased protease inhibitor metabolism.</p> <p>Quinidine: [P] Increased quinidine metabolism.</p> <p>Sirolimus: [NE] Increased sirolimus metabolism.</p> <p>Tacrolimus: [NE] Increased tacrolimus metabolism.</p> <p>Theophylline: [NE] Increased theophylline metabolism; reduced theophylline effect.</p> <p>Valproic acid: [P] Decreased phenobarbital metabolism.</p> <p><i>See also</i> Anticoagulants, oral;</p>

		Antidepressants, tricyclic.
Beta-adrenoceptor blockers	Beta-blockade (especially with nonselective agents such as propranolol) alters response to sympathomimetics with β -agonist activity (eg, epinephrine). Beta-blockers that undergo extensive first-pass metabolism may be affected by drugs capable of altering this process. Beta-blockers may reduce hepatic blood flow.	<p><i>Drugs that may increase β-blocker effect:</i></p> <p>Cimetidine: [P] Decreased metabolism of β-blockers that are cleared primarily by the liver, eg, propranolol. Less effect (if any) on those cleared by the kidneys, eg, atenolol, nadolol.</p> <p><i>Drugs that may decrease β-blocker effect:</i></p> <p>Enzyme inducers: [P] Barbiturates, phenytoin, and rifampin may enhance β-blockers metabolism; other enzyme inducers may produce similar effects.</p> <p>Nonsteroidal anti-inflammatory drugs: [P] Indomethacin reduces antihypertensive response; other prostaglandin inhibitors probably also interact.</p> <p><i>Effects of β-blockers on other drugs:</i></p> <p>Clonidine: [NE] Hypertensive reaction if clonidine is withdrawn while patient is taking propranolol.</p> <p>Insulin: [P] Inhibition of glucose recovery from hypoglycemia; inhibition of symptoms of hypoglycemia (except sweating); increased blood pressure during hypoglycemia.</p> <p>Lidocaine: [NE] Decreased clearance of intravenous lidocaine; increased plasma lidocaine levels.</p> <p>Prazosin: [P] Increased hypotensive response to first dose of prazosin.</p> <p>Sympathomimetics: [P] Increased pressor response to epinephrine (and possibly other sympathomimetics); this is more likely to occur with nonspecific β-blockers.</p>
Bile acid-binding resins	Resins may bind with orally administered drugs in gastrointestinal tract. Resins may bind in gastrointestinal tract with drugs that undergo enterohepatic circulation, even if the latter are given parenterally.	<p>Acetaminophen: [NE] Decreased gastrointestinal absorption of acetaminophen.</p> <p>Digitalis glycosides: [NE] Decreased gastrointestinal absorption of digitoxin (possibly also digoxin).</p> <p>Furosemide: [P] Decreased</p>

		gastrointestinal absorption of furosemide.
		Methotrexate: [NE] Reduced gastrointestinal absorption of methotrexate.
		Mycophenolate: [P] Reduced gastrointestinal absorption of mycophenolate.
		Thiazide diuretics: [P] Reduced gastrointestinal absorption of thiazides.
		Thyroid hormones: [P] Reduced thyroid absorption.
		<i>See also</i> Anticoagulants, oral.
Calcium channel blockers	Verapamil, diltiazem, and perhaps nifedipine (but not nifedipine) inhibit hepatic drug-metabolizing enzymes. Metabolism of diltiazem, nifedipine, verapamil, and probably other calcium channel blockers subject to induction and inhibition.	Carbamazepine: [P] Decreased carbamazepine metabolism with diltiazem and verapamil; possible increase in calcium channel blocker metabolism.
		Cimetidine: [NP] Decreased metabolism of calcium channel blockers.
		Cyclosporine: [P] Decreased cyclosporine metabolism with diltiazem, nifedipine, verapamil.
		Phenytoin: [NE] Increased metabolism of calcium channel blockers.
		Rifampin: [P] Increased metabolism of calcium channel blockers.
		<i>See also</i> Azole antifungals, Barbiturates, Theophylline.
Carbamazepine	Induction of hepatic microsomal drug-metabolizing enzymes. Susceptible to inhibition of metabolism, primarily by CYP3A4.	Cimetidine: [P] Decreased carbamazepine metabolism.
		Clarithromycin: [P] Decreased carbamazepine metabolism.
		Corticosteroids: [P] Increased corticosteroid metabolism.
		Cyclosporine: [P] Increased cyclosporine metabolism.
		Danazol: [P] Decreased carbamazepine metabolism.
		Diltiazem: [P] Decreased carbamazepine metabolism.
		Doxycycline: [P] Increased doxycycline metabolism.

		<p>Erythromycin: [NE] Decreased carbamazepine metabolism.</p> <p>Fluvoxamine: [NE] Decreased carbamazepine metabolism.</p> <p>Estrogens: [P] Increased estrogen metabolism.</p> <p>Haloperidol: [P] Increased haloperidol metabolism.</p> <p>Isoniazid: [P] Decreased carbamazepine metabolism.</p> <p>Nefazodone: [NE] Decreased carbamazepine metabolism.</p> <p>Propoxyphene: [HP] Decreased carbamazepine metabolism.</p> <p>Selective serotonin reuptake inhibitors (SSRIs): [NE] Fluoxetine and fluvoxamine decrease carbamazepine metabolism.</p> <p>Tacrolimus: [P] Increased tacrolimus metabolism.</p> <p>Theophylline: [NE] Increased theophylline metabolism.</p> <p>Troleandomycin: [P] Decreased carbamazepine metabolism.</p> <p>Verapamil: [P] Decreased carbamazepine metabolism.</p> <p><i>See also</i> Anticoagulants, oral; Antidepressants, tricyclic; Azole antifungals; Calcium channel blockers.</p>
Chloramphenicol	Inhibits hepatic drug-metabolizing enzymes.	<p>Phenytoin: [P] Decreased phenytoin metabolism.</p> <p>Sulfonylurea hypoglycemics: [P] Decreased sulfonylurea metabolism.</p> <p><i>See also</i> Anticoagulants, oral.</p>
Cimetidine	Inhibits hepatic microsomal drug-metabolizing enzymes. (Ranitidine, famotidine, and nizatidine do not appear to do so.) May inhibit the renal tubular secretion of weak bases. Purportedly reduces hepatic blood flow, thus reducing first-pass metabolism of highly extracted drugs. (However, the ability of cimetidine to affect hepatic blood	<p>Benzodiazepines: [P] Decreased metabolism of alprazolam, chlordiazepoxide, diazepam, halazepam, prazepam, and clorazepate but not oxazepam, lorazepam, or temazepam.</p> <p>Carmustine: [NE] Increased bone marrow suppression.</p> <p>Ketoconazole: [NE] Decreased gastrointestinal absorption of</p>

		<p>ketoconazole due to increased pH in gut; other H₂ blockers and proton pump inhibitors would be expected to have the same effect.</p> <p>Itraconazole: [NE] Decreased gastrointestinal absorption of itraconazole due to increased pH in gut; other H₂-receptor antagonists and proton pump inhibitors would be expected to have the same effect.</p> <p>Lidocaine: [P] Decreased metabolism of lidocaine; increased serum lidocaine.</p> <p>Phenytoin: [NE] Decreased phenytoin metabolism; increased serum phenytoin.</p> <p>Procainamide: [P] Decreased renal excretion of procainamide; increased serum procainamide levels. Similar effect with ranitidine but smaller.</p> <p>Quinidine: [P] Decreased metabolism of quinidine; increased serum quinidine levels.</p> <p>Theophylline: [P] Decreased theophylline metabolism; increased plasma theophylline.</p> <p><i>See also</i> Anticoagulants, oral; Antidepressants, tricyclic; Beta-adrenoceptor blockers; Calcium channel blockers, Carbamazepine.</p>
Cisapride	Susceptible to inhibition of metabolism by CYP3A4 inhibitors. High cisapride serum concentrations can result in ventricular arrhythmias.	<p>Clarithromycin: [NP] Decreased metabolism of cisapride; possible ventricular arrhythmia.</p> <p>Cyclosporine: [NE] Decreased metabolism of cisapride; possible ventricular arrhythmia.</p> <p>Erythromycin: [NP] Decreased metabolism of cisapride; possible ventricular arrhythmia.</p> <p>Fluconazole: [NE] Decreased metabolism of cisapride; possible ventricular arrhythmia.</p> <p>Itraconazole: [NP] Decreased metabolism of cisapride; possible ventricular arrhythmia.</p> <p>Ketoconazole: [NP] Decreased</p>

		<p>metabolism of cisapride; possible ventricular arrhythmia.</p> <p>Nefazodone: [NP] Possible decreased metabolism of cisapride by CYP3A4; possible ventricular arrhythmia.</p> <p>Ritonavir: [NE] Decreased metabolism of cisapride; possible ventricular arrhythmia.</p> <p>Selective serotonin reuptake inhibitors (SSRIs): [NP] Fluvoxamine inhibits CYP3A4 and probably decreases cisapride metabolism; possible ventricular arrhythmia.</p>
Cyclosporine	Metabolism inducible. Susceptible to inhibition of metabolism by CYP3A4. (Tacrolimus and sirolimus appear to have similar interactions.)	<p>Aminoglycosides: [NE] Possible additive nephrotoxicity.</p> <p>Amphotericin B: [NE] Possible additive nephrotoxicity.</p> <p>Androgens: [NE] Increased serum cyclosporine.</p> <p>Barbiturates: [P] Increased cyclosporine metabolism.</p> <p>Carbamazepine: [P] Increased cyclosporine metabolism.</p> <p>Clarithromycin: [P] Decreased cyclosporine metabolism.</p> <p>Diltiazem: [NE] Decreased cyclosporine metabolism.</p> <p>Erythromycin: [NE] Decreased cyclosporine metabolism.</p> <p>Lovastatin: [NE] Myopathy and rhabdomyolysis noted in patients taking lovastatin and cyclosporine.</p> <p>Nefazodone: [P] Decreased cyclosporine metabolism.</p> <p>Phenytoin: [NE] Increased cyclosporine metabolism.</p> <p>Pimozide: [NE] Decreased pimozide metabolism.</p> <p>Rifampin: [P] Increased cyclosporine metabolism.</p> <p>Ritonavir: [P] Decreased cyclosporine metabolism.</p> <p>St. John's wort: [NE] Increased cyclosporine metabolism.</p>

		<p>Verapamil: [NE] Decreased cyclosporine metabolism.</p> <p><i>See also</i> Azole antifungals, Barbiturates; Calcium channel blockers.</p>
<p>Digitalis glycosides</p>	<p>Digoxin susceptible to inhibition of gastrointestinal absorption. Digitalis toxicity may be increased by drug-induced electrolyte imbalance (eg, hypokalemia). Digitoxin metabolism inducible. Renal excretion of digoxin susceptible to inhibition.</p>	<p><i>Drugs that may increase digitalis effect:</i></p> <p>Amiodarone: [P] Reduced renal digoxin excretion leads to increased plasma digoxin concentrations.</p> <p>Clarithromycin: [NE] Reduced renal excretion of digoxin.</p> <p>Diltiazem: [P] Increased plasma digoxin (usually 20–30%) due to reduced renal and nonrenal clearance.</p> <p>Erythromycin: [NE] Reduced renal excretion of digoxin.</p> <p>Itraconazole: [NE] Reduced renal excretion of digoxin.</p> <p>Potassium-depleting drugs: [P] Increased likelihood of digitalis toxicity.</p> <p>Propafenone: [P] Increased plasma digoxin levels.</p> <p>Quinidine: [HP] Reduced digoxin excretion; displacement of digoxin from tissue binding sites; digitoxin may also be affected.</p> <p>Spirolactone: [NE] Decreased renal digoxin excretion and interference with some serum digoxin assays.</p> <p>Verapamil: [P] Increased plasma digoxin levels.</p> <p><i>Drugs that may decrease digitalis effect:</i></p> <p>Kaolin-pectin: [P] Decreased gastrointestinal digoxin absorption.</p> <p>Penicillamine: [NE] Decreased plasma digoxin.</p> <p>Rifampin: [NE] Increased metabolism of digitoxin and possibly digoxin.</p> <p>Sulfasalazine: [NE] Decreased gastrointestinal digoxin absorption.</p> <p><i>See also</i> Antacids; Azole antifungals;</p>

		Bile acid-binding resins.
Disulfiram	Inhibits hepatic microsomal drug-metabolizing enzymes. Inhibits aldehyde dehydrogenase.	<p>Benzodiazepines: [P] Decreased metabolism of chlordiazepoxide and diazepam but not lorazepam and oxazepam.</p> <p>Metronidazole: [NE] Confusion and psychoses reported in patients receiving this combination; mechanisms unknown.</p> <p>Phenytoin: [P] Decreased phenytoin metabolism.</p> <p><i>See also</i> Alcohol; Anticoagulants, oral.</p>
Estrogens	Metabolism inducible. Enterohepatic circulation of estrogen may be interrupted by alteration in bowel flora (eg, due to antibiotics).	<p>Ampicillin: [NP] Interruption of enterohepatic circulation of estrogen; possible reduction in oral contraceptive efficacy. Some other oral antibiotics may have a similar effect.</p> <p>Corticosteroids: [P] Decreased metabolism of corticosteroids leading to increased corticosteroid effect.</p> <p>Diazepam: [NE] Decreased diazepam metabolism.</p> <p>Griseofulvin: [NE] Possible inhibition of oral contraceptive efficacy; mechanism unknown.</p> <p>Phenytoin: [NP] Increased estrogen metabolism; possible reduction in oral contraceptive efficacy.</p> <p>Primidone: [NP] Increased estrogen metabolism; possible reduction in oral contraceptive efficacy.</p> <p>Rifabutin: [NP] Increased estrogen metabolism; possible reduction in oral contraceptive efficacy.</p> <p>Rifampin: [NP] Increased estrogen metabolism; possible reduction in oral contraceptive efficacy.</p> <p>St. John's wort: [NE] Increased estrogen metabolism; possible reduction in oral contraceptive efficacy.</p> <p><i>See also</i> Barbiturates; Carbamazepine.</p>
HMG-CoA reductase inhibitors	Lovastatin, simvastatin, and, to a lesser extent, atorvastatin are	Clarithromycin: [P] Decreased statin metabolism.

	<p>lesser extent, atorvastatin are susceptible to CYP3A4 inducers; increased risk of additive myopathy risk with other drugs that can cause myopathy.</p>	<p>Diltiazem: [NE] Decreased statin metabolism.</p> <p>Cyclosporine: [P] Decreased statin metabolism.</p> <p>Erythromycin: [P] Decreased statin metabolism.</p> <p>Gemfibrozil: [NP] Increased plasma lovastatin and simvastatin.</p> <p>Nefazodone: [NE] Decreased statin metabolism.</p> <p>Ritonavir: [NE] Decreased statin metabolism.</p> <p>Verapamil: [NE] Decreased statin metabolism.</p> <p><i>See also</i> Azole antifungals.</p>
<p>Iron</p>	<p>Binds with drugs in gastrointestinal tract, reducing absorption.</p>	<p>Methyldopa: [NE] Decreased methyldopa absorption.</p> <p>Quinolones: [P] Decreased absorption of ciprofloxacin.</p> <p>Tetracyclines: [P] Decreased absorption of tetracyclines; decreased efficacy of iron.</p> <p>Thyroid hormones: [P] Decreased thyroxine absorption.</p> <p><i>See also</i> Antacids.</p>
<p>Levodopa</p>	<p>Levodopa degraded in gut prior to reaching sites of absorption. Agents that alter gastrointestinal motility may alter degree of intraluminal degradation. Antiparkinsonism effect of levodopa susceptible to inhibition by other drugs.</p>	<p>Clonidine: [NE] Inhibits antiparkinsonism effect.</p> <p>Monoamine oxidase inhibitors: [P] Hypertensive reaction (carbidopa prevents the interaction).</p> <p>Papaverine: [NE] Inhibits antiparkinsonism effect.</p> <p>Phenothiazines: [P] Inhibits antiparkinsonism effect.</p> <p>Phenytoin: [NE] Inhibits antiparkinsonism effect.</p> <p>Pyridoxine: [P] Inhibits antiparkinsonism effect (carbidopa prevents the interaction).</p> <p><i>See also</i> Antimuscarinics.</p>
<p>Lithium</p>	<p>Renal lithium excretion sensitive to changes in sodium balance. (Sodium depletion tends to cause</p>	<p>ACE inhibitors: [NE] Probable reduced renal clearance of lithium; increased lithium effect.</p>

	<p>lithium retention.) Susceptible to drugs enhancing central nervous system lithium toxicity.</p>	<p>Angiotensin II receptor blockers: [NE] Probable reduced renal clearance of lithium; increased lithium effect.</p> <p>Diuretics (especially thiazides): [P] Decreased excretion of lithium; furosemide may be less likely to produce this effect than thiazide diuretics.</p> <p>Haloperidol: [NP] Occasional cases of neurotoxicity in manic patients, especially with large doses of one or both drugs.</p> <p>Methyldopa: [NE] Increased likelihood of central nervous system lithium toxicity.</p> <p>Nonsteroidal anti-inflammatory drugs: [NE] Reduced renal lithium excretion (except sulindac and salicylates).</p> <p>Theophylline: [P] Increased renal excretion of lithium; reduced lithium effect.</p>
<p>Monoamine oxidase inhibitors (MAOIs)</p>	<p>Increased norepinephrine stored in adrenergic neuron. Displacement of these stores by other drugs may produce acute hypertensive response. MAOIs have intrinsic hypoglycemic activity.</p>	<p>Anorexiant: [P] Hypertensive episodes due to release of stored norepinephrine (benzphetamine, diethylpropion, mazindol, phendimetrazine, phentermine).</p> <p>Antidiabetic agents: [P] Additive hypoglycemic effect.</p> <p>Buspirone: [NE] Possible serotonin syndrome; avoid concurrent use.</p> <p>Dextromethorphan: [NE] Severe reactions (hyperpyrexia, coma, death) have been reported.</p> <p>Guanethidine: [P] Reversal of the hypotensive action of guanethidine.</p> <p>Mirtazapine: [NE] Possible serotonin syndrome; avoid concurrent use.</p> <p>Narcotic analgesics: [NP] Some patients develop hypertension, rigidity, excitation; meperidine may be more likely to interact than morphine.</p> <p>Nefazodone: [NE] Possible serotonin syndrome; avoid concurrent use.</p> <p>Phenylephrine: [P] Hypertensive episode, since phenylephrine is</p>

		<p>metabolized by monoamine oxidase.</p> <p>Selective serotonin reuptake inhibitors (SSRIs): [P] Fatalities have occurred due to serotonin syndrome; SSRIs are contraindicated in patients taking MAOIs.</p> <p>Sibutramine: [NE] Possible serotonin syndrome; avoid concurrent use.</p> <p>Sympathomimetics (indirect-acting): [HP] Hypertensive episode due to release of stored norepinephrine (amphetamines, ephedrine, isometheptene, phenylpropanolamine, pseudoephedrine).</p> <p>Tramadol: [NE] Possible serotonin syndrome; avoid concurrent use.</p> <p>Venlafaxine: [NE] Possible serotonin syndrome; avoid concurrent use.</p> <p><i>See also</i> Antidepressants, tricyclic and heterocyclic; Levodopa.</p>
Nonsteroidal anti-inflammatory drugs	<p>Prostaglandin inhibition may result in reduced renal sodium excretion, impaired resistance to hypertensive stimuli, and reduced renal lithium excretion. Most NSAIDs inhibit platelet function; may increase likelihood of bleeding due to other drugs that impair hemostasis. Most NSAIDs are highly bound to plasma proteins. Phenylbutazone may inhibit hepatic microsomal drug metabolism (also seems to act as enzyme inducer in some cases). Phenylbutazone may alter renal excretion of some drugs.</p>	<p>ACE inhibitors: [P] Decreased antihypertensive response.</p> <p>Furosemide: [P] Decreased diuretic, natriuretic, and antihypertensive response to furosemide.</p> <p>Hydralazine: [NE] Decreased antihypertensive response to hydralazine.</p> <p>Methotrexate: [NE] Possible increase in methotrexate toxicity (especially with anticancer doses of methotrexate).</p> <p>Phenytoin: [P] Decreased hepatic phenytoin metabolism.</p> <p>Triamterene: [NE] Decreased renal function noted with triamterene plus indomethacin in both healthy subjects and patients.</p> <p><i>See also</i> Anticoagulants, oral; Beta-adrenoceptor blockers; Lithium.</p>
Phenytoin	<p>Induces hepatic microsomal drug metabolism. Susceptible to inhibition of metabolism by CYP2C9 and, to a lesser extent, CYP2C19.</p>	<p><i>Drugs whose metabolism is stimulated by phenytoin:</i></p> <p>Corticosteroids: [P] Decreased serum corticosteroid levels.</p> <p>Doxycycline: [P] Decreased serum doxycycline levels.</p>

		<p>Methadone: [P] Decreased serum methadone levels; withdrawal symptoms.</p> <p>Mexiletine: [NE] Decreased serum mexiletine levels.</p> <p>Quinidine: [P] Decreased serum quinidine levels.</p> <p>Theophylline: [NE] Decreased serum theophylline levels.</p> <p>Verapamil: [NE] Decreased serum verapamil levels.</p> <p><i>See also</i> Calcium channel blockers, Cyclosporine, Estrogens.</p> <p><i>Drugs that inhibit phenytoin metabolism:</i></p> <p>Amiodarone: [P] Increased serum phenytoin; possible reduction in serum amiodarone.</p> <p>Capecitabine: [NE] Increased serum phenytoin.</p> <p>Chloramphenicol: [P] Increased serum phenytoin.</p> <p>Felbamate: [P] Increased serum phenytoin.</p> <p>Fluorouracil: [NE] Increased serum phenytoin.</p> <p>Fluvoxamine: [NE] Increased serum phenytoin.</p> <p>Isoniazid: [NP] Increased serum phenytoin; problem primarily with slow acetylators of isoniazid.</p> <p>Miconazole: [P] Increased serum phenytoin.</p> <p>Ticlopidine: [NP] Increased serum phenytoin.</p> <p><i>See also</i> Cimetidine; Disulfiram; Phenylbutazone.</p> <p><i>Drugs that enhance phenytoin metabolism:</i></p> <p>Rifampin: [P] Decreased serum phenytoin levels.</p>
Pimozide	Susceptible to CYP3A4 inhibitors; may exhibit additive effects with	Clarithromycin: [NE] Decreased pimozide metabolism.

	other agents that prolong QT _c interval.	<p>Erythromycin: [NE] Decreased pimozide metabolism</p> <p>Nefazodone: [NE] Decreased pimozide metabolism.</p> <p><i>See also</i> Azole antifungals, Cyclosporine.</p>
Potassium-sparing diuretics (amiloride, spironolactone, triamterene)	Additive effects with other agents increasing serum potassium concentration. May alter renal excretion of substances other than potassium (eg, digoxin, hydrogen ions).	<p>ACE inhibitors: [NE] Additive hyperkalemic effect.</p> <p>Potassium supplements: [P] Additive hyperkalemic effect; especially a problem in presence of renal impairment.</p> <p><i>See also</i> Digitalis glycosides; Nonsteroidal anti-inflammatory drugs.</p>
Probenecid	Interference with renal excretion of drugs that undergo active tubular secretion, especially weak acids. Inhibition of glucuronide conjugation of other drugs.	<p>Clofibrate: [P] Reduced glucuronide conjugation of clofibric acid.</p> <p>Methotrexate: [P] Decreased renal methotrexate excretion; possible methotrexate toxicity.</p> <p>Penicillin: [P] Decreased renal penicillin excretion.</p> <p>Salicylates: [P] Decreased uricosuric effect of probenecid (interaction unlikely with less than 1.5 g of salicylate daily).</p>
Quinidine	Metabolism inducible. Inhibits CYP2D6. Renal excretion susceptible to changes in urine pH. Additive effects with other agents that prolong the QT _c interval.	<p>Acetazolamide: [P] Decreased renal quinidine excretion due to increased urinary pH; elevated serum quinidine.</p> <p>Amiodarone: [NE] Increased serum quinidine levels; mechanism not established.</p> <p>Kaolin-pectin: [NE] Decreased gastrointestinal absorption of quinidine.</p> <p>Rifampin: [P] Increased hepatic quinidine metabolism.</p> <p>Thioridazine: [NE] Decreased thioridazine metabolism; additive prolongation of QT_c interval.</p> <p><i>See also</i> Anticoagulants, oral; Antidepressants, tricyclic; Barbiturates; Cimetidine; Digitalis glycosides; Phenytoin.</p>
Quinolone antibiotics	Susceptible to inhibition of gastrointestinal absorption. Some	Caffeine: [P] Ciprofloxacin, enoxacin, piperidic acid, and to a lesser extent,

	quinolones inhibit CYP1A2.	<p>norfloxacin, inhibit caffeine metabolism.</p> <p>Sucralfate: [HP] Reduced gastrointestinal absorption of ciprofloxacin, norfloxacin, and probably other quinolones.</p> <p>Theophylline: [P] Ciprofloxacin, enoxacin, and, to a lesser extent, norfloxacin inhibit theophylline metabolism; gatifloxacin, levofloxacin, lomefloxacin, ofloxacin, and sparfloxacin appear to have little effect.</p> <p><i>See also</i> Antacids; Anticoagulants, oral.</p>
Rifampin	Induction of hepatic microsomal drug-metabolizing enzymes.	<p>Corticosteroids: [P] Increased corticosteroid hepatic metabolism; reduced corticosteroid effect.</p> <p>Mexiletine: [NE] Increased mexiletine metabolism; reduced mexiletine effect.</p> <p>Sulfonylurea hypoglycemics: [P] Increased hepatic metabolism of tolbutamide and probably other sulfonylureas metabolized by the liver (including chlorpropamide).</p> <p>Theophylline: [P] Increased theophylline metabolism; reduced theophylline effect.</p> <p><i>See also</i> Anticoagulants, oral; Azole antifungals; Beta-adrenoceptor blockers; Calcium channel blockers; Cyclosporine; Digitalis glycosides; Estrogens.</p>
Salicylates	Interference with renal excretion of drugs that undergo active tubular secretion. Salicylate renal excretion dependent on urinary pH when large doses of salicylate used. Aspirin (but not other salicylates) interferes with platelet function. Large doses of salicylates have intrinsic hypoglycemic activity. Salicylates may displace drugs from plasma protein binding sites.	<p>Carbonic anhydrase inhibitors: [NE] Increased acetazolamide serum concentrations; increased salicylate toxicity due to decreased blood pH.</p> <p>Corticosteroids: [P] Increased salicylate elimination; possible additive toxic effect on gastric mucosa.</p> <p>Heparin: [NE] Increased bleeding tendency with aspirin, but probably not with other salicylates.</p> <p>Methotrexate: [P] Decreased renal methotrexate clearance; increased methotrexate toxicity (primarily at anticancer doses).</p>

		<p>Sulfinpyrazone: [HP] Decreased uricosuric effect of sulfinpyrazone (interaction unlikely with less than 1.5 g of salicylate daily).</p> <p><i>See also</i> Antacids; Anticoagulants, oral; Probenecid.</p>
Theophylline	<p>Susceptible to inhibition of hepatic metabolism by CYP1A2. Metabolism inducible.</p>	<p>Benzodiazepines: [NE] Inhibition of benzodiazepine sedation.</p> <p>Diltiazem: [P] Decreased theophylline metabolism by CYP1A3.</p> <p>Clarithromycin: [NE] Decreased theophylline metabolism.</p> <p>Erythromycin: [P] Decreased theophylline metabolism.</p> <p>Fluvoxamine: [P] Decreased theophylline metabolism.</p> <p>Smoking: [HP] Increased theophylline metabolism.</p> <p>Tacrine: [P] Decreased theophylline metabolism.</p> <p>Ticlopidine: [NE] Decreased theophylline metabolism.</p> <p>Troleandomycin: [P] Decreased theophylline metabolism.</p> <p>Verapamil: [P] Decreased theophylline metabolism.</p> <p>Zileuton: [P] Decreased theophylline metabolism.</p> <p><i>See also</i> Barbiturates; Carbamazepine; Cimetidine; Lithium; Phenytoin; Quinolones; Rifampin.</p>
