

Section I. Basic Principles

Chapter 1. Introduction

Definitions

Pharmacology can be defined as the study of substances that interact with living systems through chemical processes, especially by binding to regulatory molecules and activating or inhibiting normal body processes. These substances may be chemicals administered to achieve a beneficial therapeutic effect on some process within the patient or for their toxic effects on regulatory processes in parasites infecting the patient. Such deliberate therapeutic applications may be considered the proper role of **medical pharmacology**, which is often defined as the science of substances used to prevent, diagnose, and treat disease. **Toxicology** is that branch of pharmacology which deals with the undesirable effects of chemicals on living systems, from individual cells to complex ecosystems.

History of Pharmacology

Prehistoric people undoubtedly recognized the beneficial or toxic effects of many plant and animal materials. The earliest written records from China and from Egypt list remedies of many types, including a few still recognized today as useful drugs. Most, however, were worthless or actually harmful. In the 2500 years or so preceding the modern era there were sporadic attempts to introduce rational methods into medicine, but none were successful owing to the dominance of systems of thought that purported to explain all of biology and disease without the need for experimentation and observation. These schools promulgated bizarre notions such as the idea that disease was caused by excesses of bile or blood in the body, that wounds could be healed by applying a salve to the weapon that caused the wound, and so on.

Around the end of the 17th century, reliance on observation and experimentation began to replace theorizing in medicine, following the example of the physical sciences. As the value of these methods in the study of disease became clear, physicians in Great Britain and on the Continent began to apply them to the effects of traditional drugs used in their own practices. Thus, *materia medica*—the science of drug preparation and the medical use of drugs—began to develop as the precursor to pharmacology. However, any understanding of the mechanisms of action of drugs was prevented by the absence of methods for purifying active agents from the crude materials that were available and—even more—by the lack of methods for testing hypotheses about the nature of drug actions.

In the late 18th and early 19th centuries, François Magendie and later his student Claude Bernard began to develop the methods of experimental animal physiology and pharmacology. Advances in chemistry and the further development of physiology in the 18th, 19th, and early 20th centuries laid the foundation needed for understanding how drugs work at the organ and tissue levels.

Paradoxically, real advances in basic pharmacology during this time were accompanied by an outburst of unscientific promotion by manufacturers and marketers of worthless "patent medicines." It was not until the concepts of rational therapeutics, especially that of the controlled clinical trial, were reintroduced into medicine—about 50 years ago—that it became possible to accurately evaluate therapeutic claims.

About 50 years ago, there also began a major expansion of research efforts in all areas of biology. As new concepts and new techniques were introduced, information accumulated about drug action and the biologic substrate of that action, the receptor. During the last half-century, many fundamentally new drug groups and new members of old groups were introduced. The last 3 decades have seen an even more rapid growth of information and understanding of the molecular basis for drug action. The molecular mechanisms of action of many drugs have now been identified, and numerous receptors have been isolated, structurally characterized, and cloned. In fact, the use of receptor identification methods (described in Chapter 2: Drug Receptors & Pharmacodynamics) has led to the discovery of many orphan receptors—receptors for which no ligand has been discovered and whose function can only be surmised. Studies of the local molecular environment of receptors have shown that receptors and effectors do not function in isolation—they are strongly influenced by companion regulatory proteins. Decoding of the genomes of many species—from bacteria to humans—has led to the recognition of unsuspected relationships between receptor families. Pharmacogenomics—the relation of the individual's genetic makeup to his or her response to specific drugs—is close to becoming a practical area of therapy (see Pharmacology & Genetics). Much of that progress is summarized in this resource.

The extension of scientific principles into everyday therapeutics is still going on, though the medication-consuming public, unfortunately, is still exposed to vast amounts of inaccurate, incomplete, or unscientific information regarding the pharmacologic effects of chemicals. This has resulted in the faddish use of innumerable expensive, ineffective, and sometimes harmful remedies and the growth of a huge "alternative health care" industry. Conversely, lack of understanding of basic scientific principles in biology and statistics and the absence of critical thinking about public health issues has led to rejection of medical science by a segment of the public and a common tendency to assume that all adverse drug effects are the result of malpractice. Two general principles that the student should always remember are, first, that all substances can under certain circumstances be toxic; and second, that all therapies promoted as health-enhancing should meet the same standards of evidence of efficacy and safety, ie, there should be no artificial separation between scientific medicine and "alternative" or "complementary" medicine.

Pharmacology & Genetics

During the last 5 years, the genomes of humans, mice, and many other organisms have been decoded in considerable detail. This has opened the door to a remarkable range of new approaches to research and treatment. It has been known for centuries that certain diseases are inherited, and we now understand that individuals with such diseases have a heritable abnormality in their DNA. It is now possible in the case of some inherited diseases to define exactly which DNA base pairs are anomalous and in which chromosome they appear. In a small number of animal models of such diseases, it has been possible to correct the abnormality by "**gene therapy**," ie, insertion of an appropriate "healthy" gene into somatic cells. Human somatic cell gene therapy has been attempted, but the technical difficulties are great.

Studies of a newly discovered receptor or endogenous ligand are often confounded by incomplete knowledge of the exact role of that receptor or ligand. One of the most powerful of the new genetic techniques is the ability to breed animals (usually mice) in which the gene for the receptor or its endogenous ligand has been "knocked out," ie, mutated so that the gene product is absent or nonfunctional. Homozygous "**knockout**" mice will usually have complete suppression of that function, while heterozygous animals will usually have partial suppression. Observation of the behavior, biochemistry, and physiology of the knockout mice will often define the role of the missing gene product very clearly. When the products of a particular gene are so essential that even heterozygotes do not survive to birth, it is sometimes possible to breed "knockdown" versions with only limited suppression of function. Conversely, "knockin" mice have been bred that overexpress certain receptors of interest.

Some patients respond to certain drugs with greater than usual sensitivity. (Such variations are discussed in Chapter 4: Drug Biotransformation.) It is now clear that such increased sensitivity is often due to a very small genetic modification that results in decreased activity of a particular enzyme responsible for eliminating that drug. **Pharmacogenomics** (or pharmacogenetics) is the study of the genetic variations that cause individual differences in drug response. Future clinicians may screen every patient for a variety of such differences before prescribing a drug.

The Nature of Drugs

In the most general sense, a drug may be defined as any substance that brings about a change in biologic function through its chemical actions. In the great majority of cases, the drug molecule interacts with a specific molecule in the biologic system that plays a regulatory role. This molecule is called a **receptor**. The nature of receptors is discussed more fully in Chapter 2: Drug Receptors & Pharmacodynamics. In a very small number of cases, drugs known as chemical antagonists may interact directly with other drugs, while a few other drugs (eg, osmotic agents) interact almost exclusively with water molecules. Drugs may be synthesized within the body (eg, **hormones**) or may be chemicals *not* synthesized in the body, ie, **xenobiotics** (from Gr *xenos* "stranger"). **Poisons** are drugs. **Toxins** are usually defined as poisons of biologic origin, ie, synthesized by plants or animals, in contrast to inorganic poisons such as lead and arsenic.

In order to interact chemically with its receptor, a drug molecule must have the appropriate size, electrical charge, shape, and atomic composition. Furthermore, a drug is often administered at a location distant from its intended site of action, eg, a pill given orally to relieve a headache. Therefore, a useful drug must have the necessary properties to be transported from its site of administration to its site of action. Finally, a practical drug should be inactivated or excreted from the body at a reasonable rate so that its actions will be of appropriate duration.

The Physical Nature of Drugs

Drugs may be solid at room temperature (eg, aspirin, atropine), liquid (eg, nicotine, ethanol), or gaseous (eg, nitrous oxide). These factors often determine the best route of administration. For example, some liquid drugs are easily vaporized and can be inhaled in that form, eg, halothane, amyl nitrite. The most common routes of administration are listed in Table 3–3. The various classes of organic compounds—carbohydrates, proteins, lipids, and their constituents—are all represented in pharmacology. Many drugs are weak acids or bases. This fact has important implications for the way they are handled by the body, because pH differences in the various compartments of the body may alter the degree of ionization of such drugs (see below).

Drug Size

The molecular size of drugs varies from very small (lithium ion, MW 7) to very large (eg, alteplase [t-PA], a protein of MW 59,050). However, the vast majority of drugs have molecular weights between 100 and 1000. The lower limit of this narrow range is probably set by the requirements for specificity of action. In order to have a good "fit" to only one type of receptor, a drug molecule must be sufficiently unique in shape, charge, etc, to prevent its binding to other receptors. To achieve such selective binding, it appears that a molecule should in most cases be at least 100 MW units in size. The upper limit in molecular weight is determined primarily by the requirement that drugs be able to move within the body (eg, from site of administration to site of action). Drugs much larger than MW 1000 will not diffuse readily between compartments of the body (see Permeation, below). Therefore, very large drugs (usually proteins) must be administered directly into the compartment where they have their effect. In the case of alteplase, a clot-dissolving enzyme, the drug is administered directly into the vascular compartment by intravenous infusion.

Drug Reactivity and Drug-Receptor Bonds

Drugs interact with receptors by means of chemical forces or bonds. These are of three major types: covalent, electrostatic, and hydrophobic. Covalent bonds are very strong and in many cases not reversible under biologic conditions. Thus, the covalent bond formed between the activated form of phenoxybenzamine and the α -receptor for norepinephrine (which results in blockade of the receptor) is not readily broken. The blocking effect of phenoxybenzamine lasts long after the free drug has disappeared from the bloodstream and is reversed only by the synthesis of new α -receptors, a process that takes about 48 hours. Other examples of highly reactive, covalent bond-forming drugs are the DNA-alkylating agents used in cancer chemotherapy to disrupt cell division in the neoplastic tissue.

Electrostatic bonding is much more common than covalent bonding in drug-receptor interactions. Electrostatic bonds vary from relatively strong linkages between permanently charged ionic molecules to weaker hydrogen bonds and very weak induced dipole interactions such as van der Waals forces and similar phenomena. Electrostatic bonds are weaker than covalent bonds.

Hydrophobic bonds are usually quite weak and are probably important in the interactions of highly lipid-soluble drugs with the lipids of cell membranes and perhaps in the interaction of drugs with the internal walls of receptor "pockets."

The specific nature of a particular drug-receptor bond is of less practical importance than the fact that drugs which bind through weak bonds to their receptors are generally more selective than drugs which bind through very strong bonds. This is because weak bonds require a very precise fit of the drug to its receptor if an interaction is to occur. Only a few receptor types are likely to provide such a precise fit for a particular drug structure. Thus, if we wished to design a highly selective short-acting drug for a particular receptor, we would avoid highly reactive molecules that form covalent bonds and instead choose molecules that form weaker bonds.

A few substances that are almost completely inert in the chemical sense nevertheless have significant pharmacologic effects. For example, xenon, an "inert gas," has anesthetic effects at elevated pressures.

Drug Shape

The shape of a drug molecule must be such as to permit binding to its receptor site. Optimally, the drug's shape is complementary to that of the receptor site in the same way that a key is complementary to a lock. Furthermore, the phenomenon of **chirality (stereoisomerism)** is so

common in biology that more than half of all useful drugs are chiral molecules, ie, they exist as enantiomeric pairs. Drugs with two asymmetric centers have four diastereomers, eg, ephedrine, a sympathomimetic drug. In the great majority of cases, one of these enantiomers will be much more potent than its mirror image enantiomer, reflecting a better fit to the receptor molecule. For example, the (S)(+) enantiomer of methacholine, a parasympathomimetic drug, is over 250 times more potent than the (R)(-) enantiomer. If one imagines the receptor site to be like a glove into which the drug molecule must fit to bring about its effect, it is clear why a "left-oriented" drug will be more effective in binding to a left-hand receptor than will its "right-oriented" enantiomer.

The more active enantiomer at one type of receptor site may not be more active at another type, eg, a receptor type that may be responsible for some unwanted effect. For example, carvedilol, a drug that interacts with adrenoceptors, has a single chiral center and thus two enantiomers (Table 1-1). One of these enantiomers, the (S)(-) isomer, is a potent β -receptor blocker. The (R)(+) isomer is 100-fold weaker at the β -receptor. However, the isomers are approximately equipotent as α -receptor blockers. Ketamine is an intravenous anesthetic. The (+) enantiomer is a more potent anesthetic and is less toxic than the (-) enantiomer. Unfortunately, the drug is still used as the racemic mixture.

Table 1-1. Dissociation Constants (K_d) of the Enantiomers and Racemate of Carvedilol.¹

Form of Carvedilol	Inverse of Affinity for α Receptors (K_d , nmol/L)	Inverse of Affinity for β Receptors (K_d , nmol/L)
R(+) enantiomer	14	45
S(-) enantiomer	16	0.4
R,S(+/-) enantiomers	11	0.9

Note: The K_d is the concentration for 50% saturation of the receptors and is inversely proportionate to the affinity of the drug for the receptors.

¹Data from Ruffolo RR et al: The pharmacology of carvedilol. Eur J Pharmacol 1990;38:S82.

Finally, because enzymes are usually stereoselective, one drug enantiomer is often more susceptible than the other to drug-metabolizing enzymes. As a result, the duration of action of one enantiomer may be quite different from that of the other.

Unfortunately, most studies of clinical efficacy and drug elimination in humans have been carried out with racemic mixtures of drugs rather than with the separate enantiomers. At present, only about 45% of the chiral drugs used clinically are marketed as the active isomer—the rest are available only as racemic mixtures. As a result, many patients are receiving drug doses of which 50% or more is either inactive or actively toxic. However, there is increasing interest—at both the scientific and the regulatory levels—in making more chiral drugs available as their active enantiomers.

Rational Drug Design

Rational design of drugs implies the ability to predict the appropriate molecular structure of a drug on the basis of information about its biologic receptor. Until recently, no receptor was known in

sufficient detail to permit such drug design. Instead, drugs were developed through random testing of chemicals or modification of drugs already known to have some effect (see Chapter 5: Basic & Clinical Evaluation of New Drugs). However, during the past 3 decades, many receptors have been isolated and characterized. A few drugs now in use were developed through molecular design based on a knowledge of the three-dimensional structure of the receptor site. Computer programs are now available that can iteratively optimize drug structures to fit known receptors. As more becomes known about receptor structure, rational drug design will become more feasible.

Receptor Nomenclature

The spectacular success of newer, more efficient ways to identify and characterize receptors (see Chapter 2: Drug Receptors & Pharmacodynamics, How Are New Receptors Discovered?) has resulted in a variety of differing systems for naming them. This in turn has led to a number of suggestions regarding more rational methods of naming them. The interested reader is referred for details to the efforts of the International Union of Pharmacology (IUPHAR) *Committee on Receptor Nomenclature and Drug Classification* (reported in various issues of *Pharmacological Reviews*) and to the annual *Receptor and Ion Channel Nomenclature Supplements* published as special issues by the journal *Trends in Pharmacological Sciences* (TIPS). The chapters in this book mainly use these sources for naming receptors.

Drug-Body Interactions

The interactions between a drug and the body are conveniently divided into two classes. The actions of the drug on the body are termed **pharmacodynamic** processes; the principles of pharmacodynamics are presented in greater detail in Chapter 2: Drug Receptors & Pharmacodynamics. These properties determine the group in which the drug is classified and often play the major role in deciding whether that group is appropriate therapy for a particular symptom or disease. The actions of the body on the drug are called **pharmacokinetic** processes and are described in Chapters 3 and 4. Pharmacokinetic processes govern the absorption, distribution, and elimination of drugs and are of great practical importance in the choice and administration of a particular drug for a particular patient, eg, one with impaired renal function. The following paragraphs provide a brief introduction to pharmacodynamics and pharmacokinetics.

Pharmacodynamic Principles

As noted above, most drugs must bind to a receptor to bring about an effect. However, at the molecular level, drug binding is only the first in what is often a complex sequence of steps.

Types of Drug-Receptor Interactions

Agonist drugs bind to and *activate* the receptor in some fashion, which directly or indirectly brings about the effect. Some receptors incorporate effector machinery in the same molecule, so that drug binding brings about the effect directly, eg, opening of an ion channel or activation of enzyme activity. Other receptors are linked through one or more intervening coupling molecules to a separate effector molecule. The several types of drug-receptor-effector coupling systems are discussed in Chapter 2: Drug Receptors & Pharmacodynamics. Pharmacologic antagonist drugs, by binding to a receptor, *prevent* binding by other molecules. For example, acetylcholine receptor blockers such as atropine are antagonists because they prevent access of acetylcholine and similar agonist drugs to the acetylcholine receptor and they stabilize the receptor in its inactive state. These agents reduce the effects of acetylcholine and similar drugs in the body.

"Agonists" That *Inhibit* Their Binding Molecules and Partial Agonists

Some drugs mimic agonist drugs by inhibiting the molecules responsible for terminating the action of an endogenous agonist. For example, acetylcholinesterase inhibitors, by slowing the destruction of endogenous acetylcholine, cause cholinomimetic effects that closely resemble the actions of cholinergic agonist molecules even though cholinesterase inhibitors do not—or only incidentally do—bind to cholinergic receptors (see Chapter 7: Cholinergic-Activating & Cholinesterase-Inhibiting Drugs). Other drugs bind to receptors and activate them but do not evoke as great a response as so-called full agonists. Thus, pindolol, a β -adrenoceptor "partial agonist," may act as either an agonist (if no full agonist is present) or as an antagonist (if a full agonist such as isoproterenol is present). (See Chapter 2: Drug Receptors & Pharmacodynamics.)

Duration of Drug Action

Termination of drug action at the receptor level results from one of several processes. In some cases, the effect lasts only as long as the drug occupies the receptor, so that dissociation of drug from the receptor automatically terminates the effect. In many cases, however, the action may persist after the drug has dissociated, because, for example, some coupling molecule is still present in activated form. In the case of drugs that bind covalently to the receptor, the effect may persist until the drug-receptor complex is destroyed and new receptors are synthesized, as described previously for phenoxybenzamine. Finally, many receptor-effector systems incorporate desensitization mechanisms for preventing excessive activation when agonist molecules continue to be present for long periods. See Chapter 2: Drug Receptors & Pharmacodynamics for additional details.

Receptors and Inert Binding Sites

To function as a receptor, an endogenous molecule must first be selective in choosing ligands (drug molecules) to bind; and second, it must change its function upon binding in such a way that the function of the biologic system (cell, tissue, etc) is altered. The first characteristic is required to avoid constant activation of the receptor by promiscuous binding of many different ligands. The second characteristic is clearly necessary if the ligand is to cause a pharmacologic effect. The body contains many molecules that are capable of binding drugs, however, and not all of these endogenous molecules are regulatory molecules. Binding of a drug to a nonregulatory molecule such as plasma albumin will result in no detectable change in the function of the biologic system, so this endogenous molecule can be called an inert binding site. Such binding is not completely without significance, however, since it affects the distribution of drug within the body and will determine the amount of free drug in the circulation. Both of these factors are of pharmacokinetic importance (see below and Chapter 3: Pharmacokinetics & Pharmacodynamics: Rational Dosing & the Time Course of Drug Action).

Pharmacokinetic Principles

In practical therapeutics, a drug should be able to reach its intended site of action after administration by some convenient route. In some cases, a chemical that is readily absorbed and distributed is administered and then converted to the active drug by biologic processes—inside the body. Such a chemical is called a **prodrug**. In only a few situations is it possible to directly apply a drug to its target tissue, eg, by topical application of an anti-inflammatory agent to inflamed skin or mucous membrane. Most often, a drug is administered into one body compartment, eg, the gut, and must move to its site of action in another compartment, eg, the brain. This requires that the drug be **absorbed** into the blood from its site of administration and **distributed** to its site of action,

permeating through the various barriers that separate these compartments. For a drug given orally to produce an effect in the central nervous system, these barriers include the tissues that comprise the wall of the intestine, the walls of the capillaries that perfuse the gut, and the "blood-brain barrier," the walls of the capillaries that perfuse the brain. Finally, after bringing about its effect, a drug should be **eliminated** at a reasonable rate by metabolic inactivation, by excretion from the body, or by a combination of these processes.

Permeation

Drug permeation proceeds by four primary mechanisms. Passive diffusion in an aqueous or lipid medium is common, but active processes play a role in the movement of many drugs, especially those whose molecules are too large to diffuse readily.

Aqueous Diffusion

Aqueous diffusion occurs within the larger aqueous compartments of the body (interstitial space, cytosol, etc) and across epithelial membrane tight junctions and the endothelial lining of blood vessels through aqueous pores that—in some tissues—permit the passage of molecules as large as MW 20,000–30,000.*

* The capillaries of the brain, the testes, and some other tissues are characterized by absence of the pores that permit aqueous diffusion of many drug molecules into the tissue. They may also contain high concentrations of drug export pumps (MDR pumps; see text). These tissues are therefore "protected" or "sanctuary" sites from many circulating drugs.

Aqueous diffusion of drug molecules is usually driven by the concentration gradient of the permeating drug, a downhill movement described by Fick's law (see below). Drug molecules that are bound to large plasma proteins (eg, albumin) will not permeate these aqueous pores. If the drug is charged, its flux is also influenced by electrical fields (eg, the membrane potential and—in parts of the nephron—the transtubular potential).

Lipid Diffusion

Lipid diffusion is the most important limiting factor for drug permeation because of the large number of lipid barriers that separate the compartments of the body. Because these lipid barriers separate aqueous compartments, the lipid:aqueous partition coefficient of a drug determines how readily the molecule moves between aqueous and lipid media. In the case of weak acids and weak bases (which gain or lose electrical charge-bearing protons, depending on the pH), the ability to move from aqueous to lipid or vice versa varies with the pH of the medium, because charged molecules attract water molecules. The ratio of lipid-soluble form to water-soluble form for a weak acid or weak base is expressed by the Henderson-Hasselbalch equation (see below).

Special Carriers

Special carrier molecules exist for certain substances that are important for cell function and too large or too insoluble in lipid to diffuse passively through membranes, eg, peptides, amino acids, glucose. These carriers bring about movement by active transport or facilitated diffusion and, unlike passive diffusion, are saturable and inhibitable. Because many drugs are or resemble such naturally occurring peptides, amino acids, or sugars, they can use these carriers to cross membranes.

Many cells also contain less selective membrane carriers that are specialized for expelling foreign molecules, eg, the **P-glycoprotein** or **multidrug-resistance type 1 (MDR1) transporter** found in the brain, testes, and other tissues, and in some drug-resistant neoplastic cells. A similar transport molecule, the **multidrug resistance-associated protein-type 2 (MRP2)** transporter, plays an important role in excretion of some drugs or their metabolites into urine and bile.

Endocytosis and Exocytosis

A few substances are so large or impermeant that they can enter cells only by endocytosis, the process by which the substance is engulfed by the cell membrane and carried into the cell by pinching off of the newly formed vesicle inside the membrane. The substance can then be released inside the cytosol by breakdown of the vesicle membrane. This process is responsible for the transport of vitamin B₁₂, complexed with a binding protein (intrinsic factor), across the wall of the gut into the blood. Similarly, iron is transported into hemoglobin-synthesizing red blood cell precursors in association with the protein transferrin. Specific receptors for the transport proteins must be present for this process to work. The reverse process (exocytosis) is responsible for the secretion of many substances from cells. For example, many neurotransmitter substances are stored in membrane-bound vesicles in nerve endings to protect them from metabolic destruction in the cytoplasm. Appropriate activation of the nerve ending causes fusion of the storage vesicle with the cell membrane and expulsion of its contents into the extracellular space (see Chapter 6: Introduction to Autonomic Pharmacology).

Fick's Law of Diffusion

The passive flux of molecules down a concentration gradient is given by Fick's law:

$$\text{Flux (molecules per unit time)} = (C_1 - C_2) \times \frac{\text{Area} \times \text{Permeability coefficient}}{\text{Thickness}}$$

where C₁ is the higher concentration, C₂ is the lower concentration, area is the area across which diffusion is occurring, permeability coefficient is a measure of the mobility of the drug molecules in the medium of the diffusion path, and thickness is the thickness (length) of the diffusion path. In the case of lipid diffusion, the lipid:aqueous partition coefficient is a major determinant of mobility of the drug, since it determines how readily the drug enters the lipid membrane from the aqueous medium.

Ionization of Weak Acids and Weak Bases; the Henderson-Hasselbalch Equation

The electrostatic charge of an ionized molecule attracts water dipoles and results in a polar, relatively water-soluble and lipid-insoluble complex. Since lipid diffusion depends on relatively high lipid solubility, ionization of drugs may markedly reduce their ability to permeate membranes. A very large fraction of the drugs in use are weak acids or weak bases (Table 1–2). For drugs, a weak acid is best defined as a neutral molecule that can reversibly dissociate into an anion (a negatively charged molecule) and a proton (a hydrogen ion). For example, aspirin dissociates as follows:

Table 1–2. Ionization Constants of Some Common Drugs.

Drug	pK _a ¹
Weak acids	
Acetaminophen	9.5
Acetazolamide	7.2
Ampicillin	2.5
Aspirin	3.5
Chlorothiazide	6.8, 9.4 ²
Chlorpropamide	5.0
Ciprofloxacin	6.09, 8.74 ²
Cromolyn	2.0
Ethacrynic acid	2.5
Furosemide	3.9
Ibuprofen	4.4, 5.2 ²
Levodopa	2.3
Methotrexate	4.8
Methyldopa	2.2, 9.2 ²
Penicillamine	1.8
Pentobarbital	8.1
Phenobarbital	7.4
Phenytoin	8.3
Propylthiouracil	8.3
Salicylic acid	3.0
Sulfadiazine	6.5
Sulfapyridine	8.4
Theophylline	8.8
Tolbutamide	5.3
Warfarin	5.0
Weak bases	
Albuterol (salbutamol)	9.3
Allopurinol	9.4, 12.3

Alprenolol	9.6
Amiloride	8.7
Amiodarone	6.56
Amphetamine	9.8
Atropine	9.7
Bupivacaine	8.1
Chlordiazepoxide	4.6
Chloroquine	10.8, 8.4 ²
Chlorpheniramine	9.2
Chlorpromazine	9.3
Clonidine	8.3
Cocaine	8.5
Codeine	8.2
Cyclizine	8.2
Desipramine	10.2
Diazepam	3
Dihydrocodeine	3
Diphenhydramine	8.8
Diphenoxylate	7.1
Ephedrine	9.6
Epinephrine	8.7
Ergotamine	6.3
Fluphenazine	8.0, 3.9 ²
Guanethidine	11.4, 8.3 ²
Hydralazine	7.1
Imipramine	9.5
Isoproterenol	8.6
Kanamycin	7.2
Lidocaine	7.9
Metaraminol	8.6
Methadone	8.4
Methamphetamine	10.0
Methyldopa	10.6
Metoprolol	9.8
Morphine	7.9

Nicotine	7.9, 3.1 ²
Norepinephrine	8.6
Pentazocine	7.9
Phenylephrine	9.8
Physostigmine	7.9, 1.8 ²
Pilocarpine	6.9, 1.4 ²
Pindolol	8.6
Procainamide	9.2
Procaine	9.0
Promazine	9.4
Promethazine	9.1
Propranolol	9.4
Pseudoephedrine	9.8
Pyrimethamine	7.0
Quinidine	8.5, 4.4 ²
Scopolamine	8.1
Strychnine	8.0, 2.3 ²
Terbutaline	10.1
Thioridazine	9.5
Tolazoline	10.6

A drug that is a weak base can be defined as a neutral molecule that can form a cation (a positively charged molecule) by combining with a proton. For example, pyrimethamine, an antimalarial drug, undergoes the following association-dissociation process:

Note that the protonated form of a weak acid is the neutral, more lipid-soluble form, whereas the unprotonated form of a weak base is the neutral form. The law of mass action requires that these reactions move to the left in an acid environment (low pH, excess protons available) and to the right in an alkaline environment. The Henderson-Hasselbalch equation relates the ratio of protonated to unprotonated weak acid or weak base to the molecule's pK_a and the pH of the medium as follows:

$$\log \frac{(\text{Protonated})}{(\text{Unprotonated})} = pK_a - pH$$

This equation applies to both acidic and basic drugs. Inspection confirms that the lower the pH relative to the pK_a , the greater will be the fraction of drug in the protonated form. Because the uncharged form is the more lipid-soluble, more of a weak acid will be in the lipid-soluble form at acid pH, while more of a basic drug will be in the lipid-soluble form at alkaline pH.

An application of this principle is in the manipulation of drug excretion by the kidney. Almost all drugs are filtered at the glomerulus. If a drug is in a lipid-soluble form during its passage down the renal tubule, a significant fraction will be reabsorbed by simple passive diffusion. If the goal is to accelerate excretion of the drug, it is important to prevent its reabsorption from the tubule. This can often be accomplished by adjusting urine pH to make certain that most of the drug is in the ionized state, as shown in Figure 1-1. As a result of this pH partitioning effect, the drug will be "trapped" in the urine. Thus, weak acids are usually excreted faster in alkaline urine; weak bases are usually excreted faster in acidic urine. Other body fluids in which pH differences from blood pH may cause trapping or reabsorption are the contents of the stomach and small intestine; breast milk; aqueous humor; and vaginal and prostatic secretions (Table 1-3).

Figure 1-1.

Trapping of a weak base (pyrimethamine) in the urine when the urine is more acidic than the blood. In the hypothetical case illustrated, the diffusible uncharged form of the drug has equilibrated across the membrane but the total concentration (charged plus uncharged) in the urine is almost eight times higher than in the blood.

Table 1-3. Body Fluids with Potential for Drug "Trapping" Through the pH-Partitioning Phenomenon.

Body Fluid	Range of pH	Total Fluid: Blood Concentration Ratios for Sulfadiazine (acid, pK _a 6.5) ¹	Total Fluid: Blood Concentration Ratios for Pyrimethamine (base, pK _a 7.0) ¹
Urine	5.0–8.0	0.12–4.65	72.24–0.79
Breast milk	6.4–7.6 ²	0.2–1.77	3.56–0.89
Jejunum, ileum contents	7.5–8.0 ³	1.23–3.54	0.94–0.79
Stomach contents	1.92–2.59 ²	0.11 ⁴	85,993–18,386
Prostatic secretions	6.45–7.4 ²	0.21	3.25–1.0

¹Body fluid protonated-to-unprotonated drug ratios were calculated using each of the pH extremes cited; a blood pH of 7.4 was used for blood:drug ratio. For example, the steady-state urine:blood ratio for sulfadiazine is 0.12 at a urine pH of 5.0; this ratio is 4.65 at a urine pH of 8.0. Thus, sulfadiazine is much more effectively trapped and excreted in alkaline urine.

⁴Insignificant change in ratios over the physiologic pH range.

As suggested by Table 1–2, a large number of drugs are weak bases. Most of these bases are amine-containing molecules. The nitrogen of a neutral amine has three atoms associated with it plus a pair of unshared electrons—see the display below. The three atoms may consist of one carbon (designated "R") and two hydrogens (a **primary amine**), two carbons and one hydrogen (a **secondary amine**), or three carbon atoms (a **tertiary amine**). Each of these three forms may reversibly bind a proton with the unshared electrons. Some drugs have a fourth carbon-nitrogen bond; these are **quaternary amines**. However, the quaternary amine is permanently charged and has no unshared electrons with which to reversibly bind a proton. Therefore, primary, secondary, and tertiary amines may undergo reversible protonation and vary their lipid solubility with pH, but quaternary amines are always in the poorly lipid-soluble charged form.

Drug Groups

To learn each pertinent fact about each of the many hundreds of drugs mentioned in this book would be an impractical goal and, fortunately, is in any case unnecessary. Almost all of the several thousand drugs currently available can be arranged in about 70 groups. Many of the drugs within each group are very similar in pharmacodynamic actions and often in their pharmacokinetic properties as well. For most groups, one or more **prototype drugs** can be identified that typify the most important characteristics of the group. This permits classification of other important drugs in the group as variants of the prototype, so that only the prototype must be learned in detail and, for the remaining drugs, only the differences from the prototype.

Sources of Information

Students who wish to review the field of pharmacology in preparation for an examination are referred to *Pharmacology: Examination and Board Review*, by Trevor, Katzung, and Masters (McGraw-Hill, 2002) or *USMLE Road Map: Pharmacology*, by Katzung and Trevor (McGraw-Hill, 2003).

The references at the end of each chapter in this book were selected to provide information specific to those chapters.

Specific questions relating to basic or clinical research are best answered by resort to the general pharmacology and clinical specialty serials. For the student and the physician, three periodicals can be recommended as especially useful sources of current information about drugs: *The New England Journal of Medicine*, which publishes much original drug-related clinical research as well as frequent reviews of topics in pharmacology; *The Medical Letter on Drugs and Therapeutics*, which publishes brief critical reviews of new and old therapies, mostly pharmacologic; and *Drugs*, which publishes extensive reviews of drugs and drug groups.

Other sources of information pertinent to the USA should be mentioned as well. The "package insert" is a summary of information the manufacturer is required to place in the prescription sales package; *Physicians' Desk Reference (PDR)* is a compendium of package inserts published annually with supplements twice a year; *Facts and Comparisons* is a more complete loose-leaf drug information service with monthly updates; and the *USP DI* (vol 1, *Drug Information for the Health Care Professional*) is a large drug compendium with monthly updates that is now published on the Internet by the Micromedex Corporation. The package insert consists of a brief description of the pharmacology of the product. While this brochure contains much practical information, it is also used as a means of shifting liability for untoward drug reactions from the manufacturer onto the practitioner. Therefore, the manufacturer typically lists every toxic effect ever reported, no matter how rare. A useful and objective handbook that presents information on drug toxicity and interactions is *Drug Interactions*. Finally, the FDA has an Internet World Wide Web site that carries news regarding recent drug approvals, withdrawals, warnings, etc. It can be reached using a personal computer equipped with Internet browser software at <http://www.fda.gov>.

The following addresses are provided for the convenience of readers wishing to obtain any of the publications mentioned above:

Chapter 2. Drug Receptors & Pharmacodynamics

Drug Receptors & Pharmacodynamics: Introduction

Therapeutic and toxic effects of drugs result from their interactions with molecules in the patient. Most drugs act by associating with specific macromolecules in ways that alter the macromolecules' biochemical or biophysical activities. This idea, more than a century old, is embodied in the term **receptor**: the component of a cell or organism that interacts with a drug and initiates the chain of biochemical events leading to the drug's observed effects.

Receptors have become the central focus of investigation of drug effects and their mechanisms of action (pharmacodynamics). The receptor concept, extended to endocrinology, immunology, and molecular biology, has proved essential for explaining many aspects of biologic regulation. Many drug receptors have been isolated and characterized in detail, thus opening the way to precise understanding of the molecular basis of drug action.

The receptor concept has important practical consequences for the development of drugs and for arriving at therapeutic decisions in clinical practice. These consequences form the basis for

understanding the actions and clinical uses of drugs described in almost every chapter of this book. They may be briefly summarized as follows:

(1) Receptors largely determine the quantitative relations between dose or concentration of drug and pharmacologic effects. The receptor's affinity for binding a drug determines the concentration of drug required to form a significant number of drug-receptor complexes, and the total number of receptors may limit the maximal effect a drug may produce.

(2) Receptors are responsible for selectivity of drug action. The molecular size, shape, and electrical charge of a drug determine whether—and with what affinity—it will bind to a particular receptor among the vast array of chemically different binding sites available in a cell, tissue, or patient. Accordingly, changes in the chemical structure of a drug can dramatically increase or decrease a new drug's affinities for different classes of receptors, with resulting alterations in therapeutic and toxic effects.

(3) Receptors mediate the actions of both pharmacologic agonists and antagonists. Some drugs and many natural ligands, such as hormones and neurotransmitters, regulate the function of receptor macromolecules as agonists; ie, they activate the receptor to signal as a direct result of binding to it. Other drugs function as pharmacologic antagonists; ie, they bind to receptors but do not activate generation of a signal; consequently, they interfere with the ability of an agonist to activate the receptor. Thus, the effect of a so-called "pure" antagonist on a cell or in a patient depends entirely on its preventing the binding of agonist molecules and blocking their biologic actions. Some of the most useful drugs in clinical medicine are pharmacologic antagonists.

Macromolecular Nature of Drug Receptors

Most receptors are proteins, presumably because the structures of polypeptides provide both the necessary diversity and the necessary specificity of shape and electrical charge. The section *How Are New Receptors Discovered?* describes some of the methods by which receptors are discovered and defined.

The best-characterized drug receptors are **regulatory proteins**, which mediate the actions of endogenous chemical signals such as neurotransmitters, autacoids, and hormones. This class of receptors mediates the effects of many of the most useful therapeutic agents. The molecular structures and biochemical mechanisms of these regulatory receptors are described in a later section entitled *Signaling Mechanisms & Drug Action*.

Other classes of proteins that have been clearly identified as drug receptors include **enzymes**, which may be inhibited (or, less commonly, activated) by binding a drug (eg, dihydrofolate reductase, the receptor for the antineoplastic drug methotrexate); **transport proteins** (eg, Na^+/K^+ ATPase, the membrane receptor for cardioactive digitalis glycosides); and **structural proteins** (eg, tubulin, the receptor for colchicine, an anti-inflammatory agent).

This chapter deals with three aspects of drug receptor function, presented in increasing order of complexity: (1) Receptors as determinants of the quantitative relation between the concentration of a drug and the pharmacologic response. (2) Receptors as regulatory proteins and components of chemical signaling mechanisms that provide targets for important drugs. (3) Receptors as key determinants of the therapeutic and toxic effects of drugs in patients.

How Are New Receptors Discovered?

Because today's new receptor sets the stage for tomorrow's new drug, it is important to know how new receptors are discovered. Receptor discovery often begins by studying the relations between structures and activities of a group of drugs on some conveniently measured response. Binding of radioactive ligands defines the molar abundance and binding affinities of the putative receptor and provides an assay to aid in its biochemical purification.

Analysis of the pure receptor protein identifies the number of its subunits, its size, and (sometimes) provides a clue to how it works (eg, agonist-stimulated autophosphorylation on tyrosine residues, seen with receptors for insulin and many growth factors). These classic steps in receptor identification serve as a warming-up exercise for molecular cloning of the segment of DNA that encodes the receptor. Receptors within a specific class or subclass generally contain highly conserved regions of similar or identical amino acid (and therefore DNA) sequence. This has led to an entirely different approach toward identifying receptors by sequence homology to already known (cloned) receptors.

Cloning of new receptors by sequence homology has identified a number of subtypes of known receptor classes, such as α -adrenoceptors and serotonin receptors, the diversity of which was only partially anticipated from pharmacologic studies. This approach has also led to the identification of receptors whose existence was not anticipated from pharmacologic studies. These putative receptors, identified only by their similarity to other known receptors, are termed **orphan** receptors until their native ligands are identified. Identifying such receptors and their ligands is of great interest because this process may elucidate entirely new signaling pathways and therapeutic targets.

Relation between Drug Concentration & Response

The relation between dose of a drug and the clinically observed response may be complex. In carefully controlled in vitro systems, however, the relation between concentration of a drug and its effect is often simple and can be described with mathematical precision. This idealized relation underlies the more complex relations between dose and effect that occur when drugs are given to patients.

Concentration-Effect Curves & Receptor Binding of Agonists

Even in intact animals or patients, responses to low doses of a drug usually increase in direct proportion to dose. As doses increase, however, the response increment diminishes; finally, doses may be reached at which no further increase in response can be achieved. In idealized or in vitro systems, the relation between drug concentration and effect is described by a hyperbolic curve (Figure 2-1 A) according to the following equation:

$$E = \frac{E_{\max} \times C}{C + EC_{50}}$$

where E is the effect observed at concentration C, E_{\max} is the maximal response that can be produced by the drug, and EC_{50} is the concentration of drug that produces 50% of maximal effect.

Figure 2-1.

This hyperbolic relation resembles the mass action law, which predicts association between two molecules of a given affinity. This resemblance suggests that drug agonists act by binding to ("occupying") a distinct class of biologic molecules with a characteristic affinity for the drug receptor. Radioactive receptor ligands have been used to confirm this occupancy assumption in many drug-receptor systems. In these systems, drug bound to receptors (B) relates to the concentration of free (unbound) drug (C) as depicted in Figure 2-1 B and as described by an analogous equation:

$$B = \frac{B_{\max} \times C}{C + K_D}$$

in which B_{\max} indicates the total concentration of receptor sites (ie, sites bound to the drug at infinitely high concentrations of free drug). K_D (the equilibrium dissociation constant) represents the concentration of free drug at which half-maximal binding is observed. This constant characterizes the receptor's affinity for binding the drug in a reciprocal fashion: If the K_D is low, binding affinity is high, and vice versa. The EC_{50} and K_D may be identical, but need not be, as discussed below. Dose-response data is often presented as a plot of the drug effect (ordinate) against the *logarithm* of the dose or concentration (abscissa). This mathematical maneuver transforms the hyperbolic curve of Figure 2-1 into a sigmoid curve with a linear midportion (eg, Figure 2-2). This expands the scale of the concentration axis at low concentrations (where the effect is changing rapidly) and compresses it at high concentrations (where the effect is changing slowly), but has no special biologic or pharmacologic significance.

Figure 2-2.

Logarithmic transformation of the dose axis and experimental demonstration of spare receptors, using different concentrations of an irreversible antagonist. Curve **A** shows agonist response in the absence of antagonist. After treatment with a low concentration of antagonist (curve **B**), the curve is shifted to the right; maximal responsiveness is preserved, however, because the remaining available receptors are still in excess of the number required. In curve **C**, produced after treatment with a larger concentration of antagonist, the available receptors are no longer "spare"; instead, they are just sufficient to mediate an undiminished maximal response. Still higher concentrations of antagonist (curves **D** and **E**) reduce the number of available receptors to the point that maximal response is diminished. The apparent EC_{50} of the agonist in curves **D** and **E** may approximate the K_D that characterizes the binding affinity of the agonist for the receptor.

Receptor-Effector Coupling & Spare Receptors

When a receptor is occupied by an agonist, the resulting conformational change is only the first of many steps usually required to produce a pharmacologic response. The transduction process between occupancy of receptors and drug response is often termed **coupling**. The relative efficiency of occupancy-response coupling is partially determined by the initial conformational change in the receptor—thus, the effects of full agonists can be considered more efficiently coupled to receptor occupancy than can the effects of partial agonists, as described below. Coupling efficiency is also determined by the biochemical events that transduce receptor occupancy into cellular response.

High efficiency of receptor-effector interaction may also be envisioned as the result of spare receptors. Receptors are said to be "spare" for a given pharmacologic response when the maximal response can be elicited by an agonist at a concentration that does not result in occupancy of the full complement of available receptors. Spare receptors are not qualitatively different from nonspare receptors. They are not hidden or unavailable, and when they are occupied they can be coupled to response. Experimentally, spare receptors may be demonstrated by using irreversible antagonists to prevent binding of agonist to a proportion of available receptors and showing that high concentrations of agonist can still produce an undiminished maximal response (Figure 2–2). Thus, a

maximal inotropic response of heart muscle to catecholamines can be elicited even under conditions where 90% of the β -adrenoceptors are occupied by a quasi-irreversible antagonist. Accordingly, myocardial cells are said to contain a large proportion of spare β -adrenoceptors.

How can we account for the phenomenon of spare receptors? In a few cases, the biochemical mechanism is understood, such as for drugs that act on some regulatory receptors. In this situation, the effect of receptor activation—eg, binding of guanosine triphosphate (GTP) by an intermediate—may greatly outlast the agonist-receptor interaction (see the following section on G Proteins & Second Messengers). In such a case, the "spareness" of receptors is *temporal* in that the response initiated by an individual ligand-receptor binding event persists longer than the binding event itself.

In other cases, where the biochemical mechanism is not understood, we imagine that the receptors might be *spare in number*. If the concentration or amount of a cellular component other than the receptor limits the coupling of receptor occupancy to response, then a maximal response can occur without occupancy of all receptors. This concept helps explain how the sensitivity of a cell or tissue to a particular concentration of agonist depends not only on the *affinity* of the receptor for binding the agonist (characterized by the K_D) but also on the *degree of spareness*—the total number of receptors present compared to the number actually needed to elicit a maximal biologic response. The K_D of the agonist-receptor interaction determines what fraction (B/B_{max}) of total receptors will be occupied at a given free concentration (C) of agonist regardless of the receptor concentration:

$$\frac{B}{B_{max}} = \frac{C}{C + K_D}$$

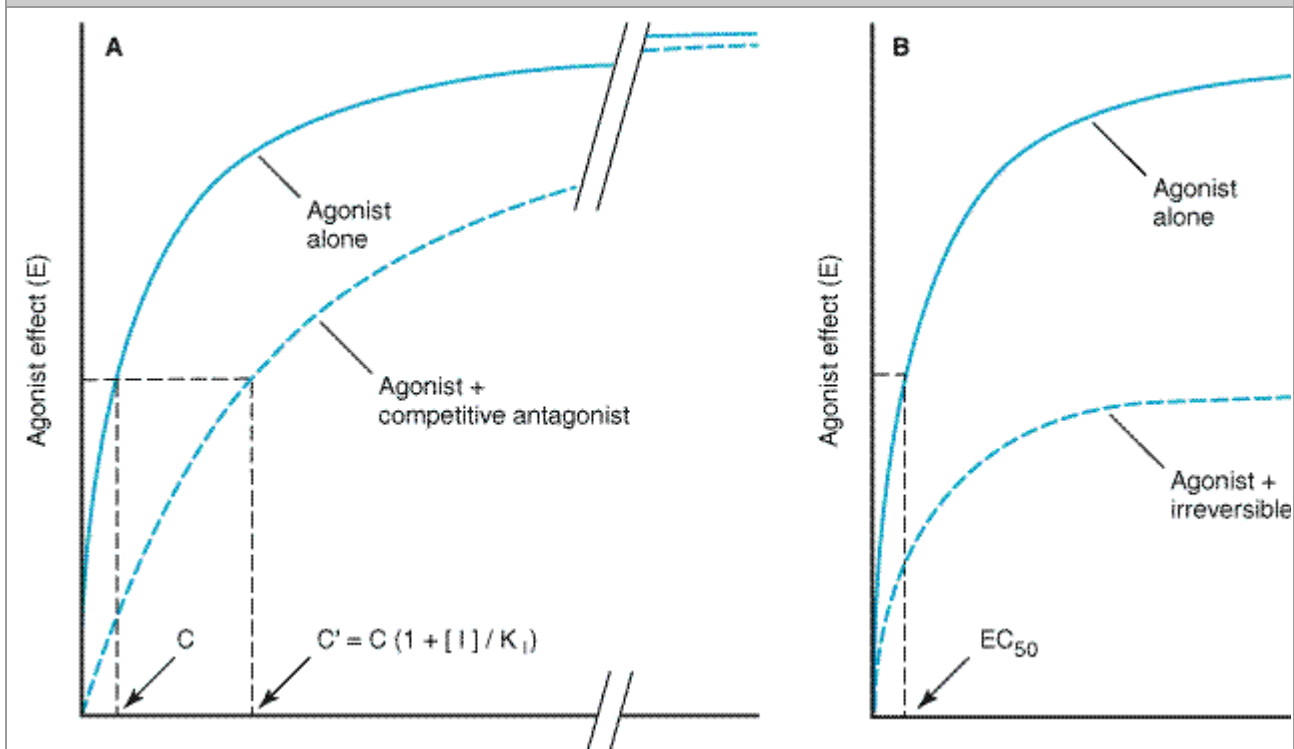

Imagine a responding cell with four receptors and four effectors. Here the number of effectors does not limit the maximal response, and the receptors are *not* spare in number. Consequently, an agonist present at a concentration equal to the K_D will occupy 50% of the receptors, and half of the effectors will be activated, producing a half-maximal response (ie, two receptors stimulate two effectors). Now imagine that the number of receptors increases 10-fold to 40 receptors but that the total number of effectors remains constant. Most of the receptors are now spare in number. As a result, a much lower concentration of agonist suffices to occupy two of the 40 receptors (5% of the receptors), and this same low concentration of agonist is able to elicit a half-maximal response (two of four effectors activated). Thus, it is possible to change the sensitivity of tissues with spare receptors by changing the receptor concentration.

Competitive & Irreversible Antagonists

Receptor antagonists bind to receptors but do not activate them. In general, the effects of these antagonists result from preventing agonists (other drugs or endogenous regulatory molecules) from binding to and activating receptors. Such antagonists are divided into two classes depending on whether or not they *reversibly* compete with agonists for binding to receptors.

In the presence of a fixed concentration of agonist, increasing concentrations of a **competitive antagonist** progressively inhibit the agonist response; high antagonist concentrations prevent response completely. Conversely, sufficiently high concentrations of agonist can completely surmount the effect of a given concentration of the antagonist; ie, the E_{max} for the agonist remains the same for any fixed concentration of antagonist (Figure 2–3 A). Because the antagonism is competitive, the presence of antagonist increases the agonist concentration required for a given degree of response, and so the agonist concentration-effect curve is shifted to the right.

Figure 2-3.

Changes in agonist concentration-effect curves produced by a competitive antagonist (panel **A**) or by an irreversible antagonist (panel **B**). In the presence of a competitive antagonist, higher concentrations of agonist are required to produce a given effect; thus the agonist concentration (C') required for a given effect in the presence of concentration $[I]$ of an antagonist is shifted to the right, as shown. High agonist concentrations can overcome inhibition by a competitive antagonist. This is not the case with an irreversible antagonist, which reduces the maximal effect the agonist can achieve, although it may not change its EC_{50} .

The concentration (C') of an agonist required to produce a given effect in the presence of a fixed concentration ($[I]$) of competitive antagonist is greater than the agonist concentration (C) required to produce the same effect in the absence of the antagonist. The ratio of these two agonist concentrations (the "dose ratio") is related to the dissociation constant (K_I) of the antagonist by the Schild equation:

$$\frac{C'}{C} = 1 + \frac{[I]}{K_I}$$

Pharmacologists often use this relation to determine the K_I of a competitive antagonist. Even without knowledge of the relationship between agonist occupancy of the receptor and response, the K_I can be determined simply and accurately. As shown in Figure 2-3, concentration response curves are obtained in the presence and in the absence of a fixed concentration of competitive antagonist; comparison of the agonist concentrations required to produce identical degrees of pharmacologic effect in the two situations reveals the antagonist's K_I . If C' is twice C , for example, then $[I] = K_I$.

For the clinician, this mathematical relation has two important therapeutic implications:

(1) The degree of inhibition produced by a competitive antagonist depends on the concentration of antagonist. Different patients receiving a fixed dose of propranolol, for example, exhibit a wide range of plasma concentrations, owing to differences in clearance of the drug. As a result, the effects of a fixed dose of this competitive antagonist of norepinephrine may vary widely in patients, and the dose must be adjusted accordingly.

(2) Clinical response to a competitive antagonist depends on the concentration of agonist that is competing for binding to receptors. Here also propranolol provides a useful example: When this competitive β -adrenoceptor antagonist is administered in doses sufficient to block the effect of basal levels of the neurotransmitter norepinephrine, resting heart rate is decreased. However, the increase in release of norepinephrine and epinephrine that occurs with exercise, postural changes, or emotional stress may suffice to overcome competitive antagonism by propranolol and increase heart rate, and thereby can influence therapeutic response.

Some receptor antagonists bind to the receptor in an **irreversible** or nearly irreversible fashion, ie, not competitive. The antagonist's affinity for the receptor may be so high that for practical purposes, the receptor is unavailable for binding of agonist. Other antagonists in this class produce irreversible effects because after binding to the receptor they form covalent bonds with it. After occupancy of some proportion of receptors by such an antagonist, the number of remaining unoccupied receptors may be too low for the agonist (even at high concentrations) to elicit a response comparable to the previous maximal response (Figure 2–3 B). If spare receptors are present, however, a lower dose of an irreversible antagonist may leave enough receptors unoccupied to allow achievement of maximum response to agonist, although a higher agonist concentration will be required (Figures 2–2 B and C; see Receptor-Effector Coupling and Spare Receptors, above).

Therapeutically, irreversible antagonists present distinctive advantages and disadvantages. Once the irreversible antagonist has occupied the receptor, it need not be present in unbound form to inhibit agonist responses. Consequently, the duration of action of such an irreversible antagonist is relatively independent of its own rate of elimination and more dependent on the rate of turnover of receptor molecules.

Phenoxybenzamine, an irreversible α -adrenoceptor antagonist, is used to control the hypertension caused by catecholamines released from pheochromocytoma, a tumor of the adrenal medulla. If administration of phenoxybenzamine lowers blood pressure, blockade will be maintained even when the tumor episodically releases very large amounts of catecholamine. In this case, the ability to prevent responses to varying and high concentrations of agonist is a therapeutic advantage. If overdose occurs, however, a real problem may arise. If the α -adrenoceptor blockade cannot be overcome, excess effects of the drug must be antagonized "physiologically," ie, by using a pressor agent that does not act via α receptors.

Partial Agonists

Based on the maximal pharmacologic response that occurs when all receptors are occupied, agonists can be divided into two classes: **partial agonists** produce a lower response, at full receptor occupancy, than do **full agonists**. Partial agonists produce concentration-effect curves that resemble those observed with full agonists in the presence of an antagonist that irreversibly blocks some of the receptor sites (compare Figures 2–2 [curve D] and 2–4 B). It is important to emphasize that the failure of partial agonists to produce a maximal response is not due to decreased affinity for binding to receptors. Indeed, a partial agonist's inability to cause a maximal pharmacologic response, even when present at high concentrations that saturate binding to all receptors, is indicated by the fact

that partial agonists competitively inhibit the responses produced by full agonists (Figure 2–4 C). Many drugs used clinically as antagonists are in fact weak partial agonists.

Figure 2–4.

Panel A: The percentage of receptor occupancy resulting from full agonist (present at a single concentration) binding to receptors in the presence of increasing concentrations of a partial agonist. Because the full agonist (filled squares) and the partial agonist (open squares) compete to bind to the same receptor sites, when occupancy by the partial agonist increases, binding of the full agonist decreases. **Panel B:** When each of the two drugs is used alone and response is measured, occupancy of all the receptors by the partial agonist produces a lower maximal response than does similar occupancy by the full agonist. **Panel C:** Simultaneous treatment with a single concentration of full agonist and increasing concentrations of the partial agonist produces the response patterns shown in the bottom panel. The fractional response caused by a single concentration of the full agonist (filled squares) decreases as increasing concentrations of the partial agonist compete to bind to the receptor with increasing success; at the same time the portion of the response caused by the partial agonist (open squares) increases, while the total response—ie, the sum of responses to the two drugs (filled triangles)—gradually decreases, eventually reaching the value produced by partial agonist alone (compare panel B).

Other Mechanisms of Drug Antagonism

Not all of the mechanisms of antagonism involve interactions of drugs or endogenous ligands at a single type of receptor. Indeed, **chemical antagonists** need not involve a receptor at all. Thus, one drug may antagonize the actions of a second drug by binding to and inactivating the second drug. For example, protamine, a protein that is positively charged at physiologic pH, can be used clinically to counteract the effects of heparin, an anticoagulant that is negatively charged; in this case, one drug antagonizes the other simply by binding it and making it unavailable for interactions with proteins involved in formation of a blood clot.

The clinician often uses drugs that take advantage of **physiologic antagonism** between endogenous regulatory pathways. For example, several catabolic actions of the glucocorticoid hormones lead to increased blood sugar, an effect that is physiologically opposed by insulin. Although glucocorticoids and insulin act on quite distinct receptor-effector systems, the clinician must sometimes administer insulin to oppose the hyperglycemic effects of glucocorticoid hormone, whether the latter is elevated by endogenous synthesis (eg, a tumor of the adrenal cortex) or as a result of glucocorticoid therapy.

In general, use of a drug as a physiologic antagonist produces effects that are less specific and less easy to control than are the effects of a receptor-specific antagonist. Thus, for example, to treat bradycardia caused by increased release of acetylcholine from vagus nerve endings, the physician could use isoproterenol, a β -adrenoceptor agonist that increases heart rate by mimicking sympathetic stimulation of the heart. However, use of this physiologic antagonist would be less rational—and potentially more dangerous—than would use of a receptor-specific antagonist such as atropine (a competitive antagonist at the receptors at which acetylcholine slows heart rate).

Signaling Mechanisms & Drug Action

Until now we have considered receptor interactions and drug effects in terms of equations and concentration-effect curves. We must also understand the molecular mechanisms by which a drug acts. Such understanding allows us to ask basic questions with important clinical implications:

- Why do some drugs produce effects that persist for minutes, hours, or even days after the drug is no longer present?
- Why do responses to other drugs diminish rapidly with prolonged or repeated administration?
- How do cellular mechanisms for amplifying external chemical signals explain the phenomenon of spare receptors?
- Why do chemically similar drugs often exhibit extraordinary selectivity in their actions?
- Do these mechanisms provide targets for developing new drugs?

Most transmembrane signaling is accomplished by a small number of different molecular mechanisms. Each type of mechanism has been adapted, through the evolution of distinctive protein families, to transduce many different signals. These protein families include receptors on the cell surface and within the cell, as well as enzymes and other components that generate, amplify, coordinate, and terminate postreceptor signaling by chemical second messengers in the cytoplasm. This section first discusses the mechanisms for carrying chemical information across the plasma membrane and then outlines key features of cytoplasmic second messengers.

Five basic mechanisms of transmembrane signaling are well understood (Figure 2–5). Each uses a different strategy to circumvent the barrier posed by the lipid bilayer of the plasma membrane.

These strategies use (1) a lipid-soluble ligand that crosses the membrane and acts on an intracellular receptor; (2) a transmembrane receptor protein whose intracellular enzymatic activity is allosterically regulated by a ligand that binds to a site on the protein's extracellular domain; (3) a transmembrane receptor that binds and stimulates a protein tyrosine kinase; (4) a ligand-gated transmembrane ion channel that can be induced to open or close by the binding of a ligand; or (5) a transmembrane receptor protein that stimulates a GTP-binding signal transducer protein (G protein), which in turn modulates production of an intracellular second messenger.

Figure 2–5.

Known transmembrane signaling mechanisms: **1:** A lipid-soluble chemical signal crosses the plasma membrane and acts on an intracellular receptor (which may be an enzyme or a regulator of gene transcription); **2:** the signal binds to the extracellular domain of a transmembrane protein, thereby activating an enzymatic activity of its cytoplasmic domain; **3:** the signal binds to the extracellular domain of a transmembrane receptor bound to a protein tyrosine kinase, which it activates; **4:** the signal binds to and directly regulates the opening of an ion channel; **5:** the signal binds to a cell-surface receptor linked to an effector enzyme by a G protein. (A,C, substrates; B, D, products; R, receptor; G, G protein; E, effector [enzyme or ion channel]; Y, tyrosine; P, phosphate.)

While the five established mechanisms do not account for all the chemical signals conveyed across cell membranes, they do transduce many of the most important signals exploited in pharmacotherapy.

Intracellular Receptors for Lipid-Soluble Agents

Several biologic signals are sufficiently lipid-soluble to cross the plasma membrane and act on intracellular receptors. One of these is a gas, nitric oxide (NO), that acts by stimulating an intracellular enzyme, guanylyl cyclase, which produces cyclic guanosine monophosphate (cGMP). Signaling via cGMP is described in more detail later in this chapter. Receptors for another class of ligands—including corticosteroids, mineralocorticoids, sex steroids, vitamin D, and thyroid hormone—stimulate the transcription of genes in the nucleus by binding to specific DNA sequences

near the gene whose expression is to be regulated. Many of the target DNA sequences (called **response elements**) have been identified.

These "gene-active" receptors belong to a protein family that evolved from a common precursor. Dissection of the receptors by recombinant DNA techniques has provided insights into their molecular mechanism. For example, binding of glucocorticoid hormone to its normal receptor protein relieves an inhibitory constraint on the transcription-stimulating activity of the protein. Figure 2–6 schematically depicts the molecular mechanism of glucocorticoid action: In the absence of hormone, the receptor is bound to hsp90, a protein that appears to prevent normal folding of several structural domains of the receptor. Binding of hormone to the ligand-binding domain triggers release of hsp90. This allows the DNA-binding and transcription-activating domains of the receptor to fold into their functionally active conformations, so that the activated receptor can initiate transcription of target genes.

Figure 2–6.

Mechanism of glucocorticoid action. The glucocorticoid receptor polypeptide is schematically depicted as a protein with three distinct domains. A heat-shock protein, hsp90, binds to the receptor in the absence of hormone and prevents folding into the active conformation of the receptor. Binding of a hormone ligand (steroid) causes dissociation of the hsp90 stabilizer and permits conversion to the active configuration.

The mechanism used by hormones that act by regulating gene expression has two therapeutically important consequences:

(1) All of these hormones produce their effects after a characteristic lag period of 30 minutes to several hours—the time required for the synthesis of new proteins. This means that the gene-active hormones cannot be expected to alter a pathologic state within minutes (eg, glucocorticoids will not immediately relieve the symptoms of acute bronchial asthma).

(2) The effects of these agents can persist for hours or days after the agonist concentration has been reduced to zero. The persistence of effect is primarily due to the relatively slow turnover of most enzymes and proteins, which can remain active in cells for hours or days after they have been synthesized. Consequently, it means that the beneficial (or toxic) effects of a gene-active hormone will usually decrease slowly when administration of the hormone is stopped.

Ligand-Regulated Transmembrane Enzymes Including Receptor Tyrosine Kinases

This class of receptor molecules mediates the first steps in signaling by insulin, epidermal growth factor (EGF), platelet-derived growth factor (PDGF), atrial natriuretic peptide (ANP), transforming growth factor- β (TGF- β), and many other trophic hormones. These receptors are polypeptides consisting of an extracellular hormone-binding domain and a cytoplasmic enzyme domain, which may be a protein tyrosine kinase, a serine kinase, or a guanylyl cyclase (Figure 2–7). In all these receptors, the two domains are connected by a hydrophobic segment of the polypeptide that crosses the lipid bilayer of the plasma membrane.

Figure 2–7.

Mechanism of activation of the epidermal growth factor (EGF) receptor, a representative receptor tyrosine kinase. The receptor polypeptide has extracellular and cytoplasmic domains, depicted above and below the plasma membrane. Upon binding of EGF (circle), the receptor converts from its inactive monomeric state (left) to an active dimeric state (right), in which two receptor

polypeptides bind noncovalently in the plane of the membrane. The cytoplasmic domains become phosphorylated (*P*) on specific tyrosine residues (*Y*) and their enzymatic activities are activated, catalyzing phosphorylation of substrate proteins (*S*).

The receptor tyrosine kinase signaling pathway begins with ligand binding to the receptor's extracellular domain. The resulting change in receptor conformation causes receptor molecules to bind to one another, which in turn brings together the tyrosine kinase domains, which become enzymatically active, and phosphorylate one another as well as additional downstream signaling proteins. Activated receptors catalyze phosphorylation of tyrosine residues on different target signaling proteins, thereby allowing a single type of activated receptor to modulate a number of biochemical processes. Insulin, for example, uses a single class of receptors to trigger increased uptake of glucose and amino acids and to regulate metabolism of glycogen and triglycerides in the cell. Similarly, each of the growth factors initiates in its specific target cells a complex program of cellular events ranging from altered membrane transport of ions and metabolites to changes in the expression of many genes. At present, a few compounds have been found to produce effects that may be due to inhibition of tyrosine kinase activities. It is easy to imagine therapeutic uses for specific inhibitors of growth factor receptors, especially in neoplastic disorders where excessive growth factor signaling is often observed. For example, a monoclonal antibody (trastuzumab) that acts as an antagonist of the HER2/neu receptor tyrosine kinase is effective in therapy of human breast cancers associated with overexpression of this growth factor receptor.

The intensity and duration of action of EGF, PDGF, and other agents that act via receptor tyrosine kinases are limited by receptor down-regulation. Ligand binding induces accelerated endocytosis of receptors from the cell surface, followed by the degradation of those receptors (and their bound ligands). When this process occurs at a rate faster than *de novo* synthesis of receptors, the total number of cell-surface receptors is reduced (down-regulated) and the cell's responsiveness to ligand is correspondingly diminished. A well-understood process by which many tyrosine kinases are down-regulated is via ligand-induced internalization of receptors followed by trafficking to lysosomes, where receptors are proteolyzed. EGF causes internalization and subsequent proteolytic down-regulation after binding to the EGF receptor protein tyrosine kinase; genetic mutations that interfere with this process of down-regulation cause excessive growth factor-induced cell proliferation and are associated with an increased susceptibility to certain types of cancer. Internalization of certain receptor tyrosine kinases, most notably receptors for nerve growth factor, serves a very different function. Internalized nerve growth factor receptors are not rapidly degraded. Instead, receptors remain intact and are translocated in endocytic vesicles from the distal axon (where receptors are activated by nerve growth factor released from the innervated tissue) to the cell body (where the signal is transduced to transcription factors regulating the expression of genes controlling cell survival). This process effectively transports a critical survival signal released from the target tissue over a remarkably long distance—more than 1 meter in certain sensory neurons. A number of regulators of growth and differentiation, including TGF- β , act on another class of transmembrane receptor enzymes that phosphorylate serine and threonine residues. ANP, an important regulator of blood volume and vascular tone, acts on a transmembrane receptor whose intracellular domain, a guanylyl cyclase, generates cGMP (see below). Receptors in both groups, like the receptor tyrosine kinases, are active in their dimeric forms.

Cytokine Receptors

Cytokine receptors respond to a heterogeneous group of peptide ligands that includes growth hormone, erythropoietin, several kinds of interferon, and other regulators of growth and differentiation. These receptors use a mechanism (Figure 2–8) closely resembling that of receptor tyrosine kinases, except that in this case, the protein tyrosine kinase activity is not intrinsic to the

receptor molecule. Instead, a separate protein tyrosine kinase, from the Janus-kinase (JAK) family, binds noncovalently to the receptor. As in the case of the EGF-receptor, cytokine receptors dimerize after they bind the activating ligand, allowing the bound JAKs to become activated and to phosphorylate tyrosine residues on the receptor. Tyrosine phosphates on the receptor then set in motion a complex signaling dance by binding another set of proteins, called STATs (signal transducers and activators of transcription). The bound STATs are themselves phosphorylated by the JAKs, two STAT molecules dimerize (attaching to one another's tyrosine phosphates), and finally the STAT/STAT dimer dissociates from the receptor and travels to the nucleus, where it regulates transcription of specific genes.

Figure 2–8.

Cytokine receptors, like receptor tyrosine kinases, have extracellular and intracellular domains and form dimers. However, after activation by an appropriate ligand, separate mobile protein tyrosine kinase molecules (JAK) are activated, resulting in phosphorylation of signal transducers and activation of transcription (STAT) molecules. STAT dimers then travel to the nucleus, where they regulate transcription.

Ligand-Gated Channels

Many of the most useful drugs in clinical medicine act by mimicking or blocking the actions of endogenous ligands that regulate the flow of ions through plasma membrane channels. The natural ligands include acetylcholine, serotonin, γ -aminobutyric acid (GABA), and the excitatory amino acids (eg, glycine, aspartate, and glutamate). All of these agents are synaptic transmitters.

Each of their receptors transmits its signal across the plasma membrane by increasing transmembrane conductance of the relevant ion and thereby altering the electrical potential across the membrane. For example, acetylcholine causes the opening of the ion channel in the nicotinic

acetylcholine receptor (AChR), which allows Na^+ to flow down its concentration gradient into cells, producing a localized excitatory postsynaptic potential—a depolarization.

The AChR (Figure 2–9) is one of the best-characterized of all cell-surface receptors for hormones or neurotransmitters. One form of this receptor is a pentamer made up of five polypeptide subunits (eg, two α chains plus one β , one γ , and one δ chain, all with molecular weights ranging from 43,000 to 50,000). These polypeptides, each of which crosses the lipid bilayer four times, form a cylindrical structure 8 nm in diameter. When acetylcholine binds to sites on the α subunits, a conformational change occurs that results in the transient opening of a central aqueous channel through which sodium ions penetrate from the extracellular fluid into the cell.

Figure 2–9.

The nicotinic acetylcholine receptor, a ligand-gated ion channel. The receptor molecule is depicted as embedded in a rectangular piece of plasma membrane, with extracellular fluid above and cytoplasm below. Composed of five subunits (two α , one β , one γ , and one δ), the receptor opens a central transmembrane ion channel when acetylcholine (ACh) binds to sites on the extracellular domain of its α subunits.

The time elapsed between the binding of the agonist to a ligand-gated channel and the cellular response can often be measured in milliseconds. The rapidity of this signaling mechanism is crucially important for moment-to-moment transfer of information across synapses. Ligand-gated ion channels can be regulated by multiple mechanisms, including phosphorylation and internalization. In the central nervous system, these mechanisms contribute to synaptic plasticity involved in learning and memory.

G Proteins & Second Messengers

Many extracellular ligands act by increasing the intracellular concentrations of second messengers such as cyclic adenosine-3',5'-monophosphate (cAMP), calcium ion, or the phosphoinositides

(described below). In most cases they use a transmembrane signaling system with three separate components. First, the extracellular ligand is specifically detected by a cell-surface receptor. The receptor in turn triggers the activation of a G protein located on the cytoplasmic face of the plasma membrane. The activated G protein then changes the activity of an effector element, usually an enzyme or ion channel. This element then changes the concentration of the intracellular second messenger. For cAMP, the effector enzyme is adenylyl cyclase, a transmembrane protein that converts intracellular adenosine triphosphate (ATP) to cAMP. The corresponding G protein, G_s , stimulates adenylyl cyclase after being activated by hormones and neurotransmitters that act via a specific receptor (Table 2–1).

Table 2–1. A Partial List of Endogenous Ligands and Their Associated Second Messengers.

Ligand	Second Messenger
Adrenocorticotrop hormone	cAMP
Acetylcholine (muscarinic receptors)	Ca^{2+} , phosphoinositides
Angiotensin	Ca^{2+} , phosphoinositides
Catecholamines (α_1 -adrenoceptors)	Ca^{2+} , phosphoinositides
Catecholamines (β -adrenoceptors)	cAMP
Chorionic gonadotropin	cAMP
Follicle-stimulating hormone	cAMP
Glucagon	cAMP
Histamine (H_2 receptors)	cAMP
Luteinizing hormone	cAMP
Melanocyte-stimulating hormone	cAMP
Parathyroid hormone	cAMP
Platelet-activating factor	Ca^{2+} , phosphoinositides
Prostacyclin, prostaglandin E2	cAMP
Serotonin ($5-HT_4$ receptors)	cAMP
Serotonin ($5-HT_{1C}$ and $5-HT_2$ receptors)	Ca^{2+} , phosphoinositides
Thyrotropin	cAMP
Thyrotropin-releasing hormone	Ca^{2+} , phosphoinositides
Vasopressin (V_1 receptors)	Ca^{2+} , phosphoinositides
Vasopressin (V_2 receptors)	cAMP

Key: cAMP = cyclic adenosine monophosphate.

G_s and other G proteins use a molecular mechanism that involves binding and hydrolysis of GTP (Figure 2–10). This mechanism allows the transduced signal to be amplified. For example, a neurotransmitter such as norepinephrine may encounter its membrane receptor for only a few milliseconds. When the encounter generates a GTP-bound G_s molecule, however, the duration of activation of adenylyl cyclase depends on the longevity of GTP binding to G_s rather than on the receptor's affinity for norepinephrine. Indeed, like other G proteins, GTP-bound G_s may remain active for tens of seconds, enormously amplifying the original signal. This mechanism explains how signaling by G proteins produces the phenomenon of spare receptors (described above). At low concentrations of agonist the proportion of agonist-bound receptors may be much less than the proportion of G proteins in the active (GTP-bound) state; if the proportion of active G proteins correlates with pharmacologic response, receptors will appear to be spare (ie, a small fraction of receptors occupied by agonist at any given time will appear to produce a proportionately larger response).

Figure 2–10.

The guanine nucleotide-dependent activation-inactivation cycle of G proteins. The agonist activates the receptor (R), which promotes release of GDP from the G protein (G), allowing entry of GTP into the nucleotide binding site. In its GTP-bound state (G-GTP), the G protein regulates activity of an effector enzyme or ion channel (E). The signal is terminated by hydrolysis of GTP, followed by return of the system to the basal unstimulated state. Open arrows denote regulatory effects. (P_i, inorganic phosphate.)

The family of G proteins contains several functionally diverse subfamilies (Table 2–2), each of which mediates effects of a particular set of receptors to a distinctive group of effectors. Receptors coupled to G proteins comprise a family of "seven-transmembrane" or "serpentine" receptors, so called because the receptor polypeptide chain "snakes" across the plasma membrane seven times (Figure 2–11). Receptors for adrenergic amines, serotonin, acetylcholine (muscarinic but not

nicotinic), many peptide hormones, odorants, and even visual receptors (in retinal rod and cone cells) all belong to the serpentine family. All were derived from a common evolutionary precursor. Some serpentine receptors exist as dimers, but it is thought that dimerization is not usually required for activation.

Table 2–2. G Proteins and Their Receptors and Effectors.		
G Protein	Receptors for:	Effector/Signaling Pathway
G _s	β-Adrenergic amines, glucagon, histamine, serotonin, and many other hormones	↑Adenylyl cyclase →↑cAMP
G _{i1} , G _{i2} , G _{i3}	α ₂ -Adrenergic amines, acetylcholine (muscarinic), opioids, serotonin, and many others	Several, including: ↓Adenylyl cyclase →↓cAMP Open cardiac K ⁺ channels →↓heart rate
G _{olf}	Odorants (olfactory epithelium)	↑Adenylyl cyclase →↑cAMP
G _o	Neurotransmitters in brain (not yet specifically identified)	Not yet clear
G _q	Acetylcholine (eg, muscarinic), bombesin, serotonin (5-HT _{1C}), and many others	↑Phospholipase C →↑IP ₃ , diacylglycerol, cytoplasmic Ca ²⁺
G _{t1} , G _{t2}	Photons (rhodopsin and color opsins in retinal rod and cone cells)	↑cGMP phosphodiesterase →↓cGMP (phototransduction)
Key: cAMP = cyclic adenosine monophosphate; cGMP = cyclic guanosine monophosphate.		

Serpentine receptors transduce signals across the plasma membrane in essentially the same way. Often the agonist ligand—eg, a catecholamine, acetylcholine, or the photon-activated chromophore of retinal photoreceptors—is bound in a pocket enclosed by the transmembrane regions of the receptor (as in Figure 2–11). The resulting change in conformation of these regions is transmitted to cytoplasmic loops of the receptor, which in turn activate the appropriate G protein by promoting replacement of GDP by GTP, as described above. Considerable biochemical evidence indicates that G proteins interact with amino acids in the third cytoplasmic loop of the serpentine receptor polypeptide (shown by arrows in Figure 2–11). The carboxyl terminal tails of these receptors, also located in the cytoplasm, can regulate the receptors' ability to interact with G proteins, as described below.

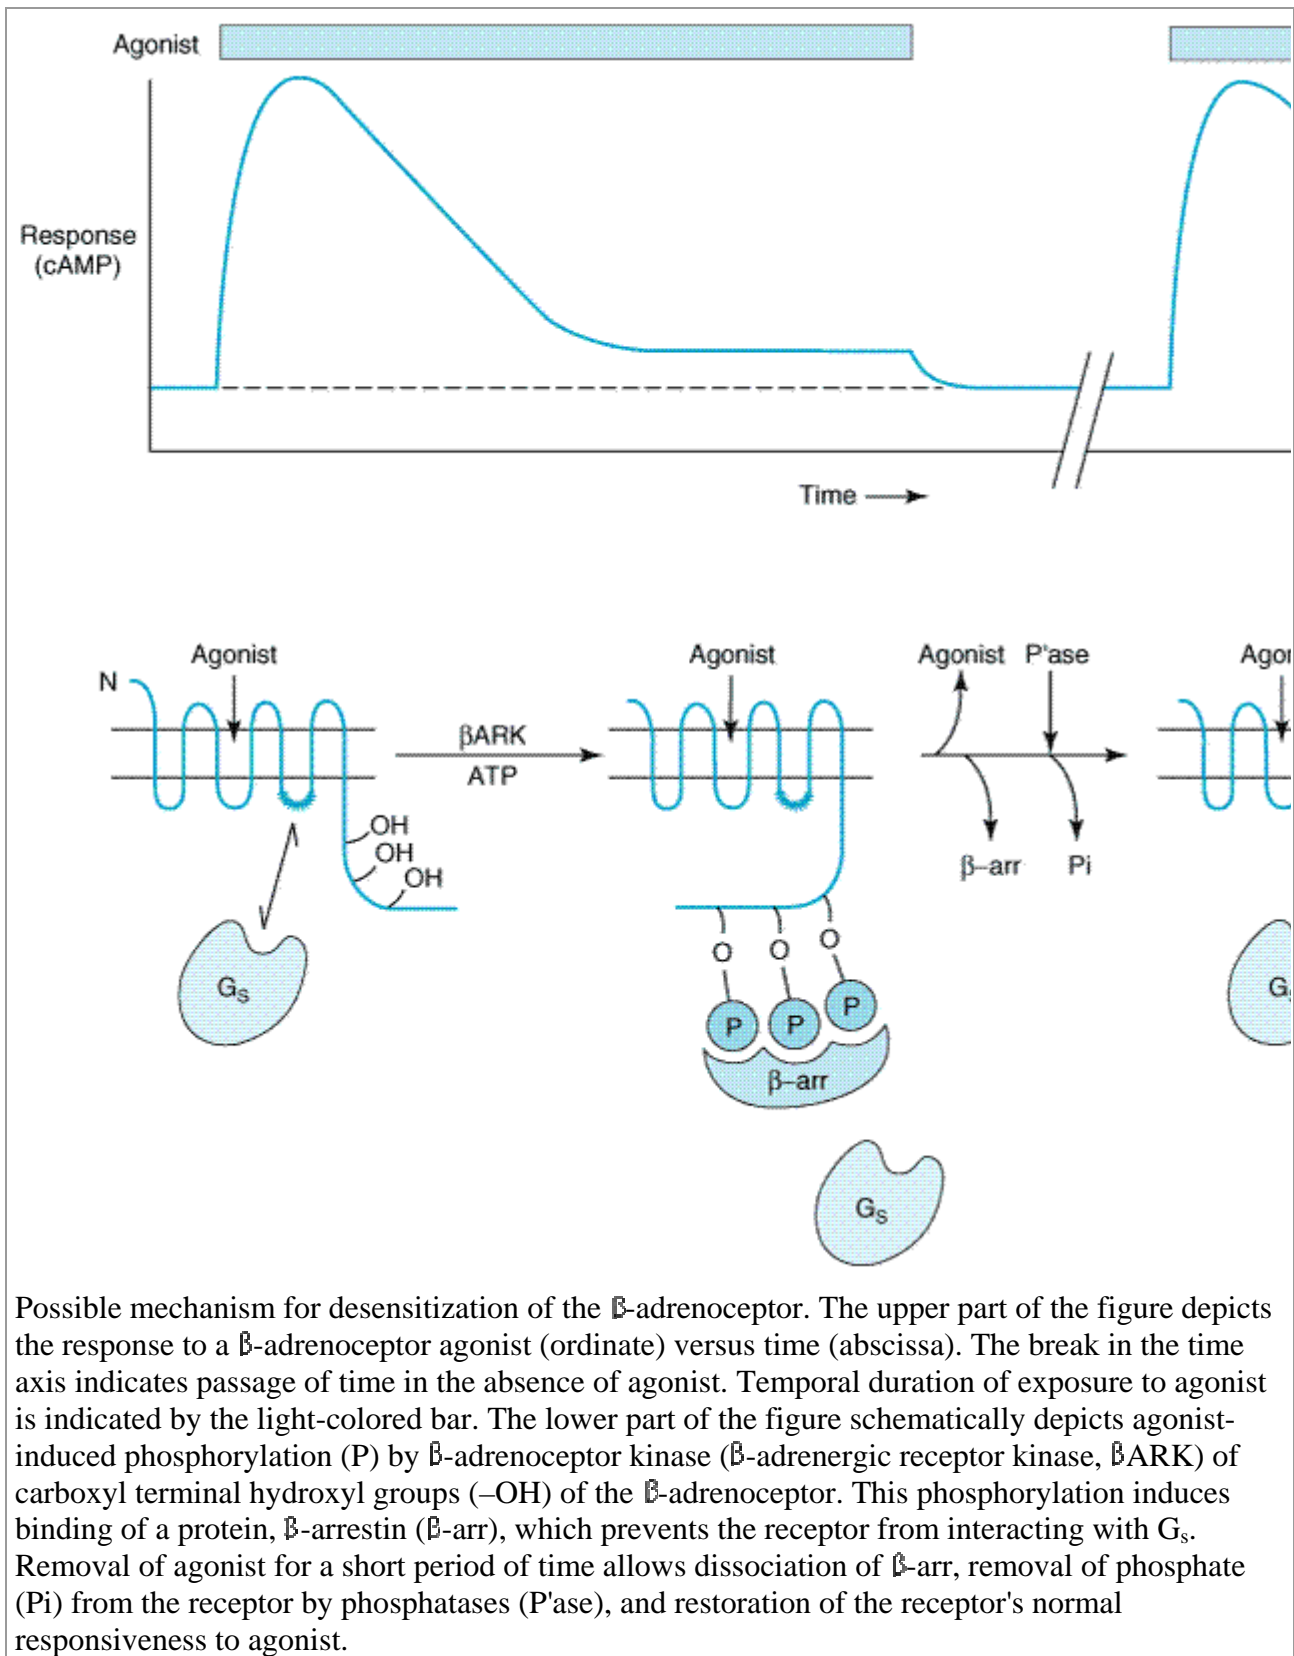

Figure 2–11.

Receptor Regulation

Receptor-mediated responses to drugs and hormonal agonists often desensitize with time (Figure 2–12, top). After reaching an initial high level, the response (eg, cellular cAMP accumulation, Na^+ influx, contractility, etc) gradually diminishes over seconds or minutes, even in the continued presence of the agonist. This desensitization is usually reversible; a second exposure to agonist, if provided a few minutes after termination of the first exposure, results in a response similar to the initial response.

Figure 2–12.

Although many kinds of receptors undergo desensitization, the mechanism is in many cases obscure. A molecular mechanism of desensitization has been worked out in some detail, however, in the case of the β -adrenoceptor (Figure 2–12, bottom). The agonist-induced change in conformation of the receptor causes it to bind, activate, and serve as a substrate for a specific kinase, β -adrenoceptor kinase (also called β ARK). β ARK then phosphorylates serine or threonine

residues in the receptor's carboxyl terminal tail. The presence of phosphoserines increases the receptor's affinity for binding a third protein, β -arrestin. Binding of β -arrestin to cytoplasmic loops of the receptor diminishes the receptor's ability to interact with G_s , thereby reducing the agonist response (ie, stimulation of adenylyl cyclase). Upon removal of agonist, however, cellular phosphatases remove phosphates from the receptor and β ARK stops putting them back on, so that the receptor—and consequently the agonist response—return to normal. This mechanism of desensitization, which rapidly and reversibly modulates the ability of the receptor to signal to G protein, turns out to regulate many G protein–coupled receptors. Another important regulatory process is down-regulation. Down-regulation, which decreases the actual number of receptors present in the cell or tissue, occurs more slowly than rapid desensitization and is less readily reversible. This is because down-regulation involves a net degradation of receptors present in the cell, requiring new receptor biosynthesis for recovery, in contrast to rapid desensitization which involves reversible phosphorylation of existing receptors. Many G protein–coupled receptors are down-regulated by undergoing ligand-induced endocytosis and delivery to lysosomes, similar to down-regulation of protein tyrosine kinases such as the EGF receptor. Down-regulation generally occurs only after prolonged or repeated exposure of cells to agonist (over hours to days). Brief periods of agonist exposure (several minutes) can also induce internalization of receptors. In this case, many receptors, including the β -adrenoceptor, do not down-regulate but instead recycle intact to the plasma membrane. This rapid cycling through endocytic vesicles promotes dephosphorylation of receptors, increasing the rate at which fully functional receptors are replenished in the plasma membrane. Thus, depending on the particular receptor and duration of activation, internalization can mediate quite different effects on receptor signaling and regulation.

Well-Established Second Messengers

Cyclic Adenosine Monophosphate (cAMP)

Acting as an intracellular second messenger, cAMP mediates such hormonal responses as the mobilization of stored energy (the breakdown of carbohydrates in liver or triglycerides in fat cells stimulated by β -adrenomimetic catecholamines), conservation of water by the kidney (mediated by vasopressin), Ca^{2+} homeostasis (regulated by parathyroid hormone), and increased rate and contraction force of heart muscle (β -adrenomimetic catecholamines). It also regulates the production of adrenal and sex steroids (in response to corticotropin or follicle-stimulating hormone), relaxation of smooth muscle, and many other endocrine and neural processes.

cAMP exerts most of its effects by stimulating cAMP-dependent protein kinases (Figure 2–13). These kinases are composed of a cAMP-binding regulatory (R) dimer and two catalytic (C) chains. When cAMP binds to the R dimer, active C chains are released to diffuse through the cytoplasm and nucleus, where they transfer phosphate from ATP to appropriate substrate proteins, often enzymes. The specificity of cAMP's regulatory effects resides in the distinct protein substrates of the kinases that are expressed in different cells. For example, liver is rich in phosphorylase kinase and glycogen synthase, enzymes whose reciprocal regulation by cAMP-dependent phosphorylation governs carbohydrate storage and release.

Figure 2–13.

The cAMP second messenger pathway. Key proteins include hormone receptors (Rec), a stimulatory G protein (G_s), catalytic adenyl cyclase (AC), phosphodiesterases (PDE) that hydrolyze cAMP, cAMP-dependent kinases, with regulatory (R) and catalytic (C) subunits, protein substrates (S) of the kinases, and phosphatases (P'ase), which remove phosphates from substrate proteins. Open arrows denote regulatory effects.

When the hormonal stimulus stops, the intracellular actions of cAMP are terminated by an elaborate series of enzymes. cAMP-stimulated phosphorylation of enzyme substrates is rapidly reversed by a diverse group of specific and nonspecific phosphatases. cAMP itself is degraded to 5'-AMP by several cyclic nucleotide phosphodiesterases (PDE, Figure 2–13). Competitive inhibition of cAMP degradation is one way caffeine, theophylline, and other methylxanthines produce their effects (see Chapter 20: Drugs Used in Asthma).

Calcium and Phosphoinositides

Another well-studied second messenger system involves hormonal stimulation of phosphoinositide hydrolysis (Figure 2–14). Some of the hormones, neurotransmitters, and growth factors that trigger this pathway (see Table 2–1) bind to receptors linked to G proteins, while others bind to receptor tyrosine kinases. In all cases, the crucial step is stimulation of a membrane enzyme, phospholipase C (PLC), which splits a minor phospholipid component of the plasma membrane, phosphatidylinositol-4,5-bisphosphate (PIP_2), into two second messengers, diacylglycerol and inositol-1,4,5-trisphosphate (IP_3 or $InsP_3$). Diacylglycerol is confined to the membrane where it activates a phospholipid- and calcium-sensitive protein kinase called protein kinase C. IP_3 is water-soluble and diffuses through the cytoplasm to trigger release of Ca^{2+} from internal storage vesicles. Elevated cytoplasmic Ca^{2+} concentration promotes the binding of Ca^{2+} to the calcium-binding

protein calmodulin, which regulates activities of other enzymes, including calcium-dependent protein kinases.

Figure 2–14.

The Ca²⁺-phosphoinositide signaling pathway. Key proteins include hormone receptors (R), a G protein (G), a phosphoinositide-specific phospholipase C (PLC), protein kinase C substrates of the kinase (S), calmodulin (CaM), and calmodulin-binding enzymes (E), including kinases, phosphodiesterases, etc. (PIP₂, phosphatidylinositol-4,5-bisphosphate; DAG, diacylglycerol. Asterisk denotes activated state. Open arrows denote regulatory effects.)

With its multiple second messengers and protein kinases, the phosphoinositide signaling pathway is much more complex than the cAMP pathway. For example, different cell types may contain one or more specialized calcium- and calmodulin-dependent kinases with limited substrate specificity (eg, myosin light chain kinase) in addition to a general calcium- and calmodulin-dependent kinase that can phosphorylate a wide variety of protein substrates. Furthermore, at least nine structurally distinct types of protein kinase C have been identified.

As in the cAMP system, multiple mechanisms damp or terminate signaling by this pathway. IP₃ is inactivated by dephosphorylation; diacylglycerol is either phosphorylated to yield phosphatidic acid, which is then converted back into phospholipids, or it is deacylated to yield arachidonic acid; Ca²⁺ is actively removed from the cytoplasm by Ca²⁺ pumps.

These and other nonreceptor elements of the calcium-phosphoinositide signaling pathway are now becoming targets for drug development. For example, the therapeutic effects of lithium ion, an established agent for treating manic-depressive illness, may be mediated by effects on the metabolism of phosphoinositides (see Chapter 29: Antipsychotic Agents & Lithium).

Cyclic Guanosine Monophosphate (cGMP)

Unlike cAMP, the ubiquitous and versatile carrier of diverse messages, cGMP has established signaling roles in only a few cell types. In intestinal mucosa and vascular smooth muscle, the cGMP-based signal transduction mechanism closely parallels the cAMP-mediated signaling mechanism. Ligands detected by cell surface receptors stimulate membrane-bound guanylyl cyclase to produce cGMP, and cGMP acts by stimulating a cGMP-dependent protein kinase. The actions of cGMP in these cells are terminated by enzymatic degradation of the cyclic nucleotide and by dephosphorylation of kinase substrates.

Increased cGMP concentration causes relaxation of vascular smooth muscle by a kinase-mediated mechanism that results in dephosphorylation of myosin light chains (see Figure 12–2). In these smooth muscle cells, cGMP synthesis can be elevated by two different transmembrane signaling mechanisms utilizing two different guanylyl cyclases. ANP, a blood-borne peptide hormone, stimulates a transmembrane receptor by binding to its extracellular domain, thereby activating the guanylyl cyclase activity that resides in the receptor's intracellular domain. The other mechanism mediates responses to NO (see Chapter 19: Nitric Oxide, Donors, & Inhibitors), which is generated in vascular endothelial cells in response to natural vasodilator agents such as acetylcholine and histamine (NO is also called endothelium-derived relaxing factor [EDRF]). After entering the target cell, NO binds to and activates a cytoplasmic guanylyl cyclase. A number of useful vasodilating drugs act by generating or mimicking NO, or by interfering with the metabolic breakdown of cGMP by phosphodiesterase (see Chapter 11: Antihypertensive Agents and Chapter 12: Vasodilators & the Treatment of Angina Pectoris).

Interplay among Signaling Mechanisms

The calcium-phosphoinositide and cAMP signaling pathways oppose one another in some cells and are complementary in others. For example, vasopressor agents that contract smooth muscle act by IP₃-mediated mobilization of Ca²⁺, whereas agents that relax smooth muscle often act by elevation of cAMP. In contrast, cAMP and phosphoinositide second messengers act together to stimulate glucose release from the liver.

Phosphorylation: A Common Theme

Almost all second messenger signaling involves reversible phosphorylation, which performs two principal functions in signaling: amplification and flexible regulation. In **amplification**, rather like GTP bound to a G protein, the attachment of a phosphoryl group to a serine, threonine, or tyrosine residue powerfully amplifies the initial regulatory signal by recording a molecular memory that the pathway has been activated; dephosphorylation erases the memory, taking a longer time to do so than is required for dissociation of an allosteric ligand. In **flexible regulation**, differing substrate specificities of the multiple protein kinases regulated by second messengers provide branch points in signaling pathways that may be independently regulated. In this way, cAMP, Ca²⁺, or other second messengers can use the presence or absence of particular kinases or kinase substrates to produce quite different effects in different cell types. Inhibitors of protein kinases have great potential as therapeutic agents, particularly in neoplastic diseases. Trastuzumab, an antibody that antagonizes growth factor receptor signaling, was discussed earlier as a therapeutic agent for breast cancer. Another example of this general approach is imatinib (Gleevec, STI571), a small molecule inhibitor of the cytoplasmic tyrosine kinase Bcr/Abl, which is activated by growth factor signaling pathways and is overexpressed in chronic myelogenous leukemia (CML). This compound, a promising agent for treating CML, was recently approved by the US Food and Drug Administration (FDA) for clinical use.

Receptor Classes & Drug Development

The existence of a specific drug receptor is usually inferred from studying the **structure-activity relationship** of a group of structurally similar congeners of the drug that mimic or antagonize its effects. Thus, if a series of related agonists exhibits identical relative potencies in producing two distinct effects, it is likely that the two effects are mediated by similar or identical receptor molecules. In addition, if identical receptors mediate both effects, a competitive antagonist will inhibit both responses with the same K_I ; a second competitive antagonist will inhibit both responses with its own characteristic K_I . Thus, studies of the relation between structure and activity of a series of agonists and antagonists can identify a species of receptor that mediates a set of pharmacologic responses.

Exactly the same experimental procedure can show that observed effects of a drug are mediated by *different* receptors. In this case, effects mediated by different receptors may exhibit different orders of potency among agonists and different K_I values for each competitive antagonist.

Wherever we look, evolution has created many different receptors that function to mediate responses to any individual chemical signal. In some cases, the same chemical acts on completely different structural receptor classes. For example, acetylcholine uses ligand-gated ion channels (nicotinic AChRs) to initiate a fast excitatory postsynaptic potential (EPSP) in postganglionic neurons. Acetylcholine also activates a separate class of G protein-coupled receptors (muscarinic AChRs), which modulate responsiveness of the same neurons to the fast EPSP. In addition, each structural class usually includes multiple subtypes of receptor, often with significantly different signaling or regulatory properties. For example, norepinephrine activates many structurally related receptors, including β -adrenergic (stimulation of G_s , increased heart rate), α_1 -adrenergic (stimulation of G_q , vasoconstriction), and α_2 -adrenergic (stimulation of G_i , opening of K^+ channels) (see Table 2–2). The existence of multiple receptor classes and subtypes for the same endogenous ligand has created important opportunities for drug development. For example, propranolol, a selective antagonist of β -adrenergic receptors, can reduce an accelerated heart rate without preventing the sympathetic nervous system from causing vasoconstriction, an effect mediated by α_1 receptors.

The principle of drug selectivity may even apply to structurally identical receptors expressed in different cells, eg, receptors for steroids such as estrogen (Figure 2–6). Different cell types express different accessory proteins, which interact with steroid receptors and change the functional effects of drug-receptor interaction. For example, tamoxifen acts as an *antagonist* on estrogen receptors expressed in mammary tissue but as an *agonist* on estrogen receptors in bone. Consequently, tamoxifen may be useful not only in the treatment and prophylaxis of breast cancer but also in the prevention of osteoporosis by increasing bone density (see Chapter 40: The Gonadal Hormones & Inhibitors and Chapter 42: Agents That Affect Bone Mineral Homeostasis). Tamoxifen may also create complications in postmenopausal women, however, by exerting an agonist action in the uterus, stimulating endometrial cell proliferation.

New drug development is not confined to agents that act on receptors for extracellular chemical signals. Pharmaceutical chemists are now determining whether elements of signaling pathways distal to the receptors may also serve as targets of selective and useful drugs. For example, clinically useful agents might be developed that act selectively on specific G proteins, kinases, phosphatases, or the enzymes that degrade second messengers.

Relation between Drug Dose & Clinical Response

We have dealt with receptors as molecules and shown how receptors can quantitatively account for the relation between dose or concentration of a drug and pharmacologic responses, at least in an idealized system. When faced with a patient who needs treatment, the prescriber must make a choice among a variety of possible drugs and devise a dosage regimen that is likely to produce maximal benefit and minimal toxicity. In order to make rational therapeutic decisions, the prescriber must understand how drug-receptor interactions underlie the relations between dose and response in patients, the nature and causes of variation in pharmacologic responsiveness, and the clinical implications of selectivity of drug action.

Dose & Response in Patients

Graded Dose-Response Relations

To choose among drugs and to determine appropriate doses of a drug, the prescriber must know the relative **pharmacologic potency** and **maximal efficacy** of the drugs in relation to the desired therapeutic effect. These two important terms, often confusing to students and clinicians, can be explained by referring to Figure 2–15, which depicts graded dose-response curves that relate dose of four different drugs to the magnitude of a particular therapeutic effect.

Figure 2–15.

Graded dose-response curves for four drugs, illustrating different pharmacologic potencies and different maximal efficacies. (See text.)

Potency

Drugs A and B are said to be more potent than drugs C and D because of the relative positions of their dose-response curves along the dose axis of Figure 2–15. Potency refers to the concentration (EC_{50}) or dose (ED_{50}) of a drug required to produce 50% of that drug's maximal effect. Thus, the pharmacologic potency of drug A in Figure 2–15 is less than that of drug B, a partial agonist,

because the EC_{50} of A is greater than the EC_{50} of B. Potency of a drug depends in part on the affinity (K_D) of receptors for binding the drug and in part on the efficiency with which drug-receptor interaction is coupled to response. Note that some doses of drug A can produce larger effects than any dose of drug B, despite the fact that we describe drug B as pharmacologically more potent. The reason for this is that drug A has a larger maximal efficacy, as described below.

For clinical use, it is important to distinguish between a drug's potency and its efficacy. The clinical effectiveness of a drug depends not on its potency (EC_{50}), but on its maximal efficacy (see below) and its ability to reach the relevant receptors. This ability can depend on its route of administration, absorption, distribution through the body, and clearance from the blood or site of action. In deciding which of two drugs to administer to a patient, the prescriber must usually consider their relative effectiveness rather than their relative potency. Pharmacologic potency can largely determine the administered dose of the chosen drug.

For therapeutic purposes, the potency of a drug should be stated in dosage units, usually in terms of a particular therapeutic end point (eg, 50 mg for mild sedation, 1 $\mu\text{g}/\text{kg}/\text{min}$ for an increase in heart rate of 25 beats/min). Relative potency, the ratio of equi-effective doses (0.2, 10, etc), may be used in comparing one drug with another.

Maximal Efficacy

This parameter reflects the limit of the dose-response relation on the **response axis**. Drugs A, C, and D in Figure 2–15 have equal maximal efficacy, while all have greater maximal efficacy than drug B. The maximal efficacy (sometimes referred to simply as efficacy) of a drug is obviously crucial for making clinical decisions when a large response is needed. It may be determined by the drug's mode of interactions with receptors (as with partial agonists, described above)* or by characteristics of the receptor-effector system involved.

* Note that "maximal efficacy," used in a therapeutic context, does not have exactly the same meaning the term denotes in the more specialized context of drug-receptor interactions described earlier in this chapter. In an idealized in vitro system, efficacy denotes the relative maximal efficacy of agonists and partial agonists that act via the same receptor. In therapeutics, efficacy denotes the extent or degree of an effect that can be achieved in the intact patient. Thus, therapeutic efficacy may be affected by the characteristics of a particular drug-receptor interaction, but it also depends on a host of other factors as noted in the text.

Thus, diuretics that act on one portion of the nephron may produce much greater excretion of fluid and electrolytes than diuretics that act elsewhere. In addition, the practical efficacy of a drug for achieving a therapeutic end point (eg, increased cardiac contractility) may be limited by the drug's propensity to cause a toxic effect (eg, fatal cardiac arrhythmia) even if the drug could otherwise produce a greater therapeutic effect.

Shape of Dose-Response Curves

While the responses depicted in curves A, B, and C of Figure 2–15 approximate the shape of a simple Michaelis-Menten relation (transformed to a logarithmic plot), some clinical responses do not. Extremely steep dose-response curves (eg, curve D) may have important clinical consequences if the upper portion of the curve represents an undesirable extent of response (eg, coma caused by a sedative-hypnotic). Steep dose-response curves in patients could result from cooperative interactions of several different actions of a drug (eg, effects on brain, heart, and peripheral vessels, all contributing to lowering of blood pressure).

Quantal Dose-Effect Curves

Graded dose-response curves of the sort described above have certain limitations in their application to clinical decision making. For example, such curves may be impossible to construct if the pharmacologic response is an either-or (quantal) event, such as prevention of convulsions, arrhythmia, or death. Furthermore, the clinical relevance of a quantitative dose-response relationship in a single patient, no matter how precisely defined, may be limited in application to other patients, owing to the great potential variability among patients in severity of disease and responsiveness to drugs.

Some of these difficulties may be avoided by determining the dose of drug required to produce a specified magnitude of effect in a large number of individual patients or experimental animals and plotting the cumulative frequency distribution of responders versus the log dose (Figure 2–16). The specified quantal effect may be chosen on the basis of clinical relevance (eg, relief of headache) or for preservation of safety of experimental subjects (eg, using low doses of a cardiac stimulant and specifying an increase in heart rate of 20 beats/min as the quantal effect), or it may be an inherently quantal event (eg, death of an experimental animal). For most drugs, the doses required to produce a specified quantal effect in individuals are lognormally distributed; ie, a frequency distribution of such responses plotted against the log of the dose produces a gaussian normal curve of variation (colored area, Figure 2–16). When these responses are summated, the resulting cumulative frequency distribution constitutes a quantal dose-effect curve (or dose-percent curve) of the proportion or percentage of individuals who exhibit the effect plotted as a function of log dose (Figure 2–16).

Figure 2–16.

Quantal dose-effect plots. Shaded boxes (and the accompanying curves) indicate the frequency distribution of doses of drug required to produce a specified effect; ie, the percentage of animals

that required a particular dose to exhibit the effect. The open boxes (and the corresponding curves) indicate the cumulative frequency distribution of responses, which are lognormally distributed.

The quantal dose-effect curve is often characterized by stating the **median effective dose (ED₅₀)**, the dose at which 50% of individuals exhibit the specified quantal effect. (Note that the abbreviation ED₅₀ has a different meaning in this context from its meaning in relation to graded dose-effect curves, described above.) Similarly, the dose required to produce a particular toxic effect in 50% of animals is called the **median toxic dose (TD₅₀)**. If the toxic effect is death of the animal, a **median lethal dose (LD₅₀)** may be experimentally defined. Such values provide a convenient way of comparing the potencies of drugs in experimental and clinical settings: Thus, if the ED₅₀s of two drugs for producing a specified quantal effect are 5 and 500 mg, respectively, then the first drug can be said to be 100 times more potent than the second for that particular effect. Similarly, one can obtain a valuable index of the selectivity of a drug's action by comparing its ED₅₀s for two different quantal effects in a population (eg, cough suppression versus sedation for opioid drugs).

Quantal dose-effect curves may also be used to generate information regarding the margin of safety to be expected from a particular drug used to produce a specified effect. One measure, which relates the dose of a drug required to produce a desired effect to that which produces an undesired effect, is the **therapeutic index**. In animal studies, the therapeutic index is usually defined as the ratio of the TD₅₀ to the ED₅₀ for some therapeutically relevant effect. The precision possible in animal experiments may make it useful to use such a therapeutic index to estimate the potential benefit of a drug in humans. Of course, the therapeutic index of a drug in humans is almost never known with real precision; instead, drug trials and accumulated clinical experience often reveal a range of usually effective doses and a different (but sometimes overlapping) range of possibly toxic doses. The clinically acceptable risk of toxicity depends critically on the severity of the disease being treated. For example, the dose range that provides relief from an ordinary headache in the great majority of patients should be very much lower than the dose range that produces serious toxicity, even if the toxicity occurs in a small minority of patients. However, for treatment of a lethal disease such as Hodgkin's lymphoma, the acceptable difference between therapeutic and toxic doses may be smaller.

Finally, note that the quantal dose-effect curve and the graded dose-response curve summarize somewhat different sets of information, although both appear sigmoid in shape on a semilogarithmic plot (compare Figures 2-15 and 2-16). Critical information required for making rational therapeutic decisions can be obtained from each type of curve. Both curves provide information regarding the **potency** and **selectivity** of drugs; the graded dose-response curve indicates the **maximal efficacy** of a drug, and the quantal dose-effect curve indicates the potential **variability** of responsiveness among individuals.

Variation in Drug Responsiveness

Individuals may vary considerably in their responsiveness to a drug; indeed, a single individual may respond differently to the same drug at different times during the course of treatment. Occasionally, individuals exhibit an unusual or **idiosyncratic** drug response, one that is infrequently observed in most patients. The idiosyncratic responses are usually caused by genetic differences in metabolism of the drug or by immunologic mechanisms, including allergic reactions.

Quantitative variations in drug response are in general more common and more clinically important. An individual patient is **hyporeactive** or **hyperreactive** to a drug in that the intensity of effect of a given dose of drug is diminished or increased in comparison to the effect seen in most individuals. (*Note:* The term **hypersensitivity** usually refers to allergic or other immunologic responses to

drugs.) With some drugs, the intensity of response to a given dose may change during the course of therapy; in these cases, responsiveness usually decreases as a consequence of continued drug administration, producing a state of relative **tolerance** to the drug's effects. When responsiveness diminishes rapidly after administration of a drug, the response is said to be subject to **tachyphylaxis**.

Even before administering the first dose of a drug, the prescriber should consider factors that may help in predicting the direction and extent of possible variations in responsiveness. These include the propensity of a particular drug to produce tolerance or tachyphylaxis as well as the effects of age, sex, body size, disease state, genetic factors, and simultaneous administration of other drugs.

Four general mechanisms may contribute to variation in drug responsiveness among patients or within an individual patient at different times.

Alteration in Concentration of Drug That Reaches the Receptor

Patients may differ in the rate of absorption of a drug, in distributing it through body compartments, or in clearing the drug from the blood (see Chapter 3: Pharmacokinetics & Pharmacodynamics: Rational Dosing & the Time Course of Drug Action). By altering the concentration of drug that reaches relevant receptors, such pharmacokinetic differences may alter the clinical response. Some differences can be predicted on the basis of age, weight, sex, disease state, liver and kidney function, and by testing specifically for genetic differences that may result from inheritance of a functionally distinctive complement of drug-metabolizing enzymes (see Chapter 3: Pharmacokinetics & Pharmacodynamics: Rational Dosing & the Time Course of Drug Action and Chapter 4: Drug Biotransformation).

Variation in Concentration of an Endogenous Receptor Ligand

This mechanism contributes greatly to variability in responses to pharmacologic antagonists. Thus, propranolol, a β -adrenoceptor antagonist, will markedly slow the heart rate of a patient whose endogenous catecholamines are elevated (as in pheochromocytoma) but will not affect the resting heart rate of a well-trained marathon runner. A partial agonist may exhibit even more dramatically different responses: Saralasin, a weak partial agonist at angiotensin II receptors, lowers blood pressure in patients with hypertension caused by increased angiotensin II production and raises blood pressure in patients who produce small amounts of angiotensin.

Alterations in Number or Function of Receptors

Experimental studies have documented changes in drug responsiveness caused by increases or decreases in the number of receptor sites or by alterations in the efficiency of coupling of receptors to distal effector mechanisms. In some cases, the change in receptor number is caused by other hormones; for example, thyroid hormones increase both the number of β receptors in rat heart muscle and cardiac sensitivity to catecholamines. Similar changes probably contribute to the tachycardia of thyrotoxicosis in patients and may account for the usefulness of propranolol, a β -adrenoceptor antagonist, in ameliorating symptoms of this disease.

In other cases, the agonist ligand itself induces a decrease in the number (eg, down-regulation) or coupling efficiency (eg, desensitization) of its receptors. These mechanisms (discussed above, under Signaling Mechanisms & Drug Actions) may contribute to two clinically important phenomena: first, tachyphylaxis or tolerance to the effects of some drugs (eg, biogenic amines and their congeners), and second, the "overshoot" phenomena that follow withdrawal of certain drugs. These

phenomena can occur with either agonists or antagonists. An antagonist may increase the number of receptors in a critical cell or tissue by preventing down-regulation caused by an endogenous agonist. When the antagonist is withdrawn, the elevated number of receptors can produce an exaggerated response to physiologic concentrations of agonist. Potentially disastrous withdrawal symptoms can result for the opposite reason when administration of an agonist drug is discontinued. In this situation, the number of receptors, which has been decreased by drug-induced down-regulation, is too low for endogenous agonist to produce effective stimulation. For example, the withdrawal of clonidine (a drug whose α_2 -adrenoceptor agonist activity reduces blood pressure) can produce hypertensive crisis, probably because the drug down-regulates α_2 -adrenoceptors (see Chapter 11: Antihypertensive Agents).

Genetic factors also can play an important role in altering the number or function of specific receptors. For example, a specific genetic variant of the α_2C -adrenoceptor—when inherited together with a specific variant of the β_1 -adrenoceptor—confers a greatly increased risk for developing congestive heart failure which may be reduced by early intervention using antagonist drugs. The identification of such genetic factors, part of the rapidly developing field of **pharmacogenetics**, holds exciting promise for clinical diagnosis and may help physicians design the most appropriate pharmacologic therapy for individual patients.

Changes in Components of Response Distal to the Receptor

Although a drug initiates its actions by binding to receptors, the response observed in a patient depends on the functional integrity of biochemical processes in the responding cell and physiologic regulation by interacting organ systems. Clinically, changes in these postreceptor processes represent the largest and most important class of mechanisms that cause variation in responsiveness to drug therapy.

Before initiating therapy with a drug, the prescriber should be aware of patient characteristics that may limit the clinical response. These characteristics include the age and general health of the patient and—most importantly—the severity and pathophysiologic mechanism of the disease. The most important potential cause of failure to achieve a satisfactory response is that the diagnosis is wrong or physiologically incomplete. Drug therapy will always be most successful when it is accurately directed at the pathophysiologic mechanism responsible for the disease.

When the diagnosis is correct and the drug is appropriate, an unsatisfactory therapeutic response can often be traced to compensatory mechanisms in the patient that respond to and oppose the beneficial effects of the drug. Compensatory increases in sympathetic nervous tone and fluid retention by the kidney, for example, can contribute to tolerance to antihypertensive effects of a vasodilator drug. In such cases, additional drugs may be required to achieve a useful therapeutic response.

Clinical Selectivity: Beneficial Versus Toxic Effects of Drugs

Although we classify drugs according to their principal actions, it is clear that *no drug causes only a single, specific effect*. Why is this so? It is exceedingly unlikely that any kind of drug molecule will bind to only a single type of receptor molecule, if only because the number of potential receptors in every patient is astronomically large. Even if the chemical structure of a drug allowed it to bind to only one kind of receptor, the biochemical processes controlled by such receptors would take place in multiple cell types and would be coupled to many other biochemical functions; as a result, the patient and the prescriber would probably perceive more than one drug effect. Accordingly, drugs are only *selective*—rather than *specific*—in their actions, because they bind to one or a few types of

receptor more tightly than to others and because these receptors control discrete processes that result in distinct effects.

It is only because of their selectivity that drugs are useful in clinical medicine. Selectivity can be measured by comparing binding affinities of a drug to different receptors or by comparing ED₅₀s for different effects of a drug in vivo. In drug development and in clinical medicine, selectivity is usually considered by separating effects into two categories: **beneficial** or **therapeutic effects** versus **toxic effects**. Pharmaceutical advertisements and prescribers occasionally use the term **side effect**, implying that the effect in question is insignificant or occurs via a pathway that is to one side of the principal action of the drug; such implications are frequently erroneous.

Beneficial and Toxic Effects Mediated by the Same Receptor-Effector Mechanism

Much of the serious drug toxicity in clinical practice represents a direct pharmacologic extension of the therapeutic actions of the drug. In some of these cases (bleeding caused by anticoagulant therapy; hypoglycemic coma due to insulin), toxicity may be avoided by judicious management of the dose of drug administered, guided by careful monitoring of effect (measurements of blood coagulation or serum glucose) and aided by ancillary measures (avoiding tissue trauma that may lead to hemorrhage; regulation of carbohydrate intake). In still other cases, the toxicity may be avoided by not administering the drug at all, if the therapeutic indication is weak or if other therapy is available.

In certain situations, a drug is clearly necessary and beneficial but produces unacceptable toxicity when given in doses that produce optimal benefit. In such situations, it may be necessary to add another drug to the treatment regimen. In treating hypertension, for example, administration of a second drug often allows the prescriber to reduce the dose and toxicity of the first drug (see Chapter 11: Antihypertensive Agents).

Beneficial and Toxic Effects Mediated by Identical Receptors But in Different Tissues or by Different Effector Pathways

Many drugs produce both their desired effects and adverse effects by acting on a single receptor type in different tissues. Examples discussed in this book include: digitalis glycosides, which act by inhibiting Na⁺/K⁺ ATPase in cell membranes; methotrexate, which inhibits the enzyme dihydrofolate reductase; and glucocorticoid hormones.

Three therapeutic strategies are used to avoid or mitigate this sort of toxicity. First, the drug should always be administered at the lowest dose that produces acceptable benefit. Second, adjunctive drugs that act through different receptor mechanisms and produce different toxicities may allow lowering the dose of the first drug, thus limiting its toxicity (eg, use of other immunosuppressive agents added to glucocorticoids in treating inflammatory disorders). Third, selectivity of the drug's actions may be increased by manipulating the concentrations of drug available to receptors in different parts of the body, for example, by aerosol administration of a glucocorticoid to the bronchi in asthma.

Beneficial and Toxic Effects Mediated by Different Types of Receptors

Therapeutic advantages resulting from new chemical entities with improved receptor selectivity were mentioned earlier in this chapter and are described in detail in later chapters. Such drugs include the α - and β -selective adrenoceptor agonists and antagonists, the H₁ and H₂ antihistamines, nicotinic and muscarinic blocking agents, and receptor-selective steroid hormones. All of these

receptors are grouped in functional families, each responsive to a small class of endogenous agonists. The receptors and their associated therapeutic uses were discovered by analyzing effects of the physiologic chemical signals—catecholamines, histamine, acetylcholine, and corticosteroids.

A number of other drugs were discovered by exploiting therapeutic or toxic effects of chemically similar agents observed in a clinical context. Examples include quinidine, the sulfonyleureas, thiazide diuretics, tricyclic antidepressants, opioid drugs, and phenothiazine antipsychotics. Often the new agents turn out to interact with receptors for endogenous substances (eg, opioids and phenothiazines for endogenous opioid and dopamine receptors, respectively). It is likely that other new drugs will be found to do so in the future, perhaps leading to the discovery of new classes of receptors and endogenous ligands for future drug development.

Thus, the propensity of drugs to bind to different classes of receptor sites is not only a potentially vexing problem in treating patients, it also presents a continuing challenge to pharmacology and an opportunity for developing new and more useful drugs.

Chapter 3. Pharmacokinetics & Pharmacodynamics: Rational Dosing & the Time Course of Drug Action

Pharmacokinetics & Pharmacodynamics: Rational Dosing & the Time Course of Drug Action: Introduction

The goal of therapeutics is to achieve a desired beneficial effect with minimal adverse effects. When a medicine has been selected for a patient, the clinician must determine the dose that most closely achieves this goal. A rational approach to this objective combines the principles of pharmacokinetics with pharmacodynamics to clarify the dose-effect relationship (Figure 3–1). Pharmacodynamics governs the concentration-effect part of the interaction, whereas pharmacokinetics deals with the dose-concentration part (Holford & Sheiner, 1981). The pharmacokinetic processes of absorption, distribution, and elimination determine how rapidly and for how long the drug will appear at the target organ. The pharmacodynamic concepts of maximum response and sensitivity determine the magnitude of the effect at a particular concentration (see E_{\max} and EC_{50} , Chapter 2: Drug Receptors & Pharmacodynamics).

Figure 3–1.

Figure 3–1 illustrates a fundamental hypothesis of pharmacology, namely, that a relationship exists between a beneficial or toxic effect of a drug and the concentration of the drug. This hypothesis has been documented for many drugs, as indicated by the Target Concentrations and Toxic Concentrations columns in Table 3–1. The apparent lack of such a relationship for some drugs does not weaken the basic hypothesis but points to the need to consider the time course of concentration at the actual site of pharmacologic effect (see below).

Table 3–1. Pharmacokinetic and Pharmacodynamic Parameters for Selected Drugs. (See Speight & Holford, 1997, for a More Comprehensive Listing.)

Drug	Oral Availability (F) (%)	Urinary Excretion (%)	Bound in Plasma (%)	Clearance (L/h/70 kg) ¹	Volume of Distribution (L/70 kg)	Half-Life (h)	Target Concentrations	Toxic Concentrations

¹Convert to mL/min by multiplying the number given by 16.6.

²Varies with concentration.

³Target area under the concentration time curve after a single dose.

⁴Can be estimated from measured C_p using $CL = V_{max}/(K_m + C_p)$; $V_{max} = 415$ mg/d, $K_m = 5$ mg/L. See text.

⁵Varies because of concentration-dependent clearance.

Knowing the relationship between dose, drug concentration and effects allows the clinician to take into account the various pathologic and physiologic features of a particular patient that make him or her different from the average individual in responding to a drug. The importance of pharmacokinetics and pharmacodynamics in patient care thus rests upon the improvement in therapeutic benefit and reduction in toxicity that can be achieved by application of these principles.

Pharmacokinetics

The "standard" dose of a drug is based on trials in healthy volunteers and patients with average ability to absorb, distribute, and eliminate the drug (see Clinical Trials: The IND and NDA in Chapter 5: Basic & Clinical Evaluation of New Drugs). This dose will not be suitable for every patient. Several physiologic processes (eg, maturation of organ function in infants) and pathologic processes (eg, heart failure, renal failure) dictate dosage adjustment in individual patients. These processes modify specific pharmacokinetic parameters. The two basic parameters are **clearance**, the measure of the ability of the body to eliminate the drug; and **volume of distribution**, the measure of the apparent space in the body available to contain the drug. These parameters are illustrated schematically in Figure 3–2, where the volume of the compartments into which the drugs diffuse represents the volume of distribution and the size of the outflow "drain" in Figures 3–2 B and D represents the clearance.

Figure 3–2.

A

B

C

D

Models of drug distribution and elimination. The effect of adding drug to the blood by rapid intravenous injection is represented by expelling a known amount of the agent into a beaker. The time course of the amount of drug in the beaker is shown in the graphs at the right. In the first example (A), there is no movement of drug out of the beaker, so the graph shows only a steep rise to maximum followed by a plateau. In the second example (B), a route of elimination is present, and the graph shows a slow decay after a sharp rise to a maximum. Because the level of material in the beaker falls, the "pressure" driving the elimination process also falls, and the slope of the curve decreases. This is an exponential decay curve. In the third model (C), drug placed in the first compartment ("blood") equilibrates rapidly with the second compartment ("extravascular volume") and the amount of drug in "blood" declines exponentially to a new steady state. The fourth model (D) illustrates a more realistic combination of elimination mechanism and extravascular equilibration. The resulting graph shows an early distribution phase followed by the slower elimination phase.

Volume of Distribution

Volume of distribution (V_d) relates the amount of drug in the body to the concentration of drug (C) in blood or plasma:

$$V_d = \frac{\text{Amount of drug in body}}{C} \quad (1)$$

The volume of distribution may be defined with respect to blood, plasma, or water (unbound drug), depending on the concentration used in equation (1) ($C = C_b, C_p,$ or C_u).

That the V_d calculated from equation (1) is an *apparent* volume may be appreciated by comparing the volumes of distribution of drugs such as digoxin or chloroquine (Table 3–1) with some of the physical volumes of the body (Table 3–2). Volume of distribution can vastly exceed any physical volume in the body because it is the volume apparently necessary to contain the amount of drug *homogeneously* at the concentration found in the blood, plasma, or water. Drugs with very high volumes of distribution have much higher concentrations in extravascular tissue than in the vascular compartment, ie, they are *not* homogeneously distributed. Drugs that are completely retained within the vascular compartment, on the other hand, have a minimum possible volume of distribution equal to the blood component in which they are distributed, eg, 0.04 L/kg body weight or 2.8 L/70 kg (Table 3–2) for a drug that is restricted to the plasma compartment.

Table 3–2. Physical Volumes (in L/Kg Body Weight) of Some Body Compartments into Which Drugs May Be Distributed.

Compartment and Volume	Examples of Drugs
Water	
Total body water (0.6 L/kg ¹)	Small water-soluble molecules: eg, ethanol.
Extracellular water (0.2 L/kg)	Larger water-soluble molecules: eg, gentamicin.
Blood (0.08 L/kg); plasma (0.04 L/kg)	Strongly plasma protein-bound molecules and very large molecules: eg, heparin.
Fat (0.2–0.35 L/kg)	Highly lipid-soluble molecules: eg, DDT.

Bone (0.07 L/kg)	Certain ions: eg, lead, fluoride.
-------------------------	-----------------------------------

¹An average figure. Total body water in a young lean man might be 0.7 L/kg; in an obese woman, 0.5 L/kg.

Clearance

Drug clearance principles are similar to the clearance concepts of renal physiology. Clearance of a drug is the factor that predicts the rate of elimination in relation to the drug concentration:

$$CL = \frac{\text{Rate of elimination}}{C} \quad (2)$$

Clearance, like volume of distribution, may be defined with respect to blood (CL_b), plasma (CL_p), or unbound in water (CL_u), depending on the concentration measured.

It is important to note the additive character of clearance. Elimination of drug from the body may involve processes occurring in the kidney, the lung, the liver, and other organs. Dividing the rate of elimination at each organ by the concentration of drug presented to it yields the respective clearance at that organ. Added together, these separate clearances equal total systemic clearance:

$$CL_{\text{renal}} = \frac{\text{Rate of elimination}_{\text{kidney}}}{C} \quad (3a)$$

$$CL_{\text{liver}} = \frac{\text{Rate of elimination}_{\text{liver}}}{C} \quad (3b)$$

$$CL_{\text{other}} = \frac{\text{Rate of elimination}_{\text{other}}}{C} \quad (3c)$$

$$CL_{\text{systemic}} = CL_{\text{renal}} + CL_{\text{liver}} + CL_{\text{other}} \quad (3d)$$

"Other" tissues of elimination could include the lungs and additional sites of metabolism, eg, blood or muscle.

The two major sites of drug elimination are the kidneys and the liver. Clearance of unchanged drug in the urine represents renal clearance. Within the liver, drug elimination occurs via biotransformation of parent drug to one or more metabolites, or excretion of unchanged drug into the bile, or both. The pathways of biotransformation are discussed in Chapter 4: Drug Biotransformation. For most drugs, clearance is constant over the concentration range encountered in clinical settings, ie, elimination is not saturable, and the rate of drug elimination is directly proportional to concentration (rearranging equation [2]):

$$\text{Rate of elimination} = CL \times C \quad (4)$$

This is usually referred to as first-order elimination. When clearance is first-order, it can be estimated by calculating the **area under the curve (AUC)** of the time-concentration profile after a dose. Clearance is calculated from the dose divided by the AUC.

Capacity-Limited Elimination

For drugs that exhibit capacity-limited elimination (eg, phenytoin, ethanol), clearance will vary depending on the concentration of drug that is achieved (Table 3–1). Capacity-limited elimination is also known as saturable, dose- or concentration-dependent, nonlinear, and Michaelis-Menten elimination.

Most drug elimination pathways will become saturated if the dose is high enough. When blood flow to an organ does not limit elimination (see below), the relation between elimination rate and concentration (C) is expressed mathematically in equation (5):

$$\text{Rate of elimination} = \frac{V_{\max} \times C}{K_m + C} \quad (5)$$

The maximum elimination capacity is V_{\max} , and K_m is the drug concentration at which the rate of elimination is 50% of V_{\max} . At concentrations that are high relative to the K_m , the elimination rate is almost independent of concentration—a state of "pseudo-zero order" elimination. If dosing rate exceeds elimination capacity, steady state cannot be achieved: The concentration will keep on rising as long as dosing continues. This pattern of capacity-limited elimination is important for three drugs in common use: ethanol, phenytoin, and aspirin. Clearance has no real meaning for drugs with capacity-limited elimination, and AUC cannot be used to describe the elimination of such drugs.

Flow-Dependent Elimination

In contrast to capacity-limited drug elimination, some drugs are cleared very readily by the organ of elimination, so that at any clinically realistic concentration of the drug, most of the drug in the blood perfusing the organ is eliminated on the first pass of the drug through it. The elimination of these drugs will thus depend primarily on the rate of drug delivery to the organ of elimination. Such drugs (see Table 4–7) can be called "high-extraction" drugs since they are almost completely extracted from the blood by the organ. Blood flow to the organ is the main determinant of drug delivery, but plasma protein binding and blood cell partitioning may also be important for extensively bound drugs that are highly extracted.

Half-Life

Half-life ($t_{1/2}$) is the time required to change the amount of drug in the body by one-half during elimination (or during a constant infusion). In the simplest case—and the most useful in designing drug dosage regimens—the body may be considered as a single compartment (as illustrated in Figure 3–2 B) of a size equal to the volume of distribution (V_d). The time course of drug in the body will depend on both the volume of distribution and the clearance:

$$t_{1/2} = \frac{0.7 \times V_d}{CL} \quad (6)$$

* The constant 0.7 in equation (6) is an approximation to the natural logarithm of 2. Because drug elimination can be described by an exponential process, the time taken for a twofold decrease can be shown to be proportional to $\ln(2)$.

Half-life is useful because it indicates the time required to attain 50% of steady state—or to decay 50% from steady-state conditions—after a change in the rate of drug administration. Figure 3–3

shows the time course of drug accumulation during a constant-rate drug infusion and the time course of drug elimination after stopping an infusion that has reached steady state.

Figure 3–3.

The time course of drug accumulation and elimination. **Solid line:** Plasma concentrations reflecting drug accumulation during a constant rate infusion of a drug. Fifty percent of the steady-state concentration is reached after one half-life, 75% after two half-lives, and over 90% after four half-lives. **Dashed line:** Plasma concentrations reflecting drug elimination after a constant rate infusion of a drug had reached steady state. Fifty percent of the drug is lost after one half-life, 75% after two half-lives, etc. The "rule of thumb" that four half-lives must elapse after starting a drug-dosing regimen before full effects will be seen is based on the approach of the accumulation curve to over 90% of the final steady-state concentration.

Disease states can affect both of the physiologically related primary pharmacokinetic parameters: volume of distribution and clearance. A change in half-life will not necessarily reflect a change in drug elimination. For example, patients with chronic renal failure have decreased renal clearance of digoxin but also a decreased volume of distribution; the increase in digoxin half-life is not as great as might be expected based on the change in renal function. The decrease in volume of distribution is due to the decreased renal and skeletal muscle mass and consequent decreased tissue binding of digoxin to Na^+/K^+ ATPase.

Many drugs will exhibit multicompartment pharmacokinetics (as illustrated in Figures 3–2 C and D). Under these conditions, the "true" terminal half-life, as given in Table 3–1, will be greater than that calculated from equation (6).

Drug Accumulation

Whenever drug doses are repeated, the drug will accumulate in the body until dosing stops. This is because it takes an infinite time (in theory) to eliminate all of a given dose. In practical terms, this means that if the dosing interval is shorter than four half-lives, accumulation will be detectable.

Accumulation is inversely proportional to the fraction of the dose lost in each dosing interval. The fraction lost is 1 minus the fraction remaining just before the next dose. The fraction remaining can be predicted from the dosing interval and the half-life. A convenient index of accumulation is the **accumulation factor**.

$$\text{Accumulation factor} = \frac{1}{\text{Fraction lost in one dosing interval}}$$

$$= \frac{1}{1 - \text{Fraction remaining}}$$

(7)

For a drug given once every half-life, the accumulation factor is 1/0.5, or 2. The accumulation factor predicts the ratio of the steady-state concentration to that seen at the same time following the first dose. Thus, the peak concentrations after intermittent doses at steady state will be equal to the peak concentration after the first dose multiplied by the accumulation factor.

Bioavailability

Bioavailability is defined as the fraction of unchanged drug reaching the systemic circulation following administration by any route (Table 3–3). The area under the blood concentration-time curve (area under the curve, AUC) is a common measure of the extent of bioavailability for a drug given by a particular route (Figure 3–4). For an intravenous dose of the drug, bioavailability is assumed to be equal to unity. For a drug administered orally, bioavailability may be less than 100% for two main reasons—incomplete extent of absorption and first-pass elimination.

Table 3–3. Routes of Administration, Bioavailability, and General Characteristics.

Route	Bioavailability (%)	Characteristics
Intravenous (IV)	100 (by definition)	Most rapid onset
Intramuscular (IM)	75 to \leq 100	Large volumes often feasible; may be painful
Subcutaneous (SC)	75 to \leq 100	Smaller volumes than IM; may be painful
Oral (PO)	5 to <100	Most convenient; first-pass effect may be significant
Rectal (PR)	30 to <100	Less first-pass effect than oral
Inhalation	5 to <100	Often very rapid onset
Transdermal	80 to \leq 100	Usually very slow absorption; used for lack of first-pass effect; prolonged duration of action

Figure 3–4.

Blood concentration-time curves, illustrating how changes in the rate of absorption and extent of bioavailability can influence both the duration of action and the effectiveness of the same total dose of a drug administered in three different formulations. The dashed line indicates the target concentration (TC) of the drug in the blood.

Extent of Absorption

After oral administration, a drug may be incompletely absorbed, eg, only 70% of a dose of digoxin reaches the systemic circulation. This is mainly due to lack of absorption from the gut. Other drugs are either too hydrophilic (eg, atenolol) or too lipophilic (eg, acyclovir) to be absorbed easily, and their low bioavailability is also due to incomplete absorption. If too hydrophilic, the drug cannot cross the lipid cell membrane; if too lipophilic, the drug is not soluble enough to cross the water layer adjacent to the cell. Drugs may not be absorbed because of a reverse transporter associated with P-glycoprotein. This process actively pumps drug out of gut wall cells back into the gut lumen. Inhibition of P-glycoprotein and gut wall metabolism, eg, by grapefruit juice, may be associated with substantially increased drug absorption.

First-Pass Elimination

Following absorption across the gut wall, the portal blood delivers the drug to the liver prior to entry into the systemic circulation. A drug can be metabolized in the gut wall (eg, by the CYP3A4 enzyme system) or even in the portal blood, but most commonly it is the liver that is responsible for metabolism before the drug reaches the systemic circulation. In addition, the liver can excrete the drug into the bile. Any of these sites can contribute to this reduction in bioavailability, and the overall process is known as first-pass elimination. The effect of first-pass hepatic elimination on bioavailability is expressed as the extraction ratio (ER):

$$ER = \frac{CL_{\text{liver}}}{Q} \quad (8a)$$

where Q is hepatic blood flow, normally about 90 L/h in a person weighing 70 kg.

The systemic bioavailability of the drug (F) can be predicted from the extent of absorption (f) and the extraction ratio (ER):

$$F = f \times (1 - ER) \quad (8b)$$

A drug such as morphine is almost completely absorbed ($f = 1$), so that loss in the gut is negligible. However, the hepatic extraction ratio for morphine is 0.67, so $(1 - ER)$ is 0.33. The bioavailability of morphine is therefore expected to be about 33%, which is close to the observed value (Table 3–1).

Rate of Absorption

The distinction between rate and extent of absorption is shown in Figure 3–4. The rate of absorption is determined by the site of administration and the drug formulation. Both the rate of absorption and the extent of input can influence the clinical effectiveness of a drug. For the three different dosage forms depicted in Figure 3–4, there would be significant differences in the intensity of clinical effect. Dosage form B would require twice the dose to attain blood concentrations equivalent to those of dosage form A. Differences in rate of availability may become important for drugs given as a single dose, such as a hypnotic used to induce sleep. In this case, drug from dosage form A would reach its target concentration earlier than drug from dosage form C; concentrations from A would also reach a higher level and remain above the target concentration for a longer period. In a multiple dosing regimen, dosage forms A and C would yield the same average blood level concentrations, although dosage form A would show somewhat greater maximum and lower minimum concentrations.

The mechanism of drug absorption is said to be zero-order when the rate is independent of the amount of drug remaining in the gut, eg, when it is determined by the rate of gastric emptying or by a controlled-release drug formulation. In contrast, when the full dose is dissolved in gastrointestinal fluids, the rate of absorption is usually proportional to the gastrointestinal concentration and is said to be first-order.

Extraction Ratio & the First-Pass Effect

Systemic clearance is not affected by bioavailability. However, clearance can markedly affect the extent of availability because it determines the extraction ratio (equation [8a]). Of course, therapeutic blood concentrations may still be reached by the oral route of administration if larger doses are given. However, in this case, the concentrations of the drug *metabolites* will be increased significantly over those that would occur following intravenous administration. Lidocaine and verapamil are both used to treat cardiac arrhythmias and have bioavailability less than 40%, but lidocaine is never given orally because its metabolites are believed to contribute to central nervous system toxicity. Other drugs that are highly extracted by the liver include isoniazid, morphine, propranolol, verapamil, and several tricyclic antidepressants (Table 3–1).

Drugs with high extraction ratios will show marked variations in bioavailability between subjects because of differences in hepatic function and blood flow. These differences can explain the marked variation in drug concentrations that occurs among individuals given similar doses of highly extracted drugs. For drugs that are highly extracted by the liver, shunting of blood past hepatic sites of elimination will result in substantial increases in drug availability, whereas for drugs that are poorly extracted by the liver (for which the difference between entering and exiting drug concentration is small), shunting of blood past the liver will cause little change in availability.

Drugs in Table 3–1 that are poorly extracted by the liver include chlorpropamide, diazepam, phenytoin, theophylline, tolbutamide, and warfarin.

Alternative Routes of Administration & the First-Pass Effect

There are several reasons for different routes of administration used in clinical medicine (Table 3–3)—for convenience (eg, oral), to maximize concentration at the site of action and minimize it elsewhere (eg, topical), to prolong the duration of drug absorption (eg, transdermal), or to avoid the first-pass effect.

The hepatic first-pass effect can be avoided to a great extent by use of sublingual tablets and transdermal preparations and to a lesser extent by use of rectal suppositories. Sublingual absorption provides direct access to systemic—not portal—veins. The transdermal route offers the same advantage. Drugs absorbed from suppositories in the lower rectum enter vessels that drain into the inferior vena cava, thus bypassing the liver. However, suppositories tend to move upward in the rectum into a region where veins that lead to the liver predominate. Thus, only about 50% of a rectal dose can be assumed to bypass the liver.

Although drugs administered by inhalation bypass the hepatic first-pass effect, the lung may also serve as a site of first-pass loss by excretion and possibly metabolism for drugs administered by nongastrointestinal ("parenteral") routes.

The Time Course of Drug Effect

The principles of pharmacokinetics (discussed in this chapter) and those of pharmacodynamics (discussed in Chapter 2: Drug Receptors & Pharmacodynamics; Holford & Sheiner, 1981) provide a framework for understanding the time course of drug effect.

Immediate Effects

In the simplest case, drug effects are directly related to plasma concentrations, but this does not necessarily mean that effects simply parallel the time course of concentrations. Because the relationship between drug concentration and effect is not linear (recall the E_{\max} model described in Chapter 2: Drug Receptors & Pharmacodynamics), the effect will not usually be linearly proportional to the concentration.

Consider the effect of an angiotensin-converting enzyme (ACE) inhibitor, such as enalapril, on plasma ACE. The half-life of enalapril is about 3 hours. After an oral dose of 10 mg, the peak plasma concentration at 3 hours is about 64 ng/mL. Enalapril is usually given once a day, so seven half-lives will elapse from the time of peak concentration to the end of the dosing interval. The concentration of enalapril after each half-life and the corresponding extent of ACE inhibition are shown in Figure 3–5. The extent of inhibition of ACE is calculated using the E_{\max} model, where E_{\max} , the maximum extent of inhibition, is 100% and the EC_{50} is about 1 ng/mL.

Figure 3–5.

Time course of angiotensin-converting enzyme (ACE) inhibitor concentrations and effects. The black line shows the plasma enalapril concentrations in nanograms per milliliter after a single oral dose. The colored line indicates the percentage inhibition of its target, ACE. Note the different shapes of the concentration-time course (exponentially decreasing) and the effect-time course (linearly decreasing in its central portion).

Note that plasma concentrations of enalapril change by a factor of 16 over the first 12 hours (four half-lives) after the peak, but ACE inhibition has only decreased by 20%. Because the concentrations over this time are so high in relation to the EC_{50} , the effect on ACE is almost constant. After 24 hours, ACE is still 33% inhibited. This explains why a drug with a short half-life can be given once a day and still maintain its effect throughout the day. The key factor is a high initial concentration in relation to the EC_{50} . Even though the plasma concentration at 24 hours is less than 1% of its peak, this low concentration is still half the EC_{50} . This is very common for drugs that act on enzymes (eg, ACE inhibitors) or compete at receptors (eg, propranolol).

When concentrations are in the range between one fourth and four times the EC_{50} , the time course of effect is essentially a linear function of time—13% of the effect is lost every half-life over this concentration range. At concentrations below one fourth the EC_{50} , the effect becomes almost directly proportional to concentration and the time course of drug effect will follow the exponential decline of concentration. It is only when the concentration is low in relation to the EC_{50} that the concept of a "half-life of drug effect" has any meaning.

Delayed Effects

Changes in drug effects are often delayed in relation to changes in plasma concentration. This delay may reflect the time required for the drug to distribute from plasma to the site of action. This will be the case for almost all drugs. The delay due to distribution is a pharmacokinetic phenomenon that can account for delays of a few minutes. This distributional delay can account for the lag of effects after rapid intravenous injection of central nervous system (CNS)-active agents such as thiopental.

A common reason for more delayed drug effects—especially those that take many hours or even days to occur—is the slow turnover of a physiologic substance that is involved in the expression of the drug effect (Jusko & Ko, 1994). For example, warfarin works as an anticoagulant by inhibiting vitamin K epoxidase in the liver. This action of warfarin occurs rapidly, and inhibition of the enzyme is closely related to plasma concentrations of warfarin. The clinical effect of warfarin, eg, on the prothrombin time, reflects a decrease in the concentration of the prothrombin complex of clotting factors (see Figure 34-7). Inhibition of vitamin K epoxidase decreases the synthesis of these clotting factors, but the complex has a long half-life (about 14 hours), and it is this half-life

that determines how long it takes for the concentration of clotting factors to reach a new steady state and for a drug effect to become manifest that reflects the warfarin plasma concentration.

Cumulative Effects

Some drug effects are more obviously related to a cumulative action than to a rapidly reversible one. The renal toxicity of aminoglycoside antibiotics (eg, gentamicin) is greater when administered as a constant infusion than with intermittent dosing. It is the accumulation of aminoglycoside in the renal cortex that is thought to cause renal damage. Even though both dosing schemes produce the same average steady-state concentration, the intermittent dosing scheme produces much higher peak concentrations, which saturate an uptake mechanism into the cortex; thus, total aminoglycoside accumulation is less. The difference in toxicity is a predictable consequence of the different patterns of concentration and the saturable uptake mechanism.

The effect of many drugs used to treat cancer also reflects a cumulative action—eg, the extent of binding of a drug to DNA is proportional to drug concentration and is usually irreversible. The effect on tumor growth is therefore a consequence of cumulative exposure to the drug. Measures of cumulative exposure, such as AUC, provide a means to individualize treatment (Evans et al, 1998).

The Target Concentration Approach to Designing a Rational Dosage Regimen

A rational dosage regimen is based on the assumption that there is a **target concentration** that will produce the desired therapeutic effect. By considering the pharmacokinetic factors that determine the dose-concentration relationship, it is possible to individualize the dose regimen to achieve the target concentration. The effective concentration ranges shown in Table 3–1 are a guide to the concentrations measured when patients are being effectively treated. The initial target concentration should usually be chosen from the lower end of this range. In some cases, the target concentration will also depend on the specific therapeutic objective—eg, the control of atrial fibrillation by digoxin often requires a target concentration of 2 ng/mL, while heart failure is usually adequately managed with a target concentration of 1 ng/mL.

Maintenance Dose

In most clinical situations, drugs are administered in such a way as to maintain a steady state of drug in the body, ie, just enough drug is given in each dose to replace the drug eliminated since the preceding dose. Thus, calculation of the appropriate maintenance dose is a primary goal. Clearance is the most important pharmacokinetic term to be considered in defining a rational steady state drug dosage regimen. At steady state, the dosing rate ("rate in") must equal the rate of elimination ("rate out"). Substitution of the target concentration (TC) for concentration (C) in equation (4) predicts the maintenance dosing rate:

$$\begin{aligned} \text{Dosing rate}_{ss} &= \text{Rate of elimination}_{ss} \\ &= CL \times TC \end{aligned} \quad (9)$$

Thus, if the desired target concentration is known, the clearance in that patient will determine the dosing rate. If the drug is given by a route that has a bioavailability less than 100%, then the dosing rate predicted by equation (9) must be modified. For oral dosing:

$$\text{Dosing rate}_{\text{oral}} = \frac{\text{Dosing rate}}{F_{\text{oral}}} \quad (10)$$

If intermittent doses are given, the maintenance dose is calculated from:

$$\text{Maintenance dose} = \text{Dosing rate} \times \text{Dosing interval} \quad (11)$$

(See Example: Maintenance Dose Calculation.)

Note that the steady-state concentration achieved by continuous infusion or the *average* concentration following intermittent dosing depends only on clearance. The volume of distribution and the half-life need not be known in order to determine the average plasma concentration expected from a given dosing rate or to predict the dosing rate for a desired target concentration. Figure 3–6 shows that at different dosing intervals, the concentration time curves will have different maximum and minimum values even though the average level will always be 10 mg/L.

Estimates of dosing rate and average steady-state concentrations, which may be calculated using clearance, are independent of any specific pharmacokinetic model. In contrast, the determination of maximum and minimum steady-state concentrations requires further assumptions about the pharmacokinetic model. The accumulation factor (equation [7]) assumes that the drug follows a one-compartment body model (Figure 3–2 B), and the peak concentration prediction assumes that the absorption rate is much faster than the elimination rate. For the calculation of estimated maximum and minimum concentrations in a clinical situation, these assumptions are usually reasonable.

Example: Maintenance Dose Calculation

A target plasma theophylline concentration of 10 mg/L is desired to relieve acute bronchial asthma in a patient. If the patient is a nonsmoker and otherwise normal except for asthma, we may use the mean clearance given in Table 3–1, ie, 2.8 L/h/70 kg. Since the drug will be given as an intravenous infusion, $F = 1$.

$$\begin{aligned} \text{Dosing rate} &= CL \times TC \\ &= 2.8 \text{ L/h} / 70 \text{ kg} \times 10 \text{ mg/L} \\ &= 28 \text{ mg/h} / 70 \text{ kg} \end{aligned}$$

Therefore, in this patient, the proper infusion rate would be 28 mg/h/70 kg.

If the asthma attack is relieved, the clinician might want to maintain this plasma level using oral theophylline, which might be given every 12 hours using an extended-release formulation to approximate a continuous intravenous infusion. According to Table 3–1, F_{oral} is 0.96. When the dosing interval is 12 hours, the size of each maintenance dose would be:

$$\begin{aligned} \text{Maintenance dose} &= \frac{\text{Dosing rate}}{F} \times \text{Dosing interval} \\ &= \frac{28 \text{ mg/h}}{0.96} \times 12 \text{ hours} \\ &= 350 \text{ mg} \end{aligned}$$

A tablet or capsule size close to the ideal dose of 350 mg would then be prescribed at 12-hourly intervals. If an 8-hour dosing interval was used, the ideal dose would be 233 mg; and if the drug

was given once a day, the dose would be 700 mg. In practice, F could be omitted from the calculation since it is so close to 1.

Loading Dose

When the time to reach steady state is appreciable, as it is for drugs with long half-lives, it may be desirable to administer a loading dose that promptly raises the concentration of drug in plasma to the target concentration. In theory, only the amount of the loading dose need be computed—not the rate of its administration—and, to a first approximation, this is so. The volume of distribution is the proportionality factor that relates the total amount of drug in the body to the concentration in the plasma (C_p); if a loading dose is to achieve the target concentration, then from equation (1):

$$\begin{aligned} \text{Loading dose} &= \text{Amount in the body immediately following} \\ &\quad \text{the loading dose} \\ &= V_d \times TC \end{aligned} \quad (12)$$

For the theophylline example given in Example: Maintenance Dose Calculation, the loading dose would be 350 mg ($35 \text{ L} \times 10 \text{ mg/L}$) for a 70 kg person. For most drugs, the loading dose can be given as a single dose by the chosen route of administration.

Up to this point, we have ignored the fact that some drugs follow more complex multicompartment pharmacokinetics, eg, the distribution process illustrated by the two-compartment model in Figure 3–2. This is justified in the great majority of cases. However, in some cases the distribution phase may not be ignored, particularly in connection with the calculation of loading doses. If the rate of absorption is rapid relative to distribution (this is always true for intravenous bolus administration), the concentration of drug in plasma that results from an appropriate loading dose—calculated using the apparent volume of distribution—can initially be considerably higher than desired. Severe toxicity may occur, albeit transiently. This may be particularly important, for example, in the administration of antiarrhythmic drugs such as lidocaine, where an almost immediate toxic response may occur. Thus, while the estimation of the *amount* of a loading dose may be quite correct, the *rate of administration* can sometimes be crucial in preventing excessive drug concentrations, and slow administration of an intravenous drug (over minutes rather than seconds) is almost always prudent practice. For intravenous doses of theophylline, initial injections should be given over a 20-minute period to reduce the possibility of high plasma concentrations during the distribution phase.

When intermittent doses are given, the loading dose calculated from equation (12) will only reach the average steady-state concentration and will not match the peak steady-state concentration (see Figure 3–6). To match the peak steady-state concentration, the loading dose can be calculated from equation (13):

$$\text{Loading dose} = \text{Maintenance dose} \times \text{Accumulation factor} \quad (13)$$

Figure 3–6.

Relationship between frequency of dosing and maximum and minimum plasma concentrations when a steady-state theophylline plasma level of 10 mg/L is desired. The smoothly rising line (solid black) shows the plasma concentration achieved with an intravenous infusion of 28 mg/h. The doses for 8-hourly administration (light color) are 224 mg; for 24-hourly administration (dark color), 672 mg. In each of the 3 cases, the mean steady-state plasma concentration is 10 mg/L.

Therapeutic Drug Monitoring: Relating Pharmacokinetics & Pharmacodynamics

The basic principles outlined above can be applied to the interpretation of clinical drug concentration measurements on the basis of three major pharmacokinetic variables: absorption, clearance, and volume of distribution (and the derived variable, half-life); and two pharmacodynamic variables: maximum effect attainable in the target tissue and the sensitivity of the tissue to the drug. Diseases may modify all of these parameters, and the ability to predict the effect of disease states on pharmacokinetic parameters is important in properly adjusting dosage in such cases. (See The Target Concentration Strategy.)

The Target Concentration Strategy

Recognition of the essential role of concentration in linking pharmacokinetics and pharmacodynamics leads naturally to the target concentration strategy. Pharmacodynamic principles can be used to predict the concentration required to achieve a particular degree of therapeutic effect. This target concentration can then be achieved by using pharmacokinetic principles to arrive at a suitable dosing regimen (Holford, 1999). The target concentration strategy is a process for optimizing the dose in an individual on the basis of a measured surrogate response such as drug concentration:

1. Choose the target concentration, TC.
2. Predict volume of distribution (V_d) and clearance (CL) based on standard population values (eg, Table 3-1) with adjustments for factors such as weight and renal function.
3. Give a loading dose or maintenance dose calculated from TC, V_d , and CL.
4. Measure the patient's response and drug concentration.
5. Revise V_d and/or CL based on the measured concentration.

6. Repeat steps 3–5, adjusting the predicted dose to achieve TC.

Pharmacokinetic Variables

Absorption

The amount of drug that enters the body depends on the patient's compliance with the prescribed regimen and on the rate and extent of transfer from the site of administration to the blood.

Overdosage and underdosage relative to the prescribed dosage—both aspects of failure of compliance—can frequently be detected by concentration measurements when gross deviations from expected values are obtained. If compliance is found to be adequate, absorption abnormalities in the small bowel may be the cause of abnormally low concentrations. Variations in the extent of bioavailability are rarely caused by irregularities in the manufacture of the particular drug formulation. More commonly, variations in bioavailability are due to metabolism during absorption.

Clearance

Abnormal clearance may be anticipated when there is major impairment of the function of the kidney, liver, or heart. Creatinine clearance is a useful quantitative indicator of renal function. Conversely, drug clearance may be a useful indicator of the functional consequences of heart, kidney, or liver failure, often with greater precision than clinical findings or other laboratory tests. For example, when renal function is changing rapidly, estimation of the clearance of aminoglycoside antibiotics may be a more accurate indicator of glomerular filtration than serum creatinine.

Hepatic disease has been shown to reduce the clearance and prolong the half-life of many drugs. However, for many other drugs known to be eliminated by hepatic processes, no changes in clearance or half-life have been noted with similar hepatic disease. This reflects the fact that hepatic disease does not always affect the hepatic intrinsic clearance. At present, there is no reliable marker of hepatic drug-metabolizing function that can be used to predict changes in liver clearance in a manner analogous to the use of creatinine clearance as a marker of renal drug clearance.

Volume of Distribution

The apparent volume of distribution reflects a balance between binding to tissues, which decreases plasma concentration and makes the apparent volume larger, and binding to plasma proteins, which increases plasma concentration and makes the apparent volume smaller. Changes in either tissue or plasma binding can change the apparent volume of distribution determined from plasma concentration measurements. Older people have a relative decrease in skeletal muscle mass and tend to have a smaller apparent volume of distribution of digoxin (which binds to muscle proteins). The volume of distribution may be overestimated in obese patients if based on body weight and the drug does not enter fatty tissues well, as is the case with digoxin. In contrast, theophylline has a volume of distribution similar to that of total body water. Adipose tissue has almost as much water in it as other tissues, so that the apparent total volume of distribution of theophylline is proportional to body weight even in obese patients.

Abnormal accumulation of fluid—edema, ascites, pleural effusion—can markedly increase the volume of distribution of drugs such as gentamicin that are hydrophilic and have small volumes of distribution.

Half-Life

The differences between clearance and half-life are important in defining the underlying mechanisms for the effect of a disease state on drug disposition. For example, the half-life of diazepam increases with age. When clearance is related to age, it is found that clearance of this drug does not change with age. The increasing half-life for diazepam actually results from changes in the volume of distribution with age; the metabolic processes responsible for eliminating the drug are fairly constant.

Pharmacodynamic Variables

Maximum Effect

All pharmacologic responses must have a maximum effect (E_{\max}). No matter how high the drug concentration goes, a point will be reached beyond which no further increment in response is achieved.

If increasing the dose in a particular patient does not lead to a further clinical response, it is possible that the maximum effect has been reached. Recognition of maximum effect is helpful in avoiding ineffectual increases of dose with the attendant risk of toxicity.

Sensitivity

The sensitivity of the target organ to drug concentration is reflected by the concentration required to produce 50% of maximum effect, the EC_{50} . Failure of response due to diminished sensitivity to the drug can be detected by measuring—in a patient who is not getting better—drug concentrations that are usually associated with therapeutic response. This may be a result of abnormal physiology—eg, hyperkalemia diminishes responsiveness to digoxin—or drug antagonism—eg, calcium channel blockers impair the inotropic response to digoxin.

Increased sensitivity to a drug is usually signaled by exaggerated responses to small or moderate doses. The pharmacodynamic nature of this sensitivity can be confirmed by measuring drug concentrations that are low in relation to the observed effect.

Interpretation of Drug Concentration Measurements

Clearance

Clearance is the single most important factor determining drug concentrations. The interpretation of measurements of drug concentrations depends on a clear understanding of three factors that may influence clearance: the dose, the organ blood flow, and the intrinsic function of the liver or kidneys. Each of these factors should be considered when interpreting clearance estimated from a drug concentration measurement. It must also be recognized that changes in protein binding may lead the unwary to believe there is a change in clearance when in fact drug elimination is not altered (see Plasma Protein Binding: Is It Important?). Factors affecting protein binding include the following:

1. Albumin concentration: Drugs such as phenytoin, salicylates, and disopyramide are extensively bound to plasma albumin. Albumin levels are low in many disease states, resulting in lower total drug concentrations.

2. Alpha₁-acid glycoprotein concentration: α_1 -Acid glycoprotein is an important binding protein with binding sites for drugs such as quinidine, lidocaine, and propranolol. It is increased in acute inflammatory disorders and causes major changes in total plasma concentration of these drugs even though drug elimination is unchanged.

3. Capacity-limited protein binding: The binding of drugs to plasma proteins is capacity-limited. Therapeutic concentrations of salicylates and prednisolone show concentration-dependent protein binding. Because unbound drug concentration is determined by dosing rate and clearance—which is not altered, in the case of these low-extraction-ratio drugs, by protein binding—increases in dosing rate will cause corresponding changes in the pharmacodynamically important unbound concentration. Total drug concentration will increase less rapidly than the dosing rate would suggest as protein binding approaches saturation at higher concentrations.

Plasma Protein Binding: Is It Important?

Plasma protein binding is often mentioned as a factor playing a role in pharmacokinetics, pharmacodynamics, and drug interactions. However, there are no clinically relevant examples of changes in drug disposition or effects that can be clearly ascribed to changes in plasma protein binding (Benet & Hoener 2002). The idea that if a drug is displaced from plasma proteins it would increase the unbound drug concentration and increase the drug effect and, perhaps, produce toxicity seems a simple and obvious mechanism. Unfortunately, this simple theory, which is appropriate for a test tube, does not work in the body, which is an open system capable of eliminating unbound drug.

First, a seemingly dramatic change in the unbound fraction from 1% to 10% releases less than 5% of the total amount of drug in the body into the unbound pool because less than one third of the drug in the body is bound to plasma proteins even in the most extreme cases, eg, warfarin. Drug displaced from plasma protein will of course distribute throughout the volume of distribution, so that a 5% increase in the amount of unbound drug in the body produces at most a 5% increase in pharmacologically active unbound drug at the site of action.

Second, when the amount of unbound drug in plasma increases, the rate of elimination will increase (if unbound clearance is unchanged), and after four half-lives the unbound concentration will return to its previous steady state value. When drug interactions associated with protein binding displacement and clinically important effects have been studied, it has been found that the displacing drug is also an inhibitor of clearance, and it is the change in *clearance* of the *unbound* drug that is the relevant mechanism explaining the interaction.

The clinical importance of plasma protein binding is only to help interpretation of measured drug concentrations. When plasma proteins are lower than normal, then total drug concentrations will be lower but unbound concentrations will not be affected.

Dosing History

An accurate dosing history is essential if one is to obtain maximum value from a drug concentration measurement. In fact, if the dosing history is unknown or incomplete, a drug concentration measurement loses all predictive value.

Timing of Samples for Concentration Measurement

Information about the rate and extent of drug absorption in a particular patient is rarely of great clinical importance. However, absorption usually occurs during the first 2 hours after a drug dose and varies according to food intake, posture, and activity. Therefore, it is important to avoid drawing blood until absorption is complete (about 2 hours after an oral dose). Attempts to measure peak concentrations early after oral dosing are usually unsuccessful and compromise the validity of the measurement, because one cannot be certain that absorption is complete.

Some drugs such as digoxin and lithium take several hours to distribute to tissues. Digoxin samples should be taken at least 6 hours after the last dose and lithium just before the next dose (usually 24 hours after the last dose). Aminoglycosides distribute quite rapidly, but it is still prudent to wait 1 hour after giving the dose before taking a sample.

Clearance is readily estimated from the dosing rate and mean steady-state concentration. Blood samples should be appropriately timed to estimate steady-state concentration. Provided steady state has been approached (at least three half-lives of constant dosing), a sample obtained near the midpoint of the dosing interval will usually be close to the mean steady-state concentration.

Initial Predictions of Volume of Distribution & Clearance

Volume of Distribution

Volume of distribution is commonly calculated for a particular patient using body weight (70 kg body weight is assumed for the values in Table 3–1). If a patient is obese, drugs that do not readily penetrate fat (eg, gentamicin and digoxin) should have their volumes calculated from ideal body weight as shown below:

$$\begin{aligned} \text{Ideal body wt (kg)} &= 52 + 1.9 \text{ kg/in height} \\ &\quad \text{over 5 ft (men)} \qquad (14) \\ &= 49 + 1.7 \text{ kg/in height} \\ &\quad \text{over 5 ft (women)} \end{aligned}$$

Patients with edema, ascites, or pleural effusions offer a larger volume of distribution to the aminoglycoside antibiotics (eg, gentamicin) than is predicted by body weight. In such patients, the weight should be corrected as follows: Subtract an estimate of the weight of the excess fluid accumulation from the measured weight. Use the resultant "normal" body weight to calculate the normal volume of distribution. Finally, this normal volume should be increased by 1 L for each estimated kilogram of excess fluid. This correction is important because of the relatively small volumes of distribution of these water-soluble drugs.

Clearance

Drugs cleared by the renal route often require adjustment of clearance in proportion to renal function. This can be conveniently estimated from the creatinine clearance, calculated from a single serum creatinine measurement and the predicted creatinine production rate.

The predicted creatinine production rate in women is 85% of the calculated value, because they have a smaller muscle mass per kilogram and it is muscle mass that determines creatinine production. Muscle mass as a fraction of body weight decreases with age, which is why age appears in the Cockcroft-Gault equation, given in Chapter 61: Special Aspects of Geriatric Pharmacology.

The decrease of renal function with age is independent of the decrease in creatinine production. Because of the difficulty of obtaining complete urine collections, creatinine clearance calculated in this way is at least as reliable as estimates based on urine collections. Ideal body weight should be used for obese patients, and correction should be made for muscle wasting in severely ill patients.

Revising Individual Estimates of Volume of Distribution & Clearance

The commonsense approach to the interpretation of drug concentrations compares predictions of pharmacokinetic parameters and expected concentrations to measured values. If measured concentrations differ by more than 20% from predicted values, revised estimates of V_d or CL for that patient should be calculated using equation (1) or equation (2). If the change calculated is more than a 100% increase or 50% decrease in either V_d or CL, the assumptions made about the timing of the sample and the dosing history should be critically examined.

For example, if a patient is taking 0.25 mg of digoxin a day, a clinician may expect the digoxin concentration to be about 1 ng/mL. This is based on typical values for bioavailability of 70% and total clearance of about 7 L/h (CL_{renal} 4 L/h, CL_{nonrenal} 3 L/h). If the patient has heart failure, the nonrenal (hepatic) clearance might be halved because of hepatic congestion and hypoxia, so the expected clearance would become 5.5 L/h. The concentration is then expected to be about 1.3 ng/mL. Suppose that the concentration actually measured is 2 ng/mL. Common sense would suggest halving the daily dose to achieve a target concentration of 1 ng/mL. This approach implies a revised clearance of 3.5 L/h. The smaller clearance compared with the expected value of 5.5 L/h may reflect additional renal functional impairment due to heart failure.

This technique will often be misleading if steady state has not been reached. At least a week of regular dosing (three to four half-lives) must elapse before the implicit method will be reliable.

Chapter 4. Drug Biotransformation

Drug Biotransformation: Introduction

Humans are exposed daily to a wide variety of foreign compounds called **xenobiotics**—substances absorbed across the lungs or skin or, more commonly, ingested either unintentionally as compounds present in food and drink or deliberately as drugs for therapeutic or "recreational" purposes. Exposure to environmental xenobiotics may be inadvertent and accidental or—when they are present as components of air, water, and food—inescapable. Some xenobiotics are innocuous, but many can provoke biologic responses. Such biologic responses often depend on conversion of the absorbed substance into an active metabolite. The discussion that follows is applicable to xenobiotics in general (including drugs) and to some extent to endogenous compounds.

Why Is Drug Biotransformation Necessary?

Renal excretion plays a pivotal role in terminating the biologic activity of some drugs, particularly those that have small molecular volumes or possess polar characteristics such as functional groups that are fully ionized at physiologic pH. However, many drugs do not possess such physicochemical properties. Pharmacologically active organic molecules tend to be lipophilic and remain un-ionized or only partially ionized at physiologic pH. They are often strongly bound to plasma proteins. Such substances are not readily filtered at the glomerulus. The lipophilic nature of renal tubular

membranes also facilitates the reabsorption of hydrophobic compounds following their glomerular filtration. Consequently, most drugs would have a prolonged duration of action if termination of their action depended solely on renal excretion.

An alternative process that may lead to the termination or alteration of biologic activity is metabolism. In general, lipophilic xenobiotics are transformed to more polar and hence more readily excretable products. The role metabolism may play in the inactivation of lipid-soluble drugs can be quite dramatic. For example, lipophilic barbiturates such as thiopental and pentobarbital would have extremely long half-lives if it were not for their metabolic conversion to more water-soluble compounds.

Metabolic products are often less pharmacodynamically active than the parent drug and may even be inactive. However, some biotransformation products have *enhanced* activity or toxic properties. It is noteworthy that the synthesis of endogenous substrates such as steroid hormones, cholesterol, active vitamin D congeners and bile acids involves many pathways catalyzed by enzymes associated with the metabolism of xenobiotics. Finally, drug-metabolizing enzymes have been exploited in the design of pharmacologically inactive prodrugs that are converted to active molecules in the body.

Where Do Drug Biotransformations Occur?

Although every tissue has some ability to metabolize drugs, the liver is the principal organ of drug metabolism. Other tissues that display considerable activity include the gastrointestinal tract, the lungs, the skin, and the kidneys. Following oral administration, many drugs (eg, isoproterenol, meperidine, pentazocine, morphine) are absorbed intact from the small intestine and transported first via the portal system to the liver, where they undergo extensive metabolism. This process has been called a **first-pass effect** (see Chapter 3: Pharmacokinetics & Pharmacodynamics: Rational Dosing & the Time Course of Drug Action). Some orally administered drugs (eg, clonazepam, chlorpromazine) are more extensively metabolized in the intestine than in the liver. Thus, intestinal metabolism may contribute to the overall first-pass effect. First-pass effects may so greatly limit the bioavailability of orally administered drugs that alternative routes of administration must be used to achieve therapeutically effective blood levels. The lower gut harbors intestinal microorganisms that

are capable of many biotransformation reactions. In addition, drugs may be metabolized by gastric acid (eg, penicillin), by digestive enzymes (eg, polypeptides such as insulin), or by enzymes in the wall of the intestine (eg, sympathomimetic catecholamines).

Although drug biotransformation in vivo can occur by spontaneous, noncatalyzed chemical reactions, the vast majority of transformations are catalyzed by specific cellular enzymes. At the subcellular level, these enzymes may be located in the endoplasmic reticulum, mitochondria, cytosol, lysosomes, or even the nuclear envelope or plasma membrane.

Microsomal Mixed Function Oxidase System & Phase I Reactions

Many drug-metabolizing enzymes are located in the lipophilic membranes of the endoplasmic reticulum of the liver and other tissues. When these lamellar membranes are isolated by homogenization and fractionation of the cell, they re-form into vesicles called **microsomes**. Microsomes retain most of the morphologic and functional characteristics of the intact membranes, including the rough and smooth surface features of the rough (ribosome-studded) and smooth (no ribosomes) endoplasmic reticulum. Whereas the rough microsomes tend to be dedicated to protein synthesis, the smooth microsomes are relatively rich in enzymes responsible for oxidative drug metabolism. In particular, they contain the important class of enzymes known as the **mixed function oxidases** (MFOs), or monooxygenases. The activity of these enzymes requires both a reducing agent (NADPH) and molecular oxygen; in a typical reaction, one molecule of oxygen is consumed (reduced) per substrate molecule, with one oxygen atom appearing in the product and the other in the form of water.

In this oxidation-reduction process, two microsomal enzymes play a key role. The first of these is a flavoprotein, **NADPH-cytochrome P450 reductase**. One mole of this enzyme contains 1 mol each of flavin mononucleotide (FMN) and flavin adenine dinucleotide (FAD). The second microsomal enzyme is a hemoprotein called **cytochrome P450** that serves as the terminal oxidase. In fact, the microsomal membrane harbors multiple forms of this hemoprotein, and this multiplicity is increased by repeated administration of exogenous chemicals (see below). The name cytochrome P450 (abbreviated as CYP or P450) is derived from the spectral properties of this hemoprotein. In its reduced (ferrous) form, it binds carbon monoxide to give a complex that absorbs light maximally at 450 nm. The relative abundance of P450, compared with that of the reductase in the liver, contributes to making P450 heme reduction a rate-limiting step in hepatic drug oxidations.

Microsomal drug oxidations require P450, P450 reductase, NADPH, and molecular oxygen. A simplified scheme of the oxidative cycle is presented in Figure 4–3. Briefly, oxidized (Fe^{3+}) P450 combines with a drug substrate to form a binary complex (step 1). NADPH donates an electron to the flavoprotein reductase, which in turn reduces the oxidized P450-drug complex (step 2). A second electron is introduced from NADPH via the same flavoprotein reductase, which serves to reduce molecular oxygen and to form an "activated oxygen"-P450-substrate complex (step 3). This complex in turn transfers activated oxygen to the drug substrate to form the oxidized product (step 4).

Figure 4–3.

Cytochrome P450 cycle in drug oxidations. (R-H, parent drug; R-OH, oxidized metabolite; e⁻, electron.)

The potent oxidizing properties of this activated oxygen permit oxidation of a large number of substrates. Substrate specificity is very low for this enzyme complex. High solubility in lipids is the only common structural feature of the wide variety of structurally unrelated drugs and chemicals that serve as substrates in this system (Table 4-1).

Table 4-1. Phase I Reactions.

Reaction Class	Structural Change	Drugs
Oxidations Cytochrome P450-dependent oxidations: Aromatic hydroxylations		Acetanilide, phenobarbital, phenylbutazone, warfarin, 17 α - naphthalene
Aliphatic hydroxylations	$RCH_2CH_3 \rightarrow RCH_2CH_2OH$ $RCH_2CH_3 \rightarrow RCH(OH)CH_3$	Amobarbital, secobarbital, ibuprofen, meprobamate, glutethimide, digitoxin
Epoxidation	$RCH=CHR \rightarrow R-\begin{array}{c} H \quad O \quad H \\ \diagdown \quad / \quad \diagdown \\ C \quad - \quad C \\ / \quad \backslash \quad / \end{array}-R$	Aldrin
Oxidative dealkylation N-Dealkylation	$RNHCH_3 \rightarrow RNH_2 + CH_2O$	Morphine, etorphine, benzphetamine, caffeine, theophylline
O-Dealkylation	$ROCH_3 \rightarrow ROH + CH_2O$	Codeine, p-nitrophenol
S-Dealkylation	$RSCH_3 \rightarrow RSH + CH_2O$	6-Methylthiothiouracil
N-Oxidation Primary amines	$RNH_2 \rightarrow RNHOH$	Aniline, chlorpheniramine
Secondary amines	$\begin{array}{c} R_1 \\ \diagdown \\ NH \\ / \\ R_2 \end{array} \rightarrow \begin{array}{c} R_1 \\ \diagdown \\ N-OH \\ / \\ R_2 \end{array}$	2-Acetylaminophenol, acetaminophen
Tertiary amines	$\begin{array}{c} R_1 \\ \diagdown \\ R_2-N \\ / \\ R_3 \end{array} \rightarrow \begin{array}{c} R_1 \\ \diagdown \\ R_2-N \rightarrow O \\ / \\ R_3 \end{array}$	Nicotine, meperidine
S-Oxidation	$\begin{array}{c} R_1 \\ \diagdown \\ S \\ / \\ R_2 \end{array} \rightarrow \begin{array}{c} R_1 \\ \diagdown \\ S=O \\ / \\ R_2 \end{array}$	Thioridazine, chlorpromazine
Deamination	$\begin{array}{c} RCHCH_3 \\ \\ NH_2 \end{array} \rightarrow \begin{array}{c} OH \\ \\ R-C-CH_3 \\ \\ NH_2 \end{array} \rightarrow \begin{array}{c} R-C(=O)CH_3 \\ \\ O \end{array} + NH_3$	Amphetamine
Desulfuration	$\begin{array}{c} R_1 \\ \diagdown \\ C=S \\ / \\ R_2 \end{array} \rightarrow \begin{array}{c} R_1 \\ \diagdown \\ C=O \\ / \\ R_2 \end{array}$	Thiopental

Enzyme Induction

Some of these chemically dissimilar drug substrates, on repeated administration, "induce" P450 by enhancing the rate of its synthesis or reducing its rate of degradation. Induction results in an acceleration of substrate metabolism and usually in a decrease in the pharmacologic action of the inducer and also of coadministered drugs. However, in the case of drugs metabolically transformed to reactive metabolites, enzyme induction may exacerbate metabolite-mediated toxicity.

Various substrates appear to induce P450 isoforms having different molecular masses and exhibiting different substrate specificities and immunochemical and spectral characteristics. The isoforms that have been most extensively studied include CYP2B1 (formerly P450b), induced by phenobarbital treatment; CYP1A1 (P₁450 or P448), induced by polycyclic aromatic hydrocarbons ("PAHs" such as benzo[*a*]pyrene and 3-methylcholanthrene); CYPs3A (including CYPs 3A4 and 3A5, the major human liver isoforms) induced by glucocorticoids, macrolide antibiotics, anticonvulsants, and some steroids. Chronic administration of isoniazid or ethanol induces a different isoform, CYP2E1, that oxidizes ethanol and activates carcinogenic nitrosamines. The VLDL-lowering drug clofibrate induces other distinct enzymes of the CYP4A class that are responsible for ω -hydroxylation of several fatty acids, leukotrienes, and prostaglandins.

Environmental pollutants are also capable of inducing P450 enzymes. As noted above, exposure to benzo[*a*]pyrene and other polycyclic aromatic hydrocarbons, which are present in tobacco smoke, charcoal-broiled meat, and other organic pyrolysis products, is known to induce CYP1A enzymes and to alter the rates of drug metabolism. Other environmental chemicals known to induce specific P450s include the polychlorinated biphenyls (PCBs), which were used widely in industry as insulating materials and plasticizers, and 2,3,7,8-tetrachlorodibenzo-*p*-dioxin (dioxin, TCDD), a trace byproduct of the chemical synthesis of the defoliant 2,4,5-T (see Chapter 57: Introduction to Toxicology: Occupational & Environmental).

Increased P450 synthesis requires enhanced transcription and translation. A cytoplasmic receptor (termed AhR) for polycyclic aromatic hydrocarbons (eg, benzo[*a*]pyrene, dioxin) has been identified, and the translocation of the inducer-receptor complex into the nucleus and subsequent activation of regulatory elements of genes have been documented. A pregnane X receptor (PXR), a member of the steroid-retinoid-thyroid hormone receptor family, has recently been shown to mediate CYP3A induction by various chemicals (dexamethasone, rifampin) in the liver and intestinal mucosa. A similar receptor, the constitutive androstane receptor (CAR) has been identified for the phenobarbital class of inducers (Sueyoshi, 2001; Willson, 2002).

P450 enzymes may also be induced by "substrate stabilization," ie, decreased degradation, as is the case with troleandomycin- or clotrimazole-mediated induction of CYP3A enzymes and the ethanol-mediated induction of CYP2E1.

Enzyme Inhibition

Certain drug substrates may inhibit cytochrome P450 enzyme activity. Imidazole-containing drugs such as cimetidine and ketoconazole bind tightly to the P450 heme iron and effectively reduce the metabolism of endogenous substrates (testosterone) or other coadministered drugs through competitive inhibition. However, macrolide antibiotics such as troleandomycin, erythromycin, and other erythromycin derivatives are metabolized, apparently by CYP3A, to metabolites that complex the cytochrome heme-iron and render it catalytically inactive. Another compound that acts through

this mechanism is the well-known inhibitor proadifen (SKF-525-A), which binds tightly to the heme-iron and quasi-irreversibly inactivates the enzyme, thereby inhibiting the metabolism of potential substrates.

Some substrates irreversibly inhibit P450s via covalent interaction of a metabolically generated reactive intermediate that may react with the P450 apoprotein or heme moiety or even cause the heme to fragment and irreversibly modify the apoprotein. The antibiotic chloramphenicol is metabolized by CYP2B1 to a species that modifies its protein and thus also inactivates the enzyme. A growing list of "**suicide inhibitors**"—inactivators that attack the heme or the protein moiety—includes the steroids ethinyl estradiol, norethindrone, and spironolactone; the anesthetic agent fluroxene; the barbiturate allobarbitol; the analgesic sedatives allylisopropylacetylurea, diethylpentenamide, and ethchlorvynol; the solvent carbon disulfide; and propylthiouracil. On the other hand, the barbiturate secobarbital is found to inactivate CYP2B1 by modification of both its heme and protein moieties.

Human Liver P450 Enzymes

Immunoblotting analyses—coupled with the use of relatively selective functional markers and selective P450 inhibitors—have identified numerous P450 isoforms (CYPs 1A2, 2A6, 2B6, 2C9, 2C19, 2D6, 2E1, 3A4, 3A5, 4A11 and 7) in human liver microsomal preparations. Of these, CYPs 1A2, 2A6, 2C9, 2D6, 2E1, and 3A4 appear to be the major forms, accounting for approximately, 12, 4, 20, 4, 6, and 28 percent, respectively, of the total human liver P450 content. Together they are responsible for catalyzing the bulk of the hepatic drug and xenobiotic metabolism (Table 4–2). It is noteworthy that CYP3A4 alone is responsible for metabolism of more than 50% of the clinically prescribed drugs metabolized by the liver. The involvement of individual P450s in the metabolism of a given drug may be screened *in vitro* by means of selective functional markers, selective chemical P450 inhibitors, and anti-P450 antibodies. *In vivo*, such screening may be accomplished by means of relatively selective noninvasive markers, which include breath tests or urinary analyses of specific metabolites after administration of a P450-selective substrate probe.

Table 4–2. Human Liver P450s (CYPs), and Some of the Drugs Metabolized (Substrates), Inducers, and Drugs Used for Screening (Noninvasive Markers).

CYP	Substrates	Inducers	Noninvasive Markers
1A2	Acetaminophen, antipyrine, caffeine, clomipramine, phenacetin, tamoxifen, theophylline, warfarin	Smoking, charcoal-broiled foods, cruciferous vegetables, omeprazole	Caffeine
2A6	Coumarin		Coumarin
2B6	Artemisinin, bupropion, cyclophosphamide, <i>S</i> -mephobarbital, <i>S</i> -mephenytoin (N-demethylation to nirvanol), propofol, selegiline, sertraline	Phenobarbital, cyclophosphamide	<i>S</i> -Mephenytoin
2C9	Hexobarbital, ibuprofen, phenytoin, tolbutamide, trimethadione, sulfaphenazole, <i>S</i> -warfarin,	Barbiturates, rifampin	Tolbutamide, warfarin

	ticrynafen		
2C19	Diazepam, <i>S</i> -mephenytoin, naproxen, nirvanol, omeprazole, propranolol	Barbiturates, rifampin	<i>S</i> -Mephenytoin
2D6	Bufuralol, bupranolol, clomipramine, clozapine, codeine, debrisoquin, dextromethorphan, encainide, flecainide, fluoxetine, guanoxan, haloperidol, hydrocodone, 4-methoxy-amphetamine, metoprolol, mexiletine, oxycodone, paroxetine, phenformin, propafenone, propoxyphene, risperidone, selegiline (deprenyl), sparteine, thioridazine, timolol, tricyclic antidepressants	None known	Debrisoquin, dextromethorphan
2E1	Acetaminophen, chlorzoxazone, enflurane, halothane, ethanol (a minor pathway)	Ethanol, isoniazid	Chlorzoxazone
3A4	Acetaminophen, alfentanil, amiodarone, astemizole, cocaine, cortisol, cyclosporine, dapsone, diazepam, dihydroergotamine, dihydropyridines, diltiazem, ethinyl estradiol, gestodene, indinavir, lidocaine, lovastatin, macrolides, methadone, miconazole, midazolam, mifepristone (RU 486), paclitaxel, progesterone, quinidine, rapamycin, ritonavir, saquinavir, spironolactone, sulfamethoxazole, sufentanil, tacrolimus, tamoxifen, terfenadine, testosterone, tetrahydro-cannabinol, triazolam, troleandomycin, verapamil	Barbiturates, carbamazepine, macrolides, glucocorticoids, pioglitazone, phenytoin, rifampin	Erythromycin, 6 β -hydroxycortisol

Phase II Reactions

Parent drugs or their phase I metabolites that contain suitable chemical groups often undergo coupling or conjugation reactions with an endogenous substance to yield drug conjugates (Table 4–3). In general, conjugates are polar molecules that are readily excreted and often inactive. Conjugate formation involves high-energy intermediates and specific transfer enzymes. Such enzymes (transferases) may be located in microsomes or in the cytosol. They catalyze the coupling of an activated endogenous substance (such as the uridine 5'-diphosphate [UDP] derivative of glucuronic acid) with a drug (or endogenous compound), or of an activated drug (such as the *S*-CoA derivative

of benzoic acid) with an endogenous substrate. Because the endogenous substrates originate in the diet, nutrition plays a critical role in the regulation of drug conjugations.

Table 4–3. Phase II Reactions.				
Type of Conjugation	Endogenous Reactant	Transferase (Location)	Types of Substrates	Examples
Glucuronidation	UDP glucuronic acid	UDP glucuronosyl-transferase (microsomes)	Phenols, alcohols, carboxylic acids, hydroxylamines, sulfonamides	Nitrophenol, morphine, acetaminophen, diazepam, <i>N</i> -hydroxydapsone, sulfathiazole, meprobamate, digitoxin, digoxin
Acetylation	Acetyl-CoA	<i>N</i> -Acetyltransferase (cytosol)	Amines	Sulfonamides, isoniazid, clonazepam, dapsone, mescaline
Glutathione conjugation	Glutathione	GSH- <i>S</i> -transferase (cytosol, microsomes)	Epoxides, arene oxides, nitro groups, hydroxylamines	Ethacrynic acid, bromobenzene
Glycine conjugation	Glycine	Acyl-CoA glycintransferase (mitochondria)	Acyl-CoA derivatives of carboxylic acids	Salicylic acid, benzoic acid, nicotinic acid, cinnamic acid, cholic acid, deoxycholic acid
Sulfate conjugation	Phosphoadenosyl phosphosulfate	Sulfotransferase (cytosol)	Phenols, alcohols, aromatic amines	Estrone, aniline, phenol, 3-hydroxycoumarin, acetaminophen, methyl dopa
Methylation	<i>S</i> -adenosyl-methionine	Transmethylases (cytosol)	Catecholamines, phenols, amines	Dopamine, epinephrine, pyridine, histamine, thiouracil
Water conjugation	Water	Epoxide hydrolase (microsomes)	Arene oxides, <i>cis</i> -disubstituted and monosubstituted oxiranes	Benzopyrene 7,8-epoxide, styrene 1,2-oxide, carbamazepine epoxide
		(cytosol)	Alkene oxides, fatty acid epoxides	Leukotriene A ₄

Drug conjugations were once believed to represent terminal inactivation events and as such have been viewed as "true detoxification" reactions. However, this concept must be modified, since it is now known that certain conjugation reactions (acyl glucuronidation of nonsteroidal anti-inflammatory drugs, O-sulfation of *N*-hydroxyacetylaminofluorene, and *N*-acetylation of isoniazid) may lead to the formation of reactive species responsible for the hepatotoxicity of the drugs. Furthermore, sulfation is known to activate the orally active prodrug minoxidil into a very efficacious vasodilator.

Metabolism of Drugs to Toxic Products

It has become evident that metabolism of drugs and other foreign chemicals may not always be an innocuous biochemical event leading to detoxification and elimination of the compound. Indeed, several compounds have been shown to be metabolically transformed to reactive intermediates that are toxic to various organs. Such toxic reactions may not be apparent at low levels of exposure to parent compounds when alternative detoxification mechanisms are not yet overwhelmed or compromised and the availability of endogenous detoxifying cosubstrates (glutathione [GSH], glucuronic acid, sulfate) is not limited. However, when these resources are exhausted, the toxic pathway may prevail, resulting in overt organ toxicity or carcinogenesis. The number of specific examples of such drug-induced toxicity is expanding rapidly. An example is acetaminophen (paracetamol)-induced hepatotoxicity (Figure 4–4). This analgesic antipyretic drug is quite safe in therapeutic doses (1.2 g/d for an adult). It normally undergoes glucuronidation and sulfation to the corresponding conjugates, which together comprise 95% of the total excreted metabolites. The alternative P450-dependent glutathione conjugation pathway accounts for the remaining 5%. When acetaminophen intake far exceeds therapeutic doses, the glucuronidation and sulfation pathways are saturated, and the P450-dependent pathway becomes increasingly important. Little or no hepatotoxicity results as long as glutathione is available for conjugation. However, with time, hepatic glutathione is depleted faster than it can be regenerated, and a reactive and toxic metabolite accumulates. In the absence of intracellular nucleophiles such as glutathione, this reactive metabolite (*N*-acetylbenzoiminoquinone) reacts with nucleophilic groups of cellular proteins, resulting in hepatotoxicity (Figure 4–4).

Figure 4–4.

Metabolism of acetaminophen (Ac) to hepatotoxic metabolites. (GSH, glutathione; GS, glutathione moiety; Ac*, reactive intermediate.)

The chemical and toxicologic characterization of the electrophilic nature of the reactive acetaminophen metabolite has led to the development of effective antidotes—cysteamine and *N*-acetylcysteine. Administration of *N*-acetylcysteine (the safer of the two) within 8–16 hours following acetaminophen overdose has been shown to protect victims from fulminant hepatotoxicity and death (see Chapter 59: Management of the Poisoned Patient).

Clinical Relevance of Drug Metabolism

The dose and the frequency of administration required to achieve effective therapeutic blood and tissue levels vary in different patients because of individual differences in drug distribution and rates of drug metabolism and elimination. These differences are determined by genetic factors and nongenetic variables such as age, sex, liver size, liver function, circadian rhythm, body temperature, and nutritional and environmental factors such as concomitant exposure to inducers or inhibitors of drug metabolism. The discussion that follows summarizes the most important of these variables.

Individual Differences

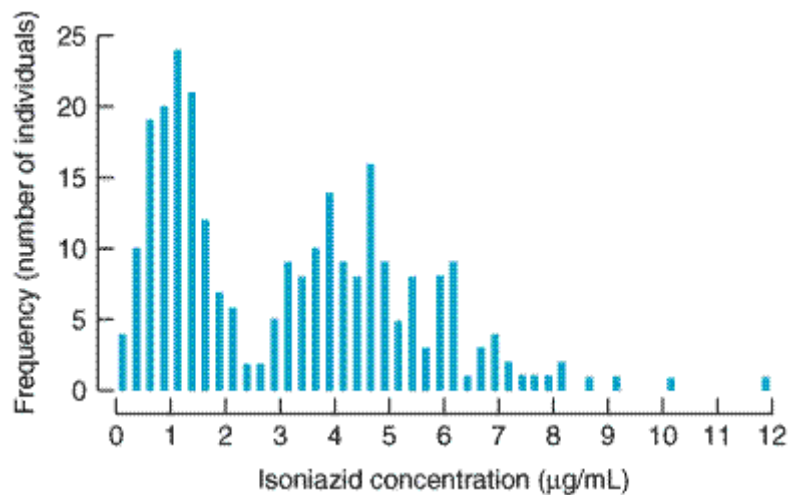

Individual differences in metabolic rate depend on the nature of the drug itself. Thus, within the same population, steady-state plasma levels may reflect a 30-fold variation in the metabolism of one drug and only a twofold variation in the metabolism of another.

Genetic Factors

Genetic factors that influence enzyme levels account for some of these differences. Succinylcholine, for example, is metabolized only half as rapidly in persons with genetically determined defects in pseudocholinesterase as in persons with normally functioning pseudocholinesterase. Analogous pharmacogenetic differences are seen in the acetylation of isoniazid (Figure 4–5) and the hydroxylation of warfarin. The defect in slow acetylators (of isoniazid and similar amines) appears to be caused by the synthesis of less of the enzyme rather than of an abnormal form of it. Inherited as an autosomal recessive trait, the slow acetylator phenotype occurs in about 50% of blacks and

whites in the USA, more frequently in Europeans living in high northern latitudes, and much less commonly in Asians and Inuits (Eskimos). Similarly, genetically determined defects in the oxidative metabolism of debrisoquin, phenacetin, guanoxan, sparteine, phenformin, warfarin and others have been reported (Table 4–4). The defects are apparently transmitted as autosomal recessive traits and may be expressed at any one of the multiple metabolic transformations that a chemical might undergo.

Figure 4–5.

Genetic polymorphism in drug metabolism. The graph shows the distribution of plasma concentrations of isoniazid in 267 individuals 6 hours after an oral dose of 9.8 mg/kg. This distribution is clearly bimodal. Individuals with a plasma concentration greater than 2.5 mg/mL at 6 hours are considered slow acetylators. (Redrawn, with permission, from Evans DAP, Manley KA, McKusick VA: Genetic control of isoniazid metabolism in man. Br Med J 1960;2:485.)

Table 4–4. Some Examples of Genetic Polymorphisms in Drug Metabolism.

Defect	Drug and Therapeutic Use	Clinical Consequences ¹
Oxidation	Bufuralol (β-adrenoceptor blocker)	Exacerbation of β-blockade, nausea
Oxidation	Codeine (analgesic) ²	Reduced analgesia
Oxidation	Debrisoquin (antihypertensive)	Orthostatic hypotension
N-Demethylation	Ethanol	Facial flushing, cardiovascular symptoms
Oxidation	Ethanol	Facial flushing, cardiovascular symptoms
N-Acetylation	Hydralazine (antihypertensive)	Lupus erythematosus-like syndrome
N-Acetylation	Isoniazid (antitubercular)	Peripheral neuropathy
Oxidation	Mephenytoin (antiepileptic)	Overdose toxicity

Thiopurine methyl-transferase	Mercaptopurines (antileukemic)	Myelotoxicity
Oxidation	Nicotine (stimulant)	Lesser addiction
Oxidation	Nortriptyline (antidepressant)	Toxicity
O-Demethylation	Omeprazole (antiulcer)	Increased therapeutic efficacy
Oxidation	Sparteine	Oxytocic symptoms
Ester hydrolysis	Succinylcholine (neuromuscular blocker)	Prolonged apnea
Oxidation	S-warfarin (anticoagulant)	Bleeding
Oxidation	Tolbutamide (hypoglycemic)	Cardiotoxicity
¹ Observed or predictable. ² Prodrug		

Of the several recognized genetic variations of drug metabolism polymorphisms, three have been particularly well characterized and afford some insight into possible underlying mechanisms. First is the debrisoquin-sparteine oxidation type of polymorphism, which apparently occurs in 3–10% of whites and is inherited as an autosomal recessive trait. In affected individuals, the CYP2D6-dependent oxidations of debrisoquin and other drugs (see Table 4–2) are impaired. These defects in oxidative drug metabolism are probably coinherited. The precise molecular basis for the defect appears to be faulty expression of the P450 protein, resulting in little or no isoform-catalyzed drug metabolism. More recently, however, another polymorphic genotype has been reported that results in ultrarapid metabolism of relevant drugs due to the presence of 2D6 allelic variants with up to 13 gene copies in tandem. This genotype is most common in Ethiopians and Saudi Arabians, populations that display it in up to one third of individuals. As a result, these subjects require twofold to threefold higher daily doses of nortriptyline (a 2D6 substrate) to achieve therapeutic plasma levels. Conversely, in these ultrarapidly metabolizing populations, the prodrug codeine (another 2D6 substrate) is metabolized much faster to morphine, often resulting in undesirable side effects of morphine such as severe abdominal pain.

A second well-studied genetic drug polymorphism involves the stereoselective aromatic (4)-hydroxylation of the anticonvulsant mephenytoin, catalyzed by CYP2C19. This polymorphism, which is also inherited as an autosomal recessive trait, occurs in 3–5% of Caucasians and 18–23% of Japanese populations. It is genetically independent of the debrisoquin-sparteine polymorphism. In normal "extensive metabolizers," (S)-mephenytoin is extensively hydroxylated by CYP2C19 at the 4 position of the phenyl ring before its glucuronidation and rapid excretion in the urine, whereas (R)-mephenytoin is slowly N-demethylated to nirvanol, an active metabolite. "Poor metabolizers," however, appear to totally lack the stereospecific (S)-mephenytoin hydroxylase activity, so both (S)- and (R)-mephenytoin enantiomers are N-demethylated to nirvanol, which accumulates in much higher concentrations. Thus, poor metabolizers of mephenytoin show signs of profound sedation and ataxia after doses of the drug that are well tolerated by normal metabolizers. The molecular basis for this defect is a single base pair mutation in exon 5 of the CYP2C19 gene that creates an aberrant splice site, a correspondingly altered reading frame of the mRNA, and, finally, a truncated nonfunctional protein. It is clinically important to recognize that the safety of a drug may be severely reduced in individuals who are poor metabolizers.

The third genetic polymorphism recently characterized is that of CYP2C9. Two well-characterized variants of this enzyme exist, each with amino acid mutations that result in altered metabolism: CYP2C9*2 allele encodes an Arg144Cys mutation, exhibiting impaired functional interactions with P450 reductase. The other allelic variant, CYP2C9*3, encodes an enzyme with an Ile359Leu mutation that has lowered affinity for many substrates. Consequently, individuals displaying the CYP2C9*3 phenotype have greatly reduced tolerance for the anticoagulant warfarin. The warfarin clearance in CYP2C9*3-homozygous individuals is only 10% of normal values, and these people can tolerate much smaller daily doses of the drug than those who are homozygous for the normal wild type allele. These individuals also have a much higher risk of adverse effects with warfarin (eg, bleeding) and with other CYP2C9 substrates such as phenytoin, losartan, tolbutamide, and some NSAIDs.

Allelic variants of CYP3A4 have also been reported but their contribution to its well-known interindividual variability in drug metabolism apparently is limited. On the other hand, the expression of CYP3A5, another human liver isoform, is markedly polymorphic, ranging from 0% to 100% of the total hepatic CYP3A content. This CYP3A5 protein polymorphism is now known to result from a single nucleotide polymorphism (SNIP) within intron 3 which enables normally spliced CYP3A5 transcripts in 5% of Caucasians, 29% of Japanese, 27% of Chinese, 30% of Koreans, and 73% of African Americans. Thus, it can significantly contribute to interindividual differences in the metabolism of preferential CYP3A5 substrates such as midazolam.

Additional genetic polymorphisms in drug metabolism that are inherited independently from those already described are being discovered. Studies of theophylline metabolism in monozygotic and dizygotic twins that included pedigree analysis of various families have revealed that a distinct polymorphism may exist for this drug and may be inherited as a recessive genetic trait. Genetic drug metabolism polymorphisms also appear to occur for aminopyrine and carbocysteine oxidations. Regularly updated information on human P450-polymorphisms is available at <http://www.imm.ki.se/CYPalleles/>.

Although genetic polymorphisms in drug oxidations often involve specific P450 enzymes, such genetic variations can occur at other sites. The recent descriptions of a polymorphism in the oxidation of trimethylamine, believed to be metabolized largely by the flavin monooxygenase (Ziegler's enzyme), suggest that genetic variants of other non-P450-dependent oxidative enzymes may also contribute to such polymorphisms.

Diet & Environmental Factors

Diet and environmental factors also contribute to individual variations in drug metabolism. Charcoal-broiled foods and cruciferous vegetables are known to induce CYP1A enzymes, whereas grapefruit juice is known to inhibit the CYP3A metabolism of coadministered drug substrates. Cigarette smokers metabolize some drugs more rapidly than nonsmokers because of enzyme induction (see above). Industrial workers exposed to some pesticides metabolize certain drugs more rapidly than nonexposed individuals. Such differences make it difficult to determine effective and safe doses of drugs that have narrow therapeutic indices.

Age & Sex

Increased susceptibility to the pharmacologic or toxic activity of drugs has been reported in very young and old patients compared with young adults (see Chapters 60 and 61). Although this may reflect differences in absorption, distribution, and elimination, differences in drug metabolism also

plays a role. Slower metabolism could be due to reduced activity of metabolic enzymes or reduced availability of essential endogenous cofactors.

Sex-dependent variations in drug metabolism have been well documented in rats but not in other rodents. Young adult male rats metabolize drugs much faster than mature female rats or prepubertal male rats. These differences in drug metabolism have been clearly associated with androgenic hormones. Clinical reports suggest that similar sex-dependent differences in drug metabolism also exist in humans for ethanol, propranolol, some benzodiazepines, estrogens, and salicylates.

Drug-Drug Interactions during Metabolism

Many substrates, by virtue of their relatively high lipophilicity, are retained not only at the active site of the enzyme but remain nonspecifically bound to the lipid membrane of the endoplasmic reticulum. In this state, they may induce microsomal enzymes; depending on the residual drug levels at the active site, they also may competitively inhibit metabolism of a simultaneously administered drug.

Enzyme-inducing drugs include various sedative-hypnotics, tranquilizers, anticonvulsants, and insecticides (Table 4–5). Patients who routinely ingest barbiturates, other sedative-hypnotics, or tranquilizers may require considerably higher doses of warfarin (an oral anticoagulant) to maintain a prolonged prothrombin time. On the other hand, discontinuance of the sedative may result in reduced metabolism of the anticoagulant and bleeding—a toxic effect of the ensuing enhanced plasma levels of the anticoagulant. Similar interactions have been observed in individuals receiving various combination drug regimens such as antipsychotics or sedatives with contraceptive agents, sedatives with anticonvulsant drugs, and even alcohol with hypoglycemic drugs (tolbutamide).

Table 4–5. Partial List of Drugs That Enhance Drug Metabolism in Humans.

Inducer	Drug Whose Metabolism Is Enhanced
Benzo[<i>a</i>]pyrene	Theophylline
Chlorcyclizine	Steroid hormones
Ethchlorvynol	Warfarin
Glutethimide	Antipyrine, glutethimide, warfarin
Griseofulvin	Warfarin
Phenobarbital and other barbiturates ¹	Barbiturates, chloramphenicol, chlorpromazine, cortisol, coumarin anticoagulants, desmethylimipramine, digitoxin, doxorubicin, estradiol, phenylbutazone, phenytoin, quinine, testosterone
Phenylbutazone	Aminopyrine, cortisol, digitoxin
Phenytoin	Cortisol, dexamethasone, digitoxin, theophylline
Rifampin	Coumarin anticoagulants, digitoxin, glucocorticoids, methadone, metoprolol, oral contraceptives, prednisone, propranolol, quinidine

¹Secobarbital is an exception. See Table 4–6 and text.

It must also be noted that an inducer may enhance not only the metabolism of other drugs but also its own metabolism. Thus, continued use of some drugs may result in a pharmacokinetic type of tolerance—progressively reduced effectiveness due to enhancement of their own metabolism.

Conversely, simultaneous administration of two or more drugs may result in impaired elimination of the more slowly metabolized drug and prolongation or potentiation of its pharmacologic effects (Table 4–6). Both competitive substrate inhibition and irreversible substrate-mediated enzyme inactivation may augment plasma drug levels and lead to toxic effects from drugs with narrow therapeutic indices. Similarly, allopurinol both prolongs the duration and enhances the chemotherapeutic action of mercaptopurine by competitive inhibition of xanthine oxidase. Consequently, to avoid bone marrow toxicity, the dose of mercaptopurine is usually reduced in patients receiving allopurinol. Cimetidine, a drug used in the treatment of peptic ulcer, has been shown to potentiate the pharmacologic actions of anticoagulants and sedatives. The metabolism of the sedative chlordiazepoxide has been shown to be inhibited by 63% after a single dose of cimetidine; such effects are reversed within 48 hours after withdrawal of cimetidine.

Table 4–6. Partial List of Drugs That Inhibit Drug Metabolism in Humans.

Inhibitor	Drug Whose Metabolism Is Inhibited
Allopurinol, chloramphenicol, isoniazid	Antipyrine, dicumarol, probenecid, tolbutamide
Cimetidine	Chlordiazepoxide, diazepam, warfarin, others
Dicumarol	Phenytoin
Diethylpentenamide	Diethylpentenamide
Disulfiram	Antipyrine, ethanol, phenytoin, warfarin
Ethanol	Chlordiazepoxide (?), diazepam (?), methanol
Grapefruit juice ¹	Alprazolam, atorvastatin, cisapride, cyclosporine, midazolam, triazolam
Ketoconazole	Cyclosporine, astemizole, terfenadine
Nortriptyline	Antipyrine
Oral contraceptives	Antipyrine
Phenylbutazone	Phenytoin, tolbutamide
Secobarbital	Secobarbital
Troleandomycin	Theophylline, methylprednisolone

¹Active components in grapefruit juice include furanocoumarins such as 6', 7'-dihydroxybergamottin (which is known to inactivate both intestinal and liver CYP3A4) as well as other unknown components that inhibit P-glycoprotein-mediated intestinal drug efflux and consequently further enhance the bioavailability of certain drugs such as cyclosporine.

Impaired metabolism may also result if a simultaneously administered drug irreversibly inactivates a common metabolizing enzyme. These inhibitors, in the course of their metabolism by cytochrome

P450, inactivate the enzyme and result in impairment of their own metabolism and that of other cosubstrates.

Interactions between Drugs & Endogenous Compounds

Various drugs require conjugation with endogenous substrates such as glutathione, glucuronic acid, and sulfate for their inactivation. Consequently, different drugs may compete for the same endogenous substrates, and the faster-reacting drug may effectively deplete endogenous substrate levels and impair the metabolism of the slower-reacting drug. If the latter has a steep dose-response curve or a narrow margin of safety, potentiation of its pharmacologic and toxic effects may result.

Diseases Affecting Drug Metabolism

Acute or chronic diseases that affect liver architecture or function markedly affect hepatic metabolism of some drugs. Such conditions include alcoholic hepatitis, active or inactive alcoholic cirrhosis, hemochromatosis, chronic active hepatitis, biliary cirrhosis, and acute viral or drug-induced hepatitis. Depending on their severity, these conditions may significantly impair hepatic drug-metabolizing enzymes, particularly microsomal oxidases, and thereby markedly affect drug elimination. For example, the half-lives of chlordiazepoxide and diazepam in patients with liver cirrhosis or acute viral hepatitis are greatly increased, with a corresponding prolongation of their effects. Consequently, these drugs may cause coma in patients with liver disease when given in ordinary doses.

Some drugs are metabolized so readily that even marked reduction in liver function does not significantly prolong their action. However, cardiac disease, by limiting blood flow to the liver, may impair disposition of those drugs whose metabolism is flow-limited (Table 4–7). These drugs are so readily metabolized by the liver that hepatic clearance is essentially equal to liver blood flow. Pulmonary disease may also affect drug metabolism as indicated by the impaired hydrolysis of procainamide and procaine in patients with chronic respiratory insufficiency and the increased half-life of antipyrine in patients with lung cancer. Impairment of enzyme activity or defective formation of enzymes associated with heavy metal poisoning or porphyria also results in reduction of hepatic drug metabolism.

Table 4–7. Rapidly Metabolized Drugs Whose Hepatic Clearance Is Blood Flow-Limited.

Alprenolol
Amitriptyline
Clomethiazole
Desipramine
Imipramine
Isoniazid
Labetalol
Lidocaine
Meperidine
Morphine
Pentazocine

Propoxyphene
Propranolol
Verapamil

Although the effects of endocrine dysfunction on drug metabolism have been well-explored in experimental animal models, corresponding data for humans with endocrine disorders are scanty. Thyroid dysfunction has been associated with altered metabolism of some drugs and of some endogenous compounds as well. Hypothyroidism increases the half-life of antipyrine, digoxin, methimazole, and practolol, whereas hyperthyroidism has the opposite effect. A few clinical studies in diabetic patients indicate no apparent impairment of drug metabolism although impairment has been noted in diabetic rats. Malfunctions of the pituitary, adrenal cortex, and gonads markedly impair hepatic drug metabolism in rats. On the basis of these findings, it may be supposed that such disorders could significantly affect drug metabolism in humans. However, until sufficient evidence is obtained from clinical studies in patients, such extrapolations must be considered tentative.

Chapter 5. Basic & Clinical Evaluation of New Drugs

Basic & Clinical Evaluation of New Drugs: Introduction

* Acknowledgment: I thank Wallace Dairman for comments and Kevin Abbey and Sema Ashkouri for their research and administrative efforts.

New drug developments have revolutionized the practice of medicine, converting many once fatal or debilitating diseases into almost routine therapeutic exercises. For example, deaths from cardiovascular disease and stroke have decreased by more than 50% in the USA over the past 30 years. This decline is due—in part—to the discovery and increased use of antihypertensives, cholesterol synthesis inhibitors, and drugs that prevent or dissolve blood clots. The process of drug discovery and development has been greatly affected by investment in new technology and by governmental support of medical research.

In most countries, the testing of therapeutic agents is now regulated by legislation and closely monitored by governmental agencies. This chapter summarizes the process by which new drugs are discovered, developed, and regulated. While the examples used reflect the experience in the USA, the pathway of new drug development is generally the same worldwide.

One of the first steps in the development of a new drug is the discovery or synthesis of a potential new drug molecule and correlating this molecule with an appropriate biologic target. Repeated application of this approach leads to compounds with increased potency and selectivity (Figure 5–1). By law, the safety and efficacy of drugs must be defined before they can be marketed. In addition to in vitro studies, most of the biologic effects of the molecule must be characterized in animals before human drug trials can be started. Human testing must then go forward in three conventional phases before the drug can be considered for approval for general use. A fourth phase of data gathering and safety monitoring follows after approval for general use.

Figure 5–1.

The development and testing process required to bring a drug to market in the USA. Some of the requirements may be different for drugs used in life-threatening diseases.

Enormous costs, from \$150 million to over \$800 million, are involved in the research and development of a single successful new drug. Thousands of compounds may be synthesized and hundreds of thousands tested from existing libraries of compounds for each successful new drug that reaches the market. It is primarily because of the economic investment and risks involved as well as the need for multiple interdisciplinary technologies that most new drugs are developed in pharmaceutical companies. At the same time, the incentives to succeed in drug development are equally enormous. The worldwide market for ethical (prescription) pharmaceuticals in 2001 was \$364 billion. Moreover, it has been estimated that during the second half of the 20th century, medications produced by the pharmaceutical industry saved more than 1.5 million lives and \$140 billion in the costs of treatment for tuberculosis, poliomyelitis, coronary artery disease, and cerebrovascular disease alone. In the USA, approximately 10% of the health care dollar is presently spent on prescription drugs.

Drug Discovery

Most new drug candidates are launched through one or more of five approaches:

1. Identification or elucidation of a new drug target
2. Rational drug design based on an understanding of biologic mechanisms, drug receptor structure, and drug structure
3. Chemical modification of a known molecule

4. Screening for biologic activity of large numbers of natural products; banks of previously discovered chemical entities; and large libraries of peptides, nucleic acids, and other organic molecules
 5. Biotechnology and cloning using genes to produce larger peptides and proteins.
- Moreover, automation, miniaturization and informatics have facilitated the process known as "high through-put screening," which permits millions of assays per month.

Major attention is now being given to the discovery of entirely new targets for drug therapy. These targets are emerging from studies with genomics, proteomics, and molecular pharmacology and are expected to increase the number of useful biologic or disease targets ten-fold and thus be a positive driver for new and improved drugs.

Drug Screening

Regardless of the source or the key idea leading to a drug candidate molecule, testing it involves a sequence of experimentation and characterization called **drug screening**. A variety of biologic assays at the molecular, cellular, organ system, and whole animal levels are used to define the activity and selectivity of the drug. The type and number of initial screening tests depend on the pharmacologic goal. Anti-infective drugs will generally be tested first against a variety of infectious organisms, hypoglycemic drugs for their ability to lower blood sugar, etc. In addition, the molecule will also be studied for a broad array of other actions to establish the mechanism of action and selectivity of the drug. This has the advantage of demonstrating unsuspected toxic effects and occasionally discloses a previously unsuspected therapeutic action. The selection of molecules for further study is most efficiently conducted in animal models of human disease. Where good predictive models exist (eg, hypertension or thrombotic disease), we generally have adequate drugs. Good drugs are conspicuously lacking for diseases for which models are poor or not yet available, eg, Alzheimer's disease.

Some of the studies performed during drug screening are listed in Table 5–1 and define the **pharmacologic profile** of the drug. For example, a broad range of tests would be performed on a drug designed to act as an antagonist at vascular α -adrenoceptors for the treatment of hypertension. At the molecular level, the compound would be screened for receptor binding affinity to cell membranes containing α receptors, possibly cloned human receptors, other receptors, and binding sites on enzymes. Early studies would be done on liver cytochrome P450 enzymes to determine whether the molecule of interest is likely to be a substrate or inhibitor of these enzymes.

Table 5–1. Pharmacologic Profile Tests.

Experimental Method or Target Organ	Species or Tissue	Route of Administration	Measurement
Molecular			
Receptor binding (example: β -adrenoceptors)	Cell membrane fractions from organs or cultured cells; cloned receptors	In vitro	Receptor affinity and selectivity
Enzyme activity (examples: tyrosine	Sympathetic nerves; adrenal glands;	In vitro	Enzyme inhibition and selectivity

hydroxylase, dopamine-3-hydroxylase, monoamine oxidase)	purified enzymes		
Cytochrome P450	Liver	In vitro	Enzyme inhibition; effects on drug metabolism
Cellular			
Cell function	Cultured cells	In vitro	Evidence for receptor activity—agonism or antagonism (example: effects on cyclic nucleotides)
Isolated tissue	Blood vessels, heart, lung, ileum (rat or guinea pig)	In vitro	Effects on vascular contraction and relaxation; selectivity for vascular receptors; effects on other smooth muscles
Systems/disease models			
Blood pressure	Dog, cat (anesthetized)	Parenteral	Systolic-diastolic changes
	Rat, hypertensive (conscious)	Oral	Antihypertensive effects
Cardiac effects	Dog (conscious)	Oral	Electrocardiography
	Dog (anesthetized)	Parenteral	Inotropic, chronotropic effects, cardiac output, total peripheral resistance
Peripheral autonomic nervous system	Dog (anesthetized)	Parenteral	Effects on response to known drugs and electrical stimulation of central and peripheral autonomic nerves
Respiratory effects	Dog, guinea pig	Parenteral	Effects on respiratory rate and amplitude, bronchial tone
Diuretic activity	Dog	Oral, parenteral	Natriuresis, kaliuresis, water diuresis, renal blood flow, glomerular filtration rate
Gastrointestinal effects	Rat	Oral	Gastrointestinal motility and secretions
Circulating hormones, cholesterol, blood sugar	Rat, dog	Parenteral, oral	Serum concentration
Blood coagulation	Rabbit	Oral	Coagulation time, clot retraction, prothrombin time
Central nervous system	Mouse, rat	Parenteral, oral	Degree of sedation, muscle relaxation, locomotor activity, stimulation

Effects on cell function would be studied to determine the efficacy of the compound. Evidence would be obtained about whether the drug is an agonist, partial agonist, or antagonist at receptors.

Isolated tissues would be utilized to characterize the pharmacologic activity and selectivity of the new compound in comparison with reference compounds. Comparison with other drugs would also be undertaken in other in vitro preparations such as gastrointestinal and bronchial smooth muscle. At each step in this process, the compound would have to meet specific performance criteria to be carried further.

Whole animal studies are generally necessary to determine the effect of the drug on organ systems and disease models. Cardiovascular and renal function studies of all new drugs are first performed in normal animals. For the hypothetical antihypertensive drug, animals with hypertension would then be treated to see if blood pressure was lowered and to characterize other effects of the compound. Evidence would be collected on duration of action and efficacy following oral and parenteral administration. If the agent possessed useful activity, it would be further studied for possible adverse effects on other major organ systems, including the respiratory, gastrointestinal, endocrine, and central nervous systems.

These studies might suggest the need for further chemical modification to achieve more desirable pharmacokinetic or pharmacodynamic properties. For example, oral administration studies might show that the drug was poorly absorbed or rapidly metabolized in the liver; modification to improve bioavailability might be indicated. If the drug was to be administered long-term, an assessment of tolerance development would be made. For drugs related to those known to cause physical dependence, abuse potential would also be studied. Finally, for each major action, a pharmacologic mechanism would be sought.

The result of this procedure (which may have to be repeated several times with variants of the original molecules) is called a **lead compound**, ie, a leading candidate for a successful new drug. A patent application may then be filed for a novel compound (composition of matter patent) that is efficacious, or for a new and nonobvious therapeutic use (use patent) for a previously known chemical entity.

Advances in molecular biology and biotechnology have introduced new approaches and new problems into the drug development process. New information about the structure of drug targets such as receptors is making possible more rational drug design. A better understanding of second messenger processes is revealing second messenger receptors as a new class of drug targets. Insertion of the genes for active peptides or proteins into bacteria, yeast, or mammalian cells makes it possible to prepare large quantities of molecules that are impractical to synthesize in the test tube. Human insulin, human growth hormone, interferon, hepatitis vaccines, tissue plasminogen activator, erythropoietin, antihemophilic factor, and bone marrow growth factors produced by these biotechnology approaches are now available for general clinical use. Antibodies used as drugs are increasingly successful.

Preclinical Safety & Toxicity Testing

Candidate drugs that survive the initial screening and profiling procedures must be carefully evaluated for potential risks before and during clinical testing. Depending on the proposed use of the drug, preclinical toxicity testing includes most or all of the procedures shown in Table 5–2. While no chemical can be certified as completely "safe" (free of risk), since every chemical is toxic at some dosage, it is usually possible to estimate the risk associated with exposure to the chemical under specified conditions if appropriate tests are performed.

Table 5–2. Safety Tests.

Type of Test	Approach	Comment
Acute toxicity	Acute dose that is lethal in approximately 50% of animals and the maximum tolerated dose. Usually two species, two routes, single dose.	Compare with therapeutic dose.
Subacute toxicity	Three doses, two species. 4 weeks to 3 months may be necessary prior to clinical trial. The longer the duration of expected clinical use, the longer the subacute test.	Clinical chemistry, physiologic signs, autopsy studies, hematology, histology, electron microscopy studies. Identify target organs of toxicity.
Chronic toxicity	Rodent and non-rodent species. 6 months or longer. Required when drug is intended to be used in humans for prolonged periods. Usually run concurrently with clinical trial.	Goals of subacute and chronic tests are to show which organs are susceptible to drug toxicity. Tests as noted above for subacute. 3 dose levels plus controls.
Effect on reproductive performance	Effects on animal mating behavior, reproduction, parturition, progeny, birth defects, postnatal development.	Examines fertility, teratology, perinatal and postnatal effects, lactation.
Carcinogenic potential	Two years, two species. Required when drug is intended to be used in humans for prolonged periods.	Hematology, histology, autopsy studies. Tests in transgenic mice for shorter periods may be permitted as one species.
Mutagenic potential	Effects on genetic stability and mutations in bacteria (Ames test) or mammalian cells in culture; dominant lethal test and clastogenicity in mice.	Increasing interest in this potential problem.
Investigative toxicology	Determine sequence and mechanisms of toxic action. Discover the genes, proteins, pathways involved. Develop new methods for assessing toxicity.	May allow rational and earlier design and identification of safer drugs. Possibly run at higher compound throughput.

The goals of preclinical toxicity studies include: identifying all potential human toxicities; designing tests to further define the toxic mechanisms; and predicting the specific and the most relevant toxicities to be monitored in clinical trials. The major kinds of information needed from preclinical toxicity studies are (1) acute toxicity—effects of large single doses up to the lethal level; (2) subacute and chronic toxicity—effects of multiple doses, which are especially important if the drug is intended for prolonged use in humans; (3) effects on reproductive functions, including teratogenicity and postnatal development; (4) carcinogenicity; (5) mutagenicity; and (6) investigative toxicology. In addition to the studies shown in Table 5–2, several quantitative estimates are desirable. These include the **"no-effect" dose**—the maximum dose at which a specified toxic effect is not seen; the **minimum lethal dose**—the smallest dose that is observed to kill any animal; and, if necessary, the **median lethal dose (LD₅₀)**—the dose that kills approximately 50% of the animals. Historically, the LD₅₀ was determined with a high degree of precision and was used to compare toxicities of compounds relative to their therapeutic doses. Presently, the LD₅₀ is now estimated from the smallest number of animals possible. These doses are

used to calculate the initial dose to be tried in humans, usually taken as one hundredth to one tenth of the no-effect dose in animals.

It is important to recognize the limitations of preclinical testing. These include the following:

1. Toxicity testing is time-consuming and expensive. During the last decade, the total cost of preclinical pharmacology and toxicology studies was estimated to be at least 41 million *per successful drug*. Two to 5 years may be required to collect and analyze data before the drug can be considered ready for testing in humans.
2. Large numbers of animals are needed to obtain valid preclinical data. Scientists are properly concerned about this situation, and progress has been made toward reducing the numbers required while still obtaining valid data. Cell and tissue culture *in vitro* methods are increasingly being used, but their predictive value is still severely limited. Nevertheless, some segments of the public attempt to halt all animal testing in the unfounded belief that it has become unnecessary.
3. Extrapolation of toxicity data from animals to humans is not completely reliable. For any given compound, the total toxicity data from all species have a very high predictive value for its toxicity in humans. However, there are limitations on the amount of information it is practical to obtain.
4. For statistical reasons, rare adverse effects are unlikely to be detected.

Evaluation in Humans

Less than one third of the drugs tested in clinical trials reach the marketplace. Federal law in the USA requires that the study of new drugs in humans be conducted in accordance with stringent guidelines. Scientifically valid results are not guaranteed simply by conforming to government regulations, however, and the design and execution of a good clinical trial requires the efforts of clinician-scientists or clinical pharmacologists, statisticians, and frequently other professionals as well. The need for careful design and execution is based on three major confounding factors inherent in the study of any therapeutic measure—pharmacologic or nonpharmacologic—in humans.

Confounding Factors in Clinical Trials

The Variable Natural History of Most Diseases

Many diseases tend to wax and wane in severity; some disappear spontaneously with time; even malignant neoplasms may, on occasion, undergo spontaneous remissions. A good experimental design must take into account the natural history of the disease under study by evaluating a large enough population of subjects over a sufficient period of time. Further protection against errors of interpretation caused by fluctuations in severity of the manifestations of disease is provided by using a crossover design, which consists of alternating periods of administration of test drug, placebo preparation (the control), and the standard treatment (positive control), if any, in each subject. These sequences are systematically varied, so that different subsets of patients receive each of the possible sequences of treatment. An example of such a design is shown in Table 5–3.

Table 5–3. Typical Crossover Design for Comparing a Mythical New Analgesic, "Novent," with Placebo and a Known Active Drug, Aspirin, in the Management of Chronic Pain. Each Therapeutic Period Lasts 7 Days, with 1 Week between Each Treatment Period for Washout of the

Preceding Medication.			
	Medication Given		
Patient Group	Week 1	Week 3	Week 5
I	Aspirin	Placebo	"Novent"
II	Placebo	"Novent"	Aspirin
III	"Novent"	Aspirin	Placebo

The Presence of Other Diseases and Risk Factors

Known and unknown diseases and risk factors (including lifestyles of subjects) may influence the results of a clinical study. For example, some diseases alter the pharmacokinetics of drugs (see Chapter 3: Pharmacokinetics & Pharmacodynamics: Rational Dosing & the Time Course of Drug Action and Chapter 4: Drug Biotransformation). Concentrations of a blood component being monitored as a measure of the effect of the new agent may be influenced by other diseases or other drugs. Attempts to avoid this hazard usually involve the crossover technique (when feasible) and proper selection and assignment of patients to each of the study groups. This requires that careful medical and pharmacologic histories (including use of recreational drugs) be obtained and that statistically valid methods of randomization be used in assigning subjects to particular study groups.

Subject and Observer Bias

Most patients tend to respond in a positive way to any therapeutic intervention by interested, caring, and enthusiastic medical personnel. The manifestation of this phenomenon in the subject is the placebo response (Latin "I shall please") and may involve objective physiologic and biochemical changes as well as changes in subjective complaints associated with the disease. The placebo response is usually quantitated by administration of an inert material, with exactly the same physical appearance, odor, consistency, etc, as the active dosage form. The magnitude of the response varies considerably from patient to patient. However, the incidence of the placebo response is fairly constant, being observed in 20–40% of patients in almost all studies. Placebo "toxicity" also occurs but usually involves subjective effects: stomach upset, insomnia, sedation, etc.

Subject bias effects can be quantitated—and discounted from the response measured during active therapy—by the **single-blind design**. This involves use of a placebo or dummy medication, as described above, which is administered to the same subjects in a crossover design, if possible, or to a separate control group of subjects. Observer bias can be taken into account by disguising the identity of the medication being used—placebo or active form—from both the subjects and the personnel evaluating the subjects' responses (**double-blind design**). In this design, a third party holds the code identifying each medication packet, and the code is not broken until all of the clinical data have been collected.

The Food & Drug Administration

The FDA is the administrative body that oversees the drug evaluation process in the USA and grants approval for marketing of new drug products. The FDA's authority to regulate drug marketing derives from several pieces of legislation (Table 5–4). If a drug has not been shown

through adequately controlled testing to be "safe and effective" for a specific use, it cannot be marketed in interstate commerce for this use.* Unfortunately, "safe" means different things to the patient, the physician, and society. As noted above, complete absence of risk is impossible to demonstrate (and probably never occurs), but this fact is not well understood by the average member of the public, who assumes that any medication sold with the approval of the FDA must indeed be free of serious "side effects." This confusion continues to be a major cause of litigation and dissatisfaction with medical care.

* Although the FDA does not directly control drug commerce within states, a variety of state and federal laws control interstate production and marketing of drugs.

The history of drug regulation reflects several medical and public health events that precipitated major shifts in public opinion. The Pure Food and Drug Act of 1906 (Table 5–4) became law mostly in response to revelations of unsanitary and unethical practices in the meat-packing industry. The Federal Food, Drug, and Cosmetic Act of 1938 was largely a reaction to a series of deaths associated with the use of a preparation of sulfanilamide that was marketed before it and its vehicle were adequately tested. Thalidomide is another example of a drug that altered drug testing methods and stimulated drug regulating legislation. This agent was introduced in Europe in 1957 and 1958 and, based on animal tests then commonly used, was promoted as a "nontoxic" hypnotic. In 1961, the first reports were published suggesting that thalidomide was responsible for a dramatic increase in the incidence of a rare birth defect called **phocomelia**, a condition involving shortening or complete absence of the limbs. Epidemiologic studies soon provided strong evidence for the association of this defect with thalidomide use by women during the first trimester of pregnancy, and the drug was withdrawn from sale worldwide. An estimated 10,000 children were born with birth defects because of maternal exposure to this one agent. The tragedy led to the requirement for more extensive testing of new drugs for teratogenic effects and played an important role in stimulating passage of the Kefauver-Harris Amendments of 1962, even though the drug was not then approved for use in the USA. In spite of its disastrous fetal toxicity, thalidomide is a relatively safe drug for humans after birth. Even the most serious risk of toxicities may be avoided or managed if understood, and despite its toxicity thalidomide is now available in the USA for limited use as a potent immunoregulatory agent and to treat leprosy.

Table 5–4. Major Legislation Pertaining to Drugs in the United States.

Law	Purpose and Effect
Pure Food and Drug Act of 1906	Prohibited mislabeling and adulteration of drugs.
Opium Exclusion Act of 1909	Prohibited importation of opium.
Amendment (1912) to the Pure Food and Drug Act	Prohibited false or fraudulent advertising claims.
Harrison Narcotic Act of 1914	Established regulations for use of opium, opiates, and cocaine (marijuana added in 1937).
Food, Drug, and Cosmetic Act of 1938	Required that new drugs be safe as well as pure (but did not require proof of efficacy). Enforcement by FDA.
Durham-Humphrey Act of 1952	Vested in the FDA the power to determine which products could be sold without prescription.
Kefauver-Harris Amendments	Required proof of efficacy as well as safety for new drugs and for

(1962) to the Food, Drug, and Cosmetic Act	drugs released since 1938; established guidelines for reporting of information about adverse reactions, clinical testing, and advertising of new drugs.
Comprehensive Drug Abuse Prevention and Control Act (1970)	Outlined strict controls in the manufacture, distribution, and prescribing of habit-forming drugs; established programs to prevent and treat drug addiction.
Orphan Drug Amendments of 1983	Amended Food, Drug, and Cosmetic Act of 1938, providing incentives for development of drugs that treat diseases with less than 200,000 patients in USA.
Drug Price Competition and Patent Restoration Act of 1984	Abbreviated new drug applications for generic drugs. Required bioequivalence data. Patent life extended by amount of time drug delayed by FDA review process. Cannot exceed 5 extra years or extend to more than 14 years post-NDA approval.
Expedited Drug Approval Act (1992)	Allowed accelerated FDA approval for drugs of high medical need. Required detailed postmarketing patient surveillance.
Prescription Drug User Fee Act (1992) Reauthorized 1997 and 2002.	Manufacturers pay user fees for certain new drug applications. FDA claims review time for new chemical entities dropped from 30 months in 1992 to 20 months in 1994.
Dietary Supplement Health and Education Act (1994)	Amended the Federal Food, Drug, and Cosmetic Act of 1938 to establish standards with respect to dietary supplements. Required the establishment of specific ingredient and nutrition information labeling that defines dietary supplements and classifies them as part of the food supply.
Bioterrorism Act of 2002	Enhanced controls on dangerous biologic agents and toxins. Seeks to protect safety of food, water, and drug supply.

Of course it is impossible, as noted above, to certify that a drug is absolutely safe, ie, free of all risk. It is possible, however, to identify most of the hazards likely to be associated with use of a new drug and to place some statistical limits on frequency of occurrence of such events in the population under study. As a result, an operational and pragmatic definition of "safety" can usually be reached that is based on the nature and incidence of drug-associated hazards compared with the hazard of nontherapy of the target disease.

Clinical Trials: The IND & NDA

The new drug approval process involves a systematic series of events (Guarino, 2000). Once a drug is judged ready to be studied in humans, a Notice of Claimed Investigational Exemption for a New Drug (IND) must be filed with the FDA (Figure 5–1). The IND includes (1) information on the composition and source of the drug, (2) manufacturing information, (3) all data from animal studies, (4) clinical plans and protocols, and (5) the names and credentials of physicians who will conduct the clinical trials.

It often requires 4–6 years of clinical testing to accumulate all required data. Testing in humans is begun after sufficient acute and subacute animal toxicity studies have been completed. Chronic safety testing in animals is usually done concurrently with clinical trials. In each of the three formal phases of clinical trials, volunteers or patients must be informed of the investigational status of the

drug as well as possible risks and must be allowed to decline or to consent to participate and receive the drug. These regulations are based on the ethical principles set forth in the Declaration of Helsinki (Editor's Page, 1966). In addition to the approval of the sponsoring organization and the FDA, an interdisciplinary institutional review board at the facility where the clinical drug trial will be conducted must review and approve the plans for testing in humans.

In **phase 1**, the effects of the drug as a function of dosage are established in a small number (25–50) of healthy volunteers. (If the drug is expected to have significant toxicity, as is often the case in cancer and AIDS therapy, volunteer patients with the disease are used in phase 1 rather than normal volunteers.) Phase 1 trials are done to determine whether humans and animals show significantly different responses to the drug and to establish the probable limits of the safe clinical dosage range. These trials are nonblind or "open," ie, both the investigators and the subjects know what is being given. Many predictable toxicities are detected in this phase. Pharmacokinetic measurements of absorption, half-life, and metabolism are often done in phase 1. Phase 1 studies are usually performed in research centers by specially trained clinical pharmacologists.

In **phase 2**, the drug is studied for the first time in patients with the target disease to determine its efficacy. A small number of patients (100–200) are studied in great detail. A single-blind design is often used, with an inert placebo medication and an older active drug (positive control) in addition to the investigational agent. Phase 2 trials are usually done in special clinical centers (eg, university hospitals). A broader range of toxicities may be detected in this phase.

In **phase 3**, the drug is evaluated in much larger numbers of patients—sometimes thousands—to further establish safety and efficacy. Using information gathered in phases 1 and 2, phase 3 trials are designed to minimize errors caused by placebo effects, variable course of the disease, etc. Therefore, double-blind and crossover techniques (like that set out in Table 5–3) are frequently used. Phase 3 trials are usually performed in settings similar to those anticipated for the ultimate use of the drug. Phase 3 studies can be difficult to design and execute and are usually expensive because of the large numbers of patients involved and the masses of data that must be collected and analyzed. The investigators are usually specialists in the disease being treated. Certain toxic effects—especially those caused by immunologic processes—may first become apparent in phase 3.

If phase 3 results meet expectations, application will be made for permission to market the new agent. The process of applying for marketing approval requires submission of a **New Drug Application (NDA)** to the FDA. The application contains, often in hundreds of volumes, full reports of all preclinical and clinical data pertaining to the drug under review. The FDA review of this material and a decision on approval may take 3 years or longer. In cases where an urgent need is perceived (eg, cancer chemotherapy), the process of preclinical and clinical testing and FDA review may be greatly accelerated. For serious diseases, the FDA may permit extensive but controlled marketing of a new drug before phase 3 studies are completed; for life-threatening diseases, it may permit controlled marketing even before phase 2 studies have been completed.

Once approval to market a drug has been obtained, **phase 4** begins. This constitutes monitoring the safety of the new drug under actual conditions of use in large numbers of patients. The importance of careful and complete reporting of toxicity by physicians after marketing begins can be appreciated by noting that many important drug-induced effects have an incidence of 1 in 10,000 or less. The sample size required to disclose drug-induced events or toxicities is very large for such rare events. For example, several hundred thousand patients may have to be exposed before the first case is observed of a toxicity that occurs with an average incidence of 1 in 10,000. Therefore low-incidence drug effects will not generally be detected before phase 4 no matter how carefully the studies are executed. Phase 4 has no fixed duration.

The time from the filing of a patent application to approval for marketing of a new drug may be 5 years or considerably longer. Since the lifetime of a patent is 20 years in the USA, the owner of the patent (usually a pharmaceutical company) has exclusive rights for marketing the product for only a limited time after approval of the NDA. Because the FDA review process can be lengthy, the time consumed by the review process is sometimes added to the patent life. However, the extension (up to 5 years) cannot increase the total life of the patent to more than 14 years post NDA approval. After expiration of the patent, any company may produce and market the drug as a **generic** product without paying license fees to the original patent owner. However, a trademark (the drug's proprietary trade name) may be legally protected indefinitely. Therefore, pharmaceutical companies are strongly motivated to give their new drugs easily remembered trade names. For example, "Prilosec" is the trade name for the antiulcer and heartburn drug "omeprazole" (see Case Study: Discovery & Development of a Blockbuster Drug—Omeprazole). For the same reason, the company's advertising material will emphasize the trade name. Generic prescribing is described in Chapter 66: Rational Prescribing & Prescription Writing.

The FDA drug approval process is one of the rate-limiting factors in the time it takes for a drug to be marketed and reach patients. The Prescription Drug User Fee Act (PDUFA) of 1992, reauthorized in 1997 and 2002, attempts to make the drug approval process more efficient by collecting fees from the drug companies that produce certain human drugs and biologic products.

Orphan Drugs

Drugs for rare diseases—so-called orphan drugs—can be difficult to research, develop, and market. Proof of drug safety and efficacy in small populations must be established, but doing so effectively is a complex process. For example, clinical testing of drugs in children is severely restricted, even for common diseases, and a number of rare diseases affect the very young. Furthermore, because basic research in the pathophysiology and mechanisms of rare diseases tends to receive little attention or funding in both academic and industrial settings, recognized rational targets for drug action may be relatively few. In addition, the cost of developing a drug can greatly influence priorities when the target population is relatively small.

The Orphan Drug Act of 1983, which amended the 1938 Federal Food, Drug, and Cosmetic Act, provides incentives for the development of drugs for treatment of diseases affecting fewer than 200,000 patients in the USA. The FDA maintains an office of Orphan Product Development to provide special assistance and grants to scientists with an interest in these products. Information on orphan drugs is also available from The National Organization for Rare Disorders.

As of 1999, more than 500 biologic or drug products were registered with the FDA as orphan drugs, most of which were products currently in development. Since 1983, the FDA has approved marketing applications for 120 orphan drugs to treat more than 82 rare diseases.

Adverse Reactions to Drugs

Severe adverse reactions to marketed drugs are uncommon, although less dangerous toxic effects, as noted elsewhere in this book, are frequent for some drug groups. Life-threatening reactions probably occur in less than 2% of patients admitted to medical wards. The mechanisms of these reactions fall into two main categories. Those in the first group are often extensions of known pharmacologic effects and thus are predictable. These toxicities are generally discovered by pharmacologists, toxicologists, and clinicians involved in phase 1–3 testing. Those in the second group, which may be immunologic or of unknown mechanism (Rawlins, 1981), are generally unexpected and may not be recognized until a drug has been marketed for many years. These

toxicities are therefore usually discovered by clinicians. It is thus important that practitioners be aware of the various types of allergic reactions to drugs. These include IgE-mediated reactions such as anaphylaxis, urticaria, and angioedema; IgG- or IgM-mediated reactions of the lupus erythematosus type; IgG-mediated responses of the serum sickness type, which involve vasculitis; and cell-mediated allergies involved in contact dermatitis. They are discussed in Chapter 56: Immunopharmacology.

Evaluating a Clinical Drug Study

The periodical literature should be the chief source of clinical information about new drugs, especially those very recently released for general use. Such information may include new indications or major new toxicities and contraindications. Therefore, health practitioners should be familiar with the sources of such information (noted in Chapter 1: Introduction) and should be prepared to evaluate it. Certain general principles can be applied to such evaluations and are discussed in detail in the Cohen (1994) and Nowak (1994) references listed below.

Case Study: Discovery & Development of a Blockbuster Drug—Omeprazole

Considerable clinical success in the treatment of gastritis, heartburn, and duodenal ulcers was achieved with the introduction of the H₂-receptor antagonist cimetidine and follow-up drugs such as ranitidine. Dr George Sachs hypothesized that control of acid secretion was accomplished via several pathways (including histamine H₂ receptors) that converged on a common target—the acid (proton) pump. He speculated that pharmacologic control of the proton pump was possible and offered a new drug target (Berkowitz and Sachs, 2002). However, because of the success of cimetidine, its producer lowered the priority for research into the direct control of the proton pump. Sachs continued his basic research on the molecular biology of this potential drug target and later began collaborating on this project with scientists at a small pharmaceutical company in Sweden.

The success of the H₂-receptor antagonist drugs significantly improved therapy, provided better regulation of gastric acid, and increased the diagnosis of acid-related disorders. However, H₂ blockers required dosing several times per day, were associated with undesirable fluctuations in gastric acid levels, and failed to optimally treat more severe disorders such as gastroesophageal reflux disease (GERD) and Zollinger-Ellison syndrome.

Sachs and his colleagues had begun work that would show that H⁺/K⁺-ATPase, as the proton pump, moves acid across the membranes of gastric parietal cells (Blum et al, 1971). Scientists at the Swedish firm had focused on imidazoles and specifically, benzimidazoles, apparently in part because cimetidine (like histamine) is an imidazole. By adding a benzimidazole moiety to pyridine-2-thioacetamide, a known antisecretory agent, a new class of substituted benzimidazoles, which would later yield omeprazole was created (Fellenius, 1981). These congeners were sufficiently novel so that patent approval, a necessary component of the project, was likely if the compounds proved useful.

Research, Development, & Marketing

Initial results yielded drugs that were found to suppress acid secretion but were too unstable, too toxic, or insufficiently selective. However, application of the drug development process described above eventually led to better molecules and omeprazole (Prilosec) was discovered in 1978. Human testing began in 1983 and 1984 (Lind et al, 1983 and Lambers et al, 1984) and marketing approval

occurred in 1989. Thus, 12 years had passed between project launch and approval for use in patients).

In 1999, worldwide sales of omeprazole were \$5.9 billion. By 2001, sales were \$5.7 billion, and the worldwide market for ulcer drugs exceeded 14 billion. There are now five benzimidazole compounds available from a number of companies. Omeprazole went off patent in 2001 and is now available as generic drug.

Section II. Autonomic Drugs

Chapter 6. Introduction to Autonomic Pharmacology

General

The motor (efferent) portion of the nervous system can be divided into two major subdivisions: **autonomic** and **somatic**. The **autonomic nervous system (ANS)** is largely autonomous (independent) in that its activities are not under direct conscious control. It is concerned primarily with visceral functions—cardiac output, blood flow to various organs, digestion, etc—that are necessary for life. The somatic division is largely concerned with consciously controlled functions such as movement, respiration, and posture. Both systems have important afferent (sensory) inputs that provide sensation and modify motor output through reflex arcs of varying size and complexity.

The nervous system has several properties in common with the endocrine system, which is the other major system for control of body function. These include high-level integration in the brain, the ability to influence processes in distant regions of the body, and extensive use of negative feedback. Both systems use chemicals for the transmission of information. In the nervous system, chemical transmission occurs between nerve cells and between nerve cells and their effector cells. Chemical transmission takes place through the release of small amounts of transmitter substances from the nerve terminals into the synaptic cleft. The transmitter crosses the cleft by diffusion and activates or inhibits the postsynaptic cell by binding to a specialized receptor molecule.

By using drugs that mimic or block the actions of chemical transmitters, we can selectively modify many autonomic functions. These functions involve a variety of effector tissues, including cardiac muscle, smooth muscle, vascular endothelium, exocrine glands, and presynaptic nerve terminals. Autonomic drugs are useful in many clinical conditions. Conversely, a very large number of drugs used for other purposes have unwanted effects on autonomic function.

Anatomy of the Autonomic Nervous System

The autonomic nervous system lends itself to division on anatomic grounds into two major portions: the **sympathetic (thoracolumbar)** division and the **parasympathetic (craniosacral)** division (Figure 6–1). Both divisions originate in nuclei within the central nervous system and give

rise to preganglionic efferent fibers that exit from the brain stem or spinal cord and terminate in motor ganglia. The sympathetic preganglionic fibers leave the central nervous system through the thoracic and lumbar spinal nerves. The parasympathetic preganglionic fibers leave the central nervous system through the cranial nerves (especially the third, seventh, ninth, and tenth) and the third and fourth sacral spinal roots.

Figure 6–1.

Schematic diagram comparing some anatomic and neurotransmitter features of autonomic and somatic motor nerves. Only the primary transmitter substances are shown. Parasympathetic ganglia are not shown because most are in or near the wall of the organ innervated. Note that some sympathetic postganglionic fibers release acetylcholine or dopamine rather than norepinephrine. The adrenal medulla, a modified sympathetic ganglion, receives sympathetic preganglionic fibers and releases epinephrine and norepinephrine into the blood. (ACh, acetylcholine; D, dopamine; Epi, epinephrine; NE, norepinephrine; N, nicotinic receptors; M, muscarinic receptors.)

Most of the sympathetic preganglionic fibers terminate in ganglia located in the paravertebral chains that lie on either side of the spinal column. The remaining sympathetic preganglionic fibers terminate in prevertebral ganglia, which lie in front of the vertebrae. From the ganglia, postganglionic sympathetic fibers run to the tissues innervated. Some preganglionic parasympathetic fibers terminate in parasympathetic ganglia located outside the organs innervated: the ciliary, pterygopalatine, submandibular, otic, and several pelvic ganglia. The majority of

parasympathetic preganglionic fibers terminate on ganglion cells distributed diffusely or in networks in the walls of the innervated organs. Note that the terms "sympathetic" and "parasympathetic" are anatomic ones and do not depend on the type of transmitter chemical released from the nerve endings nor on the kind of effect—excitatory or inhibitory—evoked by nerve activity.

In addition to these clearly defined peripheral motor portions of the autonomic nervous system, there are large numbers of afferent fibers that run from the periphery to integrating centers, including the enteric plexuses in the gut, the autonomic ganglia, and the central nervous system. Many of the sensory neurons that end in the central nervous system terminate in the integrating centers of the hypothalamus and medulla and evoke reflex motor activity that is carried to the effector cells by the efferent fibers described above. There is increasing evidence that some of these sensory fibers also have important peripheral motor functions (see Nonadrenergic, Noncholinergic Systems, below).

The **enteric nervous system (ENS)** is a large and highly organized collection of neurons located in the walls of the gastrointestinal system (Figure 6–2). It is sometimes considered a third division of the ANS. The enteric nervous system includes the myenteric plexus (the plexus of Auerbach) and the submucous plexus (the plexus of Meissner). These neuronal networks receive preganglionic fibers from the parasympathetic system as well as postganglionic sympathetic axons. They also receive sensory input from within the wall of the gut. Fibers from the cell bodies in these plexuses travel to the smooth muscle of the gut to control motility. Other motor fibers go to the secretory cells. Sensory fibers transmit information from the mucosa and from stretch receptors to motor neurons in the plexuses and to postganglionic neurons in the sympathetic ganglia. The parasympathetic and sympathetic fibers that synapse on enteric plexus neurons appear to play a modulatory role, as indicated by the observation that deprivation of input from both ANS divisions does not completely halt activity in the plexuses nor in the smooth muscle and glands innervated by them.

Figure 6–2.

A highly simplified diagram of the intestinal wall and some of the circuitry of the enteric nervous system (ENS). The ENS receives input from both the sympathetic and the parasympathetic systems and sends afferent impulses to sympathetic ganglia and to the central nervous system. Many transmitter or neuromodulator substances have been identified in the ENS; see Table 6–1. (LM, longitudinal muscle layer; MP, myenteric plexus; CM, circular muscle layer; SMP, submucosal plexus; ACh, acetylcholine; NE, norepinephrine; NO, nitric oxide; NP, neuropeptides; SP, substance P; 5-HT, serotonin.)

Neurotransmitter Chemistry of the Autonomic Nervous System

An important traditional classification of autonomic nerves is based on the primary transmitter molecules—acetylcholine or norepinephrine—released from their terminal boutons and varicosities. A large number of peripheral autonomic nervous system fibers synthesize and release acetylcholine; they are **cholinergic** fibers, ie, they act by releasing acetylcholine. As shown in Figure 6–1, these include all preganglionic efferent autonomic fibers and the somatic (nonautonomic) motor fibers to skeletal muscle as well. Thus, almost all efferent fibers leaving the central nervous system are cholinergic. In addition, most parasympathetic postganglionic and a few sympathetic postganglionic fibers are cholinergic. A significant number of parasympathetic postganglionic neurons utilize nitric

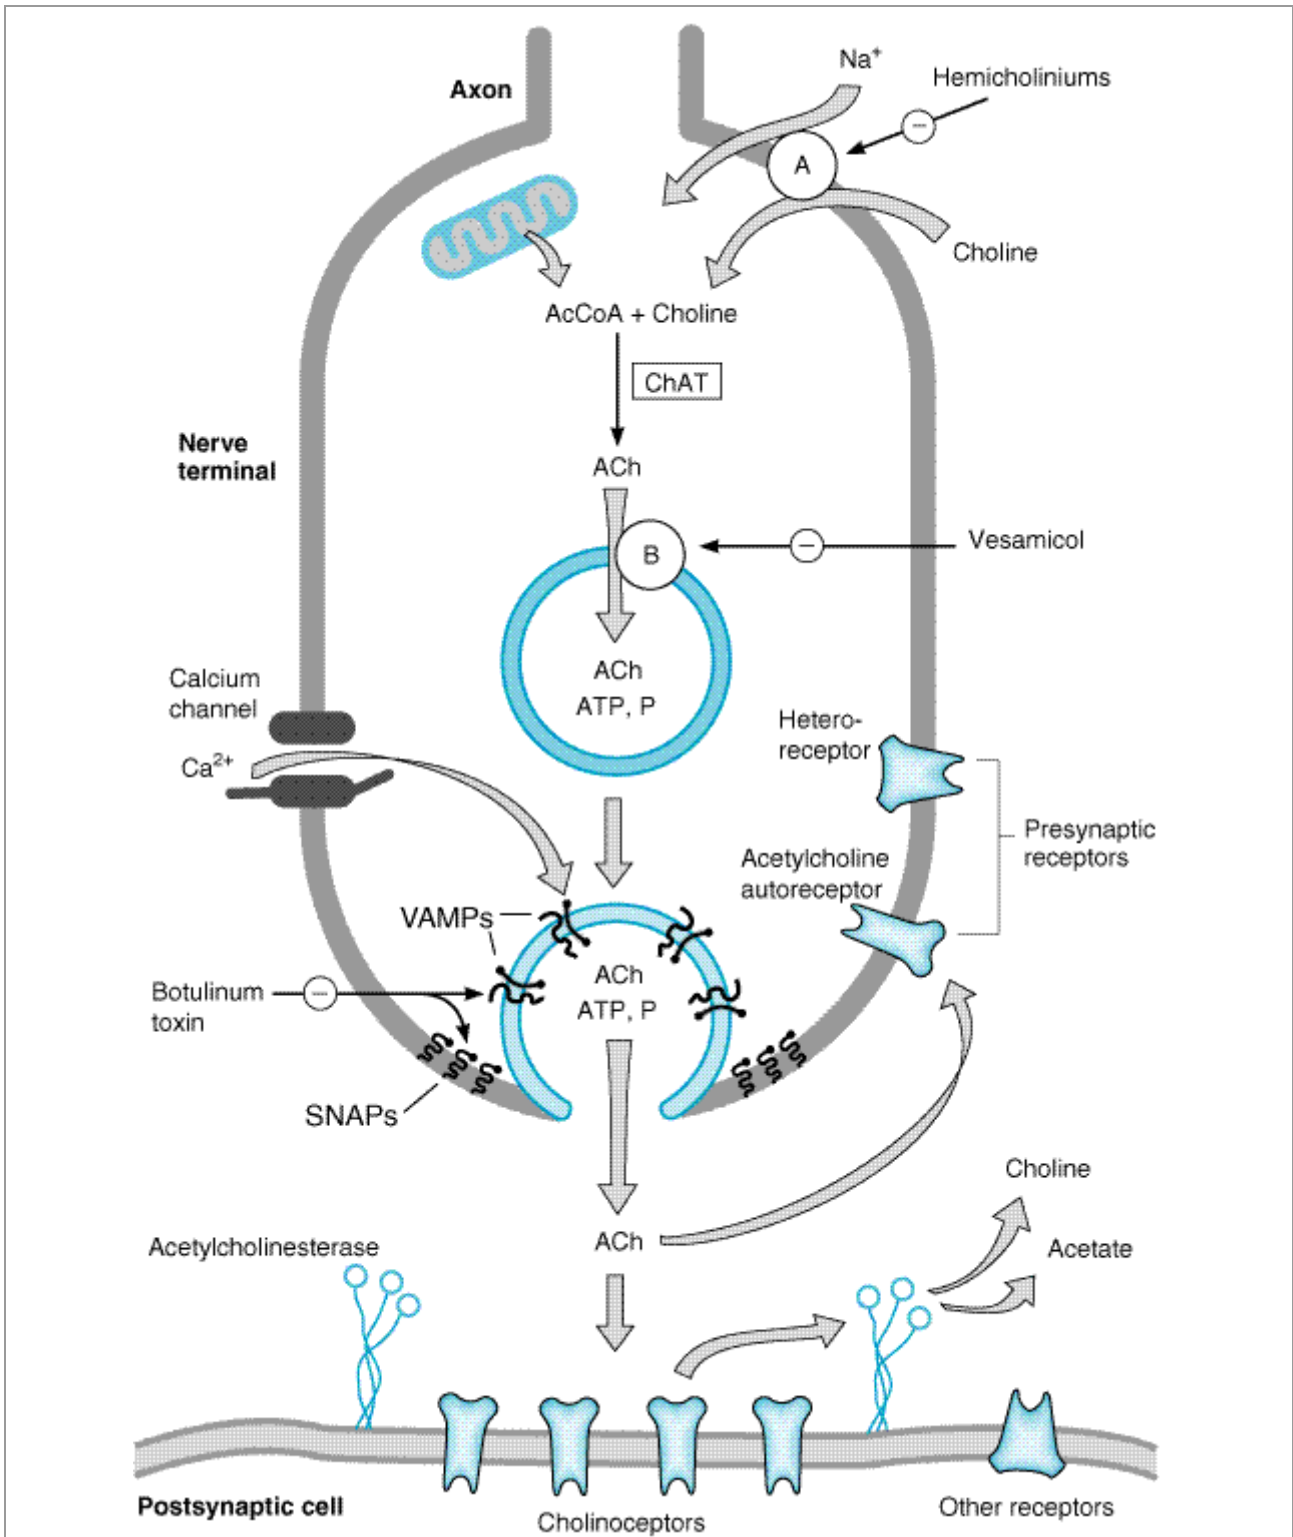

oxide or peptides for transmission. Most postganglionic sympathetic fibers release norepinephrine (noradrenaline); they are **noradrenergic** (often called simply "adrenergic") fibers—ie, they act by releasing norepinephrine. These transmitter characteristics are presented schematically in Figure 6–1. As noted above, a few sympathetic fibers release acetylcholine. Dopamine is a very important transmitter in the central nervous system, and there is evidence that it is released by some peripheral sympathetic fibers. Adrenal medullary cells, which are embryologically analogous to postganglionic sympathetic neurons, release a mixture of epinephrine and norepinephrine. Finally, most autonomic nerves also release several transmitter substances, or *cotransmitters*, in addition to the primary transmitter.

Five key features of neurotransmitter function represent potential targets of pharmacologic therapy: synthesis, storage, release, activation of receptors, and termination of action. These processes are discussed in detail below.

Cholinergic Transmission

The terminals of cholinergic neurons contain large numbers of small membrane-bound vesicles concentrated near the synaptic portion of the cell membrane (Figure 6–3) as well as a smaller number of large dense-cored vesicles located farther from the synaptic membrane. The large vesicles contain a high concentration of peptide cotransmitters (Table 6–1), while the smaller clear vesicles contain most of the acetylcholine. Vesicles are initially synthesized in the neuron soma and transported to the terminal. They may also be recycled several times within the terminal.

Figure 6–3.

Schematic illustration of a generalized cholinergic junction (not to scale). Choline is transported into the presynaptic nerve terminal by a sodium-dependent carrier (A). This transport can be inhibited by hemicholinium drugs. ACh is transported into the storage vesicle by a second carrier (B) that can be inhibited by vesamicol. Peptides (P), ATP, and proteoglycan are also stored in the vesicle. Release of transmitter occurs when voltage-sensitive calcium channels in the terminal membrane are opened, allowing an influx of calcium. The resulting increase in intracellular calcium causes fusion of vesicles with the surface membrane and exocytotic expulsion of ACh and cotransmitters into the junctional cleft. This step is blocked by botulinum toxin. Acetylcholine's action is terminated by metabolism by the enzyme acetylcholinesterase. Receptors on the

presynaptic nerve ending regulate transmitter release. (SNAPs, synaptosome-associated proteins; VAMPs, vesicle-associated membrane proteins.)

Acetylcholine is synthesized in the cytoplasm from acetyl-CoA and choline through the catalytic action of the enzyme choline acetyltransferase (ChAT). Acetyl-CoA is synthesized in mitochondria, which are present in large numbers in the nerve ending. Choline is transported from the extracellular fluid into the neuron terminal by a sodium-dependent membrane carrier (Figure 6–3, carrier A). This carrier can be blocked by a group of drugs called **hemicholiniums**. Once synthesized, acetylcholine is transported from the cytoplasm into the vesicles by an antiporter that removes protons (Figure 6–3, carrier B). This transporter can be blocked by **vesamicol**. Acetylcholine synthesis is a rapid process capable of supporting a very high rate of transmitter release. Storage of acetylcholine is accomplished by the packaging of "quanta" of acetylcholine molecules (usually 1000–50,000 molecules in each vesicle).

Release of transmitter is dependent on extracellular calcium and occurs when an action potential reaches the terminal and triggers sufficient influx of calcium ions. The increased Ca^{2+} concentration "destabilizes" the storage vesicles by interacting with special proteins associated with the vesicular membrane. Fusion of the vesicular membranes with the terminal membrane occurs through the interaction of vesicular proteins (vesicle-associated membrane proteins, **VAMPs**), eg, synaptotagmin and synaptobrevin, with several proteins of the terminal membrane (synaptosome-associated proteins, **SNAPs**), eg, SNAP-25 and syntaxin. Fusion of the membranes results in exocytotic expulsion of—in the case of somatic motor nerves—several hundred quanta of acetylcholine into the synaptic cleft. The amount of transmitter released by one depolarization of an autonomic postganglionic nerve terminal is probably smaller. In addition to acetylcholine, several cotransmitters will be released at the same time (Table 6–1). The ACh vesicle release process is blocked by botulinum toxin through the enzymatic removal of two amino acids from one or more of the fusion proteins.

Table 6–1. Some of the Transmitter Substances Found in Autonomic Nervous System (ANS), Enteric Nervous System (ENS), and Nonadrenergic, Noncholinergic Neurons.

Substance	Probable Roles
Acetylcholine (ACh)	The primary transmitter at ANS ganglia, at the somatic neuromuscular junction, and at parasympathetic postganglionic nerve endings. A primary excitatory transmitter to smooth muscle and secretory cells in the ENS. Probably also the major neuron-to-neuron ("ganglionic") transmitter in the ENS.
Adenosine triphosphate (ATP)	May act as a cotransmitter at inhibitory ENS neuromuscular junctions. Inhibits release of ACh and norepinephrine from ANS nerve endings. An excitatory transmitter in sympathetic–smooth muscle synapses.
Calcitonin gene-related peptide (CGRP)	Found with substance P in cardiovascular sensory nerve fibers. Present in some secretomotor ENS neurons and interneurons. A cardiac stimulant.
Cholecystikinin (CCK)	May act as a cotransmitter in some excitatory neuromuscular ENS neurons.
Dopamine	A possible postganglionic sympathetic transmitter in renal blood vessels. Probably a modulatory transmitter in some ganglia and the ENS.

Enkephalin and related opioid peptides	Present in some secretomotor and interneurons in the ENS. Appear to inhibit ACh release and thereby inhibit peristalsis. May <i>stimulate</i> secretion.
Galanin	Present in secretomotor neurons; may play a role in appetite-satiety mechanisms.
GABA (γ -aminobutyric acid)	May have presynaptic effects on excitatory ENS nerve terminals. Has some relaxant effect on the gut. Probably not a major transmitter in the ENS.
Gastrin-releasing peptide (GRP)	Extremely potent excitatory transmitter to gastrin cells. Also known as mammalian bombesin.
Neuropeptide Y (NPY)	Present in some secretomotor neurons in the ENS and may inhibit secretion of water and electrolytes by the gut. Causes long-lasting vasoconstriction. It is also a cotransmitter in many parasympathetic postganglionic neurons and sympathetic postganglionic noradrenergic vascular neurons.
Nitric oxide (NO)	A cotransmitter at inhibitory ENS neuromuscular junctions; especially important at sphincters. Probable transmitter for parasympathetic vasodilation.
Norepinephrine (NE)	The primary transmitter at most sympathetic postganglionic nerve endings.
Serotonin (5-HT)	A major transmitter at excitatory neuron-to-neuron junctions in the ENS.
Substance P (and related "tachykinins")	Substance P is an important sensory neuron transmitter in the ENS and elsewhere. Tachykinins appear to be excitatory cotransmitters with ACh at ENS neuromuscular junctions. Found with CGRP in cardiovascular sensory neurons. Substance P is a vasodilator (probably via release of nitric oxide).
Vasoactive intestinal peptide (VIP)	Excitatory secretomotor transmitter in the ENS; may also be an inhibitory ENS neuromuscular cotransmitter. A probable cotransmitter in many cholinergic neurons. A vasodilator (found in many perivascular neurons) and cardiac stimulant.

After release from the presynaptic terminal, acetylcholine molecules may bind to and activate an acetylcholine receptor (**cholinoceptor**). Eventually (and usually very rapidly), all of the acetylcholine released will diffuse within range of an **acetylcholinesterase** (AChE) molecule. AChE very efficiently splits acetylcholine into choline and acetate, neither of which has significant transmitter effect, and thereby terminates the action of the transmitter (Figure 6–3). Most cholinergic synapses are richly supplied with acetylcholinesterase; the half-life of acetylcholine in the synapse is therefore very short. Acetylcholinesterase is also found in other tissues, eg, red blood cells. (Another cholinesterase with a lower specificity for acetylcholine, butyrylcholinesterase [pseudocholinesterase], is found in blood plasma, liver, glia, and many other tissues.)

Adrenergic Transmission

Adrenergic neurons (Figure 6–4) also transport a precursor molecule into the nerve ending, then synthesize the catecholamine transmitter, and finally store it in membrane-bound vesicles, but—as indicated in Figure 6–5—the synthesis of the catecholamine transmitters is more complex than that of acetylcholine. In most sympathetic postganglionic neurons, norepinephrine is the final product. In the adrenal medulla and certain areas of the brain, norepinephrine is further converted to epinephrine. Conversely, synthesis terminates with dopamine in the dopaminergic neurons of the central nervous system. Several important processes in these nerve terminals are potential sites of

drug action. One of these, the conversion of tyrosine to dopa, is the rate-limiting step in catecholamine transmitter synthesis. It can be inhibited by the tyrosine analog **metyrosine** (Figure 6–4). A high-affinity carrier for catecholamines located in the wall of the storage vesicle can be inhibited by the **reserpine** alkaloids (Figure 6–4, carrier B). Depletion of transmitter stores results. Another carrier transports norepinephrine and similar molecules into the cell cytoplasm (Figure 6–4, carrier 1, commonly called uptake 1 or reuptake 1). It can be inhibited by **cocaine** and **tricyclic antidepressant** drugs, resulting in an increase of transmitter activity in the synaptic cleft.

Figure 6–4.

Schematic diagram of a generalized noradrenergic junction (not to scale). Tyrosine is transported into the noradrenergic ending or varicosity by a sodium-dependent carrier (A). Tyrosine is converted to dopamine (see Figure 6-5 for details), which is transported into the vesicle by a carrier (B) that can be blocked by reserpine. The same carrier transports norepinephrine (NE) and several other amines into these granules. Dopamine is converted to NE in the vesicle by dopamine- β -hydroxylase. Release of transmitter occurs when an action potential opens voltage-sensitive calcium channels and increases intracellular calcium. Fusion of vesicles with the surface membrane results in expulsion of norepinephrine, cotransmitters, and dopamine- β -hydroxylase.

Release can be blocked by drugs such as guanethidine and bretylium. After release, norepinephrine diffuses out of the cleft or is transported into the cytoplasm of the terminal (uptake 1 [1], blocked by cocaine, tricyclic antidepressants) or into the postjunctional cell (uptake 2 [2]). Regulatory receptors are present on the presynaptic terminal. (SNAPs, synaptosome-associated proteins; VAMPs, vesicle-associated membrane proteins.)

Figure 6-5.

Biosynthesis of catecholamines. The rate-limiting step, conversion of tyrosine to dopa, can be inhibited by metyrosine (α -methyltyrosine). The alternative pathways shown by the dashed arrows have not been found to be of physiologic significance in humans. However, tyramine and octopamine may accumulate in patients treated with monoamine oxidase inhibitors. (Reproduced, with permission, from Greenspan FS, Gardner DG (editors): *Basic and Clinical Endocrinology*, 7th ed. McGraw-Hill, 2003.)

Release of the vesicular transmitter store from noradrenergic nerve endings is similar to the calcium-dependent process described above for cholinergic terminals. In addition to the primary transmitter (norepinephrine), ATP, dopamine- β -hydroxylase, and peptide cotransmitters are also released into the synaptic cleft. Indirectly acting sympathomimetics—eg, **tyramine** and **amphetamines**—are capable of releasing stored transmitter from noradrenergic nerve endings. These drugs are poor agonists (some are inactive) at adrenoceptors but are taken up into noradrenergic nerve endings by uptake 1. In the nerve ending, they may displace norepinephrine from storage vesicles, inhibit monoamine oxidase, and have other effects that result in increased norepinephrine activity in the synapse. Their action does not require vesicle exocytosis and is not calcium-dependent.

Norepinephrine and epinephrine can be metabolized by several enzymes, as shown in Figure 6–6. Because of the high activity of monoamine oxidase in the mitochondria of the nerve terminal, there is a significant turnover of norepinephrine even in the resting terminal. Since the metabolic products are excreted in the urine, an estimate of catecholamine turnover can be obtained from laboratory analysis of total metabolites (sometimes referred to as "VMA and metanephrines") in a 24-hour urine sample. However, metabolism is not the primary mechanism for termination of action of norepinephrine physiologically released from noradrenergic nerves. Termination of noradrenergic transmission results from several processes, including simple diffusion away from the receptor site (with eventual metabolism in the plasma or liver) and reuptake into the nerve terminal (**uptake 1**) or into perisynaptic glia or smooth muscle cells (**uptake 2**) (Figure 6–4).

Figure 6–6.

Cotransmitters in Cholinergic & Adrenergic Nerves

As previously noted, the vesicles of both cholinergic and adrenergic nerves contain other substances in addition to the primary transmitter. Some of the substances identified to date are listed in Table 6-1. Many of these substances are also *primary* transmitters in the nonadrenergic, noncholinergic nerves described below. Their roles in the function of nerves that release acetylcholine or norepinephrine are not yet fully understood. In some cases, they provide a faster or slower action to

supplement or modulate the effects of the primary transmitter. They also participate in feedback inhibition of the same and nearby nerve terminals.

Autonomic Receptors

Historically, structure-activity analyses, with careful comparisons of the potency of series of autonomic agonist and antagonist analogs, led to the definition of different autonomic receptor subtypes, including muscarinic and nicotinic cholinceptors, and α , β , and dopamine adrenoceptors (Table 6–2). Molecular biology now provides techniques for the discovery and expression of genes that code for related receptors within these groups. (See Chapter 2: Drug Receptors & Pharmacodynamics, How Are New Receptors Discovered?)

Table 6–2. Autonomic Receptor Types with Documented or Probable Effects on Peripheral Autonomic Effector Tissues.		
Receptor Name	Typical Locations	Result of Ligand Binding
Cholinoceptors		
Muscarinic M ₁	CNS neurons, sympathetic postganglionic neurons, some presynaptic sites	Formation of IP ₃ and DAG, increased intracellular calcium
Muscarinic M ₂	Myocardium, smooth muscle, some presynaptic sites	Opening of potassium channels, inhibition of adenylyl cyclase
Muscarinic M ₃	Exocrine glands, vessels (smooth muscle and endothelium)	Formation of IP ₃ and DAG, increased intracellular calcium
Nicotinic N _N	Postganglionic neurons, some presynaptic cholinergic terminals	Opening of Na ⁺ , K ⁺ channels, depolarization
Nicotinic N _M	Skeletal muscle neuromuscular end plates	Opening of Na ⁺ , K ⁺ channels, depolarization
Adrenoceptors		
Alpha ₁	Postsynaptic effector cells, especially smooth muscle	Formation of IP ₃ and DAG, increased intracellular calcium
Alpha ₂	Presynaptic adrenergic nerve terminals, platelets, lipocytes, smooth muscle	Inhibition of adenylyl cyclase, decreased cAMP
Beta ₁	Postsynaptic effector cells, especially heart, lipocytes, brain; presynaptic adrenergic and cholinergic nerve terminals	Stimulation of adenylyl cyclase, increased cAMP
Beta ₂	Postsynaptic effector cells, especially smooth muscle and cardiac muscle	Stimulation of adenylyl cyclase and increased cAMP. Activates cardiac

		G _i under some conditions.
Beta ₃	Postsynaptic effector cells, especially lipocytes	Stimulation of adenylyl cyclase and increased cAMP
Dopamine receptors		
D ₁ (DA ₁), D ₅	Brain; effector tissues, especially smooth muscle of the renal vascular bed	Stimulation of adenylyl cyclase and increased cAMP
D ₂ (DA ₂)	Brain; effector tissues especially smooth muscle; presynaptic nerve terminals	Inhibition of adenylyl cyclase; increased potassium conductance
D ₃	Brain	Inhibition of adenylyl cyclase
D ₄	Brain, cardiovascular system	Inhibition of adenylyl cyclase

The primary acetylcholine receptor subtypes were named after the alkaloids originally used in their identification: muscarine and nicotine. These nouns are readily converted into adjectives—thus, **muscarinic** and **nicotinic receptors**. In the case of receptors associated with noradrenergic nerves, the coining of simple adjectives from the names of the agonists (noradrenaline, phenylephrine, isoproterenol, etc) was not practicable. Therefore, the term **adrenoceptor** is widely used to describe receptors that respond to catecholamines such as norepinephrine. By analogy, the term **cholinoceptor** denotes receptors (both muscarinic and nicotinic) that respond to acetylcholine. In North America, receptors were colloquially named after the nerves that usually innervate them; thus, **adrenergic** (or noradrenergic) **receptors** and **cholinergic receptors**. The adrenoceptors can be subdivided into α -**adrenoceptor** and β -**adrenoceptor** types on the basis of both agonist and antagonist selectivity. Development of more selective blocking drugs has led to the naming of subclasses within these major types; eg, within the α -adrenoceptor class, α_1 and α_2 receptors differ in both agonist and antagonist selectivity. Specific examples of such selective drugs are given in the chapters that follow.

Nonadrenergic, Noncholinergic Neurons

It has been known for many years that autonomic effector tissues (eg, gut, airways, bladder) contain nerve fibers that do not show the histochemical characteristics of either cholinergic or adrenergic fibers. Both motor and sensory nonadrenergic, noncholinergic fibers are present. Although peptides are the most common transmitter substances found in these nerve endings, other substances, eg, nitric oxide synthase and purines, are also present in many nerve terminals (Table 6–1). Improved immunologic assay methods now permit accurate identification and quantitation of peptides stored in and released from the fiber terminals. Capsaicin, a neurotoxin derived from chili peppers, can cause the release of transmitter (especially substance P) from such neurons and, if given in high doses, destruction of the neuron.

The enteric system in the gut wall (Figure 6–2) is the most extensively studied system containing nonadrenergic, noncholinergic neurons in addition to cholinergic and adrenergic fibers. In the small intestine, for example, these neurons contain one or more of the following: nitric oxide synthase,

calcitonin gene-related peptide, cholecystokinin, dynorphin, enkephalins, gastrin-releasing peptide, 5-hydroxytryptamine (serotonin), neuropeptide Y, somatostatin, substance P, and vasoactive intestinal peptide. Some neurons contain as many as five different transmitters. The ENS functions in a semiautonomous manner, utilizing input from the motor outflow of the ANS for modulation of gastrointestinal activity and sending sensory information back to the central nervous system. The ENS provides the necessary synchronization of impulses that, for example, ensures forward, not backward, propulsion of gut contents and relaxation of sphincters when the gut wall contracts.

The sensory fibers in the nonadrenergic, noncholinergic systems are probably better termed "sensory-efferent" or "sensory-local effector" fibers because, when activated by a sensory input, they are capable of releasing transmitter peptides from the sensory ending itself, from local axon branches, and from collaterals that terminate in the autonomic ganglia. These peptides are potent agonists at many autonomic effector tissues.

Functional Organization of Autonomic Activity

A basic understanding of the interactions of autonomic nerves with each other and with their effector organs is essential for an appreciation of the actions of autonomic drugs, especially because of the significant reflex (compensatory) effects that may be evoked by these agents.

Central Integration

At the highest level—midbrain and medulla—the two divisions of the autonomic nervous system and the endocrine system are integrated with each other, with sensory input, and with information from higher central nervous system centers. These interactions are such that early investigators called the parasympathetic system a **trophotropic** one (ie, leading to growth) used to "rest and digest" and the sympathetic system an **ergotropic** one (ie, leading to energy expenditure) that is activated for "fight or flight." While such terms offer little insight into the mechanisms involved, they do provide simple descriptions applicable to many of the actions of the systems (Table 6–3). For example, slowing of the heart and stimulation of digestive activity are typical energy-conserving actions of the parasympathetic system. In contrast, cardiac stimulation, increased blood sugar, and cutaneous vasoconstriction are responses produced by sympathetic discharge that are suited to fighting or surviving attack.

Organ	Effect of			
	Sympathetic Activity		Parasympathetic Activity	
	Action ¹	Receptor ²	Action	Receptor ²
Eye				
Iris				
Radial muscle	Contracts	α ₁
Circular muscle	Contracts	M ₃

Ciliary muscle	[Relaxes]	β	Contracts	M_3
Heart				
Sinoatrial node	Accelerates	β_1, β_2	Decelerates	M_2
Ectopic pacemakers	Accelerates	β_1, β_2
Contractility	Increases	β_1, β_2	Decreases (atria)	M_2
Blood vessels				
Skin, splanchnic vessels	Contracts	α
Skeletal muscle vessels	Relaxes	β_2
	[Contracts]	α
	Relaxes	M^3
Endothelium			Releases EDRF	M_3^4
Bronchiolar smooth muscle	Relaxes	β_2	Contracts	M_3
Gastrointestinal tract				
Smooth muscle				
Walls	Relaxes	$\alpha_2, ^5 \beta_2$	Contracts	M_3
Sphincters	Contracts	α_1	Relaxes	M_3
Secretion	Increases	M_3
Myenteric plexus			Activates	M_1
Genitourinary smooth muscle				
Bladder wall	Relaxes	β_2	Contracts	M_3
Sphincter	Contracts	α_1	Relaxes	M_3
Uterus, pregnant	Relaxes	β_2
	Contracts	α	Contracts	M_3
Penis, seminal vesicles	Ejaculation	α	Erection	M

Skin				
Pilomotor smooth muscle	Contracts	α
Sweat glands		
Thermoregulatory	Increases	M
Apocrine (stress)	Increases	α
Metabolic functions				
Liver	Gluconeogenesis	$\beta_{2,\alpha}$
Liver	Glycogenolysis	$\beta_{2,\alpha}$
Fat cells	Lipolysis	β_3
Kidney	Renin release	β_1
Autonomic nerve endings				
Sympathetic	Decreases NE release	M ⁶
Parasympathetic	Decreases ACh release	α

¹Less important actions are shown in brackets.

²Specific receptor type: α = alpha, β = beta, M = muscarinic.

³Vascular smooth muscle in skeletal muscle has sympathetic cholinergic dilator fibers.

⁴The endothelium of most blood vessels releases EDRF (endothelium-derived relaxing factor), which causes marked vasodilation, in response to muscarinic stimuli. However, unlike the receptors innervated by sympathetic cholinergic fibers in skeletal muscle blood vessels, these muscarinic receptors are not innervated and respond only to circulating muscarinic agonists.

⁵Probably through presynaptic inhibition of parasympathetic activity.

⁶Probably M₁ but M₂ may participate in some locations.

At a more subtle level of interactions in the brain stem, medulla, and spinal cord, there are important cooperative interactions between the parasympathetic and sympathetic systems. For some organs, sensory fibers associated with the parasympathetic system exert reflex control over motor outflow in the sympathetic system. Thus, the sensory carotid sinus baroreceptor fibers in the glossopharyngeal nerve have a major influence on sympathetic outflow from the vasomotor center. This example is described in greater detail below. Similarly, parasympathetic sensory fibers in the wall of the urinary bladder significantly influence sympathetic inhibitory outflow to that organ. Within the enteric nervous system, sensory fibers from the wall of the gut synapse on both preganglionic and postganglionic motor cells that control intestinal smooth muscle and secretory cells (Figure 6–2).

Integration of Cardiovascular Function

Autonomic reflexes are particularly important in understanding cardiovascular responses to autonomic drugs. As indicated in Figure 6–7, the primary controlled variable in cardiovascular function is **mean arterial pressure**. Changes in any variable contributing to mean arterial pressure (eg, a drug-induced increase in peripheral vascular resistance) will evoke powerful **homeostatic** secondary responses that tend to compensate for the directly evoked change. The homeostatic response may be sufficient to reduce the change in mean arterial pressure and to reverse the drug's effects on heart rate. A slow infusion of norepinephrine provides a useful example. This agent produces direct effects on both vascular and cardiac muscle. It is a powerful vasoconstrictor and, by increasing peripheral vascular resistance, increases mean arterial pressure. In the absence of reflex control—in a patient who has had a heart transplant, for example—the drug's effect on the heart is also stimulatory; ie, it increases heart rate and contractile force. However, in a subject with intact reflexes, the negative feedback baroreceptor response to increased mean arterial pressure causes decreased sympathetic outflow to the heart and a powerful increase in parasympathetic (vagus nerve) discharge at the cardiac pacemaker. As a result, the *net* effect of ordinary pressor doses of norepinephrine is to produce a marked increase in peripheral vascular resistance, an increase in mean arterial pressure, and a consistent *slowing* of heart rate. Bradycardia, the reflex compensatory response elicited by this agent, is the *exact opposite* of the drug's direct action; yet it is completely predictable if the integration of cardiovascular function by the autonomic nervous system is understood.

Figure 6–7.

Autonomic and hormonal control of cardiovascular function. Note that two feedback loops are present: the autonomic nervous system loop and the hormonal loop. The sympathetic nervous system directly influences four major variables: peripheral vascular resistance, heart rate, force, and venous tone. It also directly modulates renin production (not shown). The parasympathetic nervous system directly influences heart rate. Angiotensin II directly increases peripheral vascular resistance and facilitates sympathetic effects (not shown). The net feedback effect of each loop is to compensate for changes in arterial blood pressure. Thus, decreased blood pressure due to blood loss would evoke increased sympathetic outflow and renin release. Conversely, elevated pressure due to the administration of a vasoconstrictor drug would cause reduced sympathetic outflow and renin release and increased parasympathetic (vagal) outflow.

Presynaptic Regulation

The principle of negative feedback control is also found at the presynaptic level of autonomic function. Important presynaptic feedback inhibitory control mechanisms have been shown to exist at most nerve endings. A well-documented mechanism involves an α_2 receptor located on noradrenergic nerve terminals. This receptor is activated by norepinephrine and similar molecules; activation diminishes further release of norepinephrine from these nerve endings (Table 6–4). Conversely, a presynaptic β receptor appears to facilitate the release of norepinephrine. Presynaptic receptors that respond to the transmitter substances released by the nerve ending are called **autoreceptors**. Autoreceptors are usually inhibitory, but many cholinergic fibers, especially somatic motor fibers, have excitatory nicotinic autoreceptors.

Table 6–4. Autoreceptor, Heteroreceptor, and Modulatory Effects in Peripheral Synapses.¹

Transmitter/Modulator	Receptor Type	Neuron Terminals Where Found
Inhibitory effects		
Acetylcholine	M ₂	Adrenergic, enteric nervous system
Norepinephrine	Alpha ₂	Adrenergic
Dopamine	D ₂ ; less evidence for D ₁	Adrenergic
Serotonin (5-HT)	5-HT ₁ , 5-HT ₂ , 5-HT ₃	Cholinergic preganglionic
ATP and adenosine	P ₂ (ATP), P ₁ (adenosine)	Adrenergic autonomic and ENS cholinergic neurons
Histamine	H ₃ , possibly H ₂	H ₃ type identified on CNS adrenergic and serotonergic neurons
Enkephalin	Delta (also mu, kappa)	Adrenergic, ENS cholinergic
Neuropeptide Y	NPY	Adrenergic, some cholinergic

Prostaglandin E ₁ , E ₂	EP ₃	Adrenergic
Excitatory effects		
Epinephrine	Beta ₂	Adrenergic, somatic motor cholinergic
Acetylcholine	N _M	Somatic motor cholinergic, ANS cholinergic
Angiotensin II	AT ₁	Adrenergic

¹A provisional list. The number of transmitters and locations will undoubtedly increase with additional research.

Control of transmitter release is not limited to modulation by the transmitter itself. Nerve terminals also carry regulatory receptors that respond to many other substances. Such **heteroreceptors** may be activated by substances released from other nerve terminals that synapse with the nerve ending. For example, some vagal fibers in the myocardium synapse on sympathetic noradrenergic nerve terminals and inhibit norepinephrine release. Alternatively, the ligands for these receptors may diffuse to the receptors from the blood or from nearby tissues. Some of the transmitters and receptors identified to date are listed in Table 6–4. Presynaptic regulation by a variety of endogenous chemicals probably occurs in all nerve fibers.

Postsynaptic Regulation

Postsynaptic regulation can be considered from two perspectives: modulation by the prior history of activity at the primary receptor (which may up- or down-regulate receptor number or desensitize receptors; see Chapter 2: Drug Receptors & Pharmacodynamics) and modulation by other temporally associated events.

The first mechanism has been well documented in several receptor-effector systems. Up- and down-regulation are known to occur in response to decreased or increased activation, respectively, of the receptors. An extreme form of up-regulation occurs after denervation of some tissues, resulting in **denervation supersensitivity** of the tissue to activators of that receptor type. In skeletal muscle, for example, nicotinic receptors are normally restricted to the end plate regions underlying somatic motor nerve terminals. Surgical denervation results in marked proliferation of nicotinic cholinergic receptors over all parts of the fiber, including areas not previously associated with any motor nerve junctions. A pharmacologic supersensitivity related to denervation supersensitivity occurs in autonomic effector tissues after administration of drugs that deplete transmitter stores and prevent activation of the postsynaptic receptors for a sufficient period of time. For example, administration of large doses of reserpine, a norepinephrine depletor, can cause increased sensitivity of the smooth muscle and cardiac muscle effector cells served by the depleted sympathetic fibers.

The second mechanism involves modulation of the primary transmitter-receptor event by events evoked by the same or other transmitters acting on different postsynaptic receptors. Ganglionic transmission is a good example of this phenomenon (Figure 6–8). The postganglionic cells are activated (depolarized) as a result of binding of an appropriate ligand to a nicotinic (N_N) acetylcholine receptor. The resulting fast excitatory postsynaptic potential (EPSP) evokes a propagated action potential if threshold is reached. This event is often followed by a small and

slowly developing but longer-lasting hyperpolarizing afterpotential—a slow inhibitory postsynaptic potential (IPSP). The hyperpolarization involves opening of potassium channels by M_2 cholinceptors. The IPSP is followed by a small, slow excitatory postsynaptic potential caused by closure of potassium channels linked to M_1 cholinceptors. Finally, a late, very slow EPSP may be evoked by peptides released from other fibers. These slow potentials serve to modulate the responsiveness of the postsynaptic cell to subsequent primary excitatory presynaptic nerve activity. (See Chapter 21: Introduction to the Pharmacology of CNS Drugs for additional examples.)

Figure 6–8.

Excitatory and inhibitory postsynaptic potentials (*EPSP* and *IPSP*) in an autonomic ganglion cell. The postganglionic neuron shown at the left with a recording electrode might undergo the membrane potential changes shown schematically in the recording. The response begins with two EPSP responses to nicotinic (*N*) receptor activation, the first not achieving threshold. The action potential is followed by an IPSP, probably evoked by M_2 receptor activation (with possible participation from dopamine receptor activation). The IPSP is, in turn, followed by a slower M_1 -dependent EPSP, and this is sometimes followed by a still slower peptide-induced excitatory postsynaptic potential.

Pharmacologic Modification of Autonomic Function

Because transmission involves different mechanisms in different segments of the autonomic nervous system, some drugs produce highly specific effects while others are much less selective in their actions. A summary of the steps in transmission of impulses, from the central nervous system to the autonomic effector cells, is presented in Table 6–5. Drugs that block action potential propagation (local anesthetics) are very nonselective in their action, since they act on a process that is common to all neurons. On the other hand, drugs that act on the biochemical processes involved in transmitter synthesis and storage are more selective, since the biochemistry of adrenergic transmission is very different from that of cholinergic transmission. Activation or blockade of effector cell receptors offers maximum flexibility and selectivity of effect: adrenoceptors are easily distinguished from cholinceptors. Furthermore, individual subgroups can often be selectively activated or blocked within each major type. Some examples are given in Pharmacology of the Eye.

Table 6–5. Steps in Autonomic Transmission: Effects of Drugs.

Process	Drug Example	Site	Action
Action potential propagation	Local anesthetics, tetrodotoxin, ¹ saxitoxin ²	Nerve axons	Block sodium channels; block conduction
Transmitter synthesis	Hemicholinium	Cholinergic nerve terminals: membrane	Blocks uptake of choline and slows synthesis
	α -Methyltyrosine (metyrosine)	Adrenergic nerve terminals and adrenal medulla: cytoplasm	Blocks synthesis
Transmitter storage	Vesamicol	Cholinergic terminals: vesicles	Prevents storage, depletes
	Reserpine	Adrenergic terminals: vesicles	Prevents storage, depletes
Transmitter release	Many ³	Nerve terminal membrane receptors	Modulate release
	ω -Conotoxin GVIA ⁴	Nerve terminal calcium channels	Blocks calcium channels, reduces transmitter release
	Botulinum toxin	Cholinergic vesicles	Prevents release
	Alpha-latrotoxin ⁵	Cholinergic and adrenergic vesicles	Causes explosive release
	Tyramine, amphetamine	Adrenergic nerve terminals	Promote transmitter release
Transmitter uptake after release	Cocaine, tricyclic antidepressants	Adrenergic nerve terminals	Inhibit uptake; increase transmitter effect on postsynaptic receptors
	6-Hydroxydopamine	Adrenergic nerve terminals	Destroys the terminals
Receptor activation or blockade	Norepinephrine	Receptors at adrenergic junctions	Binds α receptors; causes activation
	Phentolamine	Receptors at adrenergic junctions	Binds α receptors; prevents activation
	Isoproterenol	Receptors at adrenergic junctions	Binds β receptors; activates adenylyl cyclase
	Propranolol	Receptors at adrenergic junctions	Binds β receptors; prevents activation
	Nicotine	Receptors at nicotinic cholinergic junctions (autonomic ganglia, neuromuscular end plates)	Binds nicotinic receptors; opens ion channel in

			postsynaptic membrane
	Tubocurarine	Neuromuscular end plates	Prevents activation
	Bethanechol	Receptors, parasympathetic effector cells (smooth muscle, glands)	Binds and activates muscarinic receptors
	Atropine	Receptors, parasympathetic effector cells	Binds muscarinic receptors; prevents activation
Enzymatic inactivation of transmitter	Neostigmine	Cholinergic synapses (acetylcholinesterase)	Inhibits enzyme; prolongs and intensifies transmitter action
	Tranlycypromine	Adrenergic nerve terminals (monoamine oxidase)	Inhibits enzyme; increases stored transmitter pool

²Toxin of *Gonyaulax* (red tide organism).

³Norepinephrine, dopamine, acetylcholine, peptides, various prostaglandins, etc.

⁴Toxin of marine snails of the genus *Conus*.

⁵Black widow spider venom.

The next four chapters provide many more examples of this useful diversity of autonomic control processes.

Pharmacology of the Eye

The eye is a good example of an organ with multiple ANS functions, controlled by several different autonomic receptors. As shown in Figure 6–9, the anterior chamber is the site of several tissues controlled by the ANS. These tissues include three different muscles (pupillary dilator and constrictor muscles in the iris and the ciliary muscle) and the secretory epithelium of the ciliary body.

Figure 6–9.

Structures of the anterior chamber of the eye. Tissues with significant autonomic functions and the associated ANS receptors are shown in this schematic diagram. Aqueous humor is secreted by the epithelium of the ciliary body, flows through the anterior chamber, and exits via the canal of Schlemm (arrow). Blockade of the β adrenoceptors associated with the ciliary epithelium causes decreased secretion of aqueous. Blood vessels (not shown) in the sclera are also under autonomic control and influence aqueous drainage.

Muscarinic cholinomimetics mediate contraction of the circular pupillary constrictor muscle and of the ciliary muscle. Contraction of the pupillary constrictor muscle causes miosis, a reduction in pupil size. Miosis is usually present in patients exposed to large systemic or small topical doses of cholinomimetics, especially organophosphate cholinesterase inhibitors. Ciliary muscle contraction causes accommodation of focus for near vision. Marked contraction of the ciliary muscle, which often occurs with cholinesterase inhibitor intoxication, is called *cyclospasm*. Ciliary muscle contraction also puts tension on the trabecular meshwork, opening its pores and facilitating outflow of the aqueous humor into the canal of Schlemm. Increased outflow reduces intraocular pressure, a very useful result in patients with glaucoma. All of these effects are prevented or reversed by muscarinic blocking drugs such as atropine.

Alpha adrenoceptors mediate contraction of the radially oriented pupillary dilator muscle fibers in the iris and result in mydriasis. This occurs during sympathetic discharge and when alpha agonist drugs such as phenylephrine are placed in the conjunctival sac. Beta-adrenoceptors on the ciliary

epithelium facilitate the secretion of aqueous humor. Blocking these receptors (with β -blocking drugs) reduces the secretory activity and reduces intraocular pressure, providing another therapy for glaucoma.

Chapter 7. Cholinoceptor-Activating & Cholinesterase-Inhibiting Drugs

Spectrum of Action of Cholinomimetic Drugs

Early studies of the parasympathetic nervous system showed that the alkaloid **muscarine** mimicked the effects of parasympathetic nerve discharge, ie, the effects were **parasympathomimetic**. Application of muscarine to ganglia and to autonomic effector tissues (smooth muscle, heart, exocrine glands) showed that the parasympathomimetic action of the alkaloid occurred through an action on receptors at effector cells, not those in ganglia. The effects of acetylcholine itself and of other cholinomimetic drugs at autonomic neuroeffector junctions are called parasympathomimetic effects, and are mediated by muscarinic receptors. In contrast, low concentrations of the alkaloid **nicotine** stimulated autonomic ganglia and skeletal muscle neuromuscular junctions but not autonomic effector cells. The ganglion and skeletal muscle receptors were therefore labeled nicotinic. When acetylcholine was later identified as the physiologic transmitter at both muscarinic and nicotinic receptors, both receptors were recognized as cholinoceptor subtypes.

Cholinoceptors are members of either G protein-linked (muscarinic) or ion channel (nicotinic) families on the basis of their transmembrane signaling mechanisms. Muscarinic receptors contain seven transmembrane domains whose third cytoplasmic loop is coupled to G proteins that function as intramembrane transducers (see Figure 2–11). In general, these receptors regulate the production of intracellular second messengers. Agonist selectivity is determined by the subtypes of muscarinic receptors and G proteins that are present in a given cell (Table 7–1). Muscarinic receptors are located on plasma membranes of cells in the central nervous system, in organs innervated by parasympathetic nerves as well as on some tissues that are not innervated by these nerves, eg, endothelial cells (Table 7–1), and on those tissues innervated by postganglionic sympathetic cholinergic nerves.

Table 7–1. Subtypes and Characteristics of Cholinoceptors.

Receptor Type	Other Names	Location	Structural Features	Postreceptor Mechanism
M ₁	M _{1a}	Nerves	Seven transmembrane segments, G protein-linked	IP ₃ , DAG cascade
M ₂	M _{2a} , cardiac M ₂	Heart, nerves, smooth muscle	Seven transmembrane segments, G protein-linked	Inhibition of cAMP production, activation of K ⁺ channels
M ₃	M _{2b} , glandular	Glands, smooth	Seven transmembrane	IP ₃ , DAG cascade

	M ₂	muscle, endothelium	segments, G protein-linked	
m ₄ ¹		?CNS	Seven transmembrane segments, G protein-linked	Inhibition of cAMP production
m ₅ ¹		?CNS	Seven transmembrane segments, G protein-linked	IP ₃ , DAG cascade
N _M	Muscle type, end plate receptor	Skeletal muscle neuromuscular junction	Pentamer ($\alpha_2\beta\delta\epsilon$) ²	Na ⁺ , K ⁺ depolarizing ion channel
N _N	Neuronal type, ganglion receptor	Postganglionic cell body, dendrites	α and β subunits only as $\alpha_2\beta_2$ or $\alpha_3\beta_3$	Na ⁺ , K ⁺ depolarizing ion channel

¹Genes have been cloned, but functional receptors have not been incontrovertibly identified.

²Structure in *Torpedo* electric organ and fetal mammalian muscle. In adult muscle, the ϵ subunit is replaced by an μ subunit. Several different α and β subunits have been identified in different mammalian tissues (Lukas et al, 1999).

Nicotinic receptors are part of a transmembrane polypeptide whose subunits form cation-selective ion channels (see Figure 2–9). These receptors are located on plasma membranes of postganglionic cells in all autonomic ganglia, of muscles innervated by somatic motor fibers, and of some central nervous system neurons (see Figure 6–1).

Unselective cholinergic stimulants in sufficient dosage can produce very diffuse and marked alterations in organ system function because acetylcholine has multiple sites of action where it initiates both excitatory and inhibitory effects. Fortunately, drugs are available that have a degree of selectivity, so that desired effects can often be achieved while avoiding or minimizing adverse effects. Selectivity of action is based on several factors. Some drugs stimulate either muscarinic receptors or nicotinic receptors selectively. Some agents stimulate nicotinic receptors at neuromuscular junctions preferentially and have less effect on nicotinic receptors in ganglia. Organ selectivity can also be achieved by using appropriate routes of administration ("pharmacokinetic selectivity"). For example, muscarinic stimulants can be administered topically to the surface of the eye to modify ocular function while minimizing systemic effects.

Mode of Action of Cholinomimetic Drugs

Direct-acting cholinomimetic agents directly bind to and activate muscarinic or nicotinic receptors (Figure 7–1). Indirect-acting agents produce their primary effects by inhibiting acetylcholinesterase, which hydrolyzes acetylcholine to choline and acetic acid (see Figure 6–3). By inhibiting acetylcholinesterase, the indirect-acting drugs increase the endogenous acetylcholine concentration in synaptic clefts and neuroeffector junctions, and the excess acetylcholine in turn stimulates cholinergic receptors to evoke increased responses. These drugs act primarily where acetylcholine is physiologically released and are *amplifiers* of endogenous acetylcholine.

Some cholinesterase inhibitors also inhibit butyrylcholinesterase (pseudocholinesterase). However, inhibition of butyrylcholinesterase plays little role in the action of indirect-acting cholinomimetic drugs because this enzyme is not important in the physiologic termination of synaptic acetylcholine action. Some quaternary cholinesterase inhibitors also have a modest direct action as well, eg, neostigmine, which activates neuromuscular nicotinic cholinergic receptors directly in addition to blocking cholinesterase.

Basic Pharmacology of the Direct-Acting Cholinergic Stimulants

The direct-acting cholinomimetic drugs can be divided on the basis of chemical structure into esters of choline (including acetylcholine) and alkaloids (such as muscarine and nicotine). A few of these drugs are highly selective for the muscarinic or for the nicotinic receptor. Many have effects on both receptors; acetylcholine is typical.

Chemistry & Pharmacokinetics

Structure

Four important choline esters that have been studied extensively are shown in Figure 7–2. Their permanently charged quaternary ammonium group renders them relatively insoluble in lipids. Many naturally occurring and synthetic cholinomimetic drugs that are not choline esters have been identified; a few of these are shown in Figure 7–3. The muscarinic receptor is strongly stereoselective: (*S*)-bethanechol is almost 1000 times more potent than (*R*)-bethanechol.

Figure 7–2.

Acetylcholine

Methacholine
(acetyl- β -methylcholine)

Carbamic acid

Carbachol
(carbamoylcholine)

Bethanechol
(carbamoyl- β -methylcholine)

Molecular structures of four choline esters and carbamic acid. Acetylcholine and methacholine are acetic acid esters of choline and β -methylcholine, respectively. Carbachol and bethanechol are carbamic acid esters of the same alcohols.

Absorption, Distribution, and Metabolism

Choline esters are poorly absorbed and poorly distributed into the central nervous system because they are hydrophilic. Although all are hydrolyzed in the gastrointestinal tract (and less active by the oral route), they differ markedly in their susceptibility to hydrolysis by cholinesterase in the body. Acetylcholine is very rapidly hydrolyzed (see Chapter 6: Introduction to Autonomic Pharmacology); large amounts must be infused intravenously to achieve concentrations high enough to produce detectable effects. A large intravenous bolus injection has a brief effect, typically

5–20 seconds, whereas intramuscular and subcutaneous injections produce only local effects. Methacholine is more resistant to hydrolysis, and the carbamic acid esters carbachol and bethanechol are still more resistant to hydrolysis by cholinesterase and have correspondingly longer durations of action. The β-methyl group (methacholine, bethanechol) reduces the potency of these drugs at nicotinic receptors (Table 7–2).

Table 7–2. Properties of Choline Esters.

Choline Ester	Susceptibility to Cholinesterase	Muscarinic Action	Nicotinic Action
Acetylcholine chloride	++++	+++	+++
Methacholine chloride	+	++++	None
Carbachol chloride	Negligible	++	+++
Bethanechol chloride	Negligible	++	None

The tertiary natural cholinomimetic alkaloids (pilocarpine, nicotine, lobeline; Figure 7–3) are well absorbed from most sites of administration. Nicotine, a liquid, is sufficiently lipid-soluble to be absorbed across the skin. Muscarine, a quaternary amine, is less completely absorbed from the gastrointestinal tract than the tertiary amines but is nevertheless toxic when ingested, eg, in certain mushrooms, and even enters the brain. Lobeline is a plant derivative similar to nicotine. These amines are excreted chiefly by the kidneys. Acidification of the urine accelerates clearance of the tertiary amines.

Figure 7–3.

Pharmacodynamics

Mechanism of Action

Activation of the parasympathetic nervous system modifies organ function by two major mechanisms. First, acetylcholine released from parasympathetic nerves activates muscarinic receptors on effector cells to alter organ function directly. Second, acetylcholine released from parasympathetic nerves interacts with muscarinic receptors on nerve terminals to inhibit the release of their neurotransmitter. By this mechanism, acetylcholine release and circulating muscarinic agonists indirectly alter organ function by modulating the effects of the parasympathetic and sympathetic nervous systems and perhaps nonadrenergic, noncholinergic systems.

The mechanisms by which muscarinic stimulants alter cellular function continue to be investigated. As indicated in Chapter 6: Introduction to Autonomic Pharmacology, muscarinic receptor subtypes have been characterized by binding studies and cloned. Several cellular events occur when muscarinic receptors are activated, one or more of which might serve as second messengers for muscarinic activation. All muscarinic receptors appear to be of the G-protein coupled type (see Chapter 2: Drug Receptors & Pharmacodynamics and Table 7-1). Muscarinic agonist binding activates the IP₃, DAG cascade. Some evidence implicates DAG in the opening of smooth muscle calcium channels; IP₃ releases calcium from endoplasmic and sarcoplasmic reticulum. Muscarinic agonists also increase cellular cGMP concentrations. Activation of muscarinic receptors also increases potassium flux across cardiac cell membranes and decreases it in ganglion and smooth muscle cells. This effect is mediated by the binding of an activated G protein directly to the channel. Finally, muscarinic receptor activation in some tissues (eg, heart, intestine) inhibits adenylyl cyclase activity. Moreover, muscarinic agonists can attenuate the activation of adenylyl cyclase and modulate the increase in cAMP levels induced by hormones such as catecholamines. These muscarinic effects on cAMP generation cause a reduction of the physiologic response of the organ to stimulatory hormones.

The mechanism of nicotinic receptor activation has been studied in great detail, taking advantage of three factors: (1) the receptor is present in extremely high concentration in the membranes of the electric organs of electric fish; (2) α -bungarotoxin, a component of certain snake venoms, is tightly bound to the receptors and readily labeled as a marker for isolation procedures; and (3) receptor activation results in easily measured electrical and ionic changes in the cells involved. The nicotinic receptor in muscle tissues is a pentamer of four types of glycoprotein subunits (one monomer occurs twice) with a total molecular weight of about 250,000 (see Figure 2-9). The neuronal nicotinic receptor consists of α and β subunits only (Table 7-1). Each subunit has four transmembrane segments. Each α subunit has a receptor site that, when occupied by a nicotinic agonist, causes a conformational change in the protein (channel opening) that allows sodium and potassium ions to diffuse rapidly down their concentration gradients. While binding of an agonist molecule by one of the two α subunit receptor sites only modestly increases the probability of channel opening, simultaneous binding of agonist by both of the receptor sites greatly enhances opening probability. The primary effect of nicotinic receptor activation is depolarization of the nerve cell or neuromuscular end plate membrane.

Prolonged agonist occupancy of the nicotinic receptor abolishes the effector response; ie, the postganglionic neuron stops firing (ganglionic effect), and the skeletal muscle cell relaxes (neuromuscular end plate effect). Furthermore, the continued presence of the nicotinic agonist prevents electrical recovery of the postjunctional membrane. Thus, a state of "depolarizing blockade" is induced that is refractory to reversal by other agonists. As noted below, this effect can be exploited for producing muscle paralysis.

Organ System Effects

Most of the direct organ system effects of muscarinic cholinergic stimulants are readily predicted from a knowledge of the effects of parasympathetic nerve stimulation (see Table 6–3) and the distribution of muscarinic receptors. Effects of a typical agent such as acetylcholine are listed in Table 7–3. The effects of nicotinic agonists are similarly predictable from a knowledge of the physiology of the autonomic ganglia and skeletal muscle motor end plate.

Table 7–3. Effects of Direct-Acting Cholinergic Stimulants. Only the Direct Effects Are Indicated; Homeostatic Responses to These Direct Actions May Be Important (See Text).	
Organ	Response
Eye	
Sphincter muscle of iris	Contraction (miosis)
Ciliary muscle	Contraction for near vision
Heart	
Sinoatrial node	Decrease in rate (negative chronotropy)
Atria	Decrease in contractile strength (negative inotropy). Decrease in refractory period
Atrioventricular node	Decrease in conduction velocity (negative dromotropy). Increase in refractory period
Ventricles	Small decrease in contractile strength
Blood vessels	
Arteries	Dilation (via EDRF). Constriction (high-dose direct effect)
Veins	Dilation (via EDRF). Constriction (high-dose direct effect)
Lung	
Bronchial muscle	Contraction (bronchoconstriction)
Bronchial glands	Stimulation
Gastrointestinal tract	
Motility	Increase
Sphincters	Relaxation
Secretion	Stimulation
Urinary bladder	
Detrusor	Contraction
Trigone and sphincter	Relaxation
Glands	
Sweat, salivary, lacrimal, nasopharyngeal	Secretion

Eye

Muscarinic agonists instilled into the conjunctival sac cause contraction of the smooth muscle of the iris sphincter (resulting in miosis) and of the ciliary muscle (resulting in accommodation). As a result, the iris is pulled away from the angle of the anterior chamber, and the trabecular meshwork at the base of the ciliary muscle is opened. Both effects facilitate aqueous humor outflow into the canal of Schlemm, which drains the anterior chamber.

Cardiovascular System

The primary cardiovascular effects of muscarinic agonists are reduction in peripheral vascular resistance and changes in heart rate. The direct effects listed in Table 7–3 are modified by important homeostatic reflexes, as described in Chapter 6: Introduction to Autonomic Pharmacology and depicted in Figure 6–7. Intravenous infusions of minimal effective doses of acetylcholine in humans (eg, 20–50 $\mu\text{g}/\text{min}$) cause vasodilation, resulting in a reduction in blood pressure, often accompanied by a reflex increase in heart rate. Larger doses of acetylcholine produce bradycardia and decrease atrioventricular node conduction velocity in addition to the hypotensive effect.

The direct cardiac actions of muscarinic stimulants include the following: (1) an increase in a potassium current ($I_{K(\text{ACh})}$) in atrial muscle cells and in the cells of the sinoatrial and atrioventricular nodes as well; (2) a decrease in the slow inward calcium current (I_{Ca}) in heart cells; and (3) a reduction in the hyperpolarization-activated current (I_{r}) that underlies diastolic depolarization. All of these actions are mediated by M_2 receptors and contribute to slowing the pacemaker rate. Effects (1) and (2) cause hyperpolarization and decrease the contractility of atrial cells.

The direct slowing of sinoatrial rate and atrioventricular conduction that is produced by muscarinic agonists is often opposed by reflex sympathetic discharge, elicited by the decrease in blood pressure. The resultant sympathetic-parasympathetic interaction is complex because of the muscarinic modulation of sympathetic influences that occurs by inhibition of norepinephrine release and by postjunctional cellular effects. Muscarinic receptors that are present on postganglionic parasympathetic nerve terminals allow neurally released acetylcholine to inhibit its own secretion. The neuronal muscarinic receptors need not be the same subtype as found on effector cells. Therefore, the net effect on heart rate depends on local concentrations of the agonist in the heart and in the vessels and on the level of reflex responsiveness.

Parasympathetic innervation of the ventricles is much less extensive than that of the atria and activation of ventricular muscarinic receptors results in much less physiologic effect than that seen in atria. However, during sympathetic stimulation, the effects of muscarinic agonists on ventricular function are clearly evident because of muscarinic modulation of sympathetic effects ("accentuated antagonism"; Levy et al, 1994).

In the intact organism, muscarinic agonists produce marked vasodilation. However, in earlier studies, isolated blood vessels often showed a contractile response to these agents. It is now known that acetylcholine-induced vasodilation requires the presence of intact endothelium (Figure 7–4). Muscarinic agonists release a substance (endothelium-derived relaxing factor, or EDRF) from the endothelial cells that relaxes smooth muscle. Isolated vessels prepared with the endothelium preserved consistently reproduce the vasodilation seen in the intact organism. EDRF appears to be largely nitric oxide (NO). This substance activates guanylyl cyclase and increases cGMP in smooth muscle, resulting in relaxation (see Figure 12–2).

Figure 7–4.

Activation of endothelial cell muscarinic receptors by acetylcholine releases endothelium-derived relaxing factor (nitric oxide) (EDRF [NO]), which causes relaxation of vascular smooth muscle precontracted with norepinephrine. Removal of the endothelium by rubbing eliminates the relaxant effect and reveals contraction caused by direct action of acetylcholine on vascular smooth muscle. (Modified and reproduced, with permission, from Furchgott RF, Zawadzki JV: The obligatory role of endothelial cells in the relaxation of arterial smooth muscle by acetylcholine. *Nature* 1980;288:373.)

The cardiovascular effects of all of the choline esters are similar to those of acetylcholine, the main difference being in their potency and duration of action. Because of the resistance of methacholine, carbachol, and bethanechol to acetylcholinesterase, lower doses given intravenously are sufficient to produce effects similar to those of acetylcholine, and the duration of action of these synthetic choline esters is longer. The cardiovascular effects of most of the cholinomimetic natural alkaloids and the synthetic analogs are also generally similar to those of acetylcholine.

Pilocarpine is an interesting exception to the above statement. If given intravenously (an experimental exercise), it may produce hypertension after a brief initial hypotensive response. The longer-lasting hypertensive effect can be traced to sympathetic ganglionic discharge caused by activation of postganglionic cell membrane M_1 receptors, which close K^+ channels and elicit slow excitatory (depolarizing) postsynaptic potentials. This effect, like the hypotensive effect, can be blocked by atropine, an antimuscarinic drug.

Respiratory System

Muscarinic stimulants contract the smooth muscle of the bronchial tree. In addition, the glands of the tracheobronchial mucosa are stimulated to secrete. This combination of effects can occasionally cause symptoms, especially in individuals with asthma.

Gastrointestinal Tract

Administration of muscarinic agonists, like parasympathetic nervous system stimulation, increases the secretory and motor activity of the gut. The salivary and gastric glands are strongly stimulated; the pancreas and small intestinal glands less so. Peristaltic activity is increased throughout the gut, and most sphincters are relaxed. Stimulation of contraction in this organ system involves depolarization of the smooth muscle cell membrane and increased calcium influx.

Genitourinary Tract

Muscarinic agonists stimulate the detrusor muscle and relax the trigone and sphincter muscles of the bladder, thus promoting voiding. The human uterus is not notably sensitive to muscarinic agonists.

Miscellaneous Secretory Glands

Muscarinic agonists stimulate secretion by thermoregulatory sweat, lacrimal, and nasopharyngeal glands.

Central Nervous System

The central nervous system contains both muscarinic and nicotinic receptors, the brain being relatively richer in muscarinic sites and the spinal cord containing a preponderance of nicotinic sites. The physiologic roles of these receptors are discussed in Chapter 21: Introduction to the Pharmacology of CNS Drugs.

The role of muscarinic receptors in the central nervous system has been confirmed by experiments in knockout mice (see Chapter 1: Introduction). Predictably, carbachol did not inhibit atrial rate in animals with mutated M_2 receptors. The central nervous system effects of the synthetic muscarinic agonist oxotremorine (tremor, hypothermia, and antinociception) were also lacking in mice with homozygously mutated M_2 receptors. Knockout of M_1 receptors is associated with different changes in the peripheral and central nervous systems. Oxotremorine did not suppress M current in sympathetic ganglia, and pilocarpine did not induce epileptic seizures in M_1 mutant mice.

In spite of the smaller ratio of nicotinic to muscarinic receptors in the brain, nicotine and lobeline (Figure 7–3) have important effects on the brainstem and cortex. The mild alerting action of nicotine absorbed from inhaled tobacco smoke is the best-known of these effects. In larger concentrations, nicotine induces tremor, emesis, and stimulation of the respiratory center. At still higher levels, nicotine causes convulsions, which may terminate in fatal coma. The lethal effects on the central nervous system and the fact that nicotine is readily absorbed form the basis for the use of nicotine as an insecticide. Dimethylphenylpiperazinium (DMPP), a synthetic nicotinic stimulant used in research is relatively free of these central effects because it does not cross the blood-brain barrier.

Peripheral Nervous System

The autonomic ganglia are important sites of nicotinic synaptic action. The nicotinic agents shown in Figure 7–3 cause marked activation of these nicotinic receptors and initiate action potentials in postganglionic neurons. Nicotine itself has a somewhat greater affinity for neuronal than for skeletal muscle nicotinic receptors. The action is the same on both parasympathetic and sympathetic ganglia. The initial response therefore often resembles simultaneous discharge of both the parasympathetic and the sympathetic nervous systems. In the case of the cardiovascular system, the effects of nicotine are chiefly sympathomimetic. Dramatic hypertension is produced by parenteral injection of nicotine; sympathetic tachycardia may alternate with a vagally mediated bradycardia. In the gastrointestinal and urinary tracts, the effects are largely parasympathomimetic: nausea, vomiting, diarrhea, and voiding of urine are commonly observed. Prolonged exposure may result in depolarizing blockade of the ganglia.

Neuronal nicotinic receptors are present on sensory nerve endings—especially afferent nerves in coronary arteries and the carotid and aortic bodies as well as on the glomus cells of the latter. Activation of these receptors by nicotinic stimulants and of muscarinic receptors on glomus cells by muscarinic stimulants elicits complex medullary responses, including respiratory alterations and vagal discharge.

Neuromuscular Junction

The nicotinic receptors on the neuromuscular end plate apparatus are similar but not identical to the receptors in the autonomic ganglia (see Table 7–1). Both types respond to acetylcholine and nicotine. (However, as discussed in Chapter 8: Cholinergic-Blocking Drugs, the receptors differ in their structural requirements for nicotinic blocking drugs.) When a nicotinic agonist is applied directly (by iontophoresis or by intra-arterial injection), an immediate depolarization of the end plate results, caused by an increase in permeability to sodium and potassium ions. Depending on the synchronization of depolarization of end plates throughout the muscle, the contractile response will vary from disorganized fasciculations of independent motor units to a strong contraction of the entire muscle. Depolarizing nicotinic agents that are not rapidly hydrolyzed (like nicotine itself) cause rapid development of depolarization blockade; transmission blockade persists even when the membrane has repolarized (discussed further in Chapters 8 and 27). In the case of skeletal muscle, this block is manifested as flaccid paralysis.

Basic Pharmacology of the Indirect-Acting Cholinomimetics

The actions of acetylcholine released from autonomic and somatic motor nerves are terminated by enzymatic destruction of the molecule. Hydrolysis is accomplished by the action of acetylcholinesterase, which is present in high concentrations in cholinergic synapses. The indirect-acting cholinomimetics have their primary effect at the active site of this enzyme, although some also have direct actions at nicotinic receptors. The chief differences between members of the group are chemical and pharmacokinetic—their pharmacodynamic properties are almost identical.

Chemistry & Pharmacokinetics

Structure

The commonly used cholinesterase inhibitors fall into three chemical groups: (1) simple alcohols bearing a quaternary ammonium group, eg, edrophonium; (2) carbamic acid esters of alcohols bearing quaternary or tertiary ammonium groups (carbamates, eg, neostigmine); and (3) organic derivatives of phosphoric acid (organophosphates, eg, echothiophate). Examples of the first two groups are shown in Figure 7–5. Edrophonium, neostigmine, and ambenonium are synthetic quaternary ammonium agents used in medicine. Physostigmine (eserine) is a naturally occurring tertiary amine of greater lipid solubility that is also used in therapeutics. Carbaryl (carbaril) is typical of a large group of carbamate insecticides designed for very high lipid solubility, so that absorption into the insect and distribution to its central nervous system are very rapid.

Figure 7–5.

A few of the estimated 50,000 organophosphates are shown in Figure 7–6. Many of the organophosphates (echothiophate is an exception) are highly lipid-soluble liquids. Echothiophate, a thiocholine derivative, is of clinical value because it retains the very long duration of action of other organophosphates but is more stable in aqueous solution. Soman is an extremely potent "nerve gas." Parathion and malathion are thiophosphate insecticides that are inactive as such; they are converted to the phosphate derivatives in animals and plants and are used as insecticides.

Figure 7–6.

Structures of some organophosphate cholinesterase inhibitors. The dashed lines indicate the bond that is hydrolyzed in binding to the enzyme. The shaded ester bonds in malathion represent the points of detoxification of the molecule in mammals and birds.

Absorption, Distribution, and Metabolism

Absorption of the quaternary carbamates from the conjunctiva, skin, and lungs is predictably poor, since their permanent charge renders them relatively insoluble in lipids. Similarly, much larger doses are required for oral administration than for parenteral injection. Distribution into the central nervous system is negligible. Physostigmine, in contrast, is well absorbed from all sites and can be used topically in the eye (Table 7-4). It is distributed into the central nervous system and is more toxic than the more polar quaternary carbamates. The carbamates are relatively stable in aqueous solution but can be metabolized by nonspecific esterases in the body as well as by cholinesterase. However, the duration of their effect is determined chiefly by the stability of the inhibitor-enzyme complex (see Mechanism of Action, below), not by metabolism or excretion.

Table 7-4. Therapeutic Uses and Durations of Action of Cholinesterase Inhibitors.

	Uses	Approximate Duration of Action
Alcohols		
Edrophonium	Myasthenia gravis, ileus, arrhythmias	5-15 minutes
Carbamates and related agents		
Neostigmine	Myasthenia gravis, ileus	0.5-2 hours

Pyridostigmine	Myasthenia gravis	3–6 hours
Physostigmine	Glaucoma	0.5–2 hours
Ambenonium	Myasthenia gravis	4–8 hours
Demecarium	Glaucoma	4–6 hours
Organophosphates		
Echothiophate	Glaucoma	100 hours

The organophosphate cholinesterase inhibitors (except for echothiophate) are well absorbed from the skin, lung, gut, and conjunctiva—thereby making them dangerous to humans and highly effective as insecticides. They are relatively less stable than the carbamates when dissolved in water and thus have a limited half-life in the environment (compared with the other major class of insecticides, the halogenated hydrocarbons, eg, DDT). Echothiophate is highly polar and more stable than most other organophosphates. It can be made up in aqueous solution for ophthalmic use and retains its activity for weeks.

The thiophosphate insecticides (parathion, malathion, and related compounds) are quite lipid-soluble and are rapidly absorbed by all routes. They must be activated in the body by conversion to the oxygen analogs (Figure 7–6), a process that occurs rapidly in both insects and vertebrates. Malathion and certain other organophosphate insecticides are also rapidly metabolized by other pathways to inactive products in birds and mammals but not in insects; these agents are therefore considered safe enough for sale to the general public. Unfortunately, fish cannot detoxify malathion, and significant numbers of fish have died from the heavy use of this agent on and near waterways. Parathion is not detoxified effectively in vertebrates; thus, it is considerably more dangerous than malathion to humans and livestock and is not available for general public use.

All of the organophosphates except echothiophate are distributed to all parts of the body, including the central nervous system. Poisoning with these agents therefore includes an important component of central nervous system toxicity.

Pharmacodynamics

Mechanism of Action

Acetylcholinesterase is the primary target of these drugs, but butyrylcholinesterase is also inhibited. Acetylcholinesterase is an extremely active enzyme. In the initial step, acetylcholine binds to the enzyme's active site and is hydrolyzed, yielding free choline and the acetylated enzyme. In the second step, the covalent acetylenzyme bond is split, with the addition of water (hydration). The entire process takes place in approximately 150 microseconds.

All of the cholinesterase inhibitors increase the concentration of endogenous acetylcholine at cholinceptors by inhibiting acetylcholinesterase. However, the molecular details of their interaction with the enzyme vary according to the three chemical subgroups mentioned above.

The first group, of which edrophonium is the major example, consists of quaternary alcohols. These agents reversibly bind electrostatically and by hydrogen bonds to the active site, thus preventing access of acetylcholine. The enzyme-inhibitor complex does not involve a covalent bond and is correspondingly short-lived (on the order of 2–10 minutes). The second group consists of carbamate esters, eg, neostigmine and physostigmine. These agents undergo a two-step hydrolysis sequence

analogous to that described for acetylcholine. However, the covalent bond of the *carbamoylated* enzyme is considerably more resistant to the second (hydration) process, and this step is correspondingly prolonged (on the order of 30 minutes to 6 hours). The third group consists of the organophosphates. These agents also undergo initial binding and hydrolysis by the enzyme, resulting in a *phosphorylated* active site. The covalent phosphorus-enzyme bond is extremely stable and hydrolyzes in water at a very slow rate (hundreds of hours). After the initial binding-hydrolysis step, the phosphorylated enzyme complex may undergo a process called **aging**. This process apparently involves the breaking of one of the oxygen-phosphorus bonds of the inhibitor and further strengthens the phosphorus-enzyme bond. The rate of aging varies with the particular organophosphate compound. If given before aging has occurred, strong nucleophiles like pralidoxime are able to split the phosphorus-enzyme bond and can be used as "cholinesterase regenerator" drugs for organophosphate insecticide poisoning (see Chapter 8: Cholinceptor-Blocking Drugs). Once aging has occurred, the enzyme-inhibitor complex is even more stable and is more difficult to split, even with oxime regenerator compounds.

Because of the marked differences in duration of action, the organophosphate inhibitors are sometimes referred to as "irreversible" cholinesterase inhibitors, and edrophonium and the carbamates are considered "reversible" inhibitors. However, the molecular mechanisms of action of the three groups do not support this simplistic description.

Organ System Effects

The most prominent pharmacologic effects of cholinesterase inhibitors are on the cardiovascular and gastrointestinal systems, the eye, and the skeletal muscle neuromuscular junction. Because the primary action is to amplify the actions of endogenous acetylcholine, the effects are similar (but not always identical) to the effects of the direct-acting cholinomimetic agonists.

Central Nervous System

In low concentrations, the lipid-soluble cholinesterase inhibitors cause diffuse activation on the electroencephalogram and a subjective alerting response. In higher concentrations, they cause generalized convulsions, which may be followed by coma and respiratory arrest.

Eye, Respiratory Tract, Gastrointestinal Tract, Urinary Tract

The effects of the cholinesterase inhibitors on these organ systems, all of which are well innervated by the parasympathetic nervous system, are qualitatively quite similar to the effects of the direct-acting cholinomimetics.

Cardiovascular System

The cholinesterase inhibitors can increase activation in both sympathetic and parasympathetic ganglia supplying the heart and at the acetylcholine receptors on neuroeffector cells (cardiac and vascular smooth muscles) that receive cholinergic innervation.

In the heart, the effects on the parasympathetic limb predominate. Thus, cholinesterase inhibitors such as edrophonium, physostigmine, or neostigmine mimic the effects of vagal nerve activation on the heart. Negative chronotropic, dromotropic, and inotropic effects are produced, and cardiac output falls. The fall in cardiac output is attributable to bradycardia, decreased atrial contractility, and some reduction in ventricular contractility. The latter effect occurs as a result of prejunctional

inhibition of norepinephrine release as well as inhibition of postjunctional cellular sympathetic effects.

Cholinesterase inhibitors have less marked effects on vascular smooth muscle and on blood pressure than direct-acting muscarinic agonists. This is because indirect-acting drugs can modify the tone of only those vessels that are innervated by cholinergic nerves and because the net effects on vascular tone may reflect activation of both the parasympathetic and sympathetic nervous systems. The cholinomimetic effect at the smooth muscle effector tissue is minimal since few vascular beds receive cholinergic innervation. Activation of sympathetic ganglia may increase vascular resistance.

The *net* cardiovascular effects of moderate doses of cholinesterase inhibitors therefore consist of modest bradycardia, a fall in cardiac output, and no change or a modest fall in blood pressure. Large (toxic) doses of these drugs cause more marked bradycardia (occasionally tachycardia) and hypotension.

Neuromuscular Junction

The cholinesterase inhibitors have important therapeutic and toxic effects at the skeletal muscle neuromuscular junction. Low (therapeutic) concentrations moderately prolong and intensify the actions of physiologically released acetylcholine. This increases strength of contraction, especially in muscles weakened by curare-like neuromuscular blocking agents or by myasthenia gravis. At higher concentrations, the accumulation of acetylcholine may result in fibrillation of muscle fibers. Antidromic firing of the motor neuron may also occur, resulting in fasciculations that involve an entire motor unit. With marked inhibition of acetylcholinesterase, depolarizing neuromuscular blockade occurs and that may be followed by a phase of nondepolarizing blockade as seen with succinylcholine (see Table 27–2 and Figure 27–6).

Some quaternary carbamate cholinesterase inhibitors, eg, neostigmine, have an additional *direct* nicotinic agonist effect at the neuromuscular junction. This may contribute to the effectiveness of these agents as therapy for myasthenia.

Clinical Pharmacology of the Cholinomimetics

The major therapeutic uses of the cholinomimetics are for diseases of the eye (glaucoma, accommodative esotropia), the gastrointestinal and urinary tracts (postoperative atony, neurogenic bladder), the neuromuscular junction (myasthenia gravis, curare-induced neuromuscular paralysis), and rarely, the heart (certain atrial arrhythmias). Cholinesterase inhibitors are occasionally used in the treatment of atropine overdose. Several newer cholinesterase inhibitors are being used to treat patients with Alzheimer's disease.

Clinical Uses

the Eye

Glaucoma is a disease characterized by increased intraocular pressure. Muscarinic stimulants and cholinesterase inhibitors reduce intraocular pressure by causing contraction of the ciliary body so as to facilitate outflow of aqueous humor and perhaps also by diminishing the rate of its secretion (see Figure 6–9). In the past, glaucoma was treated with either direct agonists (pilocarpine,

methacholine, carbachol) or cholinesterase inhibitors (physostigmine, demecarium, echothiophate, isofluorophate). For chronic glaucoma, these drugs have been largely replaced by topical β -blockers and prostaglandin derivatives.

Acute angle-closure glaucoma is a medical emergency that is frequently treated initially with drugs but usually requires surgery for permanent correction. Initial therapy often consists of a combination of a direct muscarinic agonist and a cholinesterase inhibitor (eg, pilocarpine plus physostigmine) as well as other drugs. Once the intraocular pressure is controlled and the danger of vision loss is diminished, the patient can be prepared for corrective surgery (iridectomy). Open-angle glaucoma and some cases of secondary glaucoma are chronic diseases that are not amenable to traditional surgical correction although newer laser techniques appear to be useful. Other treatments for glaucoma are described in the section Treatment of Glaucoma in Chapter 10: Adrenoceptor Antagonist Drugs.

Accommodative esotropia (strabismus caused by hypermetropic accommodative error) in young children is sometimes diagnosed and treated with cholinomimetic agonists. Dosage is similar to or higher than that used for glaucoma.

Gastrointestinal and Urinary Tracts

In clinical disorders that involve depression of smooth muscle activity *without obstruction*, cholinomimetic drugs with direct or indirect muscarinic effects may be helpful. These disorders include postoperative ileus (atony or paralysis of the stomach or bowel following surgical manipulation) and congenital megacolon. Urinary retention may occur postoperatively or postpartum or may be secondary to spinal cord injury or disease (neurogenic bladder). Cholinomimetics are also sometimes used to increase the tone of the lower esophageal sphincter in patients with reflux esophagitis. Of the choline esters, bethanechol is the most widely used for these disorders. For gastrointestinal problems, it is usually administered orally in a dose of 10–25 mg three or four times daily. In patients with urinary retention, bethanechol can be given subcutaneously in a dose of 5 mg and repeated in 30 minutes if necessary. Of the cholinesterase inhibitors, neostigmine is the most widely used for these applications. For paralytic ileus or atony of the urinary bladder, neostigmine can be given subcutaneously in a dose of 0.5–1 mg. If patients are able to take the drug by mouth, neostigmine can be given orally in a dose of 15 mg. In all of these situations, the clinician must be certain that there is no mechanical obstruction to outflow prior to using the cholinomimetic. Otherwise, the drug may exacerbate the problem and may even cause perforation as a result of increased pressure.

Pilocarpine has long been used to increase salivary secretion. Cevimeline is a new direct-acting muscarinic agonist used for the treatment of dry mouth associated with Sjögren's syndrome.

Neuromuscular Junction

Myasthenia gravis is a disease affecting skeletal muscle neuromuscular junctions. An autoimmune process causes production of antibodies that decrease the number of functional nicotinic receptors on the postjunctional end plates. Frequent findings are ptosis, diplopia, difficulty in speaking and swallowing, and extremity weakness. Severe disease may affect all the muscles, including those necessary for respiration. The disease resembles the neuromuscular paralysis produced by *d*-tubocurarine and similar nondepolarizing neuromuscular blocking drugs (see Chapter 27: Skeletal Muscle Relaxants). Patients with myasthenia are exquisitely sensitive to the action of curariform drugs and other drugs that interfere with neuromuscular transmission, eg, aminoglycoside antibiotics.

Cholinesterase inhibitors—but not direct-acting acetylcholine receptor agonists—are extremely valuable as therapy for myasthenia. Almost all patients are also treated with immunosuppressant drugs and some with thymectomy.

Edrophonium is sometimes used as a diagnostic test for myasthenia. A 2 mg dose is injected intravenously after baseline measurements of muscle strength have been obtained. If no reaction occurs after 45 seconds, an additional 8 mg may be injected. Some clinicians divide the 8 mg dose into two doses of 3 and 5 mg given at 45-second intervals. If the patient has myasthenia gravis, an improvement in muscle strength that lasts about 5 minutes will usually be observed.

Edrophonium is also used to assess the adequacy of treatment with the longer-acting cholinesterase inhibitors in patients with myasthenia gravis. If excessive amounts of cholinesterase inhibitor have been used, patients may become paradoxically weak because of nicotinic depolarizing blockade of the motor end plate. These patients may also exhibit symptoms of excessive stimulation of muscarinic receptors (abdominal cramps, diarrhea, increased salivation, excessive bronchial secretions, miosis, bradycardia). Small doses of edrophonium (1–2 mg intravenously) will produce no relief or even worsen weakness if the patient is receiving excessive cholinesterase inhibitor therapy. On the other hand, if the patient improves with edrophonium, an increase in cholinesterase inhibitor dosage may be indicated. Clinical situations in which severe myasthenia (myasthenic crisis) must be distinguished from excessive drug therapy (cholinergic crisis) usually occur in very ill myasthenic patients and must be managed in hospital with adequate emergency support systems (eg, mechanical ventilators) available.

Long-term therapy for myasthenia gravis is usually accomplished with neostigmine, pyridostigmine, or ambenonium. The doses are titrated to optimum levels based on changes in muscle strength. These agents are relatively short-acting and therefore require frequent dosing (every 4 hours for neostigmine and every 6 hours for pyridostigmine and ambenonium; Table 7–4). Sustained-release preparations are available but should be used only at night and if needed. Longer-acting cholinesterase inhibitors such as the organophosphate agents are not used, because the dose requirement in this disease changes too rapidly to permit smooth control with long-acting drugs.

If muscarinic effects of such therapy are prominent, they can be controlled by the administration of antimuscarinic drugs such as atropine. Frequently, tolerance to the muscarinic effects of the cholinesterase inhibitors develops, so atropine treatment is not required.

Neuromuscular blockade is frequently produced as an adjunct to surgical anesthesia, using nondepolarizing neuromuscular relaxants such as pancuronium and newer agents (see Chapter 27: Skeletal Muscle Relaxants). Following surgery, it is usually desirable to reverse this pharmacologic paralysis promptly. This can be easily accomplished with cholinesterase inhibitors; neostigmine and edrophonium are the drugs of choice. They are given intravenously or intramuscularly for prompt effect.

Heart

The short-acting cholinesterase inhibitor edrophonium had been used to treat supraventricular tachyarrhythmias, particularly paroxysmal supraventricular tachycardia. In this application, edrophonium has been replaced by newer drugs (adenosine and the calcium channel blockers verapamil and diltiazem).

Antimuscarinic Drug Intoxication

Atropine intoxication is potentially lethal in children (see Chapter 8: Cholinoceptor-Blocking Drugs) and may cause prolonged severe behavioral disturbances and arrhythmias in adults. The tricyclic antidepressants, when taken in overdosage (often with suicidal intent), also cause severe muscarinic blockade (see Chapter 30: Antidepressant Agents). The muscarinic receptor blockade produced by all these agents is competitive in nature and can be overcome by increasing the amount of endogenous acetylcholine present at the neuroeffector junctions. Theoretically, a cholinesterase inhibitor could be used to reverse these effects. Physostigmine has been used for this application, because it enters the central nervous system and reverses the central as well as the peripheral signs of muscarinic blockade. However, as noted previously, physostigmine itself can produce dangerous central nervous system effects, and such therapy is therefore used only in patients with dangerous elevation of body temperature or very rapid supraventricular tachycardia.

Central Nervous System

Tacrine is a drug with anticholinesterase and other cholinomimetic actions that has been used for the treatment of mild to moderate Alzheimer's disease. Evidence for tacrine's efficacy is modest and hepatic toxicity is significant. Donepezil, galantamine, and rivastigmine are newer, more selective acetylcholinesterase inhibitors that appear to have the same modest clinical benefit as tacrine in treatment of cognitive dysfunction in Alzheimer's patients. Donepezil may be given once daily because of its long half-life, and it lacks the hepatotoxic effect of tacrine. However, no comparative trials of these newer drugs and tacrine have been reported. These drugs are discussed in Chapter 61: Special Aspects of Geriatric Pharmacology.

Toxicity

The toxic potential of the cholinoceptor stimulants varies markedly depending on their absorption, access to the central nervous system, and metabolism.

Direct-Acting Muscarinic Stimulants

Drugs such as pilocarpine and the choline esters cause predictable signs of muscarinic excess when given in overdosage. These effects include nausea, vomiting, diarrhea, salivation, sweating, cutaneous vasodilation, and bronchial constriction. The effects are all blocked competitively by atropine and its congeners.

Certain mushrooms, especially those of the genus *Inocybe*, contain muscarinic alkaloids. Ingestion of these mushrooms causes typical signs of muscarinic excess within 15–30 minutes. Treatment is with atropine, 1–2 mg parenterally. (*Amanita muscaria*, the first source of muscarine, contains very low concentrations of the alkaloid.)

Direct-Acting Nicotinic Stimulants

Nicotine itself is the only common cause of this type of poisoning. The acute toxicity of the alkaloid is well-defined but much less important than the chronic effects associated with smoking. In addition to tobacco products, nicotine is also used in insecticides.

Acute Toxicity

The fatal dose of nicotine is approximately 40 mg, or 1 drop of the pure liquid. This is the amount of nicotine in two regular cigarettes. Fortunately, most of the nicotine in cigarettes is destroyed by

burning or escapes via the "sidestream" smoke. Ingestion of nicotine insecticides or of tobacco by infants and children is usually followed by vomiting, limiting the amount of the alkaloid absorbed.

The toxic effects of a large dose of nicotine are simple extensions of the effects described previously. The most dangerous are (1) central stimulant actions, which cause convulsions and may progress to coma and respiratory arrest; (2) skeletal muscle end plate depolarization, which may lead to depolarization blockade and respiratory paralysis; and (3) hypertension and cardiac arrhythmias.

Treatment of acute nicotine poisoning is largely symptom-directed. Muscarinic excess resulting from parasympathetic ganglion stimulation can be controlled with atropine. Central stimulation is usually treated with parenteral anticonvulsants such as diazepam. Neuromuscular blockade is not responsive to pharmacologic treatment and may require mechanical respiration.

Fortunately, nicotine is metabolized and excreted relatively rapidly. Patients who survive the first 4 hours usually recover completely if hypoxia and brain damage have not occurred.

Chronic Nicotine Toxicity

The health costs of tobacco smoking to the smoker and its socioeconomic costs to the general public are still incompletely understood. However, the 1979 *Surgeon General's Report on Health Promotion and Disease Prevention* stated that "cigarette smoking is clearly the largest single preventable cause of illness and premature death in the United States." This statement has been supported by numerous studies. Unfortunately, the fact that the most important of the tobacco-associated diseases are delayed in onset reduces the health incentive to stop smoking.

It is clear that the addictive power of cigarettes is directly related to their nicotine content. It is not known to what extent nicotine per se contributes to the other well-documented adverse effects of chronic tobacco use. It appears highly probable that nicotine contributes to the increased risk of vascular disease and sudden coronary death associated with smoking. It is also probable that nicotine contributes to the high incidence of ulcer recurrences in smokers with peptic ulcer.

Cholinesterase Inhibitors

The acute toxic effects of the cholinesterase inhibitors, like those of the direct-acting agents, are direct extensions of their pharmacologic actions. The major source of such intoxications is pesticide use in agriculture and in the home. Approximately 100 organophosphate and 20 carbamate cholinesterase inhibitors are available in pesticides and veterinary vermifuges used in the USA.

Acute intoxication must be recognized and treated promptly in patients with heavy exposure. The dominant initial signs are those of muscarinic excess: miosis, salivation, sweating, bronchial constriction, vomiting, and diarrhea. Central nervous system involvement usually follows rapidly, accompanied by peripheral nicotinic effects, especially depolarizing neuromuscular blockade. Therapy always includes (1) maintenance of vital signs—respiration in particular may be impaired; (2) decontamination to prevent further absorption—this may require removal of all clothing and washing of the skin in cases of exposure to dusts and sprays; and (3) atropine parenterally in large doses, given as often as required to control signs of muscarinic excess. Therapy often also includes treatment with pralidoxime as described in Chapter 8: Cholinoceptor-Blocking Drugs.

Chronic exposure to certain organophosphate compounds, including some organophosphate cholinesterase inhibitors, causes neuropathy associated with demyelination of axons.

Triorthocresylphosphate, an additive in lubricating oils, is the prototype agent of this class. The effects are not caused by cholinesterase inhibition.

Preparations Available

Direct-Acting Cholinomimetics

Acetylcholine (Miochol-E)

Ophthalmic: 1:100 (10 mg/mL) intraocular solution

Bethanechol (generic, Urecholine)

Oral: 5, 10, 25, 50 mg tablets

Parenteral: 5 mg/mL for SC injection

Carbachol

Ophthalmic (topical, Isopto Carbachol, Carboptic): 0.75, 1.5, 2.25, 3% drops

Ophthalmic (intraocular, Miostat, Carbastat): 0.01% solution

Cevimeline (Evoxac)

Oral: 30 mg capsules

Pilocarpine (generic, Isopto Carpine)

Ophthalmic (topical): 0.25, 0.5, 1, 2, 3, 4, 6, 8, 10% solutions, 4% gel

Ophthalmic sustained-release inserts (Ocusert Pilo-20, Ocusert Pilo-40): release 20 and 40 μg pilocarpine per hour for 1 week, respectively

Oral (Salagen): 5 mg tablets

Cholinesterase Inhibitors

Ambenonium (Mytelase)

Oral: 10 mg tablets

Demecarium (Humorsol)

Ophthalmic: 0.125, 0.25% drops

Donepezil (Aricept)

Oral: 5, 10 mg tablets

Echothiophate (Phospholine)

Ophthalmic: Powder to reconstitute for 0.03, 0.06, 0.125, 0.25% drops

Edrophonium (generic, Tensilon)

Parenteral: 10 mg/mL for IM or IV injection

Galantamine (Reminyl)

Oral: 4, 8, 12 mg capsules; 4 mg/mL solution

Neostigmine (generic, Prostigmin)

Oral: 15 mg tablets

Parenteral: 1:1000 in 10 mL; 1:2000, 1:4000 in 1 mL

Physostigmine, eserine (generic)

Parenteral: 1 mg/mL for IM or slow IV injection

Pyridostigmine (Mestinon, Regonol)

Oral: 60 mg tablets; 180 mg sustained-release tablets; 15 mg/mL syrup

Parenteral: 5 mg/mL for IM or slow IV injection

Rivastigmine (Exelon)

Oral: 1.5, 3, 4.5, 6 mg tablets; 2 mg/mL solution

Tacrine (Cognex)

Oral: 10, 20, 30, 40 mg tablets

Chapter 8. Cholinoceptor-Blocking Drugs

Cholinoceptor-Blocking Drugs: Introduction

Cholinoceptor antagonists, like agonists, are divided into muscarinic and nicotinic subgroups on the basis of their specific receptor affinities. The antinicotinic drugs consist of ganglion-blockers and neuromuscular junction blockers. The ganglion-blocking drugs have little clinical use and are

discussed at the end of this chapter. The neuromuscular blockers are discussed in Chapter 27: Skeletal Muscle Relaxants. This chapter emphasizes drugs that block muscarinic cholinergic receptors.

As noted in Chapter 6: Introduction to Autonomic Pharmacology and Chapter 7: Cholinergic-Activating & Cholinesterase-Inhibiting Drugs, five subtypes of muscarinic receptors have been described, primarily on the basis of data from ligand-binding and cDNA-cloning experiments. A standard terminology (M_1 through M_5) for these subtypes is now in common use, and evidence, based mostly on selective agonists and antagonists, indicates that functional differences exist between several of these subtypes.

As suggested in Chapter 6: Introduction to Autonomic Pharmacology, the M_1 receptor subtype appears to be located on central nervous system neurons, sympathetic postganglionic cell bodies, and many presynaptic sites. M_2 receptors are located in the myocardium, smooth muscle organs, and some neuronal sites. M_3 receptors are most common on effector cell membranes, especially glandular and smooth muscle cells.

Basic Pharmacology of the Muscarinic Receptor-Blocking Drugs

Muscarinic antagonists are often called parasympatholytic because they block the effects of parasympathetic autonomic discharge. However, they do not "lyse" parasympathetic nerves, and they have some effects that are not predictable from block of the parasympathetic nervous system. For these reasons, the term "antimuscarinic" is preferable.

Naturally occurring compounds with antimuscarinic effects have been known and used for millennia as medicines, poisons, and cosmetics. Atropine is the prototype of these drugs. Many similar plant alkaloids are known, and hundreds of synthetic antimuscarinic compounds have been prepared.

Chemistry & Pharmacokinetics

Source and Chemistry

Atropine and its naturally occurring congeners are tertiary amine alkaloid esters of tropic acid (Figure 8–1). Atropine (hyoscyamine) is found in the plant *Atropa belladonna*, or deadly nightshade, and in *Datura stramonium*, also known as jimsonweed (Jamestown weed) or thorn apple. Scopolamine (hyoscine) occurs in *Hyoscyamus niger*, or henbane, as the *l*(–) stereoisomer. Naturally occurring atropine is *l*(–)-hyoscyamine, but the compound readily racemizes, so the commercial material is racemic *d,l*-hyoscyamine. The *l*(–) isomers of both alkaloids are at least 100 times more potent than the *d*(+) isomers.

Figure 8–1.

The structure of atropine (oxygen at [1] is missing) or scopolamine (oxygen present). In homatropine, the hydroxymethyl at [2] is replaced by a hydroxyl group, and the oxygen at [1] is absent.

A variety of semisynthetic and fully synthetic molecules have antimuscarinic effects.

The tertiary members of these classes (Figure 8–2) are often used for their effects on the eye or the central nervous system. Many antihistaminic (see Chapter 16: Histamine, Serotonin, & the Ergot Alkaloids), antipsychotic (see Chapter 29: Antipsychotic Agents & Lithium), and antidepressant (see Chapter 30: Antidepressant Agents) drugs have similar structures and, predictably, significant antimuscarinic effects.

Figure 8–2.

Quaternary amines for gastrointestinal applications (peptic disease, hypermotility):

Propantheline

Glycopyrrolate

Tertiary amines for peripheral applications:

Pirenzepine
(peptic disease)

Dicyclimine
(peptic disease, hypermotility)

Tropicamide
(mydriatic, cycloplegic)

Quaternary amine for use in asthma:

Ipratropium

Tertiary amine for Parkinson's disease:

Benztropine

Structures of some semisynthetic and synthetic antimuscarinic drugs.

Quaternary amine antimuscarinic agents (Figure 8–2) have been developed to produce more peripheral effects with reduced central nervous system effects.

Absorption

The natural alkaloids and most tertiary antimuscarinic drugs are well absorbed from the gut and conjunctival membranes. When applied in a suitable vehicle, some (eg, scopolamine) are even absorbed across the skin (transdermal route). In contrast, only 10–30% of a dose of a quaternary antimuscarinic drug is absorbed after oral administration, reflecting the decreased lipid solubility of the charged molecule.

Distribution

Atropine and the other tertiary agents are widely distributed in the body. Significant levels are achieved in the central nervous system within 30 minutes to 1 hour, and this may limit the dose tolerated when the drug is taken for its peripheral effects. Scopolamine is rapidly and fully distributed into the central nervous system where it has greater effects than most other antimuscarinic drugs. In contrast, the quaternary derivatives are poorly taken up by the brain and therefore are relatively free—at low doses—of central nervous system effects.

Metabolism and Excretion

Atropine disappears rapidly from the blood after administration, with a half-life of 2 hours. About 60% of the dose is excreted unchanged in the urine. Most of the rest appears in the urine as hydrolysis and conjugation products. The drug's effect on parasympathetic function declines rapidly in all organs except the eye. Effects on the iris and ciliary muscle persist for \approx 72 hours.

Pharmacodynamics

Mechanism of Action

Atropine causes reversible (surmountable) blockade of cholinomimetic actions at muscarinic receptors—ie, blockade by a small dose of atropine can be overcome by a larger concentration of acetylcholine or equivalent muscarinic agonist. Mutation experiments suggest that a specific amino acid is required in the receptor to form the characteristic bond with the nitrogen atom of acetylcholine; this amino acid is also required for binding of antimuscarinic drugs. When atropine binds to the muscarinic receptor, it prevents the actions described in Chapter 7: Cholinergic-Activating & Cholinesterase-Inhibiting Drugs such as the release of inositol trisphosphate (IP_3) and the inhibition of adenylyl cyclase that are caused by muscarinic agonists.

The effectiveness of antimuscarinic drugs varies with the tissue under study and with the source of agonist. Tissues most sensitive to atropine are the salivary, bronchial, and sweat glands. Secretion of acid by the gastric parietal cells is the least sensitive. In most tissues, antimuscarinic agents block exogenously administered cholinergic agonists more effectively than endogenously released acetylcholine.

Atropine is highly selective for muscarinic receptors. Its potency at nicotinic receptors is much lower, and actions at nonmuscarinic receptors are generally undetectable clinically.

Atropine does not distinguish between the M_1 , M_2 , and M_3 subgroups of muscarinic receptors. In contrast, other antimuscarinic drugs have moderate selectivity for one or another of these subgroups

(Table 8–1). Most synthetic antimuscarinic drugs are considerably less selective than atropine in interactions with nonmuscarinic receptors. For example, some quaternary amine antimuscarinic agents have significant ganglion-blocking actions, and others are potent histamine receptor blockers. The antimuscarinic effects of other groups, eg, antipsychotic and antidepressant drugs, have been mentioned. Their relative selectivity for muscarinic receptor subtypes has not been defined.

Table 8–1. Muscarinic Receptor Subgroups and Their Antagonists. (Acronyms Identify Selective Antagonists Used in Research Studies Only.)

Subgroup			
Property	M ₁	M ₂	M ₃
Primary locations	Nerves	Heart, nerves, smooth muscle	Glands, smooth muscle, endothelium
Dominant effector system	↑IP ₃ , ↑DAG	↓cAMP, ↑K ⁺ channel current	↑IP ₃ , ↑DAG
Antagonists	Pirenzepine, telenzepine dicyclomine, ² trihexyphenidyl ³	Gallamine, ¹ methoctramine, AF-DX 116	4-DAMP, HHSD, darifenacin
Approximate dissociation constant ⁴			
Atropine	1	1	1
Pirenzepine	10	50	200
AF-DX 116	800	100	3000
HHSD	40	200	2

¹In clinical use as a neuromuscular blocking agent.

²In clinical use as an intestinal antispasmodic agent.

³In clinical use in the treatment of Parkinson's disease.

⁴Relative to atropine. Smaller numbers indicate higher affinity.

AF-DX 116, 11-({2-[(Diethylamino)methyl]-1-piperidinyl}acetyl)-5,11-dihydro-6*H*-pyrido-[2,3-*b*](1,4)benzodiaz-epin-6-one; DAG, Diacylglycerol; IP₃, Inositol trisphosphate; 4-DAMP, 4-Diphenylacetoxy-*N*-methylpiperidine; HHSD, Hexahydrosiladifenidol

Organ System Effects

Central Nervous System

In the doses usually used, atropine has minimal stimulant effects on the central nervous system, especially the parasympathetic medullary centers, and a slower, longer-lasting sedative effect on the brain. Scopolamine has more marked central effects, producing drowsiness when given in recommended dosages and amnesia in sensitive individuals. In toxic doses, scopolamine and to a lesser degree atropine can cause excitement, agitation, hallucinations, and coma.

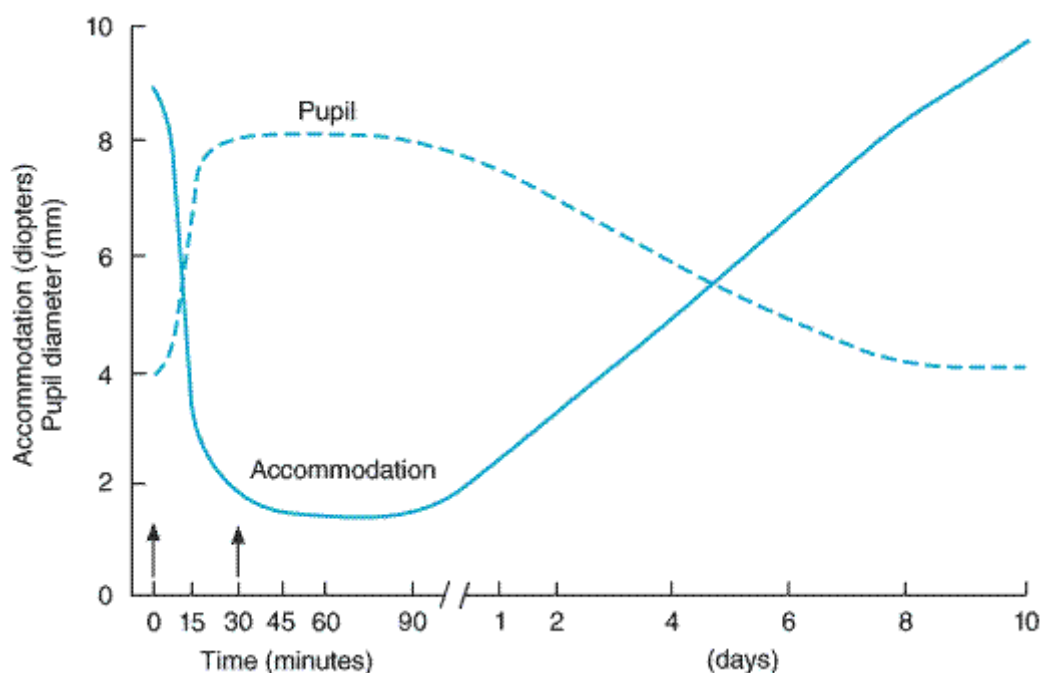

The tremor of Parkinson's disease is reduced by centrally acting antimuscarinic drugs, and atropine—in the form of belladonna extract—was one of the first drugs used in the therapy of this disease. As discussed in Chapter 28: Pharmacologic Management of Parkinsonism & Other Movement Disorders, parkinsonian tremor and rigidity seem to result from a *relative* excess of cholinergic activity because of a deficiency of dopaminergic activity in the basal ganglia-striatum system. The combination of an antimuscarinic agent with a dopamine precursor drug (levodopa) may provide more effective therapy than either drug alone.

Vestibular disturbances, especially motion sickness, appear to involve muscarinic cholinergic transmission. Scopolamine is often effective in preventing or reversing these disturbances.

Eye

The pupillary constrictor muscle (see Figure 6–9) depends on muscarinic cholinergic activation. This activation is blocked by topical atropine and other tertiary antimuscarinic drugs and results in unopposed sympathetic dilator activity and mydriasis (Figure 8–3). Dilated pupils were considered cosmetically desirable during the Renaissance and account for the name belladonna (Italian, "beautiful lady") applied to the plant and its active extract because of the use of the extract as eye drops during that time.

Figure 8–3.

Effects of topical scopolamine drops on pupil diameter (mm) and accommodation (diopters) in the normal human eye. One drop of 0.5% solution of drug was applied at zero time, and a second drop

was administered at 30 minutes (*arrows*). The responses of 42 eyes were averaged. Note the extremely slow recovery. (Redrawn from Marron J: Cycloplegia and mydriasis by use of atropine, scopolamine, and homatropine-paredrine. Arch Ophthalmol 1940;23:340.)

The second important ocular effect of antimuscarinic drugs is weakening of contraction of the ciliary muscle, or **cycloplegia**. The result of cycloplegia is loss of the ability to accommodate; the fully atropinized eye cannot focus for near vision (Figure 8–3).

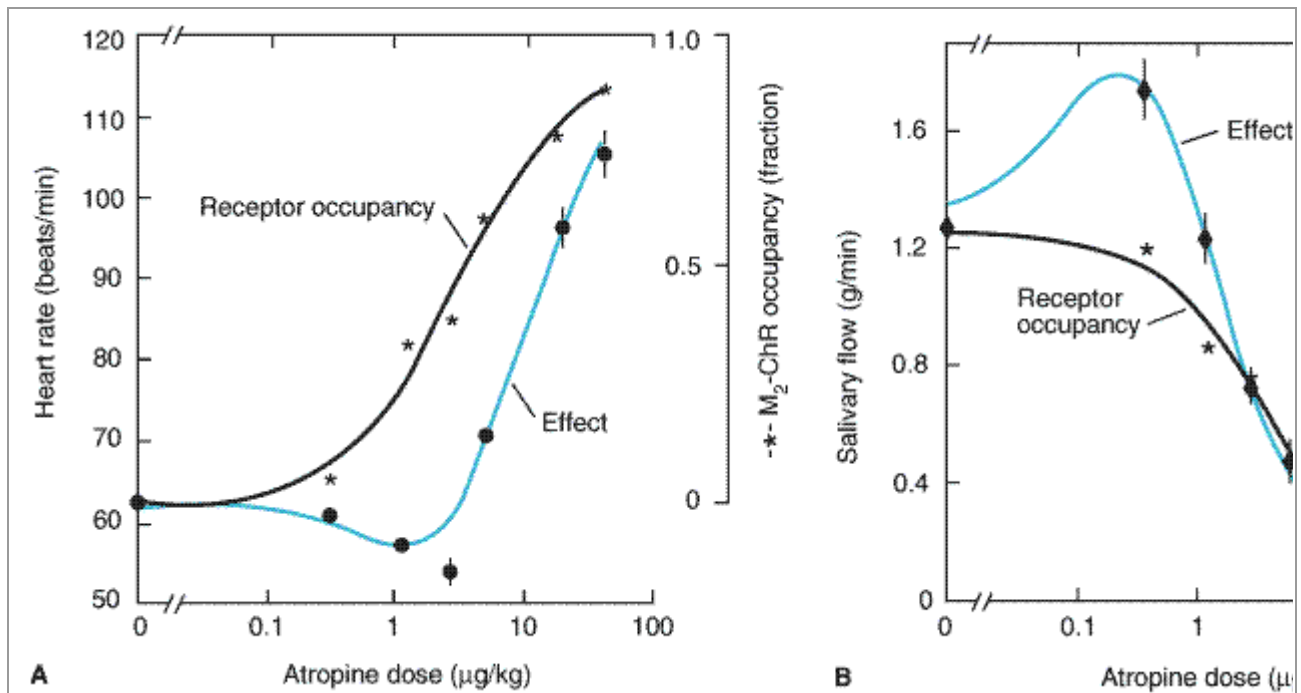

Both mydriasis and cycloplegia are useful in ophthalmology. They are also potentially hazardous, since acute glaucoma may be precipitated in patients with a narrow anterior chamber angle.

A third ocular effect of antimuscarinic drugs is reduction of lacrimal secretion. Patients occasionally complain of dry or "sandy" eyes when receiving large doses of antimuscarinic drugs.

Cardiovascular System

The sinoatrial node is very sensitive to muscarinic receptor blockade. The effect of moderate to high therapeutic doses of atropine in the innervated and spontaneously beating heart is a blockade of vagal slowing and a relative tachycardia. However, lower doses often result in initial bradycardia before the effects of peripheral vagal block become manifest (Figure 8–4). This slowing may be due to block of presynaptic muscarinic receptors on vagal postganglionic fibers that normally limit acetylcholine release in the sinus node and other tissues. The same mechanisms operate in the control of atrioventricular node function; in the presence of high vagal tone, atropine can significantly reduce the PR interval of the ECG by blocking muscarinic receptors in the atrioventricular node. Muscarinic effects on atrial muscle are similarly blocked, but these effects are of no clinical significance except in atrial flutter and fibrillation. Because of a lesser degree of muscarinic control, the ventricles are less affected by antimuscarinic drugs at therapeutic levels. In toxic concentrations, the drugs can cause intraventricular conduction block by an unknown mechanism.

Figure 8–4.

Effects of increasing doses of atropine on heart rate (**A**) and salivary flow (**B**) compared with muscarinic receptor occupancy in humans. The parasympathomimetic effect of low-dose atropine is attributed to blockade of prejunctional muscarinic receptors that suppress acetylcholine release. (Modified and reproduced, with permission, from Wellstein A, Pitschner HF: Complex dose-response curves of atropine in man explained by different functions of M_1 and M_2 cholinceptors. *Naunyn Schmiedeberg Arch Pharmacol* 1988;338:19.)

Blood vessels receive no direct innervation from the parasympathetic nervous system. However, parasympathetic nerve stimulation dilates coronary arteries, and sympathetic cholinergic nerves cause vasodilation in the skeletal muscle vascular bed (see Chapter 6: Introduction to Autonomic Pharmacology). Atropine can block this vasodilation. Furthermore, almost all vessels contain endothelial muscarinic receptors that mediate vasodilation (see Chapter 7: Cholinceptor-Activating & Cholinesterase-Inhibiting Drugs). These receptors are readily blocked by antimuscarinic drugs. At toxic doses, and in some individuals at normal doses, antimuscarinic agents cause cutaneous vasodilation, especially in the upper portion of the body. The mechanism is unknown.

The net cardiovascular effects of atropine in patients with normal hemodynamics are not dramatic: tachycardia may occur, but there is little effect on blood pressure. However, the cardiovascular effects of administered direct-acting muscarinic stimulants are easily prevented.

Respiratory System

Both smooth muscle and secretory glands of the airway receive vagal innervation and contain muscarinic receptors. Even in normal individuals, some bronchodilation and reduction of secretion can be measured after administration of atropine. The effect is more significant in patients with airway disease, although the antimuscarinic drugs are not as useful as the β -adrenoceptor stimulants in the treatment of asthma (see Chapter 20: Drugs Used in Asthma). The effectiveness of unselective antimuscarinic drugs in treating chronic obstructive pulmonary disease (COPD) is limited because block of autoinhibitory M_2 receptors on postganglionic parasympathetic nerves can oppose the bronchodilation caused by block of M_3 receptors on airway smooth muscle. Nevertheless, antimuscarinic agents are valuable in some patients with asthma or COPD.

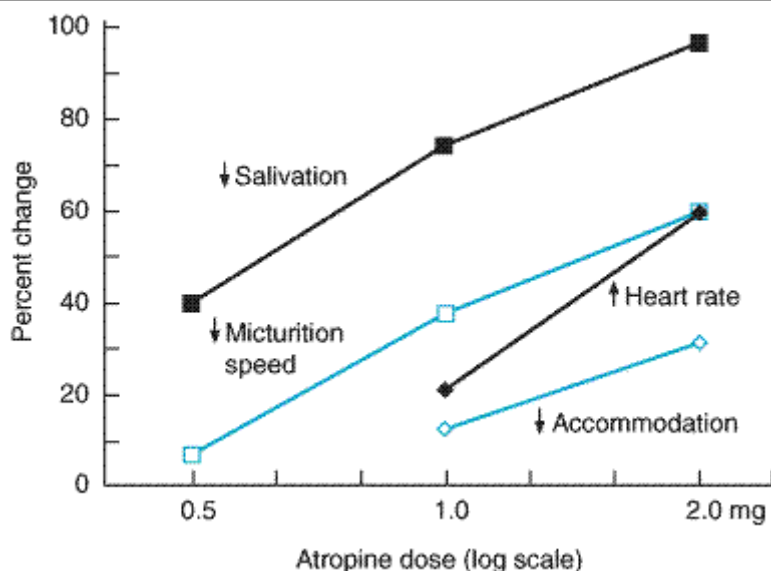

Antimuscarinic drugs are frequently used prior to administration of inhalant anesthetics to reduce the accumulation of secretions in the trachea and the possibility of laryngospasm.

Gastrointestinal Tract

Blockade of muscarinic receptors has dramatic effects on motility and some of the secretory functions of the gut. However, even complete muscarinic block cannot totally abolish activity in this organ system since local hormones and noncholinergic neurons in the enteric nervous system (see Chapters 6 and 63) also modulate gastrointestinal function. As in other tissues, exogenously administered muscarinic stimulants are more effectively blocked than the effects of parasympathetic (vagal) nerve activity. The removal of autoinhibition, a negative feedback mechanism by which neural acetylcholine suppresses its own release, might explain the greater efficacy of antimuscarinic drugs against exogenous muscarinic stimulants.

Antimuscarinic drugs have marked effects on salivary secretion; dry mouth occurs frequently in patients taking antimuscarinic drugs for Parkinson's disease or urinary conditions (Figure 8–5). Gastric secretion is blocked less effectively: the volume and amount of acid, pepsin, and mucin are all reduced, but large doses of atropine may be required. Basal secretion is blocked more effectively than that stimulated by food, nicotine, or alcohol. Pirenzepine and a more potent analog, telenzepine, reduce gastric acid secretion with fewer adverse effects than atropine and other less selective agents. This results from a selective blockade of presynaptic excitatory muscarinic receptors on vagal nerve endings as suggested by their high ratio of M_1 to M_3 affinity (Table 8–1). Pirenzepine and telenzepine are investigational in the USA. Pancreatic and intestinal secretion are little affected by atropine; these processes are primarily under hormonal rather than vagal control.

Figure 8–5.

Effects of subcutaneous injection of atropine on salivation, speed of micturition (voiding), heart rate, and accommodation in normal adults. Note that salivation is the most sensitive of these variables, accommodation the least. (Data from Herxheimer A: Br J Pharmacol 1958;13:184.)

Table 8–2. Antimuscarinic Drugs Used in Ophthalmology.

Drug	Duration of Effect (days)	Usual Concentration (%)
Atropine	7–10	0.5–1
Scopolamine	3–7	0.25
Homatropine	1–3	2–5
Cyclopentolate	1	0.5–2
Tropicamide	0.25	0.5–1

Gastrointestinal smooth muscle motility is affected from the stomach to the colon. In general, the walls of the viscera are relaxed, and both tone and propulsive movements are diminished. Therefore, gastric emptying time is prolonged, and intestinal transit time is lengthened. Diarrhea due to overdosage with parasympathomimetic agents is readily stopped, and even that caused by nonautonomic agents can usually be temporarily controlled. However, intestinal "paralysis" induced by antimuscarinic drugs is temporary; local mechanisms within the enteric nervous system will usually reestablish at least some peristalsis after 1–3 days of antimuscarinic drug therapy.

Genitourinary Tract

The antimuscarinic action of atropine and its analogs relaxes smooth muscle of the ureters and bladder wall and slows voiding (Figure 8–5). This action is useful in the treatment of spasm induced by mild inflammation, surgery, and certain neurologic conditions, but it can precipitate urinary retention in elderly men, who may have prostatic hyperplasia (see following section, Clinical Pharmacology of the Muscarinic Receptor-Blocking Drugs). The antimuscarinic drugs have no significant effect on the uterus.

Sweat Glands

Atropine suppresses thermoregulatory sweating. Sympathetic cholinergic fibers innervate eccrine sweat glands, and their muscarinic receptors are readily accessible to antimuscarinic drugs. In adults, body temperature is elevated by this effect only if large doses are administered, but in infants and children even ordinary doses may cause "atropine fever."

Clinical Pharmacology of the Muscarinic Receptor-Blocking Drugs

Therapeutic Applications

Central Nervous System Disorders

Parkinson's Disease

As described in Chapter 28: Pharmacologic Management of Parkinsonism & Other Movement Disorders, the treatment of Parkinson's disease is often an exercise in polypharmacy, since no single agent is fully effective over the course of the disease. Most antimuscarinic drugs promoted for this application (see Table 28–1) were developed before levodopa became available. Their use is accompanied by all of the adverse effects described below, but the drugs remain useful as adjunctive therapy in some patients.

Motion Sickness

Certain vestibular disorders respond to antimuscarinic drugs (and to antihistaminic agents with antimuscarinic effects). Scopolamine is one of the oldest remedies for seasickness and is as effective as any more recently introduced agent. It can be given by injection, by mouth, or as a transdermal patch. The patch formulation produces significant blood levels over 48–72 hours. Unfortunately, useful doses by any route usually cause significant sedation and dry mouth.

Ophthalmologic Disorders

Accurate measurement of refractive error in uncooperative patients, eg, young children, requires ciliary paralysis. Also, ophthalmoscopic examination of the retina is greatly facilitated by mydriasis. Therefore, antimuscarinic agents, administered topically as eye drops or ointment, are extremely helpful in doing a complete examination. For adults and older children, the shorter-acting drugs are preferred (Table 8–2). For younger children, the greater efficacy of atropine is sometimes necessary, but the possibility of antimuscarinic poisoning is correspondingly increased. Drug loss from the conjunctival sac via the nasolacrimal duct into the nasopharynx can be diminished by the use of the ointment form instead of drops. In the past, ophthalmic antimuscarinic drugs have been selected from the tertiary amine subgroup to ensure good penetration after conjunctival application. Recent experiments in animals, however, suggest that glycopyrrolate, a quaternary agent, is as rapid in onset and as long-lasting as atropine.

Antimuscarinic drugs should never be used for mydriasis unless cycloplegia or prolonged action is required. Alpha-adrenoceptor stimulant drugs, eg, phenylephrine, produce a short-lasting mydriasis that is usually sufficient for fundoscopic examination (see Chapter 9: Adrenoceptor-Activating & Other Sympathomimetic Drugs).

A second ophthalmologic use is to prevent synechia (adhesion) formation in uveitis and iritis. The longer-lasting preparations, especially homatropine, are valuable for this indication.

Respiratory Disorders

The use of atropine became part of routine preoperative medication when anesthetics such as ether were used, because these irritant anesthetics markedly increased airway secretions and were associated with frequent episodes of laryngospasm. Preanesthetic injection of atropine or scopolamine could prevent these hazardous effects. Scopolamine also produces significant amnesia for the events associated with surgery and obstetric delivery, a side effect that was considered desirable. On the other hand, urinary retention and intestinal hypomotility following surgery were often exacerbated by antimuscarinic drugs. Newer inhalational anesthetics are far less irritating to the airways.

As described in Chapter 20: Drugs Used in Asthma, the hyperactive neural bronchoconstrictor reflex present in most individuals with asthma is mediated by the vagus, acting on muscarinic receptors on bronchial smooth muscle cells. **Ipratropium** (Figure 8–2), a synthetic analog of atropine, is used as an inhalational drug in asthma. The aerosol route of administration provides the advantages of maximal concentration at the bronchial target tissue with reduced systemic effects. This application is discussed in greater detail in Chapter 20: Drugs Used in Asthma. Ipratropium has also proved useful in COPD, a condition that occurs with higher frequency in older patients, particularly chronic smokers. Patients with COPD benefit from bronchodilators, especially antimuscarinic agents such as ipratropium. Investigational agents in this category include **tiotropium**, a long-acting quaternary aerosol antimuscarinic drug.

Cardiovascular Disorders

Marked reflex vagal discharge sometimes accompanies the pain of myocardial infarction and may result in sufficient depression of sinoatrial or atrioventricular node function to impair cardiac output. Parenteral atropine or a similar antimuscarinic drug is appropriate therapy in this situation. Rare individuals without other detectable cardiac disease have hyperactive carotid sinus reflexes and may experience faintness or even syncope as a result of vagal discharge in response to pressure on the neck, eg, from a tight collar. Such individuals may benefit from the judicious use of atropine or a related antimuscarinic agent.

Pathophysiology can influence muscarinic activity in other ways as well. Circulating autoantibodies against the second extracellular loop of cardiac muscarinic receptors have been detected in some patients with idiopathic dilated cardiomyopathy. These antibodies exert parasympathomimetic actions on the heart that are prevented by atropine. Although their role in the pathology of heart failure is unknown, they should provide clues to the molecular basis of receptor activation.

Gastrointestinal Disorders

Antimuscarinic agents are now rarely used for peptic ulcer disease in the USA (see Chapter 63: Drugs Used in the Treatment of Gastrointestinal Diseases). Antimuscarinic agents can provide some relief in the treatment of common traveler's diarrhea and other mild or self-limited conditions of hypermotility. They are often combined with an opioid antidiarrheal drug, an extremely effective therapy. In this combination, however, the very low dosage of the antimuscarinic drug functions primarily to discourage abuse of the opioid agent. The classic combination of atropine with diphenoxylate, a nonanalgesic congener of meperidine, is available under many names (eg, Lomotil) in both tablet and liquid form (see Chapter 63: Drugs Used in the Treatment of Gastrointestinal Diseases).

Urinary Disorders

Atropine and other antimuscarinic drugs have been used to provide symptomatic relief in the treatment of urinary urgency caused by minor inflammatory bladder disorders (Table 8–3). However, specific antimicrobial therapy is essential in bacterial cystitis.

Table 8–3. Antimuscarinic Drugs Used in Gastrointestinal and Genitourinary Conditions.

Drug	Usual Dosage
Quaternary amines	
Anisotropine	50 mg tid
Clidinium	2.5 mg tid–qid
Glycopyrrolate	1 mg bid–tid
Isopropamide	5 mg bid
Mepenzolate	25–50 mg qid
Methantheline	50–100 mg qid
Methscopolamine	2.5 mg qid
Oxyphenonium	5–10 mg qid

Propantheline	15 mg qid
Tertiary amines	
Atropine	0.4 mg tid–qid
Dicyclomine	10–20 mg qid
Oxybutynin	5 mg tid
Oxyphencyclimine	10 mg bid
Propiverine	15 mg bid–tid
Scopolamine	0.4 mg tid
Tolterodine	2 mg bid
Tridihexethyl	25–50 mg tid–qid

Oxybutynin is often used to relieve bladder spasm after urologic surgery, eg, prostatectomy. It is also valuable in reducing involuntary voiding in patients with neurologic disease, eg, children with meningomyelocele. Oral oxybutynin or instillation of the drug by catheter into the bladder in such patients appears to improve bladder capacity and continence and to reduce infection and renal damage. **Tolterodine**, an M₃-selective antimuscarinic, is available for use in adults with urinary incontinence.

Imipramine, a tricyclic antidepressant drug with strong antimuscarinic actions, has long been used to reduce incontinence in institutionalized elderly patients. It is moderately effective but causes significant central nervous system toxicity. **Propiverine**, a newer antimuscarinic agent, has been approved for this purpose.

The antimuscarinic agents have also been used in urolithiasis to relieve the ureteral smooth muscle spasm caused by passage of the stone. However, their usefulness in this condition is debatable.

Cholinergic Poisoning

Severe cholinergic excess is a medical emergency, especially in rural communities where the use of cholinesterase inhibitor insecticides is common and in cultures where wild mushrooms are commonly eaten. The potential use of cholinesterase inhibitors as chemical warfare "nerve gases" also requires an awareness of the methods for treating acute poisoning (see Chapter 59: Management of the Poisoned Patient).

Antimuscarinic Therapy

As noted in Chapter 7: Cholinceptor-Activating & Cholinesterase-Inhibiting Drugs, both the nicotinic and the muscarinic effects of the cholinesterase inhibitors can be life-threatening. Unfortunately, there is no effective method for directly blocking the nicotinic effects of cholinesterase inhibition, because nicotinic agonists *and* blockers cause blockade of transmission (see Chapter 27: Skeletal Muscle Relaxants). To reverse the muscarinic effects, a tertiary (not quaternary) amine drug must be used (preferably atropine), since the central nervous system effects as well as the peripheral effects of the organophosphate inhibitors must be treated. Large doses of atropine may be needed to combat the muscarinic effects of extremely potent agents like parathion and chemical warfare nerve gases: 1–2 mg of atropine sulfate may be given intravenously every 5–15 minutes until signs of effect (dry mouth, reversal of miosis) appear. The drug may have to be

repeated many times, since the acute effects of the anticholinesterase agent may last for 24–48 hours or longer. In this life-threatening situation, as much as 1 g of atropine per day may be required for as long as 1 month for full control of muscarinic excess.

Cholinesterase Regenerator Compounds

A second class of compounds, capable of regenerating active enzyme from the organophosphorus-cholinesterase complex, is also available to treat organophosphorus poisoning. These oxime agents include pralidoxime (PAM), diacetylmonoxime (DAM), and others.

The oxime group (=NOH) has a very high affinity for the phosphorus atom, and these drugs are able to hydrolyze the phosphorylated enzyme if the complex has not "aged" (see Chapter 7: Cholinceptor-Activating & Cholinesterase-Inhibiting Drugs). Pralidoxime is the most extensively studied—in humans—of the agents shown and the only one available for clinical use in the USA. It is most effective in regenerating the cholinesterase associated with skeletal muscle neuromuscular junctions. Because of its positive charge, it does not enter the central nervous system and is ineffective in reversing the central effects of organophosphate poisoning. Diacetylmonoxime, on the other hand, does cross the blood-brain barrier and, in experimental animals, can regenerate some of the central nervous system cholinesterase.

Pralidoxime is administered by intravenous infusion, 1–2 g given over 15–30 minutes. In spite of the likelihood of aging of the phosphate-enzyme complex, recent reports suggest that administration of multiple doses of pralidoxime over several days may be useful in severe poisoning. In excessive doses, pralidoxime can induce neuromuscular weakness and other adverse effects. Pralidoxime is *not* recommended for the reversal of inhibition of acetylcholinesterase by carbamate inhibitors. Further details of treatment of anticholinesterase toxicity are given in Chapter 59: Management of the Poisoned Patient.

A third approach to protection against excessive AChE inhibition lies in *pretreatment* with reversible inhibitors of the enzyme to prevent binding of the irreversible organophosphate inhibitor. This prophylaxis can be achieved with pyridostigmine or physostigmine but is reserved for situations in which possibly lethal poisoning is anticipated, eg, chemical warfare. Simultaneous use of atropine is required to control muscarinic excess.

Mushroom poisoning has traditionally been divided into rapid-onset and delayed-onset types. The rapid-onset type is usually apparent within 15–30 minutes following ingestion of the mushrooms. It is often characterized entirely by signs of muscarinic excess: nausea, vomiting, diarrhea, vasodilation, reflex tachycardia (occasionally bradycardia), sweating, salivation, and sometimes bronchoconstriction. Although *Amanita muscaria* contains muscarine (the alkaloid was named after the mushroom), numerous other alkaloids, including antimuscarinic agents, are found in this fungus. In fact, ingestion of *A muscaria* may produce signs of atropine poisoning, not muscarine

excess. Other mushrooms, especially those of the *Inocybe* genus, cause rapid-onset poisoning of the muscarinic excess type. Parenteral atropine, 1–2 mg, is effective treatment in such intoxications.

Delayed-onset mushroom poisoning, usually caused by *Amanita phalloides*, *A virosa*, *Galerina autumnalis*, or *G marginata*, manifests its first symptoms 6–12 hours after ingestion. Although the initial symptoms usually include nausea and vomiting, the major toxicity involves hepatic and renal cellular injury by amatoxins that inhibit RNA polymerase. Atropine is of no value in this form of mushroom poisoning (see Chapter 59: Management of the Poisoned Patient).

Other Applications

Hyperhidrosis is sometimes reduced by antimuscarinic agents. However, relief is incomplete at best, probably because apocrine rather than eccrine glands are usually involved.

Adverse Effects

Treatment with atropine or its congeners directed at one organ system almost always induces undesirable effects in other organ systems. Thus, mydriasis and cycloplegia are adverse effects when an antimuscarinic agent is being used to reduce gastrointestinal secretion or motility, even though they are therapeutic effects when the drug is used in ophthalmology.

At higher concentrations, atropine causes block of all parasympathetic functions. However, atropine is a remarkably safe drug *in adults*. Atropine poisoning has occurred as a result of attempted suicide, but most cases are due to attempts to induce hallucinations. Poisoned individuals manifest dry mouth, mydriasis, tachycardia, hot and flushed skin, agitation, and delirium for as long as a week. Body temperature is frequently elevated. These effects are memorialized in the adage, "dry as a bone, blind as a bat, red as a beet, mad as a hatter."

Unfortunately, children, especially infants, are very sensitive to the hyperthermic effects of atropine. Although accidental administration of over 400 mg has been followed by recovery, deaths have followed doses as small as 2 mg. Therefore, atropine should be considered a highly dangerous drug when overdose occurs in infants or children.

Overdoses of atropine or its congeners are generally treated symptomatically (see Chapter 59: Management of the Poisoned Patient). In the past, physostigmine or another cholinesterase inhibitor was recommended, but most poison control experts now consider physostigmine more dangerous and no more effective in most patients than symptomatic management. When physostigmine is deemed necessary, *small* doses are given *slowly* intravenously (1–4 mg in adults, 0.5–1 mg in children). Symptomatic treatment may require temperature control with cooling blankets and seizure control with diazepam.

Poisoning caused by high doses of the quaternary antimuscarinic drugs is associated with all of the peripheral signs of parasympathetic blockade but few or none of the central nervous system effects of atropine. These more polar drugs may cause significant ganglionic blockade, however, with marked orthostatic hypotension (see below). Treatment of the antimuscarinic effects, if required, can be carried out with a quaternary cholinesterase inhibitor such as neostigmine. Control of hypotension may require the administration of a sympathomimetic drug such as phenylephrine.

Contraindications

Contraindications to the use of antimuscarinic drugs are relative, not absolute. *Obvious muscarinic excess, especially that caused by cholinesterase inhibitors, can always be treated with atropine.*

Antimuscarinic drugs are contraindicated in patients with glaucoma, especially angle-closure glaucoma. Even systemic use of moderate doses may precipitate angle closure (and acute glaucoma) in patients with shallow anterior chambers.

In elderly men, antimuscarinic drugs should always be used with caution and should be avoided in those with a history of prostatic hyperplasia.

Because the antimuscarinic drugs slow gastric emptying, they may *increase* symptoms in patients with gastric ulcer. Nonselective antimuscarinic agents should never be used to treat acid-peptic disease (see Chapter 63: Drugs Used in the Treatment of Gastrointestinal Diseases).

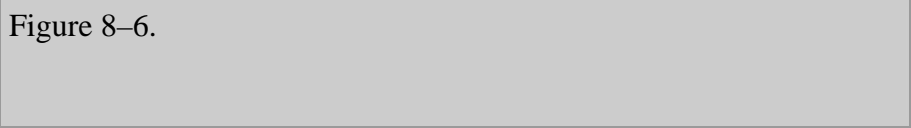

Basic & Clinical Pharmacology of the Ganglion-Blocking Drugs

These agents block the action of acetylcholine and similar agonists at the nicotinic receptors of both parasympathetic and sympathetic autonomic ganglia. Some members of the group also block the ion channel that is gated by the nicotinic cholinergic receptor. The ganglion-blocking drugs are still important and useful in pharmacologic and physiologic research because of their ability to block all autonomic outflow. However, their lack of selectivity confers such a broad range of undesirable effects that they have been abandoned for clinical use.

Chemistry & Pharmacokinetics

All ganglion-blocking drugs of interest are synthetic amines. The first to be recognized as having this action was **tetraethylammonium (TEA)**. Because of the very short duration of action of TEA, **hexamethonium ("C6")** was developed and was soon introduced into clinical medicine as the first effective drug for management of hypertension. As shown in Figure 8–6, there is an obvious relationship between the structures of the agonist acetylcholine and the nicotinic antagonists tetraethylammonium and hexamethonium. Decamethonium, the "C10" analog of hexamethonium, is an effective neuromuscular depolarizing blocking agent.

Figure 8–6.

Because the quaternary amine ganglion-blocking compounds were poorly and erratically absorbed after oral administration, **mecamylamine**, a secondary amine, was developed to improve the degree and extent of absorption from the gastrointestinal tract. **Trimethaphan**, a short-acting ganglion blocker, is inactive orally and is given by intravenous infusion.

Pharmacodynamics

Mechanism of Action

Ganglionic nicotinic receptors, like those of the skeletal muscle neuromuscular junction, are subject to both depolarizing and nondepolarizing blockade (see Chapter 7: Cholinergic-Activating & Cholinesterase-Inhibiting Drugs and Chapter 27: Skeletal Muscle Relaxants). Nicotine itself, carbamoylcholine, and even acetylcholine (if amplified with a cholinesterase inhibitor) can produce depolarizing ganglion block.

The drugs presently used as ganglion blockers are classified as nondepolarizing competitive antagonists. However, evidence suggests that hexamethonium actually produces most of its blockade by occupying sites in or on the ion channel that is controlled by the acetylcholine receptor, not by occupying the cholinergic receptor itself. In contrast, trimethaphan appears to block the nicotinic receptor, not the channel. Blockade can be at least partially overcome by increasing the concentration of normal agonists, eg, acetylcholine.

Organ System Effects

Central Nervous System

The quaternary amine agents and trimethaphan lack central effects because they do not cross the blood-brain barrier. Mecamylamine, however, readily enters the central nervous system. Sedation, tremor, choreiform movements, and mental aberrations have all been reported as effects of the latter drug.

Eye

Because the ciliary muscle receives innervation primarily from the parasympathetic nervous system, the ganglion-blocking drugs cause a predictable cycloplegia with loss of accommodation. The effect on the pupil is not so easily predicted, since the iris receives both sympathetic innervation (mediating pupillary dilation) and parasympathetic innervation (mediating pupillary constriction). Because parasympathetic tone is usually dominant in this tissue, ganglionic blockade usually causes moderate dilation of the pupil.

Cardiovascular System

The blood vessels receive chiefly vasoconstrictor fibers from the sympathetic nervous system; therefore, ganglionic blockade causes a very important decrease in arteriolar and venomotor tone. The blood pressure may drop precipitously, because both peripheral vascular resistance and venous return are decreased (see Figure 6–7). Hypotension is especially marked in the upright position (orthostatic or postural hypotension), because postural reflexes that normally prevent venous pooling are blocked.

Cardiac effects include diminished contractility and, because the sinoatrial node is usually dominated by the parasympathetic nervous system, a moderate tachycardia.

Gastrointestinal Tract

Secretion is reduced, although not enough to effectively treat peptic disease. Motility is profoundly inhibited, and constipation may be marked.

Other Systems

Genitourinary smooth muscle is partially dependent on autonomic innervation for normal function. Ganglionic blockade therefore causes hesitancy in urination and may precipitate urinary retention in men with prostatic hyperplasia. Sexual function is impaired in that both erection and ejaculation may be prevented by moderate doses.

Thermoregulatory sweating is blocked by the ganglion-blocking drugs. However, hyperthermia is not a problem except in very warm environments, because cutaneous vasodilation is usually sufficient to maintain a normal body temperature.

Response to Autonomic Drugs

Because the effector cell receptors (muscarinic, α , and β) are not blocked, patients receiving ganglion-blocking drugs are fully responsive to autonomic drugs acting on these receptors. In fact, responses may be exaggerated or even reversed (eg, norepinephrine may cause tachycardia rather than bradycardia), because homeostatic reflexes, which normally moderate autonomic responses, are absent.

Clinical Applications & Toxicity

Because of the availability of more selective autonomic blocking agents, the applications of the ganglion blockers have almost disappeared. Mecamylamine is being studied for possible use in reducing nicotine craving in patients attempting to quit smoking and for some other central indications. Trimethaphan is occasionally used in the treatment of hypertensive emergencies and dissecting aortic aneurysm, to produce controlled hypotension, which can be of value in neurosurgery to reduce bleeding in the operative field, and in patients undergoing electroconvulsive therapy. The toxicity of the ganglion-blocking drugs is limited to the autonomic effects already described. For most patients, these effects are intolerable except for acute use.

Preparations Available

Antimuscarinic Anticholinergic Drugs*

Atropine (generic)

Oral: 0.4 mg tablets

Parenteral: 0.05, 0.1, 0.3, 0.4, 0.5, 0.8, 1 mg/mL for injection

Ophthalmic (generic, Isopto Atropine): 0.5, 1, 2% drops; 1% ointments

Belladonna alkaloids, extract or tincture (generic)

Oral: 0.27–0.33 mg/mL liquid

Clidinium (Quarzan)

Oral: 2.5, 5 mg capsules

Cyclopentolate(generic, Cyclogyl, others)

Ophthalmic: 0.5, 1, 2% drops

Dicyclomine(generic, Bentyl, others)

Oral: 10, 20 mg capsules; 20 mg tablets; 10 mg/5 mL syrup

Parenteral: 10 mg/mL for injection

Flavoxate (Urispas)

Oral: 100 mg tablets

Glycopyrrolate (generic, Robinul)

Oral: 1, 2 mg tablets

Parenteral: 0.2 mg/mL for injection

Homatropine (generic, Isopto Homatropine)

Ophthalmic: 2, 5% drops

***l*-Hyoscyamine** (Anaspaz, Cystospaz-M, Levsinex)

Oral: 0.125, 0.15 mg tablets; 0.375 mg timed-release capsules; 0.125 mg/5 mL oral elixir and solution

Parenteral: 0.5 mg/mL for injection

Ipratropium (generic, Atrovent)

Aerosol: 200 dose metered-dose inhaler

Solution for nebulizer: 0.02%

Nasal spray: 0.03, 0.06%

Mepenzolate (Cantil)

Oral: 25 mg tablets

Methantheline (Banthine)

Oral: 50 mg tablets

Methscopolamine (Pamine)

Oral: 2.5 mg tablets

Oxybutynin (generic, Ditropan)

Oral: 5 mg tablets; 5, 10, 15 mg extended-release tablets; 5 mg/5 mL syrup

Propantheline (generic, Pro-Banthine)

Oral: 7.5, 15 mg tablets

Scopolamine(generic)

Oral: 0.4 mg tablets

Parenteral: 0.3, 0.4, 0.65, 0.86, 1 mg/mL for injection

Ophthalmic (Isopto Hyoscine): 0.25% solution

Transdermal (Transderm Scop): 1.5 mg (delivers 0.5 mg) patch

Tolterodine (Detrol)

Oral: 1, 2 mg tablets; 2, 4 mg extended-release capsules

Tridihexethyl (Pathilon)

Oral: 25 mg tablets

Tropicamide (generic, Mydriacyl Ophthalmic, others)

Ophthalmic: 0.5, 1% drops

Ganglion Blockers

Mecamylamine (Inversine)

Oral: 2.5 mg tablets

Trimethaphan (Arfonad)

Parenteral: 50 mg/mL

Cholinesterase Regenerator

Pralidoxime(generic, Protopam)

Parenteral: 1 g vial with 20 mL diluent for IV administration; 600 mg in 2 mL autoinjector

* Antimuscarinic drugs used in parkinsonism are listed in Chapter 28: Pharmacologic Management of Parkinsonism & Other Movement Disorders.

Chapter 9. Adrenoceptor-Activating & Other Sympathomimetic Drugs

Adrenoceptor-Activating & Other Sympathomimetic Drugs: Introduction

The sympathetic nervous system is an important regulator of the activities of organs such as the heart and peripheral vasculature, especially in responses to stress (see Chapter 6: Introduction to Autonomic Pharmacology). The ultimate effects of sympathetic stimulation are mediated by release of norepinephrine from nerve terminals that serve to activate the adrenoceptors on postsynaptic sites. Also, in response to a variety of stimuli, such as stress, the adrenal medulla releases epinephrine, which is transported in the blood to target tissues—in other words, epinephrine acts as a hormone. Drugs that mimic the actions of epinephrine or nor-epinephrine—**sympathomimetic drugs**—would be expected to have a wide range of effects. An understanding of the pharmacology of these agents is thus a logical extension of what we know about the physiologic role of the catecholamines.

The Mode & Spectrum of Action of Sympathomimetic Drugs

Like the cholinomimetic drugs, the sympathomimetics can be grouped by mode of action and by the spectrum of receptors that they activate. Some of these drugs (eg, norepinephrine, epinephrine) act by a *direct* mode, ie, they directly interact with and activate adrenoceptors. Others act *indirectly*; their actions are dependent on the release of endogenous catecholamines. These indirect agents may have either of two different mechanisms: (1) displacement of stored catecholamines from the adrenergic nerve ending (eg, amphetamine and tyramine) or (2) inhibition of reuptake of catecholamines already released (eg, cocaine and tricyclic antidepressants). Some drugs have both direct and indirect actions. Both types of sympathomimetics, direct and indirect, ultimately cause activation of adrenoceptors, leading to some or all of the characteristic effects of catecholamines. The selectivity of different sympathomimetics for various types of adrenoceptors is discussed below.

Katzung PHARMACOLOGY, 9e > Section II. Autonomic Drugs > Chapter 9. Adrenoceptor-Activating & Other Sympathomimetic Drugs >

Basic Pharmacology of Sympathomimetic Drugs

Identification of Adrenoceptors

The effort to understand the molecular mechanisms by which catecholamines act has a long and rich history. A great conceptual debt is owed to the work done by John Langley and Paul Ehrlich 100 years ago in developing the hypothesis that drugs have their effects by interacting with specific "receptive" substances. Raymond Ahlquist in 1948 rationalized a large body of observations by his conjecture that catecholamines acted via two principal receptors. He termed these receptors α and β . Alpha receptors are those that have the comparative potencies epinephrine \approx norepinephrine \gg isoproterenol. Beta receptors have the comparative potencies isoproterenol $>$ epinephrine \approx norepinephrine. Ahlquist's hypothesis was dramatically confirmed by the development of drugs that selectively antagonize β receptors but not α receptors (see Chapter 10: Adrenoceptor Antagonist Drugs). More recent evidence suggests that α receptors comprise two major families. At present, therefore, it appears appropriate to classify adrenoceptors into three major groups, namely, β , α_1 , and α_2 receptors. Each of these major groups of receptors has also three subtypes.

Beta Adrenoceptors

Soon after the demonstration of separate α and β receptors, it was found that there were at least two *subtypes* of β receptors, designated β_1 and β_2 . Beta₁ and Beta₂ Receptors are operationally defined by their affinities for epinephrine and norepinephrine: β_1 receptors have approximately equal affinity for epinephrine and norepinephrine, whereas β_2 receptors have a higher affinity for epinephrine than for norepinephrine. Subsequently, β_3 receptors were identified as a novel and distinct third β adrenoceptor subtype. Some of the properties of each of these receptor types are listed in Table 9–1.

Receptor	Agonist	Antagonist	Effects	Gene on Chromosome
α_1 type	Phenylephrine, methoxamine	Prazosin, corynanthine	\uparrow IP ₃ , DAG common to all	
α_{1A}		WB4101,		C5

		prazosin		
α 1B		CEC (irreversible)		C8
α 1D		WB4101		
α 2 type		Rauwolscine, yohimbine	\downarrow cAMP common to all	C20
α 2A	Clonidine, BHT920 Oxymetazoline		\downarrow cAMP; \uparrow K ⁺ channels; \downarrow Ca ²⁺ channels	C10
α 2B		Prazosin	\downarrow cAMP; \downarrow Ca ²⁺ channels	C2
α 2C		Prazosin	\downarrow cAMP	C4
β type	Isoproterenol	Propranolol	\uparrow cAMP common to all	
β 1	Dobutamine	Betaxolol	\uparrow cAMP	C10
β 2	Procaterol, terbutaline	Butoxamine	\uparrow cAMP	C5
β 3	BRL37344		\uparrow cAMP	C8
Dopamine type	Dopamine			
D1	Fenoldopam		\uparrow cAMP	C5
D2	Bromocriptine		\downarrow cAMP; \uparrow K ⁺ channels; \downarrow Ca ²⁺ channels	C11
D3	Quinpirol	AJ76	\downarrow cAMP; \uparrow K ⁺ channels; \uparrow Ca ²⁺ channels	C3
D4		Clozapine	\downarrow cAMP	C11
D5			\uparrow cAMP	C4

Key: BRL37344 = Sodium-4-(2-[2-hydroxy-{3-chlorophenyl}ethylamino]propyl)phenoxyacetate

BHT920 = 6-Allyl-2-amino-5,6,7,8-tetrahydro-4H-thiazolo-[4,5-d]-azepine

CEC = Chloroethylclonidine

DAG = Diacylglycerol

IP₃ = Inositol trisphosphate

WB4101 = *N*-[2-(2,6-dimethoxyphenoxy)ethyl]-2,3-dihydro-1,4-benzodioxan-2-methanamine

Alpha Adrenoceptors

Following the demonstration of the α subtypes, it was found that there are two major groups of α receptors: α_1 and α_2 . These receptors were originally identified with antagonist drugs that distinguished between α_1 and α_2 receptors. For example, α adrenoceptors were identified in a variety of tissues by measuring the binding of radiolabeled antagonist compounds that are considered to have a high affinity for these receptors, eg, dihydroergocryptine (α_1 and α_2), prazosin (α_1), and yohimbine (α_2). These radioligands were used to measure the number of receptors in tissues and to determine the affinity (by displacement of the radiolabeled ligand) of other drugs that interact with the receptors.

The concept of subtypes *within* the α_1 group emerged out of pharmacologic experiments that demonstrated complex shapes of agonist dose-response curves of smooth muscle contraction as well as differences in antagonist affinities in inhibiting contractile responses in various tissues. These experiments demonstrated the existence of two subtypes of α_1 receptor that could be distinguished on the basis of their reversible affinities for a variety of drugs and experimental compounds. A third α_1 receptor subtype was subsequently identified by molecular cloning techniques. These α_1 receptors are termed α_{1A} , α_{1B} , and α_{1D} receptors. There is evidence that the α_{1A} receptor has splice variants. A major current area of investigation is determining the importance of each of these various subtypes in mediating α_1 receptor responses in a variety of organs.

The hypothesis that there are subtypes of α_2 receptors emerged from pharmacologic experiments and molecular cloning. It is now known that there are three subtypes of α_2 receptors, termed α_{2A} , α_{2B} , and α_{2C} , that are products of distinct genes.

Dopamine Receptors

The endogenous catecholamine dopamine produces a variety of biologic effects that are mediated by interactions with specific dopamine receptors (Table 9–1). These receptors are distinct from α and β receptors and are particularly important in the brain (see Chapter 21: Introduction to the Pharmacology of CNS Drugs and Chapter 29: Antipsychotic Agents & Lithium) and in the splanchnic and renal vasculature. There is now considerable evidence for the existence of at least five subtypes of dopamine receptors. Pharmacologically distinct dopamine receptor subtypes, termed D₁ and D₂, have been known for some time. Molecular cloning has identified several distinct genes encoding each of these subtypes. Further complexity occurs because of the presence of introns within the coding region of the D₂-like receptor genes, which allows for alternative splicing of the exons in this major subtype. There is extensive polymorphic variation in the D₄ human receptor gene. The terminology of the various subtypes is D₁, D₂, D₃, D₄, and D₅. They comprise two D₁-like receptors (D₁ and D₅) and three D₂-like (D₂, D₃, and D₄). These subtypes may have importance for understanding the efficacy and adverse effects of novel antipsychotic drugs (see Chapter 29: Antipsychotic Agents & Lithium).

Receptor Selectivity

Examples of clinically useful sympathomimetic agonists that are relatively selective for α_1 -, α_2 -, and β -adrenoceptor subgroups are compared with some nonselective agents in Table 9–2. Selectivity means that a drug may preferentially bind to one subgroup of receptors at concentrations too low to interact extensively with another subgroup. For example, norepinephrine preferentially activates β_1 receptors as compared with β_2 receptors. However, selectivity is not usually absolute (nearly absolute selectivity has been termed "specificity"), and at higher concentrations related classes of receptor may also interact with the drug. As a result, the "numeric" subclassification of adrenoceptors is clinically important mainly for drugs that have relatively marked selectivity. Given interpatient variations in drug kinetics and dynamics, the extent of a drug's selectivity should be kept in mind if this property is viewed as clinically important in the treatment of an individual patient.

Table 9–2. Relative Selectivity of Adrenoceptor Agonists.	
	Relative Receptor Affinities
Alpha agonists	
Phenylephrine, methoxamine	$\alpha_1 > \alpha_2 \ggggg \beta$
Clonidine, methylnorepinephrine	$\alpha_2 > \alpha_1 \ggggg \beta$
Mixed alpha and beta agonists	
Norepinephrine	$\alpha_1 = \alpha_2; \beta_1 \gg \beta_2$
Epinephrine	$\alpha_1 = \alpha_2; \beta_1 = \beta_2$
Beta agonists	
Dobutamine ¹	$\beta_1 > \beta_2 \ggggg \alpha$
Isoproterenol	$\beta_1 = \beta_2 \ggggg \alpha$
Terbutaline, metaproterenol, albuterol, ritodrine	$\beta_2 \gggg \beta_1 \ggggg \alpha$
Dopamine agonists	
Dopamine	$D_1 = D_2 \gggg \beta \gggg \alpha$
Fenoldopam	$D_1 \gggg D_2$

¹See text.

The exact number of adrenoceptor subtypes that are actually expressed in human tissues is uncertain, but expression of subtypes has been demonstrated in tissues where the physiologic or

tissue. For example, determining which blood vessels express which subtypes of α_1 and α_2 receptors could lead to design of drugs having selectivity for certain vascular beds such as the splanchnic or coronary vessels. Similarly, there has been extensive investigation into the α_1 receptor subtypes mediating pharmacologic responses in the human prostate.

Molecular Mechanisms of Sympathomimetic Action

The effects of catecholamines are mediated by cell surface receptors. As described in Chapter 2: Drug Receptors & Pharmacodynamics, these receptors are coupled by G proteins to the various effector proteins whose activities are regulated by those receptors. Each G protein is a heterotrimer consisting of α , β , and γ subunits. G proteins are classified on the basis of their distinctive α subunits. G proteins of particular importance for adrenoceptor function include G_s , the stimulatory G protein of adenylyl cyclase; G_i , the inhibitory G protein of adenylyl cyclase; and G_q , the protein coupling α receptors to phospholipase C. The activation of G protein-coupled receptors by catecholamines promotes the dissociation of GDP from the α subunit of the appropriate G protein. GTP then binds to this G protein, and the α subunit dissociates from the β - γ unit. The activated GTP-bound α subunit then regulates the activity of its effector. Effectors of adrenoceptor-activated α subunits include adenylyl cyclase, cGMP phosphodiesterase, phospholipase C, and ion channels. The α subunit is inactivated by hydrolysis of the bound GTP to GDP and P_i , and the subsequent reassociation of the α subunit with the β - γ subunit. The β - γ subunits have additional independent effects, acting on a variety of effectors such as ion channels and enzymes.

Receptor Types

Alpha Receptors

Alpha₁ receptors stimulate polyphosphoinositide hydrolysis, leading to the formation of inositol 1,4,5-trisphosphate (IP₃) and diacylglycerol (DAG) (Figure 9–1). G proteins in the G_q family couple α_1 receptors to phospholipase C. IP₃ promotes the release of sequestered Ca²⁺ from intracellular stores, which increases the cytoplasmic concentration of free Ca²⁺ and the activation of various calcium-dependent protein kinases. Activation of these receptors may also increase influx of calcium across the cell's plasma membrane. Inositol 1,4,5-trisphosphate is sequentially dephosphorylated, which ultimately leads to the formation of free inositol. DAG activates protein kinase C that modulates activity of many signaling pathways. In addition, α_1 receptors activate signal transduction pathways that were originally described for peptide growth factor receptors which activate tyrosine kinases. For example, α_1 receptors have been found to activate mitogen-activated kinases (MAP kinases) and polyphosphoinositol-3-kinase (PI-3-kinase). These pathways may have importance for the α_1 receptor-mediated stimulation of cell growth and proliferation through the regulation of gene expression. The physiologic significance of this "cross talk" between major signaling pathways remains to be determined.

Figure 9–1.

Activation of α_1 responses. Stimulation of α_1 receptors by catecholamines leads to the activation of a G_q coupling protein. The α subunit of this G protein activates the effector, phospholipase C, which leads to the release of IP_3 (inositol 1,4,5-trisphosphate) and DAG (diacylglycerol) from phosphatidylinositol 4,5-bisphosphate (*PtdIns 4,5-P₂*). IP_3 stimulates the release of sequestered stores of calcium, leading to an increased concentration of cytoplasmic Ca^{2+} . Ca^{2+} may then activate Ca^{2+} -dependent protein kinases, which in turn phosphorylate their substrates. DAG activates protein kinase C. See text for additional effects of α_1 receptor activation.

α_2 receptors inhibit adenylyl cyclase activity and cause intracellular cAMP levels to decrease. In addition to this well-documented effect, activation of α_2 -receptors utilize additional signaling pathways, including regulation of ion channel activities and the activities of important enzymes involved in signal transduction. α_2 -receptor-mediated inhibition of adenylyl cyclase activity is transduced by the inhibitory regulatory protein, G_i , which couples α_2 receptors to the inhibition of adenylyl cyclase (Figure 9–2). How the activation of G_i leads to the inhibition of adenylyl cyclase is unclear, but it is likely that both α and the β - γ subunits of G_i contribute to this response. In addition, some of the effects of α_2 adrenoceptors are independent of their ability to inhibit adenylyl cyclase; for example, α_2 -receptor agonists cause platelet aggregation and a decrease in platelet cAMP levels, but it is not clear that aggregation is the result of the decrease in cAMP or other mechanisms involving G_i -regulated effectors.

Figure 9–2.

Activation and inhibition of adenylyl cyclase by agonists that bind to catecholamine receptors. Binding to βadrenoceptors stimulates adenylyl cyclase by activating the stimulatory G protein, G_s, which leads to the dissociation of its αsubunit charged with GTP. This α_s subunit directly activates adenylyl cyclase, resulting in an increased rate of synthesis of cAMP. Alpha₂ adrenoceptor ligands inhibit adenylyl cyclase by causing dissociation of the inhibitory G protein, G_i, into its subunits; ie, an α_i subunit charged with GTP and a β-γ unit. The mechanism by which these subunits inhibit adenylyl cyclase is uncertain. cAMP binds to the regulatory subunit (R) of cAMP-dependent protein kinase, leading to the liberation of active catalytic subunits (C) that phosphorylate specific protein substrates and modify their activity. These catalytic units also phosphorylate the cAMP response element binding protein (CREB), which modifies gene expression. See text for other actions of βand α₂ adrenoceptors.

Beta Receptors

The mechanism of action of βagonists has been studied in considerable detail. Activation of all three receptor subtypes (β₁, β₂, and β₃) results in activation of adenylyl cyclase and increased conversion of ATP to cAMP (Figure 9–2). Activation of the cyclase enzyme is mediated by the stimulatory coupling protein G_s. cAMP is the major second messenger of β-receptor activation. For example, in the liver of many species, β-receptor activation increases cAMP synthesis, which leads to a cascade of events culminating in the activation of glycogen phosphorylase. In the heart, β-receptor activation increases the influx of calcium across the cell membrane and its sequestration inside the cell. Beta-receptor activation also promotes the relaxation of smooth muscle. While the mechanism is uncertain, it may involve the phosphorylation of myosin light chain kinase to an inactive form (see Figure 12–1). Beta adrenoceptors may activate voltage-sensitive calcium

channels in the heart via G_s -mediated enhancement independently of changes in cAMP concentration. Under certain circumstances, β_2 receptors may couple to G_i proteins. These receptors have been demonstrated to activate additional kinases, such as MAP kinases, by forming multi-subunit complexes, found within cells, containing multiple signaling molecules. In addition, recent evidence suggests that formation of dimers of β receptors themselves (both homodimers and heterodimers of β_1 and β_2 receptors) is importantly involved in their signaling mechanisms.

Dopamine Receptors

The D_1 receptor is typically associated with the stimulation of adenylyl cyclase (Table 9–1); for example, D_1 -receptor-induced smooth muscle relaxation is presumably due to cAMP accumulation in the smooth muscle of those vascular beds where dopamine is a vasodilator. D_2 receptors have been found to inhibit adenylyl cyclase activity, open potassium channels, and decrease calcium influx.

Receptor Regulation

Responses mediated by adrenoceptors are not fixed and static. The number and function of adrenoceptors on the cell surface and their responses may be regulated by catecholamines themselves, other hormones and drugs, age, and a number of disease states. These changes may modify the magnitude of a tissue's physiologic response to catecholamines and can be important clinically during the course of treatment. One of the best-studied examples of receptor regulation is the **desensitization** of adrenoceptors that may occur after exposure to catecholamines and other sympathomimetic drugs. After a cell or tissue has been exposed for a period of time to an agonist, that tissue often becomes less responsive to further stimulation by that agent. Other terms such as tolerance, refractoriness, and tachyphylaxis have also been used to denote desensitization. This process has potential clinical significance because it may limit the therapeutic response to sympathomimetic agents.

Many mechanisms have been found to contribute to desensitization. Operating at transcriptional, translational, and protein levels, some mechanisms function relatively slowly—over the course of hours or days. Other mechanisms of desensitization occur quickly, within minutes. Rapid modulation of receptor function in desensitized cells may involve critical covalent modification of the receptor, especially by phosphorylation on specific amino acid residues, association of these receptors with other proteins, or changes in their subcellular location.

There are two major categories of desensitization of responses mediated by G protein coupled receptors. *Homologous* desensitization refers to loss of responsiveness exclusively of the receptors that have been exposed to repeated or sustained activation by a drug. *Heterologous* desensitization refers to loss of responsiveness of some cell surface receptors that have not been directly activated by the drug in question.

A major mechanism of desensitization that occurs rapidly involves phosphorylation of receptors by members of the G protein-coupled receptor kinase (GRK) family, of which there are at least seven members. Specific adrenoceptors are substrates for these kinases only when they are bound to an agonist. This mechanism is an example of homologous desensitization since it specifically involves only agonist-occupied receptors.

Phosphorylation of these receptors enhances their affinity for β -arrestins; upon binding of a β -arrestin molecule, the capacity of the receptor to activate G proteins is blunted, presumably due to steric hindrance (see Figure 2–12). Arrestins constitute another large family of widely expressed

proteins. Receptor phosphorylation followed by β -arrestin binding has been linked to subsequent endocytosis of the receptor. This response may be facilitated by the capacity of β -arrestins to bind to the structural protein clathrin. In addition to blunting responses requiring the presence of the receptor on the cell surface, these regulatory processes may also contribute to novel mechanisms of receptor signaling via intracellular pathways.

Receptor desensitization may also be mediated by second-messenger feedback. For example, β adrenoceptors stimulate cAMP accumulation, which leads to activation of protein kinase A; protein kinase A can phosphorylate residues on β receptors, resulting in inhibition of receptor function. For example, for the β_2 receptor, phosphorylation occurs on serine residues both in the third cytoplasmic loop and carboxyl terminal tail of the receptor. Similarly, activation of protein kinase C by G_q -coupled receptors may lead to phosphorylation of this class of G protein-coupled receptors. This second-messenger feedback mechanism has been termed *heterologous* desensitization because activated protein kinase A or protein kinase C may phosphorylate any structurally similar receptor with the appropriate consensus sites for phosphorylation by these enzymes.

Adrenoreceptor Polymorphisms

Since elucidation of the sequences of the genes encoding the α_1 , α_2 , and β subtypes of adrenoceptors, it has become clear that there are relatively common genetic polymorphisms for many of these receptor subtypes in humans. Some of these may lead to changes in critical amino acid sequences that have pharmacologic importance. There is evidence that some of these polymorphisms may change the susceptibility to diseases such as heart failure, alter the propensity of a receptor to desensitize, and alter therapeutic responses to drugs in diseases such as asthma.

Chemistry & Pharmacokinetics of Sympathomimetic Drugs

Phenylethylamine may be considered the parent compound from which sympathomimetic drugs are derived (Figure 9–3). This compound consists of a benzene ring with an ethylamine side chain. Substitutions may be made (1) on the terminal amino group, (2) on the benzene ring, and (3) on the α or β carbons. Substitution by $-OH$ groups at the 3 and 4 positions yields sympathomimetic drugs collectively known as catecholamines. The effects of modification of phenylethylamine are to change the affinity of the drugs for α and β receptors as well as to influence the intrinsic ability to activate the receptors. In addition, chemical structure determines the pharmacokinetic properties of these molecules. Sympathomimetic drugs may activate both α and β receptors; however, the relative α -receptor versus β -receptor activity spans the range from almost pure α activity (methoxamine) to almost pure β activity (isoproterenol).

Figure 9–3.

Substitution on the Amino Group

Increasing the size of alkyl substituents on the amino group tends to increase β -receptor activity. For example, methyl substitution on norepinephrine, yielding epinephrine, enhances activity at β_2 receptors. Beta activity is further enhanced with isopropyl substitution at the amino nitrogen (isoproterenol). Beta₂-selective agonists generally require a large amino substituent group. The larger the substituent on the amino group, the lower the activity at α receptors; eg, isoproterenol is very weak at α receptors.

Substitution on the Benzene Ring

Maximal α and β activity are found with catecholamines (drugs having $-\text{OH}$ groups at the 3 and 4 positions). The absence of one or the other of these groups, particularly the hydroxyl at C₃, without other substitutions on the ring may dramatically reduce the potency of the drugs. For example, phenylephrine (Figure 9-4) is much less potent than epinephrine; indeed, α -receptor affinity is decreased about 100-fold and β activity is almost negligible except at very high concentrations. However, catecholamines are subject to inactivation by catechol-*O*-methyltransferase (COMT), an enzyme found in gut and liver (see Chapter 6: Introduction to Autonomic Pharmacology). Therefore, absence of one or both $-\text{OH}$ groups on the phenyl ring increases the bioavailability after oral administration and prolongs the duration of action. Furthermore, absence of ring $-\text{OH}$ groups tends to increase the distribution of the molecule to the central nervous system. For example, ephedrine and amphetamine (Figure 9-4) are orally active, have a prolonged duration of action, and produce central nervous system effects not typically observed with the catecholamines.

Figure 9-4.

Substitution on the Alpha Carbon

Substitutions at the α carbon block oxidation by monoamine oxidase (MAO) and prolong the action of such drugs, particularly the noncatecholamines. Ephedrine and amphetamine are examples of α -substituted compounds (Figure 9-4). Alpha-methyl compounds are also called phenylisopropylamines. In addition to their resistance to oxidation by MAO, some phenylisopropylamines have an enhanced ability to displace catecholamines from storage sites in noradrenergic nerves. Therefore, a portion of their activity is dependent upon the presence of normal norepinephrine stores in the body; they are indirectly acting sympathomimetics.

Substitution on the Beta Carbon

Direct-acting agonists typically have a β -hydroxyl group, though dopamine does not. In addition to activating adrenoceptors, this hydroxyl group may be important for storage of sympathomimetic amines in neural vesicles.

Organ System Effects of Sympathomimetic Drugs

General outlines of the cellular actions of sympathomimetics are presented in Tables 6-3 and 9-3. The net effect of a given drug in the intact organism depends on its relative receptor affinity (α or β), intrinsic activity, and the compensatory reflexes evoked by its direct actions.

Table 9-3. Distribution of Adrenoceptor Subtypes.

Type	Tissue	Actions
α_1	Most vascular smooth muscle (innervated)	Contraction
	Pupillary dilator muscle	Contraction (dilates pupil)
	Pilomotor smooth muscle	Erects hair
	Prostate	Contraction
	Heart	Increases force of contraction

α_2	Postsynaptic CNS adrenoceptors	Probably multiple
	Platelets	Aggregation
	Adrenergic and cholinergic nerve terminals	Inhibition of transmitter release
	Some vascular smooth muscle	Contraction
	Fat cells	Inhibition of lipolysis
β_1	Heart	Increases force and rate of contraction
β_2	Respiratory, uterine, and vascular smooth muscle	Promotes smooth muscle relaxation
	Skeletal muscle	Promotes potassium uptake
	Human liver	Activates glycogenolysis
β_3	Fat cells	Activates lipolysis
D ₁	Smooth muscle	Dilates renal blood vessels
D ₂	Nerve endings	Modulates transmitter release

Cardiovascular System

Blood Vessels

Vascular smooth muscle tone is regulated by adrenoceptors; consequently, catecholamines are important in controlling peripheral vascular resistance and venous capacitance. Alpha receptors increase arterial resistance, whereas β_2 receptors promote smooth muscle relaxation. There are major differences in receptor types in the various vascular beds (Table 9–4). The skin vessels have predominantly α receptors and constrict in the presence of epinephrine and norepinephrine, as do the splanchnic vessels. Vessels in skeletal muscle may constrict or dilate depending on whether α or β receptors are activated. Consequently, the overall effects of a sympathomimetic drug on blood vessels depend on the relative activities of that drug at α and β receptors and the anatomic sites of the vessels affected. In addition, D₁ receptors promote vasodilation of renal, splanchnic, coronary, cerebral, and perhaps other resistance vessels. Activation of the D₁ receptors in the renal vasculature may play a major role in the natriuresis induced by pharmacologic administration of dopamine.

Heart

Direct effects on the heart are determined largely by β_1 receptors, although β_2 and to a lesser extent α receptors are also involved. Beta-receptor activation results in increased calcium influx in cardiac cells. This has both electrical (Figure 9–5) and mechanical consequences. Pacemaker activity, both normal (sinoatrial node) and abnormal (eg, Purkinje fibers), is increased (positive chronotropic effect). Conduction velocity in the atrioventricular node is increased, and the refractory period is decreased. Intrinsic contractility is increased (positive inotropic effect), and relaxation is accelerated. As a result, the twitch response of isolated cardiac muscle is increased in tension but abbreviated in duration. In the intact heart, intraventricular pressure rises and falls more rapidly, and ejection time is decreased. These direct effects are easily demonstrated in the absence of reflexes evoked by changes in blood pressure, eg, in isolated myocardial preparations and in patients with ganglionic blockade. In the presence of normal reflex activity, the direct effects on heart rate may

be dominated by a reflex response to blood pressure changes. Physiologic stimulation of the heart by catecholamines tends to increase coronary blood flow.

Figure 9–5.

Effect of epinephrine on the transmembrane potential of a pacemaker cell in the frog heart. The arrowed trace was recorded after the addition of epinephrine. Note the increased slope of diastolic depolarization and decreased interval between action potentials. This pacemaker acceleration is typical of β_1 -stimulant drugs. (Modified and reproduced, with permission, from Brown H, Giles W, Noble S: Membrane currents underlying rhythmic activity in frog sinus venosus. In: *The Sinus Node: Structure, Function, and Clinical Relevance*. Bonke FIM [editor]. Martinus Nijhoff, 1978.)

Blood Pressure

The effects of sympathomimetic drugs on blood pressure can be explained on the basis of their effects on the heart, the peripheral vascular resistance, and the venous return (see Figure 6–7 and Table 9–4). A relatively pure α agonist such as phenylephrine increases peripheral arterial resistance and decreases venous capacitance. The enhanced arterial resistance usually leads to a dose-dependent rise in blood pressure (Figure 9–6). In the presence of normal cardiovascular reflexes, the rise in blood pressure elicits a baroreceptor-mediated increase in vagal tone with slowing of the heart rate, which may be quite marked. However, cardiac output may not diminish in proportion to this reduction in rate, since increased venous return may increase stroke volume; furthermore, direct α -adrenoceptor stimulation of the heart may have a modest positive inotropic action. While these are the expected effects of pure α agonists in normal subjects, their use in hypotensive patients usually does not lead to brisk reflex responses because in this situation blood pressure is returning to normal, not exceeding normal.

Figure 9–6.

Effects of an α -selective (phenylephrine), β -selective (isoproterenol), and nonselective (epinephrine) sympathomimetic, given as an intravenous bolus injection to a dog. (BP, blood pressure; HR, heart rate.) Reflexes are blunted but not eliminated in this anesthetized animal.

The blood pressure response to a pure β -adrenoceptor agonist is quite different. Stimulation of β receptors in the heart increases cardiac output. A relatively pure β agonist such as isoproterenol also decreases peripheral resistance by activating β_2 receptors, leading to vasodilation in certain vascular beds (Table 9-4). The net effect is to maintain or slightly increase systolic pressure while permitting a fall in diastolic pressure owing to enhanced diastolic runoff (Figure 9-6). The actions of drugs with both α and β effects (eg, epinephrine and norepinephrine) are discussed below.

Table 9-4. Cardiovascular Responses to Sympathomimetic Amines.¹

	Phenylephrine	Epinephrine	Isoproterenol
Vascular resistance (tone)			
Cutaneous, mucous membranes (α)	↑↑	↑↑	0
Skeletal muscle (β_2 , α)	↑	↓ or ↑	↓↓
Renal (α , β)	↑	↑	↓
Splanchnic (α)	↑↑	↓ or ↑ ²	↓

Total peripheral resistance	↑↑↑	↓OR ↑ ²	↓↓
Venous tone (α , β)	↑	↑	↓
Cardiac			
Contractility (β_1)	0 or ↑	↑↑↑	↑↑↑
Heart rate (predominantly β_1)	↓↓(vagal reflex)	↑OR ↓	↑↑↑
Stroke volume	0, ↓, ↑	↑	↑
Cardiac output	↓	↑	↑↑
Blood pressure			
Mean	↑↑	↑	↓
Diastolic	↑↑	↓OR ↑ ²	↓↓
Systolic	↑↑	↑↑	0 or ↓
Pulse pressure	0	↑↑	↑↑

¹ ↑ = increase; ↓ = decrease; 0 = no change.

² Small doses decrease, large doses increase.

Eye

The radial pupillary dilator muscle of the iris contains α receptors; activation by drugs such as phenylephrine causes mydriasis (Figure 6–9). Alpha and β stimulants also have important effects on intraocular pressure. Present evidence suggests that α agonists increase the outflow of aqueous humor from the eye, while β antagonists decrease the production of aqueous humor. These effects are important in the treatment of glaucoma (see Chapter 10: Adrenoceptor Antagonist Drugs), a leading cause of blindness. Beta stimulants relax the ciliary muscle to a minor degree, causing an insignificant decrease in accommodation. In addition, adrenergic drugs may directly protect neuronal cells in the retina.

Respiratory Tract

Bronchial smooth muscle contains β_2 receptors that cause relaxation. Activation of these receptors results in bronchodilation (see Chapter 20: Drugs Used in Asthma and Table 9–3). The blood vessels of the upper respiratory tract mucosa contain α receptors; the decongestant action of adrenoceptor stimulants is clinically useful (see Clinical Pharmacology).

Gastrointestinal Tract

Relaxation of gastrointestinal smooth muscle can be brought about by both α - and β -stimulant agents. Beta receptors appear to be located directly on the smooth muscle cells and mediate relaxation via hyperpolarization and decreased spike activity in these cells. Alpha stimulants, especially α_2 -selective agonists, decrease muscle activity *indirectly* by presynaptically reducing the release of acetylcholine and possibly other stimulants within the enteric nervous system (see

Chapter 6: Introduction to Autonomic Pharmacology). The α -receptor-mediated response is probably of greater pharmacologic significance than the β -stimulant response. Alpha₂ receptors may also decrease salt and water flux into the lumen of the intestine.

Genitourinary Tract

The human uterus contains α and β_2 receptors. The fact that the β receptors mediate relaxation may be clinically useful in pregnancy (see Clinical Pharmacology). The bladder base, urethral sphincter, and prostate contain α receptors that mediate contraction and therefore promote urinary continence. The specific subtype of α_1 receptor involved in mediating constriction of the bladder base and prostate is uncertain, but α_{1A} receptors probably play an important role. The β_2 receptors of the bladder wall mediate relaxation. Ejaculation depends upon normal α -receptor (and possibly purinergic receptor) activation in the ductus deferens, seminal vesicles, and prostate. The detumescence of erectile tissue that normally follows ejaculation is also brought about by norepinephrine (and possibly neuropeptide Y) released from sympathetic nerves. Alpha activation appears to have a similar detumescent effect on erectile tissue in female animals.

Exocrine Glands

The salivary glands contain adrenoceptors that regulate the secretion of amylase and water. However, certain sympathomimetic drugs, eg, clonidine, produce symptoms of dry mouth. The mechanism of this effect is uncertain; it is likely that central nervous system effects are responsible, though peripheral effects may contribute.

The apocrine sweat glands, located on the palms of the hands and a few other areas, respond to adrenoceptor stimulants with increased sweat production. These are the apocrine nonthermoregulatory glands usually associated with psychologic stress. (The diffusely distributed thermoregulatory eccrine sweat glands are regulated by *sympathetic cholinergic* postganglionic nerves that activate muscarinic cholinergic receptors; see Chapter 6: Introduction to Autonomic Pharmacology.)

Metabolic Effects

Sympathomimetic drugs have important effects on intermediary metabolism. Activation of β adrenoceptors in fat cells leads to increased lipolysis with enhanced release of free fatty acids and glycerol into the blood. Beta₃ adrenoceptors play a role in mediating this response. There is considerable interest in developing β_3 receptor-selective agonists, which could be useful in some metabolic disorders. Human lipocytes also contain α_2 receptors that inhibit lipolysis by decreasing intracellular cAMP. Sympathomimetic drugs enhance glycogenolysis in the liver, which leads to increased glucose release into the circulation. In the human liver, the effects of catecholamines are probably mediated mainly by β receptors, though α_1 receptors may also play a role. Catecholamines in high concentration may also cause metabolic acidosis. Activation of β_2 adrenoceptors by endogenous epinephrine or by sympathomimetic drugs promotes the uptake of potassium into cells, leading to a fall in extracellular potassium. This may lead to a fall in the plasma potassium concentration during stress or protect against a rise in plasma potassium during exercise. Blockade of these receptors may accentuate the rise in plasma potassium that occurs during exercise. Beta receptors and α_2 receptors that are expressed in pancreatic islets tend to increase and decrease, respectively, insulin secretion, although the major regulator of insulin release is the plasma concentration of glucose.

Effects on Endocrine Function & Leukocytosis

Catecholamines are important endogenous regulators of hormone secretion from a number of glands. As mentioned above, insulin secretion is stimulated by β receptors and inhibited by α_2 receptors. Similarly, renin secretion is stimulated by β_1 and inhibited by α_2 receptors; indeed, β -receptor antagonist drugs may lower plasma renin and blood pressure in patients with hypertension at least in part by this mechanism. Adrenoceptors also modulate the secretion of parathyroid hormone, calcitonin, thyroxine, and gastrin; however, the physiologic significance of these control mechanisms is probably limited. In high concentrations, epinephrine and related agents cause leukocytosis, in part by promoting demargination of white blood cells sequestered away from the general circulation.

Effects on the Central Nervous System

The action of sympathomimetics on the central nervous system varies dramatically, depending on their ability to cross the blood-brain barrier. The catecholamines are almost completely excluded by this barrier, and subjective central nervous system effects are noted only at the highest rates of infusion. These effects have been described as ranging from "nervousness" to "a feeling of impending disaster," sensations that are undesirable. Furthermore, peripheral effects of β adrenoceptor agonists such as tachycardia and tremor are similar to the somatic manifestations of anxiety. In contrast, noncatecholamines with indirect actions, such as amphetamines, which readily enter the central nervous system from the circulation, produce qualitatively very different central nervous system effects. These actions vary from mild alerting, with improved attention to boring tasks; through elevation of mood, insomnia, euphoria, and anorexia; to full-blown psychotic behavior. These effects are not readily assigned to either α - or β -mediated actions and may represent enhancement of dopamine-mediated processes or other effects of these drugs in the central nervous system.

Specific Sympathomimetic Drugs

Catecholamines

Epinephrine (adrenaline) is a very potent vasoconstrictor and cardiac stimulant. The rise in systolic blood pressure that occurs after epinephrine release or administration is caused by its positive inotropic and chronotropic actions on the heart (predominantly β_1 receptors) and the vasoconstriction induced in many vascular beds (α receptors). Epinephrine also activates β_2 receptors in some vessels (eg, skeletal muscle blood vessels), leading to their dilation. Consequently, total peripheral resistance may actually fall, explaining the fall in diastolic pressure that is sometimes seen with epinephrine injection (Figure 9–6; Table 9–4). Activation of these β_2 receptors in skeletal muscle contributes to increased blood flow during exercise. Under physiologic conditions, epinephrine functions largely as a hormone; after release from the adrenal medulla into the blood, it acts on distant cells.

Norepinephrine (levarterenol, noradrenaline) and epinephrine have similar effects on β_1 receptors in the heart and similar potency at α receptors. Norepinephrine has relatively little effect on β_2 receptors. Consequently, norepinephrine increases peripheral resistance and both diastolic and systolic blood pressure. Compensatory vagal reflexes tend to overcome the direct positive chronotropic effects of norepinephrine; however, the positive inotropic effects on the heart are maintained (Table 9–4).

Isoproterenol (isoprenaline) is a very potent β -receptor agonist and has little effect on α receptors. The drug has positive chronotropic and inotropic actions; because isoproterenol activates β receptors almost exclusively, it is a potent vasodilator. These actions lead to a marked increase in cardiac

output associated with a fall in diastolic and mean arterial pressure and a lesser decrease or a slight increase in systolic pressure (Table 9–4; Figure 9–6).

Dopamine, the immediate metabolic precursor of norepinephrine, activates D_1 receptors in several vascular beds, which leads to vasodilation. The effect this has on renal blood flow may be of clinical value, though this is uncertain. The activation of presynaptic D_2 receptors, which suppress norepinephrine release, contributes to these effects to an unknown extent. In addition, dopamine activates β_1 receptors in the heart. At low doses, peripheral resistance may decrease. At higher rates of infusion, dopamine activates vascular α receptors, leading to vasoconstriction, including in the renal vascular bed. Consequently, high rates of infusion of dopamine may mimic the actions of epinephrine.

Fenoldopam is a D_1 receptor agonist that selectively leads to peripheral vasodilation in some vascular beds. The primary indication for fenoldopam is as an intravenously administered drug for the treatment of severe hypertension (Chapter 11: Antihypertensive Agents). Continuous infusions of the drug have prompt effects on blood pressure.

Dopamine agonists with central actions are of considerable value for the treatment of Parkinson's disease and prolactinemia. These agents are discussed in Chapter 28: Pharmacologic Management of Parkinsonism & Other Movement Disorders and Chapter 37: Hypothalamic & Pituitary Hormones.

Dobutamine is a relatively β_1 -selective synthetic catecholamine. As discussed below, dobutamine also activates α_1 receptors.

Other Sympathomimetics

These agents are of interest because of pharmacokinetic features (oral activity, distribution to the central nervous system) or because of relative selectivity for specific receptor subclasses.

Phenylephrine was previously described as an example of a relatively pure α agonist (Table 9–2). It acts directly on the receptors. Because it is not a catechol derivative (Figure 9–4), it is not inactivated by COMT and has a much longer duration of action than the catecholamines. It is an effective mydriatic and decongestant and can be used to raise the blood pressure (Figure 9–6).

Methoxamine acts pharmacologically like phenylephrine, since it is predominantly a direct-acting α_1 -receptor agonist. It may cause a prolonged increase in blood pressure due to vasoconstriction; it also causes a vagally mediated bradycardia. Methoxamine is available for parenteral use, but clinical applications are rare and limited to hypotensive states.

Midodrine is a prodrug that is enzymatically hydrolyzed to desglymidodrine, an α_1 receptor-selective agonist. The peak concentration of desglymidodrine is achieved about 1 hour after midodrine is administered. The primary indication for midodrine is the treatment of postural hypotension, typically due to impaired autonomic nervous system function. While the drug has efficacy in diminishing the fall of blood pressure when the patient is standing, it may cause hypertension when the subject is supine.

Ephedrine occurs in various plants and has been used in China for over 2000 years; it was introduced into Western medicine in 1924 as the first orally active sympathomimetic drug. It is found in Ma-huang, a popular herbal medication (see Chapter 65: Botanicals ("Herbal Medications") & Nutritional Supplements). Ma-huang contains multiple ephedrine-like alkaloids in

addition to ephedrine. Because ephedrine is a noncatechol phenylisopropylamine (Figure 9–4), it has high bioavailability and a relatively long duration of action—hours rather than minutes. As is the case with many other phenylisopropylamines, a significant fraction of the drug is excreted unchanged in the urine. Since it is a weak base, its excretion can be accelerated by acidification of the urine.

Ephedrine has not been extensively studied in humans in spite of its long history of use. Its ability to activate β receptors probably accounted for its earlier use in asthma. Because it gains access to the central nervous system, it is a mild stimulant. Ingestion of ephedrine alkaloids contained in Ma-huang has raised important safety concerns. Pseudoephedrine, one of four ephedrine enantiomers, is available over the counter as a component of many decongestant mixtures.

Xylometazoline and **oxymetazoline** are direct-acting α agonists. These drugs have been used as topical decongestants because of their ability to promote constriction of the nasal mucosa. When taken in large doses, oxymetazoline may cause hypotension, presumably because of a central clonidine-like effect (Chapter 11: Antihypertensive Agents). (As noted in Table 9–1, oxymetazoline has significant affinity for α_{2A} receptors.)

Amphetamine is a phenylisopropylamine (Figure 9–4) that is important chiefly because of its use and misuse as a central nervous system stimulant (see Chapter 32: Drugs of Abuse). Its pharmacokinetics are similar to those of ephedrine; however, amphetamine very readily enters the central nervous system, where it has marked stimulant effects on mood and alertness and a depressant effect on appetite. Its peripheral actions are mediated primarily through the release of catecholamines. **Methamphetamine** (*N*-methylamphetamine) is very similar to amphetamine with an even higher ratio of central to peripheral actions. **Phenmetrazine** (see Figure 32–1) is a variant phenylisopropylamine with amphetamine-like effects. It has been promoted as an anorexiant and is also a popular drug of abuse. **Methylphenidate** and **pemoline** are amphetamine variants whose major pharmacologic effects and abuse potential are similar to those of amphetamine. These two drugs appear to have efficacy in some children with attention deficit hyperactivity disorder (see Clinical Pharmacology). Pemoline must be used with great caution because of an association with life-threatening hepatic failure. **Modafinil** is a new drug with both similarities to and differences from amphetamine. It has significant effects on central α_{1B} receptors but in addition appears to affect GABAergic, glutaminergic, and serotonergic synapses (see Clinical Pharmacology). **Phenylpropanolamine** (PPA) is a sympathomimetic drug that for many years was used as an over-the-counter agent in numerous weight reduction and cold medications. It has been withdrawn from over-the-counter use in the USA because of concerns regarding an association with hemorrhagic stroke.

Receptor-Selective Sympathomimetic Drugs

Alpha₂-selective agonists have an important ability to decrease blood pressure through actions in the central nervous system even though direct application to a blood vessel may cause vasoconstriction. Such drugs (eg, clonidine, methyldopa, guanfacine, guanabenz) are useful in the treatment of hypertension (and some other conditions) and are discussed in Chapter 11:

Antihypertensive Agents. **Dexmedetomidine** is a centrally acting α_2 -selective agonist that is indicated for sedation of initially intubated and mechanically ventilated patients during treatment in an intensive care setting.

Beta-selective agonists are very important because of the separation of β_1 and β_2 effects that has been achieved (Table 9–2). Although this separation is incomplete, it is sufficient to reduce adverse effects in several clinical applications.

Beta₁-selective agents include dobutamine and a partial agonist, prenalterol (Figure 9–7). Because they are less effective in activating vasodilator β₂ receptors, they may increase cardiac output with less reflex tachycardia than occurs with nonselective βagonists such as isoproterenol. Dobutamine consists of two isomers, administered as a racemic mixture. The (+) isomer is a potent β₁ agonist and an α₁ receptor antagonist. The (–) isomer is a potent α₁ agonist, capable of causing significant vasoconstriction when given alone. This action tends to reduce vasodilation and may also contribute to the positive inotropic action caused by the isomer with predominantly β-receptor activity. A major limitation with these drugs—as with other direct-acting sympathomimetic agents—is that tolerance to their effects may develop with prolonged use and the likelihood that chronic cardiac stimulation in patients with heart failure may worsen long-term outcome.

Figure 9–7.

Beta₂-selective agents have achieved an important place in the treatment of asthma and are discussed in Chapter 20: Drugs Used in Asthma. An additional application is to achieve uterine relaxation in premature labor (ritodrine; see below). Some examples of β₂-selective drugs currently in use are shown in Figures 9–7 and 20–4; many more are available or under investigation.

Special Sympathomimetics

Cocaine is a local anesthetic with a peripheral sympathomimetic action that results from inhibition of transmitter reuptake at noradrenergic synapses (see Chapter 6: Introduction to Autonomic Pharmacology). It readily enters the central nervous system and produces an amphetamine-like effect that is shorter lasting and more intense. The major action of cocaine in the central nervous system is to inhibit dopamine reuptake into neurons in the "pleasure centers" of the brain. These properties and the fact that it can be smoked, "snorted" into the nose, or injected for rapid onset of

effect have made it a heavily abused drug (see Chapter 32: Drugs of Abuse). Interestingly, dopamine-transporter knockout mice still self-administer cocaine, suggesting that cocaine may have additional pharmacologic targets.

Tyramine (see Figure 6–5) is a normal by-product of tyrosine metabolism in the body and is also found in high concentrations in fermented foods such as cheese (Table 9–5). It is readily metabolized by MAO in the liver and is normally inactive when taken orally because of a very high first-pass effect, ie, low bioavailability. If administered parenterally, it has an indirect sympathomimetic action caused by the release of stored catecholamines. Consequently, its spectrum of action is similar to that of norepinephrine. In patients treated with MAO inhibitors—particularly inhibitors of the MAO-A isoform—this effect of tyramine may be greatly intensified, leading to marked increases in blood pressure. This occurs on account of increased bioavailability of tyramine and increased neuronal stores of catecholamines. Patients taking MAO inhibitors must be very careful to avoid tyramine-containing foods. There are differences in the effects of various MAO inhibitors on tyramine bioavailability, and isoform-specific or reversible enzyme antagonists may be safer (see Chapter 28: Pharmacologic Management of Parkinsonism & Other Movement Disorders and Chapter 30: Antidepressant Agents).

Table 9–5. Foods Reputed to Have a High Content of Tyramine or Other Sympathomimetic Agents.

Food	Tyramine Content of an Average Serving
Beer	(No data)
Broad beans, fava beans	Negligible (but contains dopamine)
Cheese, natural or aged	Nil to 130 mg (Cheddar, Gruyère, and Stilton especially high)
Chicken liver	Nil to 9 mg
Chocolate	Negligible (but contains phenylethylamine)
Sausage, fermented (eg, salami, pepperoni, summer sausage)	Nil to 74 mg
Smoked or pickled fish (eg, pickled herring)	Nil to 198 mg
Snails	(No data)
Wine (red)	Nil to 3 mg
Yeast (eg, dietary brewer's yeast supplements)	2–68 mg

Note: In a patient taking an irreversible MAO inhibitor drug, 20–50 mg of tyramine in a meal may increase the blood pressure significantly (see also Chapter 30: Antidepressant Agents). Note that only cheese, sausage, pickled fish, and yeast supplements contain sufficient tyramine to be consistently dangerous. This does not rule out the possibility that some preparations of other foods might contain significantly greater than average amounts of tyramine.

Clinical Pharmacology of Sympathomimetic Drugs

The rationale for the use of sympathomimetic drugs in therapy rests on a knowledge of the physiologic effects of catecholamines on tissues. Selection of a particular sympathomimetic drug from the host of compounds available depends upon such factors as whether activation of α , β_1 , or β_2 receptors is desired; the duration of action desired; and the preferred route of administration. Sympathomimetic drugs are very potent and can have profound effects on a variety of organ systems, particularly the heart and peripheral circulation. Therefore, great caution is indicated when these agents are used parenterally. In most cases, rather than using fixed doses of the drugs, careful monitoring of pharmacologic response is required to determine the appropriate dosage, especially if the drug is being infused. Generally, it is desirable to use the minimum dose required to achieve the desired response. The adverse effects of these drugs are generally understandable in terms of their known physiologic effects.

Cardiovascular Applications

Conditions in Which Blood Flow or Pressure Is to Be Enhanced

Hypotension may occur in a variety of settings such as decreased blood volume, cardiac arrhythmias, neurologic disease, adverse reactions to medications such as antihypertensive drugs, and infection. If cerebral, renal, and cardiac perfusion is maintained, hypotension itself does not usually require vigorous direct treatment. Rather, placing the patient in the recumbent position and ensuring adequate fluid volume—while the primary problem is determined and treated—is usually the correct course of action. The use of sympathomimetic drugs merely to elevate a blood pressure that is not an immediate threat to the patient may increase morbidity (see Toxicity of Sympathomimetic Drugs, below). Sympathomimetic drugs may be used in a hypotensive emergency to preserve cerebral and coronary blood flow. Such situations might arise in severe hemorrhage, spinal cord injury, or overdoses of antihypertensive or central nervous system depressant medications. The treatment is usually of short duration while the appropriate intravenous fluid or blood is being administered. Direct-acting α -agonists such as norepinephrine, phenylephrine, or methoxamine have been utilized in this setting if vasoconstriction is desired. For the treatment of chronic orthostatic hypotension, oral ephedrine has been the traditional therapy. Midodrine, an orally active α -agonist, may be the preferred sympathomimetic in this application if further studies confirm its long-term safety and efficacy.

Shock is a complex acute cardiovascular syndrome that results in a critical reduction in perfusion of vital tissues and a wide range of systemic effects. Shock is usually associated with hypotension, an altered mental state, oliguria, and metabolic acidosis. If untreated, shock usually progresses to a refractory deteriorating state and death. The three major mechanisms responsible for shock are hypovolemia, cardiac insufficiency, and altered vascular resistance. Volume replacement and treatment of the underlying disease are the mainstays of the treatment of shock. While sympathomimetic drugs have been used in the treatment of virtually all forms of shock, their efficacy is unclear. In most forms of shock, vasoconstriction mediated by the sympathetic nervous system is already intense. Indeed, efforts aimed at reducing rather than increasing peripheral resistance may be more fruitful if cerebral, coronary, and renal perfusion are improved. A decision to use vasoconstrictors or vasodilators is best made on the basis of information about the underlying cause, which may require invasive monitoring.

Cardiogenic shock, usually due to massive myocardial infarction, has a poor prognosis. Mechanically assisted perfusion and emergency cardiac surgery have been utilized in some settings. Optimal fluid replacement requires monitoring of pulmonary capillary wedge pressure and other parameters of cardiac function. Positive inotropic agents such as dopamine or dobutamine may have a role in this situation. In low to moderate doses, these drugs may increase cardiac output and, compared with norepinephrine, cause relatively little peripheral vasoconstriction. Isoproterenol increases heart rate and work more than either dopamine or dobutamine. See Chapter 13: Drugs Used in Heart Failure and Table 13–6 for a discussion of shock associated with myocardial infarction.

Unfortunately, the patient with shock may not respond to any of these therapeutic maneuvers; the temptation is then great to use vasoconstrictors to maintain adequate blood pressure. While coronary perfusion may be improved, this gain may be offset by increased myocardial oxygen demands as well as more severe vasoconstriction in blood vessels to the abdominal viscera. Therefore, the goal of therapy in shock should be to optimize tissue perfusion, not blood pressure.

Conditions in Which Blood Flow Is to Be Reduced

Reduction of regional blood flow is desirable for achieving hemostasis in surgery, for reducing diffusion of local anesthetics away from the site of administration, and for reducing mucous membrane congestion. In each instance, α -receptor activation is desired, and the choice of agent depends upon the maximal efficacy required, the desired duration of action, and the route of administration.

Effective pharmacologic hemostasis, often necessary for facial, oral, and nasopharyngeal surgery, requires drugs of high efficacy that can be administered in high concentration by local application. Epinephrine is usually applied topically in nasal packs (for epistaxis) or in a gingival string (for gingivectomy). **Cocaine** is still sometimes used for nasopharyngeal surgery, because it combines a hemostatic effect with local anesthesia. Occasionally, cocaine is mixed with epinephrine for maximum hemostasis and local anesthesia.

Combining α agonists with some local anesthetics greatly prolongs the duration of infiltration nerve block; the total dose of local anesthetic (and the probability of toxicity) can therefore be reduced. **Epinephrine**, 1:200,000, is the favored agent for this application, but norepinephrine, phenylephrine, and other α agonists have also been used. Systemic effects on the heart and peripheral vasculature may occur even with local drug administration.

Mucous membrane decongestants are α agonists that reduce the discomfort of hay fever and, to a lesser extent, the common cold by decreasing the volume of the nasal mucosa. These effects are probably mediated by α_1 receptors. Unfortunately, rebound hyperemia may follow the use of these agents, and repeated topical use of high drug concentrations may result in ischemic changes in the mucous membranes, probably as a result of vasoconstriction of nutrient arteries. Constriction of these vessels may involve activation of α_2 receptors. For example, phenylephrine is often used in nasal decongestant sprays. A longer duration of action—at the cost of much lower local concentrations and greater potential for cardiac and central nervous system effects—can be achieved by the oral administration of agents such as ephedrine or one of its isomers, pseudoephedrine. Long-acting topical decongestants include xylometazoline and oxymetazoline. All of these mucous membrane decongestants are available as over-the-counter products.

Cardiac Applications

Catecholamines such as isoproterenol and epinephrine have been utilized in the temporary emergency management of complete heart block and cardiac arrest. Epinephrine may be useful in cardiac arrest in part by redistributing blood flow during cardiopulmonary resuscitation to coronaries and to the brain. However, electronic pacemakers are both safer and more effective in heart block and should be inserted as soon as possible if there is any indication of continued high-degree block.

Heart failure may respond to the positive inotropic effects of drugs such as dobutamine. These applications are discussed in Chapter 13: Drugs Used in Heart Failure. The development of tolerance or desensitization is a major limitation to the use of catecholamines in heart failure.

Pulmonary Applications

One of the most important uses of sympathomimetic drugs is in the therapy of bronchial asthma. This use is discussed in Chapter 20: Drugs Used in Asthma. Nonselective drugs (epinephrine), β -selective agents (isoproterenol), and β_2 -selective agents (metaproterenol, terbutaline, albuterol) are all available for this indication. Sympathomimetics other than the β_2 -selective drugs are now rarely used because they are likely to have more adverse effects than the selective drugs.

Anaphylaxis

Anaphylactic shock and related immediate (type I) IgE-mediated reactions affect both the respiratory and the cardiovascular systems. The syndrome of bronchospasm, mucous membrane congestion, angioedema, and severe hypotension usually responds rapidly to the parenteral administration of **epinephrine**, 0.3–0.5 mg (0.3–0.5 mL of 1:1000 epinephrine solution). Intramuscular injection may be the preferred route of administration, since skin blood flow (and hence systemic drug absorption from subcutaneous injection) may be unpredictable in hypotensive patients. In some patients with impaired cardiovascular function, very cautious intravenous injection of epinephrine may be required. Epinephrine is the agent of choice because of extensive experimental and clinical experience with the drug in anaphylaxis and because epinephrine activates α , β_1 , and β_2 receptors, all of which may be important in reversing the pathophysiologic processes underlying anaphylaxis. Glucocorticoids and antihistamines (both H_1 and H_2 receptor antagonists) may be useful as secondary therapy in anaphylaxis; however, epinephrine is the initial treatment.

Ophthalmic Applications

Phenylephrine is an effective mydriatic agent frequently used to facilitate examination of the retina. It is also a useful decongestant for minor allergic hyperemia and itching of the conjunctival membranes. Sympathomimetics administered as ophthalmic drops are also useful in localizing the lesion in Horner's syndrome. (See An Application of Basic Pharmacology to a Clinical Problem.)

Glaucoma responds to a variety of sympathomimetic and sympathoplegic drugs. (See box in Chapter 10: Adrenoceptor Antagonist Drugs: The Treatment of Glaucoma.) Epinephrine and its prodrug dipivefrin are now rarely used, but β -blocking agents are among the most important therapies. **Apraclonidine** and **brimonidine** are α_2 -selective agonists that also lower intraocular pressure and are approved for use in glaucoma. The mechanism of action of these drugs in treating glaucoma is still uncertain; direct neuroprotective effects may be involved in addition to the benefits of lowering intraocular pressure.

Genitourinary Applications

As noted above, β_2 -selective agents relax the pregnant uterus. **Ritodrine, terbutaline**, and similar drugs have been used to suppress premature labor. The goal is to defer labor long enough to ensure adequate maturation of the fetus. These drugs may delay labor for several days. This may afford time to administer corticosteroid drugs, which decrease the incidence of neonatal respiratory distress syndrome. However, meta-analysis of older trials and a randomized study suggest that β -agonist therapy may have no significant benefit on perinatal infant mortality and may increase maternal morbidity.

Oral sympathomimetic therapy is occasionally useful in the treatment of stress incontinence. Ephedrine or pseudoephedrine may be tried.

Central Nervous System Applications

As noted above, the amphetamines have a mood-elevating (euphoriant) effect; this effect is the basis for the widespread abuse of this drug and some of its analogs (see Chapter 32: Drugs of Abuse). The amphetamines also have an alerting, sleep-deferring action that is manifested by improved attention to repetitive tasks and by acceleration and desynchronization of the EEG. A therapeutic application of this effect is in the treatment of narcolepsy. **Modafinil**, a new amphetamine substitute, is approved for use in narcolepsy and is claimed to have fewer disadvantages (excessive mood changes, insomnia, abuse potential) than amphetamine in this condition. The appetite-suppressing effect of these agents is easily demonstrated in experimental animals. In obese humans, an encouraging initial response may be observed, but there is no evidence that long-term improvement in weight control can be achieved with amphetamines alone, especially when administered for a relatively short course. A final application of the CNS-active sympathomimetics is in the attention-deficit hyperactivity disorder (ADHD) of children, a poorly defined and overdiagnosed behavioral syndrome consisting of short attention span, hyperkinetic physical behavior, and learning problems. Some patients with this syndrome respond well to low doses of methylphenidate and related agents or to clonidine. Extended-release formulations of methylphenidate may simplify dosing regimens and increase adherence to therapy, especially in school-age children. Evidence from several clinical trials suggests that modafinil may also be useful in ADHD.

Additional Therapeutic Uses

While the primary use of the α_2 agonist clonidine is in the treatment of hypertension (Chapter 11: Antihypertensive Agents), the drug has been found to have efficacy in the treatment of diarrhea in diabetics with autonomic neuropathy, perhaps due to its ability to enhance salt and water absorption from the intestines. In addition, clonidine has efficacy in diminishing craving for narcotics and alcohol during withdrawal and may facilitate cessation of cigarette smoking. Clonidine has also been used to diminish menopausal hot flashes and is being used experimentally to reduce hemodynamic instability during general anesthesia. Dexmedetomidine is indicated for sedation under intensive care circumstances.

Toxicity of Sympathomimetic Drugs

The adverse effects of adrenoceptor agonists are primarily extensions of their pharmacologic effects in the cardiovascular and central nervous systems.

Adverse cardiovascular effects seen with intravenously infused pressor agents include marked elevations in blood pressure that cause increased cardiac work, which may precipitate cardiac ischemia and failure. Systemically administered β -receptor-stimulant drugs may cause sinus

tachycardia and may even provoke serious ventricular arrhythmias. Sympathomimetic drugs may lead to myocardial damage, particularly after prolonged infusion. Special caution is indicated in elderly patients or those with hypertension or coronary artery disease. To avoid excessive pharmacologic responses, it is essential to monitor the blood pressure when administering sympathomimetic drugs parenterally.

If an adverse sympathomimetic effect requires urgent reversal, a specific adrenoceptor antagonist can be used (see Chapter 10: Adrenoceptor Antagonist Drugs).

Central nervous system toxicity is rarely observed with catecholamines or drugs such as phenylephrine. In moderate doses, amphetamines commonly cause restlessness, tremor, insomnia, and anxiety; in high doses, a paranoid state may be induced. Cocaine may precipitate convulsions, cerebral hemorrhage, arrhythmias, or myocardial infarction. Therapy is discussed in Chapter 59: Management of the Poisoned Patient.

An Application of Basic Pharmacology to a Clinical Problem

Horner's syndrome is a condition—usually unilateral—that results from interruption of the sympathetic nerves to the face. The effects include vasodilation, ptosis, miosis, and loss of sweating on the side affected. The syndrome can be caused by either a preganglionic or a postganglionic lesion, such as a tumor. Knowledge of the location of the lesion (preganglionic or postganglionic) helps determine the optimal therapy.

An understanding of the effects of denervation on neurotransmitter metabolism permits the clinician to use drugs to localize the lesion. In most situations, a localized lesion in a nerve will cause degeneration of the distal portion of that fiber and loss of transmitter contents from the degenerated nerve ending—without affecting neurons innervated by the fiber. Therefore, a preganglionic lesion will leave the postganglionic adrenergic neuron intact, whereas a postganglionic lesion results in degeneration of the adrenergic nerve endings and loss of stored catecholamines from them. Because indirectly acting sympathomimetics require normal stores of catecholamines, such drugs can be used to test for the presence of normal adrenergic nerve endings. The iris, because it is easily visible and responsive to topical sympathomimetics, is a convenient assay tissue in the patient.

If the lesion of Horner's syndrome is postganglionic, indirectly acting sympathomimetics (eg, cocaine, hydroxyamphetamine) will not dilate the abnormally constricted pupil—because catecholamines have been lost from the nerve endings in the iris. In contrast, the pupil will dilate in response to phenylephrine, which acts directly on the α -receptors on the smooth muscle of the iris. A patient with a preganglionic lesion, on the other hand, will show a normal response to both drugs, since the postganglionic fibers and their catecholamine stores remain intact in this situation.

Preparations Available¹

Amphetamine, racemic mixture (generic)

Oral: 5, 10 mg tablets

Oral (Adderall): 1:1:1:1 mixtures of amphetamine sulfate, amphetamine aspartate, dextroamphetamine sulfate, and dextroamphetamine saccharate, formulated to contain a total of 5, 7.5, 10, 12.5, 15, 20, or 30 mg in tablets; or 10, 20, or 30 mg in capsules

Apraclonidine(Iopidine)

Topical: 0.5, 1% solutions

Brimonidine (Alphagan)

Topical: 0.15, 0.2% solution

Dexmedetomidine (Precedex)

Parenteral: 100 µg/mL

Dexmethylphenidate (Focalin)

Oral: 2.5, 5, 10 mg tablets

Dextroamphetamine(generic, Dexedrine)

Oral: 5, 10 mg tablets

Oral sustained-release: 5, 10, 15 mg capsules

Oral mixtures with amphetamine: see Amphetamine (Adderall)

Dipivefrin (generic, Propine)

Topical: 0.1% ophthalmic solution

Dobutamine (generic, Dobutrex)

Parenteral: 12.5 mg/mL in 20 mL vials for injection

Dopamine(generic, Intropin)

Parenteral: 40, 80, 160 mg/mL for injection; 80, 160, 320 mg/100 mL in 5% D/W for injection

Ephedrine (generic)

Oral: 25 mg capsules

Parenteral: 50 mg/mL for injection

Nasal: 0.25% spray

Epinephrine(generic, Adrenalin Chloride, others)

Parenteral: 1:1000 (1 mg/mL), 1:2000 (0.5 mg/mL), 1:10,000 (0.1 mg/mL), 1:100,000 (0.01 mg/mL) for injection

Parenteral autoinjector (Epipen): 1:2000 (0.5 mg/mL)

Ophthalmic: 0.1, 0.5, 1, 2% drops

Nasal: 0.1% drops and spray

Aerosol for bronchospasm (Primatene Mist, Bronkaid Mist): 0.16, 0.2 mg/spray

Solution for aerosol: 1:100

Fenoldopam(Corlopam)

Parenteral: 10 mg/mL for IV infusion

Hydroxyamphetamine (Paredrine)

Ophthalmic: 1% drops

Isoproterenol (generic, Isuprel)

Parenteral: 1:5000 (0.2 mg/mL), 1:50,000 (0.02 mg/mL) for injection

Mephentermine (Wyamine Sulfate)

Parenteral: 15, 30 mg/mL for injection

Metaraminol (Aramine)

Parenteral: 10 mg/mL for injection

Methamphetamine (Desoxyn)

Oral: 5 mg tablets

Methoxamine (Vasoxyl)

Parenteral: 20 mg/mL for injection

Methylphenidate(generic, Ritalin, Ritalin-SR)

Oral: 5, 10, 20 mg tablets

Oral sustained-release: 10, 18, 20, 27, 36, 54 mg tablets; 20, 30, 40 mg capsules

Midodrine(ProAmatine)

Oral: 2.5, 5 mg tablets

Modafinil(Provigil)

Oral: 100, 200 mg tablets

Naphazoline (Privine)

Nasal: 0.05% drops and spray

Ophthalmic: 0.012, 0.02, 0.03% drops

Norepinephrine(generic, Levophed)

Parenteral: 1 mg/mL for injection

Oxymetazoline(generic, Afrin, Neo-Synephrine 12 Hour, others)

Nasal: 0.025, 0.05% sprays

Ophthalmic: 0.025% drops

Pemoline (generic, Cylert)

Oral: 18.75, 37.5, 75 mg tables; 37.5 mg chewable tablets

Phendimetrazine (generic)

Oral: 35 mg tablets, capsules; 105 mg sustained-release capsules

Phenylephrine(generic, Neo-Synephrine)

Oral: 10 mg chewable tablets

Parenteral: 10 mg/mL for injection

Nasal: 0.125, 0.16, 0.25, 0.5, 1% drops and spray; 0.5% jelly

Pseudoephedrine(generic, Sudafed, others)

Oral: 30, 60 mg tablets; 60 mg capsules; 15, 30 mg/5 mL syrups; 7.5 mg/0.8 mL drops

Oral extended-release: 120, 240 mg tablets, capsules

Tetrahydrozoline(generic, Tyzine)

Nasal: 0.05, 0.1% drops

Ophthalmic: 0.05% drops

Xylometazoline(generic, Otrivin, Neo-Synephrine Long-Acting, Chlorohist LA)

Nasal: 0.05 drops, 0.1% drops and spray

¹ α_2 -Agonists used in hypertension are listed in Chapter 11: Antihypertensive Agents. β_2 -Agonists used in asthma are listed in Chapter 20: Drugs Used in Asthma.

Adrenoceptor Antagonist Drugs: Introduction

Since catecholamines play a role in a variety of physiologic and pathophysiologic responses, drugs that block adrenoceptors have important effects, some of which are of great clinical value. These effects vary dramatically according to the drug's selectivity for α and β receptors. The classification of adrenoceptors into α_1 , α_2 , and β subtypes and the effects of activating these receptors are discussed in Chapters 6 and 9. Blockade of peripheral dopamine receptors is of no recognized clinical importance at present. In contrast, blockade of central nervous system dopamine receptors is very important; drugs that act on these receptors are discussed in Chapters 21 and 29. This chapter deals with pharmacologic antagonist drugs whose major effect is to occupy either α_1 , α_2 , or β receptors outside the central nervous system and prevent their activation by catecholamines and related agonists.

For pharmacologic research, α_1 - and α_2 -adrenoceptor antagonist drugs have been very useful in the experimental exploration of autonomic nervous system function. In clinical therapeutics, nonselective α antagonists have been used in the treatment of pheochromocytoma (tumors that secrete catecholamines), and α_1 -selective antagonists are used in primary hypertension and benign prostatic hyperplasia. Beta-receptor antagonist drugs have been found useful in a much wider variety of clinical conditions and are firmly established in the treatment of hypertension, ischemic heart disease, arrhythmias, endocrinologic and neurologic disorders, and other conditions.

Katzung PHARMACOLOGY, 9e > Section II. Autonomic Drugs > Chapter 10. Adrenoceptor Antagonist Drugs >

Basic Pharmacology of the Alpha-Receptor Antagonist Drugs

Mechanism of Action

Alpha-receptor antagonists may be reversible or irreversible in their interaction with these receptors. Reversible antagonists dissociate from receptors; irreversible drugs do not. Phentolamine (Figure 10–1) and tolazoline are examples of reversible antagonists. Prazosin (and analogs) and labetalol—drugs used primarily for their antihypertensive effects—as well as several ergot

derivatives (see Chapter 16: Histamine, Serotonin, & the Ergot Alkaloids) are also reversible α -adrenoceptor antagonists. Phenoxybenzamine, an agent related to the nitrogen mustards, forms a reactive ethyleneimmonium intermediate (Figure 10–1) that covalently binds to α receptors, resulting in irreversible blockade. Figure 10–2 illustrates the effects of a reversible drug in comparison with those of an irreversible agent.

Figure 10–1.

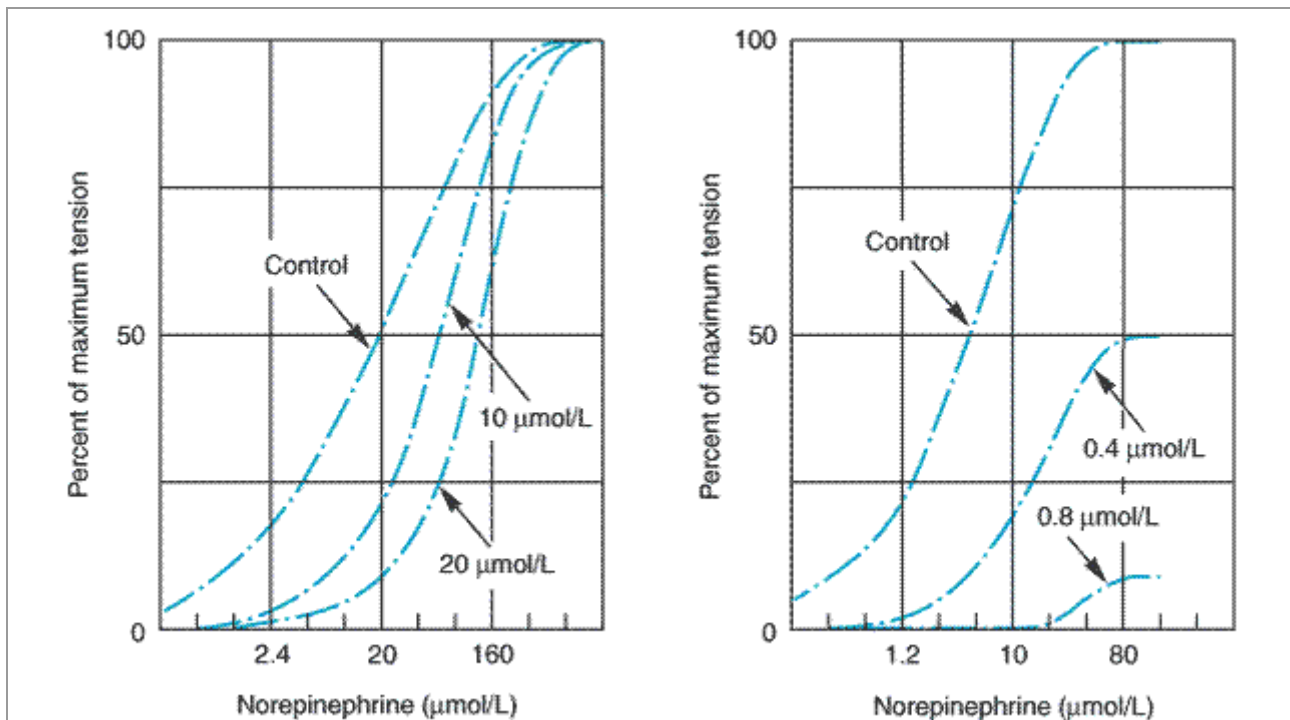

Figure 10–2.

Dose-response curves to norepinephrine in the presence of two different α -adrenoceptor-blocking drugs. The tension produced in isolated strips of cat spleen, a tissue rich in α receptors, was measured in response to graded doses of norepinephrine. **Left:** Tolazoline, a reversible blocker, shifted the curve to the right without decreasing the maximum response when present at concentrations of 10 and 20 $\mu\text{mol/L}$. **Right:** Dibenamine, an analog of phenoxybenzamine and irreversible in its action, reduced the maximum response attainable at both concentrations tested. (Modified and reproduced, with permission, from Bickerton RK: The response of isolated strips of cat spleen to sympathomimetic drugs and their antagonists. *J Pharmacol Exp Ther* 1963;142:99.)

The duration of action of a reversible antagonist is largely dependent on the half-life of the drug in the body and the rate at which it dissociates from its receptor: The shorter the half-life of the drug in the body or of binding to its receptor, the less time it takes for the effects of the drug to dissipate. However, the effects of an irreversible antagonist may persist long after the drug has been cleared from the plasma. In the case of phenoxybenzamine, the restoration of tissue responsiveness after extensive α -receptor blockade is dependent on synthesis of new receptors, which may take several days. The rate of return of α_1 adrenoceptor drug effect may be particularly important in patients having a sudden cardiovascular event or who become candidates for urgent surgery.

Pharmacologic Effects

Cardiovascular Effects

Because arteriolar and venous tone are determined to a large extent by α receptors on vascular smooth muscle, α -receptor antagonist drugs cause a lowering of peripheral vascular resistance and blood pressure (Figure 10–3). These drugs can prevent the pressor effects of usual doses of α agonists; indeed, in the case of agonists with both α and β_2 effects (eg, epinephrine), selective α_1 receptor antagonism may convert a pressor to a depressor response (Figure 10–3). This change in response is called **epinephrine reversal**; it illustrates how the activation of both α and β receptors in the same tissue may lead to opposite responses. Alpha-receptor antagonists may cause postural hypotension and reflex tachycardia. Postural hypotension is due to antagonism of sympathetic nervous system stimulation of α_1 receptors in venous smooth muscle; contraction of veins is an

important component of the capacity to maintain blood pressure in the upright position since it decreases venous pooling in the periphery. Constriction of arterioles in the legs may also contribute to the postural response. Tachycardia may be more marked with agents that block α_2 -presynaptic receptors in the heart (Table 10–1), since the augmented release of norepinephrine will further stimulate β receptors in the heart.

Figure 10–3.

Top: Effects of phentolamine, an α -receptor-blocking drug, on blood pressure in an anesthetized dog. Epinephrine reversal is demonstrated by tracings showing the response to epinephrine before (**middle**) and after (**bottom**) phentolamine. All drugs given intravenously. (BP, blood pressure; HR, heart rate.)

Other Effects

Minor effects that signal the blockade of α -receptors in other tissues include miosis and nasal stuffiness. Alpha₁-receptor blockade of the base of the bladder and the prostate is associated with decreased resistance to the flow of urine. Individual agents may have other important effects in addition to α -receptor antagonism (see below).

Specific Agents

Phentolamine, an imidazoline derivative, is a potent competitive antagonist at both α_1 and α_2 receptors (Table 10–1). Phentolamine causes a reduction in peripheral resistance through blockade

of α_1 receptors and possibly α_2 receptors on vascular smooth muscle. The cardiac stimulation induced by phentolamine is due to sympathetic stimulation of the heart resulting from baroreflex mechanisms. Furthermore, since phentolamine potently blocks α_2 receptors, antagonism of presynaptic α_2 receptors may lead to enhanced release of norepinephrine from sympathetic nerves. Enhanced norepinephrine release may contribute to cardiac stimulation via unblocked β adrenoceptors, especially after intravenous injection. In addition to being an α_1 - and α_2 -receptor antagonist, phentolamine also inhibits responses to serotonin and may be an agonist at muscarinic and H_1 and H_2 histamine receptors. Consequently, phentolamine has multiple potential actions, though it is not clear which if any of these are clinically significant.

Table 10–1. Relative Selectivity of Antagonists for Adrenoceptors.	
	Receptor Affinity
αAntagonists	
Prazosin, terazosin, doxazosin	$\alpha_1 \gggg \alpha_2$
Phenoxybenzamine	$\alpha_1 > \alpha_2$
Phentolamine	$\alpha_1 = \alpha_2$
Rauwolscine, yohimbine, tolazoline	$\alpha_2 \gggg \alpha_1$
Mixed antagonists	
Labetalol, carvedilol	$\beta_1 = \beta_2 \approx \alpha_1 > \alpha_2$
βAntagonists	
Metoprolol, acebutolol, alprenolol, atenolol, betaxolol, celiprolol, esmolol	$\beta_1 \gggg \beta_2$
Propranolol, carteolol, penbutolol, pindolol, timolol	$\beta_1 = \beta_2$
Butoxamine	$\beta_2 \gggg \beta_1$

Phentolamine has limited absorption after oral administration. Its pharmacokinetic properties are not well known; it may reach peak concentrations within an hour after oral administration and has a half-life of about 5–7 hours. The principal adverse effects are related to cardiac stimulation, which may cause severe tachycardia, arrhythmias, and myocardial ischemia, especially after intravenous administration. With oral administration, adverse effects include tachycardia, nasal congestion, and headache.

Phentolamine has been used in the treatment of pheochromocytoma—especially intraoperatively—as well as for male erectile dysfunction by injection intracavernosally and when taken orally (see below).

Tolazoline is similar to phentolamine. Tolazoline has very limited clinical application in the treatment of pulmonary hypertension in newborn infants with respiratory distress syndrome. Its efficacy in this condition is doubtful, and the drug is rarely used.

Ergot derivatives—eg, ergotamine, dihydroergotamine—cause reversible α -receptor blockade. However, most of the clinically significant effects of these drugs are the result of other actions; eg, ergotamine probably acts at serotonin receptors in the treatment of migraine (Chapter 16: Histamine, Serotonin, & the Ergot Alkaloids).

Phenoxybenzamine binds covalently to α receptors, causing irreversible blockade of long duration (14–48 hours or longer). It is somewhat selective for α_1 receptors but less so than prazosin (Table 10–1). The drug also inhibits reuptake of released norepinephrine by presynaptic adrenergic nerve terminals. Phenoxybenzamine blocks histamine (H_1), acetylcholine, and serotonin receptors as well as α receptors (see Chapter 16: Histamine, Serotonin, & the Ergot Alkaloids).

The pharmacologic actions of phenoxybenzamine are primarily related to antagonism of α -receptor-mediated events. Most importantly, phenoxybenzamine attenuates catecholamine-induced vasoconstriction. While phenoxybenzamine causes relatively little fall in blood pressure in normal supine individuals, it reduces blood pressure when sympathetic tone is high, eg, as a result of upright posture or because of reduced blood volume. Cardiac output may be increased because of reflex effects and because of some blockade of presynaptic α_2 receptors in cardiac sympathetic nerves.

Phenoxybenzamine is absorbed after oral administration, although bioavailability is low and its kinetic properties are not well known. The drug is usually given orally, starting with low doses of 10–20 mg/d and progressively increasing the dose until the desired effect is achieved. Less than 100 mg/d is usually sufficient to achieve adequate α -receptor blockade. The major use of phenoxybenzamine is in the treatment of pheochromocytoma (see below).

Many of the adverse effects of phenoxybenzamine derive from its α -receptor-blocking action; the most important are postural hypotension and tachycardia. Nasal stuffiness and inhibition of ejaculation also occur. Since phenoxybenzamine enters the central nervous system, it may cause less specific effects, including fatigue, sedation, and nausea. Since phenoxybenzamine is an alkylating agent, it may have other adverse effects that have not yet been characterized. Phenoxybenzamine causes tumors in animals, but the clinical implications of this observation are unknown.

Prazosin is a piperazinyloquinazoline effective in the management of hypertension (see Chapter 11: Antihypertensive Agents). It is highly selective for α_1 receptors, having relatively low affinity for α_2 receptors (typically 1000-fold less potent). This may partially explain the relative absence of tachycardia seen with prazosin as compared to what is reported with phentolamine and phenoxybenzamine. Prazosin leads to relaxation of both arterial and venous smooth muscle due to blockade of α_1 receptors. Prazosin is extensively metabolized in humans; because of metabolic degradation by the liver, only about 50% of the drug is available after oral administration. The half-life is normally about 3 hours.

Terazosin is another reversible α_1 -selective antagonist that is effective in hypertension (Chapter 11: Antihypertensive Agents); it has also been approved for use in men with urinary symptoms due to benign prostatic hyperplasia (BPH). Terazosin has high bioavailability but is extensively metabolized in the liver, with only a small fraction of unchanged drug excreted in the urine. The half-life of terazosin is 9–12 hours.

Doxazosin is efficacious in the treatment of hypertension and BPH. It differs from prazosin and terazosin in having a longer half-life of about 22 hours. It has moderate bioavailability and is extensively metabolized, with very little parent drug excreted in urine or feces. Doxazosin has active metabolites, although their contribution to the drug's effects is probably small.

Tamsulosin is a competitive α_1 antagonist with a structure quite different from that of most other α_1 -receptor blockers. It has high bioavailability and a long half-life of 9–15 hours. It is metabolized extensively in the liver. Tamsulosin has higher affinity for α_{1A} and α_{1D} receptors than for the α_{1B} subtype. The drug's efficacy in BPH suggests that the α_{1A} subtype may be the most important α subtype mediating prostate smooth muscle contraction. Evidence suggests that tamsulosin has relatively greater potency in inhibiting contraction in *prostate* smooth muscle versus *vascular* smooth muscle, compared with other α_1 -selective antagonists, which have equal or greater effects in vascular smooth muscle. This finding suggests that α_{1A} receptors are less important in mediating contraction in human arteries and veins. Furthermore, compared with other antagonists, tamsulosin has less effect on standing blood pressure in patients. Nonetheless, caution is appropriate in using any α -antagonist in patients with diminished sympathetic nervous system function.

Other Alpha-Adrenoceptor Antagonists

Alfuzosin is an α_1 -selective quinazoline derivative that has also been shown to be efficacious in BPH. It has a bioavailability of about 60%, is extensively metabolized, and has an elimination half-life of about 5 hours. This drug is not currently available in the USA. **Indoramin** is another α_1 -selective antagonist that also has efficacy as an antihypertensive. **Urapidil** is an α_1 antagonist (its primary effect) that also has weak α_2 -agonist and 5-HT_{1A}-agonist actions and weak antagonist action at β_1 receptors. It is used in Europe as an antihypertensive agent and for benign prostatic hyperplasia. **Labetalol** has both α_1 -selective and β -antagonistic effects; it is discussed below. Neuroleptic drugs such as chlorpromazine and haloperidol are potent dopamine receptor antagonists but may also be antagonists at α -receptors. Their antagonism of α -receptors probably contributes to some of their adverse effects, particularly hypotension. Similarly, the antidepressant trazodone has the capacity to block α_1 receptors.

Yohimbine, an indole alkaloid, is an α_2 -selective antagonist. It has no established clinical role. Theoretically, it could be useful in autonomic insufficiency by promoting neurotransmitter release through blockade of presynaptic α_2 receptors. It has been suggested that yohimbine improves male sexual function; however, evidence for this effect in humans is limited. Yohimbine can abruptly reverse the antihypertensive effects of an α_2 -adrenoceptor agonist such as clonidine—a potentially serious adverse drug interaction.

Clinical Pharmacology of the Alpha-Receptor-Blocking Drugs

Pheochromocytoma

The major clinical use of both phenoxybenzamine and phentolamine is in the management of pheochromocytoma. Pheochromocytoma is a tumor usually found in the adrenal medulla that releases a mixture of epinephrine and norepinephrine. Patients have many symptoms and signs of catecholamine excess, including intermittent or sustained hypertension, headaches, palpitations, and increased sweating.

The diagnosis of pheochromocytoma is usually made on the basis of chemical assay of circulating catecholamines and urinary excretion of catecholamine metabolites, especially 3-hydroxy-4-methoxymandelic acid, metanephrine, and normetanephrine. Measurement of plasma metanephrines has shown promise as an effective diagnostic tool. A variety of diagnostic techniques are available to localize a pheochromocytoma diagnosed biochemically, including CT and MRI scans as well as scanning with various radioisotopes.

Infusion of phentolamine was advocated in the past as a diagnostic test when pheochromocytoma was suspected, since patients with this tumor often manifest a greater drop in blood pressure in response to α -blocking drugs than do patients with primary hypertension. Provocative testing by infusion of histamine was occasionally used because this vasodilator drug may elicit a marked reflex rise in pressure in patients with pheochromocytoma. These tests are obsolete because measurement of circulating catecholamines and urinary catecholamines and their metabolites is a safer and far more reliable diagnostic approach.

Unavoidable release of stored catecholamines sometimes occurs during operative manipulation of pheochromocytoma; the resulting hypertension may be controlled with phentolamine or nitroprusside. Nitroprusside has many advantages, particularly since its effects can be more readily titrated and it has a shorter duration of action.

Alpha-receptor antagonists are most useful in the preoperative management of patients with pheochromocytoma (Figure 10–4). Administration of phenoxybenzamine in the preoperative period will help control hypertension and will tend to reverse chronic changes resulting from excessive catecholamine secretion such as plasma volume contraction, if present. Furthermore, the patient's operative course may be simplified. Oral doses of 10–20 mg/d may be increased at intervals of several days until hypertension is controlled. Some physicians give phenoxybenzamine to patients with pheochromocytoma for 1–3 weeks before surgery. Other surgeons prefer to operate on patients in the absence of treatment with phenoxybenzamine, counting on modern anesthetic techniques to control blood pressure and heart rate during surgery. Phenoxybenzamine may be very useful in the chronic treatment of inoperable or metastatic pheochromocytoma. Although there is less experience with alternative drugs, hypertension in patients with pheochromocytoma may also respond to reversible α_1 -selective antagonists or to conventional calcium channel antagonists. Beta-receptor antagonists may be required after α -receptor blockade has been instituted to reverse the cardiac effects of excessive catecholamines. Beta antagonists should not be employed prior to establishing effective α -receptor blockade, since unopposed β -receptor blockade could theoretically cause blood pressure elevation from increased vasoconstriction.

Figure 10–4.

Effects of phenoxybenzamine (Dibenzyline) on blood pressure in a patient with pheochromocytoma. Dosage of the drug was begun in the third week as shown by the shaded bar. Supine systolic and diastolic pressures are indicated by the circles, the standing pressures by triangles and the hatched area. Note that the α -blocking drug dramatically reduced blood pressure. The reduction in orthostatic hypotension, which was marked before treatment, is probably due to normalization of blood volume, a variable that is sometimes markedly reduced in patients with long-standing pheochromocytoma-induced hypertension. (Redrawn and reproduced, with permission, from Engelman E, Sjoerdsma A: Chronic medical therapy for pheochromocytoma. *Ann Intern Med* 1961;61:229.)

Pheochromocytoma is rarely treated with **metyrosine** (α -methyltyrosine), the α -methyl analog of tyrosine. This agent is a competitive inhibitor of tyrosine hydroxylase and, in oral doses of 1–4 g/d, interferes with synthesis of dopamine (see Figure 6–5), thereby decreasing the amounts of norepinephrine and epinephrine secreted by the tumor. Metyrosine, while not an α -adrenoceptor antagonist, may act additively with phenoxybenzamine and a β -adrenoceptor antagonist in the treatment of pheochromocytoma. Metyrosine is especially useful in symptomatic patients with inoperable or metastatic pheochromocytoma.

Hypertensive Emergencies

The α -adrenoceptor antagonist drugs have limited application in the management of hypertensive emergencies, although labetalol has been used in this setting. In theory, α -adrenoceptor antagonists

are most useful when increased blood pressure reflects excess circulating concentrations of α agonists. In this circumstance, which may result from pheochromocytoma, overdosage of sympathomimetic drugs, or clonidine withdrawal, phentolamine can be used to control high blood pressure. However, other drugs are generally preferable (see Chapter 11: Antihypertensive Agents), since considerable experience is necessary to use phentolamine safely in these settings and few physicians have such experience.

Chronic Hypertension

Members of the prazosin family of α_1 -selective antagonists are efficacious drugs in the treatment of mild to moderate systemic hypertension. They are generally well tolerated by most patients. However, their efficacy in preventing heart failure when used as monotherapy for hypertension has been questioned. Their major adverse effect is postural hypotension, which may be severe after the first dose but is otherwise uncommon (see Chapter 11: Antihypertensive Agents). Nonselective α antagonists are not used in primary systemic hypertension. Prazosin and related drugs may also be associated with feelings of dizziness. This symptom may not be due to a fall in blood pressure, but postural changes in blood pressure should be checked routinely in any patient being treated for hypertension.

Interestingly, the use of α -adrenoceptor antagonists such as prazosin has been found to be associated with either no changes in plasma lipids or increased concentrations of HDL, which could be a favorable alteration. The mechanism for this effect is not known.

Peripheral Vascular Disease

Although α -receptor-blocking drugs have been tried in the treatment of peripheral vascular occlusive disease, there is no evidence that the effects are significant when morphologic changes limit flow in the vessels. Occasionally, individuals with Raynaud's phenomenon and other conditions involving excessive reversible vasospasm in the peripheral circulation do benefit from phentolamine, prazosin, or phenoxybenzamine, although calcium channel blockers may be preferable for many patients.

Local Vasoconstrictor Excess

Phentolamine has been used to reverse the intense local vasoconstriction caused by inadvertent infiltration of α agonists (eg, norepinephrine) into subcutaneous tissue during intended intravenous administration. The α antagonist is administered by local infiltration into the ischemic tissue.

Urinary Obstruction

Benign prostatic hyperplasia is a prevalent disorder in elderly men. A variety of surgical treatments are effective in relieving the urinary symptoms of BPH; however, drug therapy is efficacious in many patients. Alpha-receptor blockade was first found to be helpful in BPH using phenoxybenzamine in selected patients who were poor operative risks. The mechanism of action in improving urine flow involves partial reversal of smooth muscle contraction in the enlarged prostate and in the bladder base. It has been suggested that some α_1 -receptor antagonists may have additional effects on cells in the prostate that help improve symptoms.

A number of well-controlled studies have demonstrated reproducible efficacy of several α_1 -receptor antagonists in patients with BPH—lasting for several years in many cases. Prazosin, doxazosin, and terazosin are efficacious. These drugs are particularly useful in patients who also have hypertension.

Considerable interest has focused on which α_1 -receptor subtype is most important for smooth muscle contraction in the prostate: *subtype-selective* α_{1A} -receptor antagonists might lead to improved efficacy and safety in treating this disease. As indicated above, tamsulosin is also efficacious in BPH and has little if any effect on blood pressure. This drug may be preferred in patients who have experienced postural hypotension with other α_1 -receptor antagonists. Some evidence suggests that the efficacy of α_1 -receptor antagonists exceeds that of finasteride, the 5 α -reductase inhibitor (see Chapter 40: The Gonadal Hormones & Inhibitors).

Erectile Dysfunction

A combination of the α -adrenoceptor antagonist phentolamine with the nonspecific vasodilator papaverine, when injected directly into the penis, may cause erections in men with sexual dysfunction. Fibrotic reactions may occur, especially with long-term administration. Systemic absorption may lead to orthostatic hypotension; priapism may require direct treatment with an α -adrenoceptor agonist such as phenylephrine. Orally administered phentolamine is being investigated in patients with erectile dysfunction (and in women with disorders of arousal.) Alternative therapies include prostaglandins (see Chapter 18: The Eicosanoids: Prostaglandins, Thromboxanes, Leukotrienes, & Related Compounds), sildenafil, a cGMP phosphodiesterase inhibitor (see Chapter 12: Vasodilators & the Treatment of Angina Pectoris), and apomorphine.

Applications of Alpha₂ Antagonists

Alpha₂ antagonists have relatively little clinical usefulness. There has been experimental interest in the development of highly selective antagonists for use in Raynaud's phenomenon to inhibit smooth muscle contraction and in the treatment of type 2 diabetes (α_2 receptors inhibit insulin secretion) and psychiatric depression. It is not known to what extent the recognition of multiple subtypes of α_2 receptors will lead to development of clinically useful subtype-selective new drugs.

Katzung PHARMACOLOGY, 9e > Section II. Autonomic Drugs > Chapter 10. Adrenoceptor Antagonist Drugs >

Basic Pharmacology of the Beta-Receptor-Antagonist Drugs

Drugs in this category share the common feature of antagonizing the effects of catecholamines at β adrenoceptors. Beta-blocking drugs occupy β receptors and competitively reduce receptor occupancy by catecholamines and other β agonists. (A few members of this group, used only for experimental purposes, bind irreversibly to β receptors.) Most β -blocking drugs in clinical use are pure antagonists; ie, the occupancy of a β receptor by such a drug causes no activation of the receptor. However, some are partial agonists; ie, they cause partial activation of the receptor, albeit less than that caused by the full agonists epinephrine and isoproterenol. As described in Chapter 2: Drug Receptors & Pharmacodynamics, partial agonists inhibit the activation of β receptors in the presence of high catecholamine concentrations but moderately activate the receptors in the absence of endogenous agonists. Another major difference among the many β -receptor-blocking drugs concerns their relative affinities for β_1 and β_2 receptors (Table 10–1). Some of these antagonists have a higher affinity for β_1 than for β_2 receptors, and this selectivity may have important clinical implications. Since none of the clinically available β receptor antagonists are absolutely specific for β_1 receptors, the selectivity is dose-related, ie, it tends to diminish at higher drug concentrations. Other major differences among β antagonists relate to their pharmacokinetic characteristics and local anesthetic membrane-stabilizing effects.

Chemically, the β -receptor-antagonist drugs (Figure 10–5) resemble isoproterenol (see Figure 9–3),

a potent β -receptor agonist.

Figure 10-5.

Pharmacokinetic Properties of the Beta-Receptor Antagonists

Absorption

Most of the drugs in this class are well absorbed after oral administration; peak concentrations occur 1–3 hours after ingestion. Sustained-release preparations of propranolol and metoprolol are available.

Bioavailability

Propranolol undergoes extensive hepatic (first-pass) metabolism; its bioavailability is relatively low (Table 10–2). The proportion of drug reaching the systemic circulation increases as the dose is increased, suggesting that hepatic extraction mechanisms may become saturated. A major consequence of the low bioavailability of propranolol is that oral administration of the drug leads to much lower drug concentrations than are achieved after intravenous injection of the same dose. Because the first-pass effect varies among individuals, there is great individual variability in the plasma concentrations achieved after oral propranolol. Bioavailability is limited to varying degrees for most β antagonists with the exception of betaxolol, penbutolol, pindolol, and sotalol.

Table 10–2. Properties of Several Beta-Receptor-Blocking Drugs.

	Selectivity	Partial Agonist Activity	Local Anesthetic Action	Lipid Solubility	Elimination Half-Life	Approximate Bioavailability
Acebutolol	β_1	Yes	Yes	Low	3–4 hours	50
Atenolol	β_1	No	No	Low	6–9 hours	40
Betaxolol	β_1	No	Slight	Low	14–22 hours	90
Bisoprolol	β_1	No	No	Low	9–12 hours	80
Carteolol	None	Yes	No	Low	6 hours	85
Carvedilol ¹	None	No	No	No data	6–8 hours	25–35
Celiprolol	β_1	Yes ²	No	No data	4–5 hours	70
Esmolol	β_1	No	No	Low	10 minutes	–0
Labetalol ¹	None	Yes ¹	Yes	Moderate	5 hours	30
Metoprolol	β_1	No	Yes	Moderate	3–4 hours	50
Nadolol	None	No	No	Low	14–24 hours	33
Penbutolol	None	Yes	No	High	5 hours	>90
Pindolol	None	Yes	Yes	Moderate	3–4 hours	90
Propranolol	None	No	Yes	High	3.5–6 hours	30 ³

Sotalol	None	No	No	Low	12 hours	90
Timolol	None	No	No	Moderate	4–5 hours	50

¹Carvedilol and labetalol also cause α_1 adrenoceptor blockade.

²Partial agonist effects at β_2 receptors.

³Bioavailability is dose-dependent.

Distribution and Clearance

The β antagonists are rapidly distributed and have large volumes of distribution. Propranolol and penbutolol are quite lipophilic and readily cross the blood-brain barrier (Table 10–2). Most β antagonists have half-lives in the range of 3–10 hours. A major exception is esmolol, which is rapidly hydrolyzed and has a half-life of approximately 10 minutes. Propranolol and metoprolol are extensively metabolized in the liver, with little unchanged drug appearing in the urine. The cytochrome P450 2D6 (CYP2D6) genotype is a major determinant of interindividual differences in metoprolol plasma clearance (Chapter 4: Drug Biotransformation). Poor metabolizers exhibit threefold to tenfold higher plasma concentrations after administration of metoprolol than extensive metabolizers. Atenolol, celiprolol, and pindolol are less completely metabolized. Nadolol is excreted unchanged in the urine and has the longest half-life of any available β antagonist (up to 24 hours). The half-life of nadolol is prolonged in renal failure. The elimination of drugs such as propranolol may be prolonged in the presence of liver disease, diminished hepatic blood flow, or hepatic enzyme inhibition. It is notable that the pharmacodynamic effects of these drugs are often prolonged well beyond the time predicted from half-life data.

Pharmacodynamics of the β -Receptor-Antagonist Drugs

Most of the effects of these drugs are due to occupancy and blockade of β receptors. However, some actions may be due to other effects, including partial agonist activity at β receptors and local anesthetic action, which differ among the β -blockers (Table 10–2).

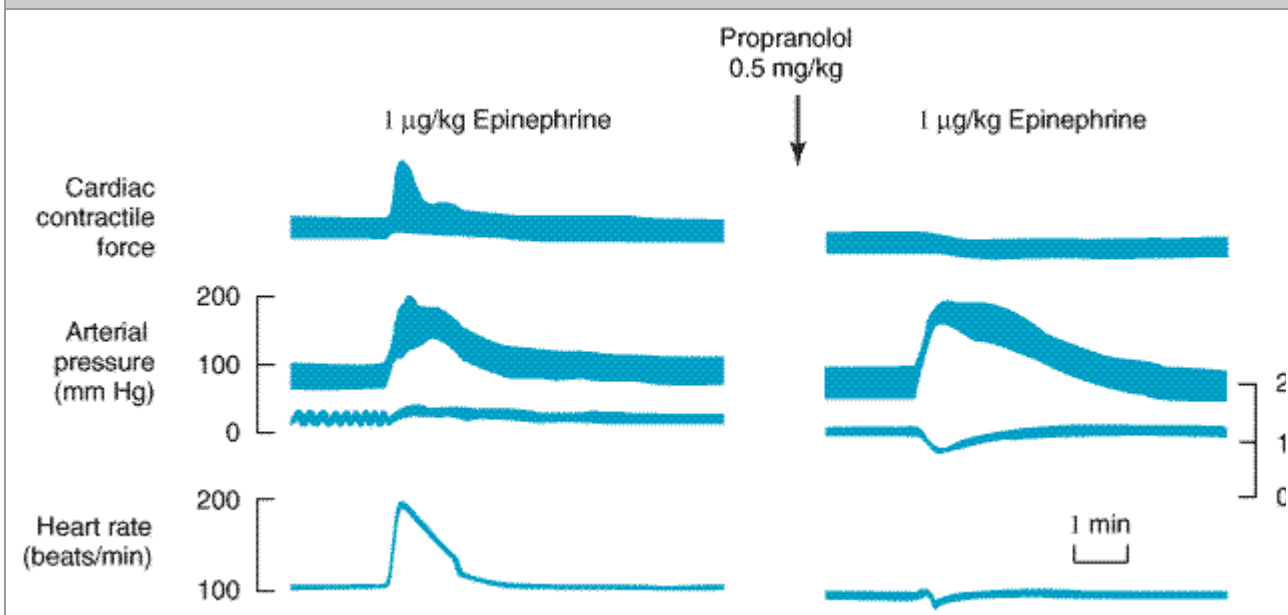

Effects on the Cardiovascular System

Beta-blocking drugs given chronically lower blood pressure in patients with hypertension. The mechanisms involved may include effects on the heart and blood vessels, suppression of the renin-angiotensin system, and perhaps effects in the central nervous system or elsewhere. Beta-adrenoceptor-blocking drugs are of major clinical importance in the treatment of hypertension (see Chapter 11: Antihypertensive Agents). In contrast, conventional doses of these drugs do *not* usually cause hypotension in healthy individuals with normal blood pressure.

Beta-receptor antagonists have prominent effects on the heart (Figure 10–6). The negative inotropic and chronotropic effects are predictable from the role of adrenoceptors in regulating these functions. Slowed atrioventricular conduction with an increased PR interval is a related result of adrenoceptor blockade in the atrioventricular node. These effects may be clinically valuable in some patients but are potentially hazardous in others. In the vascular system, β -receptor blockade opposes β_2 -mediated vasodilation. This may acutely lead to a rise in peripheral resistance from unopposed α -receptor-mediated effects as the sympathetic nervous system discharges in response to lowered blood pressure due to the fall in cardiac output. Beta-blocking drugs antagonize the release of renin

caused by the sympathetic nervous system. As noted in Chapter 11: Antihypertensive Agents, the relation between the effects on renin release and those on blood pressure is unclear. In any event, while the acute effects of these drugs may include a rise in peripheral resistance, chronic drug administration leads to a fall in peripheral resistance in patients with hypertension. How this adjustment occurs is not yet clear.

Figure 10–6.

The effect in an anesthetized dog of the injection of epinephrine before and after propranolol. In the presence of a β -receptor-blocking agent, epinephrine no longer augments the force of contraction (measured by a strain gauge attached to the ventricular wall) nor increases cardiac rate. Blood pressure is still elevated by epinephrine because vasoconstriction is not blocked. (Reproduced, with permission, from Shanks RG: The pharmacology of β sympathetic blockade. *Am J Cardiol* 1966;18:312.)

Effects on the Respiratory Tract

Blockade of the β_2 receptors in bronchial smooth muscle may lead to an increase in airway resistance, particularly in patients with asthma. Beta₁-receptor antagonists such as metoprolol or atenolol may have some advantage over nonselective β antagonists when blockade of β_1 receptors in the heart is desired and β_2 -receptor blockade is undesirable. However, no currently available β_1 -selective antagonist is sufficiently specific to *completely* avoid interactions with β_2 adrenoceptors. Consequently, these drugs should generally be avoided in patients with asthma. On the other hand, some patients with chronic obstructive pulmonary disease (COPD) may tolerate these drugs quite well.

Effects on the Eye

Several β -blocking agents reduce intraocular pressure, especially in glaucomatous eyes. The mechanism usually reported is decreased aqueous humor production. (See *Clinical Pharmacology and The Treatment of Glaucoma*.)

Metabolic and Endocrine Effects

Beta-receptor antagonists such as propranolol inhibit sympathetic nervous system stimulation of lipolysis. The effects on carbohydrate metabolism are less clear, though glycogenolysis in the human liver is at least partially inhibited after β_2 -receptor blockade. However, glucagon is the primary hormone employed to combat hypoglycemia. It is unclear to what extent β antagonists impair recovery from hypoglycemia, but they should be used with caution in insulin-dependent diabetic patients. This may be particularly important in diabetic patients with inadequate glucagon reserve and in pancreatectomized patients since catecholamines may be the major factors in stimulating glucose release from the liver in response to hypoglycemia. Beta₁-receptor-selective drugs may be less prone to inhibit recovery from hypoglycemia. Beta-receptor antagonists are much safer in those type 2 diabetic patients who do not have hypoglycemic episodes.

The chronic use of β -adrenoceptor antagonists has been associated with increased plasma concentrations of VLDL and decreased concentrations of HDL cholesterol. Both of these changes are potentially unfavorable in terms of risk of cardiovascular disease. Although LDL concentrations generally do not change, there is a variable decline in the HDL cholesterol/ LDL cholesterol ratio that may increase the risk of coronary artery disease. These changes tend to occur with both selective and nonselective β -blockers, though they are perhaps less likely to occur with β -blockers possessing intrinsic sympathomimetic activity (partial agonists). The mechanisms by which β -receptor antagonists cause these changes are not understood, though changes in sensitivity to insulin action may contribute.

Effects Not Related to Beta-Blockade

Partial β -agonist activity was significant in the first β -blocking drug synthesized, dichloroisoproterenol. It has been suggested that retention of some intrinsic sympathomimetic activity is desirable to prevent untoward effects such as precipitation of asthma or excessive bradycardia. Pindolol and other partial agonists are noted in Table 10–2. It is not yet clear to what extent partial agonism is clinically valuable. Furthermore, these drugs may not be as effective as the pure antagonists in secondary prevention of myocardial infarction. However, they may be useful in patients who develop symptomatic bradycardia or bronchoconstriction in response to pure antagonist β -adrenoceptor drugs, but only if they are strongly indicated for a particular clinical indication.

Local anesthetic action, also known as "membrane-stabilizing" action, is a prominent effect of several β -blockers (Table 10–2). This action is the result of typical local anesthetic blockade of sodium channels and can be demonstrated experimentally in isolated neurons, heart muscle, and skeletal muscle membrane. However, it is unlikely that this effect is important after systemic administration of these drugs, since the concentration in plasma usually achieved by these routes is too low for the anesthetic effects to be evident. These drugs are not used topically on the eye, where local anesthesia of the cornea would be highly undesirable. Sotalol is a nonselective β -receptor antagonist that lacks local anesthetic action but has marked class III antiarrhythmic effects, reflecting potassium channel blockade (see Chapter 14: Agents Used in Cardiac Arrhythmias).

Specific Agents

(See Table 10–2.)

Propranolol is the prototypical β -blocking drug. It has low and dose-dependent bioavailability, the result of extensive first-pass metabolism in the liver. A long-acting form of propranolol is available;

prolonged absorption of the drug may occur over a 24-hour period. The drug has negligible effects at α and muscarinic receptors; however, it may block some serotonin receptors in the brain, though the clinical significance is unclear. It has no detectable partial agonist action at β receptors.

Metoprolol, atenolol, and several other drugs (see Table 10–2) are members of the β_1 -selective group. These agents may be safer in patients who experience bronchoconstriction in response to propranolol. Since their β_1 selectivity is rather modest, they should be used with great caution, if at all, in patients with a history of asthma. However, in selected patients with chronic obstructive lung disease the benefits may exceed the risks, eg, in patients with myocardial infarction. Beta₁-selective antagonists may be preferable in patients with diabetes or peripheral vascular disease when therapy with a β -blocker is required since β_2 receptors are probably important in liver (recovery from hypoglycemia) and blood vessels (vasodilation).

Nadolol is noteworthy for its very long duration of action; its spectrum of action is similar to that of timolol. **Timolol** is a nonselective agent with no local anesthetic activity. It has excellent ocular hypotensive effects when administered topically in the eye. **Levobunolol** (nonselective) and **betaxolol** (β_1 -selective) are used for topical ophthalmic application in glaucoma; the latter drug may be less likely to induce bronchoconstriction than nonselective antagonists. **Carteolol** is a nonselective β -receptor antagonist.

Pindolol, acebutolol, carteolol, bopindolol,* oxprenolol,* celiprolol, and penbutolol are of interest because they have partial β -agonist activity.

* Not available in the USA.

They are effective in the major cardiovascular applications of the β -blocking group (hypertension and angina). Although these partial agonists may be less likely to cause bradycardia and abnormalities in plasma lipids than are antagonists, the overall clinical significance of intrinsic sympathomimetic activity remains uncertain. Pindolol, perhaps as a result of actions on serotonin signaling, may potentiate the action of traditional antidepressant medications. Celiprolol* is a β_1 -selective antagonist with a modest capacity to activate β_2 receptors.

* Not available in the USA.

There is limited evidence suggesting that celiprolol may have less adverse bronchoconstrictor effects in asthma and may even promote bronchodilation. Acebutolol is also a β_1 -selective antagonist.

Labetalol is a reversible adrenoceptor antagonist available as a racemic mixture of two pairs of chiral isomers (the molecule has two centers of asymmetry). The (S,S)- and (R,S)-isomers are inactive, (S,R)- is a potent α -blocker, and the (R,R)-isomer is a potent β -blocker. Labetalol's affinity for α receptors is less than that of phentolamine, but labetalol is α_1 -selective. Its β -blocking potency is somewhat lower than that of propranolol. Hypotension induced by labetalol is accompanied by less tachycardia than occurs with phentolamine and similar α -blockers.

Carvedilol, medroxalol,* and bucindolol* are nonselective β -receptor antagonists with some capacity to block α_1 -adrenergic receptors.

* Not available in the USA.

Carvedilol antagonizes the actions of catecholamines more potently at β receptors than at α receptors.

The drug has a half-life of 6–8 hours. It is extensively metabolized in the liver, and stereoselective metabolism of its two isomers is observed. Since metabolism of (*R*)-carvedilol is influenced by polymorphisms in cytochrome P450 2D6 activity and by drugs that inhibit this enzyme's activity (such as quinidine and fluoxetine), drug interactions may occur. Carvedilol also appears to attenuate oxygen free radical-initiated lipid peroxidation and to inhibit vascular smooth muscle mitogenesis independently of adrenoceptor blockade. These effects may contribute to the clinical benefits of the drug in chronic heart failure (see Chapter 13: Drugs Used in Heart Failure).

Esmolol is an ultra-short-acting β_1 -selective adrenoceptor antagonist. The structure of esmolol contains an ester linkage; esterases in red blood cells rapidly metabolize esmolol to a metabolite that has a low affinity for β receptors. Consequently, esmolol has a short half-life (about 10 minutes). Therefore, during continuous infusions of esmolol, steady state concentrations are achieved quickly, and the therapeutic actions of the drug are terminated rapidly when its infusion is discontinued. Esmolol is potentially safer to use than longer-acting antagonists in critically ill patients who require a β -adrenoceptor antagonist. Esmolol is useful in controlling supraventricular arrhythmias, arrhythmias associated with thyrotoxicosis, perioperative hypertension, and myocardial ischemia in acutely ill patients.

Butoxamine is selective for β_2 receptors. Selective β_2 -blocking drugs have not been actively sought because there is no obvious clinical application for them and none are available for clinical use.

Katzung PHARMACOLOGY, 9e > Section II. Autonomic Drugs > Chapter 10. Adrenoceptor Antagonist Drugs >

The Treatment of Glaucoma

Glaucoma is a major cause of blindness and of great pharmacologic interest because the chronic form often responds to drug therapy. The primary manifestation is increased intraocular pressure not initially associated with symptoms. Without treatment, increased intraocular pressure results in damage to the retina and optic nerve, with restriction of visual fields and, eventually, blindness. Intraocular pressure is easily measured as part of the routine ophthalmologic examination. Two major types of glaucoma are recognized: open-angle and closed-angle (or narrow-angle). The closed-angle form is associated with a shallow anterior chamber, in which a dilated iris can occlude the outflow drainage pathway at the angle between the cornea and the ciliary body (Figure 6–9). This form is associated with acute and painful increases of pressure, which must be controlled on an emergency basis with drugs or prevented by surgical removal of part of the iris (iridectomy). The open-angle form of glaucoma is a chronic condition, and treatment is largely pharmacologic. Because intraocular pressure is a function of the balance between fluid input and drainage out of the globe, the strategies for the treatment of closed-angle glaucoma fall into two classes: reduction of aqueous humor secretion and enhancement of aqueous outflow. Five general groups of drugs—cholinomimetics, α agonists, β -blockers, prostaglandin F_{2a} analogs, and diuretics—have been found to be useful in reducing intraocular pressure and can be related to these strategies as shown in Table 10–3. Of the five drug groups listed in Table 10–3, the prostaglandin analogs and the β -blockers are the most popular. This popularity results from convenience (once- or twice-daily dosing) and relative lack of adverse effects (except, in the case of β -blockers, in patients with asthma or cardiac pacemaker or conduction pathway disease). Other drugs that have been reported to reduce intraocular pressure include prostaglandin E2 and marijuana. The use of drugs in acute closed-angle glaucoma is limited to cholinomimetics, acetazolamide, and osmotic agents preceding surgery. The onset of action of the other agents is too slow in this situation.

Table 10–3. Drugs Used in Open-Angle Glaucoma.

	Mechanism	Methods of Administration
Cholinomimetics		
Pilocarpine, carbachol, physostigmine, echothiophate, demecarium	Ciliary muscle contraction, opening of trabecular meshwork; increased outflow	Topical drops or gel; plastic film slow-release insert
Alpha agonists		
Unselective	Increased outflow	Topical drops
Epinephrine, dipivefrin		
Alpha ₂ -selective	Decreased aqueous secretion	
Apraclonidine		Topical, postlaser only
Brimonidine		Topical
Beta-blockers		
Timolol, betaxolol, carteolol, levobunolol, metipranolol	Decreased aqueous secretion from the ciliary epithelium	Topical drops
Diuretics		
Dorzolamide, brinzolamide	Decreased secretion due to lack of HCO ₃ ⁻	Topical
Acetazolamide, dichlorphenamide, methazolamide		Oral
Prostaglandins		
Latanoprost, unoprostone	Increased outflow	Topical

Clinical Pharmacology of the Beta-Receptor-Blocking Drugs

Hypertension

The β-adrenoceptor-blocking drugs have proved to be effective and well tolerated in hypertension. While many hypertensive patients will respond to a β-blocker used alone, the drug is often used with either a diuretic or a vasodilator. In spite of the short half-life of many β-antagonists, these drugs may be administered once or twice daily and still have an adequate therapeutic effect. Labetalol, a competitive α and β-antagonist, is effective in hypertension, though its ultimate role is yet to be determined. Use of these agents is discussed in detail in Chapter 11: Antihypertensive Agents. There is some evidence that drugs in this class may be less effective in blacks and the elderly. However, these differences are relatively small and may not apply to an individual patient. Indeed, since effects on blood pressure are easily measured, the therapeutic outcome for this indication can be readily detected in any patient.

Ischemic Heart Disease

Beta-adrenoceptor blockers reduce the frequency of anginal episodes and improve exercise tolerance in many patients with angina (see Chapter 12: Vasodilators & the Treatment of Angina Pectoris). These actions relate to the blockade of cardiac β -receptors, resulting in decreased cardiac work and reduction in oxygen demand. Slowing and regularization of the heart rate may contribute to clinical benefits (Figure 10–7). Multiple large-scale prospective studies indicate that the long-term use of timolol, propranolol, or metoprolol in patients who have had a myocardial infarction prolongs survival (Figure 10–8). At the present time, data are less compelling for the use of other than the three mentioned β -adrenoceptor antagonists for this indication. Importantly, surveys in many populations have indicated that the β -receptor antagonists are underused, leading to unnecessary morbidity and mortality. Studies in experimental animals suggest that use of β -receptor antagonists during the acute phase of a myocardial infarction may limit infarct size. However, this use is still controversial.

Figure 10–7.

Heart rate in a patient with ischemic heart disease measured by telemetry while watching television. Measurements were begun 1 hour after receiving placebo (upper line, black) or 40 mg of oxprenolol (color), a nonselective β -antagonist with partial agonist activity. Not only was the heart rate decreased by the drug under the conditions of this experiment; it also varied much less in response to stimuli. (Modified and reproduced, with permission, from Taylor SH: Oxprenolol in clinical practice. *Am J Cardiol* 1983;52:34D.)

Cardiac Arrhythmias

Beta antagonists are effective in the treatment of both supraventricular and ventricular arrhythmias (see Chapter 14: Agents Used in Cardiac Arrhythmias). It has been suggested that the improved

survival following myocardial infarction in patients using β -antagonists (Figure 10–8; see above) is due to suppression of arrhythmias, but this has not been proved. By increasing the atrioventricular nodal refractory period, β -antagonists slow ventricular response rates in atrial flutter and fibrillation. These drugs can also reduce ventricular ectopic beats, particularly if the ectopic activity has been precipitated by catecholamines. Sotalol has additional antiarrhythmic effects involving ion channel blockade in addition to its β -blocking action; these are discussed in Chapter 14: Agents Used in Cardiac Arrhythmias.

Figure 10–8.

Effects of β -blocker therapy on life-table cumulated rates of mortality from all causes over 6 years among 1884 patients surviving myocardial infarctions. Patients were randomly assigned to treatment with placebo (dashed line) or timolol (color). (Reproduced, with permission, from Pederson TR: Six-year follow-up of the Norwegian multicenter study on timolol after acute myocardial infarction. *N Engl J Med* 1985;313:1055.)

Other Cardiovascular Disorders

Beta-receptor antagonists have been found to increase stroke volume in some patients with obstructive cardiomyopathy. This beneficial effect is thought to result from the slowing of ventricular ejection and decreased outflow resistance. Beta-antagonists are useful in dissecting aortic aneurysm to decrease the rate of development of systolic pressure. Clinical trials have demonstrated that at least three β -antagonists—metoprolol, bisoprolol, and carvedilol—are effective in treating chronic heart failure in selected patients. While administration of these drugs may acutely worsen congestive heart failure, cautious long-term use with gradual dose increments in patients who tolerate them may prolong life. While mechanisms are uncertain, there appear to be beneficial effects on myocardial remodeling and in decreasing the risk of sudden death (see Chapter 13: Drugs Used in Heart Failure).

Glaucoma

See The Treatment of Glaucoma.

Systemic administration of β -blocking drugs for other indications was found serendipitously to reduce intraocular pressure in patients with glaucoma. Subsequently, it was found that topical administration also reduces intraocular pressure. The mechanism appears to involve reduced production of aqueous humor by the ciliary body, which is physiologically activated by cAMP. Timolol and related β -antagonists are suitable for local use in the eye because they lack local anesthetic properties. Beta antagonists appear to have an efficacy comparable to that of epinephrine or pilocarpine in open-angle glaucoma and are far better tolerated by most patients. While the maximal daily dose applied locally (1 mg) is small compared with the systemic doses commonly used in the treatment of hypertension or angina (10–60 mg), sufficient timolol may be absorbed from the eye to cause serious adverse effects on the heart and airways in susceptible individuals. Topical timolol may interact with orally administered verapamil and increase the risk of heart block.

Betaxolol, carteolol, levobunolol, and metipranolol are newer β -receptor antagonists approved for the treatment of glaucoma. Betaxolol has the potential advantage of being β_1 -selective; to what extent this potential advantage might diminish systemic adverse effects remains to be determined. The drug apparently has caused worsening of pulmonary symptoms in some patients.

Hyperthyroidism

Excessive catecholamine action is an important aspect of the pathophysiology of hyperthyroidism, especially in relation to the heart (see Chapter 38: Thyroid & Antithyroid Drugs). The β -antagonists have salutary effects in this condition. These beneficial effects presumably relate to blockade of adrenoceptors and perhaps in part to the inhibition of peripheral conversion of thyroxine to triiodothyronine. The latter action may vary from one β -antagonist to another. Propranolol has been used extensively in patients with thyroid storm (severe hyperthyroidism); it is used cautiously in patients with this condition to control supraventricular tachycardias that often precipitate heart failure.

Neurologic Diseases

Several studies show a beneficial effect of propranolol in reducing the frequency and intensity of migraine headache. Other β -receptor antagonists with preventive efficacy include metoprolol and probably also atenolol, timolol, and nadolol. The mechanism is not known. Since sympathetic activity may enhance skeletal muscle tremor, it is not surprising that β -antagonists have been found to reduce certain tremors (see Chapter 28: Pharmacologic Management of Parkinsonism & Other Movement Disorders). The somatic manifestations of anxiety may respond dramatically to low doses of propranolol, particularly when taken prophylactically. For example, benefit has been found in musicians with performance anxiety ("stage fright"). Propranolol may contribute to the symptomatic treatment of alcohol withdrawal in some patients.

Miscellaneous

Beta-receptor antagonists have been found to diminish portal vein pressure in patients with cirrhosis. There is evidence that both propranolol and nadolol decrease the incidence of the first episode of bleeding from esophageal varices and decrease the mortality rate associated with bleeding in patients with cirrhosis. Nadolol in combination with isosorbide mononitrate appears to be more efficacious than sclerotherapy in preventing re-bleeding in patients who have previously bled from esophageal varices.

Choice of a Beta-Adrenoceptor Antagonist Drug

Propranolol is the standard against which newer β antagonists developed for systemic use have been compared. In many years of very wide use, it has been found to be a safe and effective drug for many indications. Since it is possible that some actions of a β -receptor antagonist may relate to some other effect of the drug, these drugs should not be considered interchangeable for all applications. For example, only β antagonists known to be effective in hyperthyroidism or in prophylactic therapy after myocardial infarction should be used for those indications. It is possible that the beneficial effects of one drug in these settings might not be shared by another drug in the same class. The possible advantages and disadvantages of β receptor antagonists that are partial agonists have not been clearly defined in clinical settings, although current evidence suggests that they are probably less efficacious in secondary prevention after a myocardial infarction compared to pure antagonists.

Clinical Toxicity of the Beta-Receptor Antagonist Drugs

A variety of minor toxic effects have been reported for propranolol. Rash, fever, and other manifestations of drug allergy are rare. Central nervous system effects include sedation, sleep disturbances, and depression. Rarely, psychotic reactions may occur. Discontinuing the use of β -blockers in any patient who develops a depression should be seriously considered if clinically feasible. It has been claimed that β -receptor antagonist drugs with low lipid solubility are associated with a lower incidence of central nervous system adverse effects than compounds with higher lipid solubility (Table 10–2). Further studies designed to compare the central nervous system adverse effects of various drugs are required before specific recommendations can be made, though it seems reasonable to try the hydrophilic drugs nadolol or atenolol in a patient who experiences unpleasant central nervous system effects with other β -blockers.

The major adverse effects of β -receptor antagonist drugs relate to the predictable consequences of β blockade. β_2 -receptor blockade associated with the use of nonselective agents commonly causes worsening of preexisting asthma and other forms of airway obstruction without having these consequences in normal individuals. Indeed, relatively trivial asthma may become severe after β blockade. However, because of their life-saving possibilities in cardiovascular disease, strong consideration should be given to individualized therapeutic trials in some classes of patients, eg, those with chronic obstructive pulmonary disease who have appropriate indications for β -blockers. While β_1 -selective drugs may have less effect on airways than nonselective β antagonists, they must be used very cautiously, if at all, in patients with reactive airways. While β_1 -selective antagonists are generally well tolerated in patients with mild to moderate peripheral vascular disease, caution is required in patients with severe peripheral vascular disease or vasospastic disorders.

Beta-receptor blockade depresses myocardial contractility and excitability. In patients with abnormal myocardial function, cardiac output may be dependent on sympathetic drive. If this stimulus is removed by β blockade, cardiac decompensation may ensue. Thus, caution must be exercised in using β -receptor antagonists in patients with compensated heart failure even though long-term use of these drugs in these patients may prolong life. A life-threatening adverse cardiac effect of a β antagonist may be overcome directly with isoproterenol or with glucagon (glucagon stimulates the heart via glucagon receptors, which are not blocked by β antagonists), but neither of these methods is without hazard. A very small dose of a β antagonist (eg, 10 mg of propranolol) may provoke severe cardiac failure in a susceptible individual. Beta-blockers may interact with the calcium antagonist verapamil; severe hypotension, bradycardia, heart failure, and cardiac conduction abnormalities have all been described. These adverse effects may even arise in

susceptible patients taking a topical (ophthalmic) β -blocker and oral verapamil.

Some hazards are associated with abruptly discontinuing β antagonist therapy after chronic use. Evidence suggests that patients with ischemic heart disease may be at increased risk if β blockade is suddenly interrupted. The mechanism of this effect is uncertain but might involve up-regulation of the number of β receptors. Until better evidence is available regarding the magnitude of the risk, prudence dictates the gradual tapering rather than abrupt cessation of dosage when these drugs are discontinued, especially drugs with short half-lives, such as propranolol and metoprolol.

The incidence of hypoglycemic episodes in diabetics that are exacerbated by β -blocking agents is unknown. Nevertheless, it is inadvisable to use β antagonists in insulin-dependent diabetic patients who are subject to frequent hypoglycemic reactions if alternative therapies are available. Beta₁-selective antagonists offer some advantage in these patients, since the rate of recovery from hypoglycemia may be faster compared with diabetics receiving nonselective β adrenoceptor antagonists. There is considerable potential benefit from these drugs in diabetics after a myocardial infarction, so the balance of risk versus benefit must be evaluated in individual patients.

Katzung PHARMACOLOGY, 9e > Section II. Autonomic Drugs > Chapter 10. Adrenoceptor Antagonist Drugs >

Preparations Available

Alpha Blockers

Doxazosin (generic, Cardura)

Oral: 1, 2, 4, 8 mg tablets

Phenoxybenzamine (Dibenzyline)

Oral: 10 mg capsules

Phentolamine (generic, Regitine)

Parenteral: 5 mg/vial for injection

Prazosin (generic, Minipress)

Oral: 1, 2, 5 mg capsules

Tamsulosin (Flomax)

Oral: 0.4 mg capsule

Terazosin (generic, Hytrin)

Oral: 1, 2, 5, 10 mg tablets, capsules

Tolazoline (Priscoline)

Parenteral: 25 mg/mL for injection

Beta Blockers

Acebutolol (generic, Sectral)

Oral: 200, 400 mg capsules

Atenolol (generic, Tenormin)

Oral: 25, 50, 100 mg tablets

Parenteral: 0.5 mg/mL for IV injection

Betaxolol

Oral: 10, 20 mg tablets (Kerlone)

Ophthalmic: 0.25%, 0.5% drops (generic, Betoptic)

Bisoprolol (Zebeta)

Oral: 5, 10 mg tablets

Carteolol

Oral: 2.5, 5 mg tablets (Cartrol)

Ophthalmic: 1% drops (generic, Ocupress)

Carvedilol (Coreg)

Oral: 3.125, 6.25, 12.5, 25 mg tablets

Esmolol (Brevibloc)

Parenteral: 10 mg/mL for IV injection; 250 mg/mL for IV infusion

Labetalol (generic, Normodyne, Trandate)

Oral: 100, 200, 300 mg tablets

Parenteral: 5 mg/mL for injection

Levobunolol (Betagan Liquifilm, others)

Ophthalmic: 0.25, 0.5% drops

Metipranolol (Optipranolol)

Ophthalmic: 0.3% drops

Metoprolol (generic, Lopressor, Toprol)

Oral: 50, 100 mg tablets

Oral sustained-release: 25, 50, 100, 200 mg tablets

Parenteral: 1 mg/mL for injection

Nadolol (generic, Corgard)

Oral: 20, 40, 80, 120, 160 mg tablets

Penbutolol (Levator)

Oral: 20 mg tablets

Pindolol (generic, Visken)

Oral: 5, 10 mg tablets

Propranolol (generic, Inderal)

Oral: 10, 20, 40, 60, 80, 90 mg tablets; 4, 8, 80 mg/mL solutions

Oral sustained release: 60, 80, 120, 160 mg capsules

Parenteral: 1 mg/mL for injection

Sotalol (generic, Betapace)

Oral: 80, 120, 160, 240 mg tablets

Timolol

Oral: 5, 10, 20 mg tablets (generic, Blocadren)

Ophthalmic: 0.25, 0.5% drops, gel (generic, Timoptic)

Synthesis Inhibitor

Metyrosine (Demser)

Oral: 250 mg capsules

Antihypertensive Agents >

Antihypertensive Agents: Introduction

Hypertension is the most common cardiovascular disease. Thus, the third National Health and Nutrition Examination Survey (NHANES III), conducted from 1992 to 1994, found that 27% of the USA adult population had hypertension. The prevalence varies with age, race, education, and many other variables. Sustained arterial hypertension damages blood vessels in kidney, heart, and brain and leads to an increased incidence of renal failure, coronary disease, cardiac failure, and stroke. Effective pharmacologic lowering of blood pressure has been shown to prevent damage to blood vessels and to substantially reduce morbidity and mortality rates. Many effective drugs are available. Knowledge of their antihypertensive mechanisms and sites of action allows accurate prediction of efficacy and toxicity. As a result, rational use of these agents, alone or in combination, can lower blood pressure with minimal risk of serious toxicity in most patients.

Hypertension & Regulation of Blood Pressure

Diagnosis

The diagnosis of hypertension is based on repeated, reproducible measurements of elevated blood pressure. The diagnosis serves primarily as a prediction of consequences for the patient; it seldom includes a statement about the cause of hypertension.

Epidemiologic studies indicate that the risks of damage to kidney, heart, and brain are directly related to the extent of blood pressure elevation. Even mild hypertension (blood pressure \geq 140/90 mm Hg) in young or middle-aged adults increases the risk of eventual end organ damage. The risks—and therefore the urgency of instituting therapy—increase in proportion to the magnitude of blood pressure elevation. The risk of end organ damage at any level of blood pressure or age is greater in black people and relatively less in premenopausal women than in men. Other positive risk factors include smoking, hyperlipidemia, diabetes, manifestations of end organ damage at the time of diagnosis, and a family history of cardiovascular disease.

It should be noted that the diagnosis of hypertension depends on measurement of blood pressure and not on symptoms reported by the patient. In fact, hypertension is usually asymptomatic until overt end organ damage is imminent or has already occurred.

Etiology of Hypertension

A specific cause of hypertension can be established in only 10–15% of patients. It is important to consider specific causes in each case, however, because some of them are amenable to definitive surgical treatment: renal artery constriction, coarctation of the aorta, pheochromocytoma, Cushing's disease, and primary aldosteronism.

Patients in whom no specific cause of hypertension can be found are said to have **essential hypertension**.*

* The adjective originally was intended to convey the now abandoned idea that blood pressure elevation was essential for adequate perfusion of diseased tissues.

In most cases, elevated blood pressure is associated with an overall increase in resistance to flow of blood through arterioles, while cardiac output is usually normal. Meticulous investigation of autonomic nervous system function, baroreceptor reflexes, the renin-angiotensin-aldosterone system, and the kidney has failed to identify a primary abnormality as the cause of increased peripheral vascular resistance in essential hypertension.

Elevated blood pressure is usually caused by a combination of several abnormalities (multifactorial). Epidemiologic evidence points to genetic inheritance, psychological stress, and environmental and dietary factors (increased salt and decreased potassium or calcium intake) as perhaps contributing to the development of hypertension. Increase in blood pressure with aging does not occur in populations with low daily sodium intake. Patients with labile hypertension appear more likely than normal controls to have blood pressure elevations after salt loading.

The heritability of essential hypertension is estimated to be about 30%. Mutations in several genes have been linked to various rare causes of hypertension. Functional variations of the genes for angiotensinogen, angiotensin-converting enzyme (ACE), and the β_2 adrenoceptor appear to contribute to some cases of essential hypertension.

Normal Regulation of Blood Pressure

According to the hydraulic equation, arterial blood pressure (BP) is directly proportionate to the product of the blood flow (cardiac output, CO) and the resistance to passage of blood through precapillary arterioles (peripheral vascular resistance, PVR):

$$BP = CO \times PVR$$

Physiologically, in both normal and hypertensive individuals, blood pressure is maintained by moment-to-moment regulation of cardiac output and peripheral vascular resistance, exerted at three anatomic sites (Figure 11–1): arterioles, postcapillary venules (capacitance vessels), and heart. A fourth anatomic control site, the kidney, contributes to maintenance of blood pressure by regulating the volume of intravascular fluid. Baroreflexes, mediated by autonomic nerves, act in combination with humoral mechanisms, including the renin-angiotensin-aldosterone system, to coordinate function at these four control sites and to maintain normal blood pressure. Finally, local release of hormones from vascular endothelium may also be involved in the regulation of vascular resistance. For example, nitric oxide (see Chapter 19: Nitric Oxide, Donors, & Inhibitors) dilates and endothelin-1 (see Chapter 17: Vasoactive Peptides) constricts blood vessels.

Figure 11–1.

Blood pressure in a hypertensive patient is controlled by the same mechanisms that are operative in normotensive subjects. Regulation of blood pressure in hypertensive patients differs from healthy patients in that the baroreceptors and the renal blood volume-pressure control systems appear to be "set" at a higher level of blood pressure. All antihypertensive drugs act by interfering with these normal mechanisms, which are reviewed below.

Postural Baroreflex

Baroreflexes are responsible for rapid, moment-to-moment adjustments in blood pressure, such as in transition from a reclining to an upright posture (Figure 11-2). Central sympathetic neurons arising from the vasomotor area of the medulla are tonically active. Carotid baroreceptors are stimulated by the stretch of the vessel walls brought about by the internal pressure (blood pressure). Baroreceptor activation inhibits central sympathetic discharge. Conversely, reduction in stretch results in a reduction in baroreceptor activity. Thus, in the case of a transition to upright posture, baroreceptors sense the reduction in arterial pressure that results from pooling of blood in the veins below the level of the heart as reduced wall stretch, and sympathetic discharge is disinhibited. The reflex increase in sympathetic outflow acts through nerve endings to increase peripheral vascular resistance (constriction of arterioles) and cardiac output (direct stimulation of the heart and constriction of capacitance vessels, which increases venous return to the heart), thereby restoring normal blood pressure. The same baroreflex acts in response to any event that lowers arterial pressure, including a primary reduction in peripheral vascular resistance (eg, caused by a vasodilating agent) or a reduction in intravascular volume (eg, due to hemorrhage or to loss of salt and water via the kidney).

Figure 11-2.

Renal Response to Decreased Blood Pressure

By controlling blood volume, the kidney is primarily responsible for long-term blood pressure control. A reduction in renal perfusion pressure causes intrarenal redistribution of blood flow and increased reabsorption of salt and water. In addition, decreased pressure in renal arterioles as well as sympathetic neural activity (via β -adrenoceptors) stimulates production of renin, which increases production of angiotensin II (see Figure 11–1 and Chapter 17: Vasoactive Peptides). Angiotensin II causes (1) direct constriction of resistance vessels and (2) stimulation of aldosterone synthesis in the adrenal cortex, which increases renal sodium absorption and intravascular blood volume. Vasopressin released from the posterior pituitary gland also plays a role in maintenance of blood pressure through its ability to regulate water reabsorption by the kidney (see Chapter 17: Vasoactive Peptides).

Katzung PHARMACOLOGY, 9e > Section III. Cardiovascular-Renal Drugs > Chapter 11. Antihypertensive Agents >

Basic Pharmacology of Antihypertensive Agents

All antihypertensive agents act at one or more of the four anatomic control sites depicted in Figure 11–1 and produce their effects by interfering with normal mechanisms of blood pressure regulation. A useful classification of these agents categorizes them according to the principal regulatory site or mechanism on which they act (Figure 11–3). Because of their common mechanisms of action, drugs within each category tend to produce a similar spectrum of toxicities. The categories include the following:

- (1) **Diuretics**, which lower blood pressure by depleting the body of sodium and reducing blood

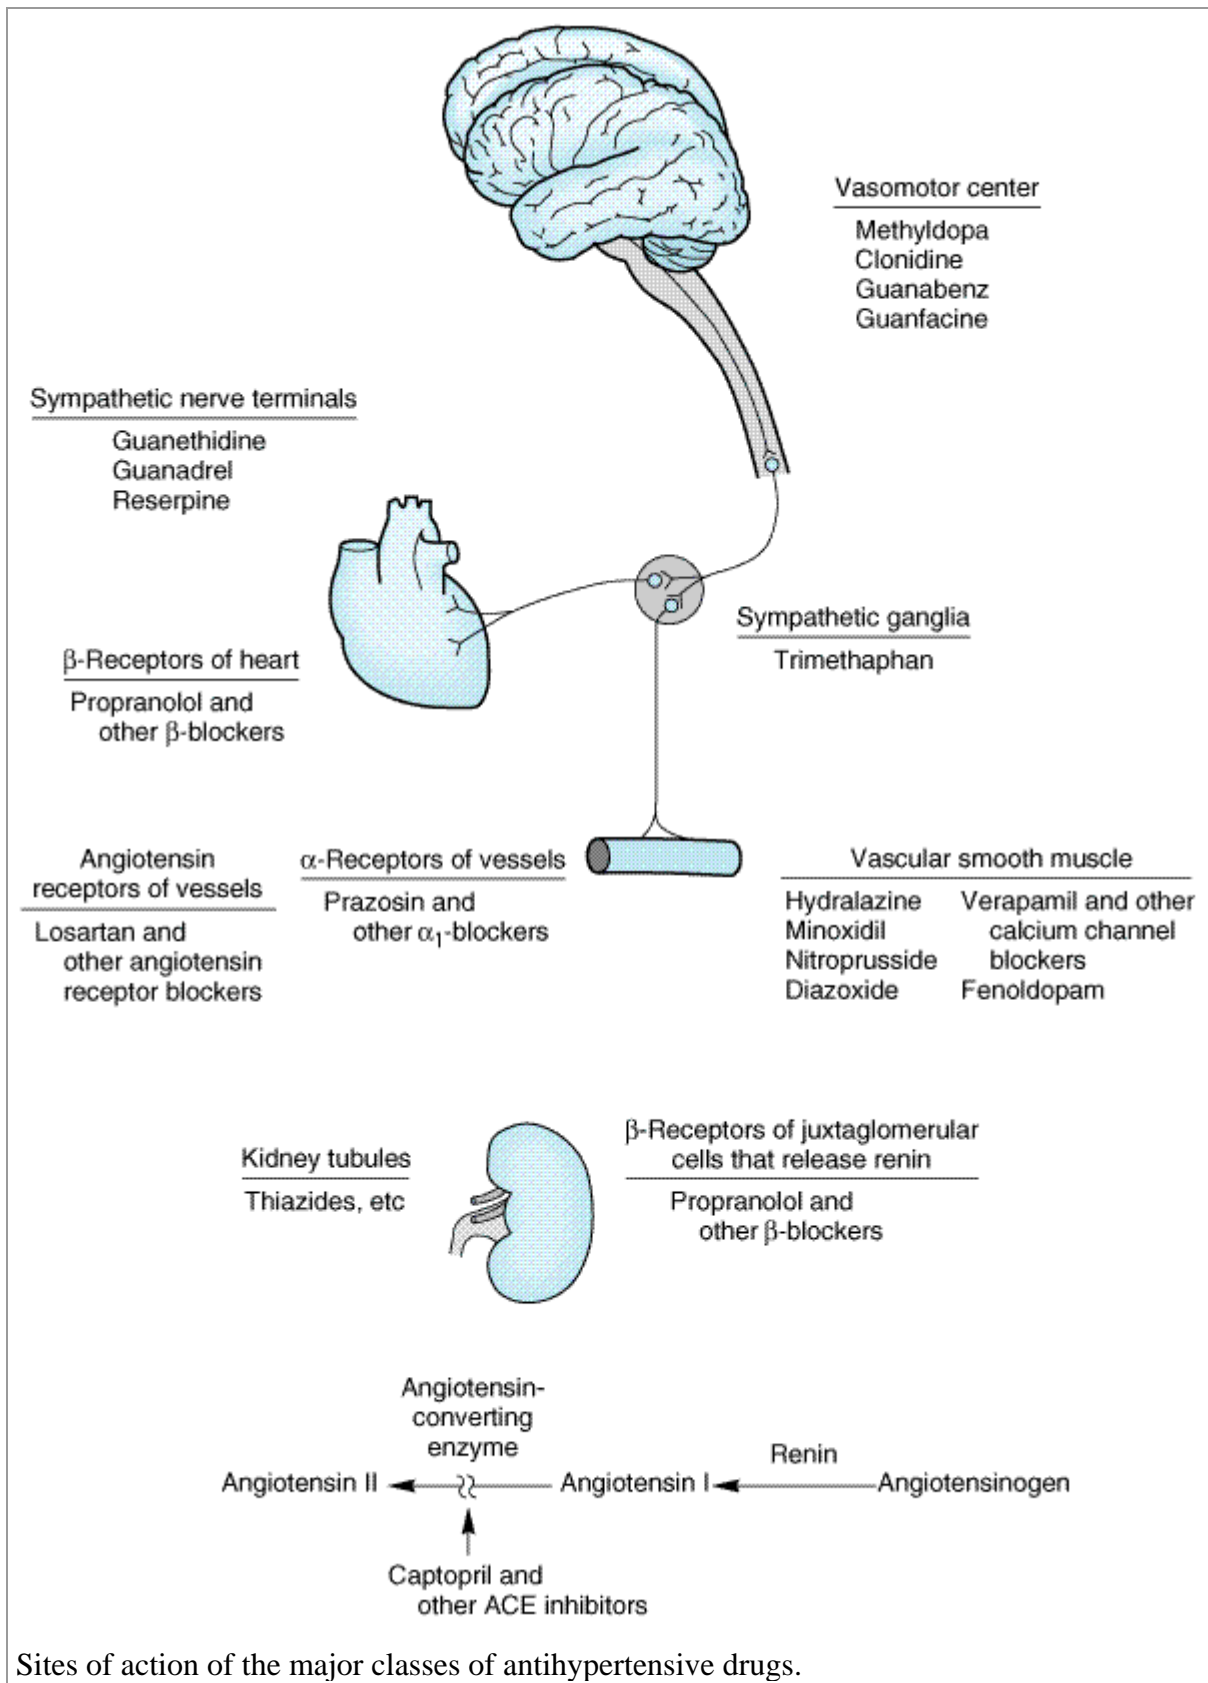

volume and perhaps by other mechanisms.

(2) Sympathoplegic agents, which lower blood pressure by reducing peripheral vascular resistance, inhibiting cardiac function, and increasing venous pooling in capacitance vessels. (The latter two effects reduce cardiac output.) These agents are further subdivided according to their putative sites of action in the sympathetic reflex arc (see below).

(3) Direct vasodilators, which reduce pressure by relaxing vascular smooth muscle, thus dilating resistance vessels and—to varying degrees—increasing capacitance as well.

(4) Agents that block production or action of angiotensin and thereby reduce peripheral vascular resistance and (potentially) blood volume.

Figure 11-3.

The fact that these drug groups act by different mechanisms permits the combination of drugs from two or more groups with increased efficacy and, in some cases, decreased toxicity. (See Monotherapy versus Polypharmacy in Hypertension.)

Drugs That Alter Sodium & Water Balance

Dietary sodium restriction has been known for many years to decrease blood pressure in hypertensive patients. With the advent of diuretics, sodium restriction was thought to be less important. However, there is now general agreement that dietary control of blood pressure is a relatively nontoxic therapeutic measure and may even be preventive. Several studies have shown that even modest dietary sodium restriction lowers blood pressure (although to varying extents) in many hypertensive individuals.

Mechanisms of Action & Hemodynamic Effects of Diuretics

Diuretics lower blood pressure primarily by depleting body sodium stores. Initially, diuretics reduce blood pressure by reducing blood volume and cardiac output; peripheral vascular resistance may increase. After 6–8 weeks, cardiac output returns toward normal while peripheral vascular resistance declines. Sodium is believed to contribute to vascular resistance by increasing vessel stiffness and neural reactivity, possibly related to increased sodium-calcium exchange with a resultant increase in intracellular calcium. These effects are reversed by diuretics or sodium restriction.

Some diuretics have direct vasodilating effects in addition to their diuretic action. Indapamide is a nonthiazide sulfonamide diuretic with both diuretic and vasodilator activity. As a consequence of vasodilation, cardiac output remains unchanged or increases slightly. Amiloride inhibits smooth muscle responses to contractile stimuli, probably through effects on transmembrane and intracellular calcium movement that are independent of its action on sodium excretion.

Diuretics are effective in lowering blood pressure by 10–15 mm Hg in most patients, and diuretics alone often provide adequate treatment for mild or moderate essential hypertension. In more severe hypertension, diuretics are used in combination with sympathoplegic and vasodilator drugs to control the tendency toward sodium retention caused by these agents. Vascular responsiveness—ie, the ability to either constrict or dilate—is diminished by sympathoplegic and vasodilator drugs, so that the vasculature behaves like an inflexible tube. As a consequence, blood pressure becomes exquisitely sensitive to blood volume. Thus, in severe hypertension, when multiple drugs are used, blood pressure may be well controlled when blood volume is 95% of normal but much too high when blood volume is 105% of normal.

Use of Diuretics

The sites of action within the kidney and the pharmacokinetics of various diuretic drugs are discussed in Chapter 15: Diuretic Agents. Thiazide diuretics are appropriate for most patients with mild or moderate hypertension and normal renal and cardiac function. More powerful diuretics (eg, those acting on the loop of Henle) are necessary in severe hypertension, when multiple drugs with sodium-retaining properties are used; in renal insufficiency, when glomerular filtration rate is less than 30 or 40 mL/min; and in cardiac failure or cirrhosis, where sodium retention is marked.

Potassium-sparing diuretics are useful both to avoid excessive potassium depletion, particularly in patients taking digitalis, and to enhance the natriuretic effects of other diuretics.

Some pharmacokinetic characteristics and the initial and usual maintenance dosages of hydrochlorothiazide are listed in Table 11–1. Although thiazide diuretics are more natriuretic at higher doses (up to 100–200 mg of hydrochlorothiazide), when used as a single agent, lower doses (25–50 mg) exert as much antihypertensive effect as do higher doses. In contrast to thiazides, the

blood pressure response to loop diuretics continues to increase at doses many times greater than the usual therapeutic dose.

Table 11–1. Pharmacokinetic Characteristics and Dosage of Selected Oral Antihypertensive Drugs.

Drug	Half-life (h)	Bioavailability (percent)	Suggested Initial Dose	Usual Maintenance Dose Range	Reduction of Dosage Required in Moderate Renal Insufficiency ¹
Atenolol	6	60	50 mg/d	50–100 mg/d	Yes
Captopril	2.2	65	50–75 mg/d	75–150 mg/d	Yes
Clonidine	8–12	95	0.2 mg/d	0.2–1.2 mg/d	Yes
Guanethidine	5 d	3–50	10 mg/d	25–50 mg/d	Yes
Hydralazine	1	25	100 mg/d	40–200 mg/d	No
Hydrochlorothiazide	12	70	25 mg/d	25–50 mg/d	No
Lisinopril	12	25	10 mg/d	10–80 mg/d	Yes
Losartan	1–2 ²	36	50 mg/d	2.5–100 mg/d	No
Methyldopa	2	25	1 g/d	1–2 g/d	No
Minoxidil	4	90	5–10 mg/d	40 mg/d	No
Nifedipine	2	50	30 mg/d	30–90 mg/d	No
Prazosin	3–4	70	3 mg/d	10–30 mg/d	No
Propranolol	3–6	25	80 mg/d	80–480 mg/d	No
Reserpine	24–48	NA	0.25 mg/d	0.25 mg/d	No
Verapamil	4–6	22	180 mg/d	240–480 mg/d	No

¹Creatinine clearance \geq 30 mL/min. Many of these drugs do require dosage adjustment if creatinine clearance falls below 30 mL/min.

²The active metabolite of losartan has a half-life of 3–4 hours.

Toxicity of Diuretics

In the treatment of hypertension, the most common adverse effect of diuretics (except for potassium-sparing diuretics) is potassium depletion. Although mild degrees of hypokalemia are tolerated well by many patients, hypokalemia may be hazardous in persons taking digitalis, those who have chronic arrhythmias, or those with acute myocardial infarction or left ventricular dysfunction. Potassium loss is coupled to reabsorption of sodium, and restriction of dietary sodium intake will therefore minimize potassium loss. Diuretics may also cause magnesium depletion, impair glucose tolerance, and increase serum lipid concentrations. Diuretics increase uric acid concentrations and may precipitate gout. The use of low doses minimizes these adverse metabolic

effects without impairing the antihypertensive action. Several case-control studies have reported a small but significant excess risk of renal cell carcinoma associated with diuretic use.

Drugs That Alter Sympathetic Nervous System Function

In patients with moderate to severe hypertension, most effective drug regimens include an agent that inhibits function of the sympathetic nervous system. Drugs in this group are classified according to the site at which they impair the sympathetic reflex arc (Figure 11–2). This neuroanatomic classification explains prominent differences in cardiovascular effects of drugs and allows the clinician to predict interactions of these drugs with one another and with other drugs.

Most importantly, the subclasses of drugs exhibit different patterns of potential toxicity. Drugs that lower blood pressure by actions on the central nervous system tend to cause sedation and mental depression and may produce disturbances of sleep, including nightmares. Drugs that act by inhibiting transmission through autonomic ganglia produce toxicity from inhibition of parasympathetic regulation, in addition to profound sympathetic blockade. Drugs that act chiefly by reducing release of norepinephrine from sympathetic nerve endings cause effects that are similar to those of surgical sympathectomy, including inhibition of ejaculation, and hypotension that is increased by upright posture and after exercise. Drugs that block postsynaptic adrenoceptors produce a more selective spectrum of effects depending on the class of receptor to which they bind.

Finally, one should note that *all* of the agents that lower blood pressure by altering sympathetic function can elicit compensatory effects through mechanisms that are not dependent on adrenergic nerves. Thus, the antihypertensive effect of any of these agents used alone may be limited by retention of sodium by the kidney and expansion of blood volume. For these reasons, sympathoplegic antihypertensive drugs are most effective when used concomitantly with a diuretic.

Centrally Acting Sympathoplegic Drugs

Mechanisms & Sites of Action

These agents reduce sympathetic outflow from vasopressor centers in the brainstem but allow these centers to retain or even increase their sensitivity to baroreceptor control. Accordingly, the antihypertensive and toxic actions of these drugs are generally less dependent on posture than are the effects of drugs that act directly on peripheral sympathetic neurons.

Methyldopa (L- α -methyl-3,4-dihydroxyphenylalanine) is an analog of L-dopa and is converted to α -methyl-dopamine and α -methyl-norepinephrine; this pathway directly parallels the synthesis of norepinephrine from dopa illustrated in Figure 6–5. Alpha-methyl-norepinephrine is stored in adrenergic nerve vesicles, where it stoichiometrically replaces norepinephrine, and is released by nerve stimulation to interact with postsynaptic adrenoceptors. However, this replacement of norepinephrine by a false transmitter in peripheral neurons is *not* responsible for methyldopa's antihypertensive effect, because the α -methyl-norepinephrine released is an effective agonist at the α -adrenoceptors that mediate peripheral sympathetic constriction of arterioles and venules. Direct electrical stimulation of sympathetic nerves in methyldopa-treated animals produces sympathetic responses similar to those observed in untreated animals.

Indeed, methyldopa's antihypertensive action appears to be due to stimulation of central α -adrenoceptors by α -methyl-norepinephrine or α -methyl-dopamine, based on the following evidence: (1) Much lower doses of methyldopa are required to lower blood pressure in animals when the drug is administered centrally by cerebral intraventricular injection rather than intravenously. (2) α -

Receptor antagonists, especially α_2 -selective antagonists, administered centrally, block the antihypertensive effect of methyldopa, whether the latter is given centrally or intravenously. (3) Potent inhibitors of dopa decarboxylase, administered centrally, block methyldopa's antihypertensive effect, thus showing that metabolism of the parent drug in the central nervous system is necessary for its action.

The antihypertensive action of **clonidine**, a 2-imidazoline derivative, was discovered in the course of testing the drug for use as a topically applied nasal decongestant.

After intravenous injection, clonidine produces a brief rise in blood pressure followed by more prolonged hypotension. The pressor response is due to direct stimulation of α -adrenoceptors in arterioles. The drug is classified as a partial agonist at α -receptors because it also inhibits pressor effects of other α -agonists.

Considerable evidence indicates that the hypotensive effect of clonidine is exerted at α -adrenoceptors in the medulla of the brain. In animals, the hypotensive effect of clonidine is prevented by central administration of α -antagonists. Clonidine reduces sympathetic and increases parasympathetic tone, resulting in blood pressure lowering and bradycardia. The reduction in pressure is accompanied by a decrease in circulating catecholamine levels. These observations suggest that clonidine sensitizes brainstem pressor centers to inhibition by baroreflexes.

Thus, studies of clonidine and methyldopa suggest that normal regulation of blood pressure involves central adrenergic neurons that modulate baroreceptor reflexes. Clonidine and α -methylnorepinephrine bind more tightly to α_2 - than to α_1 -adrenoceptors. As noted in Chapter 6: Introduction to Autonomic Pharmacology, α_2 -receptors are located on presynaptic adrenergic neurons as well as some postsynaptic sites. It is possible that clonidine and α -methylnorepinephrine act in the brain to reduce norepinephrine release onto relevant receptor sites. Alternatively, these drugs may act on postsynaptic α_2 -adrenoceptors to inhibit activity of appropriate neurons. Finally, clonidine also binds to a nonadrenoceptor site, the **imidazoline receptor**, which may also mediate antihypertensive effects.

Methyldopa and clonidine produce slightly different hemodynamic effects: clonidine lowers heart rate and cardiac output more than does methyldopa. This difference suggests that these two drugs do not have identical sites of action. They may act primarily on different populations of neurons in the vasomotor centers of the brainstem.

Guanabenz and **guanfacine** are centrally active antihypertensive drugs that share the central α -adrenoceptor-stimulating effects of clonidine. They do not appear to offer any advantages over clonidine.

Methyldopa

Methyldopa is useful in the treatment of mild to moderately severe hypertension. It lowers blood pressure chiefly by reducing peripheral vascular resistance, with a variable reduction in heart rate and cardiac output.

Most cardiovascular reflexes remain intact after administration of methyldopa, and blood pressure reduction is not markedly dependent on maintenance of upright posture. Postural (orthostatic) hypotension sometimes occurs, particularly in volume-depleted patients. One potential advantage of methyldopa is that it causes reduction in renal vascular resistance.

Pharmacokinetics & Dosage

Pharmacokinetic characteristics of methyldopa are listed in Table 11–1. Methyldopa enters the brain via an aromatic amino acid transporter. An oral dose of methyldopa produces its maximal antihypertensive effect in 4–6 hours, and the effect can persist for up to 24 hours. Because the effect depends on accumulation and storage of a metabolite (α -methylnorepinephrine) in the vesicles of nerve endings, the action persists after the parent drug has disappeared from the circulation.

Toxicity

The most frequent undesirable effect of methyldopa is overt sedation, particularly at the onset of treatment. With long-term therapy, patients may complain of persistent mental lassitude and impaired mental concentration. Nightmares, mental depression, vertigo, and extrapyramidal signs may occur but are relatively infrequent. Lactation, associated with increased prolactin secretion, can occur both in men and in women treated with methyldopa. This toxicity is probably mediated by inhibition of dopaminergic mechanisms in the hypothalamus.

Other important adverse effects of methyldopa are development of a positive Coombs test (occurring in 10–20% of patients undergoing therapy for longer than 12 months), which sometimes makes cross-matching blood for transfusion difficult and rarely is associated with hemolytic anemia, as well as hepatitis and drug fever. Discontinuation of the drug usually results in prompt reversal of these abnormalities.

Clonidine

Hemodynamic studies indicate that blood pressure lowering by clonidine results from reduction of cardiac output due to decreased heart rate and relaxation of capacitance vessels, with a reduction in peripheral vascular resistance, particularly when patients are upright (when sympathetic tone is normally increased).

Reduction in arterial blood pressure by clonidine is accompanied by decreased renal vascular resistance and maintenance of renal blood flow. As with methyldopa, clonidine reduces blood pressure in the supine position and only rarely causes postural hypotension. Pressor effects of clonidine are not observed after ingestion of therapeutic doses of clonidine, but severe hypertension can complicate overdose.

Clonidine

Pharmacokinetics & Dosage

Typical pharmacokinetic characteristics are listed in Table 11–1.

Clonidine is lipid-soluble and rapidly enters the brain from the circulation. Because of its relatively short half-life and the fact that its antihypertensive effect is directly related to blood concentration, oral clonidine must be given twice a day to maintain smooth blood pressure control. However, as is not the case with methyldopa, the dose-response curve of clonidine is such that increasing doses are more effective (but also more toxic).

A transdermal preparation of clonidine that reduces blood pressure for 7 days after a single application is also available. This preparation appears to produce less sedation than clonidine tablets but is often associated with local skin reactions.

Toxicity

Dry mouth and sedation are frequent and may be severe. Both effects are centrally mediated and dose-dependent and coincide temporally with the drug's antihypertensive effect.

The drug should not be given to patients who are at risk for mental depression and should be withdrawn if depression occurs during therapy. Concomitant treatment with tricyclic antidepressants may block the antihypertensive effect of clonidine. The interaction is believed to be due to α -adrenoceptor-blocking actions of the tricyclics.

Withdrawal of clonidine after protracted use, particularly with high dosages (greater than 1 mg/d), can result in life-threatening hypertensive crisis mediated by increased sympathetic nervous activity. Patients exhibit nervousness, tachycardia, headache, and sweating after omitting one or two doses of the drug. Although the incidence of severe hypertensive crisis is unknown, it is high enough to require that all patients who take clonidine be carefully warned of the possibility. If the drug must be stopped, this should be done gradually while other antihypertensive agents are being substituted. Treatment of the hypertensive crisis consists of reinstatement of clonidine therapy or administration of α - and β -adrenoceptor-blocking agents.

Ganglion-Blocking Agents

Historically, drugs that block stimulation of postganglionic autonomic neurons by acetylcholine were among the first agents used in the treatment of hypertension. Most such drugs are no longer available clinically because of intolerable toxicities related to their primary action (see below).

Ganglion blockers competitively block nicotinic cholinergic receptors on postganglionic neurons in both sympathetic and parasympathetic ganglia. In addition, these drugs may directly block the nicotinic acetylcholine channel, in the same fashion as neuromuscular nicotinic blockers (see Figure 27–5).

The adverse effects of ganglion blockers are direct extensions of their pharmacologic effects. These effects include both sympathoplegia (excessive orthostatic hypotension and sexual dysfunction) and parasympathoplegia (constipation, urinary retention, precipitation of glaucoma, blurred vision, dry mouth, etc). These severe toxicities are the major reason for the abandonment of ganglion blockers for the therapy of hypertension.

Adrenergic Neuron-Blocking Agents

These drugs lower blood pressure by preventing normal physiologic release of norepinephrine from postganglionic sympathetic neurons.

Guanethidine

In high enough doses, guanethidine can produce profound sympathoplegia. The resulting high maximal efficacy of this agent made it the mainstay of outpatient therapy of severe hypertension for many years. For the same reason, guanethidine can produce all of the toxicities expected from "pharmacologic sympathectomy," including marked postural hypotension, diarrhea, and impaired ejaculation. Because of these adverse effects, guanethidine is now rarely used.

Guanethidine

Guanethidine is too polar to enter the central nervous system. As a result, this drug has none of the central effects seen with many of the other antihypertensive agents described in this chapter.

Guanadrel is a guanethidine-like drug that is also available in the USA. **Bethanidine** and **debrisoquin**, antihypertensive agents not available for clinical use in the USA, are similar to guanethidine in mechanism of antihypertensive action.

Mechanism & Sites of Action

Guanethidine inhibits the release of norepinephrine from sympathetic nerve endings (Figure 11–4). This effect is probably responsible for most of the sympathoplegia that occurs in patients. Guanethidine is transported across the sympathetic nerve membrane by the same mechanism that transports norepinephrine itself (uptake 1), and uptake is essential for the drug's action. Once guanethidine has entered the nerve, it is concentrated in transmitter vesicles, where it replaces norepinephrine. Because it replaces norepinephrine, the drug causes a gradual depletion of norepinephrine stores in the nerve ending.

Figure 11–4.

Inhibition of norepinephrine release is probably caused by guanethidine's local anesthetic properties on sympathetic nerve terminals. Although the drug does not impair axonal conduction in sympathetic fibers, local blockade of membrane electrical activity may occur in nerve endings because the nerve endings specifically take up and concentrate the drug.

Because neuronal uptake is necessary for the hypotensive activity of guanethidine, drugs that block the catecholamine uptake process or displace amines from the nerve terminal (see Chapter 6: Introduction to Autonomic Pharmacology) block its effects. These include cocaine, amphetamine, tricyclic antidepressants, phenothiazines, and phenoxybenzamine.

Guanethidine increases sensitivity to the hypertensive effects of exogenously administered sympathomimetic amines. This results from inhibition of neuronal uptake of such amines and, after long-term therapy with guanethidine, supersensitivity of effector smooth muscle cells, in a fashion analogous to the process that follows surgical sympathectomy (see Chapter 6: Introduction to Autonomic Pharmacology).

The hypotensive action of guanethidine early in the course of therapy is associated with reduced cardiac output, due to bradycardia and relaxation of capacitance vessels. With long-term therapy, peripheral vascular resistance decreases. Compensatory sodium and water retention may be marked

during guanethidine therapy.

Pharmacokinetics & Dosage

Because of its long half-life (5 days) the onset of sympathoplegia is gradual (maximal effect in 1–2 weeks), and sympathoplegia persists for a comparable period after cessation of therapy. The dose should not ordinarily be increased at intervals shorter than 2 weeks.

Toxicity

Therapeutic use of guanethidine is often associated with symptomatic postural hypotension and hypotension following exercise, particularly when the drug is given in high doses, and may produce dangerously decreased blood flow to heart and brain or even overt shock. Guanethidine-induced sympathoplegia in men may be associated with delayed or retrograde ejaculation (into the bladder). Guanethidine commonly causes diarrhea, which results from increased gastrointestinal motility due to parasympathetic predominance in controlling the activity of intestinal smooth muscle.

Interactions with other drugs may complicate guanethidine therapy. Sympathomimetic agents, at doses available in over-the-counter cold preparations, can produce hypertension in patients taking guanethidine. Similarly, guanethidine can produce hypertensive crisis by releasing catecholamines in patients with pheochromocytoma. When tricyclic antidepressants are administered to patients taking guanethidine, the drug's antihypertensive effect is attenuated, and severe hypertension may follow.

Reserpine

Reserpine, an alkaloid extracted from the roots of an Indian plant, *Rauwolfia serpentina*, was one of the first effective drugs used on a large scale in the treatment of hypertension. At present, it is considered an effective and relatively safe drug for treating mild to moderate hypertension.

Mechanism & Sites of Action

Reserpine blocks the ability of aminergic transmitter vesicles to take up and store biogenic amines, probably by interfering with an uptake mechanism that depends on Mg²⁺ and ATP (Figure 6–4, carrier B). This effect occurs throughout the body, resulting in depletion of norepinephrine, dopamine, and serotonin in both central and peripheral neurons. Chromaffin granules of the adrenal

medulla are also depleted of catecholamines, although to a lesser extent than are the vesicles of neurons. Reserpine's effects on adrenergic vesicles appear irreversible; trace amounts of the drug remain bound to vesicular membranes for many days. Although sufficiently high doses of reserpine in animals can reduce catecholamine stores to zero, lower doses cause inhibition of neurotransmission that is roughly proportionate to the degree of amine depletion.

Depletion of peripheral amines probably accounts for much of the beneficial antihypertensive effect of reserpine, but a central component cannot be ruled out. The effects of low but clinically effective doses resemble those of centrally acting agents (eg, methyldopa) in that sympathetic reflexes remain largely intact, blood pressure is reduced in supine as well as in standing patients, and postural hypotension is mild. Reserpine readily enters the brain, and depletion of cerebral amine stores causes sedation, mental depression, and parkinsonism symptoms.

At lower doses used for treatment of mild hypertension, reserpine lowers blood pressure by a combination of decreased cardiac output and decreased peripheral vascular resistance.

Pharmacokinetics & Dosage

See Table 11–1.

Toxicity

At the low doses usually administered, reserpine produces little postural hypotension. Most of the unwanted effects of reserpine result from actions on the brain or gastrointestinal tract.

High doses of reserpine characteristically produce sedation, lassitude, nightmares, and severe mental depression; occasionally, these occur even in patients receiving low doses (0.25 mg/d). Much less frequently, ordinary low doses of reserpine produce extrapyramidal effects resembling Parkinson's disease, probably as a result of dopamine depletion in the corpus striatum. Although these central effects are uncommon, it should be stressed that they may occur at any time, even after months of uneventful treatment. Patients with a history of mental depression should not receive reserpine, and the drug should be stopped if depression appears.

Reserpine rather often produces mild diarrhea and gastrointestinal cramps and increases gastric acid secretion. The drug should probably not be given to patients with a history of peptic ulcer.

Adrenoceptor Antagonists

The pharmacology of drugs that antagonize catecholamines at α - and β -adrenoceptors is presented in Chapter 10: Adrenoceptor Antagonist Drugs. This chapter will concentrate on two prototypical drugs, propranolol and prazosin, primarily in relation to their use in treatment of hypertension. Other adrenoceptor antagonists will be considered only briefly.

Propranolol

Propranolol was the first β -blocker shown to be effective in hypertension and ischemic heart disease. It is now clear that all β -adrenoceptor-blocking agents are very useful for lowering blood pressure in mild to moderate hypertension. In severe hypertension, β -blockers are especially useful in preventing the reflex tachycardia that often results from treatment with direct vasodilators. Beta blockers have been shown to reduce mortality in patients with heart failure, and they are particularly advantageous for treating hypertension in that population (see Chapter 13: Drugs Used in Heart

Failure).

Mechanism & Sites of Action

Propranolol's efficacy in treating hypertension as well as most of its toxic effects result from nonselective β -blockade. Propranolol decreases blood pressure primarily as a result of a decrease in cardiac output. Other β -blockers may decrease cardiac output or decrease peripheral vascular resistance to various degrees, depending on cardioselectivity and partial agonist activities.

Beta-blockade in brain, kidney, and peripheral adrenergic neurons has been proposed as contributing to the antihypertensive effect observed with β -receptor blockers. In spite of conflicting evidence, the brain appears unlikely to be the primary site of the hypotensive action of these drugs, because some β -blockers that do not readily cross the blood-brain barrier (eg, nadolol, described below) are nonetheless effective antihypertensive agents.

Propranolol inhibits the stimulation of renin production by catecholamines (mediated by Beta_{1} -receptors). It is likely that propranolol's effect is due in part to depression of the renin-angiotensin-aldosterone system. Although most effective in patients with high plasma renin activity, propranolol also reduces blood pressure in hypertensive patients with normal or even low renin activity. Beta blockers might also act on peripheral presynaptic β -adrenoceptors to reduce sympathetic vasoconstrictor nerve activity.

In mild to moderate hypertension, propranolol produces a significant reduction in blood pressure without prominent postural hypotension.

Pharmacokinetics & Dosage

See Table 11–1. Resting bradycardia and a reduction in the heart rate during exercise are indicators of propranolol's β -blocking effect. Measures of these responses may be used as guides in regulating dosage. Propranolol can be administered once or twice daily.

Toxicity

The principal toxicities of propranolol result from blockade of cardiac, vascular, or bronchial β -receptors and are described in more detail in Chapter 10: Adrenoceptor Antagonist Drugs. The most important of these predictable extensions of the β -blocking action occur in patients with bradycardia or cardiac conduction disease, asthma, peripheral vascular insufficiency, and diabetes.

When propranolol is discontinued after prolonged regular use, some patients experience a withdrawal syndrome, manifested by nervousness, tachycardia, increased intensity of angina, or increase of blood pressure. Myocardial infarction has been reported in a few patients. Although the incidence of these complications is probably low, propranolol should not be discontinued abruptly. The withdrawal syndrome may involve up-regulation or supersensitivity of β -adrenoceptors.

Other Beta-Adrenoceptor-Blocking Agents

Of the large number of β -blockers tested, most have been shown to be effective in lowering blood pressure. The pharmacologic properties of several of these agents differ from those of propranolol in ways that may confer therapeutic benefits in certain clinical situations.

Metoprolol

Metoprolol is approximately equipotent to propranolol in inhibiting stimulation of β_1 -adrenoceptors such as those in the heart but 50- to 100-fold less potent than propranolol in blocking β_2 -receptors. Although metoprolol is in other respects very similar to propranolol, its relative cardioselectivity may be advantageous in treating hypertensive patients who also suffer from asthma, diabetes, or peripheral vascular disease. Studies of small numbers of asthmatic patients have shown that metoprolol causes less bronchial constriction than propranolol at doses that produce equal inhibition of β_1 -adrenoceptor responses. The cardioselectivity is not complete, however, and asthmatic symptoms have been exacerbated by metoprolol. Usual antihypertensive doses of metoprolol range from 100 to 450 mg/d.

Nadolol, Carteolol, Atenolol, Betaxolol, & Bisoprolol

Nadolol and carteolol, nonselective β -receptor antagonists, and atenolol, a β_1 -selective blocker, are not appreciably metabolized and are excreted to a considerable extent in the urine. Betaxolol and bisoprolol are β_1 -selective blockers that are primarily metabolized in the liver but have long half-lives. Because of these relatively long half-lives, these drugs can be administered once daily. Nadolol is usually begun at a dosage of 40 mg/d, atenolol at 50 mg/d, carteolol at 2.5 mg/d, betaxolol at 10 mg/d, and bisoprolol at 5 mg/d. Increases in dosage to obtain a satisfactory therapeutic effect should take place no more often than every 4 or 5 days. Patients with reduced renal function should receive correspondingly reduced doses of nadolol, carteolol, and atenolol. It is claimed that atenolol produces fewer central nervous system-related effects than other more lipid-soluble β -antagonists.

Pindolol, Acebutolol, & Penbutolol

Pindolol, acebutolol, and penbutolol are partial agonists, ie, β -blockers with intrinsic sympathomimetic activity. They lower blood pressure by decreasing vascular resistance and appear to depress cardiac output or heart rate less than other β -blockers, perhaps because of significantly greater agonist than antagonist effects at β_2 -receptors. This may be particularly beneficial for patients with bradyarrhythmias or peripheral vascular disease. Daily doses of pindolol start at 10 mg; of acebutolol, at 400 mg; and of penbutolol, at 20 mg.

Labetalol & Carvedilol

Labetalol is formulated as a racemic mixture of four isomers (it has two centers of asymmetry). Two of these isomers—the (S,S)- and (R,S)-isomers—are inactive, a third (S,R)- is a potent α -blocker, and the last (R,R)- is a potent β -blocker. The β -blocking isomer is thought to have selective β_2 -agonist and nonselective β -antagonist action. Labetalol has a 3:1 ratio of β : α antagonism after oral dosing. Blood pressure is lowered by reduction of systemic vascular resistance without significant alteration in heart rate or cardiac output. Because of its combined α - and β -blocking activity, labetalol is useful in treating the hypertension of pheochromocytoma and hypertensive emergencies. Oral daily doses of labetalol range from 200 to 2400 mg/d. Labetalol is given as repeated intravenous bolus injections of 20–80 mg to treat hypertensive emergencies.

Carvedilol, like labetalol, is administered as a racemic mixture. The *S*(–) isomer is a nonselective β -adrenoceptor blocker, but both *S*(–) and *R*(+) isomers have approximately equal α -blocking potency. The isomers are stereoselectively metabolized in the liver, which means that their elimination half-lives may differ. The average half-life is 7–10 hours. The usual starting dosage of carvedilol for ordinary hypertension is 6.25 mg twice daily.

Esmolol

Esmolol is a β_1 -selective blocker that is rapidly metabolized via hydrolysis by red blood cell esterases. It has a short half-life (9 minutes) and is administered by constant intravenous infusion. Esmolol is generally administered as a loading dose (0.5–1 mg/kg), followed by a constant infusion. The infusion is typically started at 50–150 $\mu\text{g}/\text{kg}/\text{min}$, and the dose increased every 5 minutes, up to 300 $\mu\text{g}/\text{kg}/\text{min}$, as needed to achieve the desired therapeutic effect. Esmolol is used for management of intraoperative and postoperative hypertension, and sometimes for hypertensive emergencies, particularly when hypertension is associated with tachycardia.

Prazosin & Other Alpha₁ Blockers

Mechanism & Sites of Action

Prazosin, terazosin, and doxazosin produce most of their antihypertensive effect by blocking α_1 -receptors in arterioles and venules. Selectivity for α_1 -receptors may explain why these agents produce less reflex tachycardia than do nonselective α -antagonists such as phentolamine. This receptor selectivity allows norepinephrine to exert unopposed negative feedback (mediated by presynaptic α_2 -receptors) on its own release (see Chapter 6: Introduction to Autonomic Pharmacology); in contrast, phentolamine blocks both presynaptic and postsynaptic α -receptors, with the result that reflex stimulation of sympathetic neurons produces greater release of transmitter onto β -receptors and correspondingly greater cardioacceleration.

Alpha blockers reduce arterial pressure by dilating both resistance and capacitance vessels. As expected, blood pressure is reduced more in the upright than in the supine position. Retention of salt and water occurs when these drugs are administered without a diuretic. The drugs are more effective when used in combination with other agents, such as a β -blocker and a diuretic, than when used alone.

Pharmacokinetics & Dosage

Pharmacokinetic characteristics of prazosin are listed in Table 11–1. Terazosin is also extensively metabolized but undergoes very little first-pass metabolism and has a half-life of 12 hours. Doxazosin has an intermediate bioavailability and a half-life of 22 hours.

Terazosin can often be given once daily, with doses of 5–20 mg/d. Doxazosin is usually given once daily starting at 1 mg/d and progressing to 4 mg/d or more as needed. Although long-term treatment with these α -blockers causes relatively little postural hypotension, precipitous drop in standing blood pressure develops in a number of patients shortly after the first dose is absorbed. For this reason, the first dose should be small and should be administered at bedtime. While the mechanism of this first-dose phenomenon is not clear, it occurs more commonly in patients who are salt- and volume-depleted.

Aside from the first-dose phenomenon, the reported toxicities of the α_1 -blockers are relatively infrequent and mild. These include dizziness, palpitations, headache, and lassitude. Some patients develop a positive test for antinuclear factor in serum while on prazosin therapy, but this has not been associated with rheumatic symptoms. The α_1 -blockers do not adversely and may even beneficially affect plasma lipid profiles but this action has not been shown to confer any benefit on clinical outcomes.

Other Alpha Adrenoceptor-Blocking Agents

Investigational α_1 -selective blockers include pinacidil, urapidil, and cromakalim. The nonselective

agents, **phentolamine** and **phenoxybenzamine**, are useful in diagnosis and treatment of pheochromocytoma and in other clinical situations associated with exaggerated release of catecholamines (eg, phentolamine may be combined with propranolol to treat the clonidine withdrawal syndrome, described above). Their pharmacology is described in Chapter 10: Adrenoceptor Antagonist Drugs.

Vasodilators

Mechanism & Sites of Action

Within this class of drugs are the oral vasodilators, hydralazine and minoxidil, which are used for long-term outpatient therapy of hypertension; the parenteral vasodilators, nitroprusside, diazoxide, and fenoldopam, which are used to treat hypertensive emergencies; and the calcium channel blockers, which are used in both circumstances.

Chapter 12 contains a general discussion of vasodilators. All of the vasodilators useful in hypertension relax smooth muscle of arterioles, thereby decreasing systemic vascular resistance. Sodium nitroprusside also relaxes veins. Decreased arterial resistance and decreased mean arterial blood pressure elicit compensatory responses, mediated by baroreceptors and the sympathetic nervous system (Figure 11–5), as well as renin, angiotensin, and aldosterone. Because sympathetic reflexes are intact, vasodilator therapy does not cause orthostatic hypotension or sexual dysfunction.

Figure 11–5.

Vasodilators work best in combination with other antihypertensive drugs that oppose the compensatory cardiovascular responses. (See Monotherapy versus Polypharmacy in Hypertension.)

Hydralazine

Hydralazine, a hydrazine derivative, dilates arterioles but not veins. It has been available for many years, although it was initially thought not to be particularly effective because tachyphylaxis to hypertensive effects developed rapidly. The benefits of combination therapy are now recognized, and hydralazine may be used more effectively, particularly in severe hypertension.

Hydralazine

Pharmacokinetics & Dosage

Hydralazine is well absorbed and rapidly metabolized by the liver during the first pass, so that bioavailability is low (averaging 25%) and variable among individuals. It is metabolized in part by acetylation at a rate that appears to be bimodally distributed in the population (see Chapter 4: Drug Biotransformation). As a consequence, rapid acetylators have greater first-pass metabolism, lower bioavailability, and less antihypertensive benefit from a given dose than do slow acetylators. The half-life of hydralazine ranges from 2 to 4 hours, but vascular effects appear to persist longer than do blood concentrations, possibly due to avid binding to vascular tissue.

Usual dosage ranges from 40 mg/d to 200 mg/d. The higher dosage was selected as the dose at which there is a small possibility of developing the lupus erythematosus-like syndrome described in the next section. However, higher dosages result in greater vasodilation and may be used if necessary. Dosing two or three times daily provides smooth control of blood pressure.

Toxicity

The most common adverse effects of hydralazine are headache, nausea, anorexia, palpitations, sweating, and flushing. In patients with ischemic heart disease, reflex tachycardia and sympathetic stimulation may provoke angina or ischemic arrhythmias. With dosages of 400 mg/d or more, there is a 10–20% incidence—chiefly in persons who slowly acetylate the drug—of a syndrome characterized by arthralgia, myalgia, skin rashes, and fever that resembles lupus erythematosus. The syndrome is not associated with renal damage and is reversed by discontinuance of hydralazine. Peripheral neuropathy and drug fever are other serious but uncommon adverse effects.

Minoxidil

Minoxidil is a very efficacious orally active vasodilator. The effect appears to result from the opening of potassium channels in smooth muscle membranes by minoxidil sulfate, the active metabolite. This action stabilizes the membrane at its resting potential and makes contraction less likely. Like hydralazine, minoxidil dilates arterioles but not veins. Because of its greater potential antihypertensive effect, minoxidil should replace hydralazine when maximal doses of the latter are not effective or in patients with renal failure and severe hypertension, who do not respond well to hydralazine.

Pharmacokinetics & Dosage

Pharmacokinetic parameters of minoxidil are listed in Table 11–1.

Even more than with hydralazine, the use of minoxidil is associated with reflex sympathetic stimulation and sodium and fluid retention. Minoxidil must be used in combination with a β -blocker and a loop diuretic.

Toxicity

Tachycardia, palpitations, angina, and edema are observed when doses of β -blockers and diuretics are inadequate. Headache, sweating, and hirsutism, which is particularly bothersome in women, are relatively common. Minoxidil illustrates how one person's toxicity may become another person's therapy. Topical minoxidil (as Rogaine) is now used as a stimulant to hair growth for correction of baldness.

Sodium Nitroprusside

Sodium nitroprusside is a powerful parenterally administered vasodilator that is used in treating hypertensive emergencies as well as severe heart failure. Nitroprusside dilates both arterial and venous vessels, resulting in reduced peripheral vascular resistance and venous return. The action occurs as a result of activation of guanylyl cyclase, either via release of nitric oxide or by direct stimulation of the enzyme. The result is increased intracellular cGMP, which relaxes vascular smooth muscle.

In the absence of heart failure, blood pressure decreases, owing to decreased vascular resistance, while cardiac output does not change or decreases slightly. In patients with heart failure and low cardiac output, output often increases owing to afterload reduction.

Pharmacokinetics & Dosage

Nitroprusside is a complex of iron, cyanide groups, and a nitroso moiety. It is rapidly metabolized by uptake into red blood cells with liberation of cyanide. Cyanide in turn is metabolized by the mitochondrial enzyme rhodanase, in the presence of a sulfur donor, to the less toxic thiocyanate. Thiocyanate is distributed in extracellular fluid and slowly eliminated by the kidney.

Nitroprusside rapidly lowers blood pressure, and its effects disappear within 1–10 minutes after discontinuation. The drug is given by intravenous infusion. Sodium nitroprusside in aqueous solution is sensitive to light and must therefore be made up fresh before each administration and covered with opaque foil. Infusion solutions should be changed after several hours. Dosage typically begins at 0.5 $\mu\text{g}/\text{kg}/\text{min}$ and may be increased up to 10 $\mu\text{g}/\text{kg}/\text{min}$ as necessary to control

blood pressure. Higher rates of infusion, if continued for more than an hour, may result in toxicity. Because of its efficacy and rapid onset of effect, the drug should be administered by infusion pump and arterial blood pressure continuously monitored via intra-arterial recording.

Toxicity

Other than excessive blood pressure lowering, the most serious toxicity is related to accumulation of cyanide; metabolic acidosis, arrhythmias, excessive hypotension, and death have resulted. In a few cases, toxicity after relatively low doses of nitroprusside suggested a defect in cyanide metabolism. Administration of sodium thiosulfate as a sulfur donor facilitates metabolism of cyanide. Hydroxocobalamin combines with cyanide to form the nontoxic cyanocobalamin. Both have been advocated for prophylaxis or treatment of cyanide poisoning during nitroprusside infusion. Thiocyanate may accumulate over the course of prolonged administration, usually a week or more, particularly in patients with renal insufficiency who do not excrete thiocyanate at a normal rate. Thiocyanate toxicity is manifested as weakness, disorientation, psychosis, muscle spasms, and convulsions, and the diagnosis is confirmed by finding serum concentrations greater than 10 mg/dL. Rarely, delayed hypothyroidism occurs, owing to thiocyanate inhibition of iodide uptake by the thyroid. Methemoglobinemia during infusion of nitroprusside has also been reported.

Diazoxide

Diazoxide is an effective and relatively long-acting parenterally administered arteriolar dilator that is occasionally used to treat hypertensive emergencies. Injection of diazoxide results in a rapid fall in systemic vascular resistance and mean arterial blood pressure associated with substantial tachycardia and increase in cardiac output. Studies of its mechanism suggest that it prevents vascular smooth muscle contraction by opening potassium channels and stabilizing the membrane potential at the resting level.

Pharmacokinetics & Dosage

Diazoxide is similar chemically to the thiazide diuretics but has no diuretic activity. It is bound extensively to serum albumin and to vascular tissue. Diazoxide is both metabolized and excreted unchanged; its metabolic pathways are not well characterized. Its half-life is approximately 24 hours, but the relationship between blood concentration and hypotensive action is not well established. The blood pressure-lowering effect after a rapid injection is established within 5 minutes and lasts for 4–12 hours.

When diazoxide was first marketed, a dose of 300 mg by rapid injection was recommended. It appears, however, that excessive hypotension can be avoided by beginning with smaller doses (50–150 mg). If necessary, doses of 150 mg may be repeated every 5 minutes until blood pressure is lowered satisfactorily. Nearly all patients respond to a maximum of three or four doses. Alternatively, diazoxide may be administered by intravenous infusion at rates of 15–30 mg/min. Because of reduced protein binding, hypotension occurs after smaller doses in persons with chronic

renal failure, and smaller doses should be administered to these patients. The hypotensive effects of diazoxide are also greater if patients are pretreated with β -blockers to prevent the reflex tachycardia and associated increase in cardiac output.

Toxicity

The most significant toxicity from diazoxide has been excessive hypotension, resulting from the recommendation to use a fixed dose of 300 mg in all patients. Such hypotension has resulted in stroke and myocardial infarction. The reflex sympathetic response can provoke angina, electrocardiographic evidence of ischemia, and cardiac failure in patients with ischemic heart disease, and diazoxide should be avoided in this situation.

Diazoxide inhibits insulin release from the pancreas (probably by opening potassium channels in the β cell membrane) and is used to treat hypoglycemia secondary to insulinoma. Occasionally, hyperglycemia complicates diazoxide use, particularly in persons with renal insufficiency.

In contrast to the structurally related thiazide diuretics, diazoxide causes renal salt and water *retention*. However, because the drug is used for short periods only, this is rarely a problem.

Fenoldopam

Fenoldopam is a newer peripheral arteriolar dilator used for hypertensive emergencies and postoperative hypertension. It acts primarily as an agonist of dopamine D_1 receptors, resulting in dilation of peripheral arteries and natriuresis. The commercial product is a racemic mixture with the (R)-isomer mediating the pharmacologic activity.

Fenoldopam is rapidly metabolized, primarily by conjugation. Its half-life is 10 minutes. The drug is administered by continuous intravenous infusion. Fenoldopam is initiated at a low dosage (0.1 μ g/kg/min), and the dose is then titrated upward every 15 or 20 minutes up to a maximum dose of 1.6 μ g/kg/min or until the desired blood pressure reduction is achieved.

As with other direct vasodilators, the major toxicities are reflex tachycardia, headache, and flushing. Fenoldopam also increases intraocular pressure and should be avoided in patients with glaucoma.

Calcium Channel Blockers

In addition to their antianginal (see Chapter 12: Vasodilators & the Treatment of Angina Pectoris) and antiarrhythmic effects (see Chapter 14: Agents Used in Cardiac Arrhythmias), calcium channel blockers also dilate peripheral arterioles and reduce blood pressure. The mechanism of action in hypertension (and, in part, in angina) is inhibition of calcium influx into arterial smooth muscle cells.

Verapamil, diltiazem, and the dihydropyridine family (amlodipine, felodipine, isradipine, nifedipine, nifedipine, and nisoldipine) are all equally effective in lowering blood pressure, and various formulations are currently approved for this use in the USA. Several others are under study. Hemodynamic differences among calcium channel blockers may influence the choice of a particular agent. Nifedipine and the other dihydropyridine agents are more selective as vasodilators and have less cardiac depressant effect than verapamil and diltiazem. Reflex sympathetic activation with slight tachycardia maintains or increases cardiac output in most patients given dihydropyridines. Verapamil has the greatest depressant effect on the heart and may decrease heart rate and cardiac output. Diltiazem has intermediate actions. The pharmacology and toxicity of these drugs is

discussed in more detail in Chapter 12: Vasodilators & the Treatment of Angina Pectoris. Doses of calcium channel blockers used in treating hypertension are similar to those used in treating angina. Some epidemiologic studies reported an increased risk of myocardial infarction or mortality in patients receiving short-acting nifedipine for hypertension. While there is still debate about causation, it is recommended that short-acting dihydropyridines not be used for hypertension. Sustained-release calcium blockers or calcium blockers with long half-lives provide smoother blood pressure control and are more appropriate for treatment of chronic hypertension. Intravenous nicardipine is available for the treatment of hypertension when oral therapy is not feasible, although parenteral verapamil and diltiazem could be used for the same indication. Nicardipine is typically infused at rates of 2–15 mg/h. Oral short-acting nifedipine has been used in emergency management of severe hypertension.

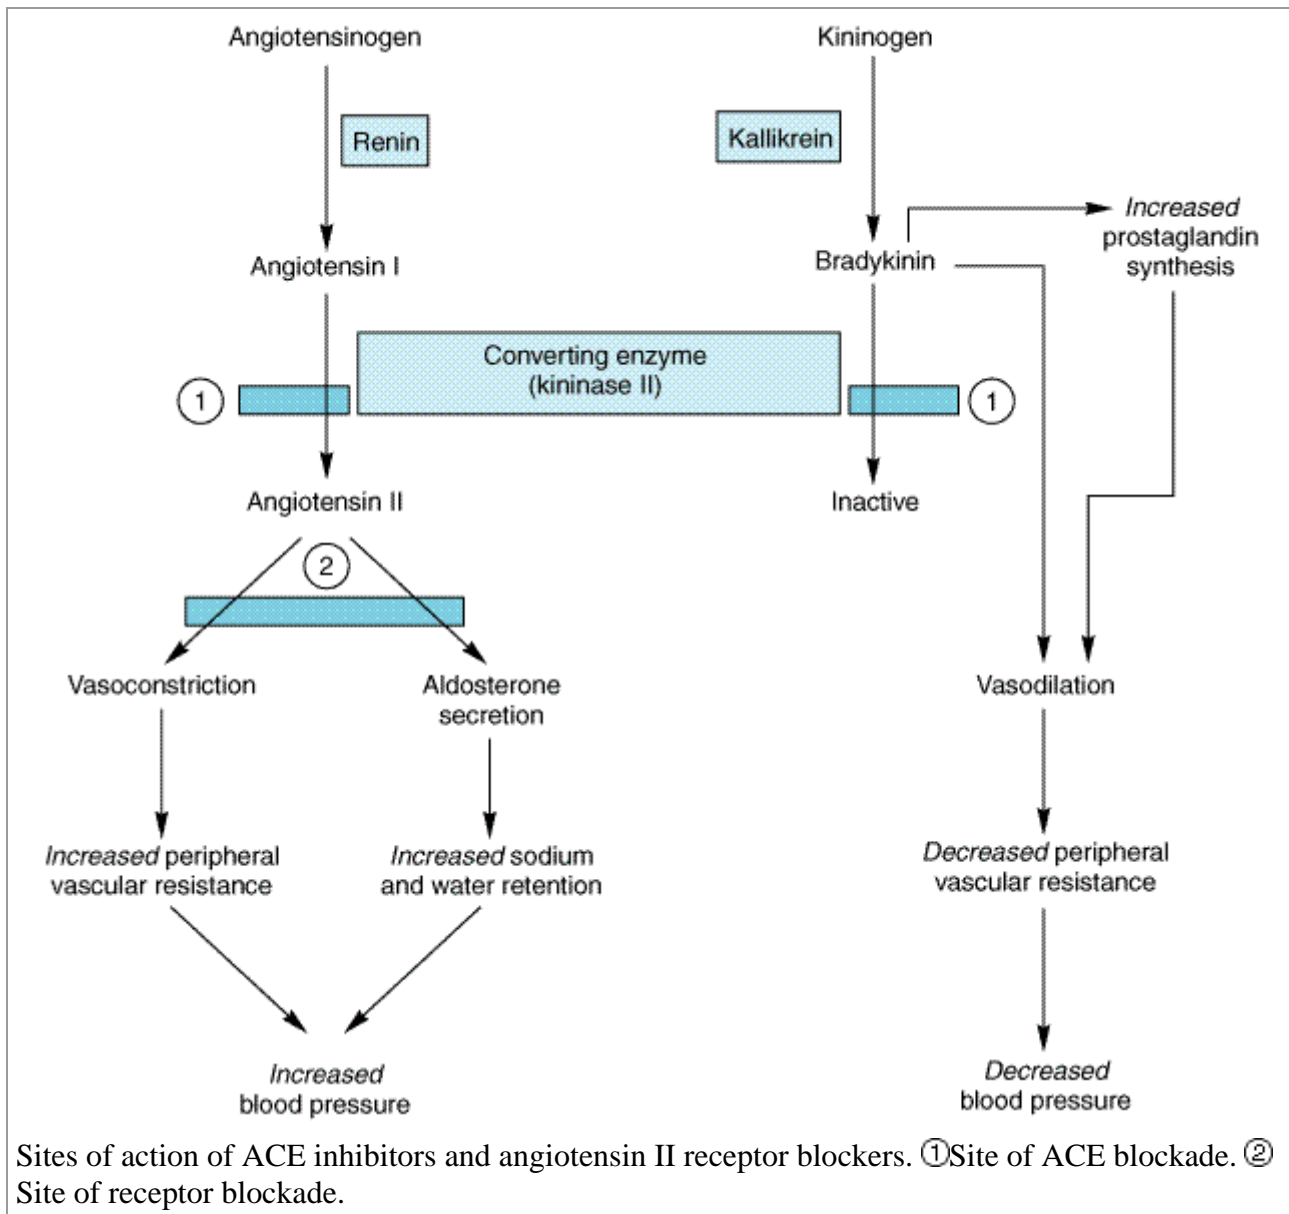

Inhibitors of Angiotensin

Although the causative roles of renin, angiotensin, and aldosterone in essential hypertension are still controversial, there do appear to be differences in the activity of this system among individuals. Approximately 20% of patients with essential hypertension have inappropriately low and 20% have inappropriately high plasma renin activity. Blood pressure of patients with high-renin hypertension responds well to β -adrenoceptor blockers, which lower plasma renin activity, and to angiotensin inhibitors—supporting a role for excess renin and angiotensin in this population.

Mechanism & Sites of Action

Renin release from the kidney cortex is stimulated by reduced renal arterial pressure, sympathetic neural stimulation, and reduced sodium delivery or increased sodium concentration at the distal renal tubule (see Chapter 17: Vasoactive Peptides). Renin acts upon angiotensinogen to split off the inactive precursor decapeptide angiotensin I. Angiotensin I is then converted, primarily by endothelial ACE, to the arterial vasoconstrictor octapeptide angiotensin II (Figure 11–6), which is in turn converted in the adrenal gland to angiotensin III. Angiotensin II has vasoconstrictor and sodium-retaining activity. Angiotensin II and III both stimulate aldosterone release. Angiotensin may contribute to maintaining high vascular resistance in hypertensive states associated with high plasma renin activity, such as renal arterial stenosis, some types of intrinsic renal disease, and malignant hypertension, as well as in essential hypertension after treatment with sodium restriction, diuretics, or vasodilators. However, even in low-renin hypertensive states, these drugs can lower blood pressure (see below).

Figure 11–6.

A parallel system for angiotensin generation exists in several other tissues (eg, heart) and may be responsible for trophic changes such as cardiac hypertrophy. The converting enzyme involved in tissue angiotensin II synthesis is also inhibited by the ACE inhibitors.

Two classes of drugs act specifically on the renin-angiotensin system: the ACE inhibitors and the competitive inhibitors of angiotensin at its receptors, including losartan and other nonpeptide antagonists, and the peptide saralasin. (Saralasin is no longer in clinical use.)

Angiotensin-Converting Enzyme (ACE) Inhibitors

Captopril (see Figure 17–2) and other drugs in this class inhibit the converting enzyme peptidyl dipeptidase that hydrolyzes angiotensin I to angiotensin II and (under the name plasma kininase) inactivates bradykinin, a potent vasodilator, which works at least in part by stimulating release of nitric oxide and prostacyclin. The hypotensive activity of captopril results both from an inhibitory action on the renin-angiotensin system and a stimulating action on the kallikrein-kinin system (Figure 11–6). The latter mechanism has been demonstrated by showing that an experimental bradykinin receptor antagonist, icatibant, blunts the blood pressure-lowering effect of captopril.

Enalapril (see Figure 17–2) is a prodrug that is converted by deesterification to a converting enzyme inhibitor, enalaprilat, with effects similar to those of captopril. Enalaprilat itself is available only for intravenous use, primarily for hypertensive emergencies. **Lisinopril** is a lysine derivative of enalaprilat. **Benazepril, fosinopril, moexipril, perindopril, quinapril, ramipril, andtrandolapril** are other long-acting members of the class. All are prodrugs, like enalapril, and are converted to the active agents by hydrolysis, primarily in the liver.

Angiotensin II inhibitors lower blood pressure principally by decreasing peripheral vascular resistance. Cardiac output and heart rate are not significantly changed. Unlike direct vasodilators, these agents do not result in reflex sympathetic activation and can be used safely in persons with ischemic heart disease. The absence of reflex tachycardia may be due to downward resetting of the baroreceptors or to enhanced parasympathetic activity.

Although converting enzyme inhibitors are most effective in conditions associated with high plasma renin activity, there is no good correlation among subjects between plasma renin activity and antihypertensive response. Accordingly, renin profiling is unnecessary.

ACE inhibitors have a particularly useful role in treating patients with diabetic nephropathy because they diminish proteinuria and stabilize renal function (even in the absence of lowering of blood pressure). These benefits probably result from improved intrarenal hemodynamics, with decreased glomerular efferent arteriolar resistance and a resulting reduction of intraglomerular capillary pressure. ACE inhibitors have also proved to be extremely useful in the treatment of heart failure, and after myocardial infarction (see Chapter 13: Drugs Used in Heart Failure).

Pharmacokinetics & Dosage

Captopril's pharmacokinetic parameters and dosing recommendations are set forth in Table 11–1.

Peak concentrations of enalaprilat, the active metabolite, occur 3–4 hours after dosing with enalapril. The half-life of enalaprilat is about 11 hours. Typical doses of enalapril are 10–20 mg once or twice daily.

Lisinopril has a half-life of 12 hours. Doses of 10–80 mg once daily are effective in most patients.

All of the ACE inhibitors except fosinopril and moexipril are eliminated primarily by the kidneys; doses of these drugs should be reduced in patients with renal insufficiency.

Toxicity

Severe hypotension can occur after initial doses of any ACE inhibitor in patients who are hypovolemic due to diuretics, salt restriction, or gastrointestinal fluid loss. Other adverse effects common to all ACE inhibitors include acute renal failure (particularly in patients with bilateral renal artery stenosis or stenosis of the renal artery of a solitary kidney), hyperkalemia, dry cough sometimes accompanied by wheezing, and angioedema. Hyperkalemia is more likely to occur in patients with renal insufficiency or diabetes. Bradykinin and substance P seem to be responsible for the cough and angioedema seen with ACE inhibition.

The use of ACE inhibitors is contraindicated during the second and third trimesters of pregnancy because of the risk of fetal hypotension, anuria, and renal failure, sometimes associated with fetal malformations or death. Captopril, particularly when given in high doses to patients with renal insufficiency, may cause neutropenia or proteinuria. Minor toxic effects seen more typically include

altered sense of taste, allergic skin rashes, and drug fever, which may occur in as many as 10% of patients. The incidence of these adverse effects may be lower with the long-acting ACE inhibitors.

Important drug interactions include those with potassium supplements or potassium-sparing diuretics, which can result in hyperkalemia. Nonsteroidal anti-inflammatory drugs may impair the hypotensive effects of ACE inhibitors by blocking bradykinin-mediated vasodilation, which is at least in part, prostaglandin mediated.

Angiotensin Receptor-Blocking Agents

Losartan and **valsartan** were the first marketed blockers of the angiotensin II type 1 (AT₁) receptor. More recently, **candesartan**, **eprosartan**, **irbesartan**, and **telmisartan** have been released. They have no effect on bradykinin metabolism and are therefore more selective blockers of angiotensin effects than ACE inhibitors. They also have the potential for more complete inhibition of angiotensin action compared with ACE inhibitors because there are enzymes other than ACE that are capable of generating angiotensin II. Losartan's pharmacokinetic parameters are listed in Table 11–1. The adverse effects are similar to those described for ACE inhibitors, including the hazard of use during pregnancy. Cough and angioedema can occur but are less common with angiotensin receptor blockers than with ACE inhibitors.

Antihypertensive Agents >

Monotherapy Versus Polypharmacy in Hypertension

Monotherapy of hypertension (treatment with a single drug) has become more popular because compliance is likely to be better and because in some cases adverse effects are fewer. However, moderate to severe hypertension is still commonly treated by a combination of two or more drugs, each acting by a different mechanism (polypharmacy). The rationale for polypharmacy is that each of the drugs acts on one of a set of interacting, mutually compensatory regulatory mechanisms for maintaining blood pressure (see Figures 6–7 and 11–1).

For example, because an adequate dose of hydralazine causes a significant decrease in peripheral vascular resistance, there will initially be a drop in mean arterial blood pressure, evoking a strong response in the form of compensatory tachycardia and salt and water retention (Figure 11–5). The result is an increase in cardiac output that is capable of almost completely reversing the effect of hydralazine. The addition of a β -blocker prevents the tachycardia; addition of a diuretic (eg, hydrochlorothiazide) prevents the salt and water retention. In effect, all three drugs increase the sensitivity of the cardiovascular system to each other's actions. Thus, partial impairment of one regulatory mechanism (sympathetic discharge to the heart) increases the antihypertensive effect of impairing regulation by another mechanism (peripheral vascular resistance). Finally, in some circumstances, a normal compensatory response accounts for the toxicity of an antihypertensive agent, and the toxic effect can be prevented by administering a second type of drug. In the case of hydralazine, compensatory tachycardia and increased cardiac output may precipitate angina in patients with coronary atherosclerosis. Addition of the β -blocker and diuretic can prevent this toxicity in many patients.

In practice, when hypertension does not respond adequately to a regimen of one drug, a second drug from a different class with a different mechanism of action and different pattern of toxicity is added. If the response is still inadequate and compliance is known to be good, a third drug

may be added. The drugs least likely to be successful as monotherapy are the vasodilators hydralazine and minoxidil. It is not completely clear why other vasodilators such as calcium channel blockers cause less marked compensatory responses for the same amount of blood pressure lowering.

Antihypertensive Agents >

Clinical Pharmacology of Antihypertensive Agents

Hypertension presents a unique problem in therapeutics. It is usually a lifelong disease that causes few symptoms until the advanced stage. For effective treatment, medicines that may be expensive and often produce adverse effects must be consumed daily. Thus, the physician must establish with certainty that hypertension is persistent and requires treatment and must exclude secondary causes of hypertension that might be treated by definitive surgical procedures. Persistence of hypertension, particularly in persons with mild elevation of blood pressure, should be established by finding an elevated blood pressure on at least three different office visits. Ambulatory blood pressure monitoring may be the best predictor of risk and therefore of need for therapy in mild hypertension. Isolated systolic hypertension and hypertension in the elderly also benefit from therapy.

Once the presence of hypertension is established, the question of whether or not to treat and which drugs to use must be considered. The level of blood pressure, the age and sex of the patient, the severity of organ damage (if any) due to high blood pressure, and the presence of cardiovascular risk factors must all be considered. At this stage, the patient must be educated about the nature of hypertension and the importance of treatment so that he or she can make an informed decision regarding therapy.

Once the decision is made to treat, a therapeutic regimen must be developed. Selection of drugs is dictated by the level of blood pressure, the presence and severity of end-organ damage, and the presence of other diseases. Severe high blood pressure with life-threatening complications requires more rapid treatment with more potent drugs. Most patients with essential hypertension, however, have had elevated blood pressure for months or years, and therapy is best initiated in a gradual fashion.

Education about the natural history of hypertension and the importance of treatment compliance as well as potential side effects of drugs is essential. Follow-up visits should be frequent enough to convince the patient that the physician thinks the illness is serious. With each follow-up visit, the importance of treatment should be reinforced and questions particularly concerning dosing or side effects of medication encouraged. Other factors that may improve compliance are simplifying dosing regimens and having the patient monitor blood pressure at home.

Outpatient Therapy of Hypertension

The initial step in treating hypertension may be nonpharmacologic. As discussed previously, sodium restriction may be effective treatment for many patients with mild hypertension. The average American diet contains about 200 mEq of sodium per day. A reasonable dietary goal in treating hypertension is 70–100 mEq of sodium per day, which can be achieved by not salting food

during or after cooking and by avoiding processed foods that contain large amounts of sodium.

Weight reduction even without sodium restriction has been shown to normalize blood pressure in up to 75% of overweight patients with mild to moderate hypertension. Regular exercise has been shown in some but not all studies to lower blood pressure in hypertensive patients.

For pharmacologic management of mild hypertension, blood pressure can be normalized in most patients with a single drug. Such "monotherapy" is also sufficient for some patients with moderate hypertension. Thiazide diuretics, β -blockers, and ACE inhibitors have been shown to reduce morbidity and mortality and are recommended for initial drug therapy in such patients. There has been concern that diuretics, by adversely affecting the serum lipid profile or impairing glucose tolerance, may add to the risk of coronary disease, thereby offsetting the benefit of blood pressure reduction. However a recent large clinical trial comparing different classes of antihypertensive medications for initial therapy found that chlorthalidone (a thiazide diuretic) was as effective as other agents in reducing coronary heart disease death and nonfatal myocardial infarction, and was superior to amlodipine in preventing heart failure and superior to lisinopril in preventing stroke (ALLHAT Collaborative Research Group, 2002).

Alternative choices for initial monotherapy include angiotensin receptor blockers, calcium channel blockers, combination α - and β -blockers (labetalol or carvedilol), and central sympathoplegic agents (eg, clonidine). Alpha blockers should not be considered first-line therapy (ALLHAT, 2000). The presence of concomitant disease should influence selection of antihypertensive drugs because two diseases may benefit from a single drug. For example, ACE inhibitors are particularly useful in diabetic patients with evidence of renal disease. Beta blockers or calcium channel blockers are useful in patients who also have angina; diuretics, ACE inhibitors, or β -blockers in patients who also have heart failure; and α_1 blockers in men who have benign prostatic hyperplasia. Race may also affect drug selection: blacks respond better to diuretics and calcium channel blockers than to β -blockers and ACE inhibitors. Chinese are more sensitive to the effects of β -blockers and may require lower doses.

If a single drug does not adequately control blood pressure, drugs with different sites of action can be combined to effectively lower blood pressure while minimizing toxicity ("stepped care"). If a diuretic is not used initially, it is often selected as the second drug. If three drugs are required, combining a diuretic, a sympathoplegic agent or an ACE inhibitor, and a direct vasodilator (eg, hydralazine or a calcium channel blocker) is often effective. In the USA, fixed-dose drug combinations containing a β -blocker plus a thiazide, an ACE inhibitor plus a thiazide, an angiotensin receptor blocker plus a diuretic, and a calcium channel blocker plus an ACE inhibitor are available. Fixed-dose combinations have the drawback of not allowing for titration of individual drug doses but have the advantage of allowing fewer pills to be taken, potentially enhancing compliance.

Assessment of blood pressure during office visits should include measurement of recumbent, sitting, and standing pressures. An attempt should be made to normalize blood pressure in the posture or activity level that is customary for the patient. The recent large Hypertension Optimal Treatment study suggests that the optimal blood pressure end point is 138/83 mm Hg. Lowering blood pressure below this level produces no further benefit (Hansson et al, 1998). In diabetic patients, however, there is a continued reduction of event rates with progressively lower blood pressures. In addition to noncompliance with medication, causes of failure to respond to drug therapy include excessive sodium intake and inadequate diuretic therapy with excessive blood volume (this can be measured directly), and drugs such as tricyclic antidepressants, nonsteroidal anti-inflammatory drugs, over-the-counter sympathomimetics, abuse of stimulants (amphetamine or

cocaine), or excessive doses of caffeine and oral contraceptives that can interfere with actions of some antihypertensive drugs or directly raise blood pressure.

Management of Hypertensive Emergencies

Despite the large number of patients with chronic hypertension, hypertensive emergencies are relatively rare. Marked or sudden elevation of blood pressure may be a serious threat to life, however, and prompt control of blood pressure is indicated. Most commonly, hypertensive emergencies occur in patients whose hypertension is severe and poorly controlled and in those who suddenly discontinue antihypertensive medications.

Clinical Presentation & Pathophysiology

Hypertensive emergencies include hypertension associated with vascular damage (termed malignant hypertension) and hypertension associated with hemodynamic complications such as heart failure, stroke, or dissecting aneurysm. The underlying pathologic process in malignant hypertension is a progressive arteriopathy with inflammation and necrosis of arterioles. Vascular lesions occur in the kidney, which releases renin, which in turn stimulates production of angiotensin and aldosterone, which further increase blood pressure.

Hypertensive encephalopathy is a classic feature of malignant hypertension. Its clinical presentation consists of severe headache, mental confusion, and apprehension. Blurred vision, nausea and vomiting, and focal neurologic deficits are common. If untreated, the syndrome may progress over a period of 12–48 hours to convulsions, stupor, coma, and even death.

Treatment of Hypertensive Emergencies

The general management of hypertensive emergencies requires monitoring the patient in an intensive care unit with continuous recording of arterial blood pressure. Fluid intake and output must be monitored carefully and body weight measured daily as an indicator of total body fluid volume during the course of therapy.

Parenteral antihypertensive medications are used to lower blood pressure rapidly (within a few hours); as soon as reasonable blood pressure control is achieved, oral antihypertensive therapy should be substituted, because this allows smoother long-term management of hypertension. The goal of treatment in the first few hours or days is not complete normalization of blood pressure because chronic hypertension is associated with autoregulatory changes in cerebral blood flow. Thus, rapid normalization of blood pressure may lead to cerebral hypoperfusion and brain injury. Rather, blood pressure should be lowered by about 25%, maintaining diastolic blood pressure at no less than 100–110 mm Hg. Subsequently, blood pressure can be reduced to normal levels using oral medications over several weeks. The drug most commonly used to treat hypertensive emergencies is the vasodilator sodium nitroprusside. Other parenteral drugs that may be effective include fenoldopam, nitroglycerin, labetalol, calcium channel blockers, diazoxide, and hydralazine. Esmolol is often used to manage intraoperative and postoperative hypertension. Diuretics such as furosemide are administered to prevent the volume expansion that typically occurs during administration of powerful vasodilators.

Preparations Available

Beta Adrenoceptor Blockers

Acebutolol(generic, Sectral)

Oral: 200, 400 mg capsules

Atenolol(generic, Tenormin)

Oral: 25, 50, 100 mg tablets

Parenteral: 0.5 mg/mL for injection

Betaxolol(Kerlone)

Oral: 10, 20 mg tablets

Bisoprolol(Zebeta)

Oral: 5, 10 mg tablets

Carteolol(Cartrol)

Oral: 2.5, 5 mg tablets

Carvedilol(Coreg)

Oral: 3.125, 6.25, 12.5, 25 mg tablets

Esmolol (BreviBloc)

Parenteral: 10, 250 mg/mL for injection

Labetalol (generic, Normodyne, Trandate)

Oral: 100, 200, 300 mg tablets

Parenteral: 5 mg/mL for injection

Metoprolol (generic, Lopressor)

Oral: 50, 100 mg tablets

Oral extended-release (Toprol-XL): 25, 50, 100, 200 mg tablets

Parenteral: 1 mg/mL for injection

Nadolol (generic, Corgard)

Oral: 20, 40, 80, 120, 160 mg tablets

Penbutolol(Levatol)

Oral: 20 mg tablets

Pindolol(generic, Visken)

Oral: 5, 10 mg tablets

Propranolol(generic, Inderal)

Oral: 10, 20, 40, 60, 80, 90 mg tablets; 4, 8 mg/mL oral solution; Intensol, 80 mg/mL solution

Oral sustained-release (generic, Inderal LA): 60, 80, 120, 160 mg capsules

Parenteral: 1 mg/mL for injection

Timolol(generic, Blocadren)

Oral: 5, 10, 20 mg tablets

Centrally Acting Sympathoplegic Drugs

Clonidine(generic, Catapres)

Oral: 0.1, 0.2, 0.3 mg tablets

Transdermal (Catapres-TTS): patches that release 0.1, 0.2, 0.3 mg/24 h

Guanabenz (generic, Wytensin)

Oral: 4, 8 mg tablets

Guanfacine(Tenex)

Oral: 1, 2 mg tablets

Methyldopa(generic)

Oral: 250, 500 mg tablets

Parenteral: 50 mg/mL for injection

Postganglionic Sympathetic Nerve Terminal Blockers

Guanadrel (Hylorel)

Oral: 10, 25 mg tablets

Guanethidine(Ismelin)

Oral: 10, 25 mg tablets

Reserpine (generic)

Oral: 0.1, 0.25 mg tablets

Alpha₁ Selective Adrenoceptor Blockers

Doxazosin(generic, Cardura)

Oral: 1, 2, 4, 8 mg tablets

Prazosin (generic, Minipress)

Oral: 1, 2, 5 mg capsules

Terazosin (generic, Hytrin)

Oral: 1, 2, 5, 10 mg capsules and tablets

Ganglion-Blocking Agents

Mecamylamine (Inversine)

Oral: 2.5 mg tablets

Vasodilators Used in Hypertension

Diazoxide (Hyperstat IV)

Parenteral: 15 mg/mL ampule

Oral (Proglycem): 50 mg capsule; 50 mg/mL oral suspension

Fenoldopam(Corlopam)

Parenteral: 10 mg/mL for IV infusion

Hydralazine(generic, Apresoline)

Oral: 10, 25, 50, 100 mg tablets

Parenteral: 20 mg/mL for injection

Minoxidil(generic, Loniten)

Oral: 2.5, 10 mg tablets

Topical (Rogaine, etc): 2% lotion

Nitroprusside(generic, Nitropress)

Parenteral: 50 mg/vial

Calcium Channel Blockers

Amlodipine (Norvasc)

Oral 2.5, 5, 10 mg tablets

Diltiazem(generic, Cardizem)

Oral: 30, 60, 90, 120 mg tablets (unlabeled in hypertension)

Oral sustained-release (Cardizem CD, Cardizem SR, Dilacor XL): 60, 90, 120, 180, 240, 300, 360, 420 mg capsules

Parenteral: 5 mg/mL for injection

Felodipine (Plendil)

Oral extended-release: 2.5, 5, 10 mg tablets

Isradipine(DynaCirc)

Oral: 2.5, 5 mg capsules; 5, 10 mg controlled-release tablets

Nicardipine (generic, Cardene)

Oral: 20, 30 mg capsules

Oral sustained-release (Cardene SR): 30, 45, 60 mg capsules

Parenteral (Cardene I.V.): 2.5 mg/mL for injection

Nisoldipine (Sular)

Oral: 10, 20, 30, 40 mg extended-release tablets

Nifedipine(generic, Adalat, Procardia)

Oral: 10, 20 mg capsules (unlabeled in hypertension)

Oral extended-release (Adalat CC, Procardia-XL): 30, 60, 90 mg tablets

Verapamil(generic, Calan, Isoptin)

Oral: 40, 80, 120 mg tablets

Oral sustained-release (generic, Calan SR, Verelan): 120, 180, 240 mg tablets; 100, 120, 180, 200, 240, 300 mg capsules

Parenteral: 2.5 mg/mL for injection

Angiotensin-Converting Enzyme Inhibitors

Benazepril(Lotensin)

Oral: 5, 10, 20, 40, mg tablets

Captopril (generic, Capoten)

Oral: 12.5, 25, 50, 100 mg tablets

Enalapril(Vasotec)

Oral: 2.5, 5, 10, 20 mg tablets

Parenteral (Enalaprilat): 1.25 mg/mL for injection

Fosinopril(Monopril)

Oral: 10, 20, 40 mg tablets

Lisinopril(Prinivil, Zestril)

Oral: 2.5, 5, 10, 20, 40 mg tablets

Moexipril(Univasc)

Oral: 7.5, 15 mg tablets

Perindopril (Aceon)

Oral: 2, 4, 8 mg tablets

Quinapril(Accupril)

Oral: 5, 10, 20, 40 mg tablets

Ramipril (Altace)

Oral: 1.25, 2.5, 5, 10 mg capsules

Trandolapril(Mavik)

Oral: 1, 2, 4 mg tablets

Angiotensin Receptor Blockers

Candesartan (Atacand)

Oral: 4, 8, 16, 32 mg tablets

Eprosartan(Teveten)

Oral: 400, 600 mg tablets

Irbesartan (Avapro)

Oral; 75, 150, 300 mg tablets

Losartan (Cozaar)

Oral: 25, 50, 100 mg tablets

Olmisartan (Benicar)

Oral: 5, 20, 40 mg tablets

Telmisartan(Micardis)

Oral: 20, 40, 80 mg tablets

Valsartan (Diovan)

Oral: 40, 80, 160, 320 mg tablet

Chapter 12. Vasodilators & the Treatment of Angina Pectoris

Katzung PHARMACOLOGY, 9e > Section III. Cardiovascular-Renal Drugs > Chapter 12.
Vasodilators & the Treatment of Angina Pectoris >

Vasodilators & the Treatment of Angina Pectoris

Angina pectoris is the most common condition involving tissue ischemia in which vasodilator drugs are used. Angina (pain) is caused by the accumulation of metabolites in striated muscle; angina pectoris is the severe chest pain that occurs when coronary blood flow is inadequate to supply the oxygen required by the heart. The organic nitrates, eg, **nitroglycerin**, are the mainstay of therapy for the immediate relief of angina. Another group of vasodilators, the **calcium channel blockers**, is also important, especially for prophylaxis, and the **β-blockers**, which are *not* vasodilators, are also useful in prophylaxis. A new group of drugs (fatty acid oxidation inhibitors) that are not vasodilators but alter myocardial metabolism are under intense investigation.

Ischemic heart disease is the most common serious health problem in many Western societies. By far the most frequent cause of angina is atheromatous obstruction of the large coronary vessels (**atherosclerotic angina, classic angina**). However, transient spasm of localized portions of these vessels, which is usually associated with underlying atheromas, can also cause significant myocardial ischemia and pain (**angiospastic or variant angina**).

The primary cause of angina pectoris is an imbalance between the oxygen requirement of the heart and the oxygen supplied to it via the coronary vessels. In classic angina, the imbalance occurs when the myocardial oxygen requirement increases, as during exercise, and coronary blood flow does not increase proportionately. The resulting ischemia usually leads to pain. Classic angina is therefore "angina of effort." (In some individuals, the ischemia is not always accompanied by pain, resulting in "silent" or "ambulatory" ischemia.) In variant angina, oxygen delivery decreases as a result of reversible coronary vasospasm. Variant angina is also called vasospastic or Prinzmetal's angina.

In theory, the imbalance between oxygen delivery and myocardial oxygen demand can be corrected by **decreasing oxygen demand** or by **increasing delivery** (by increasing coronary flow). Oxygen demand can be reduced by decreasing cardiac work or, according to recent studies, by shifting myocardial metabolism to substrates that require less oxygen per unit of ATP produced. In effort angina, acute reduction of demand has traditionally been achieved by means of organic nitrates—potent vasodilators—and several other classes of drugs, which decrease cardiac work. Increased delivery via increased coronary flow is difficult to achieve rapidly by pharmacologic means when flow is limited by fixed atheromatous plaques. In this situation, invasive measures (coronary bypass grafts or angioplasty) may be needed if reduction of oxygen demand does not control symptoms. In variant angina, on the other hand, spasm of coronary vessels can be reversed by nitrates or calcium channel blockers. It should be emphasized that not all vasodilators are effective in angina and, conversely, that some agents useful in angina (eg, propranolol) are not vasodilators. Lipid-lowering drugs, especially the "statins," have become extremely important in the long-term treatment of atherosclerotic disease (see Chapter 35: Agents Used in Hyperlipidemia).

Unstable angina, an acute coronary syndrome, is said to be present when there are episodes of angina at rest and when there is a change in the character, frequency, and duration of chest pain as well as precipitating factors in patients with previously stable angina. Unstable angina is caused by episodes of increased epicardial coronary artery tone or small platelet clots occurring in the vicinity of an atherosclerotic plaque. In most cases, formation of labile nonocclusive thrombi at the site of a fissured or ulcerated plaque is the mechanism for reduction in flow. The course and the prognosis of unstable angina are variable, but this subset of acute coronary syndrome is associated with a high risk of myocardial infarction and death.

Pathophysiology of Angina

Determinants of Myocardial Oxygen Demand

The major and minor determinants of myocardial oxygen requirement are set forth in Table 12–1. Unlike skeletal muscle, human cardiac muscle cannot develop an appreciable oxygen debt during stress and repay it later. As a consequence of its continuous activity, the heart's oxygen needs are relatively high, and it extracts approximately 75% of the available oxygen even under conditions of no stress. The myocardial oxygen requirement increases when there is an increase in heart rate, contractility, arterial pressure, or ventricular volume. These hemodynamic alterations frequently occur during physical exercise and sympathetic discharge, which often precipitate angina in patients with obstructive coronary artery disease. The relative contributions of basal metabolism and activation of contraction to the overall myocardial oxygen consumption appear to be small, but

under pathologic conditions these apparently minor determinants of myocardial oxygen consumption may become relevant.

Table 12–1. Determinants of Myocardial Oxygen Consumption.	
Major	
Wall stress

The heart favors fatty acids as a substrate for energy production. However, oxidation of fatty acids requires more oxygen per unit of ATP generated than oxidation of carbohydrates. Therefore, drugs that shift myocardial metabolism toward greater use of glucose (fatty acid oxidation inhibitors) have the potential of reducing the oxygen demand without altering hemodynamics. Experimental models suggest that ranolazine and trimetazidine may have this effect. Preliminary clinical trials have shown favorable results.

Determinants of Coronary Blood Flow & Myocardial Oxygen Supply

Increased myocardial demands for oxygen in the normal heart are met by augmenting coronary blood flow. Coronary blood flow is directly related to the perfusion pressure (aortic diastolic pressure) and the duration of diastole. Because coronary flow drops to negligible values during systole, the duration of diastole becomes a limiting factor for myocardial perfusion during tachycardia. Coronary blood flow is inversely proportional to coronary vascular bed resistance. Resistance is determined mainly by intrinsic factors, including metabolic products and autonomic activity; and by various pharmacologic agents. Damage to the endothelium of coronary vessels has been shown to alter their ability to dilate and to increase coronary vascular resistance.

Determinants of Vascular Tone

Arteriolar and venous tone (smooth muscle tension) both play a role in determining myocardial wall stress (Table 12–1). Arteriolar tone directly controls peripheral vascular resistance and thus arterial blood pressure. In systole, intraventricular pressure must exceed aortic pressure to eject blood; arterial blood pressure thus determines the *systolic* wall stress in an important way. Venous tone determines the capacity of the venous circulation and controls the amount of blood sequestered in the venous system versus the amount returned to the heart. Venous tone thereby determines the *diastolic* wall stress.

The regulation of smooth muscle contraction and relaxation is shown schematically in Figure 12–1.

As shown in Figures 12–1 and 12–2, drugs may relax vascular smooth muscle in several ways:

Figure 12–1.

Control of smooth muscle contraction and site of action of calcium channel-blocking drugs. Contraction is triggered by influx of calcium (which can be blocked by calcium channel blockers) through transmembrane calcium channels. The calcium combines with calmodulin to form a complex that converts the enzyme myosin light chain kinase to its active form (MLCK^*). The latter phosphorylates the myosin light chains, thereby initiating the interaction of myosin with actin. Beta₂ agonists (and other substances that increase cAMP) may cause relaxation in smooth muscle by accelerating the inactivation of MLCK (heavy arrows) and by facilitating the expulsion of calcium from the cell (not shown).

Figure 12–1. Control of smooth muscle contraction and site of action of calcium channel-blocking drugs. Contraction is triggered by influx of calcium (which can be blocked by calcium channel blockers) through transmembrane calcium channels. The calcium combines with calmodulin to form a complex that converts the enzyme myosin light chain kinase to its active form (MLCK^*). The latter phosphorylates the myosin light chains, thereby initiating the interaction of myosin with actin. Beta₂ agonists (and other substances that increase cAMP) may cause relaxation in smooth muscle by accelerating the inactivation of MLCK (heavy arrows) and by facilitating the expulsion of calcium from the cell (not shown).

1. Increasing cGMP—As indicated in Figure 12–2, cGMP facilitates the dephosphorylation of myosin light chains, preventing the interaction of myosin with actin. Nitric oxide is an effective activator of soluble guanylyl cyclase and acts mainly through this mechanism. Important molecular donors of nitric oxide include nitroprusside (see Chapter 11: Antihypertensive Agents) and the organic nitrates used in angina.

2. Decreasing intracellular Ca^{2+} —Calcium channel blockers predictably cause vasodilation because they reduce intracellular Ca^{2+} , a major modulator of the activation of myosin light chain kinase. (Beta blockers and calcium channel blockers reduce Ca^{2+} influx in cardiac muscle,

thereby reducing rate, contractility, and oxygen requirement unless reversed by compensatory responses.)

3. Stabilizing or preventing depolarization of the vascular smooth muscle cell membrane—The membrane potential of excitable cells is stabilized near the resting potential by increasing potassium permeability. Potassium channel openers, such as minoxidil sulfate, (see Chapter 11: Antihypertensive Agents) increase the permeability of K^+ channels, probably ATP-dependent K^+ channels. Certain newer agents under investigation for use in angina (eg, nicorandil) may act, in part, by this mechanism.

4. Increasing cAMP in the vascular cells—As shown in Figure 12–1, an increase in cAMP increases the rate of inactivation of myosin light chain kinase, the enzyme responsible for triggering the interaction of actin with myosin in these cells. This appears to be the mechanism of vasodilation caused by β_2 -agonists, drugs that are *not* used in angina.

Figure 12–2.

Mechanism of action of nitrates, nitrites, and other substances that increase the concentration of nitric oxide (NO) in smooth muscle cells. (MLCK*, activated myosin light chain kinase [see Figure 12–1]; guanylyl cyclase*, activated guanylyl cyclase; ?, unknown intermediate steps. Steps leading to relaxation are shown with heavy arrows.)

Katzung PHARMACOLOGY, 9e > Section III. Cardiovascular-Renal Drugs > Chapter 12. Vasodilators & the Treatment of Angina Pectoris >

Basic Pharmacology of Drugs Used to Treat Angina

Drug Action in Angina

All three of the drug groups currently approved for use in angina (organic nitrates, calcium channel blockers, and β -blockers) *decrease myocardial oxygen requirement* by decreasing the determinants of oxygen demand (heart rate, ventricular volume, blood pressure, and contractility). In some

patients, a redistribution of coronary flow may increase oxygen delivery to ischemic tissue. In variant angina, the nitrates and the calcium channel blockers may also *increase myocardial oxygen delivery* by reversing coronary arterial spasm.

Nitrates & Nitrites

Chemistry

These agents are simple nitric and nitrous acid esters of polyalcohols. Nitroglycerin may be considered the prototype of the group. Although it is used in the manufacture of dynamite, the formulations of nitroglycerin used in medicine are not explosive. The conventional sublingual tablet form of nitroglycerin may lose potency when stored as a result of volatilization and adsorption to plastic surfaces. Therefore, it should be kept in tightly closed glass containers. It is not sensitive to light.

All therapeutically active agents in the nitrate group have identical mechanisms of action and similar toxicities. Therefore, pharmacokinetic factors govern the choice of agent and mode of therapy when using the nitrates.

Pharmacokinetics

The liver contains a high-capacity organic nitrate reductase that removes nitrate groups in a stepwise fashion from the parent molecule and ultimately inactivates the drug. Therefore, oral bioavailability of the traditional organic nitrates (eg, nitroglycerin and isosorbide dinitrate) is very low (typically < 10–20%). The sublingual route, which avoids the first-pass effect, is therefore preferred for achieving a therapeutic blood level rapidly. Nitroglycerin and isosorbide dinitrate are both absorbed efficiently by this route and reach therapeutic blood levels within a few minutes. However, the total dose administered by this route must be limited to avoid excessive effect; therefore, the total duration of effect is brief (15–30 minutes). When much longer duration of action is needed, oral preparations can be given that contain an amount of drug sufficient to result in sustained systemic blood levels of the parent drug plus active metabolites. Other routes of administration available for nitroglycerin include transdermal and buccal absorption from slow-release preparations; these are described below.

Amyl nitrite and related nitrites are highly volatile liquids. Amyl nitrite is available in fragile glass ampules packaged in a protective cloth covering. The ampule can be crushed with the fingers, resulting in rapid release of inhalable vapors through the cloth covering. The inhalation route provides very rapid absorption and, like the sublingual route, avoids the hepatic first-pass effect. Because of its unpleasant odor and short duration of action, amyl nitrite is now obsolete for angina.

Once absorbed, the unchanged nitrate compounds have half-lives of only 2–8 minutes. The partially denitrated metabolites have much longer half-lives (up to 3 hours). Of the nitroglycerin metabolites (two dinitroglycerins and two mononitro forms), the dinitro derivatives have significant vasodilator

efficacy; they probably provide most of the therapeutic effect of orally administered nitroglycerin. The 5-mononitrate metabolite of isosorbide dinitrate is an active metabolite of the latter drug and is available for clinical use as isosorbide mononitrate. It has a bioavailability of 100%.

Excretion, primarily in the form of glucuronide derivatives of the denitrated metabolites, is largely by way of the kidney.

Pharmacodynamics

Mechanism of Action in Smooth Muscle

Nitroglycerin is denitrated by glutathione *S*-transferase. Free nitrite ion is released, which is then converted to nitric oxide (see Chapter 19: Nitric Oxide, Donors, & Inhibitors). A different unknown enzymatic reaction releases nitric oxide directly from the parent drug molecule. As shown in Figure 12–2, nitric oxide (or an *S*-nitrosothiol derivative) causes activation of guanylyl cyclase and an increase in cGMP, which are the first steps toward smooth muscle relaxation. The production of prostaglandin E or prostacyclin (PGI₂) and membrane hyperpolarization may also be involved. There is no evidence that autonomic receptors are involved in the primary nitrate response (although autonomic *reflex* responses are evoked when hypotensive doses are given).

As described below, tolerance is an important consideration in the use of nitrates. While tolerance may be caused in part by a decrease in tissue sulfhydryl groups, it can be only partially prevented or reversed with a sulfhydryl-regenerating agent. The site of this cellular tolerance may be in the unknown reaction responsible for the release of nitric oxide from the nitrate, since other agents, eg, acetylcholine, that cause vasodilation via release of nitric oxide from *endogenous* substrates do not show cross tolerance with the nitrates.

Nicorandil and several other investigational antianginal agents appear to combine the activity of nitric oxide release with potassium channel-opening action, thus providing an additional mechanism for causing vasodilation.

Organ System Effects

Nitroglycerin relaxes all types of smooth muscle irrespective of the cause of the preexisting muscle tone (Figure 12–3). It has practically no direct effect on cardiac or skeletal muscle.

Figure 12–3.

Vascular Smooth Muscle

All segments of the vascular system from large arteries through large veins relax in response to nitroglycerin. Veins respond at the lowest concentrations, arteries at slightly higher ones. Arterioles and precapillary sphincters are dilated less than the large arteries and the veins, partly because of reflex responses and partly because different vessels vary in their ability to release nitric oxide (see The Coronary Steal Phenomenon). The primary direct result of an effective dose of nitroglycerin is marked relaxation of veins with increased venous capacitance and decreased ventricular preload. Pulmonary vascular pressures and heart size are significantly reduced. In the absence of heart failure, cardiac output is reduced. Because venous capacitance is increased, orthostatic hypotension may be marked and syncope can result. Dilation of some large arteries (including the aorta) may be significant because of their large increase in compliance. Temporal artery pulsations and a throbbing headache associated with meningeal artery pulsations are frequent effects of nitroglycerin and amyl nitrite. In heart failure, preload is often abnormally high; the nitrates and other vasodilators, by reducing preload, may have a beneficial effect on cardiac output in this condition (see Chapter 13: Drugs Used in Heart Failure).

The indirect effects of nitroglycerin consist of those compensatory responses evoked by baroreceptors and hormonal mechanisms responding to decreased arterial pressure (see Figure 6–7); this consistently results in tachycardia and increased cardiac contractility. Retention of salt and water may also be significant, especially with intermediate- and long-acting nitrates. These compensatory responses contribute to the development of tolerance.

In normal subjects without coronary disease, nitroglycerin can induce a significant, if transient, increase in total coronary blood flow. In contrast, there is no evidence that total coronary flow is increased in patients with angina due to atherosclerotic obstructive coronary artery disease. However, some studies suggest that *redistribution* of coronary flow from normal to ischemic regions may play a role in nitroglycerin's therapeutic effect. Nitroglycerin also exerts a weak negative inotropic effect via nitric oxide.

Other Smooth Muscle Organs

Relaxation of smooth muscle of the bronchi, gastrointestinal tract (including biliary system), and genitourinary tract has been demonstrated experimentally. Because of their brief duration, these actions of the nitrates are rarely of any clinical value. During recent years, the use of amyl nitrite and isobutyl nitrite by inhalation as purported recreational (sex-enhancing) drugs has become popular with some segments of the population. Nitrites release nitric oxide in erectile tissue as well as vascular smooth muscle and activate guanylyl cyclase. The resulting increase in cGMP causes dephosphorylation of myosin light chains and relaxation (Figure 12–2), which enhances erection. Drugs used in the treatment of erectile dysfunction are discussed in the section, *Drugs Used in the Treatment of Erectile Dysfunction*.

Action on Platelets

Nitric oxide released from nitroglycerin stimulates guanylyl cyclase in platelets as in smooth muscle. The increase in cGMP that results is responsible for a decrease in platelet aggregation. Unfortunately, recent prospective trials have established no survival benefit when nitroglycerin is used in acute myocardial infarction.

Other Effects

Nitrite ion reacts with hemoglobin (which contains ferrous iron) to produce methemoglobin (which contains ferric iron). Because methemoglobin has a very low affinity for oxygen, large doses of nitrites can result in pseudocyanosis, tissue hypoxia, and death. Fortunately, the plasma level of *nitrite* resulting from even large doses of organic and inorganic *nitrates* is too low to cause significant methemoglobinemia in adults. However, sodium nitrite is used as a curing agent for meats. In nursing infants, the intestinal flora is capable of converting significant amounts of inorganic nitrate, eg, from well water, to nitrite ion. Thus, inadvertent exposure to large amounts of nitrite ion can occur and may produce serious toxicity.

One therapeutic application of this otherwise toxic effect of nitrite has been discovered. Cyanide poisoning results from complexing of cytochrome iron by the CN^- ion. Methemoglobin iron has a very high affinity for CN^- ; thus, administration of sodium nitrite (NaNO_2) soon after cyanide exposure will regenerate active cytochrome. The cyanmethemoglobin produced can be further detoxified by the intravenous administration of sodium thiosulfate ($\text{Na}_2\text{S}_2\text{O}_3$); this results in formation of thiocyanate ion (SCN^-), a less toxic ion that is readily excreted. Methemoglobinemia, if excessive, can be treated by giving methylene blue intravenously.

Toxicity & Tolerance

Acute Adverse Effects

The major acute toxicities of organic nitrates are direct extensions of therapeutic vasodilation: orthostatic hypotension, tachycardia, and throbbing headache. Glaucoma, once thought to be a

contraindication, does not worsen, and nitrates can be used safely in the presence of increased intraocular pressure. Nitrates are contraindicated, however, if intracranial pressure is elevated.

Tolerance

With continuous exposure to nitrates, isolated smooth muscle may develop complete tolerance (tachyphylaxis), and the intact human becomes progressively more tolerant when long-acting preparations (oral, transdermal) or continuous intravenous infusions are used for more than a few hours without interruption.

Continuous exposure to high levels of nitrates can occur in the chemical industry, especially where explosives are manufactured. When contamination of the workplace with volatile organic nitrate compounds is severe, workers find that upon starting their work week (Monday), they suffer headache and transient dizziness. After a day or so, these symptoms disappear owing to the development of tolerance. Over the weekend, when exposure to the chemicals is reduced, tolerance disappears, so symptoms recur each Monday. Other hazards of industrial exposure, including dependence, have been reported. There is no evidence that physical dependence develops as a result of the therapeutic use of short-acting nitrates for angina, even in large doses.

The mechanisms by which tolerance develops are not completely understood. As noted above, diminished release of nitric oxide may be partly responsible for tolerance to nitroglycerin. Systemic compensation also plays a role in tolerance in the intact human. Initially, significant sympathetic discharge occurs and after one or more days of therapy with long-acting nitrates, retention of salt and water may reverse the favorable hemodynamic changes normally caused by nitroglycerin.

Carcinogenicity of Nitrate and Nitrate Derivatives

Nitrosamines are small molecules with the structure R_2-N-NO formed from the combination of nitrates and nitrites with amines. Some nitrosamines are powerful carcinogens in animals, apparently through conversion to reactive derivatives. While there is no direct proof that these agents cause cancer in humans, there is a strong epidemiologic correlation between the incidence of esophageal and gastric carcinoma and the nitrate content of food in different cultures. Nitrosamines are also found in tobacco and in cigarette smoke. There is no evidence that the small doses of nitrates used in the treatment of angina result in significant body levels of nitrosamines.

Mechanisms of Clinical Effect

The beneficial and deleterious effects of nitrate-induced vasodilation are summarized in Table 12–2.

Table 12–2. Beneficial and Deleterious Effects of Nitrates in the Treatment of Angina.	
Effect	Result
Potential beneficial effects	
Decreased ventricular volume	Decreased myocardial oxygen requirement
Decreased arterial pressure	
Decreased ejection time	

Vasodilation of epicardial coronary arteries	Relief of coronary artery spasm
Increased collateral flow	Improved perfusion to ischemic myocardium
Decreased left ventricular diastolic pressure	Improved subendocardial perfusion
Potential deleterious effects	
Reflex tachycardia	Increased myocardial oxygen requirement
Reflex increase in contractility	
Decreased diastolic perfusion time due to tachycardia	Decreased myocardial perfusion

Nitrate Effects in Angina of Effort

Decreased venous return to the heart and the resulting reduction of intracardiac volume are the principal hemodynamic effects. Arterial pressure also decreases. Decreased intraventricular pressure and left ventricular volume are associated with decreased wall tension (Laplace relation) and decreased myocardial oxygen requirement. In rare instances, a paradoxical increase in myocardial oxygen demand may occur as a result of excessive reflex tachycardia and increased contractility.

Intracoronary, intravenous, or sublingual nitrate administration consistently increases the caliber of the large epicardial coronary arteries. Coronary arteriolar resistance tends to decrease, although to a lesser extent. However, nitrates administered by the usual systemic routes also consistently *decrease* overall coronary blood flow and myocardial oxygen consumption. The reduction in oxygen consumption is the major mechanism for the relief of angina.

Nitrate Effects in Variant Angina

Nitrates benefit patients with variant angina by relaxing the smooth muscle of the epicardial coronary arteries and relieving coronary artery spasm.

Nitrate Effects in Unstable Angina

Nitrates are also useful in the treatment of this acute coronary syndrome, but the precise mechanism for their beneficial effects is not clear. Because both increased coronary vascular tone and increased myocardial oxygen demand can precipitate rest angina in these patients, nitrates may exert their beneficial effects both by dilating the epicardial coronary arteries and by simultaneously reducing myocardial oxygen demand. As noted above, nitroglycerin also decreases platelet aggregation, and this effect may be of importance in unstable angina.

Clinical Use of Nitrates

Some of the forms of nitroglycerin and its congeners are listed in Table 12–3. Because of its rapid onset of action (1–3 minutes), sublingual nitroglycerin is the most frequently used agent for the immediate treatment of angina. Because its duration of action is short (not exceeding 20–30 minutes), it is not suitable for maintenance therapy. The onset of action of intravenous nitroglycerin is also rapid (minutes), but its hemodynamic effects are quickly reversed by stopping its infusion. Clinical application of intravenous nitroglycerin, therefore, is restricted to the treatment of severe,

recurrent rest angina. Slowly absorbed preparations of nitroglycerin include a buccal form, oral preparations, and several transdermal forms. These formulations have been shown to provide blood concentrations for long periods but, as noted above, this leads to the development of tolerance.

Table 12–3. Nitrate and Nitrite Drugs Used in the Treatment of Angina.

Drug	Dose	Duration of Action
"Short-acting"		
Nitroglycerin, sublingual	0.15–1.2 mg	10–30 minutes
Isosorbide dinitrate, sublingual	2.5–5 mg	10–60 minutes
Amyl nitrite, inhalant	0.18–0.3 mL	3–5 minutes
"Long-acting"		
Nitroglycerin, oral sustained-action	6.5–13 mg per 6–8 hours	6–8 hours
Nitroglycerin, 2% ointment, transdermal	1–1.5 inches per 4 hours	3–6 hours
Nitroglycerin, slow-release, buccal	1–2 mg per 4 hours	3–6 hours
Nitroglycerin, slow-release patch, transdermal	10–25 mg per 24 hours (one patch per day)	8–10 hours
Isosorbide dinitrate, sublingual	2.5–10 mg per 2 hours	1.5–2 hours
Isosorbide dinitrate, oral	10–60 mg per 4–6 hours	4–6 hours
Isosorbide dinitrate, chewable oral	5–10 mg per 2–4 hours	2–3 hours
Isosorbide mononitrate oral	20 mg per 12 hours	6–10 hours

The hemodynamic effects of sublingual or chewable isosorbide dinitrate and other organic nitrates are similar to those of nitroglycerin. The recommended dosage schedules for commonly used long-acting nitrate preparations, along with their durations of action, are listed in Table 12–3. Although transdermal administration may provide blood levels of nitroglycerin for 24 hours or longer, the full hemodynamic effects usually do not persist for more than 6–8 hours. The clinical efficacy of slow-release forms of nitroglycerin in maintenance therapy of angina is thus limited by the development of significant tolerance. Therefore, a nitrate-free period of at least 8 hours between doses should be observed to reduce or prevent tolerance.

Calcium Channel-Blocking Drugs

It has been known since the late 1800s that calcium influx was necessary for the contraction of smooth and cardiac muscle. The discovery of a calcium channel in cardiac muscle was followed by the finding of several different types of calcium channels in different tissues (Table 12–4). The discovery of these channels made possible the development of clinically useful blocking drugs. Although the successful therapeutic blockers developed to date have been exclusively L-type channel blockers, selective blockers of other types of calcium channels are under intensive investigation.

Table 12–4. Properties of Several Recognized Voltage-Activated Calcium Channels.

Type	Where Found	Properties of the Calcium Current	Blocked By
L	Muscle, neurons	Long, large, high threshold	Verapamil, DHPs, Cd ²⁺
T	Heart, neurons	Short, small, low threshold	sFTX, flunarizine ¹ , Ni ²⁺
N	Neurons	Short, high threshold	ω-CTX-GVIA, Cd ²⁺
P	Cerebellar Purkinje neurons	Long, high threshold	ω-CTX-MVIIC, ω-Aga-IVA

DHPs, dihydropyridines (eg, nifedipine); sFTX, synthetic funnel web spider toxin; ω-CTX, conotoxins extracted from several marine snails of the genus *Conus*; ω-Aga-IVA, a toxin of the funnel web spider, *Agelenopsis aperta*.

¹An organic calcium channel blocker.

Chemistry & Pharmacokinetics

Verapamil, the first clinically useful member of this group, was the result of attempts to synthesize more active analogs of papaverine, a vasodilator alkaloid found in the opium poppy. Since then, dozens of agents of varying structure have been found to have the same fundamental pharmacologic action (Table 12–5). Three chemically dissimilar calcium channel blockers are shown in Figure 12–4. Nifedipine is the prototype of the dihydropyridine family of calcium channel blockers; dozens of molecules in this family have been investigated, and eight are currently approved in the USA for angina and other indications. Nifedipine is the most extensively studied of this group, but the properties of the other dihydropyridines can be assumed to be similar to it unless otherwise noted.

Table 12–5. Pharmacokinetics of Some Calcium Channel-Blocking Drugs.

Drug	Oral Bioavailability	Onset of Action (route)	Plasma Half-Life (hours)	Disposition
Dihydropyridines				
Amlodipine	65–90%	No data available	30–50	> 90% bound to plasma proteins; extensively metabolized.
Felodipine	15–20%	2–5 hours (oral)	11–16	> 99% bound to plasma proteins; extensively metabolized.
Isradipine	15–25%	2 hours (oral)	8	95% bound to plasma protein; extensively metabolized.

Nicardipine	35%	20 minutes (oral)	2–4	95% bound; extensively metabolized in the liver.
Nifedipine	45–70%	< 1 minute (IV), 5–20 minutes (sublingual or oral)	4	About 90% bound to plasma protein; metabolized to an acid lactate. 80% of the drug and metabolites excreted in urine.
Nimodipine	13%	No data available	1–2	Extensively metabolized.
Nisoldipine	< 10%	No data available	6–12	Extensively metabolized.
Nitrendipine	10–30%	4 hours (oral)	5–12	98% bound; extensively metabolized.
Miscellaneous				
Bepidil	60%	60 minutes (oral)	24–40	> 99% bound to plasma proteins; extensively metabolized.
Diltiazem	40–65%	< 3 minutes (IV), > 30 minutes (oral)	3–4	70–80% bound to plasma protein; extensively deacylated. Drug and metabolites excreted in feces.
Verapamil	20–35%	< 1.5 minutes (IV), 30 minutes (oral)	6	About 90% bound to plasma protein. 70% eliminated by kidney; 15% by gastrointestinal tract.

Figure 12–4.

The calcium channel blockers are orally active agents and are characterized by high first-pass effect, high plasma protein binding, and extensive metabolism. Verapamil and diltiazem are also used by the intravenous route.

Pharmacodynamics

Mechanism of Action

The L-type calcium channel is the dominant type in cardiac and smooth muscle and is known to contain several drug receptors. It has been demonstrated that nifedipine and other dihydropyridines bind to one site, while verapamil and diltiazem appear to bind to closely related but not identical receptors in another region. Binding of a drug to the verapamil or diltiazem receptors also affects dihydropyridine binding. These receptor regions are stereoselective, since marked differences in both stereoisomer-binding affinity and pharmacologic potency are observed for enantiomers of verapamil, diltiazem, and optically active nifedipine congeners.

Blockade by these drugs resembles that of sodium channel blockade by local anesthetics (see Chapters 14 and 26). The drugs act from the inner side of the membrane and bind more effectively to channels in depolarized membranes. Binding of the drug reduces the frequency of opening in response to depolarization. The result is a marked decrease in transmembrane calcium current associated in smooth muscle with a long-lasting relaxation (Figure 12–3) and in cardiac muscle with a reduction in contractility throughout the heart and decreases in sinus node pacemaker rate and in atrioventricular node conduction velocity.*

* At very low doses and under certain circumstances, some dihydropyridines *increase* calcium influx. Some special dihydropyridines, eg, Bay K 8644, actually increase calcium influx over most of their dose range.

Smooth muscle responses to calcium influx through *receptor*-operated calcium channels are also reduced by these drugs but not as markedly. The block can be partially reversed by elevating the concentration of calcium, although the levels of calcium required are not easily attainable. Block can also be partially reversed by the use of drugs that increase the transmembrane flux of calcium, such as sympathomimetics.

Other types of calcium channels are less sensitive to blockade by these calcium channel blockers (Table 12–4). Therefore, tissues in which these channel types play a major role—neurons and most secretory glands—are much less affected by these drugs than are cardiac and smooth muscle.

Organ System Effects

Smooth Muscle

Most types of smooth muscle are dependent on transmembrane calcium influx for normal resting tone and contractile responses. These cells are relaxed by the calcium channel blockers (Figure 12–3). Vascular smooth muscle appears to be the most sensitive, but similar relaxation can be shown for bronchiolar, gastrointestinal, and uterine smooth muscle. In the vascular system, arterioles appear to be more sensitive than veins; orthostatic hypotension is not a common adverse effect. Blood pressure is reduced with all calcium channel blockers. Women may be more sensitive than men to the hypotensive action of diltiazem. The reduction in peripheral vascular resistance is one mechanism by which these agents may benefit the patient with angina of effort. Reduction of coronary arterial tone has been demonstrated in patients with variant angina.

Important differences in vascular selectivity exist among the calcium channel blockers. In general, the dihydropyridines have a greater ratio of vascular smooth muscle effects relative to cardiac effects than do bepridil, diltiazem, and verapamil (Table 12–6). Furthermore, the dihydropyridines may differ in their potency in different vascular beds. For example, nimodipine is claimed to be particularly selective for cerebral blood vessels.

Drug	Vascular Selectivity ¹	Indications	Usual Dosage	Toxicity
Dihydropyridines				
Amlodipine	++	Angina, hypertension	5–10 mg orally once daily	Headache, peripheral edema
Felodipine	5.4	Hypertension, Raynaud's phenomenon, congestive heart failure	5–10 mg orally once daily	Dizziness, headache
Isradipine	7.4	Hypertension	2.5–10 mg orally every 12 hours	Headache, fatigue
Nicardipine	17.0	Angina, hypertension,	20–40 mg	Peripheral edema,

		congestive heart failure	orally every 8 hours	dizziness, headache, flushing
Nifedipine	3.1	Angina, hypertension, migraine, cardiomyopathy, Raynaud's phenomenon	3–10 $\mu\text{g}/\text{kg}$ IV; 20–40 mg orally every 8 hours	Hypotension, dizziness, flushing, nausea, constipation, dependent edema
Nimodipine	++	Subarachnoid hemorrhage, migraine	60 mg orally every 4 hours	Headache, diarrhea
Nisoldipine	++	Hypertension	20–40 mg orally once daily	Probably similar to nifedipine
Nitrendipine	14.4	Investigational for angina, hypertension	20 mg orally once or twice daily	Probably similar to nifedipine
Miscellaneous				
Bepridil	–	Angina	200–400 mg orally once daily	Arrhythmias, dizziness, nausea
Diltiazem	0.3	Angina, hypertension, Raynaud's phenomenon	75–150 $\mu\text{g}/\text{kg}$ IV; 30–80 mg orally every 6 hours	Hypotension, dizziness, flushing, bradycardia
Verapamil	1.3	Angina, hypertension, arrhythmias, migraine, cardiomyopathy	75–150 $\mu\text{g}/\text{kg}$ IV; 80–160 mg orally every 8 hours	Hypotension, myocardial depression, constipation, dependent edema

¹Numerical data (Spedding, 1990) give the ratio of vascular potency to cardiac potency; higher numbers mean greater vascular, less cardiac potency. Plus and minus signs reflect estimated ratio of vascular to cardiac potency: – = myocardial depression greater than vasodilation; ++ = significant degree of vasodilation greater than myocardial depression.

2. Cardiac muscle—Cardiac muscle is highly dependent upon calcium influx for normal function. Impulse generation in the sinoatrial node and conduction in the atrioventricular node—so-called slow response, or calcium-dependent, action potentials—may be reduced or blocked by all of the calcium channel blockers. Excitation-contraction coupling in all cardiac cells requires calcium influx, so these drugs reduce cardiac contractility in a dose-dependent fashion. In some cases, cardiac output may also decrease. This reduction in cardiac mechanical function is another mechanism by which the calcium channel blockers may reduce the oxygen requirement in patients with angina.

Important differences between the available calcium channel blockers arise from the details of their interactions with cardiac ion channels and, as noted above, differences in their relative smooth muscle versus cardiac effects. Cardiac *sodium* channels are blocked by bepridil but somewhat less effectively than are calcium channels. Sodium channel block is modest with verapamil and still less marked with diltiazem. It is negligible with nifedipine and other dihydropyridines. Verapamil and

diltiazem interact kinetically with the calcium channel receptor in a different manner than the dihydropyridines; they block tachycardias in calcium-dependent cells, eg, the atrioventricular node, more selectively than do the dihydropyridines. (See Chapter 14: Agents Used in Cardiac Arrhythmias for additional details.) On the other hand, the dihydropyridines appear to block smooth muscle calcium channels at concentrations below those required for significant cardiac effects; they are therefore less depressant on the heart than verapamil or diltiazem. Bepridil also has a significant potassium channel blocking effect in the heart. This results in prolongation of cardiac repolarization (see Chapter 14: Agents Used in Cardiac Arrhythmias) and a distinct risk of induction of arrhythmias.

Skeletal Muscle

Skeletal muscle is not depressed by the calcium channel blockers because it uses intracellular pools of calcium to support excitation-contraction coupling and does not require as much transmembrane calcium influx.

Cerebral Vasospasm and Infarct Following Subarachnoid Hemorrhage

Nimodipine, a member of the dihydropyridine group of calcium channel blockers, has a high affinity for cerebral blood vessels and appears to reduce morbidity following a subarachnoid hemorrhage. Nimodipine is therefore labeled for use in patients who have had a hemorrhagic stroke. Although evidence suggests that calcium channel blockers may also reduce cerebral damage following thromboembolic stroke in experimental animals, there is no evidence that this occurs in humans.

Other Effects

Calcium channel blockers minimally interfere with stimulus-secretion coupling in glands and nerve endings because of differences between calcium channels in different tissues, as noted above. Verapamil has been shown to inhibit insulin release in humans, but the dosages required are greater than those used in management of angina.

A significant body of evidence suggests that the calcium channel blockers may interfere with platelet aggregation *in vitro* and prevent or attenuate the development of atheromatous lesions in animals. Clinical studies have not established their role in human blood clotting and atherosclerosis.

Verapamil has been shown to block the P170 glycoprotein responsible for the transport of many foreign drugs out of cancer (and other) cells; other calcium channel blockers appear to have a similar effect. This action is not stereospecific. Verapamil has been shown to partially reverse the resistance of cancer cells to many chemotherapeutic drugs *in vitro*. Some clinical results suggest similar effects in patients (see Chapter 55: Cancer Chemotherapy).

Toxicity

The most important toxic effects reported for the calcium channel blockers are direct extensions of their therapeutic action. Excessive inhibition of calcium influx can cause serious cardiac depression, including cardiac arrest, bradycardia, atrioventricular block, and heart failure. These effects have been rare in clinical use.

Retrospective case control studies reported that immediate-acting nifedipine increased the risk of myocardial infarction in patients with hypertension (Psaty, 1995). Slow-release and long-acting

vasoselective calcium channel blockers are usually well tolerated. However, dihydropyridines, compared with angiotensin-converting enzyme inhibitors, have been reported to increase the risk of adverse cardiac events in patients with hypertension with or without diabetes (ABCD Trial, FACET Trial). These results suggest that relatively short-acting calcium channel blockers have the potential to enhance the risk of adverse cardiac events and should be avoided. Bepridil consistently prolongs the cardiac action potential and may cause a dangerous torsade de pointes arrhythmia in susceptible patients. It is contraindicated in patients with a history of serious arrhythmias or prolonged QT syndrome. Patients receiving β -adrenoceptor-blocking drugs are more sensitive to the cardiodepressant effects of calcium channel blockers. Minor toxicity (troublesome but not usually requiring discontinuance of therapy) includes flushing, dizziness, nausea, constipation, and peripheral edema (Table 12–6).

Mechanisms of Clinical Effects

Calcium channel blockers decrease myocardial contractile force, which reduces myocardial oxygen requirements. Inhibition of calcium entry into arterial smooth muscle is associated with decreased arteriolar tone and systemic vascular resistance, resulting in decreased arterial and intraventricular pressure. Some of these drugs (eg, verapamil) also possess a nonspecific antiadrenergic effect, which may contribute to peripheral vasodilation. As a result of all of these effects, left ventricular wall stress declines, which reduces myocardial oxygen requirements. Decreased heart rate with the use of verapamil, diltiazem, or bepridil causes a further decrease in myocardial oxygen demand. Calcium channel-blocking agents also relieve and prevent the primary cause of variant angina—focal coronary artery spasm. Use of these agents has thus emerged as the most effective prophylactic treatment for this form of angina pectoris.

Sinoatrial and atrioventricular nodal tissues, which are mainly composed of slow response cells, are affected markedly by verapamil, moderately by diltiazem, and much less by dihydropyridines. Thus, verapamil and diltiazem decrease atrioventricular nodal conduction and are effective in the management of supraventricular reentry tachycardia and in decreasing ventricular responses in atrial fibrillation or flutter. Nifedipine does not affect atrioventricular conduction. Nonspecific sympathetic antagonism is most marked with diltiazem and much less with verapamil. Nifedipine does not appear to have this effect. Thus, significant reflex tachycardia in response to hypotension occurs most frequently with nifedipine and less so with verapamil. These differences in pharmacologic effects should be considered in selecting calcium channel-blocking agents for the management of angina.

Clinical Uses of Calcium Channel-Blocking Drugs

In addition to angina, calcium channel blockers have well-documented efficacy in hypertension (see Chapter 11: Antihypertensive Agents) and supraventricular tachyarrhythmias (see Chapter 14: Agents Used in Cardiac Arrhythmias). They also show promise in a wide variety of other conditions, including hypertrophic cardiomyopathy, migraine, and Raynaud's phenomenon.

Approved and unlabeled indications and dosages for these drugs are set forth in Table 12–6. The choice of a particular calcium channel-blocking agent should be made with knowledge of its specific potential adverse effects as well as its pharmacologic properties. Nifedipine does not decrease atrioventricular conduction and therefore can be used more safely in the presence of atrioventricular conduction abnormalities. A combination of verapamil or diltiazem with β -blockers may produce atrioventricular block and depression of ventricular function. In the presence of overt heart failure, all calcium channel blockers can cause further worsening of heart failure as a result of their negative inotropic effect. Amlodipine, however, does not increase the mortality of patients

with heart failure due to left ventricular systolic dysfunction and can be used safely in these patients. In the presence of relatively low blood pressure, dihydropyridines can cause further deleterious lowering of pressure. Verapamil and diltiazem appear to produce less hypotension and may be better tolerated in these circumstances. In patients with a history of atrial tachycardia, flutter, and fibrillation, verapamil and diltiazem provide a distinct advantage because of their antiarrhythmic effects. In the patient receiving digitalis, verapamil should be used with caution, because it may increase digoxin blood levels through a pharmacokinetic interaction. Although increases in digoxin blood level have also been demonstrated with diltiazem and nifedipine, such interactions are less consistent than with verapamil.

In patients with unstable angina, immediate-release short-acting calcium channel blockers can increase the risk of adverse cardiac events and therefore are contraindicated (see Toxicity, above). However, in patients with non-Q-wave myocardial infarction, diltiazem can decrease the frequency of postinfarction angina and may be used.

Beta-Adrenoceptor-Blocking Drugs

Although they are not vasodilators, β -blocking drugs (see Chapter 10: Adrenoceptor Antagonist Drugs) are extremely useful in the management of angina pectoris associated with effort. The beneficial effects of β -blocking agents are related primarily to their hemodynamic effects—decreased heart rate, blood pressure, and contractility—which decrease myocardial oxygen requirements at rest and during exercise. Lower heart rate is also associated with an increase in diastolic perfusion time that may increase myocardial perfusion. However, reduction of heart rate and blood pressure and consequently decreased myocardial oxygen consumption appear to be the most important mechanisms for relief of angina and improved exercise tolerance. Beta blockers may also be valuable in treating silent or ambulatory ischemia. Because this condition causes no pain, it is usually detected by the appearance of typical electrocardiographic signs of ischemia. The total amount of "ischemic time" per day is reduced by long-term therapy with a β -blocker. Beta-blocking agents decrease mortality of patients with recent myocardial infarction and improve survival and prevent stroke in patients with hypertension. Randomized trials in patients with stable angina have shown better outcome and symptomatic improvement with β -blockers compared with calcium channel blockers (Gibbons, 1999).

Undesirable effects of β -blocking agents in angina include an increase in end-diastolic volume and an increase in ejection time. Increased myocardial oxygen requirements associated with increased diastolic volume partially offset the beneficial effects of β -blocking agents. These potentially deleterious effects of β -blocking agents can be balanced by the concomitant use of nitrates as described below.

The contraindications to the use of β -blockers are asthma and other bronchospastic conditions, severe bradycardia, atrioventricular blockade, bradycardia-tachycardia syndrome, and severe unstable left ventricular failure. Potential complications include fatigue, impaired exercise tolerance, insomnia, unpleasant dreams, worsening of claudication, and erectile dysfunction. **Katzung PHARMACOLOGY, 9e** > Section III. Cardiovascular-Renal Drugs > Chapter 12. Vasodilators & the Treatment of Angina Pectoris >

The Coronary Steal Phenomenon

The development of useful vasodilators for management of angina has been marked by frustrating episodes when pharmacologists found that new drugs that were extremely effective vasodilators in normal animals were ineffective or even caused increased anginal symptoms in patients. It is now

clear that potent arteriolar dilators (eg, hydralazine, dipyridamole) are generally ineffective in angina and may reduce perfusion of ischemic areas. In fact, dipyridamole is often used in imaging studies of the coronary circulation to demonstrate regions of poor perfusion. On the other hand, drugs that are more effective dilators of veins and large arteries and relatively ineffective dilators of resistance vessels (eg, nitrates) are very useful in angina. The reason for this apparent anomaly has been called the coronary steal phenomenon.

Coronary steal occurs when two branches from a main coronary vessel have differing degrees of obstruction. For example, one branch may be relatively normal and capable of dilating and constricting in response to changes in oxygen demand, while the other branch is significantly obstructed and has significant arteriolar dilation even when cardiac oxygen demand is low, because of the accumulation of metabolites in the ischemic tissue. Perfusion in the obstructed region may be adequate at rest, because perfusion pressure is well maintained in the main coronary artery. If a powerful arteriolar dilator drug is administered, the arterioles in the unobstructed vessel will be forced to dilate, reducing the resistance in this area and greatly increasing flow through the already adequately perfused tissue. As a result of the reduction in resistance in the normal branch, perfusion pressure in the main coronary will diminish, flow through the obstructed branch will *decrease*, and angina may worsen.

It has been suggested that the lesser potency of the nitrates in dilating arterioles is the result of a reduced ability of these vessels to release nitric oxide from the parent nitrate molecule.

Katzung PHARMACOLOGY, 9e > Section III. Cardiovascular-Renal Drugs > Chapter 12. Vasodilators & the Treatment of Angina Pectoris >

Drugs Used in the Treatment of Erectile Dysfunction

Erectile dysfunction in men has long been the subject of research (by both amateur and professional scientists). Among the substances used in the past and generally discredited are "Spanish Fly" (a bladder and urethral irritant), yohimbine (an α_2 -antagonist; see Chapter 10: Adrenoceptor Antagonist Drugs), nutmeg, and mixtures containing lead, arsenic, or strychnine. Substances currently favored by practitioners of herbal medicine include ginseng and kava (see Chapter 65: Botanicals ("Herbal Medications") & Nutritional Supplements).

Scientific studies of the process have shown that erection requires *relaxation* of the nonvascular smooth muscle of the corpora cavernosa. This relaxation permits inflow of blood at nearly arterial pressure into the sinuses of the cavernosa, and it is the pressure of the blood that causes erection. Physiologic erection occurs in response to the release of nitric oxide from nonadrenergic-noncholinergic nerves (see Chapter 6: Introduction to Autonomic Pharmacology) associated with parasympathetic discharge. Thus, parasympathetic innervation must be intact and nitric oxide synthesis must be active. (It appears that a similar process occurs in female erectile tissues.) Certain other smooth muscle relaxants—eg, PGE1 analogs, α -antagonists—if present in high enough concentration, can independently cause sufficient cavernosal relaxation to result in erection. As noted in the text, NO activates guanylyl cyclase, increases the concentration of cGMP, and the latter messenger stimulates the dephosphorylation of myosin light chains (see Figure 12–2) and relaxation of the smooth muscle. Thus, any drug that increases cGMP might be of value in erectile dysfunction if normal innervation is present. **Sildenafil** (Viagra) acts to increase cGMP by inhibiting its breakdown by phosphodiesterase isoform 5. The drug has been very successful in the marketplace because it can be taken orally. However, sildenafil is of little or no value in men with loss of potency due to cord injury or other damage to innervation and in men lacking libido. Furthermore, sildenafil potentiates the action of nitrates used for angina, and severe hypotension and a few myocardial infarctions have been reported in men taking both drugs. It is recommended that at least

6 hours pass between use of a nitrate and the ingestion of sildenafil. Sildenafil also has effects on color vision, causing difficulty in blue-green discrimination. Two similar PDE-5 inhibitors **tadalafil** and **ildenafil**, were released in 2003.

The drug most commonly used in patients who do not respond to sildenafil is **alprostadil**, a PGE1 analog (see Chapter 18: The Eicosanoids: Prostaglandins, Thromboxanes, Leukotrienes, & Related Compounds) that can be injected directly into the cavernosa or placed in the urethra as a minisuppository, from which it diffuses into the cavernosal tissue. Phentolamine can be used by injection into the cavernosa. These drugs will cause erection in most men who do not respond to sildenafil.

Another oral drug, apomorphine, acts by releasing dopamine in the central nervous system and is under investigation for erectile dysfunction.

Clinical Pharmacology of Drugs Used to Treat Angina

Principles of Therapy for Angina

In addition to modification of the risk factors for coronary atherosclerosis (smoking, hypertension, hyperlipidemia), the treatment of angina and other manifestations of myocardial ischemia is based on reduction of myocardial oxygen demand and increase of coronary blood flow to the potentially ischemic myocardium to restore the balance between myocardial oxygen supply and demand. Pharmacologic therapy to prevent myocardial infarction and death is with antiplatelet agents (aspirin, clopidogrel) and lipid-lowering agents. Recently, angiotensin-converting enzyme inhibitors have also been reported to reduce the risk of adverse cardiac events in patients with high risk for coronary artery disease (Yusuf et al, 2000). In unstable angina and non-ST-segment elevation myocardial infarction, aggressive therapy with coronary stenting, antilipid drugs, heparin, and antiplatelet agents is recommended (Braunwald et al, 2000, 2002).

Angina of Effort

Many studies have demonstrated that nitrates, calcium channel blockers, and β -blockers increase time to onset of angina and ST depression during treadmill tests in patients with angina of effort (Figure 12–5). Although exercise tolerance increases, there is usually no change in the angina threshold, ie, the rate-pressure product at which symptoms occur.

Figure 12–5.

Effects of diltiazem on the double product (heart rate times systolic blood pressure) in a group of 20 patients with angina of effort. In a double-blind study using a standard protocol, patients were tested on a treadmill during treatment with placebo and three doses of the drug. Heart rate (HR) and systolic blood pressure (BP) were recorded at 180 seconds of exercise (midpoints of lines) and at the time of onset of anginal symptoms (rightmost points). Note that the drug treatment decreased the double product at all times during exercise and prolonged the time to appearance of symptoms. (Data from Lindenberg BS et al: Efficacy and safety of incremental doses of diltiazem for the treatment of angina. J Am Coll Cardiol 1983;2:1129. Used with permission of the American College of Cardiology.)

For maintenance therapy of chronic stable angina, long-acting nitrates, calcium channel-blocking agents, or β -blockers may be chosen; the best choice of drug will depend on the individual patient's response. In hypertensive patients, monotherapy with either slow-release or long-acting calcium channel blockers or β -blockers may be adequate. In normotensive patients, long-acting nitrates may be suitable. The combination of a β -blocker with a calcium channel blocker (eg, propranolol with nifedipine) or two different calcium channel blockers (eg, nifedipine and verapamil) has been shown to be more effective than individual drugs used alone. If response to a single drug is inadequate, a drug from a different class should be added to maximize the beneficial reduction of cardiac work while minimizing undesirable effects (Table 12–7). Some patients may require therapy with all three drug groups.

Table 12–7. Effects of Nitrates Alone and with β -Blockers or Calcium Channel Blockers in Angina Pectoris. (Undesirable Effects Are Shown in Italics.)

	Nitrates Alone	Beta Blockers or Calcium Channel Blockers	Combined Nitrates With Beta Blockers or Calcium Channel Blockers
Heart rate	<i>Reflex increase</i>	Decrease ¹	Decrease
Arterial pressure	Decrease	Decrease	Decrease

End-diastolic volume	Decrease	<i>Increase</i>	None or decrease
Contractility	<i>Reflex increase</i>	Decrease	None
Ejection time	Decrease	<i>Increase</i>	None

¹Nifedipine may cause a *reflex increase* in heart rate and cardiac contractility.

Surgical revascularization (ie, coronary artery bypass grafting [CABG]) and catheter-based revascularization (ie, percutaneous coronary intervention [PCI]) are the primary methods for promptly restoring coronary blood flow and increasing oxygen supply to the myocardium. Major clinical trials suggest that coronary obstruction can also be decreased by vigorous antilipidemic therapy.

Vasospastic Angina

Nitrates and the calcium channel blockers are effective drugs for relieving and preventing ischemic episodes in patients with variant angina. In approximately 70% of patients treated with nitrates plus calcium channel blockers, angina attacks are completely abolished; in another 20%, marked reduction of frequency of anginal episodes is observed. Prevention of coronary artery spasm (in the presence or absence of fixed atherosclerotic coronary artery lesions) is the principal mechanism for this beneficial response. All presently available calcium channel blockers appear to be equally effective, and the choice of a particular drug should depend on the patient, as indicated above. Surgical revascularization and angioplasty are not indicated in patients with variant angina.

Unstable Angina & Acute Coronary Syndromes

In patients with unstable angina with recurrent ischemic episodes at rest, recurrent thrombotic occlusions of the offending coronary artery occur as the result of fissuring of atherosclerotic plaques and platelet aggregation. Anticoagulant and antiplatelet drugs play a major role in therapy (see Chapter 34: Drugs Used in Disorders of Coagulation). Aspirin has been shown to reduce the incidence of cardiac events in such patients. Intravenous heparin or subcutaneous low-molecular-weight heparin is indicated in most patients. Antiplatelet agents (ticlopidine, clopidogrel, and GPIIb/IIIa antagonists) have been found to be effective in decreasing risk in unstable angina (Braunwald et al 2000, 2002). In addition, therapy with nitroglycerin and β -blockers should be considered; calcium channel blockers should be added in refractory cases. Catheter-based or surgical myocardial revascularization is indicated in high-risk patients.

Katzung PHARMACOLOGY, 9e > Section III. Cardiovascular-Renal Drugs > Chapter 12. Vasodilators & the Treatment of Angina Pectoris >

Preparations Available

Nitrates & Nitrites

Amyl nitrite (generic, Aspirols, Vaporole)

Inhalant: 0.3 mL capsules

Isosorbide dinitrate(generic, Isordil, Sorbitrate)

Oral: 5, 10, 20, 30, 40 mg tablets; 5, 10 mg chewable tablets

Oral sustained-release (generic, Sorbitrate SA, Iso-Bid): 40 mg tablets and capsules

Sublingual: 2.5, 5, 10 mg sublingual tablets

Isosorbide mononitrate(Ismo, others)

Oral: 10, 20 mg tablets; extended-release 30, 60, 120 mg tablets

Nitroglycerin

Sublingual: 0.3, 0.4, 0.6 mg tablets; 0.4 mg/metered dose aerosol

Oral sustained-release (generic, Nitrong): 2.6, 6.5, 9 mg tablets; 2.5, 6.5, 9, 13 mg capsules

Buccal (Nitrogard): 2, 3 mg buccal tablets

Parenteral (Nitro-Bid IV, Tridil, generic): 0.5, 5 mg/mL for IV administration

Transdermal patches (Minitran, Nitro-Dur, Transderm-Nitro): to release at rates of 0.1, 0.2, 0.3, 0.4, 0.6, or 0.8 mg/h.

Topical ointment (generic, Nitrol): 20 mg/mL ointment (1 inch, or 25 mm, of ointment contains about 15 mg nitroglycerin)

Calcium Channel Blockers

Amlodipine (Norvasc)

Oral: 2.5, 5, 10 mg tablets

Bepridil (Vascor)

Oral: 200, 300 mg tablets

Diltiazem(Cardizem, generic)

Oral: 30, 60, 90, 120 mg tablets

Oral sustained-release (Cardizem SR, Dilacor XL, others): 60, 90, 120, 180, 240, 300, 360, 420 mg capsules

Parenteral: 5 mg/mL for injection

Felodipine (Plendil)

Oral extended-release: 2.5, 5, 10 mg tablets

Isradipine(DynaCirc)

Oral: 2.5, 5 mg capsules

Oral controlled release: 5, 10 mg tablets

Nicardipine (Cardene, others)

Oral: 20, 30 mg capsules

Oral sustained-release (Cardene SR): 30, 45, 60 mg capsules)

Parenteral (Cardene I.V.): 2.5 mg/mL

Nifedipine (Adalat, Procardia, others)

Oral: 10, 20 mg capsules

Oral extended-release (Procardia XL, Adalat CC): 30, 60, 90 mg tablets

Nimodipine(Nimotop)

Oral: 30 mg capsules. (Labeled for use in subarachnoid hemorrhage, not angina.)

Nisoldipine(Sular)

Oral extended-release: 10, 20, 30, 40 mg tablets

Verapamil(generic, Calan, Isoptin)

Oral: 40, 80, 120 mg tablets

Oral sustained-release: 100, 120, 180, 240 mg tablets or capsules

Parenteral: 2.5 mg/mL for injection

Beta Blockers

See Chapter 10: Adrenoceptor Antagonist Drugs.

Chapter 13. Drugs Used in Heart Failure

Katzung PHARMACOLOGY, 9e > Section III. Cardiovascular-Renal Drugs > Chapter 13. Drugs Used in Heart Failure >

Drugs Used in Heart Failure: Introduction

Heart failure occurs when the cardiac output is inadequate to provide the oxygen needed by the body. It is a highly lethal condition, with a 5-year mortality rate conventionally said to be about 50%. The most common cause of heart failure in the USA is coronary artery disease. In systolic failure, the mechanical pumping action (contractility) and the ejection fraction of the heart are reduced. In diastolic failure, stiffening and loss of adequate relaxation plays a major role in reducing cardiac output and ejection fraction may be normal. Because other cardiovascular conditions are now being treated more effectively (especially myocardial infarction), more patients are surviving long enough for heart failure to develop, making this one of the cardiovascular conditions that is actually increasing in prevalence.

Although it is believed that the primary defect in early heart failure resides in the excitation-contraction coupling machinery of the heart, the clinical condition also involves many other processes and organs, including the baroreceptor reflex, the sympathetic nervous system, the kidneys, angiotensin II and other peptides, and death of cardiac cells. Recognition of these factors has resulted in evolution of a variety of treatment strategies (Table 13–1).

Table 13–1. Drug Groups Commonly Used in Heart Failure.
ACE inhibitors
Beta blockers
Angiotensin receptor blockers
Cardiac glycosides
Vasodilators
Beta agonists, dopamine
Bipyridines

ACE, angiotensin-converting enzyme.

Clinical research has shown that therapy directed at noncardiac targets may be more valuable in the long-term treatment of heart failure than traditional positive inotropic agents (cardiac glycosides [digitalis]). Thus, drugs acting on the kidneys (diuretics) have long been considered at least as valuable as digitalis. Careful clinical trials have shown that angiotensin-converting enzyme (ACE) inhibitors, β -blockers, and spironolactone (a potassium-sparing diuretic) are the only agents in current use that actually prolong life in patients with chronic heart failure. Positive inotropic drugs, on the other hand, can be very helpful in acute failure. They also reduce symptoms in chronic failure.

Control of Normal Cardiac Contractility

The vigor of contraction of heart muscle is determined by several processes that lead to the movement of actin and myosin filaments in the cardiac sarcomere (Figure 13–1). Ultimately, contraction results from the interaction of calcium (during systole) with the actin-troponin-tropomyosin system, thereby releasing the actin-myosin interaction. This *activator* calcium is released from the sarcoplasmic reticulum (SR). The amount released depends on the amount stored in the SR and on the amount of *trigger* calcium that enters the cell during the plateau of the action potential.

Figure 13-1.

Schematic diagram of a cardiac muscle sarcomere, with sites of action of several drugs that alter contractility (numbered structures). Site 1 is Na^+/K^+ ATPase, the sodium pump. Site 2 is the sodium/calcium exchanger. Site 3 is the voltage-gated calcium channel. Site 4 is a calcium transporter that pumps calcium into the sarcoplasmic reticulum (SR). Site 5 is a calcium channel in the membrane of the SR that is triggered to release stored calcium by activator calcium. Site 6 is the actin-troponin-tropomyosin complex at which activator calcium brings about the contractile interaction of actin and myosin.

Sensitivity of the Contractile Proteins to Calcium

The determinants of calcium sensitivity, ie, the curve relating the shortening of cardiac myofibrils to the cytoplasmic calcium concentration, are incompletely understood, but several types of drugs can be shown to affect it *in vitro*. Levosimendan is the most recent example of a drug that increases calcium sensitivity (it may also inhibit phosphodiesterase) and reduces symptoms in models of heart failure.

the Amount of Calcium Released from the Sarcoplasmic Reticulum

A small rise in free cytoplasmic calcium, brought about by calcium influx during the action potential, triggers the opening of calcium channels in the membrane of the SR and the rapid release

of a large amount of the ion into the cytoplasm in the vicinity of the actin-troponin-tropomyosin complex. The amount released is proportional to the amount stored in the SR and the amount of trigger calcium that enters the cell through the cell membrane. Ryanodine is a potent *negative* inotropic plant alkaloid that *interferes* with the release of calcium through the SR channels. No drugs are available that increase the release of calcium through these channels.

the Amount of Calcium Stored in the Sarcoplasmic Reticulum

The SR membrane contains a very efficient calcium uptake transporter, which maintains free cytoplasmic calcium at very low levels during diastole by pumping calcium into the SR. The amount of calcium sequestered in the SR is thus determined, in part, by the amount accessible to this transporter. This in turn is dependent on the balance of calcium influx (primarily through the voltage-gated membrane calcium channels) and calcium efflux, the amount removed from the cell (primarily via the sodium-calcium exchanger, a transporter in the cell membrane).

the Amount of Trigger Calcium

The amount of trigger calcium that enters the cell depends on the availability of calcium channels (primarily the L type) and the duration of their opening. As described in Chapter 6: Introduction to Autonomic Pharmacology and Chapter 9: Adrenoceptor-Activating & Other Sympathomimetic Drugs, sympathomimetics cause an increase in calcium influx through an action on these channels. Conversely, the calcium channel blockers (see Chapter 12: Vasodilators & the Treatment of Angina Pectoris) reduce this influx and depress contractility.

Activity of the Sodium-Calcium Exchanger

This antiporter uses the sodium gradient to move calcium against its concentration gradient from the cytoplasm to the extracellular space. Extracellular concentrations of these ions are much less labile than intracellular concentrations under physiologic conditions. The sodium-calcium exchanger's ability to carry out this transport is thus strongly dependent on the intracellular concentrations of both ions, especially sodium.

Intracellular Sodium Concentration and Activity of Na^+/K^+ ATPase

Na^+/K^+ ATPase, by removing intracellular sodium, is the major determinant of sodium concentration in the cell. The sodium influx through voltage-gated channels, which occurs as a normal part of almost all cardiac action potentials, is another determinant. As described below, Na^+/K^+ ATPase appears to be the primary target of cardiac glycosides.

Pathophysiology of Heart Failure

Heart failure is a syndrome with multiple causes that may involve the right ventricle, the left ventricle, or both. Cardiac output in heart failure is usually below the normal range. Systolic dysfunction, with reduced cardiac output and significantly reduced ejection fraction (less than 45%), is typical of acute failure, especially that resulting from myocardial infarction. Diastolic dysfunction often occurs as a result of hypertrophy and stiffening of the myocardium, and although cardiac output is reduced, ejection fraction may be normal. Heart failure due to diastolic dysfunction does not usually respond optimally to positive inotropic drugs.

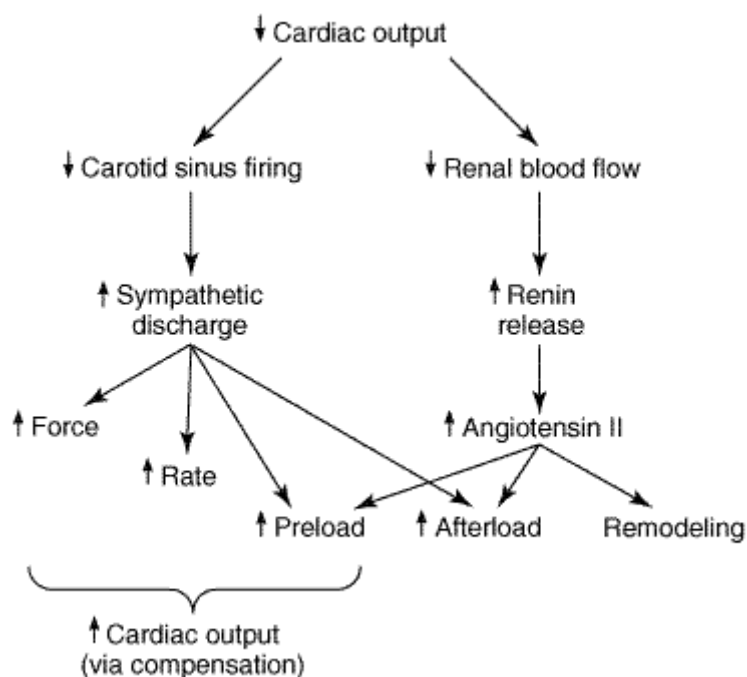

Rarely, "high-output" failure may occur. In this condition, the demands of the body are so great that even increased cardiac output is insufficient. High-output failure can result from hyperthyroidism,

beriberi, anemia, and arteriovenous shunts. This form of failure responds poorly to the drugs discussed in this chapter and should be treated by correcting the underlying cause.

The primary signs and symptoms of all types of heart failure include tachycardia, decreased exercise tolerance and shortness of breath, peripheral and pulmonary edema, and cardiomegaly. Decreased exercise tolerance with rapid muscular fatigue is the major direct consequence of diminished cardiac output. The other manifestations result from the attempts by the body to compensate for the intrinsic cardiac defect.

Neurohumoral (extrinsic) compensation involves two major mechanisms previously presented in Figure 6–7: the sympathetic nervous system and the renin-angiotensin-aldosterone hormonal response. Some of the pathologic as well as beneficial features of these compensatory responses are illustrated in Figure 13–2. The baroreceptor reflex appears to be reset, with a lower sensitivity to arterial pressure, in patients with heart failure. As a result, baroreceptor sensory input to the vasomotor center is reduced even at normal pressures; sympathetic outflow is increased, and parasympathetic outflow is decreased. Increased sympathetic outflow causes tachycardia, increased cardiac contractility, and increased vascular tone. While the increased preload, force, and heart rate initially increase cardiac output, increased arterial tone results in increased afterload and decreased ejection fraction, cardiac output, and renal perfusion. After a relatively short time, complex down-regulatory changes in the β_1 -adrenoceptor-G protein-effector system take place that result in diminished stimulatory effects. Beta₂ receptors are *not* down-regulated and may develop increased coupling to the IP₃-DAG cascade. It has also been suggested that cardiac β_3 receptors (which do not appear to be down-regulated in failure) may mediate negative inotropic effects. Increased angiotensin II production leads to increased aldosterone secretion (with sodium and water retention), to increased afterload, and to remodeling of both heart and vessels (discussed below). Other hormones may also be released, including natriuretic peptide and endothelin (see Chapter 17: Vasoactive Peptides).

Figure 13–2.

Some compensatory responses that occur during congestive heart failure. In addition to the effects shown, angiotensin II increases sympathetic effects by facilitating norepinephrine release.

The most important intrinsic compensatory mechanism is **myocardial hypertrophy**. This increase in muscle mass helps maintain cardiac performance. However, after an initial beneficial effect, hypertrophy can lead to ischemic changes, impairment of diastolic filling, and alterations in ventricular geometry. **Remodeling** is the term applied to dilation (other than that due to passive stretch) and slow structural changes that occur in the stressed myocardium. It may include proliferation of connective tissue cells as well as abnormal myocardial cells with some biochemical characteristics of fetal myocytes. Ultimately, myocytes in the failing heart die at an accelerated rate through apoptosis, leaving the remaining myocytes subject to even greater overload.

The severity of heart failure is usually described according to a scale devised by the New York Heart Association. Class I failure is associated with no limitations on ordinary activities and symptoms that occur only with greater than ordinary exercise. Class II is characterized by slight limitation of ordinary activities, which result in fatigue and palpitations. Class III results in no symptoms at rest, but fatigue, etc, with less than ordinary physical activity. Class IV is associated with symptoms even when the patient is at rest.

Pathophysiology of Cardiac Performance

Cardiac performance is a function of four primary factors:

- 1. Preload:** When some measure of left ventricular performance such as stroke volume or stroke work is plotted as a function of left ventricular filling pressure, the resulting curve is termed the left ventricular function curve (Figure 13–3). The ascending limb (< 15 mm Hg filling pressure) represents the classic Frank-Starling relation. Beyond approximately 15 mm Hg, there is a plateau of performance. Preloads greater than 20–25 mm Hg result in pulmonary congestion. As noted above, preload is usually increased in heart failure because of increased blood volume and venous tone. Reduction of high filling pressure is the goal of salt restriction and diuretic therapy in heart failure. Venodilator drugs (eg, nitroglycerin) also reduce preload by redistributing blood away from the chest into peripheral veins.
- 2. Afterload:** Afterload is the resistance against which the heart must pump blood and is represented by aortic impedance and systemic vascular resistance. As cardiac output falls in chronic failure, there is a reflex increase in systemic vascular resistance, mediated in part by increased sympathetic outflow and circulating catecholamines and in part by activation of the renin-angiotensin system. Endothelin, a potent vasoconstrictor peptide, may also be involved. This sets the stage for the use of drugs that reduce arteriolar tone in heart failure.
- 3. Contractility:** Heart muscle obtained by biopsy from patients with chronic low-output failure demonstrates a reduction in intrinsic contractility. As contractility decreases in the patient, there is a reduction in the velocity of muscle shortening, the rate of intraventricular pressure development (dP/dt), and the stroke output achieved (Figure 13–3). However, the heart is still capable of some increase in all of these measures of contractility in response to inotropic drugs.
- 4. Heart rate:** The heart rate is a major determinant of cardiac output. As the intrinsic function of the heart decreases in failure and stroke volume diminishes, an increase in heart rate—through sympathetic activation of β adrenoceptors—is the first compensatory mechanism that comes into play to maintain cardiac output.

Figure 13–3.

Relation of left ventricular (LV) performance to filling pressure in patients with acute myocardial infarction, an important cause of heart failure. The upper line indicates the range for normal, healthy individuals. If acute heart failure occurs, function is shifted down and to the right. Similar depression is observed in patients with chronic heart failure. (Modified and reproduced with permission, from Swan HJC, Parmley WW: Congestive heart failure. In: Sodeman WA Jr, Sodeman TM [editors]. *Pathologic Physiology*. Saunders, 1979.)

Katzung PHARMACOLOGY, 9e > Section III. Cardiovascular-Renal Drugs > Chapter 13. Drugs Used in Heart Failure >

Basic Pharmacology of Drugs Used in Heart Failure

Although digitalis is rarely the first drug used in heart failure, we begin our discussion with this group because other drugs are discussed in more detail in Chapter 11: Antihypertensive Agents, Chapter 12: Vasodilators & the Treatment of Angina Pectoris, and Chapter 15: Diuretic Agents.

Digitalis

Digitalis is the genus name for the family of plants that provide most of the medically useful cardiac glycosides, eg, **digoxin**. Such plants have been known for thousands of years but were used erratically and with variable success until 1785, when William Withering, an English physician and botanist, published a monograph describing the clinical effects of an extract of the foxglove plant (*Digitalis purpurea*, a major source of these agents).

Chemistry

All of the cardiac glycosides, or cardenolides—of which digoxin is the prototype—combine a steroid nucleus linked to a lactone ring at the 17 position and a series of sugars at carbon 3 of the

nucleus. Because they lack an easily ionizable group, their solubility is not pH-dependent.

Sources of these drugs include white and purple foxglove (*Digitalis lanata* and *D purpurea*) and numerous other temperate zone and tropical plants. Certain toads have skin glands capable of elaborating **bufadienolides**, which differ only slightly from the cardenolides.

Pharmacokinetics

Absorption and Distribution

Cardenolides vary in their absorption, distribution, metabolism, and excretion, as shown by comparison of three representative agents: digoxin, digitoxin, and ouabain (Table 13–2). Of these three, digoxin is the only preparation used in the USA.

Table 13–2. Properties of Three Typical Cardiac Glycosides.			
	Ouabain ¹	Digoxin	Digitoxin ¹
Lipid solubility (oil/water coefficient)	Low	Medium	High
Oral availability (percentage absorbed)	0	75	> 90
Half-life in body (hours)	21	40	168
Plasma protein binding (percentage bound)	0	20–40	> 90
Percentage metabolized	0	< 40	> 80
Volume of distribution (L/kg)	18	6.3	0.6

¹Ouabain and digitoxin are no longer in use in the USA.

Digoxin is fairly well absorbed after oral administration. However, about 10% of individuals harbor enteric bacteria that inactivate digoxin in the gut, greatly reducing bioavailability and requiring higher than average maintenance dosage. Treatment of such patients with antibiotics can result in a

glycosides is very narrow, even minor variations in bioavailability can cause serious toxicity or loss of effect.

Once absorbed into the blood, all cardiac glycosides are widely distributed to tissues, including the central nervous system. Their volumes of distribution differ, however, depending on their tendency to bind to plasma proteins versus tissue proteins.

Metabolism and Excretion

Digoxin is not extensively metabolized in humans; almost two thirds is excreted unchanged by the kidneys. Its renal clearance is proportional to creatinine clearance. Equations and nomograms are available for adjusting digoxin dosage in patients with renal impairment.

Digitoxin is metabolized in the liver and excreted into the gut via the bile. Cardioactive metabolites (which include digoxin) as well as unchanged digitoxin can then be reabsorbed from the intestine, thus establishing an **enterohepatic circulation** that contributes to the very long half-life of this agent. Renal impairment does not significantly prolong the half-life of digitoxin.

Ouabain must be given parenterally and is excreted, mostly unchanged, in the urine.

Pharmacodynamics

Digitalis has multiple direct and indirect cardiovascular effects, with both therapeutic and toxic consequences. In addition, it has undesirable effects on the central nervous system and gut.

At the molecular level, all therapeutically useful cardiac glycosides **inhibit Na^+/K^+ ATPase**, the membrane-bound transporter often called the *sodium pump*. This protein consists of α and β subunits. The binding sites for Na^+ , K^+ , ATP, and digitalis all appear to reside on the α subunit. Different isoforms of the subunits have been identified, thus providing for different isoforms of the complete enzyme with differing affinities for cardiac glycosides in various tissues. Very low concentrations of these drugs have occasionally been reported to *stimulate* the enzyme. In contrast, inhibition over most of the dose range has been extensively documented in all tissues studied. It is probable that the inhibitory action is largely responsible for the therapeutic effect (positive inotropy) in the heart. Since the sodium pump is necessary for maintenance of normal resting potential in most excitable cells, it is likely that a major portion of the toxicity of digitalis is also caused by this enzyme-inhibiting action. Other molecular-level effects of digitalis have been studied in the heart and are discussed below. The fact that the receptor for cardiac glycosides exists on the sodium pump has prompted some investigators to propose that an endogenous "digitalis-like" agent, possibly ouabain, must exist.

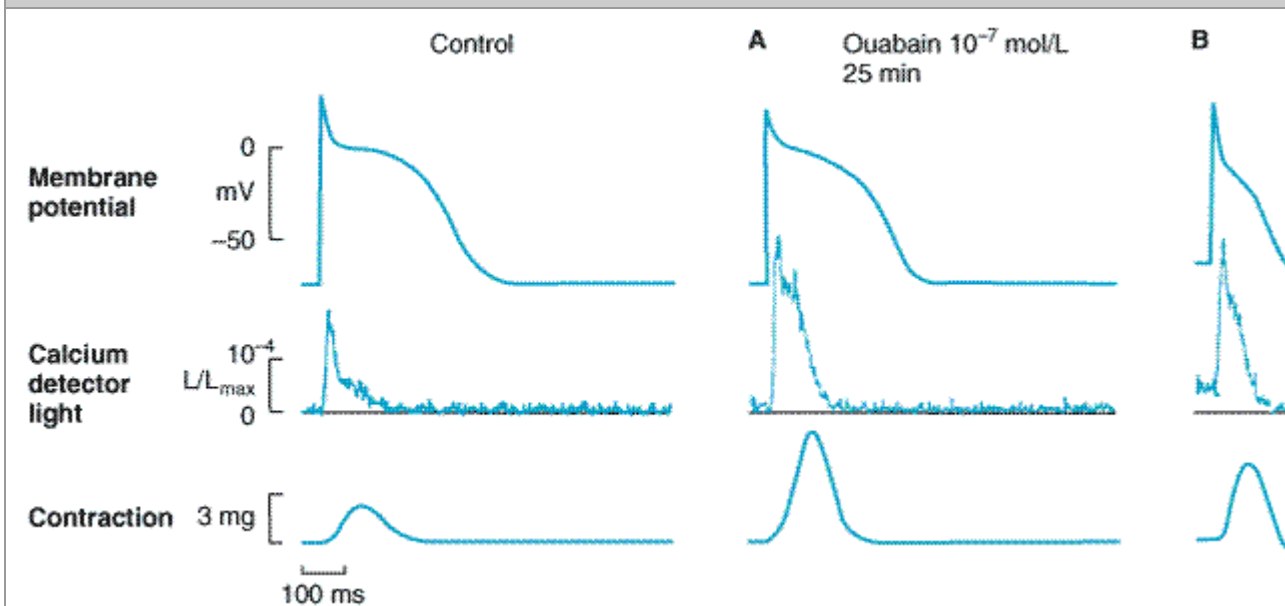

Cardiac Effects

Mechanical Effects

Cardiac glycosides increase the intensity of the interaction of the actin and myosin filaments of the cardiac sarcomere (Figure 13–1) by increasing the free calcium concentration in the vicinity of the contractile proteins during systole. The increase in calcium concentration is the result of a two-step process: first, an increase of intracellular sodium concentration because of Na^+/K^+ ATPase inhibition (1 in Figure 13–1); and second, a relative reduction of calcium expulsion from the cell by the sodium-calcium exchanger (2 in Figure 13–1) caused by the increase in intracellular sodium. Other mechanisms have been proposed but are not well supported.

The net result of the action of therapeutic concentrations of a cardiac glycoside is a distinctive increase in cardiac contractility (Figure 13–4, bottom trace). In isolated myocardial preparations, the rate of development of tension and of relaxation are both increased, with little or no change in time to peak tension. This effect occurs in both normal and failing myocardium, but in the intact animal or patient the responses are modified by cardiovascular reflexes and the pathophysiology of heart failure.

Figure 13–4.

Effects of a cardiac glycoside, ouabain, on isolated cardiac tissue. The top tracing shows action potentials evoked during the control period, early in the "therapeutic" phase, and later, when toxicity is present. The middle tracing shows the light (L) emitted by the calcium-detecting protein aequorin (relative to the maximum possible, L_{\max}) and is roughly proportionate to the free intracellular calcium concentration. The bottom tracing records the tension elicited by the action potentials. The early phase of ouabain action (A) shows a slight shortening of action potential and a marked increase in free intracellular calcium concentration and contractile tension. The toxic phase (B) is associated with depolarization of the resting potential, a marked shortening of the action potential, and the appearance of an oscillatory depolarization, calcium increment, and contraction (*arrows*). (Unpublished data kindly provided by P Hess and H Gil Wier.)

Electrical Effects

The effects of digitalis on the electrical properties of the heart are a mixture of direct and autonomic actions. Direct actions on the membranes of cardiac cells follow a well-defined progression: an early, brief prolongation of the action potential, followed by a protracted period of shortening (especially the plateau phase). The decrease in action potential duration is probably the result of increased potassium conductance that is caused by increased intracellular calcium (see Chapter 14: Agents Used in Cardiac Arrhythmias). All of these effects can be observed at therapeutic concentrations in the absence of overt toxicity. Shortening of the action potential contributes to the shortening of atrial and ventricular refractoriness (Table 13–3).

Table 13–3. Major Actions of Digitalis on Cardiac Electrical Functions.

Variable	Tissue		
	Atrial Muscle	AV Node	Purkinje System, Ventricles
Effective refractory period	↓(PANS)	↑(PANS)	↓(Direct)
Conduction velocity	↑(PANS)	↓(PANS)	Negligible
Automaticity	↑(Direct)	↑(Direct)	↑(Direct)
Electrocardiogram			
Before arrhythmias	Negligible	↑PR interval	↓QT interval; T wave inversion; ST segment depression
During arrhythmias	Atrial tachycardia, atrial fibrillation	AV nodal tachycardia, AV blockade	Premature ventricular contractions, bigeminy, ventricular tachycardia, ventricular fibrillation

Key:

(PANS) = parasympathetic actions

(Direct) = direct membrane actions

At higher concentrations, resting membrane potential is reduced (made less negative) as a result of inhibition of the sodium pump and reduced intracellular potassium. As toxicity progresses, oscillatory depolarizing afterpotentials appear following normally evoked action potentials (Figure 13–4, panel B). The afterpotentials (also known as *delayed afterdepolarizations*) are associated with overloading of the intracellular calcium stores and oscillations in the free intracellular calcium ion concentration. When below threshold, these afterpotentials may interfere with normal conduction because of the further reduction of resting potential. Eventually, an afterpotential may reach threshold, eliciting an action potential (premature depolarization or ectopic "beat") that is coupled to the preceding normal one. If afterpotentials in the Purkinje conducting system regularly reach threshold in this way, bigeminy will be recorded on the electrocardiogram (Figure 13–5). With further intoxication, each afterpotential-evoked action potential will itself elicit a suprathreshold afterpotential, and a self-sustaining tachycardia will be established. If allowed to progress, such a tachycardia may deteriorate into fibrillation; in the case of ventricular fibrillation, the arrhythmia will be rapidly fatal unless corrected.

Figure 13–5.

Electrocardiographic record showing digitalis-induced bigeminy. The complexes marked NSR are normal sinus rhythm beats; an inverted T wave and depressed ST segment are present. The complexes marked PVB are premature ventricular beats and are the electrocardiographic manifestations of depolarizations evoked by delayed oscillatory afterpotentials as shown in Figure 13–4. (Modified and reproduced, with permission, from Goldman MJ: *Principles of Clinical Electrocardiography*, 12th ed. Lange, 1986.)

Autonomic actions of cardiac glycosides on the heart involve both the parasympathetic and the sympathetic systems. In the lower portion of the dose range, cardioselective **parasympathomimetic** effects predominate. In fact, these atropine-blockable effects account for a significant portion of the early electrical effects of digitalis (Table 13–3). This action involves sensitization of the baroreceptors, central vagal stimulation, and facilitation of muscarinic transmission at the cardiac muscle cell. Because cholinergic innervation is much richer in the atria, these actions affect atrial and atrioventricular nodal function more than Purkinje or ventricular function. Some of the cholinomimetic effects are useful in the treatment of certain arrhythmias. At toxic levels, sympathetic outflow is increased by digitalis. This effect is not essential for typical cardenolide toxicity but sensitizes the myocardium and exaggerates all the toxic effects of the drug.

The most common cardiac manifestations of glycoside toxicity include atrioventricular junctional rhythm, premature ventricular depolarizations, bigeminal rhythm, and second-degree atrioventricular blockade. However, it is claimed that digitalis can cause virtually every variety of arrhythmia.

Effects on Other Organs

Cardiac glycosides affect all excitable tissues, including smooth muscle and the central nervous system. Inhibition of Na^+/K^+ ATPase in these tissues depolarizes and increases spontaneous activity both in neurons and in smooth muscle cells. The gastrointestinal tract is the most common site of digitalis toxicity outside the heart. The effects include anorexia, nausea, vomiting, and diarrhea. This toxicity may be partially caused by direct effects on the gastrointestinal tract but is also the result of central nervous system actions, including chemoreceptor trigger zone stimulation.

Central nervous system effects commonly include vagal and chemoreceptor zone stimulation. Much less often, disorientation and hallucinations—especially in the elderly—and visual disturbances are noted. The latter effect may include aberrations of color perception. Agitation and even convulsions are occasionally reported in patients taking digitalis.

Gynecomastia is a rare effect reported in men taking digitalis; it is not certain whether this effect represents a peripheral estrogenic action of these steroid drugs or a manifestation of hypothalamic stimulation.

Interactions with Potassium, Calcium, and Magnesium

Potassium and digitalis interact in two ways. First, they inhibit each other's binding to Na^+/K^+ ATPase; therefore, hyperkalemia reduces the enzyme-inhibiting actions of cardiac glycosides, whereas hypokalemia facilitates these actions. Second, abnormal cardiac automaticity is inhibited by hyperkalemia (see Chapter 14: Agents Used in Cardiac Arrhythmias). Moderately increased extracellular K^+ therefore reduces the effects of digitalis, especially the toxic effects.

Calcium ion facilitates the toxic actions of cardiac glycosides by accelerating the overloading of intracellular calcium stores that appears to be responsible for digitalis-induced abnormal automaticity. Hypercalcemia therefore increases the risk of a digitalis-induced arrhythmia. The effects of magnesium ion appear to be opposite to those of calcium. Hypomagnesemia is therefore a risk factor for arrhythmias. These interactions mandate careful evaluation of serum electrolytes in patients with digitalis-induced arrhythmias.

Other Positive Inotropic Drugs Used in Heart Failure

Drugs that inhibit **phosphodiesterases**, the family of enzymes that inactivate cAMP and cGMP, have long been used in therapy of heart failure. Although they have positive inotropic effects, most of their benefits appear to derive from vasodilation, as discussed below. Phosphodiesterase inhibitors have been intensively studied for several decades with mixed results. The bipyridines inamrinone and milrinone are the most successful of these agents found to date, but their usefulness is quite limited. Levosimendan, an investigational drug that sensitizes the troponin system to calcium, also appears to inhibit phosphodiesterase and cause some vasodilation in addition to its inotropic effects. Some early clinical trials suggest that this drug may be useful in patients with heart failure (Follath, et al, 2002). A group of β -adrenoceptor stimulants have also been used as digitalis substitutes, but they may increase mortality (see below).

Bipyridines

Inamrinone (previously called amrinone) and **milrinone** are bipyridine compounds that inhibit phosphodiesterase. They are active orally as well as parenterally but are only available in parenteral forms. They have elimination half-lives of 3–6 hours, with 10–40% being excreted in the urine.

Pharmacodynamics

The bipyridines increase myocardial contractility by increasing inward calcium flux in the heart during the action potential; they may also alter the intracellular movements of calcium by influencing the sarcoplasmic reticulum. They also have an important vasodilating effect. These drugs are relatively selective for phosphodiesterase isozyme 3, a form found in cardiac and smooth muscle. Inhibition of this isozyme results in an increase in cAMP and the increase in contractility and vasodilation noted above.

The toxicity of inamrinone includes nausea and vomiting; arrhythmias, thrombocytopenia, and liver enzyme changes have been reported in a significant number of patients. This drug has been withdrawn in some countries. Milrinone appears less likely to cause bone marrow and liver toxicity than inamrinone, but it does cause arrhythmias. Inamrinone and milrinone are now used only intravenously and only for acute heart failure or for an exacerbation of chronic heart failure.

Beta Adrenoceptor Stimulants

The general pharmacology of these agents is discussed in Chapter 9: Adrenoceptor-Activating & Other Sympathomimetic Drugs. The selective β_1 -agonist that has been most widely used in patients with heart failure is **dobutamine**. This drug produces an increase in cardiac output together with a decrease in ventricular filling pressure. Some tachycardia and an increase in myocardial oxygen consumption have been reported. The potential for producing angina or arrhythmias in patients with coronary artery disease must be considered, as well as the tachyphylaxis that accompanies the use of any β stimulant. Intermittent dobutamine infusion may benefit some patients with chronic heart failure.

Dopamine has also been used in acute heart failure and may be particularly helpful if there is a need to raise blood pressure.

Drugs Without Positive Inotropic Effects Used in Heart Failure

The drugs most commonly used in chronic heart failure are diuretics, ACE inhibitors, angiotensin receptor antagonists, and β -blockers (Table 13–1). In acute failure, diuretics and vasodilators play important roles.

Diuretics

The diuretics are discussed in detail in Chapter 15: Diuretic Agents. Their major mechanism of action in heart failure is to reduce venous pressure and ventricular preload. These reductions have two useful effects: reduction of edema and its symptoms and reduction of cardiac size, which leads to improved pump efficiency. Spironolactone, the aldosterone antagonist diuretic (see Chapter 15: Diuretic Agents), has the additional benefit of decreasing morbidity and mortality in patients with severe heart failure who are also receiving ACE inhibitors and other standard therapy. One possible mechanism for this benefit lies in accumulating evidence that aldosterone may also cause myocardial and vascular fibrosis and baroreceptor dysfunction in addition to its renal effects.

Angiotensin-Converting Enzyme Inhibitors, Angiotensin Receptor Antagonists, & Related Agents

The ACE inhibitors such as **captopril** are introduced in Chapter 11: Antihypertensive Agents and discussed again in Chapter 17: Vasoactive Peptides. These versatile drugs reduce peripheral resistance and thereby reduce afterload; they also reduce salt and water retention (by reducing aldosterone secretion) and in that way reduce preload. The reduction in tissue angiotensin levels also reduces sympathetic activity, probably through diminution of angiotensin's presynaptic effects on norepinephrine release. Finally, these drugs reduce the long-term remodeling of the heart and vessels, an effect that may be responsible for the observed reduction in mortality and morbidity (see Clinical Pharmacology).

Angiotensin AT₁ receptor-blockers such as **losartan** (see Chapter 11: Antihypertensive Agents and Chapter 17: Vasoactive Peptides) appear to have similar but more limited beneficial effects, and clinical trials of these drugs in heart failure continue.

A newer class of drugs that inhibit both ACE and neutral endopeptidase, an enzyme that inactivates bradykinin and natriuretic peptide (see below), has been introduced into clinical trials recently. **Omapatrilat** is the first of these agents and has been shown in early studies to increase exercise tolerance and to reduce morbidity and mortality. Unfortunately, it causes a significant incidence of angioedema.

Vasodilators

The vasodilators are effective in acute heart failure because they provide a reduction in preload (through venodilation), or reduction in afterload (through arteriolar dilation), or both. Some evidence suggests that long-term use of hydralazine and isosorbide dinitrate can also reduce damaging remodeling of the heart.

A synthetic form of the endogenous peptide **brain natriuretic peptide (BNP)** has recently been approved for use in acute cardiac failure as **nesiritide**. This recombinant product increases cGMP in smooth muscle cells and effectively reduces venous and arteriolar tone in experimental preparations. It also causes diuresis. The peptide has a short half-life of about 18 minutes and is administered as a bolus intravenous dose followed by continuous infusion. Excessive hypotension is the most common adverse effect. Measurement of *endogenous* BNP has been proposed as a diagnostic test because plasma concentrations rise in most patients with heart failure.

Bosentan, an orally active competitive inhibitor of endothelin (see Chapter 17: Vasoactive Peptides), has been shown to have some benefits in experimental animal models of heart failure, but results in human trials have not been impressive. This drug is approved for use in pulmonary hypertension (see Chapter 11: Antihypertensive Agents). It has significant teratogenic and hepatotoxic effects.

Beta Adrenoceptor Blockers

Most patients with chronic heart failure respond favorably to certain β -blockers in spite of the fact that these drugs can precipitate acute decompensation of cardiac function (see Chapter 10: Adrenoceptor Antagonist Drugs). Studies with bisoprolol, carvedilol, and metoprolol showed a reduction in mortality in patients with stable severe heart failure but this effect was not observed with another β -blocker, bucindolol. A full understanding of the beneficial action of β -blockade is lacking, but suggested mechanisms include attenuation of the adverse effects of high concentrations of catecholamines (including apoptosis), up-regulation of β -receptors, decreased heart rate, and reduced remodeling through inhibition of the mitogenic activity of catecholamines.

Katzung PHARMACOLOGY, 9e > Section III. Cardiovascular-Renal Drugs > Chapter 13. Drugs Used in Heart Failure >

Clinical Pharmacology of Drugs Used in Heart Failure

In the past, prescription of a diuretic plus digitalis was almost automatic in every case of chronic heart failure, and other drugs were rarely considered. At present, diuretics are still considered as first-line therapy, but digitalis is usually reserved for patients who do not respond adequately to diuretics, ACE inhibitors, and β -blockers (Table 13–1).

Management of Chronic Heart Failure

The major steps in the management of patients with chronic heart failure are outlined in Table 13–4. Reduction of cardiac work is helpful in most cases. This can be accomplished by reducing activity and weight, and—especially important—control of hypertension.

Table 13–4. Steps in the Treatment of Chronic Heart Failure.

1. Reduce workload of the heart

a. Limit activity level
b. Reduce weight
c. Control hypertension
2. Restrict sodium
3. Restrict water (rarely required)
4. Give diuretics
5. Give ACE inhibitor or angiotensin receptor blocker
6. Give digitalis if systolic dysfunction with 3rd heart sound or atrial fibrillation is present
7. Give β -blockers to patients with stable class II–IV heart failure
8. Give vasodilators

Sodium Removal

Sodium removal is the next important step—by dietary salt restriction or a diuretic—especially if edema is present. In mild failure, it is reasonable to start with a thiazide diuretic, switching to more powerful agents as required. Sodium loss causes secondary loss of potassium, which is particularly hazardous if the patient is to be given digitalis. Hypokalemia can be treated with potassium supplementation or through the addition of a potassium-sparing diuretic such as spironolactone. As noted above, spironolactone should probably be considered in all patients with moderate or severe heart failure since it appears to reduce both morbidity and mortality.

ACE Inhibitors & Angiotensin Receptor Blockers

In patients with left ventricular dysfunction but no edema, an ACE inhibitor should be used first. Several large studies have compared ACE inhibitors with digoxin or with other traditional therapies for chronic heart failure. The results show clearly that ACE inhibitors are superior to both placebo and to vasodilators and must be considered, along with diuretics, as first-line therapy for chronic failure. However, ACE inhibitors cannot replace digoxin in patients already receiving that drug because patients withdrawn from the cardiac glycoside while on ACE inhibitor therapy deteriorate.

Additional studies suggest that ACE inhibitors are also valuable in asymptomatic patients with ventricular dysfunction. By reducing preload and afterload, these drugs appear to slow the rate of ventricular dilation and thus delay the onset of clinical heart failure. Thus, ACE inhibitors are beneficial in all subsets of patients, from those who are asymptomatic to those in severe chronic failure.

It appears that all ACE inhibitors tested to date have beneficial effects in patients with chronic heart failure. Recent studies have documented these beneficial effects with enalapril, captopril, lisinopril, quinapril, and ramipril. Thus, this benefit appears to be a class effect.

The angiotensin II receptor antagonists (eg, losartan, valsartan, etc) produce beneficial hemodynamic effects similar to those of the ACE inhibitors. However, large clinical trials suggest that the angiotensin receptor blockers should only be used in patients who are intolerant of ACE inhibitors (usually because of cough).

Vasodilators

Vasodilator drugs can be divided into selective arteriolar dilators, venous dilators, and drugs with nonselective vasodilatory effects. For this purpose, the ACE inhibitors may be considered nonselective arteriolar and venous dilators. The choice of agent should be based on the patient's signs and symptoms and hemodynamic measurements. Thus, in patients with high filling pressures in whom the principal symptom is dyspnea, venous dilators such as long-acting nitrates will be most helpful in reducing filling pressures and the symptoms of pulmonary congestion. In patients in whom fatigue due to low left ventricular output is a primary symptom, an arteriolar dilator such as hydralazine may be helpful in increasing forward cardiac output. In most patients with severe chronic failure that responds poorly to other therapy, the problem usually involves both elevated filling pressures and reduced cardiac output. In these circumstances, dilation of both arterioles and veins is required. In one trial, combined therapy with hydralazine (arteriolar dilation) and isosorbide dinitrate (venous dilation) prolonged life more than placebo in patients already receiving digitalis and diuretics.

Beta Blockers & Calcium Channel Blockers

Many trials have evaluated the potential for β -blocker therapy in patients with heart failure. The rationale is based on the hypothesis that excessive tachycardia and adverse effects of high catecholamine levels on the heart contribute to the downward course of heart failure patients. However, such therapy must be initiated very cautiously at low doses, since acutely blocking the supportive effects of catecholamines can worsen heart failure. Several months of therapy may be required before improvement is noted; this usually consists of a slight rise in ejection fraction, slower heart rate, and reduction in symptoms. As noted above, bisoprolol, carvedilol, and metoprolol have been shown to reduce mortality.

The calcium-blocking drugs appear to have no role in the treatment of patients with heart failure. Their depressant effects on the heart may worsen heart failure.

Digitalis

Digoxin is indicated in patients with heart failure and atrial fibrillation. It is also most helpful in patients with a dilated heart and third heart sound. It is usually given after ACE inhibitors. Only about 50% of patients with normal sinus rhythm (usually those with documented *systolic* dysfunction) will have documentable relief of heart failure from digitalis. Better results are obtained in patients with atrial fibrillation. If the decision is made to use a cardiac glycoside, digoxin is the one chosen in the great majority of cases (and the only one available in the USA). When symptoms are mild, slow loading (digitalization) (Table 13–3) is safer and just as effective as the rapid method.

Determining the optimal level of digitalis effect may be difficult. In patients with atrial fibrillation, reduction of ventricular rate is the best measure of glycoside effect. In patients in normal sinus rhythm, symptomatic improvement and reductions in heart size, heart rate during exercise, venous pressure, or edema may signify optimum drug levels in the myocardium. Unfortunately, toxic effects may occur before the therapeutic end point is detected. If digitalis is being loaded slowly, simple omission of one dose and halving the maintenance dose will often bring the patient to the narrow range between suboptimal and toxic concentrations. Measurement of plasma digoxin levels is useful in patients who appear unusually resistant or sensitive; a level of 1.1 ng/mL or less is appropriate.

Because it has a moderate but persistent positive inotropic effect, digitalis can, in theory, reverse the signs and symptoms of heart failure. In an appropriate patient, digitalis increases stroke work and

cardiac output. The increased output (and possibly a direct action resetting the sensitivity of the baroreceptors) eliminates the stimuli evoking increased sympathetic outflow, and both heart rate and vascular tone diminish. With decreased end-diastolic fiber tension (the result of increased systolic ejection and decreased filling pressure), heart size and oxygen demand decrease. Finally, increased renal blood flow improves glomerular filtration and reduces aldosterone-driven sodium reabsorption. Thus, edema fluid can be excreted, further reducing ventricular preload and the danger of pulmonary edema. Although digitalis had a neutral effect on mortality (Digitalis Investigation Group, 1997), it reduced hospitalization and deaths from progressive heart failure at the expense of an increase in sudden death. It is important to note that the mortality rate was reduced in patients with serum digoxin concentrations of 1 ng/mL or less but increased in those with digoxin levels greater than 1.5 ng/mL.

Administration & Dosage

Long-term treatment with digoxin requires careful attention to pharmacokinetics because of its long half-life. According to the rules set forth in Chapter 3: Pharmacokinetics & Pharmacodynamics: Rational Dosing & the Time Course of Drug Action, it will take three to four half-lives to approach steady-state total body load when given at a constant dosing rate, ie, approximately 1 week for digoxin. Typical doses used in adults are given in Table 13–5. A parenteral preparation of digoxin is available but is not used to achieve a faster onset of effect because the time to peak effect is determined mainly by time-dependent ion changes in the tissue. Thus, the parenteral preparation is only suitable for patients who cannot take drugs by mouth.

Table 13–5. Clinical Use of Digoxin. ¹	
	Digoxin
Therapeutic plasma concentration	0.5–1.5 ng/mL
Toxic plasma concentration	> 2 ng/mL
Daily dose (slow loading or maintenance)	0.25 (0.125–0.5) mg
Rapid digitalizing dose (rarely used)	0.5–0.75 mg every 8 hours for three doses

¹These values are appropriate for adults with normal renal and hepatic function.

Interactions

Patients are at risk for developing serious digitalis-induced cardiac arrhythmias if hypokalemia develops, as in diuretic therapy or diarrhea. Furthermore, patients taking digoxin are at risk if given quinidine, which displaces digoxin from tissue binding sites (a minor effect) and depresses renal digoxin clearance (a major effect). The plasma level of the glycoside may double within a few days after beginning quinidine therapy, and toxic effects may become manifest. As noted above, antibiotics that alter gastrointestinal flora may increase digoxin bioavailability in about 10% of patients. Finally, agents that release catecholamines may sensitize the myocardium to digitalis-induced arrhythmias.

Other Clinical Uses of Digitalis

Digitalis is useful in the management of atrial arrhythmias because of its cardioselective

parasympathomimetic effects. In atrial flutter, the depressant effect of the drug on atrioventricular conduction will help control an excessively high ventricular rate. The effects of the drug on the atrial musculature may convert flutter to fibrillation, with a further decrease in ventricular rate. In atrial fibrillation, the same vagomimetic action helps control ventricular rate, thereby improving ventricular filling and increasing cardiac output. Digitalis has also been used in the control of paroxysmal atrial and atrioventricular nodal tachycardia. At present, calcium channel blockers and adenosine are preferred for this application.

Digitalis should be avoided in the therapy of arrhythmias associated with Wolff-Parkinson-White syndrome because it increases the probability of conduction of arrhythmic atrial impulses through the alternative rapidly conducting atrioventricular pathway. It is explicitly contraindicated in patients with Wolff-Parkinson-White syndrome and atrial fibrillation (see Chapter 14: Agents Used in Cardiac Arrhythmias).

Toxicity

In spite of its recognized hazards, digitalis is heavily used and toxicity is common. Therapy of toxicity manifested as visual changes or gastrointestinal disturbances generally requires no more than reducing the dose of the drug. If cardiac arrhythmia is present and can definitely be ascribed to digitalis, more vigorous therapy may be necessary. Serum digitalis and potassium levels and the ECG should be monitored during therapy of significant digitalis toxicity. Electrolyte status should be corrected if abnormal (see above). For patients who do not respond promptly (within one to two half-lives), calcium and magnesium as well as potassium levels should be checked. For occasional premature ventricular depolarizations or brief runs of bigeminy, oral potassium supplementation and withdrawal of the glycoside may be sufficient. If the arrhythmia is more serious, parenteral potassium and antiarrhythmic drugs may be required. Of the available antiarrhythmic agents, lidocaine is favored.

In severe digitalis intoxication (which usually involves young children or suicidal overdose), serum potassium will already be elevated at the time of diagnosis (because of potassium loss from the intracellular compartment of skeletal muscle and other tissues). Furthermore, automaticity is usually depressed, and antiarrhythmic agents administered in this setting may lead to cardiac arrest. Such patients are best treated with insertion of a temporary cardiac pacemaker catheter and administration of digitalis antibodies (**digoxin immune fab**). These antibodies are produced in sheep, and although they are raised to digoxin they also recognize digitoxin and cardiac glycosides from many other plants. They are extremely useful in reversing severe intoxication with most glycosides.

Digitalis-induced arrhythmias are frequently made worse by cardioversion; this therapy should be reserved for ventricular fibrillation if the arrhythmia is glycoside-induced.

Management of Acute Heart Failure

Acute heart failure occurs frequently in patients with chronic failure. Such episodes are usually associated with increased exertion, emotion, salt in the diet, noncompliance with medical therapy, or increased metabolic demand occasioned by fever, anemia, etc. A particularly common and important cause of acute failure—with or without chronic failure—is acute myocardial infarction.

Patients with acute myocardial infarction are best treated with emergency revascularization with either coronary angioplasty and a stent or a thrombolytic agent. Even with revascularization, acute failure may develop in such patients. Many of the signs and symptoms of acute and chronic failure

are identical, but their therapies diverge because of the need for more rapid response and the relatively greater frequency and severity of pulmonary vascular congestion in the acute form.

Measurements of arterial pressure, cardiac output, stroke work index, and pulmonary capillary wedge pressure are particularly useful in patients with acute myocardial infarction and acute heart failure. Such patients can be usefully characterized on the basis of three hemodynamic measurements: arterial pressure, left ventricular filling pressure, and cardiac index. One such classification and therapies that have proved most effective are set forth in Table 13–6. When filling pressure is greater than 15 mm Hg and stroke work index is less than 20 g-m/m², the mortality rate is high (Figure 13–3). Intermediate levels of these two variables imply a much better prognosis.

Table 13–6. Therapeutic Classification of Subsets in Acute Myocardial Infarction.¹

Subset	Systolic Arterial Pressure (mm Hg)	Left Ventricular Filling Pressure (mm Hg)	Cardiac Index (L/min/m ²)	Therapy
1. Hypovolemia	< 100	< 10	< 2.5	Volume replacement
2. Pulmonary congestion	100–150	> 20	> 2.5	Diuretics
3. Peripheral vasodilation	< 100	10–20	> 2.5	None, or vasoactive drugs
4. Power failure	< 100	> 20	< 2.5	Vasodilators, inotropic drugs
5. Severe shock	< 90	> 20	< 2.0	Vasoactive drugs, inotropic drugs, vasodilators, circulatory assist
6. Right ventricular infarct	< 100	RVFP > 10	< 2.5	Provide volume replacement for LVFP, inotropic drugs. Avoid diuretics.
		LVFP < 15		
7. Mitral regurgitation, ventricular septal defect	< 100	> 20	< 2.5	Vasodilators, inotropic drugs, circulatory assist, surgery

¹The numerical values are intended to serve as general guidelines and not as absolute cutoff points. Arterial pressures apply to patients who were previously normotensive and should be adjusted upward for patients who were previously hypertensive. (RVFP and LVFP = right and left ventricular filling pressure.)

Preparations Available

(Diuretics: See Chapter 15: Diuretic Agents.)

Digitalis

Digoxin (generic, Lanoxicaps, Lanoxin)

Oral: 0.125, 0.25 mg tablets; 0.05, 0.1, 0.2 mg capsules*; 0.05 mg/mL elixir

Parenteral: 0.1, 0.25 mg/mL for injection

Digitalis Antibody

Digoxin immune fab (ovine) (digibind, digifab)

Parenteral: 38 or 40 mg per vial with 75 mg sorbitol lyophilized powder to reconstitute for IV injection. Each vial will bind approximately 0.5 mg digoxin or digitoxin.

Sympathomimetics Most Commonly Used in Congestive Heart Failure

Dobutamine (generic, Dobutrex)

Parenteral: 12.5 mg/mL for IV infusion

Dopamine (generic, Intropin)

Parenteral: 40, 80, 160 mg/mL for IV injection; 80, 160, 320 mg/dL in 5% dextrose for IV infusion

Angiotensin-Converting Enzyme Inhibitors Labeled for Use in Congestive Heart Failure

Captopril (generic, Capoten)

Oral: 12.5, 25, 50, 100 mg tablets

Enalapril (Vasotec, Vasotec I.V.)

Oral: 2.5, 5, 10, 20 mg tablets

Parenteral: 1.25 mg enalaprilat/mL

Fosinopril (Monopril)

Oral: 10, 20, 40 mg tablets

Lisinopril (Prinivil, Zestril)

Oral: 2.5, 5, 10, 20, 40 mg tablets

Quinapril (Accupril)

Oral: 5, 10, 20, 40 mg tablets

Ramipril (Altace)

Oral: 1.25, 2.5, 5, 10 mg capsules

Trandolapril (Mavik)

Oral: 1, 2, 5 mg tablets

Angiotensin Receptor Blockers

Candesartan (Atacand)

Oral: 4, 8, 16, 32 mg tablets

Eprosartan (Teveten)

Oral: 400, 800 mg tablets

Irbesartan (Avapro)

Oral: 75, 150, 300 mg tablets

Losartan (Cozaar)

Oral: 25, 50, 100 mg tablets

Olmesartan (Benicar)

Oral: 5, 20, 40 mg tablets

Telmisartan (Micardis)

Oral: 20, 40, 80 mg tablets

Valsartan (Diovan)

Oral: 40, 80, 160, 320 mg tablets

Beta-Blockers That Have Reduced Mortality in Heart Failure

Bisoprolol (Zebeta, unlabeled use)

Oral: 5, 10 mg tablets

Carvedilol (Coreg)

Oral: 3.125, 6.25, 12.5, 25 mg tablets

Metoprolol (Lopressor, Toprol XL)

Oral: 50, 100 mg tablets; 25, 50, 100, 200 mg extended-release tablets

Parenteral: 1 mg/mL for IV injection

Other Drugs

Inamrinone

Parenteral: 5 mg/mL for IV injection

Milrinone (generic, Primacor)

Parenteral: 1 mg/mL for IV injection; 200 µg/mL premixed for IV infusion

Nesiritide (Natrecor)

Parenteral: 1.58 mg powder for IV injection

Bosentan (Tracleer)

Oral: 62.5, 125 mg tablets

Chapter 14. Agents Used in Cardiac Arrhythmias

Katzung PHARMACOLOGY, 9e > Section III. Cardiovascular-Renal Drugs > Chapter 14.
Agents Used in Cardiac Arrhythmias >

Agents Used in Cardiac Arrhythmias: Introduction

*The authors acknowledge the contributions of the previous authors of this chapter, Drs L Hondeghem and D Roden.

Cardiac arrhythmias are a frequent problem in clinical practice, occurring in up to 25% of patients treated with digitalis, 50% of anesthetized patients, and over 80% of patients with acute myocardial infarction. Arrhythmias may require treatment because rhythms that are too rapid, too slow, or asynchronous can reduce cardiac output. Some arrhythmias can precipitate more serious or even lethal rhythm disturbances—eg, early premature ventricular depolarizations can precipitate ventricular fibrillation. In such patients, antiarrhythmic drugs may be lifesaving. On the other hand, the hazards of antiarrhythmic drugs—and in particular the fact that they can *precipitate* lethal arrhythmias in some patients—has led to a reevaluation of their relative risks and benefits. In general, treatment of asymptomatic or minimally symptomatic arrhythmias should be avoided for this reason.

Arrhythmias can be treated with the drugs discussed in this chapter and with nonpharmacologic therapies such as pacemakers, cardioversion, catheter ablation, and surgery. This chapter describes

the pharmacology of drugs that suppress arrhythmias by a direct action on the cardiac cell membrane. Other modes of therapy are discussed briefly.

Electrophysiology of Normal Cardiac Rhythm

The electrical impulse that triggers a normal cardiac contraction originates at regular intervals in the sinoatrial node (Figure 14–1), usually at a frequency of 60–100 beats per minute. This impulse spreads rapidly through the atria and enters the atrioventricular node, which is normally the only conduction pathway between the atria and ventricles. Conduction through the atrioventricular node is slow, requiring about 0.15 s. (This delay provides time for atrial contraction to propel blood into the ventricles.) The impulse then propagates over the His-Purkinje system and invades all parts of the ventricles. Ventricular activation is complete in less than 0.1 s; therefore, contraction of all of the ventricular muscle is synchronous and hemodynamically effective.

Figure 14–1.

Schematic representation of the heart and normal cardiac electrical activity (intracellular recordings from areas indicated and ECG). Sinoatrial node, atrioventricular node, and Purkinje cells display pacemaker activity (phase 4 depolarization). The ECG is the body surface manifestation of the depolarization and repolarization waves of the heart. The P wave is generated by atrial depolarization, the QRS by ventricular muscle depolarization, and the T wave by ventricular repolarization. Thus, the PR interval is a measure of conduction time from atrium to ventricle, and the QRS duration indicates the time required for all of the ventricular cells to be activated (ie, the intraventricular conduction time). The QT interval reflects the duration of the ventricular action potential.

Arrhythmias consist of cardiac depolarizations that deviate from the above description in one or more aspects— ie, there is an abnormality in the site of origin of the impulse, its rate or regularity, or its conduction.

Ionic Basis of Membrane Electrical Activity

The transmembrane potential of cardiac cells is determined by the concentrations of several ions—chiefly sodium (Na^+), potassium (K^+), calcium (Ca^{2+}), and chloride (Cl^-)—on either side of the membrane and the permeability of the membrane to each ion. These water-soluble ions are unable to freely diffuse across the lipid cell membrane in response to their electrical and concentration gradients; they require aqueous channels (specific pore-forming proteins) for such diffusion. Thus, ions move across cell membranes in response to their gradients only at specific times during the cardiac cycle when these ion channels are open. The movements of these ions produce currents that form the basis of the cardiac action potential. Individual channels are relatively ion-specific, and the flux of ions through them is thought to be controlled by "gates" (probably flexible peptide chains or energy barriers). Each type of channel has its own type of gate (sodium, calcium, and some potassium channels are each thought to have two types of gates), and each type of gate is opened and closed by specific transmembrane voltage, ionic, or metabolic conditions.

At rest, most cells are not significantly permeable to sodium, but at the start of each action potential, they become quite permeable (see below). Similarly, calcium enters and potassium leaves the cell with each action potential. Therefore, the cell must have a mechanism to maintain stable transmembrane ionic conditions by establishing and maintaining ion gradients. The most important of these active mechanisms is the sodium pump, Na^+/K^+ ATPase, described in Chapter 13: Drugs Used in Heart Failure. This pump and other active ion carriers contribute indirectly to the transmembrane potential by maintaining the gradients necessary for diffusion through channels. In addition, some pumps and exchangers produce net current flow (eg, by exchanging three Na^+ for two K^+ ions) and hence are termed "electrogenic."

When the cardiac cell membrane becomes permeable to a specific ion (ie, when the channels selective for that ion are open), movement of that ion across the cell membrane is determined by Ohm's law: current = voltage \div resistance, or current = voltage \times conductance. Conductance is determined by the properties of the individual ion channel protein. The voltage term is the difference between the actual membrane potential and the reversal potential for that ion (the membrane potential at which no current would flow even if channels were open). For example, in the case of sodium in a cardiac cell at rest, there is a substantial concentration gradient (140 mmol/L Na^+ outside; 10–15 mmol/L Na^+ inside) and electrical gradient (0 mV outside; -90 mV inside) that would drive Na^+ into cells. Sodium does not enter the cell at rest because sodium channels are closed; when sodium channels open, the very large influx of Na^+ ions accounts for phase 0 depolarization. The situation for K^+ ions in the resting cardiac cell is quite different. Here, the concentration gradient (140 mmol/L inside; 4 mmol/L outside) would drive the ion out of the cell, but the electrical gradient would drive it in, ie, the inward gradient is in equilibrium with the outward gradient. In fact, certain potassium channels ("inward rectifier" channels) are open in the resting cell, but little current flows through them because of this balance. The equilibrium, or **reversal potential**, for ions is determined by the **Nernst equation**:

$$E_{\text{ion}} = 61 \times \log \left(\frac{C_e}{C_i} \right)$$

where C_e and C_i are the extracellular and intracellular concentrations, respectively, multiplied by their activity coefficients. Note that raising extracellular potassium makes E_K less negative. When this occurs, the membrane depolarizes until E_K is reached. Thus, extracellular potassium concentration and inward rectifier channel function are the major factors determining the membrane potential of the resting cardiac cell. The conditions required for application of the Nernst equation are approximated at the peak of the overshoot and during rest in most nonpacemaker cardiac cells.

If the permeability is significant for both potassium and sodium, the Nernst equation is not a good predictor of membrane potential, but the **Goldman-Hodgkin-Katz equation** may be used.

$$E_{\text{mem}} = 61 \times \log \left(\frac{P_K \times K_o + P_{Na} \times Na_o}{P_K \times K_i + P_{Na} \times Na_i} \right)$$

In pacemaker cells (whether normal or ectopic), spontaneous depolarization (the pacemaker potential) occurs during diastole (phase 4, Figure 14–1). This depolarization results from a gradual increase of depolarizing current through special hyperpolarization-activated ion channels in pacemaker cells. The effect of changing extracellular potassium is more complex in a pacemaker cell than it is in a nonpacemaker cell because the effect on permeability to potassium is much more important in a pacemaker (see Effects of Potassium). In a pacemaker—especially an ectopic one—the end result of an increase in extracellular potassium will usually be to slow or stop the pacemaker. Conversely, hypokalemia will often facilitate ectopic pacemakers.

The Active Cell Membrane

In normal atrial, Purkinje, and ventricular cells, the action potential upstroke (phase 0) is dependent on sodium current. From a functional point of view, it is convenient to describe the behavior of the sodium current in terms of three channel states (Figure 14–2). The cardiac sodium channel protein has been cloned, and it is now recognized that these channel states actually represent different protein conformations. In addition, regions of the protein that confer specific behaviors, such as voltage sensing, pore formation, and inactivation, are now being identified. The gates described below and in Figure 14–2 represent such regions.

Figure 14–2.

gate as h . Potentials typical for each state are shown under each channel schematic as a function of time. The dashed line indicates that part of the action potential during which most Na^+ channels are completely or partially inactivated and unavailable for reactivation.

Depolarization to the threshold voltage results in opening of the activation (m) gates of sodium channels (Figure 14–2, middle). If the inactivation (h) gates of these channels have not already closed, the channels are now open or activated, and sodium permeability is markedly increased, greatly exceeding the permeability for any other ion. Extracellular sodium therefore diffuses down its electrochemical gradient into the cell, and the membrane potential very rapidly approaches the sodium equilibrium potential, E_{Na} (about +70 mV when $\text{Na}_e = 140$ mmol/L and $\text{Na}_i = 10$ mmol/L). This intense sodium current is very brief because opening of the m gates upon depolarization is promptly followed by closure of the h gates and inactivation of the sodium channels (Figure 14–2, right).

Most calcium channels become activated and inactivated in what appears to be the same way as sodium channels, but in the case of the most common type of cardiac calcium channel (the "L" type), the transitions occur more slowly and at more positive potentials. The action potential plateau (phases 1 and 2) reflects the turning off of most of the sodium current, the waxing and waning of calcium current, and the slow development of a repolarizing potassium current.

Final repolarization (phase 3) of the action potential results from completion of sodium and calcium channel inactivation and the growth of potassium permeability, so that the membrane potential once again approaches the potassium equilibrium potential. The major potassium currents involved in phase 3 repolarization include a rapidly activating potassium current (I_{Kr}) and a slowly activating potassium current (I_{Ks}). These processes are diagrammed in Figure 14–3.

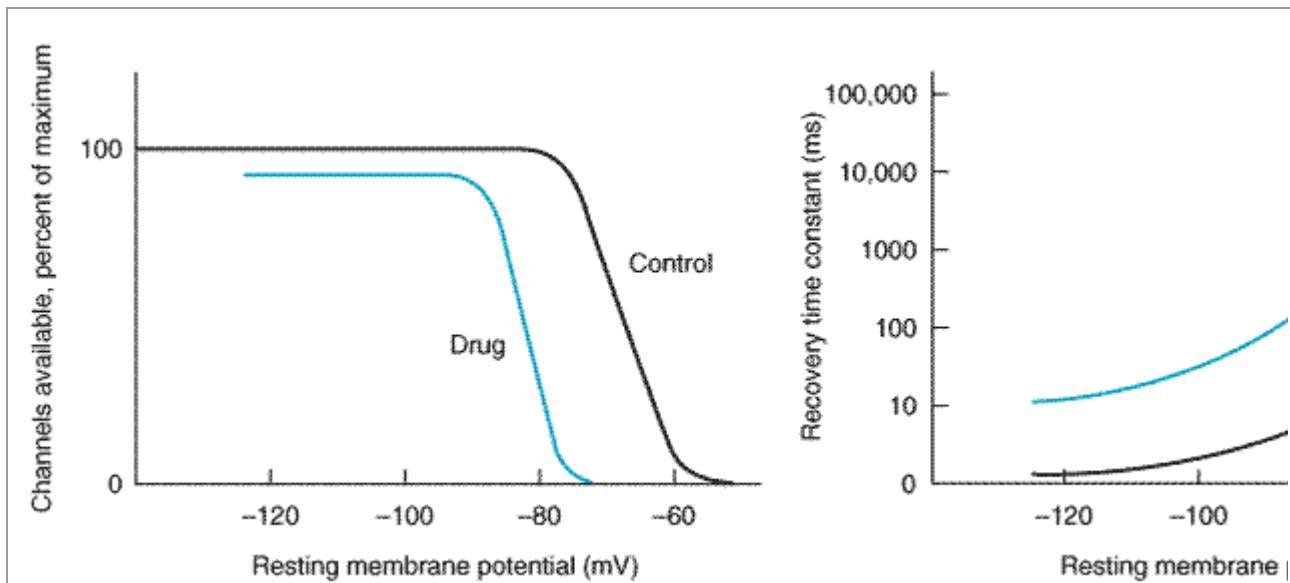

Figure 14–3.

The Effect of Resting Potential on Action Potentials

A key factor in the pathophysiology of arrhythmias and the actions of antiarrhythmic drugs is the relationship between the resting potential of a cell and the action potentials that can be evoked in it (Figure 14-4, left panel). Because the inactivation gates of sodium channels in the resting membrane close over the potential range -75 to -55 mV, fewer sodium channels are "available" for diffusion of sodium ions when an action potential is evoked from a resting potential of -60 mV than when it is evoked from a resting potential of -80 mV. Important consequences of the reduction in peak sodium permeability include reduced upstroke velocity (called \dot{V}_{\max} , for maximum rate of change of membrane voltage), reduced action potential amplitude, reduced excitability, and reduced conduction velocity.

Figure 14-4.

Dependence of sodium channel function on the membrane potential preceding the stimulus. **Left:** The fraction of sodium channels available for opening in response to a stimulus is determined by the membrane potential immediately preceding the stimulus. The decrease in the fraction available when the resting potential is depolarized in the absence of a drug (control curve) results from the voltage-dependent closure of *h* gates in the channels. The curve labeled **Drug** illustrates the effect of a typical local anesthetic antiarrhythmic drug. Most sodium channels are inactivated during the plateau of the action potential. **Right:** The time constant for recovery from inactivation after repolarization also depends on the resting potential. In the absence of drug, recovery occurs in less than 10 ms at normal resting potentials (–85 to –95 mV). Depolarized cells recover more slowly (note logarithmic scale). In the presence of a sodium channel-blocking drug, the time constant of recovery is increased, but the increase is far greater at depolarized potentials than at more negative ones.

During the plateau of the action potential, most sodium channels are inactivated. Upon repolarization, recovery from inactivation takes place (in the terminology of Figure 14–2, the *h* gates reopen), making the channels again available for excitation. The time between phase 0 and sufficient recovery of sodium channels in phase 3 to permit a new propagated response to external stimulus is the **refractory period**. Changes in refractoriness (determined by either altered recovery from inactivation or altered action potential duration) can be important in the genesis or suppression of certain arrhythmias. Another important effect of less negative resting potential is prolongation of this recovery time, as shown in Figure 14–4 (right panel). The prolongation of recovery time is reflected in an increase in the effective refractory period.

A brief depolarizing stimulus, whether caused by a propagating action potential or by an external electrode arrangement, causes the opening of large numbers of activation gates before a significant number of inactivation gates can close. In contrast, slow reduction (depolarization) of the resting potential, whether brought about by hyperkalemia, sodium pump blockade, or ischemic cell damage, results in depressed sodium currents during the upstrokes of action potentials. Depolarization of the resting potential to levels positive to –55 mV abolishes sodium currents, since all sodium channels are inactivated. However, such severely depolarized cells have been found to support special action potentials under circumstances that increase calcium permeability or decrease potassium permeability. These "slow responses"—slow upstroke velocity and slow conduction—depend on a calcium inward current and constitute the normal electrical activity in the sinoatrial and atrioventricular nodes, since these tissues have a normal resting potential in the range of –50 to –70 mV. Slow responses may also be important for certain arrhythmias. Modern techniques of

molecular biology and electrophysiology can identify multiple subtypes of calcium and potassium channels. One way in which such subtypes may differ is in sensitivity to drug effects, so drugs targeting specific channel subtypes may be developed in the future.

Mechanisms of Arrhythmias

Many factors can precipitate or exacerbate arrhythmias: ischemia, hypoxia, acidosis or alkalosis, electrolyte abnormalities, excessive catecholamine exposure, autonomic influences, drug toxicity (eg, digitalis or antiarrhythmic drugs), overstretching of cardiac fibers, and the presence of scarred or otherwise diseased tissue. However, all arrhythmias result from (1) disturbances in impulse formation, (2) disturbances in impulse conduction, or (3) both.

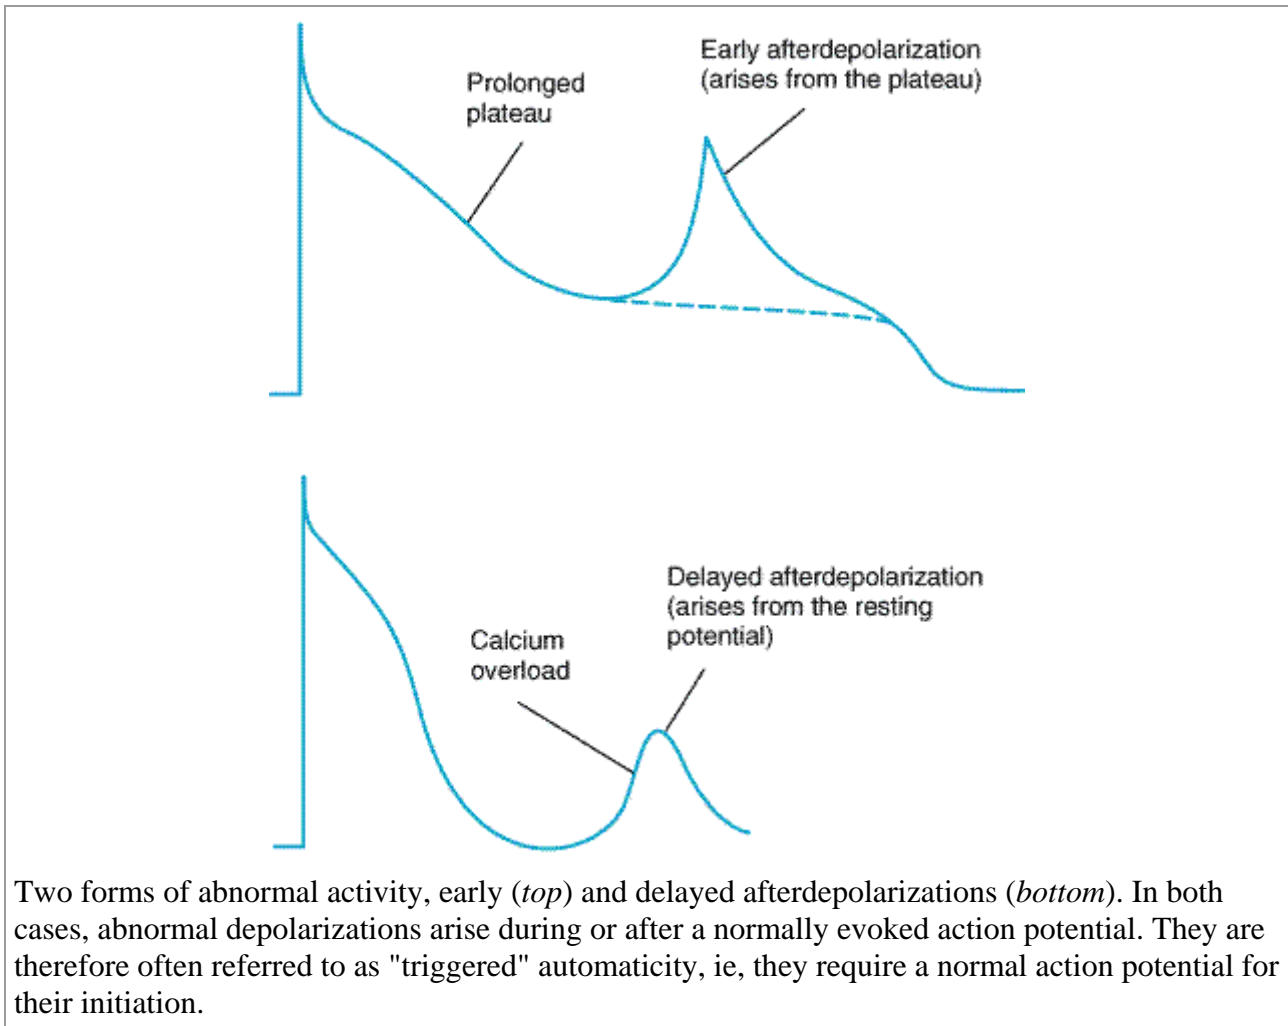

Disturbances of Impulse Formation

The interval between depolarizations of a pacemaker cell is the sum of the duration of the action potential and the duration of the diastolic interval. Shortening of either duration results in an increase in pacemaker rate. The more important of the two, diastolic interval, is determined primarily by the slope of phase 4 depolarization (pacemaker potential). Vagal discharge and β -receptor-blocking drugs slow normal pacemaker rate by reducing the phase 4 slope (acetylcholine also makes the maximum diastolic potential more negative). Acceleration of pacemaker discharge is often brought about by increased phase 4 depolarization slope, which can be caused by hypokalemia, β -adrenoceptor stimulation, positive chronotropic drugs, fiber stretch, acidosis, and partial depolarization by currents of injury.

Latent pacemakers (cells that show slow phase 4 depolarization even under normal conditions, eg, some Purkinje fibers) are particularly prone to acceleration by the above mechanisms. However, all cardiac cells, including normally quiescent atrial and ventricular cells, may show repetitive pacemaker activity when depolarized under appropriate conditions, especially if hypokalemia is also present.

Afterdepolarizations (Figure 14–5) are depolarizations that interrupt phase 3 (early afterdepolarizations, EADs) or phase 4 (delayed afterdepolarizations, DADs). DADs, discussed in Chapter 13: Drugs Used in Heart Failure, often occur when intracellular calcium is increased. They are exacerbated by fast heart rates and are thought to be responsible for some arrhythmias related to digitalis excess, to catecholamines, and to myocardial ischemia. EADs, on the other hand, are usually exacerbated at slow heart rates and are thought to contribute to the development of long QT-related arrhythmias (see Molecular & Genetic Bases of Cardiac Arrhythmias).

Figure 14–5.

Disturbances of Impulse Conduction

Severely depressed conduction may result in simple **block**, eg, atrioventricular nodal block or bundle branch block. Because parasympathetic control of atrioventricular conduction is significant, partial atrioventricular block is sometimes relieved by atropine. Another common abnormality of conduction is **reentry** (also known as "circus movement"), in which one impulse reenters and excites areas of the heart more than once (Figure 14–6). The path of the reentering impulse may be confined to very small areas, eg, within or near the atrioventricular node, or it may involve large portions of the atrial or ventricular walls. Some forms of reentry are strictly anatomically determined; for example, in the Wolff-Parkinson-White syndrome, the reentry circuit consists of atrial tissue, the AV node, ventricular tissue, and an accessory atrioventricular connection (a "bypass tract"). In other cases (eg, atrial or ventricular fibrillation), multiple reentry circuits, determined by the properties of the cardiac tissue, may meander through the heart in apparently random paths. Furthermore, the circulating impulse often gives off "daughter impulses" that can spread to the rest of the heart. Depending on how many round trips through the pathway the impulse makes before dying out, the arrhythmia may be manifest as one or a few extra beats or as a sustained tachycardia.

Figure 14–6.

A. Normal

B. Unidirectional block

Schematic diagram of a reentry circuit that might occur in small bifurcating branches of the Purkinje system where they enter the ventricular wall. **A:** Normally, electrical excitation branches around the circuit, is transmitted to the ventricular branches, and becomes extinguished at the other end of the circuit due to collision of impulses. **B:** An area of unidirectional block develops in one of the branches, preventing anterograde impulse transmission at the site of block, but the retrograde impulse may be propagated through the site of block if the impulse finds excitable tissue, ie, the refractory period is shorter than the conduction time. This impulse will then reexcite tissue it had previously passed through, and a reentry arrhythmia will be established.

In order for reentry to occur, three conditions must coexist, as indicated in Figure 14–6: (1) There must be an obstacle (anatomic or physiologic) to homogeneous conduction, thus establishing a circuit around which the reentrant wavefront can propagate; (2) there must be unidirectional block at some point in the circuit, ie, conduction must die out in one direction but continue in the opposite direction (as shown in Figure 14–6, the impulse can gradually decrease as it invades progressively more depolarized tissue until it finally blocks—a process known as decremental conduction); and (3) conduction time around the circuit must be long enough so that the retrograde impulse does not enter refractory tissue as it travels around the obstacle, ie, the conduction time must exceed the effective refractory period. Importantly, reentry depends on conduction that has been depressed by some critical amount, usually as a result of injury or ischemia. If conduction velocity is too slow,

conduction may fail, or the impulse may arrive so late that it collides with the next regular impulse. On the other hand, if conduction is too rapid, ie, almost normal, bidirectional conduction rather than unidirectional block will occur. Even in the presence of unidirectional block, if the impulse travels around the obstacle too rapidly, it will reach tissue that is still refractory.

Slowing of conduction may be due to depression of sodium current, depression of calcium current (the latter especially in the atrioventricular node), or both. Drugs that abolish reentry usually work by further slowing depressed conduction (by blocking the sodium or calcium current) and causing bidirectional block. In theory, accelerating conduction (by increasing sodium or calcium current) would also be effective, but only under very unusual circumstances does this mechanism explain the action of any available drug.

Lengthening (or shortening) of the refractory period may also make reentry less likely. The longer the refractory period in tissue near the site of block, the greater the chance that the tissue will still be refractory when reentry is attempted. (Alternatively, the shorter the refractory period in the depressed region, the less likely it is that unidirectional block will occur.) Thus, increased dispersion of refractoriness is one contributor to reentry, and drugs may suppress arrhythmias by reducing such dispersion.

Effects of Potassium

The effects of changes in serum potassium on cardiac action potential duration, pacemaker rate, and arrhythmias can appear somewhat paradoxical if changes are predicted based solely on a consideration of changes in the potassium *electrochemical gradient*. In the heart, however, changes in serum potassium concentration have an additional effect to alter potassium *conductance* (increased extracellular potassium increases potassium conductance) independent of simple changes in electrochemical driving force, and this effect often predominates. As a result, the actual observed effects of **hyperkalemia** include reduced action potential duration, slowed conduction, decreased pacemaker rate, and decreased pacemaker arrhythmogenesis. Conversely, the actual observed effects of **hypokalemia** include prolonged action potential duration, increased pacemaker rate, and increased pacemaker arrhythmogenesis. Furthermore, pacemaker rate and arrhythmias involving ectopic pacemaker cells appear to be more sensitive to changes in serum potassium concentration, compared with cells of the sinoatrial node. These effects of serum potassium on the heart probably contribute to the observed increased sensitivity to potassium channel-blocking antiarrhythmic agents (quinidine or sotalol) during hypokalemia, eg, accentuated action potential prolongation and tendency to cause torsade de pointes.

Katzung PHARMACOLOGY, 9e > Section III. Cardiovascular-Renal Drugs > Chapter 14.
Agents Used in Cardiac Arrhythmias >

Basic Pharmacology of the Antiarrhythmic Agents

Mechanisms of Action

Arrhythmias are caused by abnormal pacemaker activity or abnormal impulse propagation. Thus, the aim of therapy of the arrhythmias is to reduce ectopic pacemaker activity and modify conduction or refractoriness in reentry circuits to disable circus movement. The major mechanisms currently available for accomplishing these goals are (1) sodium channel blockade, (2) blockade of sympathetic autonomic effects in the heart, (3) prolongation of the effective refractory period, and

(4) calcium channel blockade.

Antiarrhythmic drugs decrease the automaticity of ectopic pacemakers more than that of the sinoatrial node. They also reduce conduction and excitability and increase the refractory period to a greater extent in depolarized tissue than in normally polarized tissue. This is accomplished chiefly by selectively blocking the sodium or calcium channels of depolarized cells (Figure 14–8).

Therapeutically useful channel-blocking drugs have a high affinity for activated channels (ie, during phase 0) or inactivated channels (ie, during phase 2) but very low affinity for rested channels. Therefore, these drugs block electrical activity when there is a fast tachycardia (many channel activations and inactivations per unit time) or when there is significant loss of resting potential (many inactivated channels during rest). This type of drug action is often described as **use-dependent** or **state-dependent**, ie, channels that are being used frequently, or in an inactivated state, are more susceptible to block. Channels in normal cells that become blocked by a drug during normal activation-inactivation cycles will rapidly lose the drug from the receptors during the resting portion of the cycle (Figure 14–8). Channels in myocardium that is chronically depolarized (ie, has a resting potential more positive than -75 mV) will recover from block very slowly if at all (see also right panel, Figure 14–4).

Figure 14–8.

Diagram of a mechanism for the selective depressant action of antiarrhythmic drugs on sodium channels. The upper portion of the figure shows the population of channels moving through a cycle of activity during an action potential in the absence of drugs: R (rested) \rightarrow A (activated) \rightarrow I (inactivated). Recovery takes place via the I \rightarrow R pathway. Antiarrhythmic drugs (D) that act by blocking sodium channels can bind to their receptors in the channels, as shown by the vertical arrows, to form drug-channel complexes, indicated as R-D, A-D, and I-D. Affinity of the drugs for the receptor varies with the state of the channel, as indicated by the separate rate constants (k and l) for the R \rightarrow R-D, A \rightarrow A-D, and I \rightarrow I-D steps. The data available for a variety of sodium channel blockers indicate that the affinity of the drugs for the active and inactivated channel receptor is much higher than the affinity for the rested channel. Furthermore, recovery from the I-D state to the R-D state is much slower than from I to R. As a result, rapid activity (more activations and inactivations) and depolarization of the resting potential (more channels in the I state) will favor blockade of the channels and selectively suppress arrhythmic cells.

In cells with abnormal automaticity, most of these drugs reduce the phase 4 slope by blocking either sodium or calcium channels and thereby reducing the ratio of sodium (or calcium) permeability to potassium permeability. As a result, the membrane potential during phase 4 stabilizes closer to the potassium equilibrium potential. In addition, some agents may increase the threshold (make it more positive). Beta-adrenoceptor-blocking drugs indirectly reduce the phase 4 slope by blocking the positive chronotropic action of norepinephrine in the heart.

In reentry arrhythmias, which depend on critically depressed conduction, most antiarrhythmic agents slow conduction further by one or both of two mechanisms: (1) steady-state reduction in the number of available unblocked channels, which reduces the excitatory currents to a level below that required for propagation (Figure 14–4, left); and (2) prolongation of recovery time of the channels still able to reach the rested and available state, which increases the effective refractory period (Figure 14–4, right). As a result, early extrasystoles are unable to propagate at all; later impulses propagate more slowly and are subject to bidirectional conduction block.

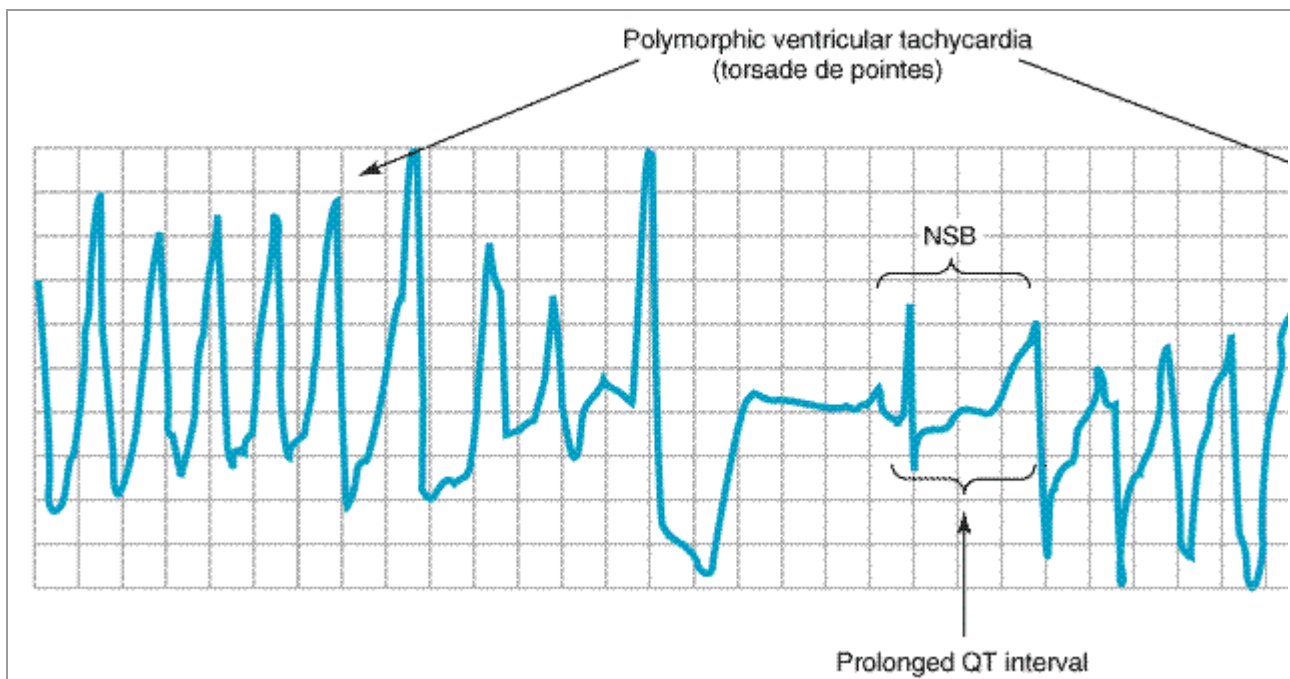

By these mechanisms, antiarrhythmic drugs can suppress ectopic automaticity and abnormal conduction occurring in depolarized cells—rendering them electrically silent—while minimally affecting the electrical activity in normally polarized parts of the heart. However, as dosage is increased, these agents also depress conduction in normal tissue, eventually resulting in *drug-induced* arrhythmias. Furthermore, a drug concentration that is therapeutic (antiarrhythmic) under the initial circumstances of treatment may become "proarrhythmic" (arrhythmogenic) during fast heart rates (more development of block), acidosis (slower recovery from block for most drugs), hyperkalemia, or ischemia.

Molecular & Genetic Basis of Cardiac Arrhythmias

During the past decade, molecular biologic, genetic, and biophysical approaches have provided remarkable new insights into the molecular basis of several congenital and acquired cardiac arrhythmias. The best example is the polymorphic ventricular tachycardia known as torsade de pointes (shown in Figure 14–7), which is associated with syncope and sudden death. The electrocardiographic hallmark of both the acquired and congenital syndromes is prolongation of the QT interval, especially at the onset of the tachycardia. As can be inferred from Figure 14–1, this must represent prolongation of the action potential of at least some ventricular cells. This effect can, in theory, be attributed either to increased inward current (gain of function) or decreased outward current (loss of function) during the plateau of the action potential. In fact, recent molecular genetic studies have identified up to 300 different mutations in at least five ion channel genes that produce the congenital long QT (LQT) syndrome (Table 14–1), and each mutation may have different clinical implications. Loss of function mutations in potassium channel genes produce decreases in outward repolarizing current and are responsible for LQT subtypes 1, 2, 5, and 6. *HERG* and *KCNE2* (*MiRP1*) genes encode subunits of the the rapid delayed rectifier potassium current (I_{Kr}), whereas *KCNQ1* and *KCNE1* (*minK*) encode subunits of the slow delayed rectifier potassium current (I_{Ks}). In contrast, gain of function mutations in the sodium channel gene (*SCN5A*) cause increases in inward plateau current and are responsible for LQT subtype 3.

Figure 14–7.

Electrocardiogram from a patient with the long QT syndrome during two episodes of torsade de pointes. The polymorphic ventricular tachycardia is seen at the start of this tracing and spontaneously halts at the middle of the panel. A single normal sinus beat (NSB) with an extremely prolonged QT interval follows, succeeded immediately by another episode of ventricular tachycardia of the torsade type. The usual symptoms would be dizziness or transient loss of consciousness.

Table 14–1. Molecular and Genetic Basis of Some Cardiac Arrhythmias.

Type	Chromosome Involved	Defective Gene	Ion Channel or Proteins Affected	Result ¹
LQT-1 ²	11	KCNQ1	I _{Ks}	LF

fibrillation				
<p>¹LF, loss of function; GF, gain of function.</p> <p>²LQT, long QT syndrome.</p> <p>³Ankyrins are intracellular proteins that associate with a variety of transport proteins including Na⁺ channels, Na⁺/K⁺ ATPase, Na⁺/Ca²⁺ exchange, Ca²⁺ release channels.</p> <p>⁴PCCD, progressive cardiac conduction disorder.</p>				

Molecular genetic studies have identified the reason why congenital and acquired cases of torsades de pointes can be so strikingly similar. The potassium channel gene (*HERG*) that encodes I_{Kr}, is blocked or modified by many drugs (eg, quinidine, sotalol) or electrolyte abnormalities (hypokalemia, hypomagnesemia, hypocalcemia) that also produce torsades de pointes. Thus, the identification of the precise molecular mechanisms underlying various forms of the long QT syndromes now raises the possibility that specific therapies may be developed for individuals with defined molecular abnormalities. Indeed, preliminary reports suggest that the sodium channel blocker mexiletine can correct the clinical manifestations of congenital long QT subtype 3 syndrome. In vitro and clinical data demonstrate that most available action potential-prolonging drugs exert greater effects at slow rates (where torsade de pointes is a risk) than at fast rates (where arrhythmia suppression would occur). This "reverse use-dependent" action potential prolongation seems to be absent with amiodarone, which may help explain that drug's apparently greater clinical efficacy with its low rate of torsade de pointes. It is likely that torsade de pointes originates from triggered upstrokes arising from early afterdepolarizations (Figure 14–5). Thus, therapy is directed at correcting hypokalemia, eliminating triggered upstrokes (eg, by using β-blockers or magnesium), or shortening the action potential (eg, by increasing heart rate with isoproterenol or pacing)—or all of these.

The molecular basis of several other congenital cardiac arrhythmias associated with sudden death has also recently been identified. The Brugada syndrome, which is characterized by ventricular fibrillation associated with persistent ST-segment elevation and progressive cardiac conduction disorder (PCCD), characterized by impaired conduction in the His-Purkinje system and right or left bundle block leading to complete atrioventricular block, have both been linked to several loss-of-function mutations in the sodium channel gene, *SCN5A*. At least one form of familial atrial fibrillation is caused by a gain-of-function mutation in the potassium channel gene, *KCNQ1*.
Katzung PHARMACOLOGY, 9e > Section III. Cardiovascular-Renal Drugs > Chapter 14. Agents Used in Cardiac Arrhythmias >

Specific Antiarrhythmic Agents

The most widely used scheme for the classification of antiarrhythmic drug actions recognizes four classes:

1. Class 1 action is sodium channel blockade. Subclasses of this action reflect effects on the action potential duration (APD) and the kinetics of sodium channel blockade. Drugs with class 1A action prolong the APD and dissociate from the channel with intermediate kinetics; drugs with class 1B action have no significant effects on the APD and dissociate from the channel with rapid kinetics; and drugs with class 1C action have minimal effects on the APD and

dissociate from the channel with slow kinetics.

2. Class 2 action is sympatholytic. Drugs with this action reduce β -adrenergic activity in the heart.

3. Class 3 action is manifest by prolongation of the APD. Most drugs with this action block the rapid component of the delayed rectifier potassium current, I_{Kr} .

4. Class 4 action is blockade of the cardiac calcium current. This action slows conduction in regions where the action potential upstroke is calcium dependent, eg, the sinoatrial and atrioventricular nodes.

A given drug may have multiple classes of action. For example, amiodarone shares all four classes of action. Drugs are usually discussed according to the predominant class of action. Certain antiarrhythmic agents, eg, adenosine and magnesium, do not fit readily into this scheme and are described separately.

See Table 14–2 and Table 14–3.

Drug	Block of Sodium Channels		Refractory Period		Calcium Channel Blockade	Effect on Pacemaker Activity	Sympatholytic Action

¹May suppress diseased sinus nodes.

²Initial stimulation by release of endogenous norepinephrine followed by depression.

³Anticholinergic effect and direct depressant action.

⁴Especially in Wolff-Parkinson-White syndrome.

⁵May be effective in atrial arrhythmias caused by digitalis.

⁶Half-life of active metabolites much longer.

Sodium Channel-Blocking Drugs (Class 1)

Quinidine (Subgroup 1a)

Cardiac Effects

Quinidine slows the upstroke of the action potential and conduction, and prolongs the QRS duration of the ECG, by blockade of activated sodium channels. Recovery from block occurs with intermediate kinetics and is slowed further in partially depolarized cells. Sodium channel-blocking concentrations of quinidine also prolong the action potential duration as a result of potassium channel blockade. This action is relatively nonspecific as most types of potassium channels are blocked by therapeutic concentrations of quinidine although the resting potential is not altered. The action potential prolonging action is greatest at slow rates. Its major cardiac effects are excessive QT interval prolongation and induction of torsade de pointes arrhythmia, and syncope. Toxic concentrations of quinidine also produce excessive sodium channel blockade with slowed conduction throughout the heart, increased PR interval, and further QRS duration prolongation.

Extracardiac Effects

Gastrointestinal side effects of diarrhea, nausea, and vomiting are observed in one third to half of patients. A syndrome of headache, dizziness, and tinnitus (cinchonism) is observed at toxic drug concentrations. Idiosyncratic reactions including thrombocytopenia, hepatitis, angioneurotic edema, and fever are observed rarely.

Pharmacokinetics

Quinidine is 70–80% bioavailable following oral administration. It is 80% bound to albumin and α_1 -acid glycoprotein. It is eliminated primarily by hepatic metabolism. The principal metabolite, 3-hydroxy quinidine is biologically active with half the activity of the parent compound. Twenty percent of the quinidine dose appears in the unchanged form in the urine. The elimination half-life is 6–8 hours. Quinidine is usually administered in a slow release formulation, eg, that of the gluconate salt.

Therapeutic Use

Quinidine is used for the maintenance of normal sinus rhythm in patients with atrial flutter or fibrillation. It is also used occasionally to treat patients with ventricular tachycardia. Because of its cardiac and extracardiac side effects, its use has decreased considerably in recent years and is now largely restricted to patients with normal (but arrhythmic) hearts. In randomized, controlled clinical trials, quinidine-treated patients are twice as likely to remain in normal sinus rhythm compared with controls. However, drug treatment was associated with a twofold to threefold increase in mortality.

Procainamide (Subgroup 1a)

Cardiac Effects

The electrophysiologic effects of procainamide are similar to those of quinidine. The drug may be somewhat less effective in suppressing abnormal ectopic pacemaker activity but more effective in blocking sodium channels in depolarized cells.

Perhaps the most important difference between quinidine and procainamide is the less prominent

antimuscarinic action of procainamide. Therefore, the directly depressant actions of procainamide on sinoatrial and atrioventricular nodes are not as effectively counterbalanced by drug-induced vagal block as in the case of quinidine.

Extracardiac Effects

Procainamide has ganglion-blocking properties. This action reduces peripheral vascular resistance and can cause hypotension, particularly with intravenous use. However, in therapeutic concentrations, its peripheral vascular effects are less prominent than those of quinidine. Hypotension is usually associated with excessively rapid procainamide infusion or the presence of severe underlying left ventricular dysfunction.

Toxicity

Cardiac

Procainamide's cardiotoxic effects are similar to those of quinidine. Antimuscarinic and direct depressant effects may occur. New arrhythmias may be precipitated.

Extracardiac

The most troublesome adverse effect of long-term procainamide therapy is a syndrome resembling lupus erythematosus and usually consisting of arthralgia and arthritis. In some patients, pleuritis, pericarditis, or parenchymal pulmonary disease also occurs. Renal lupus is rarely induced by procainamide. During long-term therapy, serologic abnormalities (eg, increased antinuclear antibody titer) occur in nearly all patients, and in the absence of symptoms these are not an indication to stop drug therapy. Approximately one third of patients receiving long-term procainamide therapy develop these reversible lupus-related symptoms.

Other adverse effects include nausea and diarrhea (about 10% of cases), rash, fever, hepatitis (< 5%), and agranulocytosis (approximately 0.2%).

Pharmacokinetics & Dosage

Procainamide can be administered safely by the intravenous and intramuscular routes and is well absorbed orally, with 75% systemic bioavailability. The major metabolite is N-acetylprocainamide (NAPA), which has class III activity. Excessive accumulation of NAPA has been implicated in torsade de pointes during procainamide therapy, especially in patients with renal failure. Some individuals rapidly acetylate procainamide and develop high levels of NAPA. The lupus syndrome appears to be less common in these patients.

Procainamide is eliminated by hepatic metabolism to NAPA and by renal elimination. Its half-life is only 3–4 hours, which necessitates frequent dosing or use of a slow-release formulation (the usual practice). NAPA is eliminated by the kidneys. Thus, procainamide dosage must be reduced in patients with renal failure. The reduced volume of distribution and renal clearance associated with heart failure also require reduction in dosage. The half-life of NAPA is considerably longer than that of procainamide, and it therefore accumulates more slowly. Thus, it is important to measure plasma levels of both procainamide and NAPA, especially in patients with circulatory or renal impairment.

If a rapid procainamide effect is needed, an intravenous loading dose of up to 12 mg/kg can be

given at a rate of 0.3 mg/kg/min or less rapidly. This dose is followed by a maintenance dosage of 2–5 mg/min, with careful monitoring of plasma levels. The risk of gastrointestinal or cardiac toxicity rises at plasma concentrations greater than 8 µg/mL or NAPA concentrations greater than 20 µg/mL.

In order to control ventricular arrhythmias, a total procainamide dosage of 2–5 g/d is usually required. In an occasional patient who accumulates high levels of NAPA, less frequent dosing may be possible. This is also possible in renal disease, where procainamide elimination is slowed.

Therapeutic Use

Like quinidine, procainamide is effective against most atrial and ventricular arrhythmias. However, many clinicians attempt to avoid long-term therapy because of the requirement for frequent dosing and the common occurrence of lupus-related effects. Procainamide is the drug of second choice (after lidocaine) in most coronary care units for the treatment of sustained ventricular arrhythmias associated with acute myocardial infarction.

Disopyramide (Subgroup 1a)

Cardiac Effects

The effects of disopyramide are very similar to those of quinidine. Its cardiac antimuscarinic effects are even more marked than those of quinidine. Therefore, a drug that slows atrioventricular conduction should be administered with disopyramide when treating atrial flutter or fibrillation.

Toxicity

Cardiac

Toxic concentrations of disopyramide can precipitate all of the electrophysiologic disturbances described under quinidine. As a result of its negative inotropic effect, disopyramide may precipitate heart failure de novo or in patients with preexisting depression of left ventricular function. Because of this effect, disopyramide is not used as a first-line antiarrhythmic agent in the USA. It should not be used in patients with heart failure.

Extracardiac

Disopyramide's atropine-like activity accounts for most of its symptomatic adverse effects: urinary retention (most often, but not exclusively, in male patients with prostatic hyperplasia), dry mouth,

blurred vision, constipation, and worsening of preexisting glaucoma. These effects may require discontinuation of the drug.

Pharmacokinetics & Dosage

In the USA, disopyramide is only available for oral use. The usual oral dosage of disopyramide is 150 mg three times a day, but as much as 1 g/d has been used. In patients with renal impairment, dosage must be reduced. Because of the danger of precipitating heart failure, the use of loading doses is not recommended.

Therapeutic Use

Although disopyramide has been shown to be effective in a variety of supraventricular arrhythmias, in the USA it is approved only for the treatment of ventricular arrhythmias.

Lidocaine (Subgroup 1b)

Lidocaine has a low incidence of toxicity and a high degree of effectiveness in arrhythmias associated with acute myocardial infarction. It is used only by the intravenous route.

Cardiac Effects

Lidocaine blocks activated and inactivated sodium channels with rapid kinetics (Figure 14–9); the inactivated state block ensures greater effects on cells with long action potentials such as Purkinje and ventricular cells, compared with atrial cells. The rapid kinetics at normal resting potentials result in recovery from block between action potentials and no effect on conduction. The increased inactivation and slower unbinding kinetics result in the selective depression of conduction in depolarized cells.

Figure 14–9.

Effect of resting membrane potential on the blocking and unblocking of sodium channels by lidocaine. **Upper tracing:** Action potentials in a ventricular muscle cell. **Lower tracing:** Percentage of channels blocked by the drug. As the membrane depolarizes through -80 , -75 , -70 and -65 mV, an 800 ms time segment is shown. Extra passage of time is indicated by breaks in the traces. **Left side:** At the normal resting potential of -85 mV, the drug combines with open (activated) and inactivated channels during each action potential, but block is rapidly reversed during diastole because the affinity of the drug for its receptor is so low when the channel recovers to the resting state at -85 mV. **Middle:** Metabolic injury has occurred, eg, ischemia due to coronary occlusion, that causes gradual depolarization over time. With subsequent action potentials arising from more depolarized potentials, the fraction of channels blocked increases because more channels remain in the inactivated state at less negative potentials (Figure 14-4, left), and the time constant for unblocking during diastole rapidly increases at less negative resting potentials (Figure 14-4, right). **Right:** Because of marked drug binding, conduction block and loss of excitability in this tissue result, ie, the "sick" (depolarized) tissue is selectively suppressed.

Toxicity

Cardiac

Lidocaine is one of the least cardiotoxic of the currently used sodium channel blockers. Proarrhythmic effects, including sinoatrial node arrest, worsening of impaired conduction, and ventricular arrhythmias are uncommon with lidocaine use. In large doses, especially in patients with preexisting heart failure, lidocaine may cause hypotension—partly by depressing myocardial contractility.

Extracardiac

Lidocaine's most common adverse effects—like those of other local anesthetics—are neurologic: paresthesias, tremor, nausea of central origin, lightheadedness, hearing disturbances, slurred speech, and convulsions. These occur most commonly in elderly or otherwise vulnerable patients or when a bolus of the drug is given too rapidly. The effects are dose-related and usually short-lived; seizures respond to intravenous diazepam. In general, if plasma levels above $9 \mu\text{g/mL}$ are avoided, lidocaine is well tolerated.

Pharmacokinetics & Dosage

Because of its very extensive first-pass hepatic metabolism, only 3% of orally administered lidocaine appears in the plasma. Thus, lidocaine must be given parenterally. Lidocaine has a half-life of 1–2 hours. In adults, a loading dose of 150–200 mg administered over about 15 minutes (as a single infusion or as a series of slow boluses) should be followed by a maintenance infusion of 2–4 mg/min to achieve a therapeutic plasma level of 2–6 $\mu\text{g/mL}$. Determination of lidocaine plasma levels is of great value in adjusting the infusion rate. Occasional patients with myocardial infarction or other acute illness require (and tolerate) higher concentrations. This may be due to increased plasma α_1 -acid glycoprotein, an acute phase reactant protein that binds lidocaine, making less free drug available to exert its pharmacologic effects.

In patients with heart failure, lidocaine's volume of distribution and total body clearance may both be decreased. Thus, both loading and maintenance doses should be decreased. Since these effects counterbalance each other, the half-life may not be increased as much as predicted from clearance changes alone. In patients with liver disease, plasma clearance is markedly reduced and the volume of distribution is often increased; the elimination half-life in such cases may be increased threefold or more. In liver disease, the maintenance dose should be decreased, but usual loading doses can be given. Elimination half-life determines the time to steady state. Thus, while steady-state concentrations may be achieved in 8–10 hours in normal patients and patients with heart failure, 24–36 hours may be required in those with liver disease. Drugs that decrease liver blood flow (eg, propranolol, cimetidine) reduce lidocaine clearance and so increase the risk of toxicity unless infusion rates are decreased. With infusions lasting more than 24 hours, clearance falls and plasma concentrations rise. Renal disease has no major effect on lidocaine disposition.

Therapeutic Use

Lidocaine is the agent of choice for termination of ventricular tachycardia and prevention of ventricular fibrillation after cardioversion in the setting of acute ischemia. However, routine *prophylactic* use of lidocaine in this setting may actually increase total mortality, possibly by increasing the incidence of asystole and is not the standard of care. Most physicians administer lidocaine only to patients with arrhythmias.

Mexiletine (Subgroup 1b)

Mexiletine is a congener of lidocaine that is resistant to first-pass hepatic metabolism and is effective by the oral route. Its electrophysiologic and antiarrhythmic actions are similar to those of lidocaine. (The anticonvulsant phenytoin [see Chapter 24: Antiseizure Drugs] also exerts similar electrophysiologic effects and has been used as an antiarrhythmic.) Mexiletine is used in the treatment of ventricular arrhythmias. The elimination half-life is 8–20 hours and permits administration two or three times a day. The usual daily dosage of mexiletine is 600–1200 mg/d. Dose-related adverse effects are seen frequently at therapeutic dosage. These are predominantly neurologic, including tremor, blurred vision, and lethargy. Nausea is also a common effect.

Mexiletine has also shown significant efficacy in relieving chronic pain, especially pain due to diabetic neuropathy and nerve injury. The usual dosage is 450–750 mg/d orally. This application is unlabeled.

Flecainide (Subgroup 1c)

Flecainide is a potent blocker of sodium and potassium channels with slow unblocking kinetics. (Note that although it does block certain potassium channels, it does not prolong the action potential or the QT interval.) It is currently used for patients with otherwise normal hearts who have supraventricular arrhythmias. It has no antimuscarinic effects.

Flecainide is very effective in suppressing premature ventricular contractions. However, it may cause severe exacerbation of arrhythmia even when normal doses are administered to patients with preexisting ventricular tachyarrhythmias and those with a previous myocardial infarction and ventricular ectopy (see The Cardiac Arrhythmia Suppression Trial). The drug is well absorbed and has a half-life of approximately 20 hours. Elimination is both by hepatic metabolism and by the kidney. The usual dosage of flecainide is 100–200 mg twice a day.

Propafenone (Subgroup 1c)

Propafenone has some structural similarities to propranolol and possesses weak β -blocking activity. Its spectrum of action is very similar to that of quinidine. Its sodium channel blocking kinetics are similar to that of flecainide. Propafenone is metabolized in the liver, with an average elimination of 5–7 hours except in poor metabolizers (7% of whites), in whom it is as much as 17 hours. The usual daily dosage of propafenone is 450–900 mg in three doses. The drug is used primarily for supraventricular arrhythmias. The most common adverse effects are a metallic taste and constipation; arrhythmia exacerbation can occur.

Moricizine (Subgroup 1c)

Moricizine is an antiarrhythmic phenothiazine derivative that is used for treatment of ventricular arrhythmias. It is a relatively potent sodium channel blocker that does not prolong action potential duration.

Moricizine has multiple metabolites, some of which are probably active and have long half-lives. Its most common adverse effects are dizziness and nausea. Like other potent sodium channel blockers, it can exacerbate arrhythmias. The usual dosage of moricizine is 200–300 mg by mouth three times a day.

Beta-Adrenoceptor-Blocking Drugs (Class 2)

Cardiac Effects

Propranolol and similar drugs have antiarrhythmic properties by virtue of their β -receptor–blocking action and direct membrane effects. As described in Chapter 10: Adrenoceptor Antagonist Drugs, some of these drugs have selectivity for cardiac β_1 -receptors; some have intrinsic sympathomimetic activity; some have marked direct membrane effects; and some prolong the cardiac action potential. The relative contributions of the β -blocking and direct membrane effects to the antiarrhythmic effects of these drugs are not fully known. Although β -blockers are fairly well tolerated, their efficacy for suppression of ventricular ectopic depolarizations is lower than that of sodium channel blockers. However, there is good evidence that these agents can prevent recurrent infarction and sudden death in patients recovering from acute myocardial infarction (see Chapter 10: Adrenoceptor Antagonist Drugs).

Esmolol is a short-acting β blocker used primarily as an antiarrhythmic drug for intraoperative and other acute arrhythmias. See Chapter 10: Adrenoceptor Antagonist Drugs for more information. Sotalol is a nonselective β -blocking drug that prolongs the action potential (class 3 action).

Drugs That Prolong Effective Refractory Period by Prolonging Action Potential (Class 3)

These drugs prolong action potentials, usually by blocking potassium channels in cardiac muscle or by enhancing inward current, eg, through sodium channels. Action potential prolongation by most of these drugs often exhibits the undesirable property of "reverse use-dependence": action potential prolongation is least marked at fast rates (where it is desirable) and most marked at slow rates, where it can contribute to the risk of torsade de pointes.

Amiodarone

In the USA, amiodarone is approved for oral and intravenous use to treat serious ventricular arrhythmias. However, the drug is also highly effective for the treatment of supraventricular arrhythmias such as atrial fibrillation. Amiodarone has a broad spectrum of cardiac actions, unusual pharmacokinetics, and important extracardiac side effects.

Cardiac Effects

Amiodarone markedly prolongs the action potential duration (and the QT interval on the ECG) by blockade of I_{Kr} . During chronic administration, I_{Ks} is also blocked. The action potential duration is prolonged uniformly over a wide range of heart rates, ie, the drug does not have reverse use-dependent action. In spite of its present classification as a class 3 agent, amiodarone also significantly blocks inactivated sodium channels. Its action potential prolonging action reinforces this effect. Amiodarone also has weak adrenergic and calcium channel blocking actions. Consequences of these actions include slowing of the heart rate and atrioventricular node conduction. The broad spectrum of actions may account for its relatively high efficacy and low incidence of torsade de pointes despite significant QT interval prolongation.

Extracardiac Effects

Amiodarone causes peripheral vasodilation. This action is prominent following intravenous administration and may be related to the action of the solvent.

Toxicity

Cardiac

Amiodarone may produce symptomatic bradycardia and heart block in patients with preexisting sinus or atrioventricular node disease.

Extracardiac

Amiodarone accumulates in many tissues, including the heart (10–50 times greater than plasma), lung, liver, and skin, and is concentrated in tears. Dose-related pulmonary toxicity is the most important adverse effect. Even on a low dose of \approx 200 mg/d, fatal pulmonary fibrosis may be observed in 1% of patients. Abnormal liver function tests and hepatitis may develop during amiodarone treatment. The skin deposits result in a photodermatitis and a gray-blue skin discoloration in sun-exposed areas, eg, the malar regions. After a few weeks of treatment, asymptomatic corneal microdeposits are present in virtually all patients treated with amiodarone. Halos develop in the peripheral visual fields of some patients. Drug discontinuation is usually not required. Rarely, an optic neuritis may progress to blindness.

Amiodarone blocks the peripheral conversion of thyroxine (T_4) to triiodothyronine (T_3). It is also a potential source of large amounts of inorganic iodine. Amiodarone may result in hypothyroidism or hyperthyroidism. Thyroid function should be evaluated prior to initiation of treatment and monitored periodically. Because effects have been described in virtually every organ system, amiodarone treatment should be reevaluated whenever new symptoms develop in a patient, including arrhythmia aggravation.

Pharmacokinetics

Amiodarone is variably absorbed with a bioavailability of 35–65%. It undergoes hepatic metabolism, and the major metabolite, desethylamiodarone, is bioactive. The elimination half-life is complex, with a rapid component of 3–10 days (50% of the drug) and a slower component of several weeks. Following discontinuation of the drug, effects are maintained for 1–3 months. Measurable tissue levels may be observed up to 1 year after dosing. A total loading dose of 10 g is usually achieved with 0.8–1.2 g daily doses. The maintenance dose is 200–400 mg daily. Pharmacologic effects may be achieved rapidly by IV loading. QT-prolonging effect is modest with this route of administration, whereas bradycardia and atrioventricular block may be significant.

Amiodarone has many important drug interactions and all medications should be reviewed during drug initiation or dose adjustments. Amiodarone is a substrate for the liver cytochrome metabolizing enzyme CYP3A4 and its levels are increased by drugs that inhibit this enzyme, eg, the histamine H_2 blocker cimetidine. Drugs that induce CYP3A4, eg, rifampin, decrease amiodarone concentration when coadministered. Amiodarone inhibits the other liver cytochrome metabolizing enzymes and may result in high levels of drugs that are substrates for these enzymes eg, digoxin and warfarin.

Therapeutic Use

Low doses (100–200 mg/d) of amiodarone are effective in maintaining normal sinus rhythm in

patients with atrial fibrillation. The drug is effective in the prevention of recurrent ventricular tachycardia. Its use is not associated with an increase in mortality in patients with coronary artery disease or heart failure. The implanted cardioverter-defibrillator (ICD) has succeeded drug therapy as the primary treatment modality for ventricular tachycardia, but amiodarone may be used for ventricular tachycardia as adjuvant therapy to decrease the frequency of uncomfortable ICD discharges. The drug increases the pacing and defibrillation threshold and these devices require retesting after a maintenance dose has been achieved.

Bretylium

Bretylium was first introduced as an antihypertensive agent. It interferes with the neuronal release of catecholamines but also has direct antiarrhythmic properties.

Cardiac Effects

Bretylium lengthens the ventricular (but not the atrial) action potential duration and effective refractory period. This effect is most pronounced in ischemic cells, which have shortened action potential durations. Thus, bretylium may reverse the shortening of action potential duration caused by ischemia.

Since bretylium causes an initial release of catecholamines, it has some positive inotropic actions when first administered. This action may also *precipitate* ventricular arrhythmias and must be watched for at the onset of therapy with the drug.

Extracardiac Effects

These result from the drug's sympathoplegic actions. The major adverse effect is postural hypotension. This effect can be almost totally prevented by concomitant administration of a tricyclic antidepressant agent such as protriptyline. Nausea and vomiting may occur after the intravenous administration of a bolus of bretylium.

Pharmacokinetics & Dosage

Bretylium is available only for intravenous use in the USA. In adults, an intravenous bolus of bretylium tosylate, 5 mg/kg, is administered over a 10-minute period. This dosage may be repeated after 30 minutes. Maintenance therapy is achieved by a similar bolus every 4–6 hours or by a constant infusion of 0.5–2 mg/min.

Therapeutic Use

Bretylium is usually used in an emergency setting, often during attempted resuscitation from ventricular fibrillation when lidocaine and cardioversion have failed.

Sotalol

Sotalol has both β -adrenergic receptor-blocking (class 2) and action potential prolonging (class 3) actions. The drug is formulated as a racemic mixture of d- and l-sotalol. All the beta-adrenergic blocking activity resides in the l-isomer; the d- and l-isomers share action potential prolonging actions. Beta-adrenergic action is noncardioselective and is maximal at doses below those required for action potential prolongation.

Sotalol is well absorbed orally with bioavailability of approximately 100%. It is not metabolized in the liver and it is not bound to plasma proteins. Excretion is predominantly by the kidneys in the unchanged form with a half-life of approximately 12 hours. Because of its relatively simple pharmacokinetics, it exhibits few direct drug interactions. Its most significant cardiac adverse effect is an extension of its pharmacologic action: a dose-related incidence of torsade de pointes that approaches 6% at the highest recommended daily dose. Patients with overt heart failure may experience further depression of left ventricular function during treatment with sotalol.

Sotalol is approved for the treatment of life-threatening ventricular arrhythmias and the maintenance of sinus rhythm in patients with atrial fibrillation. It is also approved for treatment of supraventricular and ventricular arrhythmias in the pediatric age group. Sotalol decreases the threshold for cardiac defibrillation.

Dofetilide

Dofetilide has class 3 action potential prolonging action. This action is effected by a dose-dependent blockade of the rapid component of the delayed rectifier potassium current, I_{Kr} . Dofetilide block of I_{Kr} increases in hypokalemia. Dofetilide produces no relevant blockade of the other potassium channels or the sodium channel. Because of the slow rate of recovery from blockade, the extent of blockade shows little dependence on stimulation frequency. However, dofetilide does show less action potential prolongation at rapid rates because of the increased importance of other potassium channels such as I_{Ks} at rapid rates.

Dofetilide is 100% bioavailable. Verapamil increases peak plasma dofetilide concentration by increasing intestinal blood flow. Eighty percent of an oral dose is eliminated by the kidneys unchanged; the remainder is eliminated by the kidneys as inactive metabolites. Inhibitors of the renal cation secretion mechanism, eg, cimetidine, prolong the half-life of dofetilide. Since the QT-prolonging effects and risks of ventricular proarrhythmia are directly related to plasma concentration, dofetilide dose must be based on the estimated creatinine clearance. Treatment with dofetilide should be initiated in hospital after baseline measurement of the QT_C and serum electrolytes. A baseline QT_C of > 450 ms (500 ms in the presence of an intraventricular conduction delay), bradycardia of < 50 beats/min, and hypokalemia are relative contraindications to its use.

Dofetilide is approved for the maintenance of normal sinus rhythm in patients with atrial fibrillation. It is also effective in restoring normal sinus rhythm in patients with atrial fibrillation.

Ibutilide

Ibutilide slows cardiac repolarization by blockade of the rapid component of the delayed rectifier potassium current. Activation of slow inward sodium current has also been suggested as an additional mechanism of action. After intravenous administration, ibutilide is rapidly cleared from the plasma by hepatic metabolism. The metabolites are excreted by the kidney. The elimination half-life averages 6 hours.

Intravenous ibutilide is used for the acute conversion of atrial flutter and atrial fibrillation to normal

sinus rhythm. The drug is more effective in atrial flutter than fibrillation, with a mean time to termination of 20 minutes. The most important adverse effect is excessive QT interval prolongation and torsade de pointes. Patients require continuous ECG monitoring for 4 hours following ibutilide infusion or until QT_C returns to baseline.

Calcium Channel-Blocking Drugs (Class 4)

These drugs, of which verapamil is the prototype, were first introduced as antianginal agents and are discussed in greater detail in Chapter 12: Vasodilators & the Treatment of Angina Pectoris. Verapamil, diltiazem, and bepridil also have antiarrhythmic effects.

Verapamil

Cardiac Effects

Verapamil blocks both activated and inactivated L-type calcium channels. Thus, its effect is more marked in tissues that fire frequently, those that are less completely polarized at rest, and those in which activation depends exclusively on the calcium current, such as the sinoatrial and atrioventricular nodes. Atrioventricular nodal conduction and effective refractory period are invariably prolonged by therapeutic concentrations. Verapamil usually slows the sinoatrial node by its direct action, but its hypotensive action may occasionally result in a small reflex increase of sinoatrial nodal rate.

Verapamil can suppress both early and delayed afterdepolarizations and may antagonize slow responses arising in severely depolarized tissue.

Extracardiac Effects

Verapamil causes peripheral vasodilation, which may be beneficial in hypertension and peripheral vasospastic disorders. Its effects upon smooth muscle produce a number of extracardiac effects (see Chapter 12: Vasodilators & the Treatment of Angina Pectoris).

Toxicity

Cardiac

Verapamil's cardiotoxic effects are dose-related and usually avoidable. A common error has been to administer intravenous verapamil to a patient with ventricular tachycardia misdiagnosed as supraventricular tachycardia. In this setting, hypotension and ventricular fibrillation can occur. Verapamil's negative inotropic effects may limit its clinical usefulness in diseased hearts (see Chapter 12: Vasodilators & the Treatment of Angina Pectoris). Verapamil can lead to atrioventricular block when used in large doses or in patients with atrio-ventricular nodal disease. This block can be treated with atropine and β -receptor stimulants. In patients with sinus node disease, verapamil can precipitate sinus arrest.

Extracardiac

Adverse effects include constipation, lassitude, nervousness, and peripheral edema.

Pharmacokinetics & Dosage

The half-life of verapamil is approximately 7 hours. It is extensively metabolized by the liver; after oral administration, its bioavailability is only about 20%. Therefore, verapamil must be administered with caution in patients with hepatic dysfunction.

In adult patients without heart failure or sinoatrial or atrioventricular nodal disease, parenteral verapamil can be used to terminate supraventricular tachycardia, although adenosine has become the agent of first choice. Verapamil dosage is an initial bolus of 5 mg administered over 2–5 minutes, followed a few minutes later by a second 5 mg bolus if needed. Thereafter, doses of 5–10 mg can be administered every 4–6 hours, or a constant infusion of 0.4 $\mu\text{g}/\text{kg}/\text{min}$ may be used.

Effective oral dosages are higher than with intravenous drug because of first-pass metabolism and range from 120 to 640 mg daily, divided into three or four doses.

Therapeutic Use

Supraventricular tachycardia is the major arrhythmia indication for verapamil. Adenosine or verapamil are preferred over older treatments (propranolol, digoxin, edrophonium, vasoconstrictor agents, and cardioversion) for termination. Verapamil can also reduce the ventricular rate in atrial fibrillation and flutter. It only rarely converts atrial flutter and fibrillation to sinus rhythm. Verapamil is occasionally useful in ventricular arrhythmias. However, the use of intravenous verapamil in a patient with sustained ventricular tachycardia can cause hemodynamic collapse.

Diltiazem & Bepridil

These agents appear to be similar in efficacy to verapamil in the management of supraventricular arrhythmias, including rate control in atrial fibrillation. An intravenous form of diltiazem is available for the latter indication and causes hypotension or bradyarrhythmias relatively infrequently. Bepridil also has action potential- and QT-prolonging actions that theoretically may make it more useful in some ventricular arrhythmias but also create the risk of torsade de pointes. Bepridil is only rarely used, primarily to control refractory angina.

Miscellaneous Antiarrhythmic Agents

Certain agents used for the treatment of arrhythmias do not fit the conventional class 1–4 organization. These include digitalis (already discussed in Chapter 13: Drugs Used in Heart Failure), adenosine, magnesium, and potassium.

Adenosine

Mechanism & Clinical Use

Adenosine is a nucleoside that occurs naturally throughout the body. Its half-life in the blood is less than 10 seconds. Its mechanism of action involves activation of an inward rectifier K^+ current and inhibition of calcium current. The results of these actions are marked hyperpolarization and suppression of calcium-dependent action potentials. When given as a bolus dose, adenosine directly inhibits atrioventricular nodal conduction and increases the atrioventricular nodal refractory period but has lesser effects on sinoatrial node. Adenosine is currently the drug of choice for prompt conversion of paroxysmal supraventricular tachycardia to sinus rhythm because of its high efficacy (90–95%) and very short duration of action. It is usually given in a bolus dose of 6 mg followed, if necessary, by a dose of 12 mg. An uncommon variant of ventricular tachycardia is adenosine sensitive. It is less effective in the presence of adenosine receptor blockers such as theophylline or

caffeine, and its effects are potentiated by adenosine uptake inhibitors such as dipyridamole.

Toxicity

Adenosine causes flushing in about 20% of patients and shortness of breath or chest burning (perhaps related to bronchospasm) in over 10%. Induction of high-grade atrioventricular block may occur but is very short-lived. Atrial fibrillation may occur. Less common toxicities include headache, hypotension, nausea, and paresthesias.

Magnesium

Originally used for patients with digitalis-induced arrhythmias who were hypomagnesemic, magnesium infusion has been found to have antiarrhythmic effects in some patients with normal serum magnesium levels. The mechanisms of these effects are not known, but magnesium is recognized to influence Na^+/K^+ ATPase, sodium channels, certain potassium channels, and calcium channels. Magnesium therapy appears to be indicated in patients with digitalis-induced arrhythmias if hypomagnesemia is present; it is also indicated in some patients with torsade de pointes even if serum magnesium is normal. The usual dosage is 1 g (as sulfate) given intravenously over 20 minutes and repeated once if necessary. A full understanding of the action and indications of magnesium as an antiarrhythmic drug awaits further investigation.

Potassium

The significance of the potassium ion concentrations inside and outside the cardiac cell membrane has been discussed earlier in this chapter. The effects of increasing serum K^+ can be summarized as (1) a resting potential depolarizing action and (2) a membrane potential stabilizing action, caused by increased potassium permeability. Hypokalemia results in an increased risk of early and delayed afterdepolarizations, and ectopic pacemaker activity, especially in the presence of digitalis; hyperkalemia depresses ectopic pacemakers (severe hyperkalemia is required to suppress the sinoatrial node) and slows conduction. Because both insufficient and excess potassium are potentially arrhythmogenic, potassium therapy is directed toward normalizing potassium gradients and pools in the body.

The Cardiac Arrhythmia Suppression Trial

Premature ventricular contractions (PVCs) are commonly recorded in patients convalescing from myocardial infarction. Since such arrhythmias have been associated with an increased risk of sudden cardiac death, it had been the empiric practice of many physicians to treat PVCs, even if asymptomatic, in such patients. In CAST (Cardiac Arrhythmia Suppression Trial [CAST], Echt et al, 1991), an attempt was made to document the efficacy of such therapy in a controlled clinical trial. The effects of several antiarrhythmic drugs on arrhythmia frequency were first evaluated in an open-label fashion. Then, patients in whom antiarrhythmic therapy suppressed PVCs were randomly assigned, in a double-blind fashion, to continue that therapy or its corresponding placebo.

The results showed that mortality among patients treated with the drugs flecainide and encainide (the latter is no longer available) was *increased* more than twofold compared with those treated with placebo. The mechanism underlying this effect is not known, although an interaction between conduction depression by sodium channel block and chronic or acute myocardial ischemia seems likely. Indirect evidence suggests that other sodium channel blockers may produce a similar effect.

Whatever the mechanism, the important lesson reinforced by CAST was that the decision to initiate any form of drug therapy (antiarrhythmic or otherwise) should be predicated on the knowledge (or at least a reasonable assumption) that any risk is outweighed by real or potential benefit. Large trials suggest that amiodarone (unlike flecainide) has a slightly beneficial effect on survival of patients with advanced heart disease, while many studies indicate a prominent beneficial effect of β -blockade.

Katzung PHARMACOLOGY, 9e > Section III. Cardiovascular-Renal Drugs > Chapter 14. Agents Used in Cardiac Arrhythmias >

Principles in the Clinical Use of Antiarrhythmic Agents

The margin between efficacy and toxicity is particularly narrow for antiarrhythmic drugs. Therefore, individuals prescribing antiarrhythmic drugs must be thoroughly familiar with the indications, contraindications, risks, and clinical pharmacologic characteristics of each compound they use.

Pretreatment Evaluation

Several important determinations must be made prior to initiation of any antiarrhythmic therapy:

(1) Precipitating factors must be recognized and eliminated if possible. These include not only abnormalities of internal homeostasis, such as hypoxia or electrolyte abnormalities (especially hypokalemia or hypomagnesemia), but also drug therapy and underlying disease states such as hyperthyroidism or underlying cardiac disease. It is important to separate this abnormal substrate from triggering factors, such as myocardial ischemia or acute cardiac dilation, which may be treatable and reversible.

(2) A firm arrhythmia diagnosis should be established. For example, the misuse of verapamil in patients with ventricular tachycardia mistakenly diagnosed as supraventricular tachycardia can lead to catastrophic hypotension and cardiac arrest. As increasingly sophisticated methods to characterize underlying arrhythmia mechanisms become available and are validated, it may be possible to direct certain drugs (or other therapies—see The Nonpharmacologic Therapy of Cardiac Arrhythmias) toward specific arrhythmia mechanisms.

(3) It is important to establish a reliable baseline upon which to judge the efficacy of any subsequent antiarrhythmic intervention. A number of methods are now available for such baseline quantitation. These include prolonged ambulatory monitoring, electrophysiologic studies that reproduce a target arrhythmia, reproduction of a target arrhythmia by treadmill exercise, or the use of transtelephonic monitoring for recording of sporadic but symptomatic arrhythmias.

(4) The mere identification of an abnormality of cardiac rhythm does not necessarily require that the arrhythmia be treated. An excellent justification for conservative treatment was provided by the Cardiac Arrhythmia Suppression Trial (CAST) referred to earlier.

Benefits & Risks

The benefits of antiarrhythmic therapy are actually relatively difficult to establish. Two types of benefits can be envisioned: reduction of arrhythmia-related symptoms, such as palpitations, syncope, or cardiac arrest; or reduction in long-term mortality in asymptomatic patients. Among drugs discussed here, only β -blockers have been definitely associated with reduction of mortality in

relatively asymptomatic patients, and the mechanism underlying this effect is not established (see Chapter 10: Adrenoceptor Antagonist Drugs).

Antiarrhythmic therapy carries with it a number of risks. In some cases, the risk of an adverse reaction is clearly related to high dosages or plasma concentrations. Examples include lidocaine-induced tremor or quinidine-induced cinchonism. In other cases, adverse reactions are unrelated to high plasma concentrations (eg, procainamide-induced agranulocytosis). For many serious adverse reactions to antiarrhythmic drugs, the *combination* of drug therapy and the underlying heart disease appears important.

Several specific syndromes of arrhythmia provocation by antiarrhythmic drugs have also been identified, each with its underlying pathophysiologic mechanism and risk factors. Drugs such as quinidine, sotalol, ibutilide, and dofetilide, which act—at least in part—by slowing repolarization and prolonging cardiac action potentials, can result in marked QT prolongation and torsade de pointes. Treatment of torsade de pointes requires recognition of the arrhythmia, withdrawal of any offending agent, correction of hypokalemia, and treatment with maneuvers to increase heart rate (pacing or isoproterenol); intravenous magnesium also appears effective, even in patients with normal magnesium levels.

Drugs that markedly slow conduction, such as flecainide, or high concentrations of quinidine, can result in an increased frequency of reentry arrhythmias, notably ventricular tachycardia in patients with prior myocardial infarction in whom a potential reentry circuit may be present. Treatment here consists of recognition, withdrawal of the offending agent, and intravenous sodium. Some patients with this form of arrhythmia aggravation cannot be resuscitated, and deaths have been reported.

Conduct of Antiarrhythmic Therapy

The urgency of the clinical situation determines the route and rate of drug initiation. When immediate drug action is required, the intravenous route is preferred. Therapeutic drug levels can be achieved by administration of multiple intravenous boluses. Drug therapy can be considered effective when the target arrhythmia is suppressed (according to the measure used to quantify at baseline) and toxicities are absent. Conversely, drug therapy should not be considered ineffective unless toxicities occur at a time when arrhythmias are not suppressed. Occasionally, arrhythmias may recur at a time when plasma drug concentrations are relatively high but toxicities have not recurred. Under these conditions, the prescriber must decide whether a judicious increase in dose might suppress the arrhythmia and still leave the patient free of toxicity.

Monitoring plasma drug concentrations can be a useful adjunct to managing antiarrhythmic therapy. Plasma drug concentrations are also important in establishing compliance during long-term therapy as well as in detecting drug interactions that may result in very high concentrations at low drug dosages or very low concentrations at high dosages.

Agents Used in Cardiac Arrhythmias >

The Nonpharmacologic Therapy of Cardiac Arrhythmias

It was recognized at the start of the 20th century that reentry in simple in vitro models (eg, rings of conducting tissues) was permanently interrupted by transecting the reentry circuit. This concept has now been applied to treat clinical arrhythmias that occur as a result of reentry in anatomically delineated pathways. For example, interruption of accessory atrio-ventricular connections can permanently cure arrhythmias in patients with the Wolff-Parkinson-White syndrome. Such

interruption was originally performed at open heart surgery but is now readily accomplished by delivery of radiofrequency energy through an appropriately positioned intracardiac catheter. Since the procedure carries only minimal morbidity, it is being increasingly applied to other reentry arrhythmias with defined pathways, such as atrioventricular nodal reentry, atrial flutter, and some forms of ventricular tachycardia.

Another form of nonpharmacologic therapy is the implantable cardioverter-defibrillator (ICD), a device that can automatically detect and treat potentially fatal arrhythmias such as ventricular fibrillation. ICDs are now widely used in patients who have been resuscitated from such arrhythmias, and several trials have suggested that they should be used in patients with advanced heart disease who have not yet had such arrhythmias but are judged to be at high risk. The increasing use of nonpharmacologic antiarrhythmic therapies reflects both advances in the relevant technologies and an increasing appreciation of the dangers of long-term therapy with currently available drugs.

Agents Used in Cardiac Arrhythmias >

Preparations Available

Sodium Channel Blockers

Disopyramide (generic, Norpace)

Oral: 100, 150 mg capsules

Oral controlled-release (generic, Norpace CR): 100, 150 capsules

Flecainide (Tambocor)

Oral: 50, 100, 150 mg tablets

Lidocaine (generic, Xylocaine)

Parenteral: 100 mg/mL for IM injection; 10, 20 mg/mL for IV injection; 40, 100, 200 mg/mL for IV admixtures; 2, 4, 8 mg/mL premixed IV (5% D/W) solution

Mexiletine (Mexitil)

Oral: 150, 200, 250 mg capsules

Moricizine (Ethmozine)

Oral: 200, 250, 300 mg tablets

Procainamide (generic, Pronestyl, others)

Oral: 250, 375, 500 mg tablets and capsules

Oral sustained-release (generic, Procan-SR): 250, 500, 750, 1000 mg tablets

Parenteral: 100, 500 mg/mL for injection

Propafenone (Rythmol)

Oral: 150, 225, 300 mg tablets

Quinidine sulfate [83% quinidine base] (generic)

Oral: 200, 300 mg tablets

Oral sustained-release (Quinidex Extentabs): 300 mg tablets

Quinidine gluconate [62% quinidine base] (generic)

Oral sustained-release: 324 mg tablets

Parenteral: 80 mg/mL for injection

Quinidine polygalacturonate [60% quinidine base] (Cardioquin)

Oral: 275 mg tablets

β-Blockers Labeled for Use As Antiarrhythmics

Acebutolol (generic, Sectral)

Oral: 200, 400 mg capsules

Esmolol (Brevibloc)

Parenteral: 10 mg/mL, 250 mg/mL for IV injection

Propranolol (generic, Inderal)

Oral: 10, 20, 40, 60, 80, 90 mg tablets

Oral sustained-release: 60, 80, 120, 160 mg capsules

Oral solution: 4, 8 mg/mL

Parenteral: 1 mg/mL for injection

Action Potential-Prolonging Agents

Amiodarone (Cordarone)

Oral: 200, 400 mg tablets

Parenteral: 150 mg/3 mL for intravenous infusion

Bretylum (generic)

Parenteral: 2, 4, 50 mg/mL for injection

Dofetilide (Tikosyn)

Oral: 125, 250, 500 µg capsules

Ibutilide (Corvert)

Parenteral: 0.1 g/mL solution for IV infusion

Sotalol (generic, Betapace)

Oral: 80, 120, 160, 240 mg capsules

Calcium Channel Blockers

Bepridil (Vasacor; *not labeled for use in arrhythmias*)

Oral: 200, 300 mg tablets

Diltiazem (generic, Cardizem, Dilacor)

Oral: 30, 60, 90, 120 mg tablets; 60, 90, 120, 180, 240, 300, 340, 420 mg extended- or sustained-release capsules (*not labeled for use in arrhythmias*)

Parenteral: 5 mg/mL for intravenous injection

Verapamil (generic, Calan, Isoptin)

Oral: 40, 80, 120 mg tablets;

Oral sustained-release (Calan SR, Isoptin SR): 100, 120, 180, 240 mg capsules

Parenteral: 5 mg/2 mL for injection

Miscellaneous

Adenosine (Adenocard)

Parenteral: 3 mg/mL for injection

Magnesium sulfate

Parenteral: 125, 500 mg/mL for intravenous infusion

Chapter 15. Diuretic Agents

Katzung PHARMACOLOGY, 9e > Section III. Cardiovascular-Renal Drugs > Chapter 15.
Diuretic Agents >

Diuretic Agents: Introduction

Abnormalities in fluid volume and electrolyte composition are common and important clinical problems. Drugs that block the transport functions of the renal tubules are valuable clinical tools in the treatment of these disorders. Although various agents that increase urine flow have been described since antiquity, it was not until 1957 that a practical and powerful diuretic agent (chlorothiazide) became available for widespread use. Technically, the term "diuresis" signifies an increase in urine volume, while "natriuresis" denotes an increase in renal sodium excretion. Because natriuretic drugs almost always also increase water excretion, they are usually called diuretics.

Many diuretic agents (loop diuretics, thiazides, amiloride, and triamterene) exert their effects on specific membrane transport proteins in renal tubular epithelial cells. Other diuretics exert osmotic effects that prevent water reabsorption (mannitol), inhibit enzymes (acetazolamide), or interfere with hormone receptors in renal epithelial cells (spironolactone).

Most diuretics act upon a single anatomic segment of the nephron (Figure 15–1). Because these segments have distinctive transport functions, the first section of this chapter is devoted to a review of those features of renal tubule physiology that are relevant to diuretic action. The second section is devoted to the basic pharmacology of diuretics, and the third section discusses the clinical applications of these drugs.

Figure 15–1.

Katzung PHARMACOLOGY, 9e > Section III. Cardiovascular-Renal Drugs > Chapter 15. Diuretic Agents >

Renal Tubule Transport Mechanisms

Proximal Tubule

Sodium bicarbonate, sodium chloride, glucose, amino acids, and other organic solutes are reabsorbed via specific transport systems in the early proximal tubule. Water is reabsorbed passively so as to maintain nearly constant osmolality of proximal tubular fluid. As tubule fluid is processed along the length of the proximal tubule, the luminal concentrations of the solutes decrease relative to the concentration of inulin, an experimental marker that is neither secreted nor absorbed by renal tubules (Figure 15–2). Approximately 85% of the filtered sodium bicarbonate, 40% of the sodium chloride, 60% of the water, and virtually all of the filtered organic solutes are reabsorbed in the proximal tubule.

Figure 15-2.

Reabsorption of various solutes in the proximal tubule in relation to tubule length. (TF/P, tubular fluid to plasma concentration ratio; PD, potential difference across the tubule.) (Reproduced, with permission, from Ganong WF: *Review of Medical Physiology*, 17th ed. Lange, 1993.)

Of the various solutes reabsorbed in the proximal tubule, the most relevant to diuretic action are sodium bicarbonate and sodium chloride. Of the currently available diuretics, only one group (carbonic anhydrase inhibitors, which block NaHCO_3 reabsorption) acts predominantly in the proximal tubule. In view of the large quantity of sodium chloride absorbed in the proximal tubule, a drug that specifically blocked reabsorption of this salt at this site might be a particularly powerful diuretic agent. No such drug is currently available.

Sodium bicarbonate reabsorption by the proximal tubule is initiated by the action of a Na^+/H^+ exchanger located in the luminal membrane of the proximal tubule epithelial cell (Figure 15-3). This transport system allows sodium to enter the cell from the tubular lumen in exchange for a proton from inside the cell. As in all portions of the nephron, Na^+/K^+ ATPase in the basolateral

membrane pumps the reabsorbed Na^+ into the interstitium so as to maintain the normal intracellular concentration of this ion. Protons secreted into the lumen combine with bicarbonate to form carbonic acid, H_2CO_3 . Carbonic acid is rapidly dehydrated to CO_2 and H_2O by carbonic anhydrase. CO_2 produced by dehydration of H_2CO_3 enters the proximal tubule cell by simple diffusion where it is then rehydrated back to H_2CO_3 . After dissociation of H_2CO_3 , the H^+ is available for transport by the Na^+/H^+ exchanger, and the bicarbonate is transported out of the cell by a basolateral membrane transporter (Figure 15–3). Bicarbonate reabsorption by the proximal tubule is thus dependent on carbonic anhydrase. This enzyme can be inhibited by acetazolamide and related agents.

Figure 15–3.

Apical membrane Na^+/H^+ exchange and bicarbonate reabsorption in the proximal convoluted tubule cell. Na^+/K^+ ATPase is present in the basolateral membrane to maintain intracellular sodium and potassium levels within the normal range. Because of rapid equilibration, concentrations of the solutes shown are approximately equal in the interstitial fluid and the blood. Carbonic anhydrase (CA) is found in other locations in addition to the brush border of the luminal membrane.

In the late proximal tubule, as bicarbonate and organic solutes have been largely removed from the tubular fluid, the residual luminal fluid contains predominantly NaCl . Under these conditions, Na^+ reabsorption continues, but the protons secreted by the Na^+/H^+ exchanger can no longer bind to bicarbonate. Free H^+ causes luminal pH to fall, activating a still poorly defined Cl^-/base exchanger (Figure 15–3). The net effect of parallel Na^+/H^+ exchange and Cl^-/base exchange is NaCl reabsorption. As yet, there are no diuretic agents that are known to act on this conjoint process.

Because of the high water permeability of the proximal tubule, water is reabsorbed in direct proportion to salt reabsorption in this segment. Thus, luminal fluid osmolality and sodium concentration remain nearly constant along the length of the proximal tubule (Figure 15–2). An experimental impermeant solute like inulin will rise in concentration as water is reabsorbed (Figure 15–2). If large amounts of an impermeant solute such as mannitol are present in the tubular fluid,

water reabsorption will cause the concentration of the solute to rise to a point at which further water reabsorption is prevented. This is the mechanism by which osmotic diuretics act (see below).

Organic acid secretory systems are located in the middle third of the proximal tubule (S_2 segment). These systems secrete a variety of organic acids (uric acid, nonsteroidal anti-inflammatory drugs NSAIDs, diuretics, antibiotics, etc) into the luminal fluid from the blood. These systems thus help deliver diuretics to the luminal side of the tubule, where most of them act. Organic base secretory systems (creatinine, choline, etc) are also present, in the early (S_1) and middle (S_2) segments of the proximal tubule.

Loop of Henle

At the boundary between the inner and outer stripes of the outer medulla, the thin limb of Henle's loop begins. Water is extracted from the thin descending limb of the loop of Henle by osmotic forces created in the hypertonic medullary interstitium. As in the proximal tubule, impermeant luminal solutes such as mannitol oppose water extraction.

The thick ascending limb of the loop of Henle actively reabsorbs NaCl from the lumen (about 35% of the filtered sodium), but unlike the proximal tubule and the thin limb, it is nearly impermeable to water. Salt reabsorption in the thick ascending limb therefore dilutes the tubular fluid, leading to its designation as a "diluting segment." Medullary portions of the thick ascending limb contribute to medullary hypertonicity and thereby also play an important role in concentration of urine.

The NaCl transport system in the luminal membrane of the thick ascending limb is a $\text{Na}^+/\text{K}^+/2\text{Cl}^-$ cotransporter (Figure 15–4). This transporter is selectively blocked by diuretic agents known as "loop" diuretics (see below). Although the $\text{Na}^+/\text{K}^+/2\text{Cl}^-$ transporter is itself electrically neutral (two cations and two anions are cotransported), the action of the transporter contributes to excess K^+ accumulation within the cell. This results in back diffusion of K^+ into the tubular lumen and development of a lumen-positive electrical potential. This electrical potential provides the driving force for reabsorption of cations—including Mg^{2+} and Ca^{2+} —via the paracellular pathway (between the cells). Thus, inhibition of salt transport in the thick ascending limb by loop diuretics causes an increase in urinary excretion of divalent cations in addition to NaCl.

Figure 15–4.

Ion transport pathways across the luminal and basolateral membranes of the thick ascending limb cell. The lumen positive electrical potential created by K^+ back diffusion drives divalent cation reabsorption via the paracellular pathway.

Distal Convoluted Tubule

Only about 10% of the filtered NaCl is reabsorbed in the distal convoluted tubule. Like the thick ascending limb, this segment is relatively impermeable to water, and the NaCl reabsorption therefore further dilutes the tubular fluid. The mechanism of NaCl transport in the distal convoluted tubule is electrically neutral Na^+ and Cl^- cotransport (Figure 15–5). This NaCl transporter is blocked by diuretics of the thiazide class.

Figure 15–5.

Ion transport pathways across the luminal and basolateral membranes of the distal convoluted tubule cell. As in all tubular cells, Na^+/K^+ ATPase is present in the basolateral membrane. (R, PTH receptor.)

Because K^+ does not recycle across the apical membrane of the distal convoluted tubule as it does in the loop of Henle, there is no lumen-positive potential in this segment, and Ca^{2+} and Mg^{2+} are not driven out of the tubular lumen by electrical forces. However, Ca^{2+} is actively reabsorbed by the distal convoluted tubule epithelial cell via an apical Ca^{2+} channel and basolateral Na^+/Ca^{2+} exchanger (Figure 15–5). This process is regulated by parathyroid hormone. As will be seen below, the differences in the mechanism of Ca^{2+} transport in the distal convoluted tubule and in the loop of Henle have important implications for the effects of various diuretics on Ca^{2+} transport.

Collecting Tubule

The collecting tubule is responsible for only 2–5% of NaCl reabsorption by the kidney. Despite this small contribution, the collecting tubule plays an important role in renal physiology and in diuretic action. As the final site of NaCl reabsorption, the collecting tubule is responsible for volume regulation and for determining the final Na^+ concentration of the urine. Furthermore, the collecting tubule is a site at which mineralocorticoids exert a significant influence. Lastly, the collecting tubule is the major site of potassium secretion by the kidney and the site at which virtually all diuretic-induced changes in potassium balance occur.

The mechanism of NaCl reabsorption in the collecting tubule is distinct from the mechanisms found in other tubule segments. The **principal cells** are the major sites of Na^+ , K^+ , and H_2O transport (Figure 15–6), and the **intercalated cells** are the primary sites of proton secretion. Unlike cells in other nephron segments, the principal cells do not contain cotransport systems for Na^+ and other ions in their apical membranes. Rather, principal cell membranes exhibit separate ion channels for Na^+ and K^+ . Since these channels exclude anions, transport of Na^+ or K^+ leads to a net movement of charge across the membrane. Because the driving force for Na^+ entry into the principal cell greatly exceeds that for K^+ exit, Na^+ reabsorption predominates, and a 10–50 mV lumen-negative electrical potential develops. Na^+ that enters the principal cell from the urine is then transported back to the blood via the basolateral Na^+/K^+ ATPase (Figure 15–6). The lumen-negative electrical potential drives the transport of Cl^- back to the blood via the paracellular pathway and also pulls K^+ out of the cell through the apical membrane K^+ channel. Thus, there is an important relationship between Na^+ delivery to the collecting tubule and the resulting secretion of K^+ . Diuretics that act upstream of the collecting tubule will increase Na^+ delivery to this site and will enhance K^+ secretion. If the Na^+ is delivered with an anion which cannot be reabsorbed as readily as Cl^- (eg, bicarbonate), the lumen-negative potential is increased, and K^+ secretion will be enhanced. This mechanism, combined with enhanced aldosterone secretion due to volume depletion, is the basis for most diuretic-induced K^+ wasting.

Figure 15–6.

Ion and H_2O transport pathways across the luminal and basolateral membranes of collecting tubule and collecting duct cells. Inward diffusion of Na^+ leaves a lumen-negative potential, which drives reabsorption of Cl^- and efflux of K^+ . (R, aldosterone or ADH receptor.)

Reabsorption of Na^+ via the epithelial Na channel (ENaC) and its coupled secretion of K^+ is regulated by aldosterone. This steroid hormone, through its actions on gene transcription, increases the activity of both apical membrane channels and the basolateral Na^+/K^+ ATPase. This leads to an increase in the transepithelial electrical potential and a dramatic increase in both Na^+ reabsorption and K^+ secretion.

A key determinant of the final urine concentration is antidiuretic hormone (ADH; also called vasopressin). In the absence of ADH, the collecting tubule (and duct) is impermeable to water, and dilute urine is produced. However, membrane water permeability of principal cells can be increased by ADH-induced fusion of vesicles containing preformed water channels with the apical membranes (Figure 15–6). ADH secretion is regulated by serum osmolality and by volume status.

Katzung PHARMACOLOGY, 9e > Section III. Cardiovascular-Renal Drugs > Chapter 15. Diuretic Agents >

Basic Pharmacology of Diuretic Agents

Carbonic Anhydrase Inhibitors

Carbonic anhydrase is present in many nephron sites, but the predominant location of this enzyme is the luminal membrane of the proximal tubule cells (Figure 15–3), where it catalyzes the dehydration of H_2CO_3 , a critical step in the reabsorption of bicarbonate. By blocking carbonic

anhydrase, inhibitors block sodium bicarbonate reabsorption and cause diuresis.

The carbonic anhydrase inhibitors were the forerunners of modern diuretics. They are unsubstituted sulfonamide derivatives and were discovered when it was found that bacteriostatic sulfonamides caused an alkaline diuresis and hyperchloremic metabolic acidosis. With the development of newer agents, carbonic anhydrase inhibitors are now rarely used as diuretics, but they still have several specific applications that are discussed below. The prototypical carbonic anhydrase inhibitor is **acetazolamide**.

Pharmacokinetics

The carbonic anhydrase inhibitors are well absorbed after oral administration. An increase in urine pH from the bicarbonate diuresis is apparent within 30 minutes, maximal at 2 hours, and persists for 12 hours after a single dose. Excretion of the drug is by secretion in the proximal tubule S₂ segment. Therefore, dosing must be reduced in renal insufficiency.

Pharmacodynamics

Inhibition of carbonic anhydrase activity profoundly depresses bicarbonate reabsorption in the proximal tubule. At its maximal safely administered dosage, 85% of the bicarbonate reabsorptive capacity of the superficial proximal tubule is inhibited. Some bicarbonate can still be absorbed at other nephron sites by carbonic anhydrase-independent mechanisms, and the overall effect of maximal acetazolamide dosage is about 45% inhibition of whole kidney bicarbonate reabsorption. Nevertheless, carbonic anhydrase inhibition causes significant bicarbonate losses and hyperchloremic metabolic acidosis. Because of this and the fact that HCO₃⁻ depletion leads to enhanced NaCl reabsorption by the remainder of the nephron, the diuretic efficacy of acetazolamide decreases significantly with use over several days.

The major clinical applications of acetazolamide involve carbonic anhydrase-dependent bicarbonate transport at sites other than the kidney. The ciliary body of the eye secretes bicarbonate from the blood into the aqueous humor. Likewise, formation of cerebrospinal fluid by the choroid plexus involves bicarbonate secretion into the cerebrospinal fluid. Although these processes remove bicarbonate from the blood (the direction opposite to that in the proximal tubule), they are significantly inhibited by carbonic anhydrase inhibitors, which in both cases dramatically alter the pH and quantity of fluid produced.

Clinical Indications & Dosage

See Table 15–1.

Drug	Usual Oral Dose (1–4 Times Daily)
Acetazolamide	250 mg
Dichlorphenamide	50 mg
Methazolamide	50 mg

Glaucoma

The reduction of aqueous humor formation by carbonic anhydrase inhibitors decreases the intraocular pressure. This effect is valuable in the management of severe forms of glaucoma, making it the most common indication for use of carbonic anhydrase inhibitors. Topically active carbonic anhydrase inhibitors (dorzolamide, brinzolamide) are also available. These topical compounds reduce intraocular pressure, but plasma levels are undetectable. Thus, diuretic and systemic metabolic effects are eliminated.

Urinary Alkalinization

Uric acid, cystine, and some other weak acids are relatively insoluble in, and easily reabsorbed from, acidic urine. Renal excretion of these compounds can be enhanced by increasing urinary pH with carbonic anhydrase inhibitors. In the absence of continuous bicarbonate administration, these effects of acetazolamide are of relatively short duration (2–3 days). Prolonged therapy requires bicarbonate administration.

Metabolic Alkalosis

Metabolic alkalosis is generally treated by correction of abnormalities in total body K^+ , intravascular volume, or mineralocorticoid levels.

However, when the alkalosis is due to excessive use of diuretics in patients with severe heart failure, saline administration may be contraindicated. In these cases, acetazolamide can be useful in correcting the alkalosis as well as producing a small additional diuresis for the correction of heart failure. Acetazolamide has also been used to rapidly correct the metabolic alkalosis that may develop in the setting of respiratory acidosis.

Acute Mountain Sickness

Weakness, dizziness, insomnia, headache, and nausea can occur in mountain travelers who rapidly ascend above 3000 m. The symptoms are usually mild and last for a few days. In more serious cases, rapidly progressing pulmonary or cerebral edema can be life-threatening. By decreasing cerebrospinal fluid formation and by decreasing the pH of the cerebrospinal fluid and brain, acetazolamide can enhance performance status and diminish symptoms of mountain sickness.

Other Uses

Carbonic anhydrase inhibitors have been used as adjuvants for the treatment of epilepsy, in some forms of hypokalemic periodic paralysis, and to increase urinary phosphate excretion during severe hyperphosphatemia.

Toxicity

Hyperchloremic Metabolic Acidosis

Acidosis predictably results from chronic reduction of body bicarbonate stores by carbonic anhydrase inhibitors and limits the diuretic efficacy of these drugs to 2 or 3 days.

Renal Stones

Phosphaturia and hypercalciuria occur during the bicarbonaturic response to inhibitors of carbonic anhydrase. Renal excretion of solubilizing factors (eg, citrate) may also decline with chronic use. Calcium salts are relatively insoluble at alkaline pH, which means that the potential for renal stone formation from these salts is enhanced.

Renal Potassium Wasting

Potassium wasting can occur because NaHCO_3 presented to the collecting tubule increases the lumen-negative electrical potential in that segment and enhances K^+ secretion. This effect can be counteracted by simultaneous administration of KCl .

Other Toxicities

Drowsiness and paresthesias are common following large doses. Carbonic anhydrase inhibitors may accumulate in patients with renal failure, leading to nervous system toxicity. Hypersensitivity reactions (fever, rashes, bone marrow suppression, and interstitial nephritis) may also occur.

Contraindications

Carbonic anhydrase inhibitor-induced alkalinization of the urine will decrease urinary excretion of NH_4^+ and may contribute to the development of hyperammonemia and hepatic encephalopathy in patients with cirrhosis.

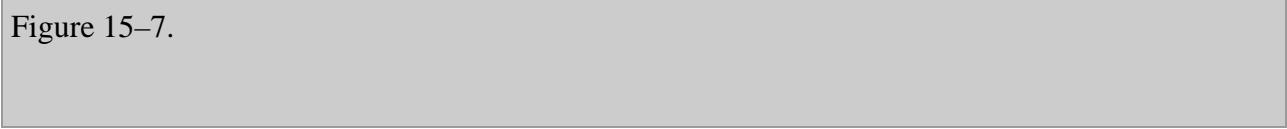

Loop Diuretics

Loop diuretics selectively inhibit NaCl reabsorption in the thick ascending limb of the loop of Henle. Due to the large NaCl absorptive capacity of this segment and the fact that diuresis is not limited by development of acidosis, as it is with the carbonic anhydrase inhibitors, these drugs are the most efficacious diuretic agents available.

Chemistry

The two prototypical drugs of this group are **furosemide** and **ethacrynic acid**. The structures of several loop diuretics are shown in Figure 15–7. Like the carbonic anhydrase inhibitors, furosemide, bumetanide, and torsemide are sulfonamide derivatives.

Figure 15–7.

Furosemide

Bumetanide

Ethacrynic acid

Some loop diuretics. The shaded methylene group on ethacrynic acid is reactive and may combine with free sulfhydryl groups.

Ethacrynic acid—not a sulfonamide derivative—is a phenoxyacetic acid derivative containing an adjacent ketone and methylene group (Figure 15–7). The methylene group (shaded) forms an adduct with the free sulfhydryl group of cysteine. The cysteine adduct appears to be an active form of the drug.

Organic **mercurial diuretics** also inhibit salt transport in the thick ascending limb but are no longer used because of their high toxicity.

Pharmacokinetics

The loop diuretics are rapidly absorbed. They are eliminated by tubular secretion as well as by glomerular filtration. Absorption of oral torsemide is more rapid (1 hour) than that of furosemide (2–3 hours) and is nearly as complete as with intravenous administration. Diuretic response is extremely rapid following intravenous injection. The duration of effect for furosemide is usually 2–3 hours and that of torsemide is 4–6 hours. Half-life depends on renal function. Since loop agents act on the luminal side of the tubule, their diuretic activity correlates with their secretion by the proximal tubule. Reduction in the secretion of loop diuretics may result from simultaneous administration of agents such as NSAIDs or probenecid, which compete for weak acid secretion in the proximal tubule. Metabolites of ethacrynic acid and furosemide have been identified, but it is not known if they have any diuretic activity. Torsemide has at least one active metabolite with a

half-life considerably longer than that of the parent compound.

Pharmacodynamics

These drugs inhibit the luminal $\text{Na}^+/\text{K}^+/\text{2Cl}^-$ transporter in the thick ascending limb of Henle's loop. By inhibiting this transporter, the loop diuretics reduce the reabsorption of NaCl and also diminish the lumen-positive potential that derives from K^+ recycling (Figure 15–4). This electrical potential normally drives divalent cation reabsorption in the loop, and by reducing this potential, loop diuretics cause an increase in Mg^{2+} and Ca^{2+} excretion. Prolonged use can cause significant hypomagnesemia in some patients. Since Ca^{2+} is actively reabsorbed in the distal convoluted tubule, loop diuretics do not generally cause hypocalcemia. However, in disorders that cause hypercalcemia, Ca^{2+} excretion can be greatly enhanced by combining loop agents with saline infusions.

Loop diuretics induce renal prostaglandin synthesis, and these prostaglandins participate in the renal actions of these drugs. NSAIDs (eg, indomethacin) can interfere with the actions of the loop diuretics by reducing prostaglandin synthesis in the kidney. This interference is minimal in otherwise normal subjects but may be significant in patients with nephrotic syndrome or hepatic cirrhosis.

In addition to their diuretic activity, loop agents appear to have direct effects on blood flow through several vascular beds. Furosemide increases renal blood flow. Furosemide and ethacrynic acid have also been shown to reduce pulmonary congestion and left ventricular filling pressures in heart failure before a measurable increase in urinary output occurs, and in anephric patients.

Clinical Indications & Dosage

The most important indications for the use of the loop diuretics include acute pulmonary edema, other edematous conditions, and acute hypercalcemia (Table 15–2). The use of loop diuretics in these conditions is discussed in Clinical Pharmacology. Other indications for loop diuretics include hyperkalemia, acute renal failure, and anion disease.

Table 15–2. Loop Diuretics: Dosages.

Drug	Daily Oral Dose ¹
Bumetanide	0.5–2 mg
Ethacrynic acid	50–200 mg
Furosemide	20–80 mg
Torsemide	2.5–20 mg

¹As single dose or in two divided doses.

Hyperkalemia

In mild hyperkalemia—or after acute management of severe hyperkalemia by other measures—loop diuretics can significantly enhance urinary excretion of K^+ . This response is enhanced by

simultaneous NaCl and water administration.

Acute Renal Failure

Loop agents can increase the rate of urine flow and enhance K^+ excretion in acute renal failure. However, they do not seem to shorten the duration of renal failure. If a large pigment load has precipitated acute renal failure or threatens to do so, loop agents may help flush out intratubular casts and ameliorate intratubular obstruction. On the other hand, loop agents can theoretically worsen cast formation in myeloma and light chain nephropathy.

Anion Overdose

Loop diuretics are useful in treating toxic ingestions of bromide, fluoride, and iodide, which are reabsorbed in the thick ascending limb. Saline solution must be administered to replace urinary losses of Na^+ and to provide Cl^- , so as to avoid extracellular fluid volume depletion.

Toxicity

Hypokalemic Metabolic Alkalosis

Loop diuretics increase delivery of salt and water to the collecting duct and thus enhance the renal secretion of K^+ and H^+ , causing hypokalemic metabolic alkalosis. This toxicity is a function of the magnitude of the diuretic effect and can be reversed by K^+ replacement and correction of hypovolemia.

Ototoxicity

Loop diuretics can cause dose-related hearing loss that is usually reversible. It is most common in patients who have diminished renal function or who are also receiving other ototoxic agents such as aminoglycoside antibiotics.

Hyperuricemia

Loop diuretics can cause hyperuricemia and precipitate attacks of gout. This is caused by hypovolemia-associated enhancement of uric acid reabsorption in the proximal tubule. It may be avoided by using lower doses.

Hypomagnesemia

Magnesium depletion is a predictable consequence of the chronic use of loop agents and occurs most often in patients with dietary magnesium deficiency. It can be reversed by administration of oral magnesium preparations.

Allergic Reactions

Skin rash, eosinophilia and, less often, interstitial nephritis are occasional side effects of furosemide, bumetanide, and torsemide therapy. These usually resolve rapidly after drug withdrawal. Allergic reactions are much less common with ethacrynic acid.

Other Toxicities

Even more than other diuretics, loop agents can cause severe dehydration. Hyponatremia is less common than with the thiazides (see below), but patients who increase water intake in response to hypovolemia-induced thirst can become severely hyponatremic with loop agents. Loop agents are known for their calciuric effect, but hypercalcemia can occur in patients who have another—previously occult—cause for hypercalcemia, such as an oat cell carcinoma of the lung if they become severely volume-depleted.

Contraindications

Furosemide, bumetanide, and torsemide may demonstrate cross-reactivity in patients who are sensitive to other sulfonamides. Overzealous use of any diuretic is dangerous in hepatic cirrhosis, borderline renal failure, or heart failure (see below).

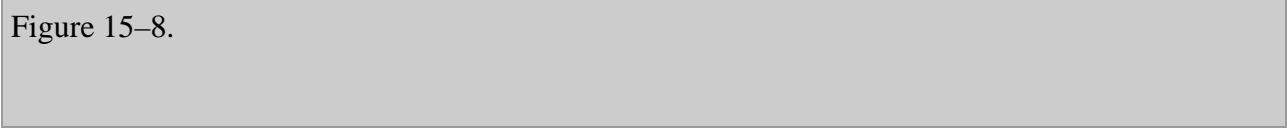

Thiazides

The thiazide diuretics emerged from efforts to synthesize more potent carbonic anhydrase inhibitors. It subsequently became clear that the thiazides inhibit NaCl transport predominantly in the distal convoluted tubule. However, some members of this group retain significant carbonic anhydrase inhibitory activity. The prototypical thiazide is **hydrochlorothiazide**.

Chemistry & Pharmacokinetics

Similar to the carbonic anhydrase inhibitors, all of the thiazides have an unsubstituted sulfonamide group (Figure 15–8).

Figure 15–8.

All of the thiazides can be administered orally, but there are differences in their metabolism. Chlorothiazide, the parent of the group, is not very lipid-soluble and must be given in relatively large doses. It is the only thiazide available for parenteral administration. Chlorthalidone is slowly absorbed and has a longer duration of action. Although indapamide is excreted primarily by the biliary system, enough of the active form is cleared by the kidney to exert its diuretic effect in the distal convoluted tubule.

All of the thiazides are secreted by the organic acid secretory system in the proximal tubule and compete with the secretion of uric acid by that system. As a result, uric acid secretion may be reduced, with an elevation in serum uric acid level.

Pharmacodynamics

Thiazides inhibit NaCl reabsorption from the luminal side of epithelial cells in the distal convoluted tubule by blocking the Na^+/Cl^- transporter. In contrast to the situation in the loop of Henle, where loop diuretics inhibit Ca^{2+} reabsorption, thiazides actually enhance Ca^{2+} reabsorption in the distal convoluted tubule. This enhancement has been postulated to result from a lowering of intracellular Na^+ upon blockade of Na^+ entry by thiazides. The lower cell Na^+ would enhance $\text{Na}^+/\text{Ca}^{2+}$ exchange in the basolateral membrane (Figure 15–5), increasing overall reabsorption of Ca^{2+} . While thiazides rarely cause hypercalcemia as the result of this enhanced reabsorption, they can unmask

hypercalcemia due to other causes (eg, hyperparathyroidism, carcinoma, sarcoidosis). Thiazides are useful in the treatment of kidney stones caused by hypercalciuria.

The action of thiazides depends in part on renal prostaglandin production. As described above for the loop diuretics, the actions of thiazides can also be inhibited by NSAIDs under certain conditions.

Clinical Indications & Dosage

The major indications for thiazide diuretics are (1) hypertension, (2) heart failure, (3) nephrolithiasis due to idiopathic hypercalciuria, and (4) nephrogenic diabetes insipidus (Table 15–3). Use of the thiazides in each of these conditions is described below in the section on clinical pharmacology.

Drug	Daily Oral Dose	Frequency of Dosage
Bendroflumethiazide	2.5–10 mg	As single dose
Benzthiazide	25–100 mg	In two divided doses
Chlorothiazide	0.5–1 g	In two divided doses
Chlorthalidone ¹	50–100 mg	As single dose
Hydrochlorothiazide	25–100 mg	As single dose
Hydroflumethiazide	25–100 mg	In two divided doses
Indapamide ¹	2.5–10 mg	As single dose
Methyclothiazide	2.5–10 mg	As single dose
Metolazone ¹	2.5–10 mg	As single dose
Polythiazide	1–4 mg	As single dose
Quinethazone ¹	50–100 mg	As single dose
Trichlormethiazide	2–8 mg	As single dose

¹Not a thiazide but a sulfonamide qualitatively similar to the thiazides.

Toxicity

Hypokalemic Metabolic Alkalosis and Hyperuricemia

These toxicities are similar to those observed with loop diuretics (see above).

Impaired Carbohydrate Tolerance

Hyperglycemia may occur in patients who are overtly diabetic or who have even mildly abnormal glucose tolerance tests. The effect is due both to impaired pancreatic release of insulin and to diminished tissue utilization of glucose. Hyperglycemia may be partially reversible with correction of hypokalemia.

Hyperlipidemia

Thiazides cause a 5–15% increase in serum cholesterol and increased low-density lipoproteins (LDL). These levels may return toward baseline after prolonged use.

Hyponatremia

Hyponatremia is an important adverse effect of thiazide diuretics. It is due to a combination of hypovolemia-induced elevation of ADH, reduction in the diluting capacity of the kidney, and increased thirst. It can be prevented by reducing the dose of the drug or limiting water intake.

Allergic Reactions

The thiazides are sulfonamides and share cross-reactivity with other members of this chemical group. Photosensitivity or generalized dermatitis occurs rarely. Serious allergic reactions are extremely rare but do include hemolytic anemia, thrombocytopenia, and acute necrotizing pancreatitis.

Other Toxicities

Weakness, fatigability, and paresthesias similar to those of carbonic anhydrase inhibitors may occur. Impotence has been reported but is probably related to volume depletion.

Contraindications

Excessive use of any diuretic is dangerous in hepatic cirrhosis, borderline renal failure, or heart failure (see below).

Potassium-Sparing Diuretics

These diuretics antagonize the effects of aldosterone at the late distal tubule and cortical collecting tubule. Inhibition may occur by direct pharmacologic antagonism of mineralocorticoid receptors (**spironolactone, eplerenone**) or by inhibition of Na^+ influx through ion channels in the luminal membrane (**amiloride, triamterene**).

Chemistry & Pharmacokinetics

Spironolactone is a synthetic steroid that acts as a competitive antagonist to aldosterone. Its onset and duration of action are determined by the kinetics of the aldosterone response in the target tissue. Substantial inactivation of spironolactone occurs in the liver. Overall, spironolactone has a rather slow onset of action, requiring several days before full therapeutic effect is achieved. Eplerenone, a new spironolactone analog with greater selectivity for the aldosterone receptor, has recently been approved for the treatment of hypertension.

Amiloride is excreted unchanged in the urine. Triamterene is metabolized in the liver, but renal excretion is a major route of elimination for the active form and the metabolites. Because

triamterene is extensively metabolized, it has a shorter half-life and must be given more frequently than amiloride. The structures of spironolactone, triamterene, and amiloride are shown in Figure 15–9.

Figure 15–9.

Spironolactone

Triamterene

Amiloride

Aldosterone antagonists.

Pharmacodynamics

Potassium-sparing diuretics reduce Na⁺ absorption in the collecting tubules and ducts. Na⁺ absorption (and K⁺ secretion) at this site is regulated by aldosterone, as described above. Aldosterone antagonists interfere with this process. Similar effects are observed with respect to H⁺ handling by the intercalated cells of the collecting tubule, in part explaining the metabolic acidosis seen with aldosterone antagonists.

Spironolactone and eplerenone bind to aldosterone receptors and may also reduce the intracellular formation of active metabolites of aldosterone. Triamterene and amiloride do not block the aldosterone receptor but instead directly interfere with Na⁺ entry through the sodium-selective (ENaC) ion channels in the apical membrane of the collecting tubule. Since K⁺ secretion is coupled

with Na⁺ entry in this segment, these agents are also effective potassium-sparing diuretics.

The actions of triamterene and spironolactone depend on renal prostaglandin production. As described above for loop diuretics and thiazides, the actions of triamterene and spironolactone can also be inhibited by NSAIDs under certain conditions.

Clinical Indications & Dosage

These agents are most useful in states of mineralocorticoid excess, due either to primary hypersecretion (Conn's syndrome, ectopic ACTH production) or to secondary aldosteronism (from heart failure, hepatic cirrhosis, nephrotic syndrome, and other conditions associated with diminished effective intravascular volume) (Table 15–4). Use of other diuretics, like thiazides or loop agents, can cause or exacerbate volume contraction and thus intensify secondary aldosteronism. In the setting of enhanced mineralocorticoid secretion and continuing delivery of Na⁺ to distal nephron sites, renal K⁺ wasting occurs. Potassium-sparing diuretics of either type may be used in this setting to blunt the K⁺ secretory response.

Trade Name	Potassium-Sparing Agent	Hydrochlorothiazide	Frequency of Dosage
Aldactazide	Spironolactone 25 mg	25 mg	1–4 times daily
Aldactone	Spironolactone 25 mg	. . .	1–4 times daily
Dyazide	Triamterene 50 mg	25 mg	1–4 times daily
Dyrenium	Triamterene 50 mg	. . .	1–3 times daily
Inspra ¹	Eplerenone 25, 50 mg	. . .	Once or twice daily
Maxzide	Triamterene 75 mg	50 mg	Once daily
Maxzide-25 mg	Triamterene 27.5 mg	25 mg	Once daily
Midamor	Amiloride 5 mg	. . .	Once daily
Moduretic	Amiloride 5 mg	50 mg	Once or twice daily

¹Eplerenone is currently approved for use only in hypertension.

Toxicity

Hyperkalemia

Unlike other diuretics, these agents can cause mild, moderate, or even life-threatening hyperkalemia. The risk of this complication is greatly increased in the presence of renal disease or of other drugs that reduce renin (β-blockers, NSAIDs) or angiotensin II activity (angiotensin-converting enzyme [ACE] inhibitors, angiotensin receptor inhibitors). Since most other diuretic agents lead to K⁺ losses, hyperkalemia is more common when aldosterone antagonists are used as the sole diuretic agent, especially in patients with renal insufficiency. With fixed-dosage combinations of potassium-sparing and thiazide diuretics, the thiazide-induced hypokalemia and metabolic alkalosis are ameliorated by the aldosterone antagonist. However, owing to variations in

the bioavailability of the components of fixed-dosage forms, the thiazide-associated adverse effects may predominate. Therefore, it is generally preferable to adjust the doses of the two drugs separately.

Hyperchloremic Metabolic Acidosis

By inhibiting H^+ secretion in parallel with K^+ secretion, the potassium-sparing diuretics can cause acidosis similar to that seen with type IV renal tubular acidosis.

Gynecomastia

Synthetic steroids may cause endocrine abnormalities by effects on other steroid receptors. Gynecomastia, impotence, and benign prostatic hyperplasia have all been reported with spironolactone. Such effects have not been reported with eplerenone.

Acute Renal Failure

The combination of triamterene with indomethacin has been reported to cause acute renal failure. This has not been reported with other potassium-sparing agents.

Kidney Stones

Triamterene is poorly soluble and may precipitate in the urine, causing kidney stones.

Contraindications

These agents can cause severe, even fatal hyperkalemia in susceptible patients. Oral K^+ administration should be discontinued if aldosterone antagonists are administered. Patients with chronic renal insufficiency are especially vulnerable and should rarely be treated with aldosterone antagonists. Concomitant use of other agents that blunt the renin-angiotensin system (β -blockers or ACE inhibitors) increases the likelihood of hyperkalemia. Patients with liver disease may have impaired metabolism of triamterene and spironolactone, and dosing must be carefully adjusted. Strong CYP3A4 inhibitors (eg, ketoconazole, itraconazole) can markedly increase blood levels of eplerenone.

Agents That Alter Water Excretion

Osmotic Diuretics

The proximal tubule and descending limb of Henle's loop are freely permeable to water. An osmotic agent that is not reabsorbed causes water to be retained in these segments and promotes a water diuresis. Such agents can be used to reduce increased intracranial pressure and to promote prompt removal of renal toxins. The prototypic osmotic diuretic is **mannitol**.

Pharmacokinetics

Osmotic diuretics are poorly absorbed, which means that they must be given parenterally. If administered orally, mannitol causes osmotic diarrhea. Mannitol is not metabolized and is excreted primarily by glomerular filtration within 30–60 minutes, without any important tubular reabsorption or secretion.

Pharmacodynamics

Osmotic diuretics have their major effect in those segments of the nephron that are freely permeable to water: the proximal tubule and the descending limb of the loop of Henle. They also oppose the action of ADH in the collecting tubule. The presence of a nonreabsorbable solute such as mannitol prevents the normal absorption of water by interposing a countervailing osmotic force. As a result, urine volume increases. The increase in urine flow rate decreases the contact time between fluid and the tubular epithelium, thus reducing Na^+ reabsorption. However, the resulting natriuresis is of lesser magnitude than the water diuresis, leading eventually to hypernatremia.

Clinical Indications & Dosage

to Increase Urine Volume

Osmotic diuretics are used to increase water excretion in preference to sodium excretion. This effect can be useful when avid Na^+ retention limits the response to conventional agents. It can be used to maintain urine volume and to prevent anuria that might otherwise result from presentation of large pigment loads to the kidney (eg, from hemolysis or rhabdomyolysis). Some oliguric patients do not respond to an osmotic diuretic. Therefore, a test dose of mannitol (12.5 g intravenously) should be given prior to starting a continuous infusion. Mannitol should not be continued unless there is an increase in urine flow rate to more than 50 mL/h during the 3 hours following the test dose. Mannitol (12.5–25 g) can be repeated every 1–2 hours to maintain urine flow rate greater than 100 mL/h. Prolonged use of mannitol is not advised.

Reduction of Intracranial and Intraocular Pressure

Osmotic diuretics alter Starling forces so that water leaves cells and reduces intracellular volume. This effect is used to reduce intracranial pressure in neurologic conditions and to reduce intraocular pressure before ophthalmologic procedures. A dose of 1–2 g/kg mannitol is administered intravenously. Intracranial pressure, which must be monitored, should fall in 60–90 minutes.

Toxicity

Extracellular Volume Expansion

Mannitol is rapidly distributed in the extracellular compartment and extracts water from cells. Prior to the diuresis, this leads to expansion of the extracellular volume and hyponatremia. This effect can complicate heart failure and may produce florid pulmonary edema. Headache, nausea, and vomiting are commonly observed in patients treated with osmotic diuretics.

Dehydration and Hypernatremia

Excessive use of mannitol without adequate water replacement can ultimately lead to severe dehydration, free water losses, and hypernatremia. These complications can be avoided by careful attention to serum ion composition and fluid balance.

Antidiuretic Hormone (ADH) Agonists

Vasopressin and **desmopressin** are used in the treatment of pituitary diabetes insipidus. They are discussed in Chapter 37: Hypothalamic & Pituitary Hormones.

Antidiuretic Hormone (ADH) Antagonists

A variety of medical conditions cause water retention as the result of ADH excess. Unfortunately, specific ADH antagonists are available only for investigational purposes. Two nonselective agents, lithium and demeclocycline (a tetracycline derivative), are of limited use in some situations.

Pharmacokinetics

Both lithium and demeclocycline are orally active. Lithium is excreted by the kidney, and demeclocycline is metabolized in the liver.

Pharmacodynamics

ADH antagonists inhibit the effects of ADH in the collecting tubule. Both lithium and demeclocycline appear to reduce the formation of cyclic adenosine monophosphate (cAMP) in response to ADH and also to interfere with the actions of cAMP in the collecting tubule cells.

Clinical Indications & Dosage

Syndrome of Inappropriate ADH Secretion (SIADH)

ADH antagonists are used to manage SIADH when water restriction has failed to correct the abnormality. This generally occurs in the outpatient setting, where water restriction cannot be enforced, or in the hospital when large quantities of intravenous fluid are administered with drugs. Lithium carbonate has been used to treat this syndrome, but the response is unpredictable. Serum levels of lithium must be monitored closely, as serum concentrations greater than 1 mmol/L are toxic. Demeclocycline, in dosages of 600–1200 mg/d, yields a more predictable result and is less toxic. Appropriate plasma levels (2 µg/mL) should be maintained by monitoring.

Other Causes of Elevated Antidiuretic Hormone (ADH)

ADH is also elevated in response to diminished effective circulating blood volume. When treatment by volume replacement is not possible, as in heart failure or liver disease, hyponatremia may result. As for SIADH, water restriction is the treatment of choice, but if it is not successful, demeclocycline may be used.

Toxicity

Nephrogenic Diabetes Insipidus

If serum Na⁺ is not monitored closely, ADH antagonists can cause severe hypernatremia and nephrogenic diabetes insipidus. If lithium is being used for an affective disorder, nephrogenic diabetes insipidus can be treated with a thiazide diuretic or amiloride (see below).

Renal Failure

Both lithium and demeclocycline have been reported to cause acute renal failure. Long-term lithium therapy may also cause chronic interstitial nephritis.

Other

Adverse effects associated with lithium therapy include tremulousness, mental obtundation, cardiotoxicity, thyroid dysfunction, and leukocytosis (see Chapter 29: Antipsychotic Agents & Lithium). Demeclocycline should be avoided in patients with liver disease (see Chapter 44: Chloramphenicol, Tetracyclines, Macrolides, Clindamycin, & Streptogramins) and in children younger than 12 years.

Diuretic Combinations

Loop Agents & Thiazides

Some patients are refractory to the usual dose of loop diuretics or become refractory after an initial response. Since these agents have a short half-life, refractoriness may be due to an excessively long interval between doses. Renal Na^+ retention is enhanced during the time period when the drug is no longer active. After the dosing interval for loop agents is minimized or the dose is maximized, the use of two drugs acting at different nephron sites may exhibit synergy. Loop agents and thiazides in combination will often produce diuresis when neither agent acting alone is even minimally effective. There are several reasons for this phenomenon. First, salt and water reabsorption in either the thick ascending limb or the distal convoluted tubule can increase when the other is blocked. Inhibition of both can therefore produce more than an additive diuretic response. Second, thiazide diuretics may produce a mild natriuresis in the proximal tubule that is usually masked by increased reabsorption in the thick ascending limb. The combination of loop diuretics and thiazides will therefore blunt Na^+ reabsorption, to some extent, from all three segments.

Metolazone is the usual choice of thiazide-like drug in patients refractory to loop agents alone, but it is likely that other thiazides would be as effective as metolazone. Moreover, metolazone is available only in an oral preparation, while chlorothiazide can be given parenterally.

The combination of loop diuretics and thiazides can mobilize large amounts of fluid, even in patients who have not responded to single agents. Therefore, close hemodynamic monitoring is essential. Routine outpatient use is not recommended. Furthermore, K^+ -wasting is extremely common and may require parenteral K^+ administration with careful monitoring of fluid and electrolyte status.

Potassium-Sparing Diuretics & Loop Agents or Thiazides

Hypokalemia eventually develops in many patients who are placed on loop diuretics or thiazides. This can often be managed with dietary NaCl restriction. When hypokalemia cannot be managed in this way, or with dietary KCl supplements, the addition of a potassium-sparing diuretic can significantly lower potassium excretion. While this approach is generally safe, it should be avoided in patients with renal insufficiency in whom life-threatening hyperkalemia can develop in response to potassium-sparing diuretics.

Katzung PHARMACOLOGY, 9e > Section III. Cardiovascular-Renal Drugs > Chapter 15.
Diuretic Agents >

Clinical Pharmacology of Diuretic Agents

This section discusses the clinical use of diuretic agents in edematous and nonedematous states. The effects of these agents on urinary electrolyte excretion are shown in Table 15–5.

Table 15–5. Changes in Urinary Electrolyte Patterns in Response to Diuretic Drugs.

Agent	Urinary Electrolyte Patterns		
	NaCl	NaHCO ₃	K ⁺
Carbonic anhydrase inhibitors	+	+++	+
Loop agents	++++	–	+
Thiazides	++	±	+
Loop agents plus thiazides	+++++	+	++
K ⁺ -sparing agents	+	–	–

+, increase; –, decrease.

Edematous States

The most common reason for diuretic use is for reduction of peripheral or pulmonary edema that has accumulated as a result of cardiac, renal, or vascular diseases, or abnormalities in the blood oncotic pressure. Salt and water retention with edema formation often occurs when diminished blood delivery to the kidney is sensed as insufficient "effective" arterial blood volume. Judicious use of diuretics can mobilize interstitial edema fluid without significant reductions in plasma volume. However, excessive diuretic therapy in this setting may lead to further compromise of the effective arterial blood volume with reduction in perfusion of vital organs. Therefore, the use of diuretics to mobilize edema requires careful monitoring of the patient's hemodynamic status and an understanding of the pathophysiology of the underlying condition.

Heart Failure

When cardiac output is reduced by disease, the resultant changes in blood pressure and blood flow to the kidney are sensed as hypovolemia and thus induce renal retention of salt and water. This physiologic response initially expands the intravascular volume and venous return to the heart and may partially restore the cardiac output toward normal (see Chapter 13: Drugs Used in Heart Failure).

If the underlying disease causes cardiac function to deteriorate despite expansion of plasma volume, the kidney continues to retain salt and water, which then leaks from the vasculature and becomes interstitial or pulmonary edema. At this point, diuretic use becomes necessary to reduce the accumulation of edema, particularly that which is in the lungs. Reduction of pulmonary vascular congestion with diuretics may actually improve oxygenation and thereby improve myocardial function. Edema associated with heart failure is generally managed with loop diuretics. In some instances, salt and water retention may become so severe that a combination of thiazides and loop diuretics is necessary.

In treating the heart failure patient with diuretics, it must always be remembered that cardiac output in these patients is being maintained in part by high filling pressures and that excessive use of diuretics may diminish venous return and thereby impair cardiac output. This issue is especially

critical in right ventricular failure. Systemic rather than pulmonary vascular congestion is the hallmark of this disorder. Diuretic-induced volume contraction will predictably reduce venous return and can severely compromise cardiac output if left ventricular filling pressure is reduced below 15 mm Hg.

Diuretic-induced metabolic alkalosis is another adverse effect that may further compromise cardiac function. While this effect is generally treated with replacement of potassium and restoration of intravascular volume with saline, severe heart failure may preclude the use of saline even in patients who have received too much diuretic. In these cases, adjunctive use of acetazolamide can help correct the alkalosis.

Another serious toxicity of diuretic use, particularly in the cardiac patient, is hypokalemia. Hypokalemia can exacerbate underlying cardiac arrhythmias and contribute to digitalis toxicity. This can often be avoided by having the patient reduce sodium intake, thus decreasing sodium delivery to the K^+ -secreting collecting tubule. Patients who are noncompliant with a low sodium diet must take oral KCl supplements or a potassium-sparing diuretic or must stop using the thiazide diuretic.

Finally, it should be kept in mind that diuretics can never correct the underlying cardiac disease. Drugs that improve myocardial contractility or reduce peripheral vascular resistance are more direct approaches to the basic problem.

Kidney Disease

A variety of renal diseases may interfere with the kidney's critical role in volume homeostasis. Although renal disorders will occasionally cause salt wasting, most kidney diseases cause retention of salt and water. When loss of renal function is severe, diuretic agents are of little benefit, because there is insufficient glomerular filtration to sustain a natriuretic response. However, a large number of patients with milder degrees of renal insufficiency can be treated with diuretics when they retain sodium.

Many primary and secondary glomerular diseases, such as those associated with diabetes mellitus or systemic lupus erythematosus, exhibit renal retention of salt and water. The cause of this sodium retention is not precisely known, but it probably involves disordered regulation of the renal microcirculation and tubular function through release of vasoconstrictors, prostaglandins, cytokines, and other mediators. When edema or hypertension develops in these patients, diuretic therapy can be very effective. If heart failure is also present, see the warnings mentioned above.

Certain forms of renal disease, particularly diabetic nephropathy, are frequently associated with development of hyperkalemia at a relatively early stage of renal failure. In these cases, a thiazide or loop diuretic will enhance K^+ excretion by increasing delivery of salt to the K^+ -secreting collecting tubule.

Patients with renal diseases leading to the nephrotic syndrome often present complex problems in volume management. These patients may have reduced plasma volume in conjunction with reduced plasma oncotic pressures, especially those with "minimal change" nephropathy. In these patients, diuretic use may cause further reductions in plasma volume that can impair glomerular filtration rate and may lead to orthostatic hypotension. However, most other causes of nephrotic syndrome are associated with a primary retention of salt and water by the kidney, leading to expanded plasma volume and hypertension despite the low plasma oncotic pressure. In these cases, diuretic therapy may be beneficial in controlling the volume-dependent component of hypertension. In choosing a

diuretic for the patient with kidney disease, there are a number of important limitations. Acetazolamide and potassium-sparing diuretics must usually be avoided because of their tendency to exacerbate acidosis and hyperkalemia, respectively. Thiazide diuretics are generally ineffective when glomerular filtration rate falls below 30 mL/min. Thus, loop diuretics are often the best choice in treating edema associated with kidney failure. Lastly, excessive use of diuretics will cause renal function to decline in all patients, but the consequences are more serious in those with underlying renal disease.

Hepatic Cirrhosis

Liver disease is often associated with edema and ascites in conjunction with elevated portal hydrostatic pressures and reduced plasma oncotic pressures. The mechanisms for retention of sodium by the kidney are complex. They probably involve a combination of factors, including diminished renal perfusion resulting from systemic vascular alterations, diminished plasma volume as the result of ascites formation, and diminished oncotic pressure from hypoalbuminemia. In addition, there may be primary sodium retention by the kidney. Plasma aldosterone levels are usually high in response to the reduction in effective circulating volume.

When ascites and edema become severe, diuretic therapy can be useful in initiating and maintaining diuresis. Cirrhotic patients are often resistant to loop diuretics, in part because of a decrease in secretion of the drug into the tubular fluid and in part because of high aldosterone levels leading to enhanced collecting duct salt reabsorption. In contrast, cirrhotic edema is unusually responsive to spironolactone. The combination of loop diuretics and spironolactone may be useful in some patients. However, even more than in heart failure, overly aggressive use of diuretics in this setting can be disastrous. Vigorous diuretic therapy can cause marked depletion of intravascular volume, hypokalemia, and metabolic alkalosis. Hepatorenal syndrome and hepatic encephalopathy are the unfortunate consequences of excessive diuretic use in the cirrhotic patient.

Idiopathic Edema

Despite intensive study, the pathophysiology of this disorder (fluctuating salt retention and edema) remains obscure. Some studies suggest that intermittent diuretic use may actually contribute to the syndrome. Therefore, idiopathic edema should be managed with mild salt restriction alone if possible.

Nonedematous States

Hypertension

The diuretic and mild vasodilator actions of the thiazides are useful in treating virtually all patients with essential hypertension, and may be completely sufficient in two thirds. Moderate restriction of dietary Na⁺ intake (60–100 meq/d) has been shown to potentiate the effects of diuretics in essential hypertension and to lessen renal K⁺ wasting.

A recent very large study (over 30,000 participants) has shown that inexpensive diuretics are similar or superior in outcomes to ACE inhibitor or calcium channel blocker therapy (ALLHAT, 2002). This important result reinforces the importance of thiazide therapy in hypertension.

Diuretics also play an important role in patients who require multiple drugs to control blood pressure. Diuretics enhance the efficacy of many agents, particularly the ACE inhibitors. Patients being treated with powerful vasodilators such as hydralazine or minoxidil usually require diuretics

simultaneously because the vasodilators cause significant salt and water retention.

Nephrolithiasis

Approximately two thirds of all renal stones contain calcium phosphate or calcium oxalate. Many patients with such stones exhibit a renal defect in calcium reabsorption that causes hypercalciuria. This can be treated with thiazide diuretics, which enhance calcium reabsorption in the distal convoluted tubule and thus reduce the urinary calcium concentration. Salt intake must be reduced in this setting, as excess dietary NaCl will overwhelm the hypocalciuric effect of thiazides. Calcium stones may also be caused by increased intestinal absorption of calcium, or they may be idiopathic. In these situations, thiazides are also effective, but should be used as adjunctive therapy with decreased calcium intake and other measures.

Hypercalcemia

Hypercalcemia can be a medical emergency. Since the loop of Henle is an important site of calcium reabsorption, loop diuretics can be quite effective in promoting calcium diuresis. However, loop diuretics alone can cause marked volume contraction. If this occurs, loop diuretics are ineffective (and potentially counterproductive) because calcium reabsorption in the proximal tubule is enhanced. Thus, saline must be administered simultaneously with loop diuretics if an effective calcium diuresis is to be achieved. The usual approach is to infuse normal saline and furosemide (80–120 mg) intravenously. Once the diuresis begins, the rate of saline infusion can be matched with the urine flow rate to avoid volume depletion. Potassium may be added to the saline infusion as needed.

Diabetes Insipidus

Thiazide diuretics can reduce polyuria and polydipsia in patients who are not responsive to ADH. This seemingly paradoxical beneficial effect is mediated through plasma volume reduction, with an associated fall in glomerular filtration rate, enhanced proximal reabsorption of NaCl and water, and decreased delivery of fluid to the diluting segments. Thus, the maximum volume of dilute urine that can be produced is lowered and thiazides can significantly reduce urine flow in the polyuric patient. Dietary sodium restriction can potentiate the beneficial effects of thiazides on urine volume in this setting. Lithium, used in the treatment of manic-depressive disorder, is a common cause of drug-induced diabetes insipidus, and thiazide diuretics have been found to be helpful in treating it. Serum lithium levels must be carefully monitored in this situation, since diuretics may *reduce* renal clearance of lithium and raise plasma lithium levels into the toxic range (see Chapter 29: Antipsychotic Agents & Lithium). Lithium polyuria can also be partially reversed by amiloride, which appears to block lithium entry into collecting duct cells, much as it blocks Na⁺ entry.

Katzung PHARMACOLOGY, 9e > Section III. Cardiovascular-Renal Drugs > Chapter 15.
Diuretic Agents >

Preparations Available

Acetazolamide(generic, Diamox)

Oral: 125, 250 mg tablets

Oral sustained-release: 500 mg capsules

Parenteral: 500 mg powder for injection

Amiloride(generic, Midamor, combination drugs)

Oral: 5 mg tablets

Bendroflumethiazide (Naturetin)

Oral: 5, 10 mg tablets

Benzthiazide (Exna, combination drugs)

Oral: 50 mg tablets

Brinzolamide(Azopt)

Ophthalmic: 1% suspension

Bumetanide(generic, Bumex)

Oral: 0.5, 1, 2 mg tablets

Parenteral: 0.5 mg/2 mL ampule for IV or IM injection

Chlorothiazide (generic, Diuril, others)

Oral: 250, 500 mg tablets; 250 mg/5 mL oral suspension

Parenteral: 500 mg for injection

Chlorthalidone(generic, Thalitone, combination drugs)

Oral: 15, 25, 50, 100 mg tablets

Demeclocycline(Declomycin)

Oral: 150 mg tablets and capsules; 300 mg tablets

Dichlorphenamide (Daranide)

Oral: 50 mg tablets

Dorzolamide(Trusopt)

Ophthalmic: 2% solution

Eplerenone (Inspra)

Oral: 25, 50, 100 mg tablets

Ethacrynic acid(Edecrin)

Oral: 25, 50 mg tablets

Parenteral: 50 mg IV injection

Furosemide(generic, Lasix, others)

Oral: 20, 40, 80 mg tablets; 8 mg/mL solutions

Parenteral: 10 mg/mL for IM or IV injection

Hydrochlorothiazide (generic, Microzide, Hydro-DIURIL, combination drugs)

Oral: 12.5 mg capsules; 25, 50, 100 mg tablets; 10 mg/mL solution

Hydroflumethiazide (generic, Diucardin)

Oral: 50 mg tablets

Indapamide(generic, Lozol)

Oral: 1.25, 2.5 mg tablets

Mannitol(generic, Osmitrol)

Parenteral: 5, 10, 15, 20, 25% for injection

Methazolamide (generic, Neptazane)

Oral: 25, 50 mg tablets

Methyclothiazide (generic, Aquatensen)

Oral: 2.5, 5 mg tablets

Metolazone (Mykrox, Zaroxolyn) (Note: Bio-

Availability of Mykrox is greater than that of Zaroxolyn.)

Oral: 0.5 (Mykrox); 2.5, 5, 10 mg (Zaroxolyn) tablets

Polythiazide (Renese)

Oral: 1, 2, 4 mg tablets

Quinethazone (Hydromox)

Oral: 50 mg tablets

Spirolactone(generic, Aldactone)

Oral: 25, 50, 100 mg tablets

Torsemide(Demadex)

Oral: 5, 10, 20, 100 mg tablets

Parenteral: 10 mg/mL for injection

Triamterene(Dyrenium)

Oral: 50, 100 mg capsules

Trichlormethiazide (generic, Diurese, others)

Oral: 2, 4 mg tablets

Section IV. Drugs with Important Actions on Smooth Muscle

Katzung PHARMACOLOGY, 9e > Section IV. Drugs with Important Actions on Smooth Muscle > Chapter 16. Histamine, Serotonin, & the Ergot Alkaloids >

Histamine, Serotonin, & the Ergot Alkaloids: Introduction

Histamine and serotonin (5-hydroxytryptamine) are biologically active amines that are found in many tissues, have complex physiologic and pathologic effects through multiple receptor subtypes, and are often released locally. Together with endogenous peptides (see Chapter 17: Vasoactive Peptides), prostaglandins and leukotrienes (see Chapter 18: The Eicosanoids: Prostaglandins, Thromboxanes, Leukotrienes, & Related Compounds), and cytokines (see Chapter 56: Immunopharmacology), they are sometimes called autacoids (Gk "self-remedy") or local hormones in recognition of these properties.

Because of their broad and largely undesirable effects, neither histamine nor serotonin has any clinical application in the treatment of disease. However, compounds that *selectively* activate certain receptor subtypes or selectively antagonize the actions of these amines are of considerable clinical usefulness. This chapter therefore emphasizes the basic pharmacology of the agonist amines and the clinical pharmacology of the more selective agonist and antagonist drugs. The ergot alkaloids, compounds with partial agonist activity at serotonin and several other receptors, are discussed at the end of the chapter.

Katzung PHARMACOLOGY, 9e > Section IV. Drugs with Important Actions on Smooth Muscle > Chapter 16. Histamine, Serotonin, & the Ergot Alkaloids >

Histamine

Histamine was synthesized in 1907 and later isolated from mammalian tissues. Early hypotheses concerning the possible physiologic roles of tissue histamine were based on similarities between histamine's actions and the symptoms of anaphylactic shock and tissue injury. Marked species variation is observed, but in humans histamine is an important mediator of immediate allergic and

inflammatory reactions; has an important role in gastric acid secretion; and functions as a neurotransmitter and neuromodulator. New evidence indicates that histamine also plays a role in chemotaxis of white blood cells.

Basic Pharmacology of Histamine

Chemistry & Pharmacokinetics

Histamine occurs in plants as well as in animal tissues and is a component of some venoms and stinging secretions.

Histamine is formed by decarboxylation of the amino acid L-histidine, a reaction catalyzed in mammalian tissues by the enzyme histidine decarboxylase. Once formed, histamine is either stored or rapidly inactivated. Very little histamine is excreted unchanged. The major inactivation pathways involve conversion to methylhistamine, methylimidazoleacetic acid, and imidazoleacetic acid. Certain neoplasms (systemic mastocytosis, urticaria pigmentosa, gastric carcinoid, and occasionally myelogenous leukemia) are associated with increased numbers of mast cells or basophils and with increased excretion of histamine and its metabolites.

Histamine

Most tissue histamine is sequestered and bound in granules (vesicles) in mast cells or basophils; the histamine content of many tissues is directly related to their mast cell content. The bound form of histamine is biologically inactive, but many stimuli, as noted below, can trigger the release of mast cell histamine, allowing the free amine to exert its actions on surrounding tissues. Mast cells are especially rich at sites of potential tissue injury—nose, mouth, and feet; internal body surfaces; and blood vessels, particularly at pressure points and bifurcations.

Non-mast cell histamine is found in several tissues, including the brain, where it functions as a neurotransmitter (see Chapter 21: Introduction to the Pharmacology of CNS Drugs). Endogenous neurotransmitter histamine may play a role in many brain functions such as neuroendocrine control, cardiovascular regulation, thermal and body weight regulation, and arousal.

A second important nonneuronal site of histamine storage and release is the enterochromaffin-like (ECL) cell of the fundus of the stomach. These cells release histamine, one of the primary acid secretagogues, to activate the acid-producing parietal cells of the mucosa (see Chapter 63: Drugs Used in the Treatment of Gastrointestinal Diseases).

Storage & Release of Histamine

The stores of histamine in mast cells can be released through several mechanisms.

Immunologic Release

The important pathophysiologic mechanism of mast cell and basophil histamine release is immunologic. These cells, if sensitized by IgE antibodies attached to their surface membranes, degranulate when exposed to the appropriate antigen (see Figure 56–5, effector phase). This type of

release also requires energy and calcium. Degranulation leads to the simultaneous release of histamine, ATP, and other mediators that are stored together in the granules. Histamine released by this mechanism is a mediator in immediate (type I) allergic reactions. Substances released during IgG- or IgM-mediated immune reactions that activate the complement cascade also release histamine from mast cells and basophils.

By a negative feedback control mechanism mediated by H₂ receptors, histamine appears to modulate its own release and that of other mediators from sensitized mast cells in some tissues. In humans, mast cells in skin and basophils show this negative feedback mechanism; lung mast cells do not. Thus, histamine may act to limit the intensity of the allergic reaction in the skin and blood.

Endogenous histamine has a modulating role in a variety of inflammatory and immune responses. Upon injury to a tissue, released histamine causes local vasodilation and leakage of plasma containing mediators of acute inflammation (complement, C-reactive protein), and antibodies. Histamine has an active chemotactic attraction for inflammatory cells (neutrophils, eosinophils, basophils, monocytes, and lymphocytes). Histamine inhibits the release of lysosome contents and several T and B lymphocyte functions. Most of these actions are mediated by H₂ or H₄ receptors acting through increased intracellular cAMP. Release of peptides from nerves in response to inflammation is also probably modulated by histamine, in this case acting through presynaptic H₃ receptors.

Chemical and Mechanical Release

Certain amines, including drugs such as morphine and tubocurarine, can displace histamine from the heparin-protein complex within cells. This type of release does not require energy and is not associated with mast cell injury or degranulation. Loss of granules from the mast cell will also release histamine, since sodium ions in the extracellular fluid rapidly displace the amine from the complex. Chemical and mechanical mast cell injury causes degranulation and histamine release. **Compound 48/80**, an experimental diamine polymer, specifically releases histamine from tissue mast cells by an exocytotic degranulation process requiring energy and calcium.

Pharmacodynamics

Mechanism of Action

Histamine exerts its biologic actions by combining with specific cellular receptors located on the surface membrane. The four different histamine receptors thus far characterized are designated H₁–H₄ and are described in Table 16–1. Unlike the other amine transmitter receptors discussed previously, no subfamilies have been found within these major types.

Table 16–1. Histamine Receptor Subtypes.

Receptor Subtype	Distribution	Postreceptor Mechanism	Partially Selective Agonists	Partially Selective Antagonists
H ₁	Smooth muscle, endothelium, brain	↑IP ₃ , DAG (G _q)	2-(<i>m</i> -Fluorophenyl)-histamine ¹	Mepyramine, triprolidine

H ₂	Gastric mucosa, cardiac muscle, mast cells, brain	↑cAMP (G _s)	Dimaprit, impromidine, amthamine	Ranitidine, tiotidine
H ₃	Presynaptic: brain, myenteric plexus, other neurons	↓cAMP, Ca _i ²⁺ (G _i)	R-α-Methylhistamine, imetit, immepip	Thioperamide, iodophenpropit, clobenpropit
H ₄	Eosinophils, neutrophils, CD4 T cells	↓cAMP, Ca _i ²⁺ (G _i)	Clobenpropit, imetit, clozapine	Thioperamide

¹Partial agonist.

All four receptor types have been cloned and belong to the large superfamily of receptors having seven membrane-spanning regions and intracellular association with G proteins. The structures of the H₁ and H₂ receptors differ significantly and appear to be more closely related to muscarinic and 5-HT₁ receptors, respectively, than to each other. The H₄ receptor has about 40% homology with the H₃ receptor but does not seem to be closely related to any other histamine receptor.

In the brain, H₁ and H₂ receptors are located on postsynaptic membranes, while H₃ receptors are predominantly presynaptic. Activation of H₁ receptors, which are present in endothelium, smooth muscle cells, and nerve endings, usually elicits an increase in phosphoinositol hydrolysis and an increase in intracellular calcium. Activation of H₂ receptors, present in gastric mucosa, cardiac muscle cells, and some immune cells, increases intracellular cAMP. Like the β₂ adrenoceptor, under certain circumstances the H₂ receptor may couple to G_q, activating the IP₃-DAG cascade. Activation of H₃ receptors decreases transmitter release from histaminergic and other neurons, probably mediated by a decrease in calcium influx through N-type calcium channels in nerve endings. H₄ receptors are mainly found on blood cells in the bone marrow and circulating blood. They may modulate production of these cell types and they may mediate, in part, the previously recognized effects of histamine on cytokine production.

Tissue and Organ System Effects of Histamine

Histamine exerts powerful effects on smooth and cardiac muscle, on certain endothelial and nerve cells, and on the secretory cells of the stomach. However, sensitivity to histamine varies greatly among species. Humans, guinea pigs, dogs, and cats are quite sensitive, while mice and rats are much less so.

Nervous System

Histamine is a powerful stimulant of sensory nerve endings, especially those mediating pain and itching. This H₁-mediated effect is an important component of the urticarial response and reactions to insect and nettle stings. Some evidence suggests that local high concentrations can also depolarize efferent (axonal) nerve endings (see ¶ 8, below). In the mouse, and probably in humans, respiratory neurons signaling inspiration and expiration are modulated by H₁ receptors. Presynaptic H₃ receptors play important roles in modulating transmitter release in the nervous system. H₃ agonists reduce the release of acetylcholine, amine, and peptide transmitters in various areas of the brain and in peripheral nerves.

Cardiovascular System

In humans, injection or infusion of histamine causes a decrease in systolic and diastolic blood pressure and an increase in heart rate (Figure 16–1). The blood pressure changes are caused by the direct vasodilator action of histamine on arterioles and precapillary sphincters; the increase in heart rate involves both stimulatory actions of histamine on the heart and a reflex tachycardia. Flushing, a sense of warmth, and headache may also occur during histamine administration, consistent with the vasodilation. Histamine-induced vasodilation is mediated primarily by release of nitric oxide (see Chapter 19: Nitric Oxide, Donors, & Inhibitors). Studies with histamine receptor antagonists show that both H₁ and H₂ receptors are involved in these cardiovascular responses to high doses. However, in humans, the cardiovascular effects of small doses of histamine can usually be antagonized by H₁ receptor antagonists alone.

Figure 16–1.

Effects of histamine on blood pressure and heart rate in humans. Histamine was infused at 40 µg/kg/h for 5 minutes as shown at the top of the panel. (Modified and reproduced, with permission, from Torsoli A, Lucchelli PE, Brimblecombe RW [editors]: *H-Antagonists: H₂ Receptor Antagonists in Peptic Ulcer Disease and Progress in Histamine Research*. Excerpta Medica, 1980.)

Histamine-induced edema results from the action of the amine on H₁ receptors in the vessels of the microcirculation, especially the postcapillary vessels. The effect is associated with the separation of the endothelial cells, which permits the transudation of fluid and molecules as large as small proteins into the perivascular tissue. This effect is responsible for the urticaria (hives) that signals the release of histamine in the skin. Studies of endothelial cells suggest that actin and myosin within these cells contract, resulting in separation of the endothelial cells and increased permeability.

Direct cardiac effects of histamine include both increased contractility and increased pacemaker rate. These effects are mediated chiefly by H₂ receptors. In human atrial muscle, histamine can also decrease contractility; this effect is mediated by H₁ receptors. The physiologic significance of these

cardiac actions is not clear. Some of the cardiovascular signs and symptoms of anaphylaxis are due to released histamine, though several other mediators are involved and appear to be more important than histamine in humans.

Bronchiolar Smooth Muscle

In both humans and guinea pigs, histamine causes bronchoconstriction mediated by H₁ receptors. In the guinea pig, this effect is the cause of death from histamine toxicity, but in normal humans, bronchoconstriction following small doses of histamine is not marked. However, patients with asthma are very sensitive to histamine. The bronchoconstriction induced in these patients probably represents a hyperactive neural response, since such patients also respond excessively to many other stimuli, and the response to histamine can be blocked by autonomic blocking drugs such as ganglionic blocking agents as well as by H₁ receptor antagonists (see Chapter 20: Drugs Used in Asthma). Provocative tests using increasing doses of inhaled histamine are of diagnostic value for bronchial hyperreactivity in patients with suspected asthma or cystic fibrosis. Such individuals may be 100- to 1000-fold more sensitive to histamine than are normal subjects. Curiously, a few species (eg, rabbit) respond to histamine with bronchodilation, reflecting the dominance of the H₂ receptor in their airways.

Gastrointestinal Tract Smooth Muscle

Histamine causes contraction of intestinal smooth muscle, and histamine-induced contraction of guinea pig ileum is a standard bioassay for this amine. The human gut is not as sensitive as that of the guinea pig, but large doses of histamine may cause diarrhea, partly as a result of this effect. This action of histamine is mediated by H₁ receptors.

Other Smooth Muscle Organs

In humans, histamine generally has insignificant effects on the smooth muscle of the eye and genitourinary tract. However, pregnant women suffering anaphylactic reactions may abort as a result of histamine-induced contractions, and in some species the sensitivity of the uterus is sufficient to form the basis for a bioassay.

Secretory Tissue

Histamine has long been recognized as a powerful stimulant of gastric acid secretion and, to a lesser extent, of gastric pepsin and intrinsic factor production. The effect is caused by activation of H₂ receptors on gastric parietal cells and is associated with increased adenylyl cyclase activity, cAMP concentration, and intracellular Ca²⁺ concentration. Other stimulants of gastric acid secretion such as acetylcholine and gastrin do not increase cAMP even though their maximal effects on acid output can be reduced—but not abolished—by H₂-receptor antagonists. These actions are discussed in detail in Chapter 63: Drugs Used in the Treatment of Gastrointestinal Diseases. Histamine also stimulates secretion in the small and large intestine. In contrast, H₃-selective histamine agonists *inhibit* acid secretion stimulated by food or pentagastrin in several species.

Histamine has much smaller effects on the activity of other glandular tissue at ordinary concentrations. Very high concentrations can cause adrenal medullary discharge.

Metabolic Effects

Recent studies of H₃ receptor knockout mice demonstrate that absence of this receptor results in

animals with increased food intake, decreased energy expenditure, and obesity. They also show insulin resistance and increased blood levels of leptin and insulin. It is not yet known whether the H₃ receptor has a similar role in humans.

The "Triple Response"

Intradermal injection of histamine causes a characteristic wheal-and-flare response that was first described over 60 years ago. The effect involves three separate cell types: smooth muscle in the microcirculation, capillary or venular endothelium, and sensory nerve endings. At the site of injection, a reddening appears owing to dilation of small vessels, followed soon by an edematous wheal at the injection site and a red irregular flare surrounding the wheal. The flare is said to be caused by an axon reflex. The sensation of itch may also accompany the appearance of these effects. The wheal is due to local edema.

Similar local effects may be produced by injecting histamine liberators (compound 48/80, morphine, etc) intradermally or by applying the appropriate antigens to the skin of a sensitized person. Although most of these local effects can be blocked by prior administration of an H₁ receptor-blocking agent, H₂ and H₃ receptors may also be involved.

Other Effects Possibly Mediated by Histamine Receptors

In addition to the local stimulation of peripheral pain nerve endings via H₃ and H₁ receptors, histamine may play a role in nociception in the central nervous system. **Burimamide**, an early candidate for H₂ blocking action, and **improgran**, a newer analog with no effect on H₁, H₂, or H₃ receptors, have been shown to have significant analgesic action in rodents when administered into the central nervous system. The analgesia is said to be comparable to that produced by opioids, but tolerance, respiratory depression, and constipation have not been reported. Although the mechanism of this action is not known, these compounds may represent an important new class of analgesics.

Other Histamine Agonists

Small substitutions on the imidazole ring of histamine significantly modify the selectivity of the compounds for the histamine receptor subtypes. Some of these are listed in Table 16-1.

Clinical Pharmacology of Histamine

Clinical Uses

In pulmonary function laboratories, histamine aerosol (in addition to other agents) is sometimes used as a provocative test of **bronchial hyperreactivity**. Histamine has no other current clinical applications.

Toxicity & Contraindications

Adverse effects of histamine release, like those following administration of histamine, are dose-related. Flushing, hypotension, tachycardia, headache, wheals, bronchoconstriction, and gastrointestinal upset are noted. These effects are also observed after the ingestion of spoiled fish (scombroid fish poisoning), and there is evidence that histamine produced by bacterial action in the flesh of the fish is the major causative agent.

Histamine should not be given to asthmatics (except as part of a carefully monitored test of

pulmonary function) or to patients with active ulcer disease or gastrointestinal bleeding.

Histamine Antagonists

The effects of histamine released in the body can be reduced in several ways. **Physiologic antagonists**, especially epinephrine, have smooth muscle actions opposite to those of histamine, but they act at different receptors. This is important clinically because injection of epinephrine can be lifesaving in systemic **anaphylaxis** and in other conditions in which massive release of histamine—and other mediators—occurs.

Release inhibitors reduce the degranulation of mast cells that results from immunologic triggering by antigen-IgE interaction. Cromolyn and nedocromil appear to have this effect (see Chapter 20: Drugs Used in Asthma) and are used in the treatment of asthma, though the molecular mechanism underlying their action is presently unknown. Beta₂ adrenoceptor agonists also appear capable of reducing histamine release.

Histamine **receptor antagonists** represent a third approach to the reduction of histamine-mediated responses. For over 60 years, compounds have been available that competitively antagonize many of the actions of histamine on smooth muscle. However, not until the H₂ receptor antagonist burimamide was described in 1972 was it possible to antagonize the gastric acid-stimulating activity of histamine. The development of selective H₂ receptor antagonists has led not only to more precise definition of histamine's actions in terms of receptors involved but also to more effective therapy for peptic ulcer. Selective H₃ antagonists are not yet available for clinical use. However, potent and selective experimental H₃ receptor antagonists, thioperamide and clobenpropit, have been developed.

H₁ Receptor Antagonists

Compounds that competitively block histamine at H₁ receptors have been used clinically for many years, and many H₁ antagonists are currently marketed in the USA. Many are available without prescription, both alone and in combination formulations such as "cold pills" and sleep aids (see Chapter 64: Therapeutic & Toxic Potential of Over-the-Counter Agents).

Basic Pharmacology of H₁ Receptor Antagonists

Chemistry & Pharmacokinetics

The H₁ antagonists are conveniently divided into first-generation and second-generation agents. These groups are distinguished by the relatively strong sedative effects of most of the first-generation drugs. The first-generation agents are also more likely to block autonomic receptors. The relatively less sedating characteristic of the second-generation H₁ blockers is due in part to their less complete distribution into the central nervous system. All of the H₁ antagonists are stable amines with the general structure illustrated in Figure 16–2. There are several chemical subgroups, and the structures of compounds representing different subgroups are shown in the figure. Doses of some of these drugs are given in Table 16–2.

Figure 16-2.

GENERAL STRUCTURE

ETHERS OR ETHANOLAMINE DERIVATIVE

Diphenhydramine or dimenhydrinate

ETHYLENEDIAMINE DERIVATIVE

Tripeleennamine

PIPERAZINE DERIVATIVE

Cyclizine

ALKYLAMINE DERIVATIVE

Chlorpheniramine

Promethazine

PIPERIDINE DERIVATIVES

Terfenadine

Fexofenadine

General structure of H₁ antagonist drugs and examples of the major subgroups.

Table 16–2. Some H₁ Antihistaminic Drugs in Past or Current Clinical Use.

Drugs	Usual Adult Dose	Anticholinergic Activity	Comments
FIRST-GENERATION ANTIHISTAMINES			
Ethanolamines			
Carbinoxamine (Clistin)	4–8 mg	+++	Slight to moderate sedation
Dimenhydrinate (salt of diphenhydramine) (Dramamine)	50 mg	+++	Marked sedation; anti-motion sickness activity
Diphenhydramine (Benadryl, etc)	25–50 mg	+++	Marked sedation; anti-motion sickness activity
Doxylamine	1.25–25 mg	nd	Marked sedation; now available only in OTC "sleep aids"
Ethylaminediamines			
Pyrilamine (Neo-Antergan)	25–50 mg	+	Moderate sedation; component of OTC "sleep aids"
Tripelennamine (PBZ, etc)	25–50 mg	+	Moderate sedation
Piperazine derivatives			
Hydroxyzine (Atarax, etc)	15–100 mg	nd	Marked sedation
Cyclizine (Marezine)	25–50 mg	–	Slight sedation; anti-motion sickness activity
Meclizine (Bonine, etc)	25–50 mg	–	Slight sedation; anti-motion sickness activity
Alkylamines			
Brompheniramine (Dimetane, etc)	4–8 mg	+	Slight sedation
Chlorpheniramine (Chlor-Trimeton, etc)	4–8 mg	+	Slight sedation; common component of OTC "cold" medication
Phenothiazine derivatives			
Promethazine (Phenergan, etc)	10–25 mg	+++	Marked sedation; antiemetic
Miscellaneous			
Cyproheptadine (Periactin, etc)	4 mg	+	Moderate sedation; also has antiserotonin activity
SECOND-GENERATION ANTIHISTAMINES			
Piperidines			
Fexofenadine (Allegra)	60 mg	–	Lower risk of arrhythmia

Miscellaneous			
Loratadine (Claritin)	10 mg	–	Longer action
Cetirizine (Zyrtec)	5–10 mg	–	

Nd, no data found.

These agents are rapidly absorbed following oral administration, with peak blood concentrations occurring in 1–2 hours. They are widely distributed throughout the body, and the first-generation drugs enter the central nervous system readily. Some of them are extensively metabolized, primarily by microsomal systems in the liver. Several of the second-generation agents are metabolized by the CYP3A4 system and thus are subject to important interactions when other drugs (such as ketoconazole) inhibit this subtype of P450 enzymes. Most of the drugs have an effective duration of action of 4–6 hours following a single dose, but meclizine and several second-generation agents are longer-acting, with a duration of action of 12–24 hours. The newer agents also are considerably less lipid-soluble and enter the central nervous system with difficulty or not at all. Many H₁ antagonists have active metabolites. The active metabolites of hydroxyzine, terfenadine, and loratadine are available as drugs (cetirizine, fexofenadine, and desloratadine, respectively).

Pharmacodynamics

Histamine Receptor Blockade

H₁ receptor antagonists block the actions of histamine by reversible competitive antagonism at the H₁ receptor. They have negligible potency at the H₂ receptor and little at the H₃ receptor. For example, histamine-induced contraction of bronchiolar or gastrointestinal smooth muscle can be completely blocked by these agents, but the effects on gastric acid secretion and the heart are unmodified.

Actions Not Caused by Histamine Receptor Blockade

The first-generation H₁ receptor antagonists have many actions not ascribable to blockade of the actions of histamine. The large number of these actions probably results from the similarity of the general structure (Figure 16–2) to the structure of drugs that have effects at muscarinic cholinergic, α -adrenoceptor, serotonin, and local anesthetic receptor sites. Some of these actions are of therapeutic value and some are undesirable.

Sedation

A common effect of first-generation H₁ antagonists is sedation, but the intensity of this effect varies among chemical subgroups (Table 16–2) and among patients as well. The effect is sufficiently prominent with some agents to make them useful as "sleep aids" (see Chapter 64: Therapeutic & Toxic Potential of Over-the-Counter Agents) and unsuitable for daytime use. The effect resembles that of some antimuscarinic drugs and is considered very unlike the disinhibited sedation produced by sedative-hypnotic drugs. Compulsive use has not been reported. At ordinary dosages, children occasionally (and adults rarely) manifest excitation rather than sedation. At very high toxic dose levels, marked stimulation, agitation, and even convulsions may precede coma. Second-generation H₁ antagonists have little or no sedative or stimulant actions. These drugs (or their active metabolites) also have far fewer autonomic effects than the first-generation antihistamines.

Antinausea and Antiemetic Actions

Several first-generation H₁ antagonists have significant activity in preventing motion sickness (Table 16–2). They are less effective against an episode of motion sickness already present. Certain H₁ antagonists, notably doxylamine (in Bendectin), were used widely in the past in the treatment of nausea and vomiting of pregnancy (see below).

Antiparkinsonism Effects

Perhaps because of their anticholinergic effects (cf benztropine, Chapter 28: Pharmacologic Management of Parkinsonism & Other Movement Disorders), some of the H₁ antagonists have significant acute suppressant effects on the parkinsonism symptoms associated with certain antipsychotic drugs.

Anticholinergic Actions

Many of the first-generation agents, especially those of the ethanolamine and ethylenediamine subgroups, have significant atropine-like effects on peripheral muscarinic receptors. This action may be responsible for some of the (uncertain) benefits reported for nonallergic rhinorrhea but may also cause urinary retention and blurred vision.

Adrenoceptor-Blocking Actions

Alpha receptor-blocking effects can be demonstrated for many H₁ antagonists, especially those in the phenothiazine subgroup, eg, promethazine. This action may cause orthostatic hypotension in susceptible individuals. Beta receptor blockade is not observed.

Serotonin-Blocking Action

Strong blocking effects at serotonin receptors have been demonstrated for some first-generation H₁ antagonists, notably cyproheptadine. This drug is promoted as an antiserotonin agent and is discussed with that drug group. Nevertheless, its structure resembles that of the phenothiazine antihistamines, and it is a potent H₁ blocking agent.

Local Anesthesia

Many first-generation H₁ antagonists are potent local anesthetics. They block sodium channels in excitable membranes in the same fashion as procaine and lidocaine. Diphenhydramine and promethazine are actually more potent than procaine as local anesthetics. They are occasionally used to produce local anesthesia in patients allergic to the conventional local anesthetic drugs. A small number of these agents also block potassium channels; this action is discussed below (see Toxicity).

Other Actions

Certain H₁ antagonists, eg, cetirizine, inhibit mast cell release of histamine and some other mediators of inflammation. This action is not due to H₁ receptor blockade. The mechanism is not understood but could play a role in the beneficial effects of these drugs in the treatment of allergies such as rhinitis. A few H₁ antagonists (eg, terfenadine, acrivastine) have been shown to inhibit the P-glycoprotein transporter found in cancer cells, the epithelium of the gut, and the capillaries of the brain. The significance of this effect is not known.

Clinical Pharmacology of H₁ Receptor Antagonists

Clinical Uses

Allergic Reactions

The H₁ antihistaminic agents are often the first drugs used to prevent or treat the symptoms of allergic reactions. In allergic rhinitis and urticaria, in which histamine is the primary mediator, the H₁ antagonists are the drugs of choice and are often quite effective. However, in bronchial asthma, which involves several mediators, the H₁ antagonists are largely ineffective.

Angioedema may be precipitated by histamine release but appears to be maintained by peptide kinins that are not affected by antihistaminic agents. For atopic dermatitis, antihistaminic drugs such as diphenhydramine are used mostly for their sedative side effects and for some control of the itching.

The H₁ antihistamines used for treating allergic conditions such as hay fever are usually selected with the goal of minimizing sedative effects; in the USA, the drugs in widest use are the alkylamines and the second-generation nonsedating agents. However, the sedative effect and the therapeutic efficacy of different agents vary widely among individuals. In addition, the clinical effectiveness of one group may diminish with continued use, and switching to another group may restore drug effectiveness for as yet unexplained reasons.

The second-generation H₁ antagonists are used mainly for the treatment of allergic rhinitis and chronic urticaria. Several double-blind comparisons with older agents (such as chlorpheniramine) indicated about equal therapeutic efficacy. However, sedation and interference with safe operation of machinery, which occur in about 50% of subjects taking first-generation antihistamines, occurred in only about 7% of subjects taking second generation agents. The newer drugs are much more expensive.

Motion Sickness and Vestibular Disturbances

Scopolamine and certain first-generation H₁ antagonists are the most effective agents available for the prevention of motion sickness. The antihistaminic drugs with the greatest effectiveness in this application are diphenhydramine and promethazine. Dimenhydrinate, which is promoted for the treatment of motion sickness, is a salt of diphenhydramine. The piperazines (cyclizine and meclizine) also have significant activity in preventing motion sickness and are less sedative in most patients. Dosage is the same as that recommended for allergic disorders (Table 16–2). Both scopolamine and the H₁ antagonists are more effective in preventing motion sickness when combined with ephedrine or amphetamine.

It has been claimed that the antihistaminic agents effective in prophylaxis of motion sickness are also useful in Meniere's syndrome, but efficacy in the latter application is not well established.

Nausea and Vomiting of Pregnancy

Several H₁ antagonist drugs have been studied for possible use in treating "morning sickness." The piperazine derivatives were withdrawn from such use when it was demonstrated that they have teratogenic effects in rodents. Doxylamine, an ethanolamine H₁ antagonist, was promoted for this application as a component of Bendectin, a prescription medication that also contained pyridoxine. Possible teratogenic effects of doxylamine were widely publicized in the lay press after 1978 as a

result of a few case reports of fetal malformation associated with maternal ingestion of Bendectin. However, several large prospective studies involving over 60,000 pregnancies, of which more than 3000 involved maternal Bendectin ingestion, disclosed no increase in the incidence of birth defects. However, because of the continuing controversy, adverse publicity, and lawsuits, the manufacturer of Bendectin withdrew the product from the market. Doxylamine is still available over-the-counter as a sleep aid.

Toxicity

The wide spectrum of adverse effects of the H₁ antihistamines is described above. Several of these effects (sedation, antimuscarinic action) have been used for therapeutic purposes, especially in OTC remedies (see Chapter 64: Therapeutic & Toxic Potential of Over-the-Counter Agents). Nevertheless, these two effects constitute the most common undesirable actions when these drugs are used to block histamine receptors.

Less common toxic effects of systemic use include excitation and convulsions in children, postural hypotension, and allergic responses. Drug allergy is relatively common after topical use of H₁ antagonists. The effects of severe systemic overdosage of the older agents resemble those of atropine overdosage and are treated in the same way (see Chapter 8: Cholinoceptor-Blocking Drugs and Chapter 59: Management of the Poisoned Patient). Overdosage of astemizole or terfenadine may induce cardiac arrhythmias, but these drugs are no longer marketed in the USA; the same effect may be caused by interaction with enzyme inhibitors (see Drug Interactions, below).

Drug Interactions

Lethal ventricular arrhythmias occurred in several patients taking either of the early second-generation agents, terfenadine or astemizole, in combination with ketoconazole, itraconazole, or macrolide antibiotics such as erythromycin. These antimicrobial drugs inhibit the metabolism of many drugs by CYP3A4 and cause significant increases in blood concentrations of the antihistamines. The mechanism of this toxicity involves blockade of the potassium channels in the heart that are responsible for repolarization of the action potential, the I_K channels (see Chapter 14: Agents Used in Cardiac Arrhythmias). The result is prolongation of the action potential, and excessive prolongation leads to arrhythmias. Both terfenadine and astemizole were withdrawn from the United States market in recognition of these problems. Where still available, terfenadine and astemizole should be considered to be contraindicated in patients taking ketoconazole, itraconazole, or macrolides and in patients with liver disease. Grapefruit juice also inhibits CYP3A4 and has been shown to increase terfenadine's blood levels significantly.

For those H₁ antagonists that cause significant sedation, concurrent use of other drugs that cause central nervous system depression produces additive effects and is contraindicated while driving or operating machinery. Similarly, the autonomic blocking effects of older antihistamines are additive with those of muscarinic and α -blocking drugs.

H₂ Receptor Antagonists

The development of H₂ receptor antagonists was based on the observation that H₁ antagonists had no effect on histamine-induced acid secretion in the stomach. Molecular manipulation of the histamine molecule resulted in a compound that blocked rather than stimulated acid production and

then a series of drugs with progressive increases in the acid secretion-blocking action and reduction in irrelevant effects. This development led to renewed interest in possible physiologic roles for histamine and to a classification of effects of both agonists and antagonists based upon histamine receptor subtypes. The high incidence of peptic ulcer disease and related gastrointestinal complaints created great interest in the therapeutic potential of H₂ receptor antagonists. Because of the ability of this class of drugs to reduce gastric acid secretion and their low toxicity, they are now among the most frequently used drugs in the USA and have become OTC items. These drugs are discussed in Chapter 63: Drugs Used in the Treatment of Gastrointestinal Diseases.

Katzung PHARMACOLOGY, 9e > Section IV. Drugs with Important Actions on Smooth Muscle > Chapter 16. Histamine, Serotonin, & the Ergot Alkaloids >

Serotonin (5-Hydroxy-Tryptamine)

Before the identification of 5-hydroxytryptamine (5-HT), it was known that when blood is allowed to clot, a vasoconstrictor (tonic) substance is released from the clot into the serum; this substance was called serotonin. Independent studies established the existence of a smooth muscle stimulant in intestinal mucosa; this was called enteramine. The synthesis of 5-hydroxytryptamine in 1951 permitted the identification of serotonin and enteramine as the same metabolite of 5-hydroxytryptophan.

Serotonin is thought to play a role in migraine headache. Serotonin is also one of the mediators of the signs and symptoms of carcinoid syndrome, an unusual manifestation of carcinoid tumor, a neoplasm of enterochromaffin cells. In patients whose tumor is not operable, serotonin antagonists may constitute the best treatment.

Basic Pharmacology of Serotonin

Chemistry & Pharmacokinetics

Like histamine, serotonin is widely distributed in nature, being found in plant and animal tissues, venoms, and stings. It is an indoleethylamine formed in biologic systems from the amino acid L-tryptophan by hydroxylation of the indole ring followed by decarboxylation of the amino acid (Figure 16–3). Hydroxylation at C5 is the rate-limiting step and can be blocked by *p*-chlorophenylalanine (PCPA; fenclonine) and by *p*-chloroamphetamine. These agents have been used experimentally to reduce serotonin synthesis in carcinoid syndrome.

Figure 16–3.

After synthesis, the free amine is stored or is rapidly inactivated, usually by oxidation catalyzed by the enzyme monoamine oxidase. In the pineal gland, serotonin serves as a precursor of melatonin, a melanocyte-stimulating hormone. In mammals (including humans), over 90% of the serotonin in the body is found in enterochromaffin cells in the gastrointestinal tract. In the blood, serotonin is found in platelets, which are able to concentrate the amine by means of an active carrier mechanism similar to that in the vesicles of noradrenergic and serotonergic nerve endings. Serotonin is also found in the raphe nuclei of the brain stem, which contain cell bodies of serotonergic neurons that synthesize, store, and release serotonin as a transmitter. Brain serotonergic neurons are involved in various functions such as mood, sleep, appetite, temperature regulation, the perception of pain, the regulation of blood pressure, and vomiting (see Chapter 21: Introduction to the Pharmacology of CNS Drugs). Serotonin also appears to be involved in conditions such as depression, anxiety, and migraine. Serotonergic neurons are also found in the enteric nervous system of the gastrointestinal tract and around blood vessels. In rodents (but not in humans), serotonin is found in mast cells.

The function of serotonin in enterochromaffin cells is not clear. These cells synthesize serotonin, store the amine in a complex with ATP and with other substances in granules, and can release serotonin in response to mechanical and neuronal stimuli. Some of the released serotonin diffuses into blood vessels and is taken up and stored in platelets.

Stored serotonin can be depleted by **reserpine** in much the same manner as this drug depletes catecholamines from vesicles in adrenergic nerves (see Chapter 6: Introduction to Autonomic Pharmacology).

Serotonin is metabolized by monoamine oxidase, and the intermediate product, 5-hydroxyindoleacetaldehyde, is further oxidized by aldehyde dehydrogenase to 5-hydroxyindoleacetic acid (5-HIAA). In humans consuming a normal diet, the excretion of 5-HIAA is a measure of serotonin synthesis. Therefore, the 24-hour excretion of 5-HIAA can be used as a diagnostic test for tumors that synthesize excessive quantities of serotonin, especially carcinoid tumor. A few foods (eg, bananas) contain large amounts of serotonin or its precursors and must be prohibited during such diagnostic tests.

Pharmacodynamics

Mechanisms of Action

Serotonin exerts many actions and, like histamine, has many species differences, making generalizations difficult. The actions of serotonin are mediated through a remarkably large number of cell membrane receptors. The serotonin receptors that have been characterized thus far are described in Table 16–3. Seven families of 5-HT-receptor subtypes (those given numeric subscripts 1 through 7) have been identified, six involving G protein-coupled receptors and one a ligand-gated ion channel. Among these receptor subtypes, several lack any recognized physiologic function. Discovery of these functions awaits the development of subtype-selective drugs or the mutation or deletion of genes encoding these receptors from the mouse genome.

Receptor Subtype	Distribution	Postreceptor Mechanism	Partially Selective Agonists	Partially Selective Antagonists
5-HT _{1A}	Raphe nuclei, hippocampus	Multiple, G _i coupling dominates	8-OH-DPAT	WAY100635
5-HT _{1B}	Substantia nigra, globus pallidus, basal ganglia	G _i , ↓cAMP	CP93129	
5-HT _{1Da,b}	Brain	G _i , ↓cAMP	Sumatriptan	
5-HT _{1E}	Cortex, putamen	G _i , ↓cAMP		
5-HT _{1F}	Cortex, hippocampus	G _i , ↓cAMP		
5-HT _{1P}	Enteric nervous system	G _o ; slow EPSP	5-Hydroxyindalpine	Renzapride
5-HT _{2A}	Platelets, smooth muscle, cerebral cortex, skeletal muscle	G _q , ↑IP ₃	α-Methyl-5-HT	Ketanserin

5-HT _{2B}	Stomach fundus	G _q , ↑IP ₃	α-Methyl-5-HT	SB204741
5-HT _{2C}	Choroid, hippocampus, substantia nigra	G _q , ↑IP ₃	α-Methyl-5-HT	Mesulergine
5-HT ₃	Area postrema, sensory and enteric nerves	Receptor is a Na ⁺ -K ⁺ ion channel	2-Methyl-5-HT, <i>m</i> - chlorophenylbiguanide	Tropisetron, ondansetron, granisetron
5-HT ₄	CNS and myenteric neurons, smooth muscle	G _s , ↑cAMP	5-Methoxytryptamine, renzapride, metoclopramide	
5-HT _{5A,B}	Brain	↓cAMP		
5-HT _{6,7}	Brain	G _s , ↑cAMP		Clozapine (5- HT ₇)

8-OH-DPAT = 8-Hydroxy-2-(di-*n*-propylamine)tetralin; CP93129 = 5-Hydroxy-3(4-1,2,5,6-tetrahydropyridyl)-4-azaindole; SB204741 = *N*-(1-methyl-5-indolyl)-*N'*-(3-methyl-5-isothiazolyl)urea; WAY100635 = *N-tert*-Butyl 3-4-(2-methoxyphenyl) piperazin-1-yl-2-phenylpropanamide

Tissue and Organ System Effects

Nervous System

Serotonin is present in a variety of sites in the brain. Its role as a neurotransmitter and its relation to the actions of drugs acting in the central nervous system are discussed in Chapters 21 and 30. Serotonin is also a precursor of melatonin (see Chapter 65: Botanicals ("Herbal Medications") & Nutritional Supplements).

5-HT₃ receptors in the gastrointestinal tract and in the vomiting center of the medulla participate in the vomiting reflex (see Chapter 63: Drugs Used in the Treatment of Gastrointestinal Diseases). They are particularly important in vomiting caused by chemical triggers such as cancer chemotherapy drugs. 5-HT_{1P} and 5-HT₄ receptors also play a role in enteric nervous system function.

Like histamine, serotonin is a potent stimulant of pain and itch sensory nerve endings and is responsible for some of the symptoms caused by insect and plant stings. In addition, serotonin is a powerful activator of chemosensitive endings located in the coronary vascular bed. Activation of 5-HT₃ receptors on these afferent vagal nerve endings is associated with the **chemoreceptor reflex** (also known as the Bezold-Jarisch reflex). The reflex response consists of marked bradycardia and hypotension. The bradycardia is mediated by vagal outflow to the heart and can be blocked by atropine. The hypotension is a consequence of the decrease in cardiac output that results from bradycardia. A variety of other agents can activate the chemoreceptor reflex. These include nicotinic cholinergic agonists and some cardiac glycosides, eg, ouabain.

Airways

Serotonin has a small direct stimulant effect on bronchiolar smooth muscle in normal humans. It also appears to facilitate acetylcholine release from bronchial vagal nerve endings. In patients with carcinoid syndrome, episodes of bronchoconstriction occur in response to elevated levels of the amine or peptides released from the tumor. Serotonin may also cause hyperventilation as a result of the chemoreceptor reflex or stimulation of bronchial sensory nerve endings.

Cardiovascular System

Serotonin directly causes the contraction of vascular smooth muscle, mainly through 5-HT₂ receptors. In humans, serotonin is a powerful vasoconstrictor except in skeletal muscle and heart, where it dilates blood vessels. At least part of this 5-HT-induced vasodilation requires the presence of vascular endothelial cells. When the endothelium is damaged, coronary vessels constrict. As noted previously, serotonin can also elicit reflex bradycardia by activation of 5-HT₃ receptors on chemoreceptor nerve endings. A triphasic blood pressure response is often seen following injection of serotonin. Initially, there is a decrease in heart rate, cardiac output, and blood pressure caused by the chemoreceptor response. Following this decrease, blood pressure increases as a result of vasoconstriction. The third phase is again a decrease in blood pressure attributed to vasodilation in vessels supplying skeletal muscle. Pulmonary and renal vessels seem especially sensitive to the vasoconstrictor action of serotonin.

Serotonin also constricts veins, and venoconstriction with a resulting increased capillary filling appears responsible for the flush that is observed following serotonin administration. Serotonin has small direct positive chronotropic and inotropic effects on the heart that are probably of no clinical significance. However, prolonged elevation of the blood level of serotonin (which occurs in carcinoid syndrome) is associated with pathologic alterations in the endocardium (subendocardial fibroplasia) that may result in valvular or electrical malfunction.

Serotonin causes blood platelets to aggregate by activating surface 5-HT₂ receptors. This response, in contrast to aggregation induced during clot formation, is not accompanied by the release of serotonin stored in the platelets. The physiologic role of this effect is unclear.

Gastrointestinal Tract

Serotonin is a powerful stimulant of gastrointestinal smooth muscle, increasing tone and facilitating peristalsis. This action is caused by the direct action of serotonin on 5-HT₂ smooth muscle receptors plus a stimulating action on ganglion cells located in the enteric nervous system (see Chapter 6: Introduction to Autonomic Pharmacology). Activation of 5-HT₄ receptors in the ENS causes increased acetylcholine release and thereby mediates a motility-enhancing or "prokinetic" effect of selective serotonin agonists such as cisapride. These agents are useful in several gastrointestinal disorders (see Chapter 63: Drugs Used in the Treatment of Gastrointestinal Diseases).

Overproduction of serotonin (and other substances) in carcinoid tumor is associated with severe diarrhea. Serotonin has little effect on secretions, and what effects it has are generally inhibitory.

Skeletal Muscle

5-HT₂ receptors are present on skeletal muscle membranes, but their physiologic role is not understood. **Malignant hyperthermia** is a condition precipitated by certain anesthetic and neuromuscular agents that results in severe hyperthermia due to skeletal muscle overactivity and metabolic and autonomic instability. In a genetic porcine model of this condition, administration of

serotonin or serotonin agonists can precipitate a typical attack. 5-HT₂ blockers such as ketanserin can reduce or prevent many manifestations of the condition when evoked in this way. However, malignant hyperthermia provoked by anesthetic agents in these animals is not effectively prevented by 5-HT₂ antagonists. **Serotonin syndrome** is a similar but not identical condition precipitated when MAO inhibitors are given with serotonin agonists, especially antidepressants of the selective serotonin reuptake inhibitor class (SSRIs).

Clinical Pharmacology of Serotonin

Serotonin Agonists

Serotonin has no clinical applications as a drug. However, several receptor subtype-selective agonists have proved to be of value. **Buspirone**, a 5-HT_{1A} agonist, has received wide attention for its utility as an effective nonbenzodiazepine anxiolytic (see Chapter 22: Sedative-Hypnotic Drugs). **Dexfenfluramine**, another selective 5-HT agonist, was widely used as an appetite suppressant (see Appetite Control Through Serotonin?) but was withdrawn because of toxicity. Sumatriptan and its congeners are agonists effective in the treatment of acute migraine and cluster headache attacks (see below).

5-HT_{1D} Agonists

Sumatriptan and several other "triptans" are selective agonists for 5-HT_{1D} and 5-HT_{1B} receptors. These receptor types are found in cerebral and meningeal vessels and mediate vasoconstriction. They are also found on neurons and probably function as presynaptic inhibitory receptors. These drugs have proved to be very effective in the treatment of acute migraine headache. The mechanism of action is discussed in more detail below under Clinical Pharmacology of Ergot Alkaloids.

The bioavailability of sumatriptan is only about 15%, but the other agents in the group have availabilities of 40–80%. Sumatriptan, almotriptan, eletriptan, rizatriptan, and zolmitriptan have half-lives of 2–3 hours, while the half-life of naratriptan is 6 hours and that of frovatriptan more than 25 hours. Sumatriptan can be administered subcutaneously by self-injection, as a nasal spray, or orally. The other members of the group are available only for oral administration.

The efficacy of 5-HT₁ agonists in migraine is equal to or greater than that of other drug treatments, eg, parenteral or oral ergot alkaloids. Most adverse effects are mild and include altered sensations (tingling, warmth, etc), dizziness, muscle weakness, neck pain, and injection site reactions. Chest discomfort occurs in 1–5% of patients, and chest pain has been reported, probably because of the ability of these drugs to cause coronary vasospasm. They are therefore contraindicated in patients with coronary artery disease and in patients with angina. Another disadvantage is the fact that their duration of effect (especially that of almotriptan, sumatriptan, rizatriptan, and zolmitriptan) is often shorter than the duration of the headache. As a result, several doses may be required during a prolonged migraine attack. In addition, these drugs are extremely expensive at present. Naratriptan and eletriptan are contraindicated in patients with severe hepatic or renal impairment or peripheral vascular syndromes; frovatriptan in patients with peripheral vascular disease; and zolmitriptan in patients with Wolff-Parkinson-White syndrome.

Other Serotonin Agonists in Clinical Use

Cisapride, a 5-HT₄ agonist, was used in the treatment of gastroesophageal reflux and motility disorders. Because of toxicity, it is now available only for compassionate use in the USA.

Tegaserod, a newer 5-HT₄ partial agonist, is used for irritable bowel syndrome with constipation.

These drugs are discussed in Chapter 63: Drugs Used in the Treatment of Gastrointestinal Diseases.

Compounds such as fluoxetine and other serotonin-selective reuptake inhibitors, which modulate serotonergic transmission by blocking reuptake of the transmitter, are among the most widely prescribed drugs for the management of depression and other behavioral disorders. These drugs are discussed in Chapter 30: Antidepressant Agents.

Serotonin Antagonists

The actions of serotonin, like those of histamine, can be antagonized in several different ways. Such antagonism is clearly desirable in those rare patients who have carcinoid tumor and may also be valuable in certain other conditions.

As noted above, serotonin synthesis can be inhibited by *p*-chlorophenylalanine and *p*-chloroamphetamine. However, these agents are too toxic for general use. Storage of serotonin can be inhibited by the use of reserpine, but the sympatholytic effects of this drug (see Chapter 11: Antihypertensive Agents) and the high levels of circulating serotonin that result from release prevent its use in carcinoid. Therefore, receptor blockade is the major approach to therapeutic limitation of serotonin effects.

Serotonin Receptor Antagonists

A wide variety of drugs with actions at other receptors (α adrenoceptors, H₁ histamine receptors, etc) are also serotonin receptor-blocking agents. **Phenoxybenzamine** (see Chapter 10: Adrenoceptor Antagonist Drugs) has a long-lasting blocking action at 5-HT₂ receptors. In addition, the ergot alkaloids discussed in the last portion of the chapter are partial agonists at serotonin receptors.

Cyproheptadine resembles the phenothiazine antihistaminic agents in chemical structure and has potent H₁ receptor-blocking as well as 5-HT₂-blocking actions. The actions of cyproheptadine are predictable from its H₁ histamine and serotonin receptor affinities. It prevents the smooth muscle effects of both amines but has no effect on the gastric secretion stimulated by histamine. It has significant antimuscarinic effects and causes sedation.

The major clinical applications of cyproheptadine are in the treatment of the smooth muscle manifestations of carcinoid tumor and in the postgastrectomy dumping syndrome. It is also the preferred drug in cold-induced urticaria. The usual dosage in adults is 12–16 mg/d in three or four divided doses.

Ketanserin (Figure 16–3) blocks 5-HT_{1c} and 5-HT₂ receptors and has little or no reported antagonist activity at other 5-HT or H₁ receptors. However, this drug potently blocks vascular α_1 adrenoceptors. The drug blocks 5-HT₂ receptors on platelets and antagonizes platelet aggregation promoted by serotonin. The mechanism involved in ketanserin's hypotensive action is not clear but probably involves α_1 adrenoceptors more than 5-HT₂ receptors. Ketanserin is available in Europe for the treatment of hypertension and vasospastic conditions but has not been approved in the USA.

Ritanserin, another 5-HT₂ antagonist, has little or no α -blocking action. It has been reported to alter bleeding time and to reduce thromboxane formation, presumably by altering platelet function.

Ondansetron (Figure 16–3) is the prototypical 5-HT₃ antagonist. This drug and its analogs are very important in the prevention of nausea and vomiting associated with surgery and cancer

chemotherapy. They are discussed in Chapter 63: Drugs Used in the Treatment of Gastrointestinal Diseases.

Considering the diverse effects attributed to serotonin and the heterogeneous nature of 5-HT receptors, other selective 5-HT antagonists may prove to be clinically useful.

Katzung PHARMACOLOGY, 9e > Section IV. Drugs with Important Actions on Smooth Muscle > Chapter 16. Histamine, Serotonin, & the Ergot Alkaloids >

Appetite Control Through Serotonin?

As noted in the text, serotonin appears to be related to several general behaviors such as sleep, emotion, sex, and appetite, and early studies with the amine suggested that it could reduce food intake in animals, an anorexigenic effect.

Fenfluramine, a racemic chemical more closely related to amphetamine than to serotonin, affects brain levels of serotonin and its metabolites at relatively low doses. It was introduced as an anorexigenic drug almost 20 years ago. Its *d*- isomer, *d*-fenfluramine (**dexfenfluramine, Redux**) was about twice as potent as fenfluramine. After several controlled clinical trials demonstrated that dexfenfluramine could help patients maintain weight loss for at least a year, it was quickly introduced into the market in the USA and became a best-selling drug overnight.

Dexfenfluramine caused serotonin release and inhibited reuptake at moderately low concentrations. It also stimulated 5-HT receptors at relatively low concentrations. Metergoline, an ergot derivative with high affinity for 5-HT receptors, completely blocked the anorexiatic effect of dexfenfluramine, further suggesting a serotonergic action.

Unfortunately, after the introduction of the drug, several cases of fatal and nonfatal pulmonary hypertension were reported in individuals with no known risk factor for this devastating condition other than consumption of dexfenfluramine. These reports were followed by reports of valvular lesions appearing in young women with a similar lack of risk factors other than the consumption of weight-loss products. Assignment of causality was somewhat slowed by the fact that dexfenfluramine was usually used in combination with a much older amphetamine-like anorexiatic, phentermine. (This combination was known as "Fen-Phen.") It soon became clear that the valvular lesions fell into the same class of drug-induced pathology as that caused by chronic ergot treatment for migraine (endocardial fibroplasia, retroperitoneal fibroplasia). These effects appear to be associated with 5-HT agonist action. Dexfenfluramine was withdrawn but not before multiple lawsuits had been filed against the manufacturer. Unfortunately, some weight loss clinics now recommend the combination of the antidepressant fluoxetine (Prozac) with phentermine, a combination known as "Phen-Pro."

Katzung PHARMACOLOGY, 9e > Section IV. Drugs with Important Actions on Smooth Muscle > Chapter 16. Histamine, Serotonin, & the Ergot Alkaloids >

The Ergot Alkaloids

Ergot alkaloids are produced by *Claviceps purpurea*, a fungus that infects grain—especially rye—under damp growing or storage conditions. This fungus synthesizes histamine, acetylcholine, tyramine, and other biologically active products in addition to a score or more of unique ergot alkaloids. These alkaloids affect α -adrenoceptors, dopamine receptors, 5-HT receptors, and perhaps

other receptor types. Similar alkaloids are produced by fungi parasitic to a number of other grass-like plants.

The accidental ingestion of ergot alkaloids in contaminated grain can be traced back more than 2000 years from descriptions of epidemics of ergot poisoning (**ergotism**). The most dramatic effects of poisoning are dementia with florid hallucinations; prolonged vasospasm, which may result in gangrene; and stimulation of uterine smooth muscle, which in pregnancy may result in abortion. In medieval times, ergot poisoning was called **St. Anthony's fire** after the saint whose help was sought in relieving the burning pain of vasospastic ischemia. Identifiable epidemics have occurred sporadically up to modern times (see Ergot Poisoning: Not Just an Ancient Disease) and mandate continuous surveillance of all grains used for food. Poisoning of grazing animals is common in many areas because the same and related fungi may grow on pasture grasses.

In addition to the effects noted above, the ergot alkaloids produce a variety of other central nervous system and peripheral effects. Detailed structure-activity analysis and appropriate semisynthetic modifications have yielded a large number of agents with documented or potential clinical value.

Basic Pharmacology of Ergot Alkaloids

Chemistry & Pharmacokinetics

Two major families of compounds that incorporate the tetracyclic **ergoline** nucleus may be identified; the amine alkaloids and the peptide alkaloids (Table 16–4). Drugs of therapeutic and toxicologic importance are found in both groups.

Table 16–4. Major Ergoline Derivatives (Ergot Alkaloids).

Amine alkaloids			Peptide alkaloids		
	R ₁	R ₈		R ₂	R ₂ '
6-Methylergoline	—H	—H			
Lysergic acid	—H	—COOH			Ergotamine ¹ —H —CH ₃
Lysergic acid diethylamide (LSD)	—H	$\begin{array}{c} \text{O} \\ \\ -\text{C}-\text{N}(\text{CH}_2-\text{CH}_3)_2 \end{array}$			α-Ergocryptine —H —CH(CH ₃) ₂
Ergonovine (ergometrine)	—H	$\begin{array}{c} \text{O} \quad \text{CH}_2\text{OH} \\ \quad \\ -\text{C}-\text{NHCHCH}_3 \end{array}$			Bromocriptine —Br —CH(CH ₃) ₂
Methysergide	—CH ₃	$\begin{array}{c} \text{O} \\ \\ -\text{C}-\text{NH}-\text{CH}-\text{CH}_2-\text{CH}_3 \\ \\ \text{CH}_2\text{OH} \end{array}$			

¹Dihydroergotamine lacks the double bond between carbons 9 and 10.

The ergot alkaloids are variably absorbed from the gastrointestinal tract. The oral dose of ergotamine is about ten times larger than the intramuscular dose, but the speed of absorption and peak blood levels after oral administration can be improved by administration with caffeine (see below). The amine alkaloids are also absorbed from the rectum and the buccal cavity and after administration by aerosol inhaler. Absorption after intramuscular injection is slow but usually reliable. Bromocriptine and the amine derivative cabergoline are well absorbed from the gastrointestinal tract.

The ergot alkaloids are extensively metabolized in the body. The primary metabolites are hydroxylated in the A ring, and peptide alkaloids are also modified in the peptide moiety.

Pharmacodynamics

Mechanism of Action

As suggested above, the ergot alkaloids act on several types of receptors. Their effects include agonist, partial agonist, and antagonist actions at α -adrenoceptors and serotonin receptors (especially 5-HT_{1A} and 5-HT_{1D}; less for 5-HT_{1C}, 5-HT₂, and 5-HT₃); and agonist or partial agonist actions at central nervous system dopamine receptors (Table 16–5). Furthermore, some members of the ergot family have a high affinity for presynaptic receptors, while others are more selective for postjunctional receptors. There is a powerful stimulant effect on the uterus that seems to be most closely associated with agonist or partial agonist effects at 5-HT₂ receptors. Structural variations increase the selectivity of certain members of the family for specific receptor types.

Table 16–5. Effects of Ergot Alkaloids at Several Receptors.¹

Ergot Alkaloid	α Adrenoceptor	Dopamine Receptor	Serotonin Receptor (5-HT ₂)	Uterine Smooth Muscle Stimulation
Bromocriptine	–	+++	–	0
Ergonovine	+	+	– (PA)	+++
Ergotamine	– – (PA)	0	+ (PA)	+++
Lysergic acid diethylamide (LSD)	0	+++	– –, ++ in CNS	+
Methysergide	+/0	+/0	– – – (PA)	+/0

¹Agonist effects are indicated by +, antagonist by –, no effect by 0. Relative affinity for the receptor is indicated by the number of + or – signs. PA means partial agonist (both agonist and antagonist effects can be detected).

Organ System Effects

Central Nervous System

As indicated by traditional descriptions of ergotism, certain of the naturally occurring alkaloids are powerful hallucinogens. Lysergic acid diethylamide (LSD; "acid") is a synthetic ergot compound that clearly demonstrates this action. The drug has been used in the laboratory as a potent peripheral 5-HT₂ antagonist, but good evidence suggests that its behavioral effects are mediated by *agonist* effects at prejunctional or postjunctional 5-HT₂ receptors in the central nervous system. In spite of extensive research, no clinical value has been discovered for LSD's dramatic effects. Abuse of this drug has waxed and waned but is still widespread. It is discussed in Chapter 32: Drugs of Abuse.

Dopamine receptors in the central nervous system play important roles in extrapyramidal motor control and the regulation of prolactin release. The actions of the peptide ergoline **bromocriptine** on the extrapyramidal system are discussed in Chapter 28: Pharmacologic Management of Parkinsonism & Other Movement Disorders. Of all the currently available ergot derivatives, bromocriptine, **cabergoline**, and **pergolide** have the highest selectivity for the pituitary dopamine receptors. These drugs directly suppress prolactin secretion from pituitary cells by activating regulatory dopamine receptors (Chapter 37: Hypothalamic & Pituitary Hormones). They compete for binding to these sites with dopamine itself and with other dopamine agonists such as

apomorphine.

Vascular Smooth Muscle

The action of ergot alkaloids on vascular smooth muscle is drug-, species-, and vessel-dependent, so few generalizations are possible. Ergotamine and related compounds constrict most human blood vessels in a predictable, prolonged, and potent manner (Figure 16–4). This response is partially blocked by conventional α -blocking agents. However, ergotamine's effect is also associated with "epinephrine reversal" (see Chapter 10: Adrenoceptor Antagonist Drugs) and with *blockade* of the response to other α agonists. This dual effect represents partial agonist action (Table 16–5). Because ergotamine dissociates very slowly from the α receptor, it produces very long-lasting agonist and antagonist effects at this receptor. There is little or no effect at β adrenoceptors.

Figure 16–4.

Effects of ergot derivatives on contraction of isolated segments of human basilar artery strips removed at surgery. All of the ergot derivatives are partial agonists, and all are more potent than the full agonists, norepinephrine and serotonin. (NE, norepinephrine; 5-HT, serotonin; ERG, ergotamine; MT, methylergometrine; DHE, dihydroergotamine; MS, methysergide.) (Modified and reproduced, with permission, from Müller-Schweinitzer E in: 5-Hydroxytryptamine Mechanisms in Primary Headaches. Oleson J, Saxena PR [editors]. Raven Press, 1992.)

While much of the vasoconstriction elicited by ergot alkaloids can be ascribed to partial agonist effects at α adrenoceptors, some may be the result of effects at 5-HT receptors. Ergotamine, ergonovine, and methysergide all have partial agonist effects at 5-HT₂ vascular receptors. The remarkably specific antimigraine action of the ergot derivatives was originally thought to be related to their actions on vascular serotonin receptors. Current hypotheses, however, emphasize their action on presynaptic neuronal 5-HT receptors.

After overdosage with ergotamine and similar agents, vasospasm is severe and prolonged (see Toxicity, below). This vasospasm is not easily reversed by α antagonists, serotonin antagonists, or combinations of both.

Ergotamine is typical of the ergot alkaloids that have a strong vasoconstrictor spectrum of action. The hydrogenation of ergot alkaloids at the 9 and 10 positions (Table 16–4) yields dihydro derivatives that have reduced serotonin partial agonist effects and increased selective α_2 receptor-blocking actions.

Uterine Smooth Muscle

The stimulant action of ergot alkaloids on the uterus, as on vascular smooth muscle, appears to combine α -agonist, serotonin, and other effects. Furthermore, the sensitivity of the uterus to the stimulant effects of ergot changes dramatically during pregnancy, perhaps because of increasing dominance of α_1 receptors as pregnancy progresses. As a result, the uterus at term is more sensitive than earlier in pregnancy and far more sensitive than the nonpregnant organ.

In very small doses, ergot preparations can evoke rhythmic contraction and relaxation of the uterus. At higher concentrations, these drugs induce powerful and prolonged contracture. Ergonovine is more selective than other ergot alkaloids in affecting the uterus and is the agent of choice in obstetric applications of these drugs.

Other Smooth Muscle Organs

In most patients, the ergot alkaloids have no significant effect on bronchiolar smooth muscle. The gastrointestinal tract, on the other hand, is quite sensitive in most patients. Nausea, vomiting, and diarrhea may be induced even by low doses in some patients. The effect is consistent with action on the central nervous system emetic center and on gastrointestinal serotonin receptors.

Clinical Pharmacology of Ergot Alkaloids

Clinical Uses

Migraine

Migraine headache in its "classic" form is characterized by a brief aura that may involve visual scotomas or even hemianopia and speech abnormalities, followed by a severe throbbing unilateral headache that lasts for a few hours to 1–2 days. "Common" migraine lacks the aura phase, but the headache is similar. Although the symptom pattern varies among patients, the severity of migraine headache justifies vigorous therapy in the great majority of cases.

Migraine involves the trigeminal nerve distribution to intracranial (and possibly extracranial) arteries. These nerves appear to release peptide neurotransmitters, especially **calcitonin gene-related peptide** (CGRP; see Chapter 17: Vasoactive Peptides), an extremely powerful vasodilator. Substance P and neurokinin A may also be involved. Extravasation of plasma and plasma proteins into the perivascular space appears to be a common feature of animal migraine models and biopsy specimens from migraine patients and probably represents the effect of the neuropeptides on the vessels. The mechanical stretching caused by this perivascular edema may be the immediate cause of activation of pain nerve endings in the dura. The onset of headache is sometimes associated with a marked increase in amplitude of temporal artery pulsations, and relief of pain by administration of ergotamine is sometimes accompanied by diminution of the arterial pulsations.

The mechanisms of action of drugs used in migraine are poorly understood because they include such a wide variety of drug groups and actions. These include ergot alkaloids and synthetic 5-HT agonists (triptans), nonsteroidal anti-inflammatory analgesic agents, β -adrenoceptor blockers,

tricyclic and serotonin-selective reuptake-inhibiting antidepressants, and several antiseizure agents. Furthermore, some of these drug groups are effective only for prophylaxis and not for the acute attack.

Two primary hypotheses have been proposed to explain the actions of these drugs. First, 5-HT agonists, such as ergot alkaloids, the triptans, and antidepressants may activate 5-HT₁ receptors on presynaptic trigeminal nerve endings to inhibit the release of vasodilating peptides, and antiseizure agents may suppress excessive firing of these nerve endings. Second, the vasoconstrictor actions of direct 5-HT agonists (ergot and the triptans) may prevent vasodilation and stretching of the pain endings. It is possible that both mechanisms contribute in the case of some drugs. **Sumatriptan** and its congeners, discussed above, are currently first-line therapy for acute severe migraine attacks in most patients. However, they should not be used in patients at risk for coronary artery disease. Anti-inflammatory analgesics such as aspirin and ibuprofen are often helpful in controlling the pain of migraine. Rarely, parenteral opioids may be needed in refractory cases. For patients with very severe nausea and vomiting, parenteral metoclopramide may be helpful.

Ergot derivatives are highly specific for migraine pain; they are not analgesic for any other condition. Although the triptan drugs discussed above are preferred by most clinicians and patients, traditional therapy with **ergotamine** can also be quite effective when given during the prodrome of an attack; it becomes progressively less effective if delayed. Ergotamine tartrate is available for oral, sublingual, rectal suppository, and inhaler use. It is often combined with caffeine (100 mg caffeine for each 1 mg ergotamine tartrate) to facilitate absorption of the ergot alkaloid.

The vasoconstriction induced by ergotamine is long-lasting and cumulative when the drug is taken repeatedly, as in a severe migraine attack. Therefore, patients must be carefully informed that no more than 6 mg of the oral preparation may be taken for each attack and no more than 10 mg per week. For very severe attacks, ergotamine tartrate, 0.25–0.5 mg, may be given intravenously or intramuscularly. **Dihydroergotamine**, 0.5–1 mg intravenously, is favored by some clinicians for treatment of intractable migraine. Intranasal dihydroergotamine may also be effective.

Because of the cumulative toxicity of ergotamine, safer agents useful for the prophylaxis of migraine have been sought. **Methysergide**, a derivative of the amine subgroup (Table 16–5), was shown to be effective in this application in about 60% of patients. Unfortunately, significant toxicity (discussed below) occurred in almost 40% of patients. Furthermore, methysergide was relatively *ineffective* in treatment of impending or active episodes of migraine. Although relatively free of the rapidly cumulative vasospastic toxicity of ergotamine, chronic use of methysergide was sometimes associated with retroperitoneal fibroplasia and subendocardial fibrosis, possibly through its vascular effects.

Propranolol and **amitriptyline** have also been found to be effective for the prophylaxis of migraine in some patients. Like methysergide, they are of no value in the treatment of acute migraine. The anticonvulsant valproic acid in the form of divalproex (see Chapter 24: Antiseizure Drugs) has recently been found to have good prophylactic efficacy in many migraine patients. **Flunarizine**, a calcium channel blocker used in Europe, has been reported in clinical trials to effectively reduce the severity of the acute attack and to prevent recurrences. **Verapamil** appears to have modest efficacy as prophylaxis against migraine.

Hyperprolactinemia

Increased serum levels of the anterior pituitary hormone prolactin are associated with secreting tumors of the gland and also with the use of centrally acting dopamine antagonists, especially the

antipsychotic drugs. Because of negative feedback effects, hyperprolactinemia is associated with amenorrhea and infertility in women as well as galactorrhea in both sexes.

Bromocriptine is extremely effective in reducing the high levels of prolactin that result from pituitary tumors and has even been associated with regression of the tumor in some cases. The usual dosage of bromocriptine is 2.5 mg two or three times daily. **Cabergoline** is similar but more potent. Bromocriptine has also been used in the same dosage to suppress physiologic lactation. However, serious postpartum cardiovascular toxicity has been reported in association with the latter use of bromocriptine or pergolide, and this application is discouraged (Chapter 37: Hypothalamic & Pituitary Hormones).

Postpartum Hemorrhage

The uterus at term is extremely sensitive to the stimulant action of ergot, and even moderate doses produce a prolonged and powerful spasm of the muscle quite unlike natural labor. This was not appreciated when the drugs were introduced into obstetrics in the 18th century. Their use at that time to accelerate labor caused a dramatic *increase* in fetal and maternal mortality rates. Therefore, ergot derivatives are useful only for control of late uterine bleeding and should never be given before delivery. Oxytocin is the preferred agent for control of postpartum hemorrhage, but if this peptide agent is ineffective, ergonovine maleate, 0.2 mg usually given intramuscularly, can be tried. It is usually effective within 1–5 minutes and is less toxic than other ergot derivatives for this application. It is given at the time of delivery of the placenta or immediately afterward if bleeding is significant.

Diagnosis of Variant Angina

Ergonovine produces prompt vasoconstriction during coronary angiography to diagnose variant angina.

Senile Cerebral Insufficiency

Dihydroergotoxine, a mixture of dihydro-~~er~~-ergocryptine and three similar dihydrogenated peptide ergot alkaloids (ergoloid mesylates), has been promoted for many years for the relief of senility and more recently for the treatment of Alzheimer's dementia. There is no evidence of significant benefit.

Toxicity & Contraindications

The most common toxic effects of the ergot derivatives are gastrointestinal disturbances, including diarrhea, nausea, and vomiting. Activation of the medullary vomiting center and of the gastrointestinal serotonin receptors is involved. Since migraine attacks are often associated with these symptoms before therapy is begun, these adverse effects are rarely contraindications to the use of ergot.

A more dangerous toxic effect of overdosage with agents like ergotamine and ergonovine is prolonged vasospasm. As described above, this sign of vascular smooth muscle stimulation may result in gangrene and require amputation. Most cases involve the circulation to the arms and legs. However, bowel infarction resulting from mesenteric artery vasospasm has also been reported. Peripheral vascular vasospasm caused by ergot is refractory to most vasodilators, but infusions of large doses of nitroprusside or nitroglycerin have been successful in some cases.

Chronic therapy with methysergide was associated with connective tissue proliferation in the

retroperitoneal space, the pleural cavity, and the endocardial tissue of the heart. These changes occurred insidiously over months and presented as hydronephrosis (from obstruction of the ureters) or a cardiac murmur (from distortion of the valves of the heart). In some cases, valve damage required surgical replacement. As a result, this drug was withdrawn.

Other toxic effects of the ergot alkaloids include drowsiness and, in the case of methysergide, occasional instances of central stimulation and hallucinations. In fact, methysergide was sometimes used as a substitute for LSD by members of the "drug culture."

Contraindications to the use of ergot derivatives consist of the obstructive vascular diseases and collagen diseases.

There is no evidence that ordinary use of ergotamine for migraine is hazardous in pregnancy. However, most clinicians counsel restraint in the use of the ergot derivatives by pregnant patients.

Ergot Poisoning: Not Just an Ancient Disease

As noted in the text, epidemics of ergotism, or poisoning by ergot-contaminated grain, are known to have occurred sporadically in ancient times and through the Middle Ages. It is easy to imagine the social chaos that might result if fiery pain, gangrene, hallucinations, convulsions, and abortions occurred simultaneously throughout a community in which all or most of the people believed in witchcraft, demonic possession, and the visitation of supernatural punishments upon humans for their misdeeds. Such beliefs are uncommon in most cultures today. However, ergotism has not disappeared. A most convincing demonstration of ergotism occurred in the small French village of Pont-Saint-Esprit in 1951. It was described in the *British Medical Journal* in 1951 (Gabbai et al, 1951) and in a later book-length narrative account (Fuller, 1968). Several hundred individuals suffered symptoms of hallucinations, convulsions, and ischemia—and several died—after eating bread made from contaminated flour. Similar events have occurred even more recently when poverty, famine, or incompetence resulted in the consumption of contaminated grain.

Iatrogenic ergot toxicity caused by excessive use of medical ergot preparations is still frequently reported.

Katzung PHARMACOLOGY, 9e > Section IV. Drugs with Important Actions on Smooth Muscle > Chapter 16. Histamine, Serotonin, & the Ergot Alkaloids >

Preparations Available

Antihistamines (H₁ Blockers)*

Azelastine (Astelin)

Nasal: 137 µg/puff nasal spray

Ophthalmic: 0.5 mg/mL solution

Brompheniramine (Brovex)

Oral: 12 mg tablets; 12 mg/5 mL suspension

Buclizine (Bucladin-S Softabs)

Oral: 50 mg tablets

Carbinoxamine (Histex, Pediatex)

Oral: 8 mg timed-release tablets; 1.75, 4 mg/5 mL liquid

Cetirizine (Zyrtec)

Oral: 5, 10 mg tablets; 5 mg/5 mL syrup

Chlorpheniramine (generic, Chlor-Trimeton, Teldrin, others)

Oral: 2 mg chewable tablets; 4 mg tablets; 2 mg/5 mL syrup

Oral sustained-release: 8, 12, 16 mg tablets; 8, 12 mg capsules

Clemastine (generic, Tavist)

Oral: 1.34, 2.68 mg tablets; 0.67 mg/5 mL syrup

Cyclizine (Marezine)

Oral: 50 mg tablets

Cyproheptadine (generic)

Oral: 4 mg tablets; 2 mg/5 mL syrup

Desloratadine (Clarinx)

Oral: 5 mg regular or rapidly disintegrating tablets

Dimenhydrinate (Dramamine, others)[†]

Oral: 50 mg tablets; 50 mg chewable tablets; 12.5/5 mL, 12.5 mg/4 mL, 15.62 mg/5 mL liquid

Diphenhydramine (generic, Benadryl)

Oral: 12.5 mg chewable tablets; 25, 50 mg capsules; 25, 50 mg tablets; 12.5 mg/5 mL elixir and syrup

Parenteral: 50 mg/mL for injection

Emedastine (Emadine)

Ophthalmic: 0.05% solution

Fexofenadine (Allegra)

Oral: 30, 60, 180 mg tablets; 60 mg capsules

Hydroxyzine (generic, Atarax, Vistaril)

Oral: 10, 25, 50, 100 mg tablets; 25, 50, 100 mg capsules; 10 mg/5 mL syrup; 25 mg/5 mL suspension

Parenteral: 25, 50 mg/mL for injection

Ketotifen (Zaditor)

Ophthalmic: 0.025% solution

Levocabastine (Livostin)

Ophthalmic: 0.05% solution

Loratadine (Claritin)

Oral: 10 mg tablets; 10 mg rapidly disintegrating tablets; 1 mg/mL syrup

Meclizine (generic, Antivert, others)

Oral: 12.5, 25, 50 mg tablets; 25, 30 mg capsules; 25 mg chewable tablets

Olopatadine (Patanol)

Ophthalmic: 0.1% solution

Phenindamine (Nolahist)

Oral: 25 mg tablets

Promethazine (generic, Phenergan, others)

Oral: 12.5, 25, 50 mg tablets; 6.25 mg/5 mL syrups

Parenteral: 25 mg/mL for injection; 50 mg/mL for IM injection

Rectal: 12.5, 25, 50 mg suppositories

H₂ Blockers

See Chapter 63: Drugs Used in the Treatment of Gastrointestinal Diseases.

5-HT Agonists

Almotriptan (Axert)

Oral: 6.25, 12.5 mg tablets

Eletriptan (Relpax)

Oral: 24.2, 48.5 mg tablets

Frovatriptan (Frova)

Oral: 2.5 mg tablets

Naratriptan (Amerge)

Oral: 1, 2.5 mg tablets

Rizatriptan

Oral: 5, 10 mg tablets (Maxalt); 5, 10 mg orally disintegrating tablets (Maxalt-MLT)

Sumatriptan (Imitrex)

Oral: 25, 50, 100 mg tablets

Nasal: 5, 20 mg unit dose spray devices

Parenteral: 6 mg/0.5 mL in *SELFdose* autoinjection units for subcutaneous injection

Zolmitriptan (Zomig)

Oral: 2.5, 5 mg tablets; 2.5 mg orally disintegrating tablets

5-HT Antagonists

See Chapter 63: Drugs Used in the Treatment of Gastrointestinal Diseases.

Ergot Alkaloids

Dihydroergotamine

Nasal (Migranal): 4 mg/mL nasal spray

Parenteral (D.H.E. 45): 1 mg/mL for injection

Ergonovine (Ergorate maleate)

Parenteral: 0.2 mg/mL for injection

Ergotamine [mixtures] (generic, Cafergot, others)

Oral: 1 mg ergotamine/100 mg caffeine tablets

Rectal: 2 mg ergotamine/100 mg caffeine suppositories

Ergotamine tartrate (Ergomar)

Sublingual: 2 mg sublingual tablets

Methylergonovine (Methergine)

Oral: 0.2 mg tablets

Parenteral: 0.2 mg/mL for injection

* Several other antihistamines are available only in combination products with, for example, pseudoephedrine.

† Dimenhydrinate is the chlorotheophylline salt of diphenhydramine.

Chapter 17. Vasoactive Peptides

Katzung PHARMACOLOGY, 9e > Section IV. Drugs with Important Actions on Smooth Muscle > Chapter 17. Vasoactive Peptides >

Vasoactive Peptides: Introduction

Peptides are used by most tissues for cell-to-cell communication. As noted in Chapters 6 and 21, they play important roles in the autonomic and central nervous systems. Several peptides exert important direct effects on vascular and other smooth muscles. These peptides include vasoconstrictors (**angiotensin II, vasopressin, endothelins, neuropeptide Y, and urotensin**) and vasodilators (**bradykinin** and related **kinins, natriuretic peptides, vasoactive intestinal peptide, substance P, neurotensin, calcitonin gene-related peptide, and adrenomedullin**). This chapter focuses on the smooth muscle actions of the peptides.

Angiotensin

Biosynthesis of Angiotensin

The pathway for the formation and metabolism of angiotensin II is summarized in Figure 17–1. The principal steps include enzymatic cleavage of angiotensin I from angiotensinogen by renin, conversion of angiotensin I to angiotensin II by converting enzyme, and degradation of angiotensin

II by several peptidases.

Figure 17-1.

Chemistry of the renin-angiotensin system. The amino acid sequence of the amino terminal of human angiotensinogen is shown. R denotes the remainder of the protein molecule.

Renin & Factors Controlling Renin Secretion

Renin is an aspartyl protease that specifically catalyzes the hydrolytic release of the decapeptide angiotensin I from angiotensinogen. It is synthesized as a prohormone that is processed to prorenin, which is inactive, and then to active renin, a glycoprotein consisting of 340 amino acids.

Renin in the circulation originates in the kidneys. Enzymes with renin-like activity are present in several extrarenal tissues, including blood vessels, uterus, salivary glands, and adrenal cortex, but no physiologic role for these enzymes has been established. Within the kidney, renin is synthesized and stored in the juxtaglomerular apparatus of the nephron. Specialized granular cells called juxtaglomerular cells are the site of synthesis, storage, and release of renin. The macula densa is a specialized tubular segment closely associated with the vascular components of the juxtaglomerular apparatus. The vascular and tubular components of the juxtaglomerular apparatus, including the

juxtaglomerular cells, are innervated by noradrenergic neurons.

The rate at which renin is secreted by the kidney is the primary determinant of activity of the renin-angiotensin system. Renin secretion is controlled by a variety of factors, including a renal vascular receptor, the macula densa, the sympathetic nervous system, and angiotensin II.

Renal Vascular Receptor

The renal vascular receptor functions as a stretch receptor, decreased stretch leading to increased renin release and vice versa. The receptor is apparently located in the afferent arteriole, possibly in the juxtaglomerular cells. Stretch-induced changes in renin release are mediated by changes in Ca^{2+} concentration in the juxtaglomerular cells.

Macula Densa

The macula densa contains a different type of receptor, sensitive to changes in the rate of delivery of sodium or chloride to the distal tubule. Decreases in distal delivery result in stimulation of renin secretion and vice versa. Potential candidates for signal transmission between the macula densa and the juxtaglomerular cells include adenosine, prostaglandins, and nitric oxide.

Sympathetic Nervous System

Maneuvers that increase renal nerve activity cause stimulation of renin secretion, while renal denervation results in suppression of renin secretion. Norepinephrine stimulates renin secretion by a direct action on the juxtaglomerular cells. In humans, this effect is mediated by β_1 adrenoceptors.

Circulating epinephrine and norepinephrine may act via the same mechanisms as the norepinephrine released locally from the renal sympathetic nerves, but there is evidence that a major component of the renin secretory response to circulating catecholamines is mediated by extrarenal β receptors.

Angiotensin

Angiotensin II inhibits renin secretion. The inhibition, which results from a direct action of the peptide on the juxtaglomerular cells, forms the basis of a short-loop negative feedback mechanism controlling renin secretion. Interruption of this feedback with inhibitors of the renin-angiotensin system (see below) results in stimulation of renin secretion.

Pharmacologic Alteration of Renin Release

The release of renin is altered by a wide variety of pharmacologic agents. Renin release is stimulated by vasodilators (hydralazine, minoxidil, nitroprusside), β -adrenoceptor agonists (isoproterenol), α -adrenoceptor antagonists, phosphodiesterase inhibitors (theophylline, milrinone, rolipram), and most diuretics and anesthetics. This stimulation can be accounted for by the control mechanisms just described. Drugs that inhibit renin release are discussed below in the section on inhibition of the renin-angiotensin system.

Angiotensinogen

Angiotensinogen is the circulating protein substrate from which renin cleaves angiotensin I. It is synthesized in the liver. Human angiotensinogen is a glycoprotein with a molecular weight of approximately 57,000. The 14 amino acids at the amino terminal of the molecule are shown in

Figure 17–1. In humans, the concentration of angiotensinogen in the circulation is less than the K_m of the renin-angiotensinogen reaction and is therefore an important determinant of the rate of formation of angiotensin.

The production of angiotensinogen is increased by corticosteroids, estrogens, thyroid hormones, and angiotensin II. It is also elevated during pregnancy and in women taking estrogen-containing oral contraceptives. The increased plasma angiotensinogen concentration is thought to contribute to the hypertension that may occur in these situations. There is also evidence for a genetic linkage between the angiotensinogen gene and essential hypertension (Lalouel et al, 2001).

Angiotensin I

Although angiotensin I contains the peptide sequences necessary for all of the actions of the renin-angiotensin system, it has little or no biologic activity. Instead, it must be converted to angiotensin II by converting enzyme (Figure 17–1). Angiotensin I may also be acted on by plasma or tissue aminopeptidases to form [des-Asp¹]angiotensin I; this in turn is converted to [des-Asp¹]angiotensin II (commonly known as angiotensin III) by converting enzyme.

Converting Enzyme (Peptidyl Dipeptidase [PDP], Kininase II)

Converting enzyme is a dipeptidyl carboxypeptidase that catalyzes the cleavage of dipeptides from the carboxyl terminal of certain peptides. Its most important substrates are angiotensin I, which it converts to angiotensin II, and bradykinin, which it inactivates (see below). It also cleaves enkephalins and substance P, but the physiologic significance of these effects has not been established. The action of converting enzyme is prevented by a penultimate prolyl residue, and angiotensin II is therefore not hydrolyzed by converting enzyme. Converting enzyme is distributed widely in the body. In most tissues, converting enzyme is located on the luminal surface of vascular endothelial cells and is thus in close contact with the circulation.

Angiotensinase

Angiotensin II, which has a plasma half-life of 15–60 seconds, is removed rapidly from the circulation by a variety of peptidases collectively referred to as angiotensinase. It is metabolized during passage through most vascular beds (a notable exception being the lung). Most metabolites of angiotensin II are biologically inactive, but the initial product of aminopeptidase action—[des-Asp¹]angiotensin II—retains considerable biologic activity.

Actions of Angiotensin II

Angiotensin II exerts important actions at several sites in the body, including vascular smooth muscle, adrenal cortex, kidney, and brain. Through these actions, the renin-angiotensin system plays a key role in the regulation of fluid and electrolyte balance and arterial blood pressure. Excessive activity of the renin-angiotensin system can result in hypertension and disorders of fluid and electrolyte homeostasis.

Blood Pressure

Angiotensin II is a very potent pressor agent—on a molar basis, approximately 40 times more potent than norepinephrine. The pressor response to intravenous angiotensin II is rapid in onset (10–15 seconds) and sustained during long-term infusions of the peptide. A large component of the pressor response to intravenous angiotensin II is due to direct contraction of vascular—especially

arteriolar—smooth muscle. In addition, however, angiotensin II can also increase blood pressure through actions on the brain and autonomic nervous system. The pressor response to angiotensin is usually accompanied by little or no reflex bradycardia because the peptide acts on the brain to reset the baroreceptor reflex control of heart rate to a higher pressure.

Angiotensin II also interacts with the autonomic nervous system. It stimulates autonomic ganglia, increases the release of epinephrine and norepinephrine from the adrenal medulla, and—what is most important—facilitates sympathetic transmission by an action at adrenergic nerve terminals. The latter effect involves both increased release and reduced reuptake of norepinephrine. Angiotensin II also has a less important direct positive inotropic action on the heart.

Adrenal Cortex

Angiotensin II acts directly on the zona glomerulosa of the adrenal cortex to stimulate aldosterone biosynthesis. At higher concentrations, angiotensin II also stimulates glucocorticoid biosynthesis.

Kidney

Angiotensin II acts on the kidney to cause renal vasoconstriction, increase proximal tubular sodium reabsorption, and inhibit the secretion of renin.

Central Nervous System

In addition to its central effects on blood pressure, angiotensin II acts on the central nervous system to stimulate drinking (dipsogenic effect) and increase the secretion of vasopressin and adrenocorticotrophic hormone (ACTH). The physiologic significance of the effects of angiotensin II on drinking and pituitary hormone secretion is not known.

Cell Growth

Angiotensin II is mitogenic for vascular and cardiac muscle cells and may contribute to the development of cardiovascular hypertrophy. Considerable evidence now indicates that angiotensin-converting enzyme (ACE) inhibitors and angiotensin II receptor antagonists (see below) slow or prevent morphologic changes (remodeling) following myocardial infarction that would otherwise lead to heart failure.

Angiotensin Receptors & Mechanism of Action

Angiotensin II receptors are widely distributed in the body. Like the receptors for other peptide hormones, angiotensin II receptors are located on the plasma membrane of target cells, and this permits rapid onset of the various actions of angiotensin II.

Two distinct subtypes of angiotensin II receptors, termed **AT₁** and **AT₂**, have been identified on the basis of their differential affinity for antagonists, and their sensitivity to sulfhydryl-reducing agents. **AT₁** receptors have a high affinity for losartan and a low affinity for PD 123177 (an experimental nonpeptide antagonist), while **AT₂** receptors have a high affinity for PD 123177 and a low affinity for losartan. Angiotensin II and saralasin (see below) bind equally to both subtypes. The relative proportion of the two subtypes varies from tissue to tissue: **AT₁** receptors predominate in vascular smooth muscle.

Most of the known actions of angiotensin II are mediated by the **AT₁** receptor, a G protein-coupled

receptor. Binding of angiotensin II to AT₁ receptors in vascular smooth muscle results in activation of phospholipase C and generation of inositol trisphosphate and diacylglycerol (see Chapter 2: Drug Receptors & Pharmacodynamics). These events, which occur within seconds, result in smooth muscle contraction.

The stimulation of vascular and cardiac growth by angiotensin II is mediated by other pathways, probably receptor and nonreceptor tyrosine kinases such as the Janus tyrosine kinase Jak2 and increased transcription of specific genes (see Chapter 2: Drug Receptors & Pharmacodynamics).

The AT₂ receptor has a structure and affinity for angiotensin II similar to those of the AT₁ receptor. However, signal transduction by the AT₂ receptor differs from transduction by the AT₁ receptor, and current evidence suggests that serine and tyrosine phosphatases, phospholipase A₂, nitric oxide, and cyclic guanosine monophosphate (cGMP) are involved. AT₂ receptors are present at high density in all tissues during fetal development, but they are much less abundant in the adult where they are expressed at high concentration only in the adrenal medulla, reproductive tissues, vascular endothelium and parts of the brain. AT₂ receptors are upregulated in pathologic conditions including heart failure and myocardial infarction. The functions of the AT₂ receptor appear to include fetal tissue development, inhibition of growth and proliferation, cell differentiation, apoptosis, and possibly, vasodilation.

Inhibition of the Renin-Angiotensin System

A wide variety of agents are now available that block the formation or actions of angiotensin II. These drugs may block renin secretion, the enzymatic action of renin, the conversion of angiotensin I to angiotensin II, or angiotensin II receptors.

Drugs That Block Renin Secretion

Several drugs that interfere with the sympathetic nervous system inhibit the secretion of renin. Examples are clonidine and propranolol. Clonidine inhibits renin secretion by causing a centrally mediated reduction in renal sympathetic nerve activity, and it may also exert a direct intrarenal action. Propranolol and other β-adrenoceptor-blocking drugs act by blocking the intrarenal and extrarenal βreceptors involved in the neural control of renin secretion.

Renin Inhibitors

Several orally active renin inhibitors have been developed. Two inhibitors that have been tested in humans are **remikiren** and **enalkiren**. They have a high specificity for renin, cause marked suppression of plasma renin activity and plasma angiotensin II concentration, and lower blood pressure in hypertensive patients. However, the bioavailability of these inhibitors is generally poor, mainly because of poor absorption and a considerable first pass effect. They also increase plasma renin concentrations because of interruption of the negative feedback effect of angiotensin II on renin secretion, and this further limits the reduction in plasma renin activity that can be achieved. Renin inhibitors have the potential to be as effective as converting enzyme inhibitors in inhibiting the renin-angiotensin system, but further improvement of their bioavailability and efficacy is needed.

Converting Enzyme Inhibitors

An important class of orally active **ACE** inhibitors, directed against the active site of ACE, is now extensively used. **Captopril** and **enalapril** (Figure 17–2) are examples of the many potent ACE

inhibitors that are available. These drugs differ in their structure and pharmacokinetics, but in clinical use, they are interchangeable. ACE inhibitors decrease systemic vascular resistance without increasing heart rate, and they promote natriuresis. As described in Chapter 11: Antihypertensive Agents and Chapter 13: Drugs Used in Heart Failure, they are effective in the treatment of hypertension, decrease morbidity and mortality in heart failure and left ventricular dysfunction after myocardial infarction, and delay the progression of diabetic nephropathy.

Figure 17–2.

Two orally active converting enzyme inhibitors. Enalapril is a prodrug ethyl ester that is hydrolyzed in the body.

ACE inhibitors not only block the conversion of angiotensin I to angiotensin II but also inhibit the degradation of other substances, including bradykinin, substance P, and enkephalins. The action of ACE inhibitors to inhibit bradykinin metabolism contributes significantly to their hypotensive action (Figure 11–6) and is apparently responsible for some adverse side effects, including cough and angioedema.

Angiotensin Antagonists

Substitution of certain amino acids, especially sarcosine, for the phenylalanine in position 8 of angiotensin II results in the formation of potent peptide antagonists of the action of angiotensin II. The best-known of these antagonists is **saralasin**.

Saralasin exhibits some agonist activity and may elicit pressor responses, particularly when circulating angiotensin II levels are low. Saralasin must be administered intravenously, and this severely restricts its use as an antihypertensive agent. However, it has been used for the detection of renin-dependent hypertension and other hyperreninemic states.

The *nonpeptide* angiotensin II antagonists are of much greater interest. **Losartan**, **valsartan** (Figure 17–3), **eprosartan**, **irbesartan**, **candesartan**, and **telmesartan** are orally active, potent, and specific competitive antagonists of angiotensin AT₁ receptors. The blood pressure-lowering efficacy of these drugs is similar to that of enalapril, a typical ACE inhibitor, but associated with a lower

incidence of cough. Like the ACE inhibitors, they are well tolerated but should not be used by patients with nondiabetic renal disease or in pregnancy.

Figure 17–3.

Structures of two angiotensin AT₁ receptor antagonists.

The current angiotensin II receptor antagonists are selective for the AT₁ receptor. Since prolonged treatment with the drugs disinhibits renin secretion and increases circulating angiotensin II levels, there may be increased stimulation of AT₂ receptors. This may be significant in view of the evidence that activation of the AT₂ receptor causes vasodilation and other beneficial effects. AT₂ receptor antagonists such as PD 123177 are available for research but have no clinical applications at this time.

The clinical benefits of AT₁ receptor antagonists are similar to those of ACE inhibitors, and it is currently not clear if one group of drugs has significant advantages over the other.

Katzung PHARMACOLOGY, 9e > Section IV. Drugs with Important Actions on Smooth Muscle > Chapter 17. Vasoactive Peptides >

Kinins

Biosynthesis of Kinins

Kinins are a group of potent vasodilator peptides. They are formed enzymatically by the action of enzymes known as kallikreins or kininogenases acting on protein substrates called kininogens. From the biochemical point of view, the kallikrein-kinin system has several features in common with the renin-angiotensin system.

Kallikreins

Kallikreins are glycoprotein enzymes produced in the liver as prekallikreins and present in plasma and in several tissues, including the kidneys, pancreas, intestine, sweat glands, and salivary glands. They are serine proteases with active sites and catalytic properties similar to those of enzymes such as trypsin, chymotrypsin, elastase, thrombin, plasmin, and other serine proteases. Plasma prekallikrein can be activated to kallikrein by trypsin, Hageman factor, and possibly kallikrein itself. In general, the biochemical properties of glandular kallikreins are quite different from those of plasma kallikreins. Kallikreins can convert prorenin to active renin, but the physiologic significance of this action has not been established.

Kininogens

Kininogens—the precursors of kinins and substrates of kallikreins—are present in plasma, lymph, and interstitial fluid. Two kininogens are known to be present in plasma: a low-molecular-weight form (LMW kininogen) and a high-molecular-weight form (HMW kininogen). About 15–20% of the total plasma kininogen is in the HMW form. It is thought that LMW kininogen crosses capillary walls and serves as the substrate for tissue kallikreins, while HMW kininogen is confined to the bloodstream and serves as the substrate for plasma kallikrein.

Formation of Kinins in Plasma & Tissues

The pathway for the formation and metabolism of kinins is shown in Figure 17–4. Three kinins have been identified in mammals: bradykinin, lysylbradykinin (also known as kallidin), and methionyllslylbradykinin. Their structures are shown below:

Arg-Pro-Pro-Gly-Phe-Ser-Pro-Phe-Arg
1 2 3 4 5 6 7 8 9

Bradykinin

Lys-Arg-Pro-Pro-Gly-Phe-Ser-Pro-Phe-Arg

Lysylbradykinin (kallidin; Lys-bradykinin)

Met-Lys-Arg-Pro-Pro-Gly-Phe-Ser-Pro-Phe-Arg

Methionyllslylbradykinin (Met-Lys-bradykinin)

Figure 17–4.

Note that each kinin contains bradykinin in its structure. Each kinin is formed from a kininogen by the action of a different enzyme. Bradykinin is released by plasma kallikrein, lysylbradykinin by glandular kallikrein, and methionyllysylbradykinin by pepsin and pepsin-like enzymes. The three kinins have been found in plasma and urine. Bradykinin is the predominant kinin in plasma, while lysylbradykinin is the major urinary form.

Actions of Kinins

Effects on the Cardiovascular System

Kinins produce marked vasodilation in several vascular beds, including the heart, kidney, intestine, skeletal muscle, and liver. In this respect, kinins are approximately 10 times more potent on a molar basis than histamine. The vasodilation may result from a direct inhibitory effect of kinins on arteriolar smooth muscle or may be mediated by the release of endothelium-derived relaxing factor (EDRF, nitric oxide) or vasodilator prostaglandins such as PGE₂ and PGI₂. In contrast, the predominant effect of kinins on veins is contraction; again, this may result from direct stimulation of venous smooth muscle or from the release of vasoconstrictor prostaglandins such as PGF_{2α}. Kinins also produce contraction of most visceral smooth muscle.

When injected intravenously, kinins produce a rapid fall in blood pressure that is due to their arteriolar vasodilator action. The hypotensive response to bradykinin is of very brief duration. Intravenous infusions of the peptide fail to produce a sustained decrease in blood pressure; prolonged hypotension can only be produced by progressively increasing the rate of infusion. The rapid reversibility of the hypotensive response to kinins is due primarily to reflex increases in heart rate, myocardial contractility, and cardiac output. In some species, bradykinin produces a biphasic change in blood pressure—an initial hypotensive response followed by an increase above the preinjection level. The increase in blood pressure may be due to a reflex activation of the sympathetic nervous system, but under some conditions, bradykinin can directly release catecholamines from the adrenal medulla and stimulate sympathetic ganglia. Bradykinin also increases blood pressure when injected into the central nervous system, but the physiologic significance of this effect is not clear, since it is unlikely that kinins cross the blood-brain barrier.

Kinins have no consistent effect on sympathetic or parasympathetic nerve endings.

The arteriolar dilation produced by kinins causes an increase in pressure and flow in the capillary bed, thus favoring efflux of fluid from blood to tissues. This effect may be facilitated by increased capillary permeability resulting from contraction of endothelial cells and widening of intercellular junctions, and by increased venous pressure secondary to constriction of veins. As a result of these changes, water and solutes pass from the blood to the extracellular fluid, lymph flow increases, and edema may result.

Effects on Endocrine & Exocrine Glands

As noted earlier, prekallikreins and kallikreins are present in several glands, including the pancreas, kidney, intestine, salivary glands, and sweat glands, and can be released into the secretory fluids of these glands. The function of the enzymes in these tissues is not known. The enzymes (or active kinins) may diffuse from the organs to the blood and act as local modulators of blood flow. Since kinins have such marked effects on smooth muscle, they may also modulate the tone of salivary and pancreatic ducts and help regulate gastrointestinal motility. Kinins also influence the transepithelial transport of water, electrolytes, glucose, and amino acids, and may regulate the transport of these substances in the gastrointestinal tract and kidney. Finally, kallikreins may play a role in the physiologic activation of various prohormones, including proinsulin and prorenin.

Role in Inflammation

Kinins play an important role in the inflammatory process. Kallikreins and kinins can produce redness, local heat, swelling, and pain, and the production of kinins is increased in inflammatory lesions produced by a variety of methods.

Effects on Sensory Nerves

Kinins are potent pain-producing substances when applied to a blister base or injected intradermally. They elicit pain by stimulating nociceptive afferents in the skin and viscera.

Kinin Receptors & Mechanisms of Action

The biologic actions of kinins are mediated by specific receptors located on the membranes of the target tissues. Two types of kinin receptors, termed B₁ and B₂, have been defined based on the rank orders of agonist potencies: for B₁ receptors, [des-Arg⁹]bradykinin > [Tyr(Me)⁸] bradykinin > bradykinin. For B₂ receptors, [Tyr(Me)⁸] bradykinin > bradykinin > [des-Arg⁹]bradykinin. (Note that *B* here stands for bradykinin, not for β-adrenoceptor.) Bradykinin displays the highest affinity in most B₂ receptor systems, followed by Lys-bradykinin and then by Met-Lys-bradykinin. One exception is the B₂ receptor that mediates contraction of venous smooth muscle; this appears to be most sensitive to Lys-bradykinin. Recent evidence suggests the existence of two B₂ receptor subtypes, which have been termed B_{2A} and B_{2B}.

B₁ receptors appear to have a very limited distribution in mammalian tissues. Known functional roles for B₁ receptors are limited. Studies with knockout mice that lack functional B₁ receptors have provided evidence that these receptors participate in the inflammatory response (Pesquero, 2000). B₁ receptors may also be important in long-lasting kinin effects such as collagen synthesis and cell multiplication. By contrast, B₂ receptors have a widespread distribution that is consistent with the multitude of biologic effects that are mediated by this receptor type. B₂ receptors belong to the G protein-coupled family of receptors. Receptor binding sets in motion multiple signal transduction

events, including calcium mobilization, chloride transport, formation of nitric oxide, and activation of phospholipase C, phospholipase A₂, and adenylyl cyclase.

Metabolism of Kinins

Kinins are metabolized rapidly (half-life < 15 seconds) by nonspecific exopeptidases or endopeptidases, commonly referred to as kininases. Two plasma kininases have been well characterized. Kininase I, apparently synthesized in the liver, is a carboxypeptidase that releases the carboxyl terminal arginine residue. Kininase II is present in plasma and vascular endothelial cells throughout the body. It is identical to angiotensin-converting enzyme (ACE, peptidyl dipeptidase), discussed above. Kininase II inactivates kinins by cleaving the carboxyl terminal dipeptide phenylalanyl-arginine. Like angiotensin I, bradykinin is almost completely hydrolyzed during a single passage through the pulmonary vascular bed.

Drugs Affecting the Kallikrein-Kinin System

Drugs that modify the activity of the kallikrein-kinin system are available, though none are in wide clinical use. Considerable effort has been directed toward developing kinin receptor antagonists, since such drugs have considerable therapeutic potential as anti-inflammatory and antinociceptive agents. Competitive antagonists of both B₁ and B₂ receptors are available for research use. Examples of B₁ receptor antagonists are the peptides [Leu⁸-des-Arg⁹]bradykinin and Lys[Leu⁸-des-Arg⁹]bradykinin. Nonpeptide B₁ receptor antagonists are not yet available. The first B₂ receptor antagonists to be discovered were also peptide derivatives of bradykinin. These first-generation antagonists were used extensively in animal studies of kinin receptor pharmacology. However, their half-life is short, and they are almost inactive on the human B₂ receptor.

Icatibant is a second generation B₂ receptor antagonist. It is orally active, potent, and selective, has a long duration of action (> 60 minutes), and displays high B₂ receptor affinity in humans and all other species in which it has been tested. Icatibant has been used extensively in animal studies to block exogenous and endogenous bradykinin and in human studies to evaluate the role of kinins in pain, hyperalgesia, and inflammation.

Recently, a third generation of B₂ receptor antagonists was developed; examples are FR 173657, FR 172357, and NPC 18884. These antagonists block both human and animal B₂ receptors and are orally active. They have been reported to inhibit bradykinin-induced bronchoconstriction in guinea pigs, carrageenin-induced inflammatory responses in rats, and capsaicin-induced nociception in mice.

The synthesis of kinins can be inhibited with the kallikrein inhibitor aprotinin. Actions of kinins mediated by prostaglandin generation can be blocked nonspecifically with inhibitors of prostaglandin synthesis such as aspirin. Conversely, the actions of kinins can be enhanced with ACE inhibitors, which block the degradation of the peptides. Indeed, as noted above, inhibition of bradykinin metabolism by ACE inhibitors contributes significantly to their antihypertensive action.

There is evidence that by acting on B₂ receptors, bradykinin may play a beneficial, protective role in cardiovascular disease. Selective B₂ agonists are available and have been shown to be effective in some animal models of human cardiovascular disease. These drugs may have potential for the treatment of hypertension and myocardial hypertrophy.

Vasopressin

Vasopressin (antidiuretic hormone, ADH) plays an important role in the long-term control of blood pressure through its action on the kidney to increase water reabsorption. This and other aspects of the physiology of vasopressin are discussed in Chapter 15: Diuretic Agents and Chapter 37: Hypothalamic & Pituitary Hormones and will not be reviewed here.

Vasopressin also plays an important role in the short-term regulation of arterial pressure by its vasoconstrictor action. It increases total peripheral resistance when infused in doses less than those required to produce maximum urine concentration. Such doses do not normally increase arterial pressure because the vasopressor activity of the peptide is buffered by a reflex decrease in cardiac output. When the influence of this reflex is removed, eg, in shock, pressor sensitivity to vasopressin is greatly increased. Pressor sensitivity to vasopressin is also enhanced in patients with idiopathic orthostatic hypotension. Higher doses of vasopressin increase blood pressure even when baroreceptor reflexes are intact.

Vasopressin Receptors & Antagonists

Three subtypes of vasopressin receptors have been identified. **V_{1a} receptors** mediate the vasoconstrictor action of vasopressin; **V_{1b} receptors** potentiate the release of ACTH by pituitary corticotropes; and **V₂ receptors** mediate the antidiuretic action. V_{1a} effects are mediated by activation of phospholipase C, formation of inositol trisphosphate, and increased intracellular calcium concentration. V₂ effects are mediated by activation of adenylyl cyclase.

Vasopressin-like peptides selective for either vasoconstrictor or antidiuretic activity have been synthesized. The most specific V₁ vasoconstrictor agonist synthesized to date is [Phe², Ile³, Orn⁸]vasotocin. Selective V₂ antidiuretic analogs include 1-deamino[D-Arg⁸]arginine vasopressin (dDAVP) and 1-deamino[Val⁴,D-Arg⁸]arginine vasopressin (dVDAVP).

Specific antagonists of the vasoconstrictor action of vasopressin are also available. The peptide antagonist [1-(β-mercapto-β,β-cyclopentamethylenepropionic acid)-2-(*O*-methyl)tyrosine] arginine vasopressin also has antioxytotic activity but does not antagonize the antidiuretic action of vasopressin. Recently, nonpeptide, orally active V_{1a} receptor antagonists have been discovered, examples being OPC-21268 and SR-49059 (Thibonnier et al, 2001).

The vasopressor antagonists have been particularly useful in revealing the important role that vasopressin plays in blood pressure regulation in situations such as dehydration and hemorrhage. They have potential for the treatment of hypertension and heart failure.

Katzung PHARMACOLOGY, 9e > Section IV. Drugs with Important Actions on Smooth Muscle > Chapter 17. Vasoactive Peptides >

Natriuretic Peptides

Synthesis & Structure

The atria and other tissues of mammals contain a family of peptides with natriuretic, diuretic, vasorelaxant and other properties. The family consists of atrial natriuretic peptide (ANP), brain natriuretic peptide (BNP) and C-type natriuretic peptide (CNP). The structures of the three peptides are similar (Figure 17–5), but there are differences in their biologic effects. ANP is derived from the

carboxyl terminal end of a common precursor termed preproANP which, in humans, is a 151-amino-acid peptide. ANP is synthesized primarily in cardiac atrial cells, but small amounts are synthesized in ventricular cells. It is also synthesized by neurons in the central and peripheral nervous systems and in the lungs. ANP circulates as a 28-amino-acid peptide with a single disulfide bridge that forms a 17-residue ring.

Figure 17–5.

Structures of the atrial natriuretic peptide (ANP), brain natriuretic peptide (BNP), and C-type natriuretic peptide (CNP). Sequences common to the peptides are indicated in blue.

Several factors increase the release of ANP from the heart, but the most important one appears to be atrial stretch via mechanosensitive ion channels (Thibault et al, 1999). ANP release is also increased by volume expansion, head-out water immersion, changing from the standing to the supine position, and exercise. In each case, the increase in ANP release is probably due to increased atrial stretch. ANP release can also be increased by sympathetic stimulation via α_{1A} -adrenoceptors, endothelins (see below) via the ET_A receptor subtype, glucocorticoids, and vasopressin. Finally, plasma ANP concentration increases in various pathologic states, including heart failure, primary aldosteronism, chronic renal failure, and inappropriate ADH secretion syndrome.

Administration of ANP produces prompt and marked increases in sodium excretion and urine flow. Glomerular filtration rate increases, with little or no change in renal blood flow, so that the filtration fraction increases. The ANP-induced natriuresis is apparently due to both the increase in glomerular filtration rate and a decrease in proximal tubular sodium reabsorption. ANP also inhibits the secretion of renin, aldosterone, and vasopressin; these changes may also increase sodium and water excretion. Finally, ANP decreases arterial blood pressure. This hypotensive action is due to vasodilation, which results from stimulated particulate guanylyl cyclase activity, increased cGMP levels, and decreased cytosolic free calcium concentration. ANP also reduces sympathetic tone to the peripheral vasculature and antagonizes the vasoconstrictor action of angiotensin II and other vasoconstrictors. These actions may contribute to the hypotensive action of the peptide.

There is considerable evidence that ANP participates in the physiologic regulation of sodium excretion and blood pressure. For example, suppression of ANP production or blockade of its action impairs the natriuretic response to volume expansion, and increases blood pressure.

BNP was originally isolated from porcine brain but, like ANP, it is synthesized primarily in the heart. It exists in two forms, having either 26 or 32 amino acids (Figure 17–5). Like ANP, the release of BNP appears to be volume-related; indeed, the two peptides may be co-secreted. BNP exhibits natriuretic, diuretic, and hypotensive activities similar to those of ANP but circulates at a lower concentration.

CNP consists of 22 amino acids (Figure 17–5). It is located predominantly in the central nervous system but is also present in several tissues including the vascular endothelium, kidneys, and intestine. It has not been found in significant concentrations in the circulation. CNP has less natriuretic and diuretic activity than ANP and BNP but is a potent vasodilator. Its physiologic role is unclear.

Pharmacodynamics & Pharmacokinetics

The biologic actions of the natriuretic peptides are mediated through association with specific high-affinity receptors located on the surface of the target cells. Three receptor subtypes termed **ANP_A**, **ANP_B**, and **ANP_C** have been identified. The ANP_A receptor consists of a 120 kDa protein; its primary ligands are ANP and BNP. The ANP_B receptor is similar in structure to the ANP_A receptor, but its primary ligand appears to be CNP. The ANP_A and ANP_B receptors, but not the ANP_C receptor, are coupled to guanylyl cyclase.

The natriuretic peptides have a short half-life in the circulation. They are metabolized in the kidneys, liver, and lungs by the neutral endopeptidase NEP 24.11. Inhibition of this endopeptidase results in increases in circulating levels of the natriuretic peptides, natriuresis, and diuresis. The peptides are also removed from the circulation by binding to ANP_C receptors in the vascular endothelium. This receptor binds the three natriuretic peptides with equal affinity. The receptor and bound peptide are internalized, the peptide is degraded enzymatically, and the receptor is returned to the cell surface.

Administration of BNP as **nesiritide** (see Chapter 13: Drugs Used in Heart Failure) in patients with severe heart failure increases sodium excretion and improves hemodynamics. However, the peptide has to be given by constant intravenous infusion. A more promising approach may be the use of drugs that inhibit the neutral endopeptidase responsible for the breakdown of ANP. This is discussed below under Vasopeptidase Inhibitors.

Pathophysiology

Patients with heart failure have high plasma levels of ANP and BNP, which have emerged as important diagnostic and prognostic markers in this condition. Thus, plasma ANP concentration has been shown to be closely correlated with the New York Heart Association functional class of symptomatic heart failure (Boomsma, 2001). Through the actions described above, the peptides reduce salt and water retention. However, renal responsiveness to the peptides decreases as heart failure worsens. The natriuretic peptides may also play a role in preventing the development of hypertension. For example, studies in experimental animals have identified an important role of the peptides in helping prevent mineralocorticoid-induced and salt-induced hypertension.

Katzung PHARMACOLOGY, 9e > Section IV. Drugs with Important Actions on Smooth Muscle > Chapter 17. Vasoactive Peptides >

Vasopeptidase Inhibitors

Vasopeptidase inhibitors are a new class of cardiovascular drugs that inhibit two metalloprotease enzymes, NEP 24.11 and ACE. They thus simultaneously increase the levels of natriuretic peptides and decrease the formation of angiotensin II. As a result, they enhance vasodilation, reduce vasoconstriction, and increase sodium excretion, in turn reducing peripheral vascular resistance and blood pressure.

Recently developed vasopeptidase inhibitors include **omapatrilat**, **sampatrilat**, and **fasidotrilat**. Of these, omapatrilat is at the most advanced stage of clinical development. It lowers blood pressure in animal models of hypertension as well as in hypertensive patients and improves cardiac function in patients with heart failure. Unfortunately, omapatrilat causes a significant incidence of angioedema in addition to cough and dizziness. Nevertheless, combined inhibition of neutral endopeptidase NEP 24.11 and ACE with this new class of drugs may be a promising approach to treat cardiovascular disease and further clinical trials are underway.

Katzung PHARMACOLOGY, 9e > Section IV. Drugs with Important Actions on Smooth Muscle > Chapter 17. Vasoactive Peptides >

Endothelins

The endothelium is the source of a variety of substances with vasodilator (PGI₂ and nitric oxide) and vasoconstrictor activities. The latter include the endothelin family, potent vasoconstrictor peptides that were first isolated from aortic endothelial cells.

Biosynthesis, Structure, & Clearance

Three isoforms of endothelin have been identified: the originally described endothelin (**ET-1**) and two similar peptides, **ET-2** and **ET-3**. Each isoform is a product of a different gene and is synthesized as a prepro form that is processed to a propeptide and then to the mature peptide. Processing to the mature peptides occurs through the action of endothelin-converting enzyme. Each endothelin is a 21-amino-acid peptide containing two disulfide bridges (Figure 17–6).

Figure 17–6.

Structures of the endothelin peptides endothelin-1, endothelin-2, and endothelin-3. Sequences different in the three peptides are shown in blue.

Endothelins are widely distributed in the body. ET-1 is the predominant endothelin secreted by the vascular endothelium. It is also produced by neurons and astrocytes in the central nervous system and in endometrial, renal mesangial, Sertoli, breast epithelial, and other cells. ET-2 is produced predominantly in the kidneys and intestine, while ET-3 is found in highest concentration in the brain but is also present in the gastrointestinal tract, lungs, and kidneys. Endothelins are present in the blood but in low concentration; they apparently act locally in a paracrine or autocrine fashion rather than as circulating hormones.

The expression of the ET-1 gene is increased by growth factors and cytokines, including transforming growth factor- β (TGF- β) and interleukin 1 (IL-1), vasoactive substances including angiotensin II and vasopressin, and mechanical stress. Expression is inhibited by nitric oxide, prostacyclin, and atrial natriuretic peptide.

Clearance of endothelins from the circulation is rapid, and involves both enzymatic degradation by NEP 24.11 and clearance by the ET_B receptor.

Actions

Endothelins exert widespread actions in the body. In particular, they cause dose-dependent vasoconstriction in most vascular beds. Intravenous administration of ET-1 causes a rapid and transient decrease in arterial blood pressure followed by a prolonged increase. The depressor response results from release of prostacyclin and nitric oxide from the vascular endothelium, while the pressor response is due to direct constriction of vascular smooth muscle. Endothelins also exert direct positive inotropic and chronotropic actions on the heart and are potent coronary vasoconstrictors. They act on the kidneys to cause vasoconstriction and decrease glomerular

filtration rate and sodium and water excretion. In the respiratory system, they cause potent constriction of tracheal and bronchial smooth muscle. Endothelins interact with several endocrine systems, increasing the secretion of renin, aldosterone, vasopressin, and atrial natriuretic peptide. They exert a variety of actions on the central and peripheral nervous systems, the gastrointestinal system, the liver, the urinary tract, the male and female reproductive systems, the eye, the skeletal system, and the skin. Finally, ET-1 is a potent mitogen for vascular smooth muscle cells, cardiac myocytes, and glomerular mesangial cells.

Endothelin receptors are present in many tissues and organs, including the blood vessel wall, cardiac muscle, central nervous system, lung, kidney, adrenal, spleen, and intestine. Two receptor subtypes, termed **ET_A** and **ET_B**, have been cloned and sequenced. ET_A receptors have a high affinity for ET-1 and a low affinity for ET-3 and are located on smooth muscle cells, where they mediate vasoconstriction. ET_B receptors have approximately equal affinities for ET-1 and ET-3 and are located on vascular endothelial cells, where they mediate release of PGI₂ and nitric oxide. Both receptor subtypes belong to the G protein-coupled seven-transmembrane domain family of receptors.

The signal transduction mechanisms triggered by binding of ET-1 to its receptors are summarized in Figure 17–7. Major effects include stimulation of phospholipase C, formation of inositol trisphosphate, and release of calcium from the endoplasmic reticulum, which results in vasoconstriction. Stimulation of PGI₂ and nitric oxide synthesis results in decreased intracellular calcium concentration and vasodilation.

Figure 17–7.

Signal transduction mechanisms mediating the effects of ET-1 on vascular smooth muscle.

Inhibitors of Endothelin Synthesis & Action

The endothelin system can be blocked with receptor antagonists and drugs that block endothelin-converting enzyme. Endothelin ET_A or ET_B receptors can be blocked selectively, or both can be blocked with nonselective ET_A-ET_B antagonists.

An example of a nonselective antagonist is **bosentan**. This drug is active both intravenously and orally, and blocks both the initial transient depressor (ET_B) and the prolonged pressor (ET_A) responses to intravenous endothelin. Many orally active endothelin receptor antagonists with increased selectivity have been developed and are available for research use.

The formation of endothelins can be blocked by inhibiting endothelin-converting enzyme with phosphoramidon. This compound is not specific for endothelin-converting enzyme, but several potent and more selective inhibitors are now available. The therapeutic potential of these drugs may be similar to that of the endothelin receptor antagonists (see below).

Physiologic & Pathologic Roles of Endothelin: Effects of Endothelin Antagonists

Systemic administration of endothelin receptor antagonists or endothelin-converting enzyme inhibitors causes vasodilation and decreases arterial pressure in humans and experimental animals. Intra-arterial administration of the drugs also causes slow-onset forearm vasodilation in humans. These observations provide evidence that the endothelin system participates in the regulation of vascular tone, even under resting conditions.

There is increasing evidence that endothelins participate in a variety of cardiovascular diseases, including hypertension, cardiac hypertrophy, heart failure, atherosclerosis, coronary artery disease, and myocardial infarction. Endothelins have also been implicated in pulmonary diseases, including asthma and pulmonary hypertension, as well as in several renal diseases. This evidence includes findings of increased endothelin levels in the blood, increased expression of endothelin mRNA in endothelial or vascular smooth muscle cells, and the responses to administration of endothelin antagonists.

Endothelin antagonists have considerable potential in the treatment of these diseases. In clinical trials, bosentan and other nonselective antagonists as well as ET_A-selective antagonists have produced beneficial effects on hemodynamics and other symptoms in heart failure, pulmonary

hypertension, and essential hypertension. Bosentan is currently approved for use in pulmonary hypertension (see Chapter 11: Antihypertensive Agents).

Endothelin antagonists occasionally cause systemic hypotension, increased heart rate, facial flushing or edema, and headaches. Potential gastrointestinal effects include nausea, vomiting, and constipation. Because of their teratogenic effects, ET antagonists are contraindicated in pregnancy. Thus, despite their considerable potential, additional research is needed before these drugs can be considered safe for more extensive clinical use.

Vasoactive Intestinal Peptide

Vasoactive intestinal peptide (VIP) is a 28-amino-acid peptide related structurally to secretin and glucagon. Its structure is shown below.

His-Ser-Asp-Ala-Val-Thr-Asp-Asn-Tyr-Thr-Arg-Leu-Arg-
Lys-Gln-Met-Ala-Val-Lys-Lys-Tyr-Leu-Asn-Ser-Ile-Leu-Asn-NH₂

Vasoactive intestinal peptide (VIP)

VIP is widely distributed in the central and peripheral nervous systems where it functions as a neurotransmitter or neuromodulator. It is also present in several organs including the gastrointestinal tract, heart, lungs, kidneys, and thyroid gland. Many blood vessels are innervated by VIP neurons. VIP is present in the circulation but does not appear to function as a hormone.

VIP exerts marked effects on the cardiovascular system. It produces marked vasodilation in most vascular beds and in this regard is more potent on a molar basis than acetylcholine. In the heart, VIP causes coronary vasodilation and exerts positive inotropic and chronotropic effects. It may thus participate in the regulation of coronary blood flow, cardiac contraction, and heart rate.

The effects of VIP are mediated by G protein-coupled receptors, of which two subtypes termed **VPAC1** and **VPAC2** have been cloned from human tissues. Both subtypes are widely distributed in the central nervous system and in the heart, blood vessels, and other tissues. Binding of VIP to its receptors results in activation of adenylyl cyclase and formation of cAMP, which is responsible for the vasodilation and many other effects of the peptide. Other actions may be mediated by nitric oxide and cGMP.

Specific VIP receptor agonists and antagonists are currently available for research use.

Katzung PHARMACOLOGY, 9e > Section IV. Drugs with Important Actions on Smooth Muscle > Chapter 17. Vasoactive Peptides >

Substance P

Substance P belongs to the **tachykinin** family of peptides, which share the common carboxyl terminal sequence Phe-X-Gly-Leu-Met. Other members of this family are **neurokinin A** and **neurokinin B**. Substance P is an undecapeptide, while neurokinins A and B are decapeptides. They have the following structures:

Arg-Pro-Lys-Pro-Gln-Gln-Phe-Phe-Gly-Leu-Met

Substance P

His-Lys-Thr-Asp-Ser-Phe-Val-Gly-Leu-Met

Neurokinin A

Asp-Met-His-Asp-Phe-Phe-Val-Gly-Leu-Met

Neurokinin B

The amino terminal of substance P is not essential for biologic activity, but the carboxyl terminal is. The minimum fragment of substance P with significant activity is the carboxyl terminal hexapeptide.

Substance P is present in the central nervous system, where it is a neurotransmitter (see Chapter 21: Introduction to the Pharmacology of CNS Drugs), and in the gastrointestinal tract, where it may play a role as a transmitter in the enteric nervous system and as a local hormone (see Chapter 6: Introduction to Autonomic Pharmacology).

Substance P exerts a variety of incompletely understood central actions that implicate the peptide in behavior, anxiety, depression, nausea, and emesis. It is a potent vasodilator, producing marked hypotension in humans and several animal species. The vasodilation is mediated by release of nitric oxide from the endothelium. Conversely, substance P causes contraction of venous, intestinal, and bronchial smooth muscle. It also stimulates secretion by the salivary glands and causes diuresis and natriuresis by the kidneys.

The actions of substance P and neurokinins A and B are mediated by three G protein-coupled receptors designated **NK₁**, **NK₂**, and **NK₃**. Substance P is the preferred ligand for the **NK₁** receptor, the predominant tachykinin receptor in the human brain. However, neurokinins A and B also possess considerable affinity for this receptor. In humans, the majority of the central and peripheral effects of substance P are mediated by **NK₁** receptors.

Several nonpeptide **NK₁** receptor antagonists have been developed. These compounds are highly selective, orally active, and enter the brain. Recent clinical trials have shown that these antagonists may be useful in treating depression and other disorders, and in preventing chemotherapy-induced emesis. The first of these to be approved for the prevention of chemotherapy-induced nausea and vomiting is **aprepitant**.

Katzung PHARMACOLOGY, 9e > Section IV. Drugs with Important Actions on Smooth Muscle > Chapter 17. Vasoactive Peptides >

Neurotensin

Neurotensin is a tridecapeptide that was first isolated from the central nervous system but subsequently was found to be present in the gastrointestinal tract and in the circulation. It is synthesized as part of a larger precursor that also contains **neuromedin N**, a six-amino-acid neurotensin-like peptide. Neurotensin and neuromedin N have the following structures:

Glu-Leu-Tyr-Glu-Asn-Lys-Pro-Arg-Arg-Pro-Tyr-Ile-Leu

Neurotensin

Lys-Ile-Pro-Tyr-Ile-Leu

Neuromedin N

In the brain, processing of the precursor leads primarily to the formation of neurotensin and neuromedin N; these are released together from nerve endings. In the gut, processing leads mainly to the formation of neurotensin and a larger peptide that contains the neuromedin N sequence at the carboxyl terminal. Both peptides are secreted into the circulation after ingestion of food.

Like many other neuropeptides, neurotensin serves a dual function as a neurotransmitter or neuromodulator in the central nervous system and as a local hormone in the periphery. When administered centrally, neurotensin exerts potent effects including hypothermia, antinociception and modulation of dopamine neurotransmission. When administered into the peripheral circulation, it causes vasodilation, hypotension, increased vascular permeability, increased secretion of several anterior pituitary hormones, hyperglycemia, inhibition of gastric acid and pepsin secretion, and inhibition of gastric motility.

Three subtypes of neurotensin receptors designated **NT₁**, **NT₂**, and **NT₃** have been cloned. **NT₁** and **NT₂** receptors belong to the G protein-coupled superfamily; **NT₃** receptors are structurally different.

Neurotensin agonists that cross the blood-brain barrier have been developed and have potential as potential therapeutic agents for diseases such as schizophrenia and Parkinson's disease (McMahon, 2002).

Neurotensin receptors can be blocked with the nonpeptide antagonists SR142948A and SR48692. SR142948A is a potent antagonist of the hypothermia and analgesia produced by centrally administered neurotensin. It also blocks the cardiovascular effects of systemic neurotensin.

Katzung PHARMACOLOGY, 9e > Section IV. Drugs with Important Actions on Smooth Muscle > Chapter 17. Vasoactive Peptides >

Calcitonin Gene-Related Peptide

Calcitonin gene-related peptide (**CGRP**) is a member of the calcitonin family of peptides, which also includes calcitonin, adrenomedullin (see below) and amylin. CGRP consists of 37 amino acids and displays approximately 30% structural homology with salmon calcitonin.

Like calcitonin, CGRP is present in large quantities in the C cells of the thyroid gland. It is also distributed widely in the central and peripheral nervous systems, in the cardiovascular system, the gastrointestinal tract, and the urogenital system. CGRP is found with substance P (see above) in some of these regions and with acetylcholine in others.

When CGRP is injected into the central nervous system, it produces a variety of effects, including hypertension and suppression of feeding. When injected into the systemic circulation, the peptide causes hypotension and tachycardia. The hypotensive action of CGRP results from the potent vasodilator action of the peptide; indeed, CGRP is the most potent vasodilator yet discovered.

Katzung PHARMACOLOGY, 9e > Section IV. Drugs with Important Actions on Smooth Muscle > Chapter 17. Vasoactive Peptides >

Adrenomedullin

Adrenomedullin is a 52-amino-acid peptide that was discovered in human adrenal medullary pheochromocytoma tissue. Like CGRP, it is a member of the calcitonin family of peptides. Adrenomedullin is present in several organs including the adrenals, lungs, heart, vascular tissue, and kidneys. It also circulates in the blood.

In animals, adrenomedullin dilates resistance vessels in the kidney, brain, lung, hind limbs, and mesentery, resulting in a marked, long-lasting hypotension. The hypotension in turn causes reflex increases in heart rate and cardiac output. Adrenomedullin also acts on the kidneys to increase sodium excretion, and exerts several endocrine effects including inhibition of aldosterone and insulin secretion. Finally it acts on the central nervous system to increase sympathetic outflow. These diverse actions of adrenomedullin are mediated both by CGRP receptors and unique adrenomedullin receptors, the properties of which are incompletely defined. The major second messenger for both receptors is cAMP.

Circulating adrenomedullin levels increase during intense exercise. Levels are also elevated in patients with hypertension, as well as in patients with renal failure, heart failure, and septic shock.

Katzung PHARMACOLOGY, 9e > Section IV. Drugs with Important Actions on Smooth Muscle > Chapter 17. Vasoactive Peptides >

Neuropeptide Y

Neuropeptide Y is a member of the family that also includes peptide YY and pancreatic polypeptide. Each peptide consists of 36 amino acids. The amino acid sequence of neuropeptide Y is shown below.

Tyr-Pro-Ser-Lys-Pro-Asp-Asn-Pro-Gly-Glu-Asp-Ala-
Pro-Ala-Glu-Asp-Met-Ala-Arg-Tyr-Tyr-Ser-Ala-Leu-
Arg-His-Tyr-Ile-Asn-Leu-Ile-Thr-Arg-Gln-Arg-Tyr-NH₂

Neuropeptide Y

Neuropeptide Y is one of the most abundant neuropeptides in both the central and peripheral nervous systems. In the sympathetic nervous system, neuropeptide Y is frequently localized in noradrenergic neurons and apparently functions both as a vasoconstrictor and as a cotransmitter with norepinephrine. Peptide YY and pancreatic polypeptide are both gut endocrine peptides.

Neuropeptide Y produces a variety of central nervous system effects, including increased feeding (it is one of the most potent orexigenic molecules in the brain), hypotension, hypothermia, and respiratory depression. Other effects include vasoconstriction of cerebral blood vessels, positive chronotropic and inotropic actions on the heart, and hypertension. The peptide is a potent renal vasoconstrictor and suppresses renin secretion, but can cause diuresis and natriuresis. Prejunctional actions include inhibition of transmitter release from sympathetic and parasympathetic nerves; vascular actions include direct vasoconstriction, potentiation of the action of vasoconstrictors, and inhibition of the action of vasodilators.

These diverse effects are mediated by multiple receptors designated Y₁ through Y₆. All receptors except Y₃ have been cloned and shown to be G protein-coupled receptors coupled to mobilization of Ca²⁺ and inhibition of adenylyl cyclase. Y₁ and Y₂ receptors are of major importance in the

cardiovascular and other peripheral effects of the peptide. Y₄ receptors have a high affinity for pancreatic polypeptide and may be a receptor for this peptide rather than for neuropeptide Y. Y₅ receptors are found mainly in the central nervous system and may be involved in the control of food intake. Y₆ receptors do not appear to contribute significantly to the physiologic effects of neuropeptide Y in humans.

Selective nonpeptide neuropeptide Y receptor antagonists are now available. The first nonpeptide Y₁ receptor antagonist, BIBP3226, is also the most thoroughly studied. In animal models, it blocks the vasoconstrictor and pressor responses to neuropeptide Y. It has a short half-life in vivo. Structurally related Y₁ antagonists include BIB03304 and H 409/22, which has been tested in humans. SR120107A and SR120819A are orally active Y₁ antagonists and have a long duration of action. BIIE0246 is the first nonpeptide antagonist selective for the Y₂ receptor.

These antagonists have been useful in analyzing the role of neuropeptide Y in cardiovascular regulation. It now appears that the peptide is not important in the regulation of hemodynamics under resting conditions, but may be of increased importance in cardiovascular disorders including hypertension and heart failure. Other studies have implicated neuropeptide Y in feeding disorders, seizures, anxiety, and diabetes, and Y₁ and Y₅ receptor antagonists have potential as anti-obesity agents (Parker, 2002).

Katzung PHARMACOLOGY, 9e > Section IV. Drugs with Important Actions on Smooth Muscle > Chapter 17. Vasoactive Peptides >

Urotensin

Urotensin II was originally identified in fish, but isoforms are now known to be present in mammalian species including the mouse, rat, pig, and human. The structure of human urotensin II is shown below.

There are species differences in the structure of urotensin II but the cyclic hexapeptide is conserved in all known isoforms. Major sites of urotensin II expression in humans are the brain, spinal cord, and kidneys. The kidneys may be the major source of circulating urotensin II.

In vitro, urotensin II is a potent constrictor of vascular smooth muscle; its activity depends on the type of blood vessel and the species from which it was obtained. Vasoconstriction occurs primarily in arterial vessels, where urotensin II can be more potent than endothelin 1, making it the most potent known vasoconstrictor. In vivo, urotensin II has complex hemodynamic effects, the most prominent being regional vasoconstriction and cardiac depression. The extent to which the peptide is involved in the regulation of vascular tone and blood pressure in humans is not clear; recent studies have produced conflicting results. The actions of urotensin II are mediated by G protein-coupled receptors that are widely distributed in the brain, spinal cord, heart, vascular smooth muscle, skeletal muscle, and pancreas. Some effects of the peptide including vasoconstriction are mediated by the phospholipase C/IP₃/DAG signal transduction pathway.

It has been reported that the expression of urotensin II is upregulated in the heart of humans with end-stage heart failure, but it is not clear if the increase was a cause or consequence of the disease.

Katzung PHARMACOLOGY, 9e > Section IV. Drugs with Important Actions on Smooth Muscle > Chapter 17. Vasoactive Peptides >

Preparations Available¹

Aprepitant (Emend)

Oral: 80, 125 mg capsules

Bosentan (Tracleer)

Oral: 62.5, 125 mg tablets

¹Preparations of angiotensin-converting enzyme inhibitors and angiotensin receptor antagonists are found in Chapter 11: Antihypertensive Agents; preparations of vasopressin are found in Chapter 37: Hypothalamic & Pituitary Hormones.

Chapter 18. The Eicosanoids: Prostaglandins, Thromboxanes, Leukotrienes, & Related Compounds

Katzung PHARMACOLOGY, 9e > Section IV. Drugs with Important Actions on Smooth Muscle > Chapter 18. The Eicosanoids: Prostaglandins, Thromboxanes, Leukotrienes, & Related Compounds >

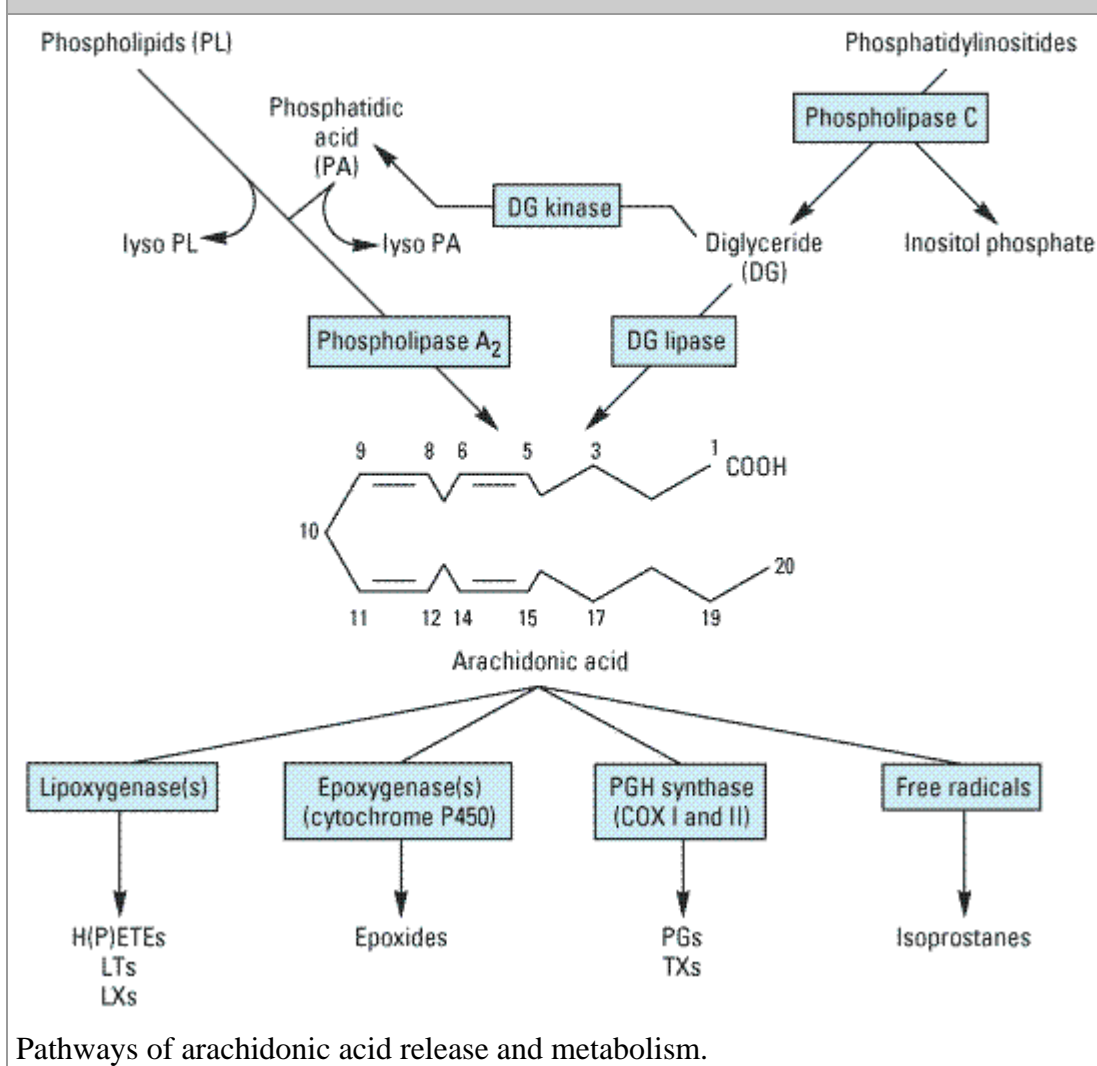

The Eicosanoids: Prostaglandins, Thromboxanes, Leukotrienes, & Related Compounds:
Introduction

The eicosanoids are oxygenation products of polyunsaturated long chain fatty acids. They are ubiquitous in the animal kingdom and are also found—together with their precursor oils—in a variety of plants. They constitute a very large family of compounds that are not only highly potent but also display an extraordinarily wide spectrum of biologic activity. Because of their biologic activity, the eicosanoids, their specific receptor and enzyme inhibitors, and their plant and fish oil precursors have great therapeutic potential. Their short half-lives—seconds to minutes—make special delivery systems or synthesis of stable analogs mandatory for their clinical use.

Arachidonic Acid & Other Polyunsaturated Precursors

Arachidonic acid is the most abundant and the most important of the precursors of the eicosanoids. Arachidonic acid is a 20-carbon (C₂₀) fatty acid that contains four double bonds beginning at the omega-6 position to yield a 5,8,11,14-eicosatetraenoic acid (designated C₂₀:4–6). For eicosanoid synthesis to occur, arachidonate must first be released or mobilized from membrane phospholipids by one or more lipases of the phospholipase A₂ (PLA₂) type (Figure 18–1). At least three phospholipases mediate arachidonate release from membrane lipids: cardiac PLA₂ (cPLA₂), cytosolic PLA₂, and secretory PLA₂. In addition, arachidonate is also released by a combination of phospholipase C and diglyceride lipase. These lipase pathways are interdicted by corticosteroids. The precise mechanisms are still conjectural.

Figure 18-1.

Following mobilization, arachidonic acid is oxygenated by four separate routes: the cyclooxygenase (COX), lipoxygenase, P450 epoxygenase, and isoprostane pathways (Figure 18-1). A number of factors determine the type of eicosanoid synthesized: (1) the species, (2) the type of cell, and (3) the cell's particular phenotype. The pattern of eicosanoids synthesized also frequently reflects (4) the manner in which the cell is stimulated. Finally, an important factor governing the pattern of eicosanoid release is (5) the nature of the precursor polyunsaturated fatty acid that has been esterified in specific membrane phospholipids. For example, homo-*n*-linoleic acid (C20:3-6), which is trienoic, yields products that differ from those derived from arachidonate (C20:4-6), which has four double bonds. Similarly, the products derived from eicosapentaenoic acid (C20:5-3), which has five double bonds, are also quantitatively different. This is the basis for using as nutritional supplements in humans the structurally different fatty acids obtained from cold water fish or from plants. An example of the significance of the polyunsaturated fatty acid precursors is evident when one considers thromboxane A (TXA) derived from the COX pathway. TXA₂ is synthesized from arachidonate, a tetraenoic acid and is a powerful vasoconstrictor and aggregator of platelets. However 5,8,11,14,17-eicosapentaenoic acid yields TXA₃, which is relatively inactive. In theory, dietary eicosapentaenoate substitution for arachidonate should minimize thrombotic events due to the displacement of tetraenoic arachidonate in the membrane by a pentaenoic acid.

Synthesis of Eicosanoids

Products of Prostaglandin Endoperoxide Synthases (Cyclooxygenases)

Two unique COX isozymes convert arachidonic acid into prostaglandin endoperoxide. PGH synthase-1 (COX-1) is constitutively expressed, ie, it is always present. In contrast, PGH synthase-2 (COX-2) is inducible, ie, its expression varies markedly depending on the stimulus. The two isozymes also differ in function in that COX-1 is widely distributed and has "housekeeping" functions, eg, gastric cytoprotection. Two-fold to four-fold increases occur following humoral stimulation. In contrast, COX-2 is an immediate early response gene product in inflammatory and immune cells and expression is stimulated ten-fold to eighteen-fold by growth factors, tumor promoters, and cytokines. Lipopolysaccharide (endotoxin) is particularly potent in this respect. However, COX-2 is also involved in normal renal development and vascular prostacyclin production. Several additional COX isoforms have been described recently (Chandrasekharan, 2002).

The synthases are important because it is at this step that the nonsteroidal anti-inflammatory drugs (NSAIDs) exert their therapeutic effects (see Chapter 36: Nonsteroidal Anti-Inflammatory Drugs, Disease-Modifying Antirheumatic Drugs, Nonopioid Analgesics, & Drugs Used in Gout). Indomethacin and sulindac are slightly selective for COX-1. Meclofenamate and ibuprofen are approximately equipotent on COX-1 and COX-2, while celecoxib and rofecoxib preferentially inhibit COX-2. The steroidal anti-inflammatory drugs such as dexamethasone can inhibit COX-2 gene expression. Aspirin acetylates and inhibits both enzymes to different extents.

Both COXs promote the uptake of two molecules of oxygen by cyclization of arachidonic acid to yield a C₉–C₁₁ endoperoxide C₁₅ hydroperoxide (Figure 18–2). This product is PGG₂, which is then rapidly modified by the peroxidase moiety of the COX enzyme to add a 15-hydroxyl group that is essential for biologic activity. This product is PGH₂. Both endoperoxides are highly unstable. Analogous families—PGH₁ and PGH₃ and all their subsequent products—are derived from homo-*γ*-linolenic acid and eicosapentaenoic acid, respectively.

Figure 18–2.

Prostaglandin and thromboxane biosynthesis. Compound names are enclosed in boxes. The asterisks indicate that both cyclooxygenase and peroxidase steps are catalyzed by the single enzyme prostaglandin endoperoxide (PGH) synthase.

PGH₂ then yields the prostaglandins, thromboxane, and prostacyclin by separate pathways. The prostaglandins differ from each other in two ways: (1) in the substituents of the pentane ring (indicated by the last letter, eg, E and F in PGE and PGF) and (2) in the number of double bonds in the side chains (indicated by the subscript, eg, PGE₁, PGE₂). Several products of the arachidonate series are of current clinical importance. **Alprostadil** (PGE₁) is used for its smooth muscle relaxing

ulcer and in combination with mifepristone for terminating early pregnancies. **PGE₂** and **PGF_{2α}** are used in obstetrics. **Latanoprost** and several similar compounds are topically active PGF_{2α} derivatives used in ophthalmology. **Prostacyclin** (PGI₂, epoprostenol) is synthesized mainly by the vascular endothelium and is a powerful vasodilator and inhibitor of platelet aggregation. In contrast, **thromboxane (TXA₂)** has undesirable properties (aggregation of platelets, vasoconstriction). Therefore TXA₂ receptor antagonists and synthesis inhibitors are developed for cardiovascular indications.

All the naturally occurring COX products rapidly undergo metabolism by β-oxidation, ω-oxidation, and oxidation of the key 15-hydroxyl group to the corresponding ketone. These inactive metabolites can be determined in blood and urine by immunoassay or mass spectrometry as a measure of the in vivo synthesis of their parent compounds.

Products of Lipoxygenase

The metabolism of arachidonic acid by the 5-, 12-, and 15-lipoxygenases results in the production of hydroperoxyeicosatetraenoic acids (HPETEs), which rapidly convert to hydroxy derivatives (HETEs) and leukotrienes (Figure 18–3). The most actively investigated leukotrienes are those produced by the 5-lipoxygenase present in inflammatory cells (PMNs, basophils, mast cells, eosinophils, macrophages). This pathway is of great interest since it is associated with asthma and anaphylactic shock. Stimulation of these cells elevates intracellular Ca²⁺, and releases arachidonate; incorporation of molecular oxygen by 5-lipoxygenase then yields the unstable epoxide leukotriene A₄ (LTA₄). This intermediate either converts to the dihydroxy leukotriene B₄ (LTB₄) or conjugates with glutathione to yield leukotriene C₄ (LTC₄), which undergoes sequential degradation of the glutathione moiety by peptidases to yield LTD₄ and LTE₄. These three products are called cysteinyl leukotrienes or peptidoleukotrienes.

Figure 18–3.

LTC₄ and **LTD₄** are potent bronchoconstrictors and are recognized as the primary components of the **slow-reacting substance of anaphylaxis (SRS-A)** that is secreted in asthma and anaphylaxis. There are four current approaches to anti-leukotriene drug development: 5-lipoxygenase enzyme inhibitors, leukotriene receptor antagonists, inhibitors of an important membrane-bound 5-lipoxygenase activating protein (FLAP), and phospholipase A₂ inhibitors. Two selective leukotriene receptor antagonists are currently used for treatment of asthma.

Another group of 5-lipoxygenase products are the **lipoxins** LXA and LXB. Their biologic roles are still to be defined.

Epoxygenase Products

Specific isozymes of microsomal P450 monooxygenases convert arachidonic acid to four epoxyeicosatrienoic acids (EETs) (Figure 18–1). These are the 5,6-, 6,9-, 11,12-, and 14,15-oxido products. Each EET has two stereoisomers. These epoxides are unstable and rapidly form the corresponding dihydroxyeicosatrienoic (DHET) acid, eg, 5,6-DHET. Unlike the prostaglandins, both the EETs and the DHETs can be incorporated into phospholipids that then act as storage sites. The epoxygenase products are active on smooth muscle cells and in cell signaling pathways and are thought to have important roles in renal function.

Isoprostanes

The generation of isoprostanes from arachidonic acid is another potentially important pathway. The isoprostanes are prostaglandin stereoisomers. Because prostaglandins have many asymmetric centers, they have a large number of potential stereoisomers. Prostaglandin synthase (COX) is not needed for the formation of the isoprostanes, and aspirin and other nonsteroidal inhibitors of COX should not affect the isoprostane pathway. The primary epimerization mechanism is peroxidation of arachidonate by free radicals. Peroxidation occurs while arachidonic acid is still esterified to the membrane phospholipids. Thus, unlike prostaglandins, these stereoisomers are "stored" as part of the membrane. The importance of the isoprostane pathway lies in the relatively large amounts of these products (ten-fold greater in blood and urine than the COX-derived prostaglandins) and their potent vasoconstrictor effects in the renal and other vascular beds. It has been proposed that isoprostanes play an important role in the hepatorenal syndrome.

Basic Pharmacology of Eicosanoids

Mechanisms & Effects of Eicosanoids

Receptor Mechanisms

The eicosanoids act in an autocrine and paracrine fashion. These ligands bind to receptors on the cell surface, and pharmacologic specificity is determined by receptor density and type on different cells. A number of the membrane receptors and their subtypes have been cloned. All of these receptors appear to be G protein-linked; properties of the best-studied receptors are listed in Table 18–1.

Table 18–1. Some Properties of Prostanoid Membrane Receptors.

Receptor Type	Endogenous Agonist	G protein, Second Messenger	Smooth Muscle Tone	Result of Receptor Knockout
DP	PGD ₂	G _s , inc cAMP	+/-	Dec allergic bronchial responses

EP ₁	PGE ₂	G _q , inc IP ₃ , DAG	+	Dec response to colon carcinogens
EP ₂	PGE ₂	G _s , inc cAMP	-	Impaired ovulation and fertilization; salt-sensitive HTN, dec bronchodilation to EP ₂
EP ₃	PGE ₂	G _i , G _s , G _q , inc or dec cAMP, IP ₃ , DAG	+/-	Dec febrile response; inc hypotensive response to PGE ₂
EP ₄	PGE ₂	G _s , inc cAMP	-	Patent ductus; dec bone inflammatory resorption response

inc, increased; dec, decreased; HTN, hypertension.

Binding of PGI₂, PGE₁, and PGD₂ to their platelet receptors inhibits platelet aggregation by activating adenylyl cyclase. This leads to increased intracellular cAMP levels, which in turn activates specific protein kinases. These kinases phosphorylate internal calcium pump proteins, an action that decreases free intracellular calcium concentration. In contrast, the binding of TXA₂ to its specific receptors activates phosphatidylinositol metabolism, leading to the formation of IP₃. IP₃ causes mobilization of Ca²⁺ stores and an increase of free intracellular calcium. LTB₄ also generates IP₃ release and causes activation, degranulation, and superoxide anion generation in polymorphonuclear leukocytes.

Subtypes are described for PGE₂ receptors (EP₁, EP₂, EP₃, and EP₄), each of which activates distinct signaling pathways. EP₁ is coupled to activation of phospholipase C, EP₂ and EP₄ to stimulation of adenylyl cyclase. EP₃ appears to have multiple effects depending on concentration. The recent description of isoforms of receptor subtypes with coupling to different G proteins makes the issue of second messenger activation more complex. However this multiplicity of pathways may help clarify seemingly paradoxical experimental results.

The contractile effects of eicosanoids on smooth muscle are mediated by the release of calcium, while their relaxing effects are mediated by the generation of cAMP. The effects of eicosanoids on many target systems, including the immune system, can be similarly explained (see below). Many of the eicosanoids' contractile effects on smooth muscle can be inhibited by lowering extracellular calcium or by using calcium channel blocking drugs.

Action on nuclear PPAR receptors has also been proposed but the physiologic role of this interaction has not been determined.

Effects of Prostaglandins & Thromboxanes

The prostaglandins and thromboxanes have major effects on four types of smooth muscle: airway, gastrointestinal, reproductive, and vascular. Other important targets include platelets and monocytes, kidneys, the central nervous system, autonomic presynaptic nerve terminals, sensory nerve endings, endocrine organs, adipose tissue, and the eye (the effects on the eye may involve smooth muscle).

Smooth Muscle

Vascular

TXA₂ is a smooth muscle cell mitogen and is the only eicosanoid that has convincingly been shown to have this effect. The mitogenic effect is potentiated by exposure of smooth muscle cells to testosterone, which up-regulates smooth muscle cell TXA₂ receptors. In addition to its mitogenic effect, TXA₂ is a potent vasoconstrictor. PGF_{2α} is also a vasoconstrictor (via FP receptors) but is not a mitogen for smooth muscle cells. Another potent vasoconstrictor is 8-*epi*-PGF_{2α}. In patients with cirrhosis, it is produced in large amounts in the liver and is thought to play a pathophysiologic role as an important vasoconstrictor substance in the hepatorenal syndrome.

Vasodilator prostaglandins, especially PGI₂ and PGE₂, promote vasodilation by increasing cAMP and decreasing smooth muscle intracellular calcium, primarily via IP and EP₄ receptors. Vascular prostacyclin is synthesized by both smooth muscle and endothelial cells, with the latter as the major contributor. PGI₂ undergoes rapid metabolism in a few seconds to more stable but inactive products. In the microcirculation, PGE₂ is an endothelial vasodilator product.

Gastrointestinal Tract

Most of the prostaglandins and thromboxanes activate gastrointestinal smooth muscle. Longitudinal muscle is contracted by PGE₂ (via EP₃) and PGF_{2α} (via FP), while circular muscle is contracted strongly by PGF_{2α} and weakly by PGI₂, and relaxed by PGE₂ (via EP₄). Administration of either PGE₂ or PGF_{2α} results in colicky cramps (see Clinical Pharmacology of Eicosanoids, below).

Airways

Respiratory smooth muscle is relaxed by PGD₂, PGE₁, PGE₂, and PGI₂ and contracted by TXA₂ and PGF_{2α}. Although PGD₂ is less well-studied than the other prostaglandins, studies of PGD₂ receptor knockout mice suggest an important role of this receptor in asthma.

Platelets and Blood Cells

Platelet aggregation is markedly affected by eicosanoids. PGE₁ and especially PGI₂ effectively inhibit aggregation, while TXA₂ is a potent platelet aggregator. Platelets release TXA₂ during activation and aggregation, suggesting that thrombotic events such as myocardial infarction may result in the release of TXA₂. In fact, urinary metabolites of TXA₂ increase in patients experiencing a myocardial infarction even if they are receiving low-dosage aspirin. At this aspirin dosage, thromboxane synthesis is significantly inhibited only in platelets. This suggests that other cells may contribute to the increase in TXA₂; these other cells may be monocytes, since monocytes have a high capacity for sustained release of TXA₂. Neutrophils and lymphocytes synthesize little if any prostaglandins, while monocytes have a substantial capacity for prostaglandin and thromboxane synthesis through both constitutive and inducible COXs. Human eosinophils also seem to have a high capacity for prostaglandin and thromboxane synthesis.

Kidney

Both the renal medulla and the renal cortex synthesize prostaglandins, the medulla substantially more than the cortex. The kidney also synthesizes several hydroxyeicosatetraenoic acids, leukotrienes, cytochrome P450 products, and epoxides. These compounds play important autoregulatory roles in renal function by modifying renal hemodynamics and glomerular and tubular function. This regulatory role is especially important in marginally functioning kidneys, as shown by the decline in kidney function caused by COX inhibitors in elderly patients and those with renal disease.

The major eicosanoid products of the renal cortex are PGE₂ and PGI₂. Both compounds increase renin release; normally, however, renin release is more directly under β₁ adrenoceptor control. The glomeruli synthesize small amounts of TXA₂ but this potent vasoconstrictor does not appear to be responsible for regulating glomerular function in healthy humans.

PGE₁, PGE₂, and PGI₂ increase glomerular filtration through their vasodilating effects. These prostaglandins also increase water and sodium excretion. The increase in water clearance probably results from an attenuation of the action of antidiuretic hormone on adenylyl cyclase. It is uncertain whether the natriuretic effect is caused by the direct inhibition of sodium resorption in the distal tubule or by increased medullary blood flow. Loop diuretics, eg, furosemide, produce some of their effect by stimulating COX activity. In the normal kidney, this increases the synthesis of the vasodilator prostaglandins. Therefore, patient response to a loop diuretic will be diminished if a COX inhibitor is administered concurrently (see Chapter 15: Diuretic Agents).

TXA₂ causes intrarenal vasoconstriction (and perhaps an ADH-like effect), resulting in a decline in renal function. The normal kidney synthesizes only small amounts of TXA₂. However, in renal conditions involving inflammatory cell infiltration (such as glomerulonephritis and renal transplant rejection), the inflammatory cells (monocyte-macrophages) release substantial amounts of TXA₂. Theoretically, TXA₂ synthase inhibitors or receptor antagonists should improve renal function in these patients, but no such drug is clinically available.

Hypertension is associated with increased TXA₂ and decreased PGE₂ and PGI₂ synthesis in some animal models, eg, the Goldblatt kidney model. It is not known whether these changes are primary contributing factors or secondary responses. Similarly, increased TXA₂ formation has been reported in cyclosporine-induced nephrotoxicity, but no causal relationship has been established.

PGE₂ may also be involved in renal phosphate excretion, because exogenous PGE₂ antagonizes the inhibition of phosphate resorption by parathyroid hormone in the proximal tubule. However, the physiologic role of this eicosanoid may be limited because the proximal tubule, the major site for phosphate transport, produces few prostaglandins.

Reproductive Organs

Female Reproductive Organs

The effects of prostaglandins on uterine function are of great clinical importance. They are discussed below. (See Clinical Pharmacology of Eicosanoids.)

Male Reproductive Organs

The role of prostaglandins in semen is still conjectural. The major source of these prostaglandins is

the seminal vesicle; the prostate and the testes synthesize only small amounts. Thus, the term prostaglandin (referring to the prostate gland) is now known to be a misnomer. Semen from fertile men contains about 400 $\mu\text{g}/\text{mL}$ of PGE and PGF and their 19-hydroxy metabolites. There is about 20 times more PGE than PGF in fertile semen, although this ratio varies greatly among individuals. However, within individuals, this ratio remains fairly constant as long as the sperm characteristics are unchanged. The factors that regulate the concentration of prostaglandins in human seminal plasma are not known in detail, but testosterone does promote prostaglandin production. Thromboxane and leukotrienes have not been found in seminal plasma. Men with a low seminal fluid concentration of prostaglandins are relatively infertile. Large doses of aspirin reduce the prostaglandin content of seminal plasma.

Smooth muscle-relaxing prostaglandins such as PGE₁ enhance penile erection by relaxing the smooth muscle of the corpora cavernosa. (See Clinical Pharmacology of Eicosanoids.)

Central and Peripheral Nervous Systems

Fever

PGE₁ and PGE₂ increase body temperature, probably via EP₃ receptors, especially when administered into the cerebral ventricles. Pyrogens release interleukin-1, which in turn promotes the synthesis and release of PGE₂. This synthesis is blocked by aspirin and other antipyretic compounds.

Sleep

When infused into the cerebral ventricles, PGD₂ induces natural sleep (as determined by electroencephalographic analysis) in a number of species, including primates.

Neurotransmission

PGE compounds inhibit the release of norepinephrine from postganglionic sympathetic nerve endings. Moreover, NSAIDs increase norepinephrine release in vivo, suggesting that the prostaglandins play a physiologic role in this process. Thus, vasoconstriction observed during treatment with COX inhibitors may be due to increased release of norepinephrine as well as to inhibition of the endothelial synthesis of the vasodilators PGE₂ and PGI₂.

Neuroendocrine Organs

Both in vitro and in vivo tests have shown that some of the eicosanoids affect the secretion of anterior pituitary hormones. PGE compounds promote the release of growth hormone, prolactin, TSH, ACTH, FSH, and LH. However, endocrine changes reflecting significant release of these hormones have not been reported in patients receiving PGE compounds. LTC₄ and LTD₄ stimulate LHRH and LH secretion (see below).

Bone Metabolism

Prostaglandins are abundant in skeletal tissue and are produced by the osteoblasts and the adjacent hematopoietic cells. The major effect of prostaglandins (especially PGE₂, acting on EP₄ receptors) in vivo is to increase bone turnover, ie, stimulation of bone resorption and formation. Prostaglandins may mediate the effects of mechanical forces on bones and some of the changes that occur in bones with inflammation. Finally, prostaglandins may play a role in the bone loss that

occurs at menopause.

Eye

PGE and PGF derivatives lower the intraocular pressure. The mechanism of this action is unclear but probably involves increased outflow of aqueous humor from the anterior chamber via the uveoscleral pathway (see Clinical Pharmacology of the Eicosanoids).

Effects of Lipoxygenase & Cytochrome P450-Derived Metabolites

The actions of lipoxygenases generate compounds that can regulate specific cellular responses important in inflammation and immunity. Cytochrome P450-derived metabolites affect nephron transport functions either directly or via metabolism to active compounds (see below). The biologic functions of the various forms of hydroxy- and hydroperoxyeicosanoic acids are largely unknown, but their pharmacologic potency is impressive.

Blood Cells and Inflammation

LTB₄ is a potent chemoattractant for neutrophils; LTC₄ and LTD₄ are potent chemoattractants for eosinophils. These leukotrienes also promote eosinophil adherence, degranulation, and oxygen radical formation. The leukotrienes have been strongly implicated in the pathogenesis of inflammation, especially in chronic diseases such as asthma and inflammatory bowel disease. Lipoxin A seems to exert effects similar to those of LTB₄ on neutrophils. Lymphocyte proliferation and differentiation are modified by LTB₄. Both lipoxin A and lipoxin B inhibit natural killer cell cytotoxicity.

Heart and Smooth Muscle

Cardiovascular—1

2(*S*)-HETE is a potent chemoattractant for smooth muscle cells, causing migration at concentrations as low as 1 fmol/L; it may play a role in myointimal proliferation that occurs after vascular injury such as that caused by angioplasty. Its stereoisomer, 12(*R*)-HETE, is not a chemoattractant but is a potent inhibitor of the Na⁺/K⁺ ATPase in the cornea. LTC₄ and LTD₄ reduce myocardial contractility and coronary blood flow, leading to cardiac depression. Lipoxin A and lipoxin B seem to exert coronary vasoconstrictor effects.

Gastrointestinal

Human colonic epithelial cells synthesize LTB₄, a chemoattractant for neutrophils. The colonic mucosa of patients with inflammatory bowel disease contains substantially increased amounts of LTB₄.

Airways

The peptidoleukotrienes, particularly LTC₄ and LTD₄, are potent bronchoconstrictors and cause increased microvascular permeability, plasma exudation, and mucus secretion in the airways. Controversies exist over whether the pattern and specificity of the leukotriene receptors differ in animal models and humans. LTC₄-specific receptors have not been found in human lung tissue, whereas both high- and low-affinity LTD₄ receptors are present.

Renal System

The roles of leukotrienes and cytochrome P450 products in the human kidney are currently speculative. Recently, the 5,6-epoxide has been shown to be a powerful vasodilator in animal experiments. Another recent discovery is that free radicals attack arachidonic acid-containing phospholipids to yield an 8-*epi*-PGF_{2α} that has powerful thromboxane-like properties. Synthesis is not blocked by COX inhibitors but can be blocked by antioxidants. This vasoconstrictor, which is present in humans, is thought to be another important mediator causing renal failure in the hepatorenal syndrome.

Miscellaneous

The effects of these products on the reproductive organs remain to be elucidated. Similarly, actions on the nervous system have been suggested (recent data indicate that 12-HPETE acts as a neurotransmitter in *Aplysia* neurons), but this has not been confirmed in higher organisms. Very low concentrations of LTC₄ increase and higher concentrations of arachidonate-derived epoxides augment LH and LHRH release from isolated rat anterior pituitary cells.

Inhibition of Eicosanoid Synthesis

Corticosteroids block all the known pathways of eicosanoid synthesis, perhaps by stimulating the synthesis of several inhibitory proteins collectively called **annexins** or **lipocortins**. They inhibit phospholipase A₂ activity, probably by interfering with phospholipid binding and thus preventing the release of arachidonic acid.

The NSAIDs (eg, aspirin, indomethacin, ibuprofen) block both prostaglandin and thromboxane formation by inhibiting COX activity. For example, aspirin is a long-lasting inhibitor of platelet COX and of TXA₂ biosynthesis because it irreversibly acetylates the enzyme. Once acetylated, platelet COX cannot be restored via protein biosynthesis because platelets lack a nucleus.

The development of selective thromboxane synthase inhibitors and TXA₂ receptor antagonists has required considerable effort. The resulting compounds, eg, **sulotroban**, have been useful for characterizing TXA₂-related effects in vitro and in vivo. They are being tested in the treatment of thromboembolism, pulmonary hypertension, and preeclampsia-eclampsia.

Selective inhibitors of the lipoxygenase pathway are also mainly investigational. With a few exceptions, NSAIDs do not inhibit lipoxygenase activity at concentrations that markedly inhibit COX activity. In fact, by preventing arachidonic acid conversion via the COX pathway, NSAIDs may cause more substrate to be metabolized through the lipoxygenase pathways, leading to an increased formation of the inflammatory leukotrienes. Even among the COX-dependent pathways, inhibiting the synthesis of one derivative may increase the synthesis of an enzymatically related product. Therefore, researchers are attempting to develop drugs that inhibit both COX and lipoxygenase.

Katzung PHARMACOLOGY, 9e > Section IV. Drugs with Important Actions on Smooth Muscle > Chapter 18. The Eicosanoids: Prostaglandins, Thromboxanes, Leukotrienes, & Related Compounds >

Clinical Pharmacology of Eicosanoids

Several approaches have been used in the clinical application of eicosanoids. First, stable oral or parenteral long-acting analogs of the naturally occurring prostaglandins have been developed.

Several such compounds have been approved for clinical use overseas and are being introduced in the USA (Figure 18–4). Second, enzyme inhibitors and receptor antagonists have been developed to interfere with the synthesis or effects of the "pathologic" eicosanoids (ie, thromboxanes and leukotrienes). For example, knowledge of eicosanoid synthesis and metabolism has led to the development of new NSAIDs that inhibit COX (especially COX-2), with improved pharmacokinetic and pharmacodynamic characteristics. One objective, described earlier, is to develop dual inhibitors that block both the COX (especially COX-2) and lipoxygenase pathways. Another goal is to decrease gastrointestinal and renal toxicity. Third, dietary manipulation—to change the polyunsaturated fatty acid precursors in the cell membrane phospholipids and so change eicosanoid synthesis—is used extensively in over-the-counter products and in diets emphasizing increased consumption of cold water fish.

Figure 18–4.

Female Reproductive System

The physiologic role of prostaglandins in reproduction has been intensively studied since the discovery of prostaglandins in the seminal plasma of primates and sheep. It has been suggested that

the prostaglandins in seminal plasma facilitate blastocyst implantation or egg transport and that uterine secretion of prostaglandins causes luteolysis. The latter is not true in humans but appears to be true in cattle and pigs. This finding has led to the marketing of veterinary preparations of $\text{PGF}_{2\alpha}$ and its analogs for synchronizing ovulation in animals.

Abortion

PGE_2 and $\text{PGF}_{2\alpha}$ have potent oxytocic actions. The ability of the E and F prostaglandins and their analogs to terminate pregnancy at any stage by promoting uterine contractions has been adapted to routine clinical use. Many studies worldwide have established that prostaglandin administration efficiently terminates pregnancy. The drugs are used for first- and second-trimester abortion and for priming or ripening the cervix before abortion. These prostaglandins appear to soften the cervix by increasing proteoglycan content and changing the biophysical properties of collagen.

Early studies found that intravenous PGE_2 and $\text{PGF}_{2\alpha}$ produced abortion in about 80% of cases. The success rate is dependent on the dose, the duration of the infusion, and parity of the woman. Dose-limiting adverse effects include vomiting, diarrhea, fever, and bronchoconstriction. Hypotension, hypertension, syncope, dizziness, and flushing can occur and may be related to the vasomotor and vasovagal effects of PGE_2 .

In current practice, **dinoprostone**, a synthetic preparation of PGE_2 , is administered vaginally for oxytocic use. In the USA, it is approved for inducing abortion in the second trimester of pregnancy, for missed abortion, for benign hydatidiform mole, and for ripening of the cervix for induction of labor in patients at or near term.

Dinoprostone stimulates the contraction of the uterus throughout pregnancy. As the pregnancy progresses, the uterus increases its contractile response, and the contractile effect of oxytocin is potentiated as well. Dinoprostone also directly affects the collagenase of the cervix, resulting in softening. The vaginal dose enters the maternal circulation, and a small amount is absorbed directly by the uterus via the cervix and the lymphatic system. Dinoprostone is metabolized in local tissues and on the first pass through the lungs (about 95%). The metabolites are mainly excreted in the urine. The plasma half-life is 2.5–5 minutes.

For the induction of labor, dinoprostone is available either as a gel (0.5 mg PGE_2) or as a controlled-release formulation (10 mg PGE_2) that releases PGE_2 in vivo at a rate of about 0.3 mg/h over 12 hours. An advantage of the controlled-release formulation is a lower incidence of gastrointestinal side effects (< 1%). A further advantage of this delivery system is that the medication is contained within a vaginal insert that can be retrieved at any time.

For abortifacient purposes, the recommended dosage is a 20 mg dinoprostone vaginal suppository repeated at 3- to 5-hour intervals depending on the response of the uterus. The mean time to abortion is 17 hours, but in more than 25% of cases the abortion is incomplete and requires additional intervention.

For softening of the cervix at term, the preparations used are either a single vaginal insert containing 10 mg PGE_2 or a vaginal gel containing 0.5 mg PGE_2 administered every 6 hours. The softening of the cervix for induction of labor substantially shortens the time to onset of labor and the delivery time.

The use of PGE analogs for "menstrual regulation" or very early abortions—within 1–2 weeks after the last menstrual period—has been explored extensively. There are two problems: prolonged

vaginal bleeding and severe menstrual cramps.

Antiprogestins (eg, **mifepristone**) have been combined with an oral oxytocic prostaglandin (eg, **misoprostol**) to produce early abortion. This regimen is now available in the USA (see Chapter 39: Adrenocorticosteroids & Adrenocortical Antagonists). The ease of use and the effectiveness of the combination have aroused considerable opposition in some quarters. The major toxicities are cramping pain and diarrhea.

PGF_{2α} is available for clinical gynecologic use. This drug, **carboprost tromethamine** (15-methyl-PGF_{2α}; the 15-methyl group prolongs the duration of action) was withdrawn from the United States market. Carboprost is used to induce second-trimester abortions and is usually administered as a single 2.5 mg intra-amniotic injection. The abortion is normally completed in less than 20 hours. The most serious adverse effects of this route of administration involve cardiovascular collapse. Most of the reported cases have been diagnosed as anaphylactic shock, but others may have been due to the drug escaping into the circulation and causing severe pulmonary hypertension. In pregnant anesthetized women, PGF_{2α}, 300 μg/min intravenously, doubles pulmonary resistance and increases the work of the right side of the heart three-fold. Thus, only minimal amounts of the 40 mg intra-amniotic dose need to reach the circulation to cause cardiovascular effects. This problem may be avoided by instilling the drug under ultrasonic guidance.

Intramuscular injection of carboprost tromethamine can also be used to induce abortion. Unlike the one-time intrauterine instillation of dinoprost, carboprost is given repeatedly up to the total dose of 2.6 mg normally required to cause abortion. Intra-amniotic administration has close to a 100% success rate, with fewer and less severe adverse effects than intravenous administration.

Facilitation of Labor

Numerous studies have shown that PGE₂, PGF_{2α}, and their analogs effectively initiate and stimulate labor. However, this is an unlabeled use. There appears to be no difference in the efficacy of the two drugs when they are administered intravenously, but PGF_{2α} is one tenth as potent as PGE₂. These agents and oxytocin have similar success rates and comparable induction-to-delivery intervals. The adverse effects of the prostaglandins are moderate, with a slightly higher incidence of nausea, vomiting, and diarrhea than that produced by oxytocin. PGF_{2α} has more gastrointestinal toxicity than PGE₂. Neither drug has significant maternal cardiovascular toxicity in the recommended doses. In fact, PGE₂ must be infused at a rate about 20 times faster than that used for induction of labor to decrease blood pressure and increase heart rate. PGF_{2α} is a bronchoconstrictor and should be used with caution in persons with asthma; however, neither asthma attacks nor bronchoconstriction have been observed during the induction of labor. Although both PGE₂ and PGF_{2α} pass the fetoplacental barrier, fetal toxicity is uncommon.

The effects of oral PGE₂ administration (0.5–1.5 mg/h) have been compared with those of intravenous oxytocin and oral demoxytocin, an oxytocin derivative, in the induction of labor. Oral PGE₂ is superior to the oral oxytocin derivative and in most studies is as efficient as intravenous oxytocin. However, the only available form of PGE₂ in the USA at present is dinoprostone for vaginal administration, and by this route of administration the drug is slightly less effective than oxytocin. Vaginal PGE₂ is also used to soften the cervix before inducing labor. Oral PGF_{2α} causes too much gastrointestinal toxicity to be useful by this route.

Theoretically, PGE₂ and PGF_{2α} should be superior to oxytocin for inducing labor in women with preeclampsia-eclampsia or cardiac and renal diseases because, unlike oxytocin, they have no antidiuretic effect. In addition, PGE₂ has natriuretic effects. However, the clinical benefits of these

effects have not been documented. In cases of intrauterine fetal death, the prostaglandins alone or with oxytocin seem to cause delivery effectively. In some cases of postpartum bleeding, 15-methyl-PGF_{2α} will successfully control hemorrhage when oxytocin and methylergonovine fail to do so.

Dysmenorrhea

Primary dysmenorrhea is attributable to increased endometrial synthesis of PGE₂ and PGF_{2α} during menstruation, with contractions of the uterus that lead to ischemic pain. NSAIDs successfully inhibit the formation of these prostaglandins (see Chapter 36: Nonsteroidal Anti-Inflammatory Drugs, Disease-Modifying Antirheumatic Drugs, Nonopioid Analgesics, & Drugs Used in Gout) and so relieve dysmenorrhea in 75–85% of cases. Some of these drugs are available over the counter. Aspirin is also effective in dysmenorrhea, but because it has low potency and is quickly hydrolyzed, large doses and frequent administration are necessary. In addition, the acetylation of platelet COX, causing irreversible inhibition of platelet TXA₂ synthesis, may have an adverse effect on the amount of menstrual bleeding.

Male Reproductive System

Intracavernosal injection or urethral suppository therapy with **alprostadil** (PGE₁) is useful in the treatment of erectile dysfunction, especially in spinal cord injury. Doses of 2.5–25 μg are used. Penile pain is a frequent side effect that may be related to the algescic effects of PGE derivatives; however, only a few patients discontinue the use due to pain. Prolonged erection and priapism are less frequent side effects that occur in fewer than 4% of patients and are minimized by careful titration to the minimal effective dose. When given by injection, alprostadil may be used as monotherapy or in combination with either papaverine or phentolamine.

Cardiovascular System

The vasodilator effects of PGE compounds have been studied extensively in hypertensive patients. These compounds also promote sodium diuresis. Practical application will require derivatives with oral activity, longer half-lives, and fewer adverse effects.

Pulmonary Hypertension

Prostacyclin lowers peripheral, pulmonary, and coronary resistance. It has been used to treat both primary pulmonary hypertension and secondary pulmonary hypertension, which sometimes occurs after mitral valve surgery. A commercial preparation of prostacyclin (epoprostenol) is approved for treatment of primary pulmonary hypertension, in which it appears to improve symptoms and prolong survival. However, because of its extremely short plasma half-life, the drug must be administered as a continuous intravenous infusion through a central line. Several prostacyclin analogs with longer half-lives have been developed and **treprostinil** was recently approved for use in pulmonary hypertension (Horn, 2002). This drug is administered by continuous subcutaneous infusion.

Peripheral Vascular Disease

A number of studies have investigated the use of PGE and PGI₂ compounds in Raynaud's phenomenon and peripheral atherosclerosis. In the latter case, prolonged infusions have been used to permit remodeling of the vessel wall and to enhance regression of ischemic ulcers.

Patent Ductus Arteriosus

Patency of the fetal ductus arteriosus is now generally believed to depend on local PGE₂ and PGI₂ synthesis. In certain types of congenital heart disease (eg, transposition of the great arteries, pulmonary atresia, pulmonary artery stenosis), it is important to maintain the patency of the neonate's ductus arteriosus before surgery. This is done with alprostadil, PGE₁. Like PGE₂, PGE₁ is a vasodilator and an inhibitor of platelet aggregation, and it contracts uterine and intestinal smooth muscle. Adverse effects include apnea, bradycardia, hypotension, and hyperpyrexia. Because of rapid pulmonary clearance, the drug must be continuously infused at an initial rate of 0.05–0.1 μg/kg/min, which may be increased to 0.4 μg/kg/min. Prolonged treatment has been associated with ductal fragility and rupture.

In delayed closure of the ductus arteriosus, COX inhibitors are often used to inhibit synthesis of PGE₂ and PGI₂ and so close the ductus. Premature infants in whom respiratory distress develops due to failure of ductus closure can be treated with a high degree of success with indomethacin. This treatment often precludes the need for surgical closure of the ductus.

Blood

As noted above, eicosanoids are involved in thrombosis because TXA₂ promotes platelet aggregation and PGI₂ inhibits it. Aspirin inhibits platelet COX to produce a mild clotting defect. The mildness of this defect is supported by the fact that very modest hemostatic defects are noted in patients with diseases involving deficiencies of platelet COX and thromboxane synthase—eg, these patients have no history of increased or decreased bleeding. Blockade of either of these two enzymes inhibits secondary aggregation of platelets induced by ADP, by low concentrations of thrombin and collagen, or by epinephrine. Thus, these platelet enzymes are not necessary for platelet function but may amplify an aggregating stimulus.

Epidemiologic studies in the USA and United Kingdom indicate that low doses of aspirin reduce the risk of death due to infarction but may *increase* overall mortality rates due to hemorrhagic stroke (see Chapter 34: Drugs Used in Disorders of Coagulation). It is now difficult to find patients at risk for thromboembolism—as in orthopedic surgery or angioplasty for coronary artery stenosis—who do not take aspirin. The beneficial effects of aspirin are discussed in greater detail in Chapter 34: Drugs Used in Disorders of Coagulation.

Respiratory System

PGE₂ is a powerful bronchodilator when given in aerosol form. Unfortunately, it also promotes coughing, and an analog that possesses only the bronchodilator properties has been difficult to obtain.

PGF_{2α} and TXA₂ are both strong bronchoconstrictors and were once thought to be primary mediators in asthma. However, the identification of the peptidoleukotrienes—LTC₄, LTD₄, and LTE₄—expanded the role of eicosanoids as important mediators in asthma and other immune responses. As described in Chapter 20: Drugs Used in Asthma, leukotriene receptor inhibitors (eg, **zafirlukast**, **montelukast**) are effective in asthma. A lipoxygenase inhibitor (**zileuton**) has also been used in asthma but is not as popular as the receptor inhibitors. It remains unclear whether leukotrienes are partially responsible for the acute respiratory distress syndrome.

Corticosteroids and cromolyn are also useful in asthma. Corticosteroids inhibit eicosanoid synthesis and thus limit the amounts of eicosanoid mediator available for release. Cromolyn appears to inhibit the release of eicosanoids and other mediators such as histamine and platelet-activating factor from mast cells.

Gastrointestinal System

The word "cytoprotection" was coined to signify the remarkable protective effect of the E prostaglandins against peptic ulcers in animals at doses that do not reduce acid secretion. These prostaglandins were independently discovered also to inhibit gastric acid secretion (at higher doses). Since then, numerous experimental and clinical investigations have shown that the PGE compounds and their analogs protect against peptic ulcers produced by either steroids or NSAIDs. **Misoprostol** is an orally active synthetic analog of PGE₁ available in Europe and the USA for ulcer treatment. The FDA-approved indication is for prevention of NSAID-induced peptic ulcers. The drug is administered at a dosage of 200 µg four times daily. This and other PGE analogs (eg, enprostil) are cytoprotective at low doses and inhibit gastric acid secretion at higher doses. The adverse effects are abdominal discomfort and occasional diarrhea; both effects are dose-related. More recently, dose-dependent bone pain and hyperostosis have been described in patients with liver disease who were given long-term PGE treatment. This adverse effect can be explained by a PGE-induced, EP₄-mediated acceleration of osteoclast and osteoblast activity. Recurrent calcium oxalate kidney stones were described in the same group of patients. This may be related to PGE-induced hypercalciuria.

Gastrointestinal side effects seen in many patients using NSAIDs may be reduced by the recent introduction of selective inhibitors of COX-2 that spare gastric COX-1 so that the natural cytoprotection by locally synthesized PGE₂ is undisturbed (see Chapter 36: Nonsteroidal Anti-Inflammatory Drugs, Disease-Modifying Antirheumatic Drugs, Nonopioid Analgesics, & Drugs Used in Gout).

Immune System

Monocyte-macrophages are the only principal cells of the immune system that can synthesize all the eicosanoids. T and B lymphocytes are interesting exceptions to the general rule that all nucleated cells produce eicosanoids. However, in a B lymphoma cell line, there is non-receptor-mediated uptake of LTB₄ and 5-HETE. Interaction between lymphocytes and monocyte-macrophages may cause the lymphocytes to release arachidonic acid from their cell membranes. The arachidonic acid is then used by the monocyte-macrophages for eicosanoid synthesis. In addition to these cells, there is evidence for eicosanoid-mediated cell-cell interaction by platelets, erythrocytes, PMNs, and endothelial cells.

The eicosanoids modulate the effects of the immune system, as illustrated by the cell-mediated immune response. As shown in Figure 18–5, PGE₂ and PGI₂ affect T cell proliferation in vitro as corticosteroids do. T cell clonal expansion is attenuated through inhibition of interleukin-1 and interleukin-2 and class II antigen expression by macrophages or other antigen-presenting cells. The leukotrienes, TXA₂, and platelet-activating factor stimulate T cell clonal expansion. These compounds stimulate the formation of interleukin-1 and interleukin-2 as well as the expression of interleukin-2 receptors. The leukotrienes also promote interferon-γ release and can replace interleukin-2 as a stimulator of interferon-γ. These in vitro effects of the eicosanoids agree with in vivo findings in animals with acute organ transplant rejection, as described below.

Figure 18–5.

Modulation of macrophage and lymphocyte interactions by eicosanoids, platelet-activating factor, and corticosteroids. Corticosteroids, PGE₂, and possibly PGI₂ inhibit the expression of interleukin-1 (IL-1) and its effect on T lymphocytes. Platelet-activating factor (PAF), LTB₄, and LTD₄ increase IL-1 expression. Similar inhibitory and stimulant effects are exerted on the action of interferon- γ on the macrophage and on the action of interleukin-2 (IL-2). Agents marked with an asterisk are suspected, but not yet proved, to have the effects indicated. (DR, class II MHC [major histocompatibility complex] receptor; T, T lymphocytes.) (Modified and reproduced, with permission, from Foegh ML, Ramwell PW: PAF and transplant immunology. In: Braquet P [editor]: *The Role of Platelet Activating Factor in Immune Disorders*. Karger, 1988.)

Cell-Mediated Organ Transplant Rejection

Acute organ transplant rejection is a cell-mediated immune response. Administration of PGI₂ to renal transplant patients has reversed the rejection process in some cases. Experimental in vitro and in vivo data show that PGE₂ and PGI₂ can attenuate T cell proliferation and rejection, which can also be seen with drugs that inhibit TXA₂ and leukotriene formation. In organ transplant patients, urinary excretion of TXB₂, a metabolite of TXA₂, increases during acute rejection. Corticosteroids, the primary drugs used for treatment of acute rejection due to their effects on lymphocytes, inhibit both phospholipase and COX-2 activity.

Inflammation

Aspirin has been used to treat arthritis for nearly a century, but its mechanism of action—inhibition of COX activity—was not discovered until 1971. Aspirin and other anti-inflammatory agents that inhibit COX are discussed in Chapter 36: Nonsteroidal Anti-Inflammatory Drugs, Disease-Modifying Antirheumatic Drugs, Nonopioid Analgesics, & Drugs Used in Gout. COX-2 appears to be the form of the enzyme associated with cells involved in the inflammatory process. The prostaglandins are not chemoattractants, but the leukotrienes and some of the HETEs (eg, 12-HETE) are strong chemoattractants. PGE₂ inhibits both antigen-driven and mitogen-induced B

lymphocyte proliferation and differentiation to plasma cells, resulting in inhibition of IgM synthesis. The concomitant elevation of serum IgE and monocyte PGE₂ synthesis, seen in patients with severe trauma and patients with Hodgkin's disease, is explained by PGE₂ ability to enhance immunoglobulin class switching to IgE.

Rheumatoid Arthritis

In rheumatoid arthritis, immune complexes are deposited in the affected joints, causing an inflammatory response that is amplified by eicosanoids. Lymphocytes and macrophages accumulate in the synovium, while PMNs localize mainly in the synovial fluid. The major eicosanoids produced by PMNs are leukotrienes, which facilitate T cell proliferation and act as chemoattractants. Human macrophages synthesize the COX products PGE₂ and TXA₂ and large amounts of leukotrienes.

Infection

The relationship of eicosanoids to infection is not well defined. The association between the use of the anti-inflammatory steroids and increased risk of infection is well established. However, the NSAIDs do not seem to alter patient responses to infection.

Glaucoma

Latanoprost, a stable long-acting PGF_{2 α} derivative, was the first prostanoid used for glaucoma. The success of latanoprost has stimulated development of similar prostanoids with ocular hypotensive effects, and **bimatoprost**, **travaprost**, and **unoprostone** are now available. These drugs act at the FP receptor and are administered as drops into the conjunctival sac once or twice daily. Adverse effects include irreversible brown pigmentation of the iris and eyelashes, drying of the eyes, and conjunctivitis.

Dietary Manipulation of Arachidonic Acid Metabolism

Because arachidonic acid is derived from dietary linoleic and α -linolenic acids, which are essential fatty acids, the effects of dietary manipulation on arachidonic acid metabolism have been extensively studied. Two approaches have been used. The first adds corn, safflower, and sunflower oils, which contain linoleic acid (C18:2), to the diet. The second approach adds oils containing eicosapentaenoic (C20:5) and docosahexaenoic acids (C22:6), so-called omega-3 fatty acids, from cold water fish. Both types of diet change the phospholipid composition of cell membranes by replacing arachidonic acid with the dietary fatty acids. It has been claimed that the synthesis of both TXA₂ and PGI₂ is reduced and that changes in platelet aggregation, vasomotor spasm, and cholesterol metabolism follow.

As indicated above, there are many possible oxidation products of the different polyenoic acids. It is probably naive to ascribe the effects of dietary intervention reported thus far to such metabolites. Carefully controlled clinical studies will be needed before these questions can be satisfactorily answered. However, subjects on diets containing highly saturated fatty acids clearly show increased platelet aggregation when compared with other study groups. Such diets (eg, in Finland and the USA) are associated with higher rates of myocardial infarction than are more polyunsaturated diets (eg, in Italy).

Preparations Available

Nonsteroidal Anti-Inflammatory Drugs Are Listed in Chapter 36: Nonsteroidal Anti-Inflammatory Drugs, Disease-Modifying Antirheumatic Drugs, Nonopioid Analgesics, & Drugs Used in Gout.

Alprostadil

Penile injection (Caverject, Edex): 5, 10, 20, 40 μg sterile powder for reconstitution

Penile pellet (Muse): 125, 250, 500, 1000 μg

Parenteral (Prostin VR Pediatric): 500 $\mu\text{g}/\text{mL}$ ampules

Bimatoprost (Lumigan)

Ophthalmic drops: 0.03% solution

Carboprost tromethamine (Hemabate)

Parenteral: 250 μg carboprost and 83 μg tromethamine per mL ampules

Dinoprostone [prostaglandin E₂] (Prostin E₂, Prepidil, Cervidil)

Vaginal: 20 mg suppositories, 0.5 mg gel, 10 mg controlled release system

Epoprostenol [prostacyclin] (Flolan)

Intravenous: powder to make 3, 5, 10, 15 $\mu\text{g}/\text{mL}$

Latanoprost (Xalatan)

Topical: 50 $\mu\text{g}/\text{mL}$ ophthalmic solution

Misoprostol (Cytotec)

Oral: 100 and 200 μg tablets

Monteleukast (Singulair)

Oral: 5 mg chewable, 10 mg tablets

Travaprost (Travatan)

Ophthalmic solution: 0.0004%

Treprostinil (Remodulin)

Parenteral: 1, 2.5, 5, 10 mg/mL for continuous subcutaneous infusion

Unoprostone (Rescula)

Ophthalmic solution 0.15%

Zafirleukast (Accolate)

Oral: 10, 20 mg tablets

Zileuton (Zyflo)

Oral: 600 mg tablets

Chapter 19. Nitric Oxide, Donors, & Inhibitors

Katzung PHARMACOLOGY, 9e > Section IV. Drugs with Important Actions on Smooth Muscle > Chapter 19. Nitric Oxide, Donors, & Inhibitors >

Nitric Oxide, Donors, & Inhibitors: Introduction

Nitric oxide (NO) is a gaseous signaling molecule that readily diffuses across cell membranes and regulates a wide range of physiologic and pathophysiologic processes including cardiovascular, inflammation, immune and neuronal functions.

Katzung PHARMACOLOGY, 9e > Section IV. Drugs with Important Actions on Smooth Muscle > Chapter 19. Nitric Oxide, Donors, & Inhibitors >

Discovery of Endogenous Nitric Oxide

Early observations of the biologic role of endogenously generated NO were made in rodent macrophages and neutrophils: In vitro exposure of these cells to endotoxin lipopolysaccharide released significant amounts of nitrite and nitrate into the cell culture medium. Furthermore, injection of endotoxin in vivo elevated urinary nitrite and nitrate, the two oxidation products of nitric oxide. This nitric oxide was found to originate from oxidation of the guanidino group of L-arginine.

The second observation was made by Furchgott and Zawadzki in 1980 using isolated vascular smooth muscle preparations. They discovered that following stimulation with acetylcholine or carbachol, the endothelium released a short-lived vasodilator, which—unlike endothelium-derived prostacyclin—was not blocked by cyclooxygenase inhibitors. They named this vasodilator **endothelium-derived relaxing factor (EDRF)** since it promoted relaxation of precontracted smooth muscle preparations. Other workers confirmed and extended these findings. In 1987, by comparing the pharmacologic and biochemical properties of the suspect molecule, three independent groups reported that EDRF and nitric oxide are the same molecule. It was later reported that other vasodilator molecules may be a part of EDRF, but it appears clear that nitric

oxide provides the major part of its activity. Subsequent studies revealed that nitric oxide was generated by many cells and was, like the eicosanoids (see Chapter 18: The Eicosanoids: Prostaglandins, Thromboxanes, Leukotrienes, & Related Compounds), found in almost all tissues. The major exogenous donors of nitric oxide (nitrates, nitrites, nitroprusside) have been discussed (see Chapter 11: Antihypertensive Agents and Chapter 12: Vasodilators & the Treatment of Angina Pectoris).

Biologic Synthesis & Inactivation of Nitric Oxide

Synthesis

Nitric oxide, written as NO. or simply NO, is a highly diffusible stable gas composed of one atom each of nitrogen and oxygen. It is synthesized by a family of enzymes that are collectively called **nitric oxide synthase, NOS** (EC 1.14.13.49). Three isoforms of NOS have been identified (Table 19–1). These isoforms are heme-containing flavoproteins employing L-arginine as a substrate and requiring NADPH, flavin adenine dinucleotide, and tetrahydrobiopterin as cofactors. Phosphorylation also has differential regulatory effects on the activity of NOS. For example, phosphorylation significantly reduces the activity of NOS-1, whereas phosphorylation of NOS-3 by a serine-threonine protein kinase activates the enzyme. Furthermore, NOS-2 expression is tightly controlled by several transcription factors.

Table 19–1. Properties of the Three Isoforms of Nitric Oxide Synthase (NOS).

	Isoform Names		
Property	NOS-1	NOS-2	NOS-3
Other names	nNOS (neuronal NOS)	iNOS (inducible NOS)	eNOS (endothelial NOS)
Tissue	Neuronal, epithelial cells	Macrophages, smooth muscle cells	Endothelial cells
Expression	Constitutive	Transcriptional induction	Constitutive
Calcium requirement	Yes	No	Yes
Chromosome	12	17	7
Approximate mass	150–160 kDa	125–135 kDa	133 kDa

Formation of nitric oxide from L-arginine and several nitric oxide donors is shown in Figure 19–1. Activation of NOS by the influx of extracellular calcium and binding of calmodulin, as in the case of the constitutive enzyme, or following the activation of the inducible NOS (NOS-2) by cytokines, results in the metabolism of L-arginine to L-citrulline and nitric oxide. The conversion of L-arginine to nitric oxide and L-citrulline is inhibited by several arginine competitors such as N^G -monomethyl-L-arginine (below). Some nitric oxide donors, eg, oxygenated nitroprusside, spontaneously generate

such as nitroglycerin, require the presence of a thiol compound such as cysteine. Once generated, nitric oxide interacts with the heme moiety of soluble guanylyl cyclase in the cytoplasm of cells (Figure 19–1, right). This results in allosteric transformation and activation of the enzyme and leads to the formation of 3',5'-cyclic-guanosine monophosphate (cGMP) from GTP. Activation of the soluble guanylyl cyclase by nitric oxide can be inhibited by methylene blue. The affinity of nitric oxide for iron is also responsible for its inhibitory effect on several enzymes by interacting with the iron-sulfur centers of these enzymes. Inhibition of enzymes such as cytochrome P450 by nitric oxide is a major problem in inflammatory liver disease and can be reversed by NO synthase inhibitors. Carbon monoxide, another gaseous compound produced endogenously from the catabolism of heme, shares many of the properties of nitric oxide such as activation of soluble guanylyl cyclase. However, unlike nitric oxide, which has an extra electron, carbon monoxide is a stable molecule in the presence of oxygen. The affinity of nitric oxide for hemoglobin is several orders of magnitude greater than that of carbon monoxide. Nitric oxide undergoes both oxidative and reductive reactions, resulting in the formation of a variety of oxides of nitrogen (Table 19–2).

Figure 19–1.

Nitric oxide generation from L-arginine and nitric oxide donors and the formation of cGMP. L-NMMA inhibits nitric oxide synthase. Some of the nitric oxide donors such as furoxans and organic nitrates and nitrites require a thiol cofactor such as cysteine or glutathione to form nitric oxide.

Table 19–2. Oxides of Nitrogen.

Name	Symbol	Known Function
Nitric oxide	NO [•]	Vasodilator, platelet inhibitor, immune regulator, neurotransmitter
Nitroxyl anion	NO ⁻	Smooth muscle relaxant
Nitrogen dioxide	NO ₂ [•]	Free radical, nitrosating agent, lung irritant
Nitrous oxide	N ₂ O	Anesthetic
Dinitrogen trioxide	N ₂ O ₃	Nitrosating agent
Dinitrogen tetroxide	N ₂ O ₄	Nitrosating agent
Nitrite	NO ₂ ⁻	Produce NO [•] at acidic pH
Nitrate	NO ₃ ⁻	Stable oxidation product of NO [•]

Inactivation

Nitric oxide is inactivated by heme and by the free radical, superoxide. Thus, scavengers of superoxide anion such as superoxide dismutase may protect nitric oxide, enhancing its potency and prolonging its duration of action. Conversely, interaction of nitric oxide with superoxide may generate the potent tissue-damaging moiety, peroxynitrite (ONOO⁻), which has a high affinity for sulfhydryl groups and thus inactivates several key sulfhydryl-bearing enzymes. This effect of peroxynitrite is regulated by the cellular content of glutathione. Since glutathione is the major intracellular soluble sulfhydryl-containing compound, factors that regulate the biosynthesis and decomposition of glutathione may have important consequences.

Glutathione also interacts with nitric oxide under physiologic conditions to generate *S*-nitrosoglutathione, a more stable form of nitric oxide. Nitrosoglutathione may serve as an endogenous long-lived adduct or carrier of nitric oxide. Vascular glutathione is decreased in diabetes mellitus and atherosclerosis, and this may account for the increased incidence of cardiovascular complications in these conditions. Ischemia followed by reperfusion is another situation in which endothelial function is compromised owing to increased production of free radicals, resulting in reduced nitric oxide formation.

Katzung PHARMACOLOGY, 9e > Section IV. Drugs with Important Actions on Smooth Muscle > Chapter 19. Nitric Oxide, Donors, & Inhibitors >

Inhibitors of Nitric Oxide

In theory, several methods are available for reducing nitric oxide levels in tissues and thus

inhibiting its actions. Drugs may inhibit the uptake of L-arginine into cells, thus depriving the NOS isoforms of substrate. Other methods include deprivation of the cofactors and calmodulin antagonists; inhibitors of NOS synthesis; inhibitors of binding of arginine to NOS, and scavengers of nitric oxide. The most important thus far have been inhibitors of NOS. Unfortunately, the selectivity of these inhibitors for the individual isoforms is incomplete. Most of these inhibitors are substrate analogs (Table 19–3).

Table 19–3. Some Inhibitors of Nitric Oxide Synthesis or Action.		
Inhibitor	Mechanism	Comment
<i>N</i> ^ε -Monomethyl-L-arginine (L-NMMA)	NOS inhibition	May act as substrate in some tissues
<i>N</i> ^ε -Nitro-L-arginine methyl ester (L-NAME)	NOS inhibition	Less selective NOS inhibitor
7-Nitroindazole	NOS inhibition	Markedly selective for NOS–1 in vivo
S-Methylthiocitrulline	NOS inhibition	Partially selective for NOS–1
Heme	Nitric oxide scavenger	
Protein inhibitor of NOS	Unknown mechanism	Endogenous inhibitor found in brain

Katzung PHARMACOLOGY, 9e > Section IV. Drugs with Important Actions on Smooth Muscle > Chapter 19. Nitric Oxide, Donors, & Inhibitors >

Effects of Nitric Oxide

Nitric oxide has major effects that are mediated by activation of cytoplasmic **soluble guanylyl cyclase** and stimulated production of **cGMP**, an important second messenger. In addition, nitric oxide can produce several reactive nitrogen derivatives by interaction with molecular oxygen and superoxide radicals (Table 19–2). These highly unstable molecules react with a variety of proteins, lipids, nucleic acids, and metals (especially iron) in cells (Davis, 2001). The remainder of this chapter discusses some of the second messenger-mediated effects of nitric oxide and the effects of inhibition of its production.

Vascular Effects

Nitric oxide has a significant effect on vascular smooth muscle tone and blood pressure. As stated previously, it is released by acetylcholine and other endothelium-dependent vasodilators. It may play a role in the normal regulation of vascular tone as suggested by the fact that a reduction of nitric oxide synthesis (caused by knockout mutations, infusion of NOS inhibitors such as L-NMMA, or by injury to the vascular endothelium) increases vascular tone and elevates mean arterial pressure. The effects of vasopressor drugs are increased by inhibition of NOS. As described in Chapter 12: Vasodilators & the Treatment of Angina Pectoris and shown in Figure 12–2, increased cGMP synthesis by guanylyl cyclase results in smooth muscle relaxation.

Apart from being a vasodilator, nitric oxide is also a potent inhibitor of neutrophil adhesion to the vascular endothelium. This is due to the inhibitory effect of nitric oxide on the expression of adhesion molecules on the endothelial surface. The role of nitric oxide in protecting the endothelium has been demonstrated by studies that showed that treatment with nitric oxide donors protects against ischemia- and reperfusion-mediated endothelial dysfunction.

Respiratory Disorders

Nitric oxide has been shown to improve cardiopulmonary function in adult patients with pulmonary artery hypertension and is approved for this indication (see Preparations Available). It is administered by inhalation. It has also been administered by inhalation to newborns with pulmonary hypertension and acute respiratory distress syndrome. The current treatment for severely defective gas exchange in the newborn is with extracorporeal membrane oxygenation (ECMO), which does not directly affect pulmonary vascular pressures. Nitric oxide inhalation decreases pulmonary arterial pressure and improves blood oxygenation. Thus, when pulmonary resistance is elevated, it is possible to exploit the vasodilator properties of nitric oxide by administering it via inhalation of a few parts per million. Adults with respiratory distress syndrome also appear—in open trials—to benefit from nitric oxide inhalation. Nitric oxide may have an additional role in relaxing airway smooth muscle and thus acting as a bronchodilator. For these reasons, nitric oxide inhalation therapy is being widely tested in both infants and adults with acute respiratory distress syndrome. The adverse effects of this use of nitric oxide are being assessed.

Septic Shock

As mentioned previously, increased urinary excretion of nitrate, the oxidative product of nitric oxide, is reported in gram-negative bacterial infection. Lipopolysaccharide components from the bacterial wall activate the inducible NOS (NOS-2), resulting in exaggerated hypotension, shock, and possible death. This hypotension is reversed by NOS inhibitors such as L-NMMA (Table 19–3) in humans as well as animal models and by compounds such as methylene blue, which prevent the action of nitric oxide, as well as by scavengers of nitric oxide such as hemoglobin. Furthermore, knockout mice lacking a functional NOS-2 gene are more resistant to endotoxin than wild-type mice. However, there has been no correlation between the hemodynamic effects of the nitric oxide inhibitors and survival rate in gram-negative sepsis thus far.

Atherosclerosis

Vascular plaque formation in hypercholesterolemia leads to reduced nitric oxide formation and endothelium-dependent vasodilator responses. *In vitro*, nitric oxide carriers and donors and cGMP analogs inhibit smooth muscle cell proliferation. In animal models, myointimal proliferation following angioplasty can be blocked by feeding arginine, by using nitric oxide donors, by NOS gene transfer, and by nitric oxide inhalation. In addition, nitric oxide may act as an antioxidant, blocking the oxidation of low-density lipoproteins (LDL) and thus preventing the formation of foam cells in the vascular wall.

Platelets

Abnormal activation of platelets is associated with increased platelet adhesion and aggregation and therefore a higher incidence of thrombotic events. Platelet activation also leads to release of smooth muscle mitogens such as growth factors and thromboxane. Nitric oxide is a potent inhibitor of platelet adhesion and aggregation. Thus, endothelial dysfunction and the associated decrease in nitric oxide generation may result in abnormal platelet function. Platelets also contain both

constitutive and inducible NOS, although to a much lesser extent than endothelial cells. As in vascular smooth muscle, cGMP mediates the protective effect of nitric oxide in platelets. Nitric oxide may have an additional beneficial effect on blood coagulation by enhancing fibrinolysis via an effect on plasminogen.

Organ Transplantation

Accelerated graft atherosclerosis following organ transplantation is a chronic condition and is a major cause of transplant failure, leading to retransplantation or death. Continuous vascular smooth muscle proliferation occurs within the vasculature of most grafts and is a central event in luminal narrowing. Ischemic and reperfusion injuries at the time of organ harvesting, preservation, and revascularization initiate myointimal proliferation, which is also promoted by the continuous immune response to the allogeneic organ graft. By reducing free radical toxicity under these conditions, nitric oxide may act as a cytoprotective agent, inhibiting platelet and neutrophil aggregation and adhesion to the vascular wall. Dietary L-arginine supplementation increases plasma nitrite and nitrate formation and has been shown to attenuate accelerated graft atherosclerosis. However, excessively high concentrations of nitric oxide may be detrimental during *acute* organ rejection due to up-regulation of inducible NOS by cytokines; under these circumstances, *inhibition* of nitric oxide synthesis has been shown to prolong graft survival in experimental animals.

The Central Nervous System

Nitric oxide has been proposed to have a major role in the central nervous system—as a neurotransmitter, as a modulator of ligand-gated receptors, or both. In addition, nitric oxide probably plays a role in neuronal degeneration in some conditions. The likely cellular targets of nitric oxide in the central nervous system include presynaptic and postsynaptic nerve terminals. Nitric oxide modifies neurotransmitter release in different areas of the brain. Postsynaptic release of nitric oxide following activation of the NMDA receptor may initiate presynaptic transmitter release of glutamate, ie, nitric oxide may function as a *retrograde* messenger that is synthesized in postsynaptic sites following opening of the Ca^{2+} channels and activation of NOS. It is proposed that the nitric oxide thus produced rapidly diffuses to the presynaptic nerve terminal where guanylyl cyclase is activated to yield cGMP and thus facilitate transmitter release. In the cerebellum and in neuroblastoma cells, this effect is blocked by NOS inhibitors such as L-NMMA and is enhanced by L-arginine. It has been suggested that nitric oxide (like many other substances) may have a role in short- and long-term potentiating effects on excitatory amino acids in brain development and learning.

7-Nitroindazole, an inhibitor of NOS-1, and L-NAME, a less selective inhibitor of neuronal NOS, have significant antinociceptive effects in humans and animals and 7-nitroindazole reduces the signs of opioid withdrawal and cocaine action in animal models. This inhibitor also reduces cerebral blood flow. Nevertheless, 7-nitroindazole can reduce the size of cerebral infarcts in animal models. In contrast, NOS-3-deficient mice are more susceptible to ischemic cerebral damage. NOS-1 inhibition by 7-nitroindazole also reduces the neurotoxicity of MPTP and MPP^+ (see Chapter 28: Pharmacologic Management of Parkinsonism & Other Movement Disorders) in several animal models.

It is well known that prolonged NMDA glutamate receptor activation results in degeneration of neurons (excitotoxicity). This has been attributed to a large increase in calcium influx, which activates the calmodulin-dependent NOS-1 and leads to sustained elevation of nitric oxide concentrations. The increase in neurodegeneration caused by excitatory amino acids may be due to enhanced oxygen radical formation since superoxide dismutase has a beneficial effect in

experimental models. The damage may also be mediated by the generation of secondary radicals such as peroxynitrite, which has a high affinity for sulfhydryl-containing enzymes such as calcium ATPase. Inhibition of calcium ATPases by peroxynitrite may in turn lead to enhanced Ca^{2+} accumulation and associated neurodegeneration. NOS-2 has been implicated in several other degenerative neurologic conditions, eg, Alzheimer's disease, multiple sclerosis, and Huntington's disease.

High levels of nitric oxide have also been shown to cause destruction of photoreceptor cells in the retina. This is believed to be due to a prolonged increase in cGMP formation. Finally, nitric oxide and cGMP have been reported to have a role in epileptic seizures.

The Peripheral Nervous System

Nonadrenergic, noncholinergic (NANC) neurons are widely distributed in peripheral tissues, especially the gastrointestinal and reproductive tracts (see Chapter 6: Introduction to Autonomic Pharmacology). Considerable evidence implicates nitric oxide as a mediator of certain NANC actions, and some NANC neurons appear to release nitric oxide. Penile erection is thought to be caused by the release of nitric oxide from NANC neurons; it is well documented that nitric oxide promotes relaxation of the smooth muscle in the corpora cavernosa—the initiating factor in penile erection—and inhibitors of NOS have been shown to prevent erection caused by pelvic nerve stimulation in the rat. Thus, impotence is a possible clinical indication for the use of a nitric oxide donor, and trials have been carried out with nitroglycerin ointment and the nitroglycerin patch. Another approach is to inhibit the breakdown of cGMP by the phosphodiesterase (PDE isoform 5) present in the smooth muscle of the corpora cavernosa with drugs such as sildenafil (see Chapter 12: Vasodilators & the Treatment of Angina Pectoris).

Inflammation

Nitric oxide has a role in both acute and chronic inflammation. NOS-3 is involved in the vasodilation associated with acute inflammation. In experimental models of acute inflammation, inhibitors of NOS-3 have a dose-dependent protective effect, suggesting that nitric oxide promotes edema and vascular permeability. Nitric oxide has a detrimental effect in chronic models of arthritis; dietary L-arginine supplementation exacerbates arthritis whereas protection is seen with NOS-2 inhibitors. Psoriasis lesions, airway epithelium in asthma, and inflammatory bowel lesions in humans all demonstrate elevated levels of nitric oxide and NOS-2. Synovial fluid from patients with arthritis contains increased oxidation products of nitric oxide, particularly peroxynitrite. Recent studies have shown that nitric oxide stimulates the synthesis of inflammatory prostaglandins by activating cyclooxygenase isoenzyme II (COX-2). Thus, inhibition of the nitric oxide pathway may have a beneficial effect on inflammatory diseases, including joint diseases. Studies using inhibitors of NOS-2 have shown that nitric oxide is required for maintaining COX-2 gene expression.

Nitric oxide also appears to play an important protective role in the body via immune cell function. When challenged with foreign antigens, TH1 cells (see Chapter 56: Immunopharmacology) respond by synthesizing nitric oxide. Inhibition of NOS and knockout of the NOS-2 gene can markedly impair the protective response to injected parasites in animal models.

Preparations Available

Nitric Oxide (INOmax)

Inhalation: 100, 800 ppm gas

Katzung PHARMACOLOGY, 9e > Section IV. Drugs with Important Actions on Smooth Muscle > Chapter 19. Nitric Oxide, Donors, & Inhibitors >

Chapter 20. Drugs Used in Asthma

Katzung PHARMACOLOGY, 9e > Section IV. Drugs with Important Actions on Smooth Muscle > Chapter 20. Drugs Used in Asthma >

Drugs Used in Asthma: Introduction

The clinical hallmarks of asthma are recurrent, episodic bouts of coughing, shortness of breath, chest tightness, and wheezing. In mild asthma, symptoms occur only occasionally, eg, on exposure to allergens or certain pollutants, on exercise, or after a viral upper respiratory infection. More severe forms of asthma are associated with frequent attacks of wheezing dyspnea, especially at night, and even chronic limitation of activity. Asthma is the most common chronic disabling disease of childhood, but it affects all age groups.

Asthma is physiologically characterized by increased responsiveness of the trachea and bronchi to various stimuli and by widespread narrowing of the airways that changes in severity either spontaneously or as a result of therapy. Its pathologic features are contraction of airway smooth muscle, mucosal thickening from edema and cellular infiltration, and inspissation in the airway lumen of abnormally thick, viscid plugs of mucus. Of these causes of airway obstruction, contraction of smooth muscle is most easily reversed by current therapy; reversal of the edema and cellular infiltration requires sustained treatment with anti-inflammatory agents. Asthma therapies are thus sometimes divided into two categories: "short-term relievers" and "long-term controllers."

Short-term relief is most effectively achieved with bronchodilators, agents that increase airway caliber by relaxing airway smooth muscle, and of these the β -adrenoceptor stimulants (see Chapter 9: Adrenoceptor-Activating & Other Sympathomimetic Drugs) are the most widely used. Theophylline, a methylxanthine drug, and antimuscarinic agents (see Chapter 8: Cholinergic-Blocking Drugs) are also used for reversal of airway constriction. Long-term control is most often achieved with an anti-inflammatory agent such as an inhaled corticosteroid, with a leukotriene antagonist, or with an inhibitor of mast cell degranulation, eg, cromolyn or nedocromil. The distinction between "short-term relievers" and "long-term controllers" has become blurred by the finding that theophylline inhibits some lymphocyte functions and modestly reduces airway mucosal inflammation and that budesonide, an inhaled corticosteroid, produces modest immediate bronchodilation. Similarly, two recently released long-acting β -adrenoceptor stimulants, salmeterol and formoterol, appear to be effective in improving asthma control when taken regularly. Finally, clinical trials are demonstrating the efficacy of specifically targeting a mechanism thought to be fundamental to asthma's pathogenesis by repeated treatment with a humanized monoclonal anti-IgE antibody.

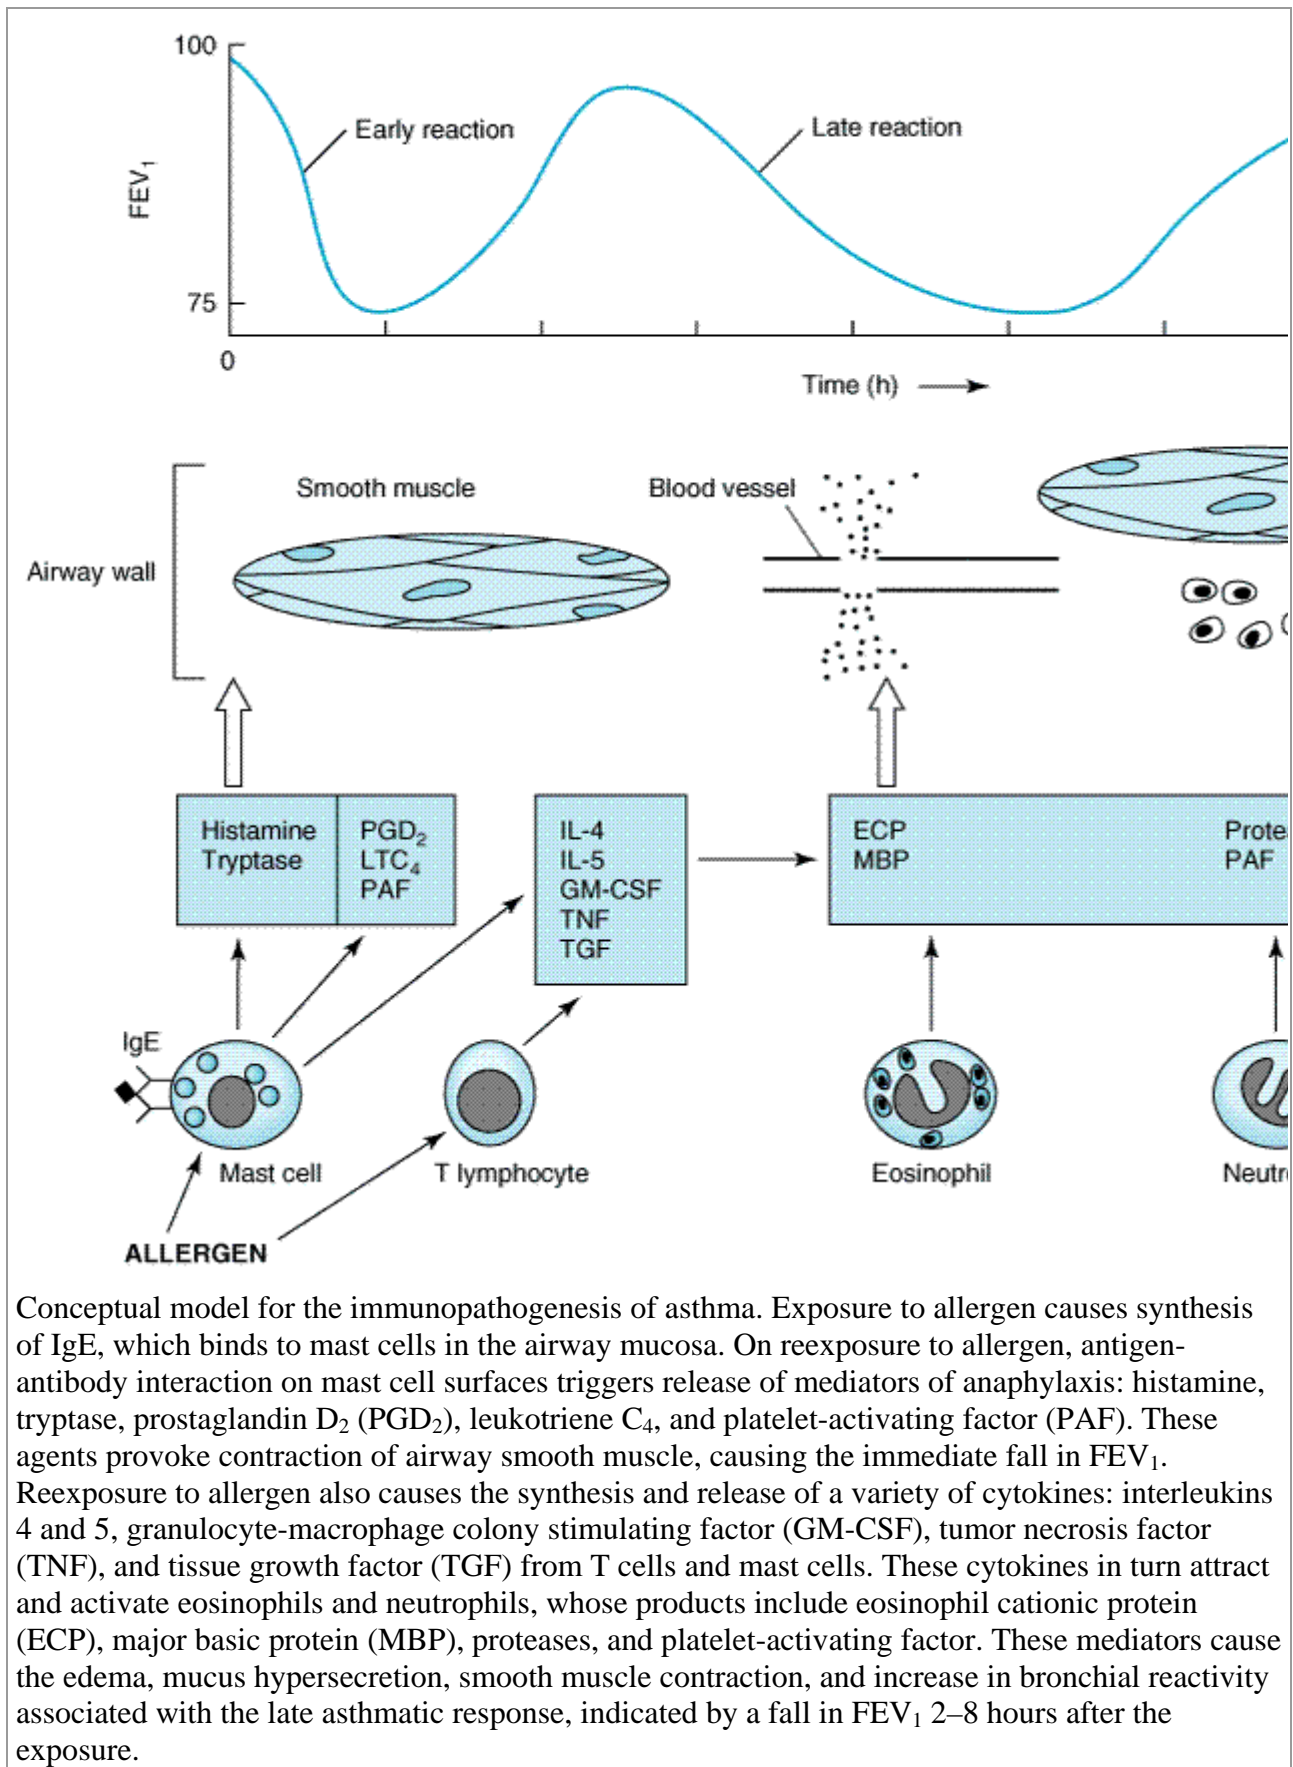

This chapter presents the basic pharmacology of the methylxanthines, cromolyn, leukotriene pathway inhibitors, and monoclonal anti-IgE antibody—agents whose medical use is almost exclusively for pulmonary disease. The other classes of drugs listed above are discussed in relation

to the therapy of asthma.

Pathogenesis of Asthma

A rational approach to the pharmacotherapy of asthma depends on an understanding of the disease's pathogenesis. In the classic immunologic model, asthma is a disease mediated by reagenic (IgE) antibodies bound to mast cells in the airway mucosa (Figure 20–1). On reexposure to an antigen, antigen-antibody interaction on the surface of the mast cells triggers both the release of mediators stored in the cells' granules and the synthesis and release of other mediators. The agents responsible for the early reaction—immediate bronchoconstriction—include histamine, tryptase and other neutral proteases, leukotrienes C₄ and D₄, and prostaglandins. These agents diffuse throughout the airway wall and cause muscle contraction and vascular leakage. Other mediators are responsible for the more sustained bronchoconstriction, cellular infiltration of the airway mucosa, and mucus hypersecretion of the late asthmatic reaction that occurs 2–8 hours later. These mediators are thought to be cytokines characteristically produced by TH2 lymphocytes, especially GM-CSF and interleukins 4, 5, 9, and 13, which attract and activate eosinophils and stimulate IgE production by B lymphocytes. It is not clear whether lymphocytes or mast cells in the airway mucosa are the primary source of the cytokines and other mediators responsible for the late inflammatory response, but it is now thought that the benefits of corticosteroid therapy may result from their inhibition of cytokine production in the airways.

Figure 20–1.

Conceptual model for the immunopathogenesis of asthma. Exposure to allergen causes synthesis of IgE, which binds to mast cells in the airway mucosa. On reexposure to allergen, antigen-antibody interaction on mast cell surfaces triggers release of mediators of anaphylaxis: histamine, tryptase, prostaglandin D₂ (PGD₂), leukotriene C₄, and platelet-activating factor (PAF). These agents provoke contraction of airway smooth muscle, causing the immediate fall in FEV₁. Reexposure to allergen also causes the synthesis and release of a variety of cytokines: interleukins 4 and 5, granulocyte-macrophage colony stimulating factor (GM-CSF), tumor necrosis factor (TNF), and tissue growth factor (TGF) from T cells and mast cells. These cytokines in turn attract and activate eosinophils and neutrophils, whose products include eosinophil cationic protein (ECP), major basic protein (MBP), proteases, and platelet-activating factor. These mediators cause the edema, mucus hypersecretion, smooth muscle contraction, and increase in bronchial reactivity associated with the late asthmatic response, indicated by a fall in FEV₁ 2–8 hours after the exposure.

with asthma have no evidence of immediate hypersensitivity to antigens, most severe exacerbations of asthma appear to be provoked by viral respiratory infection, the severity of symptoms correlates poorly with the quantity of antigen in the atmosphere, and in many patients bronchospasm can be provoked by nonantigenic stimuli such as distilled water, exercise, cold air, sulfur dioxide, and rapid respiratory maneuvers.

This tendency to develop bronchospasm upon encountering stimuli that do not affect healthy nonasthmatic airways is characteristic of asthma and is sometimes called "nonspecific bronchial hyperreactivity" to distinguish it from bronchial responsiveness to specific antigens. Bronchial hyperreactivity is quantitated by measuring the fall in forced expiratory volume in 1 second (FEV₁) provoked by inhaling serially increasing concentrations of aerosolized histamine or methacholine. This exaggerated sensitivity of the airways appears to be fundamental to asthma's pathogenesis, for it is nearly ubiquitous in patients with asthma and its degree correlates with the symptomatic severity of the disease.

The mechanisms underlying bronchial hyperreactivity are somehow related to inflammation of the airway mucosa. The agents that increase bronchial reactivity, such as ozone exposure, allergen inhalation, and infection with respiratory viruses, also cause airway inflammation. In both dogs and humans, the increase in bronchial reactivity induced by ozone is associated with an increase in the number of polymorphonuclear leukocytes found in fluid obtained by bronchial lavage or from bronchial mucosal biopsies. The increase in reactivity due to allergen inhalation is associated with an increase in both eosinophils and polymorphonuclear leukocytes in bronchial lavage fluid. The increase in reactivity that is associated with the late asthmatic response to allergen inhalation (Figure 20–1) is sustained and, because it is prevented by treatment with inhaled corticosteroids immediately before antigen challenge, is thought to be caused by airway inflammation.

How the increase in airway reactivity is linked to inflammation is uncertain. Much evidence points to the eosinophil. The most consistent difference in bronchial mucosal biopsies obtained from asthmatic and healthy subjects is an increase in the number of eosinophils found beneath the airway epithelium. Immunohistochemical staining shows increased levels of eosinophil cationic protein, indicating activation of the cells. The number of eosinophils in expectorated sputum or in fluid lavaged from the lungs correlates roughly with the degree of bronchial hyperreactivity. Eosinophil products have in turn been shown to cause epithelial sloughing and an increase in contractile responsiveness of airway smooth muscle. The importance of the eosinophil has been challenged, however, by a study showing that treatment with an anti-IL-5 monoclonal antibody effectively blocks airway eosinophilia caused by allergen challenge but does not prevent bronchoconstriction or any further increase in bronchial hyperactivity (Leckie, 2000).

The products of other cells in the airways, such as lymphocytes, macrophages, mast cells, sensory nerves, and epithelial cells, have also been shown to alter airway smooth muscle function, so a specific antagonist to a single mediator or class of mediators might not prove wholly effective as asthma therapy. Other evidence suggests a role for sensitization of sensory nerves in the airways as a mechanism for hyperreactivity (see Pharmacologic Significance of Lung Innervation).

Whatever the mechanisms responsible for bronchial hyperreactivity, bronchoconstriction itself seems to result not simply from the direct effect of the released mediators but also from their activation of neural or humoral pathways. Evidence for the importance of neural pathways stems largely from studies of laboratory animals. Thus, the bronchospasm provoked in dogs by histamine can be greatly reduced by pretreatment with an inhaled topical anesthetic agent, by transection of the vagus nerves, and by pretreatment with atropine. Studies of asthmatic humans, however, have shown that treatment with atropine causes only a reduction in—not abolition of—the

bronchospastic responses to antigens and to nonantigenic stimuli. While it is possible that activity in some other neural pathway (eg, the nonadrenergic, noncholinergic system; see Pharmacologic Significance of Lung Innervation) contributes to bronchomotor responses to nonspecific nonantigenic stimuli, their inhibition by cromolyn, a drug that appears to inhibit mast cell degranulation, suggests that both antigenic and nonantigenic stimuli may provoke the release from mast cells of mediators that stimulate smooth muscle contraction by direct and indirect mechanisms (Figure 20–2).

Figure 20–2.

Mechanisms of response to inhaled irritants. The airway is represented microscopically by a cross-section of the wall with branching vagal sensory endings lying adjacent to the lumen. Afferent pathways in the vagus nerves travel to the central nervous system; efferent pathways from the central nervous system travel to efferent ganglia. Postganglionic fibers release acetylcholine

(ACh), which binds to muscarinic receptors on airway smooth muscle. Inhaled materials may provoke bronchoconstriction by several possible mechanisms. First, they may trigger the release of chemical mediators from mast cells. Second, they may stimulate afferent receptors to initiate reflex bronchoconstriction or to release tachykinins (eg, substance P) that directly stimulate smooth muscle contraction.

The hypothesis suggested by these studies—that asthmatic bronchospasm results from a combination of release of mediators and an exaggeration of responsiveness to their effects—predicts that asthma may be effectively treated by drugs with different modes of action. Asthmatic bronchospasm might be reversed or prevented, for example, by drugs that reduce the amount of IgE bound to mast cells (anti-IgE antibody), prevent mast cell degranulation (cromolyn or nedocromil, sympathomimetic agents, calcium channel blockers), block the action of the products released (antihistamines and leukotriene receptor antagonists), inhibit the effect of acetylcholine released from vagal motor nerves (muscarinic antagonists), or directly relax airway smooth muscle (sympathomimetic agents, theophylline).

The second approach to the treatment of asthma is aimed not just at preventing or reversing acute bronchospasm but at reducing the level of bronchial responsiveness. Because increased responsiveness appears to be linked to airway inflammation and because airway inflammation is a feature of late asthmatic responses, this strategy is implemented both by reducing exposure to the allergens that provoke inflammation and by prolonged therapy with anti-inflammatory agents, especially inhaled corticosteroids.

Katzung PHARMACOLOGY, 9e > Section IV. Drugs with Important Actions on Smooth Muscle > Chapter 20. Drugs Used in Asthma >

Pharmacologic Significance of Lung Innervation

As noted previously, the airways are richly supplied with afferent and efferent vagal nerves. The cholinergic motor fibers are clearly responsible in some patients for a portion of the bronchoconstriction characteristic of acute asthma. Such fibers innervate M_3 receptors on the smooth muscle and contain modulatory M_2 receptors on the nerve terminals. Selective inhibition of M_2 receptors can increase bronchoconstrictor responses to a variety of stimuli, while M_3 inhibitors can produce dilation of constricted airways.

In contrast, noradrenergic sympathetic innervation of the airways is sparse, and these fibers do not appear to play a major role in controlling airway diameter. Bronchodilation may be brought about by nonadrenergic, noncholinergic nerves releasing nitric oxide since nitric oxide synthase inhibitors have been shown to reduce bronchodilation produced by electrical field stimulation *in vitro*.

The role of peptidergic neurons is not so clear. Capsaicin, the hot chile pepper chemical that evokes release of peptide transmitters from several types of sensory nerves, has been shown to reproduce some of the signs of bronchial hyperreactivity in animal and human experiments. These findings led to the proposal that sensitization of afferent nerve endings played a major role in chronic airway hyperreactivity. However, peptide transmitter antagonists have not been able to prevent bronchoconstriction in several models. Clearly, much remains to be learned about airway pharmacology.

Basic Pharmacology of Agents Used in the Treatment of Asthma

The drugs most used for management of asthma are adrenoceptor agonists (used as "relievers" or bronchodilators) and inhaled corticosteroids (used as "controllers" or anti-inflammatory agents). Their basic pharmacology is presented elsewhere (see Chapter 9: Adrenoceptor-Activating & Other Sympathomimetic Drugs and Chapter 39: Adrenocorticosteroids & Adrenocortical Antagonists). In this chapter, we review their pharmacology relevant to asthma.

Sympathomimetic Agents

The adrenoceptor agonists have several pharmacologic actions important in the treatment of asthma. They relax airway smooth muscle and inhibit release of some bronchoconstricting substances from mast cells. They may also inhibit microvascular leakage and increase mucociliary transport by increasing ciliary activity or by affecting the composition of mucous secretions. As in other tissues, the β agonists stimulate adenylyl cyclase and increase the formation of cAMP in the airway tissues (Figure 20–3).

Figure 20–3.

Bronchodilation is promoted by cAMP. Intracellular levels of cAMP can be increased by β -adrenoceptor agonists, which increase the rate of its synthesis by adenylyl cyclase (AC); or by phosphodiesterase (PDE) inhibitors such as theophylline, which slow the rate of its degradation. Bronchoconstriction can be inhibited by muscarinic antagonists and possibly by adenosine antagonists.

The best-characterized action of the adrenoceptor agonists on airways is relaxation of airway smooth muscle that results in bronchodilation. Although there is no evidence for significant sympathetic innervation of human airway smooth muscle, there is ample evidence for the presence

smooth muscle, inhibits mediator release, and causes tachycardia and skeletal muscle tremor as toxic effects.

The sympathomimetic agents that have been widely used in the treatment of asthma include epinephrine, ephedrine, isoproterenol, and a number of β_2 -selective agents (Figure 20–4). Because epinephrine and isoproterenol cause more cardiac stimulation (mediated mainly by β_1 receptors), they should probably be reserved for special situations (see below).

Figure 20–4.

Epinephrine is an effective, rapidly acting bronchodilator when injected subcutaneously (0.4 mL of 1:1000 solution) or inhaled as a microaerosol from a pressurized canister (320 μg per puff). Maximal bronchodilation is achieved 15 minutes after inhalation and lasts 60–90 minutes. Because epinephrine stimulates β_1 as well as β_2 receptors, tachycardia, arrhythmias, and worsening of angina pectoris are troublesome adverse effects. Epinephrine is the active agent in many nonprescription inhalants (eg, Primatene Mist) but is now rarely prescribed.

Ephedrine was used in China for more than 2000 years before its introduction into Western medicine in 1924. Compared with epinephrine, ephedrine has a longer duration, oral activity, more pronounced central effects, and much lower potency. Because of the development of more efficacious and β_2 -selective agonists, ephedrine is now used infrequently in treating asthma.

Isoproterenol is a potent bronchodilator; when inhaled as a microaerosol from a pressurized canister, 80–120 μg causes maximal bronchodilation within 5 minutes. Isoproterenol has a 60- to 90-minute duration of action. An increase in the asthma mortality rate that occurred in the United Kingdom in the mid 1960s was attributed to cardiac arrhythmias resulting from the use of high doses of inhaled isoproterenol, though this attribution remains a subject of controversy.

Beta₂ Selective Drugs

The β_2 -selective adrenoceptor agonist drugs are the most widely used sympathomimetics for the treatment of asthma at the present time (Figure 20–4). These agents differ structurally from epinephrine in having a larger substitution on the amino group and in the position of the hydroxyl groups on the aromatic ring. They are effective after inhaled or oral administration and have a long duration of action and significant β_2 selectivity.

Albuterol, terbutaline, metaproterenol, and pirbuterol are available as metered-dose inhalers. Given by inhalation, these agents cause bronchodilation equivalent to that produced by isoproterenol. Bronchodilation is maximal by 30 minutes and persists for 3–4 hours. Albuterol, levalbuterol, bitolterol, and metaproterenol can be diluted in saline for administration from a handheld nebulizer. Because the particles generated by a nebulizer are much larger than those from a metered-dose inhaler, much higher doses must be given (15 mg vs 2.5–5 mg) but are no more effective. Nebulized therapy should thus be reserved for patients unable to coordinate inhalation from a metered-dose inhaler.

Albuterol and terbutaline are also prepared in tablet form. One tablet two or three times daily is the usual regimen; the principal adverse effects of skeletal muscle tremor, nervousness, and occasional weakness may be reduced by starting the patient on half-strength tablets for the first 2 weeks of therapy.

Of these agents, only terbutaline is available for subcutaneous injection (0.25 mg). The indications for this route are similar to those for subcutaneous epinephrine—severe asthma requiring emergency treatment when aerosolized therapy is not available or has been ineffective—but it should be remembered that terbutaline's longer duration of action means that cumulative effects may be seen after repeated injections.

A new generation of long-acting β_2 -selective agonists includes **salmeterol** and **formoterol**. Both drugs are potent selective β_2 agonists that appear to achieve their long duration of action (12 hours or more) as a result of high lipid solubility, which permits them to dissolve in the smooth muscle cell membrane in high concentration or, possibly, attach to "mooring" molecules in the vicinity of the adrenoceptor. It is postulated that this local drug functions as a slow-release depot that provides drug to adjacent β receptors over a long period. These drugs appear to interact with inhaled corticosteroids to improve asthma control. They are not recommended as the sole therapy for asthma.

Although adrenoceptor agonists may be administered by inhalation or by the oral or parenteral routes, delivery by inhalation results in the greatest local effect on airway smooth muscle with the least systemic toxicity. Aerosol deposition depends on the particle size, the pattern of breathing

(tidal volume and rate of airflow), and the geometry of the airways. Even with particles in the optimal size range of 2–5 μm , 80–90% of the total dose of aerosol is deposited in the mouth or pharynx. Particles under 1–2 μm in size remain suspended and may be exhaled. Deposition can be increased by holding the breath in inspiration.

Toxicities

The use of sympathomimetic agents by inhalation at first raised fears about possible tachyphylaxis or tolerance to β -agonists, cardiac arrhythmias, and hypoxemia. The concept that β -agonist drugs cause worsening of clinical asthma by inducing tachyphylaxis to their own action remains unestablished. Most studies have shown only a small change in the bronchodilator response to β stimulation after prolonged treatment with β -agonist drugs, but other studies have shown a loss in the ability of β -agonist treatment to inhibit the response to subsequent challenge with exercise, methacholine, or antigen challenge (referred to as a loss of bronchoprotective action).

Other experiments have demonstrated that arterial oxygen tension (PaO_2) may decrease after administration of β -agonists if ventilation/perfusion ratios in the lung worsen. This effect is usually small, however, and may occur with any bronchodilator drug; the significance of such an effect will depend on the initial PaO_2 of the patient. Supplemental oxygen may be necessary if the initial PaO_2 is decreased markedly or if there is a large decrease in PaO_2 during treatment with bronchodilators. Finally, there is concern over myocardial toxicity from Freon propellants contained in all of the commercially available metered-dose canisters. While fluorocarbons may sensitize the heart to toxic effects of catecholamines, such an effect occurs only at very high myocardial concentrations, which are not achieved if inhalers are used as recommended. Under the terms of an international agreement, fluorocarbon-free inhalers will soon replace existing preparations.

Fears that heavy use of β -agonist inhalers could actually increase morbidity and mortality have not been borne out by careful epidemiologic investigations. Heavy use most often indicates that the patient should be receiving more effective prophylactic therapy with corticosteroids. In general, β_2 -adrenoceptor agonists are safe and effective bronchodilators when given in doses that avoid systemic adverse effects.

Methylxanthine Drugs

The three important methylxanthines are **theophylline**, **theobromine**, and **caffeine**. Their major source is beverages (tea, cocoa, and coffee, respectively). The importance of theophylline as a therapeutic agent in the treatment of asthma has waned as the greater effectiveness of inhaled adrenoceptor agents for acute asthma and of inhaled anti-inflammatory agents for chronic asthma has been established, but theophylline's very low cost is an important advantage for economically disadvantaged patients in societies where health care resources are limited.

Chemistry

As shown below, theophylline is 1,3-dimethylxanthine; theobromine is 3,7-dimethylxanthine; and caffeine is 1,3,7-trimethylxanthine. A theophylline preparation commonly used for therapeutic purposes is **aminophylline**, a theophylline-ethylenediamine complex. A synthetic analog of theophylline (dyphylline) is both less potent and shorter-acting than theophylline. The pharmacokinetics of theophylline are discussed below (see Clinical Use of Methylxanthines). The metabolic products, partially demethylated xanthines (not uric acid), are excreted in the urine.

Xanthine

Theobromine

Caffeine

Theophylline

Mechanism of Action

Theophylline produces direct bronchodilation and has some anti-inflammatory actions in the airway as well. Several mechanisms have been proposed for these actions, but none have been firmly established. At high concentrations, the methylxanthines can be shown *in vitro* to inhibit several members of the phosphodiesterase (PDE) enzyme family (Figure 20–3). Since the phosphodiesterases hydrolyze cyclic nucleotides, this inhibition results in higher concentrations of intracellular cAMP and, in some tissues, cGMP. This effect could explain the cardiac stimulation and smooth muscle relaxation produced by these drugs as well as decreased release of inflammatory mediators from mast cells. PDE4 appears to be the isoform most directly involved in the airway actions of methylxanthines. More selective inhibitors of PDE4 have been developed in an effort to reduce toxicity while maintaining therapeutic efficacy. Thus far, such selective PDE4 inhibitors have proved more effective in chronic obstructive pulmonary disease (COPD) than in asthma. A major adverse effect of the PDE4-selective drugs is nausea and vomiting.

Another proposed mechanism is the inhibition of cell surface receptors for adenosine. These receptors modulate adenylyl cyclase activity, and adenosine has been shown to cause contraction of isolated airway smooth muscle and to provoke histamine release from airway mast cells. These effects are antagonized by theophylline, which blocks cell surface adenosine receptors. It has also been shown, however, that xanthine derivatives devoid of adenosine-antagonistic properties (eg, enprofylline) may be more potent than theophylline in inhibiting bronchoconstriction in asthmatic subjects.

Pharmacodynamics of Methylxanthines

The methylxanthines have effects on the central nervous system, kidney, and cardiac and skeletal muscle as well as smooth muscle. Of the three agents, theophylline is most selective in its smooth muscle effects, while caffeine has the most marked central nervous system effects.

Central Nervous System Effects

In low and moderate doses, the methylxanthines—especially caffeine—cause mild cortical arousal with increased alertness and deferral of fatigue. The caffeine contained in beverages—eg, 100 mg in a cup of coffee—is sufficient to cause nervousness and insomnia in unusually sensitive individuals and slight bronchodilation in patients with asthma. At very high doses, medullary stimulation and convulsions may occur and can lead to death; theophylline has been used successfully in suicide attempts. Nervousness and tremor are primary side effects in patients taking large doses of aminophylline for asthma.

Cardiovascular Effects

The methylxanthines have direct positive chronotropic and inotropic effects on the heart. At low concentrations, these effects appear to result from increased catecholamine release that is caused by inhibition of presynaptic adenosine receptors. At higher concentrations ($> 10 \mu\text{mol/L}$), calcium influx may be increased directly through the increase in cAMP that results from inhibition of phosphodiesterase. At very high concentrations ($> 100 \mu\text{mol/L}$), sequestration of calcium by the sarcoplasmic reticulum is impaired. In unusually sensitive individuals, consumption of a few cups of coffee may result in arrhythmias, but in most people even parenteral administration of higher doses of the methylxanthines produces only sinus tachycardia and increased cardiac output. In large doses, these agents also relax vascular smooth muscle except in cerebral blood vessels, where they cause contraction. Ordinary consumption of coffee and other methylxanthine-containing beverages, however, usually raises the peripheral vascular resistance and blood pressure slightly, probably through the release of catecholamines.

Methylxanthines decrease blood viscosity and may improve blood flow under certain conditions. The mechanism of this action is not well defined, but the effect is exploited in the treatment of intermittent claudication with **pentoxifylline**, a dimethylxanthine agent. However, no evidence suggests that this therapy is superior to other approaches.

Effects on Gastrointestinal Tract

The methylxanthines stimulate secretion of both gastric acid and digestive enzymes. However, even decaffeinated coffee has a potent stimulant effect on secretion, which means that the primary secretagogue in coffee is not caffeine.

Effects on Kidney

The methylxanthines—especially theophylline—are weak diuretics. This effect may involve both increased glomerular filtration and reduced tubular sodium reabsorption. The diuresis is not of sufficient magnitude to be therapeutically useful.

Effects on Smooth Muscle

The bronchodilation produced by the methylxanthines is the major therapeutic action in asthma. Tolerance does not develop, but adverse effects, especially in the central nervous system, may limit the dose (see below). In addition to this direct effect on the airway smooth muscle, these agents—in sufficient concentration—inhibit antigen-induced release of histamine from lung tissue; their effect on mucociliary transport is unknown.

Effects on Skeletal Muscle

The therapeutic actions of the methylxanthines may not be confined to the airways, for they also

strengthen the contractions of isolated skeletal muscle *in vitro* and have potent effects in improving contractility and in reversing fatigue of the diaphragm in patients with chronic obstructive lung diseases. This effect on diaphragmatic performance—rather than an effect on the respiratory center—may account for theophylline's ability to improve the ventilatory response to hypoxia and to diminish dyspnea even in patients with irreversible airflow obstruction.

Clinical Use of Methylxanthines

Of the xanthines, theophylline is the most effective bronchodilator, and it has been shown repeatedly both to relieve airflow obstruction in acute asthma and to reduce the severity of symptoms and time lost from work or school in patients with chronic asthma. Theophylline base is only slightly soluble in water, so it has been administered as several salts containing varying amounts of theophylline base. Most preparations are well absorbed from the gastrointestinal tract, but absorption of rectal suppositories is unreliable.

Improvements in theophylline preparations have come from alterations in the physical state of the drugs rather than from new chemical formulations. For example, several companies now provide anhydrous theophylline in a microcrystalline form in which the increased surface area facilitates solubilization for complete and rapid absorption after oral administration. In addition, several sustained-release preparations (eg, Slo-Phyllin, Theo-Dur) are available and can produce therapeutic blood levels of theophylline for 12 hours or more. These preparations offer the advantages of less frequent drug administration, less fluctuation of theophylline blood levels, and, in many cases, more effective treatment of nocturnal bronchospasm.

Theophylline should only be used where methods to measure theophylline blood levels are available because it has a narrow therapeutic window and its therapeutic and toxic effects are related to its plasma concentrations. Improvement in pulmonary function is correlated with plasma concentration in the range of 5–20 mg/L. Anorexia, nausea, vomiting, abdominal discomfort, headache, and anxiety occur at concentrations of 15 mg/L in some patients and become common at concentrations greater than 20 mg/L. Higher levels (> 40 mg/L) may cause seizures or arrhythmias; these may not be preceded by gastrointestinal or neurologic warning symptoms.

The plasma clearance of theophylline varies widely. Theophylline is metabolized by the liver, so usual doses may lead to toxic concentrations of the drug in patients with liver disease. Conversely, clearance may be increased through the induction of hepatic enzymes by cigarette smoking or by changes in diet. In normal adults, the mean plasma clearance is 0.69 mL/kg/min. Children clear theophylline faster than adults (1–1.5 mL/kg/min). Neonates and young infants have the slowest clearance (see Chapter 60: Special Aspects of Perinatal & Pediatric Pharmacology). Even when maintenance doses are altered to correct for the above factors, plasma concentrations vary widely.

Theophylline improves long-term control of asthma when taken as the sole maintenance treatment or when added to inhaled corticosteroids. It is inexpensive, and it can be taken orally. Its use, however, also requires occasional measurement of plasma levels; it often causes unpleasant minor side effects (especially insomnia); and accidental or intentional overdose can result in severe toxicity or death. For oral therapy with the prompt-release formulation, the usual dose is 3–4 mg/kg of theophylline every 6 hours. Changes in dosage will result in a new steady state concentration of theophylline in 1–2 days, so the dose may be increased at intervals of 2–3 days until therapeutic plasma concentrations are achieved (10–20 mg/L) or until adverse effects develop.

Antimuscarinic Agents

Leaves from *Datura stramonium* have been used in treating asthma for hundreds of years. Interest in the potential value of antimuscarinic agents increased with demonstration of the importance of the vagus in bronchospastic responses of laboratory animals and by the development of a potent antimuscarinic agent that is poorly absorbed after aerosol administration to the airways and is therefore not associated with systemic atropine effects.

Mechanism of Action

Muscarinic antagonists competitively inhibit the effect of acetylcholine at muscarinic receptors (see Chapter 8: Cholinoceptor-Blocking Drugs). In the airways, acetylcholine is released from efferent endings of the vagus nerves, and muscarinic antagonists can effectively block the contraction of airway smooth muscle and the increase in secretion of mucus that occurs in response to vagal activity (Figure 20–2). Very high concentrations—well above those achieved even with maximal therapy—are required to inhibit the response of airway smooth muscle to nonmuscarinic stimulation. This selectivity of muscarinic antagonists accounts for their usefulness as investigative tools in examining the role of parasympathetic pathways in bronchomotor responses but limits their usefulness in preventing bronchospasm. In the doses given, antimuscarinic agents inhibit only that portion of the response mediated by muscarinic receptors, and the involvement of parasympathetic pathways in bronchospastic responses appears to vary among individuals.

Clinical Use of Muscarinic Antagonists

Antimuscarinic agents are effective bronchodilators. When given intravenously, atropine, the prototypical muscarinic antagonist, causes bronchodilation at a lower dose than that needed to cause an increase in heart rate. The selectivity of atropine's effect can be increased further by administering the drug by inhalation or by use of a more selective quaternary ammonium derivative of atropine, **ipratropium bromide**. Ipratropium can be delivered in high doses to muscarinic receptors in the airways because this compound is poorly absorbed and does not readily enter the central nervous system. Studies with this agent have shown that the degree of involvement of parasympathetic pathways in bronchomotor responses varies among subjects. In some, bronchoconstriction is inhibited effectively; in others, only modestly. The failure of higher doses of the muscarinic antagonist to further inhibit the response in these individuals indicates that mechanisms other than parasympathetic reflex pathways must be involved.

Even in the subjects least protected by this antimuscarinic agent, however, the bronchodilation and partial inhibition of provoked bronchoconstriction are of potential clinical value, and antimuscarinic agents are valuable for patients intolerant of inhaled β -agonist agents. While antimuscarinic drugs appear to be slightly less effective than β -agonist agents in reversing asthmatic bronchospasm, the addition of ipratropium enhances the bronchodilation produced by nebulized albuterol in acute severe asthma.

Ipratropium appears to be at least as effective in patients with chronic obstructive pulmonary disease that includes a partially reversible component. A longer-acting, selective antimuscarinic agent, **tiotropium**, is in clinical trials as treatment for COPD. This drug's 24-hour duration of action is a potentially important advantage.

Corticosteroids

Mechanism of Action

Corticosteroids have been used to treat asthma since 1950 and are presumed to act by their broad

anti-inflammatory efficacy, mediated in part by inhibition of production of inflammatory cytokines (see Chapter 39: Adrenocorticosteroids & Adrenocortical Antagonists). They do not relax airway smooth muscle directly but reduce bronchial reactivity and reduce the frequency of asthma exacerbations if taken regularly. Their effect on airway obstruction may be due in part to their potentiation of the effects of β -receptor agonists, but their most important action is their inhibition of the lymphocytic, eosinophilic airway mucosal inflammation of asthmatic airways.

Clinical Use of Corticosteroids

Clinical studies of corticosteroids consistently show them to be effective in improving all indices of asthma control—severity of symptoms, tests of airway caliber and bronchial reactivity, frequency of exacerbations, and quality of life. Because of severe adverse effects when given chronically, oral and parenteral corticosteroids are reserved for patients who require urgent treatment, ie, those who have not improved adequately with bronchodilators or who experience worsening symptoms despite maintenance therapy. Regular or "controller" therapy is maintained with aerosol corticosteroids.

Urgent treatment is often begun with an oral dose of 30–60 mg of prednisone per day or an intravenous dose of 1 mg/kg of methylprednisolone every 6 hours; the daily dose is decreased gradually after airway obstruction has improved. In most patients, systemic corticosteroid therapy can be discontinued in a week or 10 days, but in other patients symptoms may worsen as the dose is decreased to lower levels. Because adrenal suppression by corticosteroids is related to dose and because secretion of corticosteroids has a diurnal variation, it has become customary to administer corticosteroids early in the morning, after endogenous ACTH secretion has peaked. For prevention of nocturnal asthma, however, oral or inhaled corticosteroids are most effective when given in the late afternoon.

Aerosol treatment is the most effective way to decrease the systemic adverse effects of corticosteroid therapy. The introduction of lipid-soluble corticosteroids such as **beclomethasone**, **budesonide**, **flunisolide**, **fluticasone**, and **triamcinolone** makes it possible to deliver corticosteroids to the airways with minimal systemic absorption. An average daily dose of four puffs twice daily of beclomethasone (400 μ g/d) is equivalent to about 10–15 mg/d of oral prednisone for the control of asthma, with far fewer systemic effects. Indeed, one of the cautions in switching patients from oral to inhaled corticosteroid therapy is to taper oral therapy slowly to avoid precipitation of adrenal insufficiency. In patients requiring continued prednisone treatment despite inhalation of standard doses of an aerosol corticosteroid, higher doses appear to be more effective; inhaled dosages up to 2000 μ g/d of fluticasone are effective in weaning patients from chronic prednisone therapy. While these high doses of inhaled steroids may cause adrenal suppression, the risks of systemic toxicity from chronic use appear negligible compared with those of the oral corticosteroid therapy they replace. A special problem caused by inhaled topical corticosteroids is the occurrence of oropharyngeal candidiasis. The risk of this complication can be reduced by having patients gargle water and spit after each inhaled treatment. Hoarseness can also result from a direct local effect of inhaled corticosteroids on the vocal cords. These agents are remarkably free of other short-term complications in adults but may increase the risks of osteoporosis and cataracts over the long term. In children, inhaled corticosterone therapy has been shown to slow the rate of growth, but asthma itself delays puberty, and there is no evidence that inhaled corticosteroid therapy influences adult height.

Chronic use of inhaled corticosteroids effectively reduces symptoms and improves pulmonary function in patients with mild asthma. Such use also reduces or eliminates the need for oral corticosteroids in patients with more severe disease. In contrast to β -stimulant agents and theophylline, chronic use of inhaled corticosteroids reduces bronchial reactivity. Because of the

efficacy and safety of inhaled corticosteroids, they are now routinely prescribed for patients who require more than occasional inhalations of a β agonist for relief of symptoms. This therapy is continued for 10–12 weeks and then withdrawn to determine if more prolonged therapy is needed.

Inhaled corticosteroids are not curative. In most patients, the manifestations of asthma return within a few weeks after stopping therapy even if they have been taken in high doses for 2 years or longer.

Cromolyn & Nedocromil

Cromolyn sodium (disodium cromoglycate) and nedocromil sodium are stable but extremely insoluble salts (see structures below). When used as aerosols (metered-dose inhalers), they effectively inhibit both antigen- and exercise-induced asthma, and chronic use (four times daily) slightly reduces the overall level of bronchial reactivity. However, these drugs have no effect on airway smooth muscle tone and are ineffective in reversing asthmatic bronchospasm; they are only of value when taken prophylactically.

Cromolyn sodium

Nedocromil sodium

Cromolyn is poorly absorbed from the gastrointestinal tract and must be inhaled as a microfine powder or aerosolized solution. Nedocromil also has a very low bioavailability and is available only in metered-dose aerosol form.

Mechanism of Action

Cromolyn and nedocromil differ structurally but are thought to share a common mechanism of action, an alteration in the function of delayed chloride channels in the cell membrane, inhibiting cellular activation. This action on airway nerves is thought to be responsible for nedocromil's inhibition of cough; on mast cells, for inhibition of the early response to antigen challenge; and on eosinophils, for inhibition of the inflammatory response to inhalation of allergens. The inhibitory effect on mast cells appears to be specific for cell type, since cromolyn has little inhibitory effect on mediator release from human basophils. It may also be specific for different organs, since cromolyn inhibits mast cell degranulation in human and primate lung but not in skin. This in turn may reflect known differences in mast cells found in different sites, as in their neutral protease content.

Until recently, the idea that cromolyn inhibits mast cell degranulation was so well accepted that the inhibition of a response by cromolyn was thought to indicate the involvement of mast cells in the response. This simplistic idea has been overturned in part by the finding that cromolyn and nedocromil inhibit the function of cells other than mast cells and in part by the finding that nedocromil inhibits appearance of the late response even when given after the early response to antigen challenge, ie, after mast cell degranulation has occurred.

Clinical Use of Cromolyn & Nedocromil

In short-term clinical trials, pretreatment with cromolyn or nedocromil blocks the bronchoconstriction caused by antigen inhalation, by exercise, by aspirin, and by a variety of causes of occupational asthma. This acute protective effect of a single treatment makes cromolyn useful for administration shortly before exercise or before unavoidable exposure to an allergen.

When taken regularly (two to four puffs two to four times daily) by patients with perennial asthma, both agents reduce symptomatic severity and the need for bronchodilator medications. These drugs are neither as potent nor as predictably effective as inhaled corticosteroids. In general, young patients with extrinsic asthma are most likely to respond favorably. At present, the only way of determining whether a patient will respond is by a therapeutic trial for 4 weeks. The addition of nedocromil to a standard dose of an inhaled corticosteroid appears to improve asthma control.

Cromolyn solution is also useful in reducing symptoms of **allergic rhinoconjunctivitis**. Applying the solution by nasal spray or eye drops several times a day is effective in about 75% of patients, even during the peak pollen season.

Because the drugs are so poorly absorbed, adverse effects of cromolyn and nedocromil are minor and are localized to the sites of deposition. These include such symptoms as throat irritation, cough, mouth dryness, chest tightness, and wheezing. Some of these symptoms can be prevented by inhaling a β_2 -adrenoceptor agonist before cromolyn or nedocromil treatment. Serious adverse effects are rare. Reversible dermatitis, myositis, or gastroenteritis occurs in fewer than 2% of patients, and a very few cases of pulmonary infiltration with eosinophilia and anaphylaxis have been reported. This lack of toxicity accounts for cromolyn's widespread use in children, especially those at ages of rapid growth. For children who have difficulty coordinating the use of the inhaler device, cromolyn may be given by aerosol of a 1% solution.

Leukotriene Pathway Inhibitors

Because of the evidence of leukotriene involvement in many inflammatory diseases (see Chapter 18: The Eicosanoids: Prostaglandins, Thromboxanes, Leukotrienes, & Related Compounds) and in anaphylaxis, considerable effort has been expended on the development of drugs that block the synthesis of these arachidonic acid derivatives or their receptors. Leukotrienes result from the action of 5-lipoxygenase on arachidonic acid and are synthesized by a variety of inflammatory cells in the airways, including eosinophils, mast cells, macrophages, and basophils. Leukotriene B₄ is a potent neutrophil chemoattractant, and LTC₄ and LTD₄ exert many effects known to occur in asthma, including bronchoconstriction, increased bronchial reactivity, mucosal edema, and mucus hypersecretion. Early studies established that antigen challenge of sensitized human lung tissue results in the generation of leukotrienes, while other studies of human subjects have shown that inhalation of leukotrienes causes not only bronchoconstriction but also an increase in bronchial reactivity to histamine that persists for several days.

Two approaches to interrupting the leukotriene pathway have been pursued: inhibition of 5-

lipoxygenase, thereby preventing leukotriene synthesis; and inhibition of the binding of leukotriene D₄ to its receptor on target tissues, thereby preventing its action. Efficacy in blocking airway responses to exercise and to antigen challenge has been shown for drugs in both categories: **zileuton**, a 5-lipoxygenase inhibitor, and **zafirlukast** and **montelukast**, LTD₄-receptor antagonists. All have been shown to be effective when taken regularly in outpatient clinical trials. Their effects on symptoms, airway caliber, bronchial reactivity, and airway inflammation are less marked than the effects of inhaled corticosteroids, but they are almost equally effective in reducing the frequency of exacerbations. Their principal advantage is that they are taken orally; some patients—especially children—comply poorly with inhaled therapies. Montelukast is approved for children as young as 6 years of age.

Zafirlukast

Montelukast

Zileuton

Some patients appear to have particularly favorable responses, but no clinical features allow identification of "responders" before a trial of therapy. In the USA, zileuton is approved for use in an oral dosage of 600 mg given four times daily; zafirlukast, 20 mg twice daily; and montelukast, 10 mg once daily.

Trials with leukotriene inhibitors have demonstrated an important role for leukotrienes in aspirin-induced asthma. It has long been known that 5–10% of asthmatics are exquisitely sensitive to aspirin, so that ingestion of even a very small dose causes profound bronchoconstriction and symptoms of systemic release of histamine, such as flushing and abdominal cramping. Because this reaction to aspirin is not associated with any evidence of allergic sensitization to aspirin or its metabolites, and because it is produced by any of the nonsteroidal anti-inflammatory agents, it is thought to result from inhibition of prostaglandin synthetase, shifting arachidonic acid metabolism from the prostaglandin to the leukotriene pathway. Support for this idea was provided by the

demonstration that leukotriene pathway inhibitors impressively reduce the response to aspirin challenge and improve overall control of asthma on a day-to-day basis.

Of these agents, zileuton is the least prescribed because of the requirement of four times daily dosing and because of occasional liver toxicity. The receptor antagonists appear to be safe to use. Reports of Churg-Strauss syndrome (a systemic vasculitis characterized by worsening asthma, pulmonary infiltrates, and eosinophilia) appear to have been coincidental, with the syndrome unmasked by the reduction in prednisone dosage made possible by the addition of zafirlukast or montelukast.

Other Drugs in the Treatment of Asthma

Anti-IgE Monoclonal Antibodies

An entirely new approach to the treatment of asthma exploits advances in molecular biology to target IgE antibody. From a collection of monoclonal antibodies raised in mice against IgE antibody itself, a monoclonal antibody was selected that appeared to be targeted against the portion of IgE that binds to its receptors (FCε-R1 and -R2 receptors) on mast cells and other inflammatory cells. **Omalizumab** (anti-IgE Mab) inhibits the binding of IgE to mast cells but does not activate IgE already bound to these cells and thus does not provoke mast cell degranulation. In mice, it also appears to inhibit IgE synthesis by B lymphocytes. The murine antibody has been genetically "humanized" by replacing all but a small fraction of its amino acids with those found in human proteins, and it does not appear to cause sensitization when given to human subjects.

Studies of omalizumab in asthmatic volunteers showed that its administration over 10 weeks lowered plasma IgE to undetectable levels and significantly reduced the magnitude of both the early and the late bronchospastic responses to antigen challenge. Clinical trials have shown repeated intravenous or subcutaneous injection of anti-IgE MAb to lessen asthma severity and reduce the corticosteroid requirement in patients with moderate to severe disease, especially those with a clear environmental antigen precipitating factor, and to improve nasal and conjunctival symptoms in patients with perennial or seasonal allergic rhinitis.

Calcium Channel Blockers

Each of the cell functions that may become abnormal in patients with asthma depends to some degree on the movement of calcium into cells. The calcium channel blockers have no effect on baseline airway diameter but do significantly inhibit the airway narrowing that is induced by various stimuli. In patients, both **nifedipine** and **verapamil** given by inhalation significantly inhibited the bronchoconstriction induced by a variety of stimuli. However, both drugs were much less effective than inhaled albuterol.

Nitric Oxide Donors

Preliminary studies in animals suggest that airway smooth muscle, like that in the vasculature, is effectively relaxed by nitric oxide. This very lipophilic drug can be inhaled as a gas in acute asthma and dilates the pulmonary blood vessels as well as the airway smooth muscle. Although nitric oxide itself—or nitric oxide donors—may prove of value in acute severe asthma, it appears likely that they will be more useful in pulmonary hypertension (for which nitric oxide is already approved).

Possible Future Therapies

The rapid advance in the scientific description of the immunopathogenesis of asthma has spurred the development of many new therapies targeting different sites in the immune cascade. These include monoclonal antibodies directed against cytokines (IL-4, IL-5, IL-8), antagonists of cell adhesion molecules, protease inhibitors, and immunomodulators aimed at shifting CD4 lymphocytes from the TH2 to the TH1 phenotype. There is evidence that asthma may be aggravated—or even caused—by chronic airway infection with *Chlamydia pneumoniae* or *Mycoplasma pneumoniae*. This may explain the reports of benefit from treatment with macrolide antibiotics and, if confirmed, would stimulate the development of new diagnostic methods and antimicrobial therapies.

Katzung PHARMACOLOGY, 9e > Section IV. Drugs with Important Actions on Smooth Muscle > Chapter 20. Drugs Used in Asthma >

Clinical Pharmacology of Drugs Used in the Treatment of Asthma

Bronchodilators

Patients with mild asthma and only occasional symptoms require no more than an inhaled β_2 -receptor agonist (eg, albuterol) on an "as-needed" basis. If symptoms require frequent inhalations (more often than twice a week), or if nocturnal symptoms occur, additional treatment is needed, preferably with an inhaled anti-inflammatory agent such as a corticosteroid or cromolyn, or with oral therapy with a leukotriene receptor antagonist. Theophylline is now largely reserved for patients in whom symptoms remain poorly controlled despite the combination of regular treatment with an inhaled anti-inflammatory agent and as-needed use of a β_2 agonist. If the addition of theophylline fails to improve symptoms or if adverse effects become bothersome, it is important to check the plasma level of theophylline to be sure it is in the therapeutic range (10–20 mg/L).

Corticosteroids

If asthmatic symptoms occur frequently or if significant airflow obstruction persists despite bronchodilator therapy, inhaled corticosteroids should be started. For patients with severe symptoms or severe airflow obstruction (eg, FEV₁ < 1.5 L), initial treatment with oral corticosteroid (eg, 30 mg/d of prednisone for 3 weeks) is appropriate. Once clinical improvement is noted, inhaled corticosteroid treatment should be started and the oral dose reduced to the minimum necessary to control symptoms. For patients with milder symptoms but still inadequately controlled by as-needed use of an inhaled bronchodilator, corticosteroids may be initiated by the inhaled route.

In patients whose symptoms are inadequately controlled by a standard dose of an inhaled corticosteroid, the addition of a long-acting inhaled β_2 -receptor agonist (salmeterol, formoterol) is more effective than is doubling the dose of the inhaled corticosteroid. The improvement in clinical symptoms and peak flow is usually prompt and sustained. In patients on such a combined treatment regimen, it is important to provide explicit instructions that a standard, short-acting inhaled β_2 agonist, like albuterol, be used for relief of acute symptoms. It is also important that the patient not stop the inhaled corticosteroid, continuing only the long-acting β_2 agonist, because exacerbations are not prevented by this monotherapy. For this reason—and because long-acting β_2 agonists appear to enhance the local but not the systemic actions of inhaled corticosteroids—inhalers containing both agents have been developed (see Preparations Available).

Cromolyn & Nedocromil

Cromolyn or nedocromil may be considered as an alternative to inhaled corticosteroids in patients with symptoms occurring more than twice a week or who are wakened from sleep by asthma. They may also be useful in patients whose symptoms occur seasonally or after clear-cut inciting stimuli such as exercise or exposure to animal danders or irritants. In patients whose symptoms are continuous or occur without an obvious inciting stimulus, the value of these drugs can only be established with a therapeutic trial of inhaled drug four times a day for 4 weeks. If the patient responds to this therapy, the dose can be reduced. Maintenance therapy with cromolyn appears to be as effective as maintenance therapy with theophylline and, because of concerns over the possible long-term toxicity of systemic absorption of inhaled corticosteroids, has become widely used for treating children in the USA.

Muscarinic Antagonists

Inhaled muscarinic antagonists have so far earned a limited place in the treatment of asthma. When adequate doses are given, their effect on baseline airway resistance is nearly as great as that of the sympathomimetic drugs. The airway effects of antimuscarinic and sympathomimetic drugs given in full doses have been shown to have significant additive effects only in patients with severe airflow obstruction who present for emergency care. Antimuscarinic agents appear to be of significant value in chronic obstructive pulmonary disease—perhaps more so than in asthma. They are useful as alternative therapies for patients intolerant of β -adrenoceptor agonists.

When muscarinic antagonists are used for long-term treatment, they appear to be effective bronchodilators. Although it was predicted that muscarinic antagonists might dry airway secretions, direct measurements of fluid volume secretion from single airway submucosal glands in animals show that atropine decreases secretory rates only slightly; however, the drug does prevent excessive secretion caused by vagal reflex stimulation. No cases of inspissation of mucus have been reported following administration of these drugs.

Other Anti-Inflammatory Therapies

Some recent reports suggest that agents commonly used to treat rheumatoid arthritis might also be used to treat patients with chronic steroid-dependent asthma. The development of an alternative treatment is important, since chronic treatment with oral corticosteroids may cause osteoporosis, cataracts, glucose intolerance, worsening of hypertension, and cushingoid changes in appearance. Initial studies suggested that oral methotrexate or gold salt injections were beneficial in prednisone-dependent asthmatics, but subsequent studies did not confirm this promise. The benefit from treatment with cyclosporine seems real. However, this drug's great toxicity makes this finding only a source of hope that other immunomodulatory therapies will ultimately be developed for the small proportion of patients whose asthma can be managed only with high oral doses of prednisone.

Management of Acute Asthma

The treatment of acute attacks of asthma in patients reporting to the hospital requires more continuous assessment and repeated objective measurement of lung function. For patients with mild attacks, inhalation of a β -receptor agonist is as effective as subcutaneous injection of epinephrine. Both of these treatments are more effective than intravenous administration of aminophylline. Severe attacks require treatment with oxygen, frequent or continuous administration of aerosolized albuterol, and systemic treatment with prednisone or methylprednisolone (0.5 mg/kg every 6 hours). Even this aggressive treatment is not invariably effective, and patients must be watched closely for

signs of deterioration. Intubation and mechanical ventilation of asthmatic patients cannot be undertaken lightly but may be lifesaving if respiratory failure supervenes.

Katzung PHARMACOLOGY, 9e > Section IV. Drugs with Important Actions on Smooth Muscle > Chapter 20. Drugs Used in Asthma >

Preparations Available

Sympathomimetics Used in Asthma

Albuterol (generic, Proventil, Ventolin, others)

Inhalant: 90 μg /puff aerosol; 0.083, 0.5% solution for nebulization

Oral: 2, 4 mg tablets; 2 mg/5 mL syrup

Oral sustained-release: 4, 8 mg tablets

Albuterol/Ipratropium (Combivent, DuoNeb)

Inhalant: 103 μg albuterol + 18 μg ipratropium/ puff; 3 mg albuterol + 0.5 mg ipratropium/3 mL solution for nebulization

Bitolterol (Tornalate)

Inhalant: 0.2% solution for nebulization

Ephedrine (generic)

Oral: 25 mg capsules

Parenteral: 50 mg/mL for injection

Epinephrine (generic, Adrenalin, others)

Inhalant: 1, 10 mg/mL for nebulization; 0.22 mg epinephrine base aerosol

Parenteral: 1:10,000 (0.1 mg/mL), 1:1000 (1 mg/mL)

Formoterol (Foradil)

Inhalant: 12 μg /puff aerosol; 12 μg /unit inhalant powder

Isoetharine (generic)

Inhalant: 1% solution for nebulization

Isoproterenol (generic, Isuprel, others)

Inhalant: 0.5, 1% for nebulization; 80, 131 μg /puff aerosols

Parenteral: 0.02, 0.2 mg/mL for injection

Levalbuterol (Xenopex)

Inhalant: 0.31, 0.63, 1.25 mg/3 mL solution

Metaproterenol (Alupent, generic)

Inhalant: 0.65 mg/puff aerosol in 7, 14 g containers; 0.4, 0.6, 5% for nebulization

Pirbuterol (Maxair)

Inhalant: 0.2 mg/puff aerosol in 80 and 300 dose containers

Salmeterol (Serevent)

Inhalant aerosol: 25 µg salmeterol base/puff in 60 and 120 dose containers

Inhalant powder: 50 µg/unit

Salmeterol/Fluticasone (Advair Diskus)

Inhalant: 100, 250, 500 µg fluticasone + 50 µg salmeterol/unit

Terbutaline (Brethine, Bricanyl)

Inhalant: 0.2 mg/puff aerosol

Oral: 2.5, 5 mg tablets

Parenteral: 1 mg/mL for injection

Aerosol Corticosteroids (See Also Chapter 39: Adrenocorticosteroids & Adrenocortical Antagonists.)

Beclomethasone (QVAR, Vanceril)

Aerosol: 40, 80 µg/puff in 200 dose containers

Budesonide (Pulmicort)

Aerosol powder: 160 µg/activation

Flunisolide (AeroBid)

Aerosol: 250 µg/puff in 100 dose container

Fluticasone (Flovent)

Aerosol: 44, 110, and 220 µg/puff in 120 dose container; powder, 50, 100, 250 µg/activation

Fluticasone/Salmeterol (Advair Diskus)

Inhalant: 100, 250, 500 µg fluticasone + 50 µg salmeterol/unit

Triamcinolone (Azmacort)

Aerosol: 100 µg/puff in 240 dose container

Leukotriene Inhibitors

Montelukast (Singulair)

Oral: 10 mg tablets; 4, 5 mg chewable tablets; 4 mg/packet granules

Zafirlukast (Accolate)

Oral: 10, 20 mg tablets

Zileuton (Zyflo)

Oral: 600 mg tablets

Cromolyn Sodium & Nedocromil Sodium

Cromolyn sodium

Pulmonary aerosol (generic, Intal): 800 µg/puff in 200 dose container; 20 mg/2 mL for nebulization (for asthma)

Nasal aerosol (Nasal crom):* 5.2 mg/puff (for hay fever)

Oral (Gastrocrom): 100 mg/5 mL concentrate (for gastrointestinal allergy)

Nedocromil sodium (Tilade)

Pulmonary aerosol: 1.75 mg/puff in 112 metered-dose container

*OTC preparation.

Methylxanthines: Theophylline & Derivatives

Aminophylline (theophylline ethylenediamine, 79% theophylline) (generic, others)

Oral: 105 mg/5 mL liquid; 100, 200 mg tablets

Oral sustained-release: 225 mg tablets

Rectal: 250, 500 mg suppositories

Parenteral: 250 mg/10 mL for injection

Theophylline (generic, Elixophyllin, Slo-Phyllin, Uniphyl, Theo-Dur, Theo-24, others)

Oral: 100, 125, 200, 250, 300 mg tablets; 100, 200 mg capsules; 26.7, 50 mg/5 mL elixirs, syrups, and solutions

Oral sustained-release, 8–12 hours: 50, 60, 75, 100, 125, 130, 200, 250, 260, 300 mg capsules

Oral sustained-release, 8–24 hours: 100, 200, 300, 450 mg tablets

Oral sustained-release, 12 hours: 100, 125, 130, 200, 250, 260, 300 mg capsules

Oral sustained-release, 12–24 hours: 100, 200, 300 tablets

Oral sustained-release, 24 hours: 100, 200, 300 mg tablets and capsules; 400, 600 mg tablets

Parenteral: 200, 400, 800 mg/container, theophylline and 5% dextrose for injection

Other Methylxanthines

Dyphylline (generic, other)

Oral: 200, 400 mg tablets; 33.3, 53.3 mg/5 mL elixir

Parenteral: 250 mg/mL for injection

Oxtriphylline (generic, Choledyl)

Oral: equivalent to 64, 127, 254, 382 mg theophylline tablets; 32, 64 mg/5 mL syrup

Pentoxifylline (generic, Trental)

Oral: 400 mg tablets and controlled-release tablets

Note: Pentoxifylline is labeled for use in intermittent claudication only.

Antimuscarinic Drugs Used in Asthma

Ipratropium (generic, Atrovent)

Aerosol: 18 μg /puff in 200 metered-dose inhaler; 0.02% (500 μg /vial) for nebulization

Nasal spray: 21, 42 μg /spray

Antibody

Omalizumab (Xolair)

Powder for SC injection, 202.5 mg

Section V. Drugs That Act in the Central Nervous System

Chapter 21. Introduction to the Pharmacology of CNS Drugs

Introduction to the Pharmacology of CNS Drugs

Drugs acting in the central nervous system (CNS) were among the first to be discovered by primitive humans and are still the most widely used group of pharmacologic agents. In addition to their use in therapy, many drugs acting on the CNS are used without prescription to increase one's sense of well-being.

The mechanisms by which various drugs act in the CNS have not always been clearly understood. Since the causes of many of the conditions for which these drugs are used (schizophrenia, anxiety, etc) are themselves poorly understood, it is not surprising that in the past much of CNS pharmacology has been purely descriptive. In the last 3 decades, however, dramatic advances have been made in the methodology of CNS pharmacology. It is now possible to study the action of a drug on individual cells and even single ion channels within synapses. The information obtained from such studies is the basis for several major developments in studies of the CNS.

First, it is clear that nearly all drugs with CNS effects act on specific receptors that modulate synaptic transmission. A very few agents such as general anesthetics and alcohol may have nonspecific actions on membranes (although these exceptions are not fully accepted), but even these non-receptor-mediated actions result in demonstrable alterations in synaptic transmission.

Second, drugs are among the most important tools for studying all aspects of CNS physiology, from the mechanism of convulsions to the laying down of long-term memory. As will be described below, agonists that mimic natural transmitters (and in many cases are more selective than the endogenous substances) and antagonists are extremely useful in such studies. The section on Natural Toxins: Tools for Characterizing Ion Channels describes the uses of some of these substances.

Third, unraveling the actions of drugs with known clinical efficacy has led to some of the most fruitful hypotheses regarding the mechanisms of disease. For example, information on the action of antipsychotic drugs on dopamine receptors has provided the basis for important hypotheses regarding the pathophysiology of schizophrenia. Studies of the effects of a variety of agonists and antagonists on γ -aminobutyric acid (GABA) receptors are resulting in new concepts pertaining to the pathophysiology of several diseases, including anxiety and epilepsy.

This chapter provides an introduction to the functional organization of the CNS and its synaptic transmitters as a basis for understanding the actions of the drugs described in the following

chapters.

Methods for the Study of CNS Pharmacology

Although scientists (and the public) have always been interested in the action of drugs in the CNS, a detailed description of synaptic transmission was not possible until glass microelectrodes, which permit intracellular recording, were developed. Detailed electrophysiologic studies of the action of drugs on both voltage- and transmitter-operated channels were further facilitated by the introduction of the patch clamp technique, which permits the recording of current through single channels. Histochemical, immunologic, and radioisotopic methods are widely used to map the distribution of specific transmitters, their associated enzyme systems, and their receptors. Molecular cloning has had a major impact on our understanding of CNS receptors. These techniques make it possible to determine the precise molecular structure of the receptors and their associated channels. Finally, mice with mutated genes for specific receptors or enzymes (knockout mice) can provide important information regarding the physiologic and pharmacologic roles of these components.

Katzung PHARMACOLOGY, 9e > Section V. Drugs That Act in the Central Nervous System > Chapter 21. Introduction to the Pharmacology of CNS Drugs >

Natural Toxins: Tools for Characterizing Ion Channels

Evolution is a tireless chemist when it comes to inventing toxins. A vast number of variations are possible with even a small number of amino acids in peptides, and peptides are only one of a broad array of toxic compounds. For example, the predatory marine snail genus *Conus* is estimated to include at least 500 different species. Each species kills or paralyzes its prey with a venom that contains 50–200 different peptides or proteins. Furthermore, there is little duplication of peptides among *Conus* species. Other animals with useful toxins include snakes, frogs, spiders, bees, wasps, and scorpions. Plant species with toxic (or therapeutic) substances are too numerous to mention here; they are referred to in many chapters of this book.

Since many toxins act on ion channels, they provide a wealth of chemical tools for studying the function of these channels. In fact, much of our current understanding of the properties of ion channels comes from studies utilizing only a small fraction of the highly potent and selective toxins that are now available. The toxins typically target voltage-sensitive ion channels, but a number of very useful toxins block ionotropic neurotransmitter receptors. Table 21–1 lists some of the toxins most commonly used in research, their mode of action, and their source.

Katzung PHARMACOLOGY, 9e > Section V. Drugs That Act in the Central Nervous System > Chapter 21. Introduction to the Pharmacology of CNS Drugs >

Ion Channels & Neurotransmitter Receptors

The membranes of nerve cells contain two types of channels defined on the basis of the mechanisms controlling their gating (opening and closing): **voltage-gated** and **ligand-gated** channels (Figures 21–1 A and B). Voltage-gated channels respond to changes in the membrane potential of the cell. The voltage-gated sodium channel described in Chapter 14: Agents Used in Cardiac Arrhythmias for the heart is an example of the first type and is very important in the CNS. In nerve cells, these channels are concentrated on the initial segment and the axon and are responsible for the fast action potential, which transmits the signal from cell body to nerve terminal. There are many types of voltage-sensitive calcium and potassium channels on the cell body, dendrites, and initial segment,

which act on a much slower time scale and modulate the rate at which the neuron discharges. For example, some types of potassium channels opened by depolarization of the cell result in slowing of further depolarization and act as a brake to limit further action potential discharge.

Figure 21-1.

Types of ion channels and neurotransmitter receptors in the CNS. **A** shows a voltage-gated channel in which a voltage sensor controls the gating (broken arrow) of the channel. **B** shows a ligand-gated channel in which the binding of the neurotransmitter to the channel controls the gating (broken arrow) of the channel. **C** shows a G protein coupled receptor, which when bound, activates a G protein which then interacts directly with an ion channel. **D** shows a G protein coupled receptor, which when bound, activates a G protein which then activates an enzyme. The activated enzyme generates a diffusible second messenger that interacts with an ion channel.

Ligand-gated channels, also called **ionotropic receptors**, are opened by the binding of neurotransmitters to the channel. The receptor is formed of subunits, and the channel is an integral part of the receptor complex. These channels are insensitive or only weakly sensitive to membrane potential. Activation of these channels typically results in a brief (a few milliseconds to tens of milliseconds) opening of the channel. Ligand-gated channels are responsible for fast synaptic transmission typical of hierarchical pathways in the CNS (see below).

It is now well established that the traditional view of completely separate voltage-gated and ligand-gated channels requires substantial modifications. As discussed in Chapter 2: Drug Receptors & Pharmacodynamics, most neurotransmitters, in addition to binding to ionotropic receptors, also bind to G protein-coupled receptors, often referred to as **metabotropic** receptors. Metabotropic receptors, via G proteins, modulate voltage-gated channels. This interaction can occur entirely within the membrane and is referred to as a **membrane delimited** pathway (Figure 21–1 C). In this case the G protein interacts directly with the voltage-gated ion channel. In general, two types of voltage-gated ion channel are involved in this type of signaling: calcium channels and potassium channels. When G proteins interact with calcium channels, they inhibit channel function. This mechanism accounts for the presynaptic inhibition that occurs when presynaptic metabotropic receptors are activated. In contrast, when these receptors are postsynaptic, they activate (cause the opening of) potassium channels, resulting in a slow postsynaptic inhibition. Metabotropic receptors can also modulate voltage-gated channels less directly by the generation of **diffusible second messengers** (Figure 21–1 D). A classic example of this type of action is provided by the β adrenoceptor, which generates cAMP via the activation of adenylyl cyclase (see Chapter 2: Drug Receptors & Pharmacodynamics). Whereas membrane-delimited actions occur within microdomains in the membrane, second messenger-mediated effects can occur over considerable distances. Finally, an important consequence of the involvement of G proteins in receptor signaling is that, in contrast to the brief effect of ionotropic receptors, the effects of metabotropic receptor activation can last tens of seconds to minutes. Metabotropic receptors predominate in the diffuse neuronal systems in the CNS (see below).

Katzung PHARMACOLOGY, 9e > Section V. Drugs That Act in the Central Nervous System > Chapter 21. Introduction to the Pharmacology of CNS Drugs >

The Synapse & Synaptic Potentials

The communication between neurons in the CNS occurs through chemical synapses in the vast majority of cases. (A few instances of electrical coupling between neurons have been documented, and such coupling may play a role in synchronizing neuronal discharge. However, it is unlikely that these electrical synapses are an important site of drug action.) The events involved in the release of transmitter from the presynaptic terminal have been studied most extensively at the vertebrate neuromuscular junction and at the giant synapse of the squid. More recently, the calyx of Held synapse, a specialized synapse in the brain stem with a large presynaptic terminal, has served as a model for the study of transmitter release from CNS synapses.

An action potential in the presynaptic fiber propagates into the synaptic terminal and activates voltage-sensitive calcium channels in the membrane of the terminal (Figure 6–3). The calcium channels responsible for the release of transmitter are generally resistant to the calcium channel-blocking agents discussed in Chapter 12: Vasodilators & the Treatment of Angina Pectoris (verapamil, etc) but are sensitive to blockade by certain marine toxins and metal ions (Tables 12–4 and 21–1). Calcium flows into the terminal, and the increase in intraterminal calcium concentration promotes the fusion of synaptic vesicles with the presynaptic membrane. The transmitter contained in the vesicles is released into the synaptic cleft and diffuses to the receptors on the postsynaptic

membrane. Binding of the transmitter to its receptor causes a brief change in membrane conductance (permeability to ions) of the postsynaptic cell. The time delay from the arrival of the presynaptic action potential to the onset of the postsynaptic response is approximately 0.5 ms. Most of this delay is consumed by the release process, particularly the time required for calcium channels to open.

Table 21–1. Some Toxins Used to Characterize Ion Channels.

Channel Types	Mode of Toxin Action	Source
Voltage-gated		
Sodium channels		
Tetrodotoxin (TTX)	Blocks from outside	Puffer fish
α -Scorpion toxin	Slows inactivation	Scorpion
Batrachotoxin (BTX)	Slows inactivation, shifts activation	Colombian frog
Potassium channels		
Apamin	Blocks "small Ca^{2+} -activated" K^+ channel	Honeybee
Charybdotoxin	Blocks "big Ca^{2+} -activated" K^+ channel	Scorpion
Dendrotoxin	Blocks delayed rectifier	Snake
Calcium channels		
Omega conotoxin (ω -CTX-GVIA)	Blocks N-type channel	Pacific cone snail
Agatoxin (ω -AGA-IVA)	Blocks P-type channel	Funnel web spider
Ligand-gated		
Nicotinic ACh receptor		
α -Bungarotoxin	Irreversible antagonist	Marine snake
<i>d</i> -Tubocurarine	Competitive antagonist	Amazon plant
GABA _A receptor		
Picrotoxin	Blocks channel	South Pacific plant
Bicuculline	Competitive antagonist	Plant
Glycine receptor		
Strychnine	Competitive antagonist	Indian plant
AMPA receptor		
Philanthotoxin	Blocks channel	Wasp

associates, who recorded intracellularly from spinal motoneurons. When a microelectrode enters a cell, there is a sudden change in the potential recorded by the electrode, which is typically about -70 mV (Figure 21–2). This is the resting membrane potential of the neuron. Two types of pathways, excitatory and inhibitory, impinge on the motoneuron. When an excitatory pathway is stimulated, a small depolarization or excitatory postsynaptic potential (EPSP) is recorded. This potential is due to the excitatory transmitter acting on an ionotropic receptor, causing an increase in sodium and potassium permeability. The duration of these potentials is quite brief, usually less than 20 ms. Changing the stimulus intensity to the pathway and therefore the number of presynaptic fibers activated results in a graded change in the size of the depolarization. This indicates that the contribution a single fiber makes to the EPSP is quite small. When a sufficient number of excitatory fibers are activated, the EPSP depolarizes the postsynaptic cell to threshold, and an all-or-none action potential is generated.

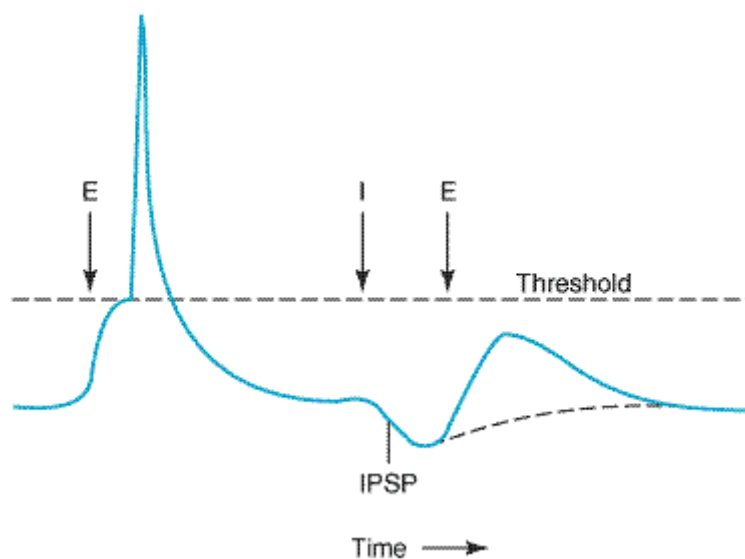

Figure 21–2.

Excitatory synaptic potentials and spike generation. The figure shows a resting membrane potential of -70 mV in a postsynaptic cell. Stimulation of an excitatory pathway (E) generates transient depolarization. Increasing the stimulus strength (second E) increases the size of the depolarization, so that the threshold for spike generation is reached.

When an inhibitory pathway is stimulated, the postsynaptic membrane is hyperpolarized, producing an inhibitory postsynaptic potential (IPSP) (Figure 21–3). A number of inhibitory synapses must be activated simultaneously to appreciably alter the membrane potential. This hyperpolarization is due to a selective increase in membrane permeability to chloride ions that flow into the cell during the IPSP. If an EPSP that under resting conditions would evoke an action potential in the postsynaptic cell (Figure 21–3) is elicited during an IPSP, it no longer evokes an action potential, because the IPSP has moved the membrane potential farther away from the threshold for action potential generation. A second type of inhibition is termed presynaptic inhibition. It was first described for sensory fibers entering the spinal cord, where excitatory synaptic terminals receive synapses called axoaxonic synapses (Figure 21–5 B). When activated, axoaxonic synapses reduce the amount of transmitter released from the synapses of sensory fibers. Interestingly, presynaptic inhibitory receptors are present on virtually all presynaptic terminals in the brain even though axoaxonic synapses appear to be restricted to the spinal cord. In this case, transmitter spills over to neighboring synapses to activate those presynaptic receptors.

Figure 21-3.

Interaction of excitatory and inhibitory synapses. On the left, a suprathreshold stimulus is given to an excitatory pathway (*E*). On the right, this same stimulus is given shortly after stimulating an inhibitory pathway (*I*), which prevents the excitatory potential from reaching threshold.

Sites of Drug Action

Virtually all of the drugs that act in the CNS produce their effects by modifying some step in chemical synaptic transmission. Figure 21-4 illustrates some of the steps that can be altered. These transmitter-dependent actions can be divided into presynaptic and postsynaptic categories.

Figure 21-4.

Sites of drug action. Schematic drawing of steps at which drugs can alter synaptic transmission. (1) Action potential in presynaptic fiber; (2) synthesis of transmitter; (3) storage; (4) metabolism; (5) release; (6) reuptake; (7) degradation; (8) receptor for the transmitter; (9) receptor-induced increase or decrease in ionic conductance.

Drugs acting on the synthesis, storage, metabolism, and release of neurotransmitters fall into the presynaptic category. Synaptic transmission can be depressed by blockade of transmitter synthesis or storage. For example, *p*-chlorophenylalanine blocks the synthesis of serotonin, and reserpine depletes the synapses of monoamines by interfering with intracellular storage. Blockade of transmitter catabolism can increase transmitter concentrations and has been reported to increase the amount of transmitter released per impulse. Drugs can also alter the release of transmitter. The stimulant amphetamine induces the release of catecholamines from adrenergic synapses. Capsaicin causes the release of the peptide substance P from sensory neurons, and tetanus toxin blocks the release of transmitters. After a transmitter has been released into the synaptic cleft, its action is terminated either by uptake or degradation. For most neurotransmitters, there are uptake mechanisms into the synaptic terminal and also into surrounding neuroglia. Cocaine, for example, blocks the uptake of catecholamines at adrenergic synapses and thus potentiates the action of these amines. However, acetylcholine is inactivated by enzymatic degradation. Anticholinesterases block the degradation of acetylcholine and thereby prolong its action. In contrast, no uptake mechanism has been found for any of the numerous CNS peptides, and it has yet to be demonstrated whether specific enzymatic degradation terminates the action of peptide transmitters.

In the postsynaptic region, the transmitter receptor provides the primary site of drug action. Drugs

can act either as neurotransmitter agonists, such as the opioids, which mimic the action of enkephalin, or they can block receptor function. Receptor antagonism is a common mechanism of action for CNS drugs. An example is strychnine's blockade of the receptor for the inhibitory transmitter glycine. This block, which underlies strychnine's convulsant action, illustrates how the blockade of inhibitory processes results in excitation. Drugs can also act directly on the ion channel of ionotropic receptors. For example, barbiturates can enter and block the channel of many excitatory ionotropic receptors. In the case of metabotropic receptors, drugs can act at any of the steps downstream of the receptor. Perhaps the best example is provided by the methylxanthines, which can modify neurotransmitter responses mediated through the second-messenger cAMP. At high concentrations, the methylxanthines elevate the level of cAMP by blocking its metabolism and thereby prolong its action in the postsynaptic cell.

The selectivity of CNS drug action is based almost entirely on the fact that different transmitters are used by different groups of neurons. Furthermore, these transmitters are often segregated into neuronal systems that subservise broadly different CNS functions. Without such segregation, it would be impossible to selectively modify CNS function even if one had a drug that operated on a single neurotransmitter system. It is not entirely clear why the CNS has relied on so many neurotransmitters and segregated them into different neuronal systems, since the primary function of a transmitter is either excitation or inhibition; this could be accomplished with two transmitter substances or perhaps even one. That such segregation does occur has provided neuroscientists with a powerful pharmacologic approach for analyzing CNS function and treating pathologic conditions. **Katzung PHARMACOLOGY, 9e** > Section V. Drugs That Act in the Central Nervous System > Chapter 21. Introduction to the Pharmacology of CNS Drugs >

Identification of Central Neurotransmitters

Since drug selectivity is based on the fact that different pathways utilize different transmitters, it is a primary goal of neuropharmacologists to identify the transmitters in CNS pathways. Establishing that a chemical substance is a transmitter has been far more difficult for central synapses than for peripheral synapses. In theory, to identify a transmitter it is sufficient to show that stimulation of a pathway releases enough of the substance to produce the postsynaptic response. In practice, this experiment cannot be done satisfactorily for at least two reasons. First, the anatomic complexity of the CNS prevents the selective activation of a single set of synaptic terminals. Second, available techniques for measuring the released transmitter and applying the transmitter are not sufficiently precise to satisfy the quantitative requirements. Therefore, the following criteria have been established for transmitter identification.

Localization

A number of approaches have been used to prove that a suspected transmitter resides in the presynaptic terminal of the pathway under study. These include biochemical analysis of regional concentrations of suspected transmitters, often combined with interruption of specific pathways, and microcytochemical techniques. Immunocytochemical techniques have proved very useful in localizing peptides and enzymes that synthesize or degrade nonpeptide transmitters.

Release

To determine whether the substance can be released from a particular region, local collection (in vivo) of the extracellular fluid can sometimes be accomplished. In addition, slices of brain tissue can be electrically or chemically stimulated in vitro and the released substances measured. To determine if the release is relevant to synaptic transmission, it is important to establish that the

release is calcium-dependent. As mentioned above, anatomic complexity often prevents identification of the synaptic terminals responsible for the release, and the amount collected in the perfusate is a small fraction of the amount actually released.

Synaptic Mimicry

Finally, application of the suspected substance should produce a response that mimics the action of the transmitter released by nerve stimulation. Microiontophoresis, which permits highly localized drug administration, has been a valuable technique in assessing the action of suspected transmitters. In practice, this criterion has two parts: physiologic and pharmacologic identity. To establish physiologic identity of action, the substance must be shown to initiate the same change in ionic conductance in the postsynaptic cell as synaptically released transmitter. This requires intracellular recording and determination of the reversal potential and ionic dependencies of the responses. However, since different transmitters can elicit identical ionic conductance changes, this finding is not sufficient. Thus, selective pharmacologic antagonism is used to further establish that the suspected transmitter is acting in a manner identical to synaptically released transmitter. Because of the complexity of the CNS, specific pharmacologic antagonism of a synaptic response provides a particularly powerful technique for transmitter identification.

Cellular Organization of the Brain

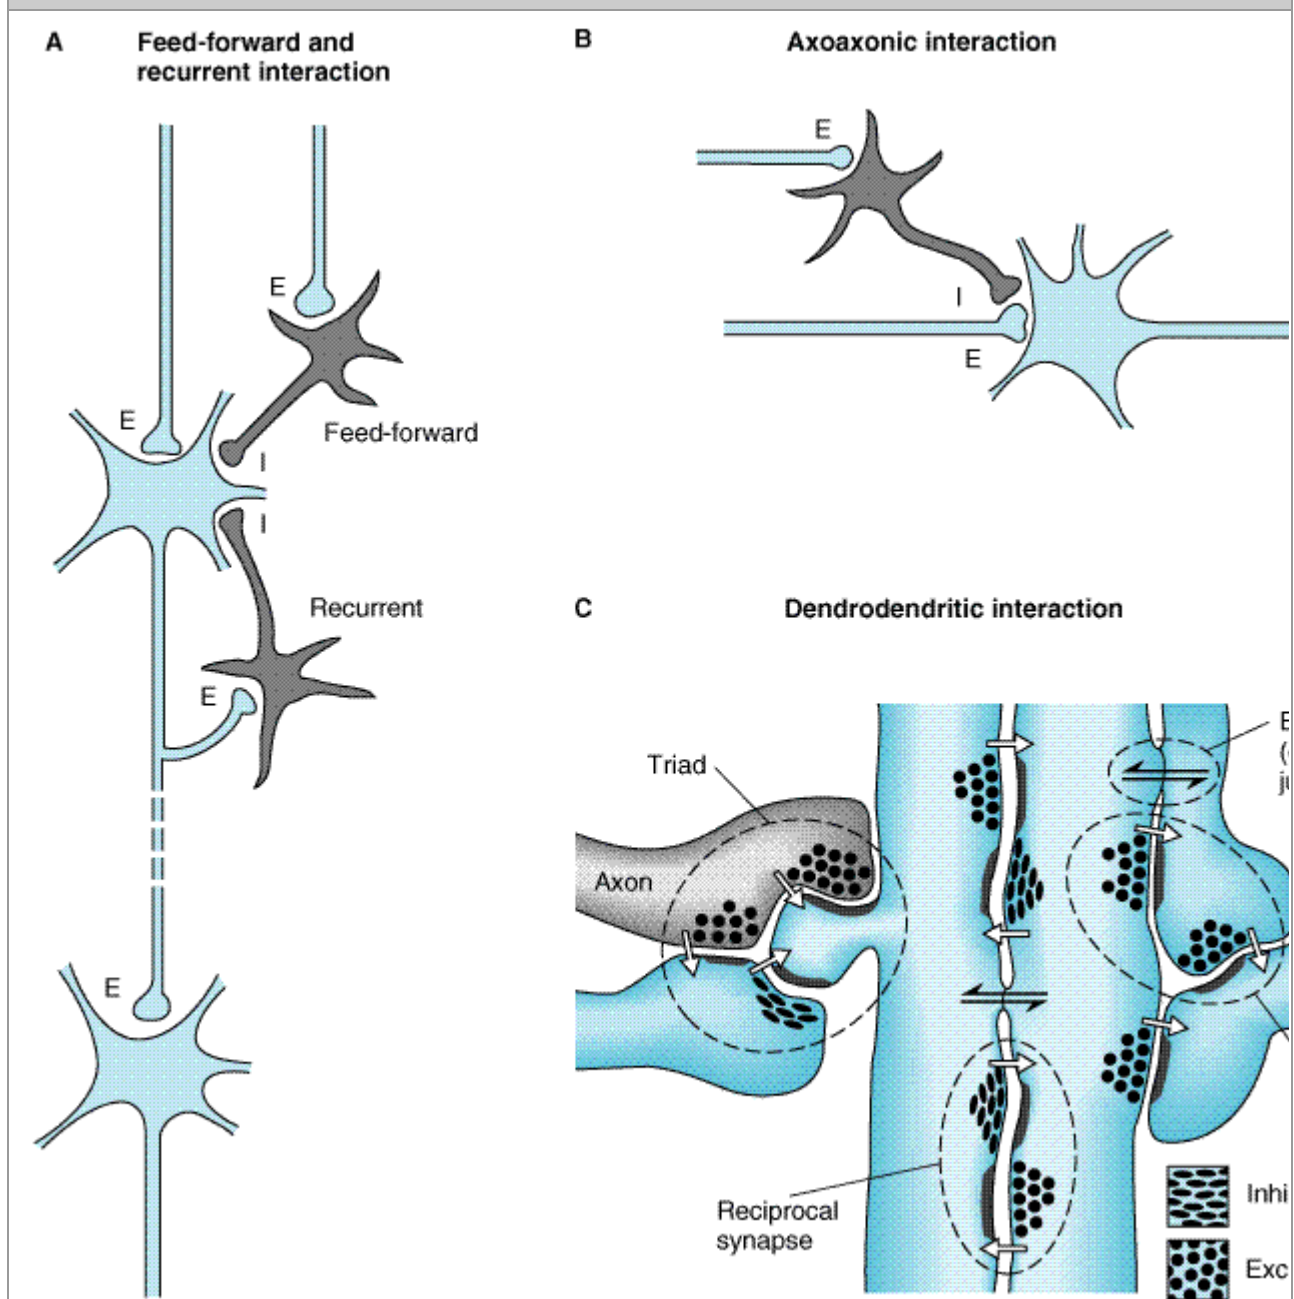

Most of the neuronal systems in the CNS can be divided into two broad categories: hierarchical systems and nonspecific or diffuse neuronal systems.

Hierarchical Systems

These systems include all of the pathways directly involved in sensory perception and motor control. The pathways are generally clearly delineated, being composed of large myelinated fibers that can often conduct action potentials at a rate in excess of 50 m/s. The information is typically phasic, and in sensory systems the information is processed sequentially by successive integrations at each relay nucleus on its way to the cortex. A lesion at any link will incapacitate the system. Within each nucleus and in the cortex, there are two types of cells: relay or projection neurons and local circuit neurons (Figure 21–5 A). The projection neurons that form the interconnecting pathways transmit signals over long distances. The cell bodies are relatively large, and their axons emit collaterals that arborize extensively in the vicinity of the neuron. These neurons are excitatory, and their synaptic influences, which involve ionotropic receptors, are very short-lived. The excitatory transmitter released from these cells is, in most instances, glutamate. Local circuit neurons are typically smaller than projection neurons, and their axons arborize in the immediate vicinity of the cell body. The vast majority of these neurons are inhibitory, and they release either GABA or glycine. They synapse primarily on the cell body of the projection neurons but can also synapse on the dendrites of projection neurons as well as with each other. A special class of local circuit neurons in the spinal cord forms axoaxonic synapses on the terminals of sensory axons (Figure 21–5 B). Two common types of pathways for these neurons (Figure 21–5 A) include recurrent feedback pathways and feed-forward pathways. In some sensory pathways such as the retina and olfactory bulb, local circuit neurons may actually lack an axon and release neurotransmitter from dendritic synapses in a graded fashion in the absence of action potentials.

Some pathways involving presynaptic dendrites of local circuit neurons are shown in Figure 21–5 C.

Figure 21–5.

Pathways in the central nervous system. **A** shows two relay neurons and two types of inhibitory pathways, recurrent and feed-forward. The inhibitory neurons are shown in black. **B** shows the pathway responsible for presynaptic inhibition in which the axon of an inhibitory neuron synapses on the axon terminal of an excitatory fiber. **C**: Diagram illustrating that dendrites may be both pre- and postsynaptic to each other, forming reciprocal synapses, two of which are shown between the same dendrite pair. In triads, an axon synapses on two dendrites, and one of these dendrites synapses on the second. In serial synapses, a dendrite may be postsynaptic to one dendrite and presynaptic to another, thus connecting a series of dendrites. Dendrites also interact through low-resistance electrotonic ("gap") junctions (two of which are shown). Except for one axon, all

structures shown in *C* are dendrites. (Reproduced, with permission, from Schmitt FO, Dev P, Smith BH: Electrotonic processing of information by brain cells. *Science* 1976;193:114. Copyright © 1976 by the American Association for the Advancement of Science.)

Although there is a great variety of synaptic connections in these hierarchical systems, the fact that a limited number of transmitters are utilized by these neurons indicates that any major pharmacologic manipulation of this system will have a profound effect on the overall excitability of the CNS. For instance, selectively blocking GABA receptors with a drug such as picrotoxin results in generalized convulsions. Thus, while the mechanism of action of picrotoxin is quite specific in blocking the effects of GABA, the overall functional effect appears to be quite nonspecific, since GABA-mediated synaptic inhibition is so widely utilized in the brain.

Nonspecific or Diffuse Neuronal Systems

Neuronal systems that contain one of the monoamines—norepinephrine, dopamine, or 5-hydroxytryptamine (serotonin)—provide examples in this category. Certain other pathways emanating from the reticular formation and possibly some peptide-containing pathways also fall into this category. These systems differ in fundamental ways from the hierarchical systems, and the noradrenergic systems will serve to illustrate the differences.

Noradrenergic cell bodies are found primarily in a compact cell group called the locus ceruleus located in the caudal pontine central gray matter. The number of neurons in this cell group is quite small, approximately 1500 on each side of the brain in the rat. The axons of these neurons are very fine and unmyelinated. Indeed, they were entirely missed with classic anatomic techniques. It was not until the mid 1960s, when the formaldehyde fluorescence histochemical technique was applied to the study of CNS tissues, that the anatomy of the monoamine-containing systems was described. Because these axons are fine and unmyelinated, they conduct very slowly, at about 0.5 m/s. The axons branch repeatedly and are extraordinarily divergent. Branches from the same neuron can innervate several functionally different parts of the CNS. In the neocortex, these fibers have a tangential organization and therefore can monosynaptically influence large areas of cortex. The pattern of innervation in the cortex and nuclei of the hierarchical systems is diffuse, and the noradrenergic fibers form a very small percentage of the total number in the area. In addition, the axons are studded with periodic enlargements called varicosities that contain large numbers of vesicles. In some instances, these varicosities do not form synaptic contacts, suggesting that norepinephrine may be released in a rather diffuse manner, as occurs with the noradrenergic innervation of smooth muscle. This indicates that the cellular targets of these systems will be determined largely by the location of the receptors rather than the location of the release sites. Finally, most neurotransmitters utilized by diffuse neuronal systems, including norepinephrine, act—perhaps exclusively—on metabotropic receptors and therefore initiate long-lasting synaptic effects. Based on all of these observations, it is clear that the monoamine systems cannot be conveying specific topographic types of information—rather, vast areas of the CNS must be affected simultaneously and in a rather uniform way. It is not surprising, then, that these systems have been implicated in such global functions as sleeping and waking, attention, appetite, and emotional states.

Central Neurotransmitters

A vast number of small molecules have been isolated from brain, and studies using a variety of approaches suggest that the agents listed in Table 21–2 are neurotransmitters. A brief summary of

the evidence for some of these compounds follows.

Table 21–2. Summary of Neurotransmitter Pharmacology in the Central Nervous System.				
Transmitter	Anatomy	Receptor Subtypes and Preferred Agonists	Receptor Antagonists	Mechanisms
Acetylcholine	Cell bodies at all levels; long and short connections	Muscarinic (M ₁): muscarine, McN-A-343	Pirenzepine, atropine	Excitatory: ↓ in K ⁺ conductance; ↑ IP ₃ , DAG
		Muscarinic (M ₂): muscarine, bethanechol	Atropine, methoctramine	Inhibitory: ↑ K ⁺ conductance; ↓ cAMP
	Motoneuron-Renshaw cell synapse	Nicotinic: nicotine	Dihydro-β-erythroidine, α-bungarotoxin	Excitatory: ↑ cation conductance
Dopamine	Cell bodies at all levels; short, medium, and long connections	D ₁ : SKF 38393	Phenothiazines, SCH 23390	Inhibitory (?): ↓ cAMP
		D ₂ : quinpirole, bromocriptine	Phenothiazines, butyrophenones	Inhibitory (presynaptic): ↓ Ca ²⁺ ; Inhibitory (postsynaptic): ↑ in K ⁺ conductance, ↓ cAMP
GABA	Supraspinal interneurons involved in pre- and postsynaptic inhibition	GABA _A : muscimol	Bicuculline, picrotoxin	Inhibitory: ↑ Cl ⁻ conductance
		GABA _B : baclofen	2-OH saclofen, CGP 35348, CGP55845	Inhibitory (presynaptic): ↓ Ca ²⁺ conductance; Inhibitory (postsynaptic): ↑ K ⁺ conductance
Glutamate	Relay neurons at all levels and some interneurons	<i>N</i> -Methyl-D-aspartate (NMDA): NMDA	2-Amino-5-phosphonovalerate, CPP, MK-801	Excitatory: ↑ cation conductance, particularly Ca ²⁺
		AMPA: AMPA	CNQX,	Excitatory: ↑

			GYKI52466	cation conductance
		Kainate: kainate, domoic acid	CNQX	
		Metabotropic: ACPD, quisqualate	MCPG	Inhibitory (presynaptic): ↓ Ca^{2+} conductance; ↓ cAMP; Excitatory: ↓ K^+ conductance, ↑ IP_3 , DAG
Glycine	Spinal interneurons and some brain stem interneurons	Taurine, β -alanine	Strychnine	Inhibitory: ↑ Cl^- conductance
5-Hydroxytryptamine (serotonin)	Cell bodies in midbrain and pons project to all levels	5-HT _{1A} : LSD, 8-OH-DPAT	Metergoline, spiperone	Inhibitory: ↑ K^+ conductance, ↓ cAMP
		5-HT _{2A} : LSD, DOB	Ketanserin	Excitatory: ↓ K^+ conductance, ↑ IP_3 , DAG
		5-HT ₃ : 2-methyl-5-HT, phenylbiguanide	ICS 205930, ondansetron	Excitatory: ↑ cation conductance
		5-HT ₄ : BIMU8	GR 1138089	Excitatory: ↓ K^+ conductance
Norepinephrine	Cell bodies in pons and brain stem project to all levels	α_1 : phenylephrine	Prazosin	Excitatory: ↓ K^+ conductance, ↑ IP_3 , DAG
		α_2 : clonidine	Yohimbine	Inhibitory (presynaptic): ↓ Ca^{2+} conductance; Inhibitory: ↑ K^+ conductance, ↓ cAMP
		β_1 : isoproterenol, dobutamine	Atenolol, practolol	Excitatory: ↓ K^+ conductance, ↑ cAMP

		β_2 : salbutamol	Butoxamine	Inhibitory: may involve \uparrow in electrogenic sodium pump; \uparrow cAMP
Histamine	Cells in ventral posterior hypothalamus	H ₁ : 2(<i>m</i> -fluorophenyl)-histamine phenyl-histamine	Mepyramine	Excitatory: \downarrow K ⁺ conductance, \uparrow IP ₃ , DAG
		H ₂ : dimaprit	Ranitidine	Excitatory: \downarrow K ⁺ conductance, \uparrow cAMP
Opioid peptides	Cell bodies at all levels; long and short connections	Mu: bendorphin, DAMGO	Naloxone, CTOP	Inhibitory (presynaptic): \downarrow Ca ²⁺ conductance, \downarrow cAMP
		Delta: enkephalin, DPDPE	Naloxone	Inhibitory (postsynaptic): \uparrow K ⁺ conductance, \downarrow cAMP
		Kappa: dynorphin, U-69593	Naloxone, nor-BNI	
Tachykinins	Primary sensory neurons, cell bodies at all levels; long and short connections	NK1: Substance P methylester	CP99994	Excitatory: \downarrow K ⁺ conductance, \uparrow IP ₃ , DAG
		NK2: β -[Ala ⁸] NKA ₄₋₁₀	SR48968	
		NK3: GR138676	[Pro ⁷]NKB	
Endocannabinoids (anandamide, 2-arachidonylglycerol)	Widely distributed	CB1: WIN55212-2 methylester	SR141716	Inhibitory (presynaptic): \downarrow Ca ²⁺ conductance, \downarrow cAMP

8-OH DPAT, 8-hydroxy-2(di-*n*-propylamino)tetralin; ACPD, *trans*-1-amino-cyclopentyl-1,3-dicarboxylate; AMPA, DL- α -amino-3-hydroxy-5-methylisoxazole-4-propionate; BIMU8, [endo-*N*-8-methyl-8-azabicyclo(3.2.1)oct-3-yl]-2,3-dihydro-3-isopropyl-2-oxo-1*H*-benzimidazol-1-carboxamide hydrochloride; CGP 35348, 3-aminopropyl(diethoxymethyl)phosphinic acid; CNQX, 6-cyano-7-nitroquinoxaline-2,3-dione; CP 99994, (+)-(2*S*, 3*S*)-3-(2-methoxybenzylamino)-2-

phenylpiperidine; CPP, 3-(2-carboxypiperazin-4-yl)propyl-1-phosphonic acid; CTOP, D-Phe-Cys-Tyr-D-Trp-Orn-Thr-Pen-Thr-NH₂; DAG, diacylglycerol; DAMGO, D-ala-2,Me-Phe⁴,Gly¹-enkephalin; DOB, 5-bromo-2,5-dimethoxyamphetamine; DPDPE, D-pen²D-pen⁵(-enkephalin); GR 113808, (1-{2-[(methylsulfonyl)amino]ethyl}-4-piperidinyl)methyl-1-methyl-1*H*-indole-3-carboxylate; GYKI 52466, 1-(4-aminophenyl)-4-methyl-7,8-methylenedioxy-5*H*-2,3-benzodiazepine; IP₃, inositol trisphosphate; MCPG, α-methyl-4-carboxyphenylglycine; MK-801, (dizocilpine), 10,11-dihydro-5-methyl-5*H*-dibenzo(a,d)cyclohepten-5,10-imine; NK1,2,3, neurokinin and derivatives; nor-BNI, nor-binaltorphimine; SR 141716, *N*-(piperidine-1-yl)-5-(4-chlorophenyl)-1-(2,4-dichlorophenyl)-4-methyl-1*H*-pyrazole-3-carboxamide; SR 48968, (*S*)-*N*-methyl-*N*-(4-acetylamino-4-phenylpiperidino)-2-(3,4-dichlorophenyl)butylbenzamide; U-69593, (+)-(5α,7α,8β)-*N*-methyl-*N*-[7-(1-pyrrolidinyl)]-1-oxaspiro(4,5)dec-8-yl-benzenacetamide; WIN 55212-2, (*R*)-(+)-[2,3-dihydro-5-methyl-3-[(morpholino)methyl]pyrrolo-[1,2,3-*de*]-1,4-benzoxazin-6-yl] (1-naphthyl)methanone

Amino Acids

The amino acids of primary interest to the pharmacologist fall into two categories: the neutral amino acids **glycine** and **GABA** and the acidic amino acid **glutamate**. All of these compounds are present in high concentrations in the CNS and are extremely potent modifiers of neuronal excitability.

Neutral Amino Acids

The neutral amino acids are inhibitory and increase membrane permeability to chloride ions, thus mimicking the IPSP. Glycine concentrations are particularly high in the gray matter of the spinal cord, and strychnine, which is a potent spinal cord convulsant and has been used in some rat poisons, selectively antagonizes both the action of glycine and the IPSPs recorded in spinal cord neurons. Thus, it is generally agreed that glycine is released from spinal cord inhibitory local circuit neurons involved in postsynaptic inhibition.

GABA receptors are divided into two types: GABA_A and GABA_B. GABA_A receptors open chloride channels and are antagonized by picrotoxin and bicuculline, which both cause generalized convulsions. GABA_B receptors, which can be selectively activated by the antispastic drug baclofen, are coupled to G proteins that either inhibit calcium channels or activate potassium channels. In most regions of the brain, IPSPs have a fast and slow component mediated by GABA_A and GABA_B receptors, respectively. Immunohistochemical studies indicate that a large majority of the local circuit neurons synthesize GABA. A special class of local circuit neuron localized in the dorsal horn of the spinal cord also synthesizes GABA. These neurons form axoaxonic synapses with primary sensory nerve terminals and are responsible for presynaptic inhibition (Figure 21-5 B).

Acidic Amino Acids

Glutamate is present in very high concentrations in the CNS. Virtually all neurons that have been tested are strongly excited by this amino acid. This excitation is caused by the activation of both ionotropic and metabotropic receptors, which have been extensively characterized by molecular cloning. The ionotropic receptors can be further divided into three subtypes based on the action of the selective agonists: kainate (KA), α-amino-3-hydroxy-5-methylisoxazole-4-propionate (AMPA), and *N*-methyl-D-aspartate (NMDA). The AMPA- and KA-activated channels are permeable to sodium and potassium ions and, for certain subtypes, calcium as well. They are often grouped together and referred to as non-NMDA channels. The NMDA-activated channel is highly permeable to sodium, potassium, and calcium ions.

The metabotropic glutamate receptors act indirectly on ion channels via G proteins. They are selectively activated by *trans*-1-amino-cyclopentyl-1,3-dicarboxylate (ACPD). These G protein-coupled receptors are either positively coupled to (ie, stimulate) phospholipase C or negatively coupled to adenylyl cyclase. Depending on the type of synapse, metabotropic glutamate receptors can initiate a slow postsynaptic excitation or a presynaptic inhibition. Although the presence of metabotropic receptors at excitatory synapses varies, most excitatory synapses contain both NMDA receptors and non-NMDA receptors in the postsynaptic membrane.

The role of NMDA receptors has received considerable attention. These receptors play a critical role in synaptic plasticity, which is thought to underlie certain forms of learning and memory. They are selectively blocked by the dissociative anesthetic ketamine and the hallucinogenic drug phencyclidine. These drugs exert their effects by entering and blocking the open channel. Some drugs that block this receptor channel have potent antiepileptic activity in animal models, though these drugs have yet to be tested clinically. Considerable evidence exists that the release of glutamate during neuronal injury can, by activating the NMDA receptor, cause further cell injury and death. Thus, a particularly exciting finding is that blocking the NMDA receptor can attenuate the neuronal damage caused by anoxia in experimental animals. The potential therapeutic benefits of this action are considerable, although clinical trials to date have been disappointing.

Acetylcholine

Acetylcholine was the first compound to be identified pharmacologically as a transmitter in the CNS. Eccles showed in the early 1950s that excitation of Renshaw cells by motor axon collaterals was blocked by nicotinic antagonists. Furthermore, Renshaw cells were extremely sensitive to nicotinic agonists. These experiments were remarkable for two reasons. First, this early success at identifying a transmitter for a central synapse was followed by disappointment, because it remained the sole central synapse for which the transmitter was known until the late 1960s, when comparable data became available for the neutral amino acids. Second, the motor axon collateral synapse remains one of the best-documented examples of a cholinergic nicotinic synapse in the mammalian CNS, despite the rather widespread distribution of nicotinic receptors as defined by *in situ* hybridization studies. Most CNS responses to acetylcholine are mediated by a large family of G protein-coupled muscarinic receptors. At a few sites, acetylcholine causes slow inhibition of the neuron by activating the M₂ subtype of receptor, which opens potassium channels. A far more widespread muscarinic action in response to acetylcholine is a slow excitation that in some cases is mediated by M₁ receptors. These muscarinic effects are much slower than either nicotinic effects on Renshaw cells or the effect of amino acids. Furthermore, this muscarinic excitation is unusual in that acetylcholine produces it by *decreasing* the membrane permeability to potassium, ie, the opposite of conventional transmitter action.

A number of pathways contain acetylcholine, including neurons in the neostriatum, the medial septal nucleus, and the reticular formation. Cholinergic pathways appear to play an important role in cognitive functions, especially memory. Presenile dementia of the Alzheimer type is reportedly associated with a profound loss of cholinergic neurons. However, the specificity of this loss has been questioned since the levels of other putative transmitters, eg, somatostatin, are also decreased.

Monoamines

Monoamines include the catecholamines (dopamine and norepinephrine) and 5-hydroxytryptamine. Although these compounds are present in very small amounts in the CNS, they can be localized using extremely sensitive histochemical methods. These pathways are the site of action of many drugs; for example, the CNS stimulants cocaine and amphetamine are believed to act primarily at

catecholamine synapses. Cocaine blocks the reuptake of dopamine and norepinephrine, while amphetamines cause presynaptic terminals to release these transmitters.

Dopamine

The major pathways containing dopamine are the projection linking the substantia nigra to the neostriatum and the projection linking the ventral tegmental region to limbic structures, particularly the limbic cortex. The therapeutic action of the antiparkinsonism drug levodopa is associated with the former area, whereas the therapeutic action of the antipsychotic drugs is thought to be associated with the latter area. Dopamine-containing neurons in the tuberobasal ventral hypothalamus play an important role in regulating hypothalamohypophysial function. A number of dopamine receptors have been identified, and they fall into two categories: D₁-like and D₂-like. All dopamine receptors are metabotropic. Dopamine generally exerts a slow inhibitory action on CNS neurons. This action has been best characterized on dopamine-containing substantia nigra neurons, where D₂ receptor activation opens potassium channels.

Norepinephrine

This system has already been discussed. Most noradrenergic neurons are located in the locus ceruleus or the lateral tegmental area of the reticular formation. Although the density of fibers innervating various sites differs considerably, most regions of the central nervous system receive diffuse noradrenergic input. All noradrenergic receptor subtypes are metabotropic. When applied to neurons, norepinephrine can hyperpolarize them by increasing potassium conductance. This effect is mediated by α_2 receptors and has been characterized most thoroughly on locus ceruleus neurons. In many regions of the CNS, norepinephrine actually enhances excitatory inputs by both indirect and direct mechanisms. The indirect mechanism involves disinhibition, ie, inhibitory local circuit neurons are inhibited. The direct mechanism is blockade of potassium conductances that slow neuronal discharge. Depending on the type of neuron, this effect is mediated by either α_1 or β receptors. Facilitation of excitatory synaptic transmission is in accordance with many of the behavioral processes thought to involve noradrenergic pathways, eg, attention and arousal.

5-Hydroxytryptamine

Most 5-hydroxytryptamine (5-HT, serotonin) pathways originate from neurons in the raphe or midline regions of the pons and upper brain stem. 5-HT is contained in unmyelinated fibers that diffusely innervate most regions of the CNS, but the density of the innervation varies. 5-HT acts on more than a dozen receptor subtypes. Except for the 5-HT₃ receptor, all of these receptors are metabotropic. The ionotropic 5-HT₃ receptor exerts a rapid excitatory action at a very limited number of sites in the CNS. In most areas of the central nervous system, 5-HT has a strong inhibitory action. This action is mediated by 5-HT_{1A} receptors and is associated with membrane hyperpolarization caused by an increase in potassium conductance. It has been found that 5-HT_{1A} receptors and GABA_B receptors share the same potassium channels. Some cell types are slowly excited by 5-HT owing to its blockade of potassium channels via 5-HT₂ or 5-HT₄ receptors. Both excitatory and inhibitory actions can occur on the same neurons. It has often been speculated that 5-HT pathways may be involved in the hallucinations induced by LSD, since this compound can antagonize the peripheral actions of 5-HT. However, LSD does not appear to be a 5-HT antagonist in the central nervous system, and typical LSD-induced behavior is still seen in animals after raphe nuclei are destroyed. Other proposed regulatory functions of 5-HT-containing neurons include sleep, temperature, appetite, and neuroendocrine control.

Peptides

A great many CNS peptides have been discovered that produce dramatic effects both on animal behavior and on the activity of individual neurons. Many of the peptides have been mapped with immunohistochemical techniques and include opioid peptides (enkephalins, endorphins, etc), neurotensin, substance P, somatostatin, cholecystokinin, vasoactive intestinal polypeptide, neuropeptide Y, and thyrotropin-releasing hormone. As in the peripheral autonomic nervous system, peptides often coexist with a conventional nonpeptide transmitter in the same neuron. A good example of the approaches used to define the role of these peptides in the central nervous system comes from studies on substance P and its association with sensory fibers. Substance P is contained in and released from small unmyelinated primary sensory neurons of the spinal cord and brain stem and causes a slow EPSP in target neurons. These sensory fibers are known to transmit noxious stimuli, and it is therefore surprising that—while substance P receptor antagonists can modify responses to certain types of pain—they do not block the response. Glutamate, which is released with substance P from these synapses, presumably plays an important role in transmitting pain stimuli. Substance P is certainly involved in many other functions, since it is found in many areas of the central nervous system that are unrelated to pain pathways.

Many of these peptides are also found in peripheral structures, including peripheral synapses. They are described in Chapter 6: Introduction to Autonomic Pharmacology and Chapter 17: Vasoactive Peptides.

Nitric Oxide

The CNS contains a substantial amount of nitric oxide synthase (NOS), which is found within certain classes of neurons. This neuronal NOS is an enzyme activated by calcium-calmodulin, and activation of NMDA receptors, which increases intracellular calcium, results in the generation of nitric oxide. While a physiologic role for nitric oxide has been clearly established for vascular smooth muscle, its role in synaptic transmission and synaptic plasticity remains controversial.

Endocannabinoids

The primary psychoactive ingredient in cannabis, Δ^9 -tetrahydrocannabinol (Δ^9 -THC), affects the brain mainly by activating a specific cannabinoid receptor, CB1. CB1 is expressed at high levels in many brain regions, and several endogenous brain lipids, including anandamide and 2-arachidonylglycerol, have been identified as CB1 ligands. These ligands are not stored, as are classic neurotransmitters, but instead are rapidly synthesized by neurons in response to depolarization and consequent calcium influx. In further contradistinction to classic neurotransmitters, endogenous cannabinoids can function as retrograde synaptic messengers: they are released from postsynaptic neurons and travel backward across synapses, activating CB1 receptors on presynaptic neurons and suppressing transmitter release. Cannabinoids may affect memory, cognition, and pain perception by this mechanism.

Chapter 22. Sedative-Hypnotic Drugs

Sedative-Hypnotic Drugs: Introduction

Assignment of a drug to the sedative-hypnotic class indicates that its major therapeutic use is to cause sedation (with concomitant relief of anxiety) or to encourage sleep. Because there is considerable chemical variation within this group, this drug classification is based on clinical uses

rather than on similarities in chemical structure. Anxiety states and sleep disorders are common problems, and sedative-hypnotics are among the most widely prescribed drugs worldwide.

Katzung PHARMACOLOGY, 9e > Section V. Drugs That Act in the Central Nervous System > Chapter 22. Sedative-Hypnotic Drugs >

Basic Pharmacology of Sedative-Hypnotics

An effective **sedative** (anxiolytic) agent should reduce anxiety and exert a calming effect. The degree of central nervous system depression caused by a sedative should be the minimum consistent with therapeutic efficacy. A **hypnotic** drug should produce drowsiness and encourage the onset and maintenance of a state of sleep. Hypnotic effects involve more pronounced depression of the central nervous system than sedation, and this can be achieved with most drugs in this class simply by increasing the dose. Graded dose-dependent depression of central nervous system function is a characteristic of sedative-hypnotics. However, individual drugs differ in the relationship between the dose and the degree of central nervous system depression. Two examples of such dose-response relationships are shown in Figure 22–1. The linear slope for drug A is typical of many of the older sedative-hypnotics, including the barbiturates and alcohols. With such drugs, an increase in dose above that needed for hypnosis may lead to a state of general anesthesia. At still higher doses, sedative-hypnotics may depress respiratory and vasomotor centers in the medulla, leading to coma and death. Deviations from a linear dose-response relationship, as shown for drug B, will require proportionately greater dosage increments in order to achieve central nervous system depression more profound than hypnosis. This appears to be the case for benzodiazepines and certain newer hypnotics; the greater margin of safety this offers is an important reason for their widespread use to treat anxiety states and sleep disorders.

Figure 22–1.

Dose-response curves for two hypothetical sedative-hypnotics.

Chemical Classification

The benzodiazepines (Figure 22–2) are the most widely used sedative-hypnotics. All of the structures shown are 1,4-benzodiazepines, and most contain a carboxamide group in the 7-

membered heterocyclic ring structure. A substituent in the 7 position, such as a halogen or a nitro group, is required for sedative-hypnotic activity. The structures of triazolam and alprazolam include the addition of a triazole ring at the 1,2-position, and such drugs are sometimes referred to as triazolobenzodiazepines.

Figure 22–2.

Chemical structures of benzodiazepines.

The chemical structures of some older and less commonly used sedative-hypnotics, including several barbiturates, are shown in Figure 22–3. Glutethimide (a piperidinedione) and meprobamate (a carbamate) are of distinctive chemical structure but are practically equivalent to barbiturates in their pharmacologic effects, and their clinical use is rapidly declining. The sedative-hypnotic class also includes compounds of simple chemical structure, including ethanol (see Chapter 23: The Alcohols), chloral hydrate, trichloroethanol, and paraldehyde (not shown).

Figure 22–3.

Several drugs with novel chemical structures have been introduced recently. Buspirone is an anxiolytic agent that has actions different from those of conventional sedative-hypnotic drugs. Zolpidem and zaleplon, while structurally unrelated to benzodiazepines, share a similar mechanism of action.

Zolpidem

Zaleplon

Other classes of drugs not included in Figure 22–3 that may exert sedative effects include most antipsychotic and many antidepressant drugs and certain antihistaminic agents (eg, hydroxyzine, promethazine). As discussed in other chapters, these agents differ from conventional sedative-hypnotics in both their effects and their major therapeutic uses. Since they commonly exert marked effects on the peripheral autonomic nervous system, they are sometimes referred to as "**sedative-autonomic**" drugs. Certain antihistaminics with sedative effects are available in over-the-counter sleep aids. Their autonomic properties and their long durations of action can result in adverse effects.

The Benzodiazepines & Barbiturates

Pharmacokinetics

Absorption and Distribution

The rates of oral absorption of benzodiazepines differ depending on a number of factors, including lipophilicity. Oral absorption of triazolam is extremely rapid, and that of diazepam and the active metabolite of clorazepate is more rapid than other commonly used benzodiazepines. Clorazepate is converted to its active form, desmethyldiazepam (nordiazepam), by acid hydrolysis in the stomach. Oxazepam, lorazepam, and temazepam are absorbed from the gut at slower rates than other benzodiazepines. The bioavailability of several benzodiazepines, including chlordiazepoxide and diazepam, may be unreliable after intramuscular injection. Most of the barbiturates and other older sedative-hypnotics are absorbed rapidly into the blood following their oral administration.

Lipid solubility plays a major role in determining the rate at which a particular sedative-hypnotic enters the central nervous system. For example, diazepam and triazolam are more lipid-soluble than chlordiazepoxide and lorazepam; thus, the central nervous system actions of the former drugs are

more rapid in onset. The thiobarbiturates (eg, thiopental), in which the oxygen on C₂ is replaced by sulfur, are very lipid-soluble, and a high rate of entry into the central nervous system contributes to the rapid onset of their central effects (see Chapter 25: General Anesthetics). In contrast, phenobarbital and meprobamate have quite low lipid solubility and penetrate the brain slowly.

All sedative-hypnotics cross the placental barrier during pregnancy. If sedative-hypnotics are given in the predelivery period, they may contribute to the depression of neonatal vital functions. Sedative-hypnotics are detectable in breast milk and may exert depressant effects in the nursing infant.

Although sedative-hypnotic drugs, including benzodiazepines, bind to plasma proteins, few clinically significant interactions involving these drugs appear to be based on such protein binding. One exception is chloral hydrate, which transiently increases the anticoagulant effects of warfarin by displacement of the anticoagulant drug from such binding sites.

Biotransformation

Metabolic transformation to more water-soluble metabolites is necessary for clearance of sedative-hypnotics from the body. The microsomal drug-metabolizing enzyme systems of the liver are most important in this regard. Few sedative-hypnotics are excreted from the body in unchanged form, so elimination half-life depends mainly on the rate of metabolic transformation.

Benzodiazepines

Hepatic metabolism accounts for the clearance of all benzodiazepines. The patterns and rates of metabolism depend on the individual drugs. Most benzodiazepines undergo microsomal oxidation (phase I reactions), including *N*-dealkylation and aliphatic hydroxylation. The metabolites are subsequently conjugated (phase II reactions) to form glucuronides that are excreted in the urine. However, many phase I metabolites of benzodiazepines are pharmacologically active, with long half-lives.

As shown in Figure 22–4, desmethyldiazepam, which has an elimination half-life of more than 40 hours, is an active metabolite of chlordiazepoxide, diazepam, prazepam, and clorazepate. Desmethyldiazepam in turn is biotransformed to the active compound, oxazepam. Other active metabolites of chlordiazepoxide include desmethylchlordiazepoxide and demoxepam. While diazepam is metabolized mainly to desmethyldiazepam, it is also converted to temazepam (not shown in Figure 22–4), which is further metabolized in part to oxazepam. Flurazepam, which is used mainly for hypnosis, is oxidized by hepatic enzymes to three active metabolites, desalkylflurazepam, hydroxyethylflurazepam, and flurazepam aldehyde (not shown), which have elimination half-lives ranging from 30 to 100 hours. Alprazolam and triazolam undergo α -hydroxylation, and the resulting metabolites appear to exert short-lived pharmacologic effects since they are rapidly conjugated to form inactive glucuronides.

Figure 22–4.

Biotransformation of benzodiazepines. (Boldface, drugs available for clinical use; *, active metabolite.)

The formation of active metabolites has complicated studies on the pharmacokinetics of the benzodiazepines in humans because the elimination half-life of the parent drug may have little relationship to the time course of pharmacologic effects. Those benzodiazepines for which the parent drug or active metabolites have long half-lives are more likely to cause cumulative effects with multiple doses. Cumulative and residual effects such as excessive drowsiness appear to be less of a problem with such drugs as estazolam, oxazepam, and lorazepam, which have shorter half-lives and are metabolized directly to inactive glucuronides. Some pharmacokinetic properties of selected benzodiazepines are listed in Table 22–1.

Drug	Peak Blood Level (hours)	Elimination Half-Life ¹ (hours)	Comments
Alprazolam	1–2	12–15	Rapid oral absorption
Chlordiazepoxide	2–4	15–40	Active metabolites; erratic bioavailability from IM injection
Clorazepate	1–2 (nordiazepam)	50–100	Prodrug; hydrolyzed to active form in stomach

Diazepam	1–2	20–80	Active metabolites; erratic bioavailability from IM injection
Estazolam	2	10–24	No active metabolites
Flurazepam	1–2	40–100	Active metabolites with long half-lives
Lorazepam	1–6	10–20	No active metabolites
Oxazepam	2–4	10–20	No active metabolites
Prazepam	1–2	50–100	Active metabolites with long half-lives
Quazepam	2	30–100	Active metabolites with long half-lives
Temazepam	2–3	10–40	Slow oral absorption
Triazolam	1	2–3	Rapid onset; short duration of action

¹Includes half-lives of major metabolites.

Barbiturates

With the exception of phenobarbital, only insignificant quantities of the barbiturates are excreted unchanged. The major metabolic pathways involve oxidation by hepatic enzymes of chemical groups attached to C₅, which are different for the individual barbiturates. The alcohols, acids, and ketones formed appear in the urine as glucuronide conjugates. With very few exceptions, the metabolites of the barbiturates lack pharmacologic activity. The overall rate of hepatic metabolism in humans depends on the individual drug but (with the exception of the thiobarbiturates) is usually slow. The elimination half-lives of secobarbital and pentobarbital range from 18 to 48 hours in different individuals. The elimination half-life of phenobarbital in humans is 4–5 days. Multiple dosing with these agents can lead to cumulative effects.

Excretion

The water-soluble metabolites of benzodiazepines and other sedative-hypnotics are excreted mainly via the kidney. In most cases, changes in renal function do not have a marked effect on the elimination of parent drugs. Phenobarbital is excreted unchanged in the urine to a certain extent (20–30% in humans), and its elimination rate can be increased significantly by alkalization of the urine. This is partly due to increased ionization at alkaline pH, since phenobarbital is a weak acid with a pK_a of 7.4. Only trace amounts of the benzodiazepines appear in the urine unchanged.

Factors Affecting Biodisposition

The biodisposition of sedative-hypnotics can be influenced by several factors, particularly alterations in hepatic function resulting from disease or drug-induced increases or decreases in microsomal enzyme activities (see Chapter 4: Drug Biotransformation).

In very old patients and in patients with severe liver disease, the elimination half-lives of these drugs are often increased significantly. In such cases, multiple normal doses of these sedative-hypnotics often result in excessive central nervous system effects.

The activity of hepatic microsomal drug-metabolizing enzymes may be increased in patients exposed to certain older sedative-hypnotics on a chronic basis (enzyme induction; see Chapter 4: Drug Biotransformation). Barbiturates (especially phenobarbital) and meprobamate are most likely to cause this effect, which may result in an increase in their hepatic metabolism as well as that of other drugs. Increased biotransformation of other pharmacologic agents as a result of enzyme induction by barbiturates is a potential mechanism underlying drug interactions (Appendix II). In contrast, the benzodiazepines do not change hepatic drug-metabolizing enzyme activity with continuous use.

Pharmacodynamics of Benzodiazepines & Barbiturates

Molecular Pharmacology of the GABA_A Receptor

The benzodiazepines, the barbiturates, zolpidem, and many other drugs bind to molecular components of the GABA_A receptor present in neuronal membranes in the central nervous system. This receptor, which functions as a chloride ion channel, is activated by the inhibitory neurotransmitter GABA (see Chapter 21: Introduction to the Pharmacology of CNS Drugs).

The GABA_A receptor has a pentameric structure assembled from five subunits (each with four transmembrane-spanning domains) selected from multiple polypeptide classes (α , β , γ , δ , ϵ , π , σ , etc). Different subunits of several of these classes have been characterized, eg, six different α , four β , and three γ . A major isoform of the GABA_A receptor found in many regions of the brain consists of two α_1 and two β_2 subunits and one γ_2 subunit. In this receptor isoform, the binding site for GABA is located between an α_1 and a β_2 subunit and the binding pocket for benzodiazepines (a benzodiazepine receptor subtype, BZ₁ or α_1) is between an α_1 and the γ_2 subunit. However, GABA_A receptors in different areas of the central nervous system consist of various combinations of the essential subunits, and the benzodiazepines bind to many of these, including receptor isoforms containing α_2 , α_3 , and α_5 subunits. Barbiturates also bind to multiple isoforms of the GABA_A receptor but at different sites from those with which benzodiazepines interact. In contrast to benzodiazepines, zolpidem and zaleplon bind more selectively since these drugs only interact with GABA_A receptor isoforms that contain α_1 subunits (BZ₁ subtype). The heterogeneity of GABA_A receptors may constitute the molecular basis for the varied pharmacologic actions of benzodiazepines and related drugs (see GABA Receptor Heterogeneity & Pharmacologic Selectivity).

A model of the hypothetical GABA-BZ receptor-chloride ion channel macromolecular complex is shown in Figure 22–5.

Figure 22–5.

A model of the GABA_A receptor-chloride ion channel macromolecular complex (many others could be proposed). A heterooligomeric glycoprotein, the complex consists of five or more membrane-spanning subunits. Multiple forms of α , β , and γ subunits are arranged in different pentameric combinations so that GABA_A receptors exhibit molecular heterogeneity. GABA appears to interact with α or β subunits triggering chloride channel opening with resultant membrane hyperpolarization. Binding of benzodiazepines to γ subunits or to an area of the α unit influenced by the γ unit facilitates the process of channel opening but does not directly initiate chloride current. (Modified and reproduced, with permission, from Zorumsky CF, Isenberg KE: Insights into the structure and function of GABA-benzodiazepine receptors: Ion channels and psychiatry. Am J Psychiatry 1991;148:162.)

Neuropharmacology

Gamma-aminobutyric acid (GABA) is the major inhibitory neurotransmitter in the central nervous system. Electrophysiologic studies have shown that benzodiazepines potentiate GABAergic inhibition at all levels of the neuraxis, including the spinal cord, hypothalamus, hippocampus, substantia nigra, cerebellar cortex, and cerebral cortex. Benzodiazepines appear to increase the efficiency of GABAergic synaptic inhibition. The benzodiazepines do not substitute for GABA but appear to enhance GABA's effects without directly activating GABA receptors or opening the associated chloride channels. The enhancement in chloride ion conductance induced by the interaction of benzodiazepines with GABA takes the form of an increase in the *frequency* of channel-opening events

Barbiturates also facilitate the actions of GABA at multiple sites in the central nervous system, but—in contrast to benzodiazepines—they appear to increase the *duration* of the GABA-gated chloride channel openings. At high concentrations, the barbiturates may also be GABA-mimetic, directly activating chloride channels. These effects involve a binding site or sites distinct from the benzodiazepine binding sites. Barbiturates are less selective in their actions than benzodiazepines, since they also depress the actions of excitatory neurotransmitters (eg, glutamic acid) and exert nonsynaptic membrane effects in parallel with their effects on GABA neurotransmission. This

multiplicity of sites of action of barbiturates may be the basis for their ability to induce full surgical anesthesia (see Chapter 25: General Anesthetics) and for their more pronounced central depressant effects (which result in their low margin of safety) compared to benzodiazepines.

Benzodiazepine Receptor Ligands

The components of the GABA_A receptor-chloride ion channel macromolecule that function as benzodiazepine receptors exhibit heterogeneity and include BZ₁ (α_1) and BZ₂ (α_2) subtypes (see The Versatility of the Chloride Channel GABA Receptor Complex). Three types of ligand-benzodiazepine receptor interactions have been reported: **(1) Agonists** facilitate GABA actions, and this occurs at multiple BZ receptor sites in the case of the benzodiazepines. The nonbenzodiazepines zolpidem and zaleplon are selective agonists at the BZ₁ (α_1) receptor subtype. Endogenous agonist ligands for the BZ receptors have been proposed, since benzodiazepine-like chemicals have been isolated from brain tissue of animals never exposed to these drugs. Nonbenzodiazepine molecules that have affinity for benzodiazepine receptors have also been detected in human brain. Such "endozepines" facilitate GABA-mediated chloride channel gating in cultured neurons. **(2) Antagonists** are typified by the synthetic benzodiazepine derivative flumazenil, which blocks the actions of benzodiazepines and zolpidem but does not antagonize the actions of barbiturates, meprobamate, or ethanol. Certain endogenous compounds, eg, diazepam-binding inhibitor (DBI), are also capable of blocking the interaction of benzodiazepines with benzodiazepine receptors. **(3) Inverse agonists** act as negative allosteric modulators of GABA receptor function. Their interaction with benzodiazepine receptors can produce anxiety and seizures, an action that has been demonstrated for several compounds, especially the β -carbolines, eg, *n*-butyl- β -carboline-3-carboxylate (β -CCB). In addition to their direct actions, these molecules can block the effects of benzodiazepines.

The physiologic significance of endogenous modulators of the functions of GABA in the central nervous system remains unclear. To date it has not been established that the putative endogenous ligands of BZ receptors play a role in the control of states of anxiety, sleep patterns, or any other characteristic behavioral expression of central nervous system function.

Organ Level Effects

Sedation

Benzodiazepines, barbiturates, and most older sedative-hypnotic drugs exert calming effects with concomitant reduction of anxiety at relatively low doses. In most cases, however, the anxiolytic actions of sedative-hypnotics are accompanied by some decremental effects on psychomotor and cognitive functions. In experimental animal models, sedative-hypnotic drugs are able to disinhibit punishment-suppressed behavior. This disinhibition has been equated with antianxiety effects of sedative-hypnotics, and it is not a characteristic of all drugs that have sedative effects, eg, the tricyclic antidepressants and antihistamines. However, the disinhibition of previously suppressed behavior may be more related to behavioral disinhibitory effects of sedative-hypnotics, including euphoria, impaired judgment, and loss of self-control, which can occur at dosages in the range of those used for management of anxiety. The benzodiazepines also exert dose-dependent anterograde amnesic effects (inability to remember events occurring during the drug's duration of action).

Hypnosis

By definition, all of the sedative-hypnotics will induce sleep if high enough doses are given. The effects of sedative-hypnotics on the stages of sleep depend on several factors, including the specific

drug, the dose, and the frequency of its administration. The effects of benzodiazepines and older sedative-hypnotics on patterns of normal sleep are as follows: (1) the latency of sleep onset is decreased (time to fall asleep); (2) the duration of stage 2 NREM sleep is increased; (3) the duration of REM sleep is decreased; and (4) the duration of stage 4 NREM slow-wave sleep is decreased. Zolpidem also decreases REM sleep but has minimal effect on slow-wave sleep. Zaleplon decreases the latency of sleep onset with little effect on total sleep time, NREM, or REM sleep.

More rapid onset of sleep and prolongation of stage 2 are presumably clinically useful effects. However, the significance of sedative-hypnotic drug effects on REM and slow-wave sleep is not clear. Deliberate interruption of REM sleep causes anxiety and irritability followed by a rebound increase in REM sleep at the end of the experiment. A similar pattern of "REM rebound" can be detected following abrupt cessation of drug treatment with sedative-hypnotics, especially when drugs with short durations of action are used at high doses. Despite possible reductions in slow-wave sleep, there are no reports of disturbances in the secretion of pituitary or adrenal hormones when either barbiturates or benzodiazepines are used as hypnotics. The use of sedative-hypnotics for more than 1–2 weeks leads to some tolerance to their effects on sleep patterns.

Anesthesia

As shown in Figure 22–1, certain sedative-hypnotics in high doses will depress the central nervous system to the point known as stage III of general anesthesia (see Chapter 25: General Anesthetics). However, the suitability of a particular agent as an adjunct in anesthesia depends mainly on the physicochemical properties that determine its rapidity of onset and duration of effect. Among the barbiturates, thiopental and methohexital are very lipid-soluble, penetrating brain tissue rapidly following intravenous administration, a characteristic favoring their use for induction of the anesthetic state. Rapid tissue redistribution accounts for the short duration of action of these drugs, a feature useful in recovery from anesthesia.

Benzodiazepines—including diazepam, lorazepam, and midazolam—are used intravenously in anesthesia (see Chapter 25: General Anesthetics), often in combination with other agents. Not surprisingly, benzodiazepines given in large doses as adjuncts to general anesthetics may contribute to a persistent postanesthetic respiratory depression. This is probably related to their relatively long half-lives and the formation of active metabolites.

Anticonvulsant Effects

Most of the sedative-hypnotics are capable of inhibiting the development and spread of epileptiform activity in the central nervous system. Some selectivity exists in that some members of the group can exert anticonvulsant effects without marked central nervous system depression (although psychomotor function may be impaired). Several benzodiazepines—including clonazepam, nitrazepam, lorazepam, and diazepam—are sufficiently selective to be clinically useful in the management of seizure states (see Chapter 24: Antiseizure Drugs). Of the barbiturates, phenobarbital and metharbital (converted to phenobarbital in the body) are effective in the treatment of generalized tonic-clonic seizures.

Muscle Relaxation

Some sedative-hypnotics, particularly members of the carbamate and benzodiazepine groups, exert inhibitory effects on polysynaptic reflexes and internuncial transmission and at high doses may also depress transmission at the skeletal neuromuscular junction. Somewhat selective actions of this type that lead to muscle relaxation can be readily demonstrated in animals and have led to claims of

usefulness for relaxing contracted voluntary muscle in joint disease or muscle spasm (see Clinical Pharmacology).

Effects on Respiration and Cardiovascular Function

At hypnotic doses in healthy patients, the effects of sedative-hypnotics on respiration are comparable to changes during natural sleep. However, even at therapeutic doses, sedative-hypnotics can produce significant respiratory depression in patients with pulmonary disease. Effects on respiration are dose-related, and depression of the medullary respiratory center is the usual cause of death due to overdose of sedative-hypnotics.

At doses up to those causing hypnosis, no significant effects on the cardiovascular system are observed in healthy patients. However, in hypovolemic states, heart failure, and other diseases that impair cardiovascular function, normal doses of sedative-hypnotics may cause cardiovascular depression, probably as a result of actions on the medullary vasomotor centers. At toxic doses, myocardial contractility and vascular tone may both be depressed by central and peripheral effects, leading to circulatory collapse. Respiratory and cardiovascular effects are more marked when sedative-hypnotics are given intravenously.

Tolerance; Psychologic & Physiologic Dependence

Tolerance—decreased responsiveness to a drug following repeated exposure—is a common feature of sedative-hypnotic use. It may result in an increase in the dose needed to maintain symptomatic improvement or to promote sleep. It is important to recognize that partial cross-tolerance occurs between the sedative-hypnotics described here and also with ethanol (Chapter 23: The Alcohols)—a feature of some clinical importance, as explained below. The mechanisms responsible for tolerance to sedative-hypnotics are not well understood. An increase in the rate of drug metabolism (metabolic tolerance) may be partly responsible in the case of chronic administration of barbiturates, but changes in responsiveness of the central nervous system (pharmacodynamic tolerance) are of greater importance for most sedative-hypnotics. In the case of benzodiazepines, the development of tolerance in animals is associated with down-regulation of brain benzodiazepine receptors.

The perceived desirable properties of relief of anxiety, euphoria, disinhibition, and promotion of sleep have led to the compulsive misuse of virtually all sedative-hypnotics. For this reason, most sedative-hypnotic drugs are classified as Schedule III or Schedule IV drugs for prescribing purposes. (See Chapter 32: Drugs of Abuse for a detailed discussion.) The consequences of abuse of these agents can be defined in both psychologic and physiologic terms. The psychologic component may initially parallel simple neurotic behavior patterns difficult to differentiate from those of the inveterate coffee drinker or cigarette smoker. When the pattern of sedative-hypnotic use becomes compulsive, more serious complications develop, including physiologic dependence and tolerance.

Physiologic dependence can be described as an altered physiologic state that requires continuous drug administration to prevent the appearance of an abstinence or withdrawal syndrome. In the case of sedative-hypnotics, this syndrome is characterized by states of increased anxiety, insomnia, and central nervous system excitability that may progress to convulsions. Most sedative-hypnotics—including benzodiazepines—are capable of causing physiologic dependence when used on a chronic basis. However, the severity of withdrawal symptoms differs between individual drugs and depends also on the magnitude of the dose used immediately prior to cessation of use. When higher doses of sedative-hypnotics are used, abrupt withdrawal leads to more serious withdrawal signs. Differences in the severity of withdrawal symptoms between individual sedative-hypnotics relate in part to half-

life, since drugs with long half-lives are eliminated slowly enough to accomplish gradual withdrawal with few physical symptoms. The use of drugs with very short half-lives for hypnotic effects may lead to signs of withdrawal even between doses. For example, triazolam, a benzodiazepine with a half-life of about 4 hours, has been reported to cause daytime anxiety when used to treat sleep disorders.

Benzodiazepine Antagonists: Flumazenil

Flumazenil is one of several 1,4-benzodiazepine derivatives with high affinity for the benzodiazepine receptor that act as competitive antagonists. It is the only benzodiazepine receptor antagonist available for clinical use at present. It blocks many of the actions of benzodiazepines (and imidazopyridines) but does not antagonize the central nervous system effects of other sedative-hypnotics, ethanol, opioids, or general anesthetics. Flumazenil is approved for use in reversing the central nervous system depressant effects of benzodiazepine overdose and to hasten recovery following use of these drugs in anesthetic and diagnostic procedures. While the drug reverses the sedative effects of benzodiazepines, antagonism of benzodiazepine-induced respiratory depression is less predictable. When given intravenously, flumazenil acts rapidly but has a short half-life (0.7–1.3 hours) due to rapid hepatic clearance. Since all benzodiazepines have a longer duration of action than flumazenil, sedation commonly recurs, requiring repeated administration of the antagonist.

Adverse effects of flumazenil include agitation, confusion, dizziness, and nausea. Flumazenil may cause a severe precipitated abstinence syndrome in patients who have developed physiologic benzodiazepine dependence. In patients who have ingested benzodiazepines with tricyclic antidepressants, seizures and cardiac arrhythmias may occur following flumazenil administration. Transient improvement in mental status has been reported with flumazenil when used in patients with hepatic encephalopathy.

Newer Drugs for Anxiety & Sleep Disorders

Although the benzodiazepines continue to be widely used in the treatment of anxiety states and for insomnia, their adverse effects include daytime sedation and drowsiness, synergistic depression of the central nervous system with other drugs (especially alcohol), and the possibility of psychologic and physiologic dependence with repeated use. Anxiolytic drugs that act through non-GABAergic systems might have a reduced propensity for such actions. Several nonbenzodiazepines, including buspirone, have such characteristics. In addition, the newer hypnotics zolpidem and zaleplon are more selective in their central actions even though they appear to act through benzodiazepine receptors.

Buspirone

Buspirone has selective anxiolytic effects, and its pharmacologic characteristics are quite different from those of other drugs described in this chapter. Buspirone relieves anxiety without causing marked sedative or euphoric effects. Unlike benzodiazepines, the drug has no hypnotic, anticonvulsant, or muscle relaxant properties. Buspirone does not interact directly with GABAergic systems. It may exert its anxiolytic effects by acting as a partial agonist at brain 5-HT_{1A} receptors, but it also has affinity for brain dopamine D₂ receptors. Buspirone-treated patients show no rebound anxiety or withdrawal signs on abrupt discontinuance. The drug is not effective in blocking the acute withdrawal syndrome resulting from abrupt cessation of use of benzodiazepines or other sedative-hypnotics. Buspirone has minimal abuse liability. In marked contrast to the benzodiazepines, the anxiolytic effects of buspirone may take more than a week to become established, making the drug unsuitable for management of acute anxiety states. The drug is used in

generalized anxiety states but is not very effective in panic disorders.

Buspirone is rapidly absorbed orally but undergoes extensive first-pass metabolism via hydroxylation and dealkylation reactions to form several active metabolites. The major metabolite is 1-(2-pyrimidyl)-piperazine (1-PP), which has α_2 -adrenoceptor-blocking actions and which enters the central nervous system to reach higher levels than the parent drug. It is not known what role (if any) 1-PP plays in the central actions of buspirone. The elimination half-life of buspirone is 2–4 hours, and liver dysfunction may decrease its clearance. Rifampin, an inducer of cytochrome P450, decreases the half-life of buspirone; inhibitors of CYP3A4 (eg, erythromycin, ketoconazole) increase plasma levels of buspirone.

Buspirone causes less psychomotor impairment than diazepam and does not affect driving skills. The drug does not potentiate the central nervous system depressant effects of conventional sedative-hypnotic drugs, ethanol, or tricyclic antidepressants, and elderly patients do not appear to be more sensitive to its actions. Tachycardia, palpitations, nervousness, gastrointestinal distress, and paresthesias may occur more frequently than with benzodiazepines. Buspirone also causes a dose-dependent pupillary constriction. Blood pressure may be elevated in patients receiving MAO inhibitors. A number of buspirone analogs have been developed (eg, **ipsapirone**, **gepirone**, **tandospirone**) and are under study.

Zolpidem

Zolpidem, an imidazopyridine derivative structurally unrelated to benzodiazepines, has hypnotic actions. The drug binds selectively to the BZ₁ (α_1) subtype of benzodiazepine receptors that contain α_1 subunits and facilitates GABA-mediated neuronal inhibition. Like the benzodiazepines, the actions of zolpidem are antagonized by flumazenil. Unlike benzodiazepines, zolpidem has minimal muscle relaxing and anticonvulsant effects. However, amnestic effects have been reported with use of doses greater than recommended. The drug has a rapid onset of action, and its duration of hypnotic action is close to that of triazolam. Zolpidem causes minor effects on sleep patterns at the recommended hypnotic dose but can suppress REM sleep at higher doses. Rebound insomnia may occur on abrupt discontinuance of higher doses. Respiratory depression occurs if large doses of zolpidem are ingested with other CNS depressants, including ethanol.

The risk of development of tolerance and dependence with extended use of zolpidem appears to be less than with the use of hypnotic benzodiazepines. Zolpidem is rapidly metabolized to inactive metabolites by the liver via oxidation and hydroxylation. The elimination half-life of the drug is 1.5–3.5 hours, with clearance decreased in elderly patients. Dosage reductions are recommended in patients with hepatic dysfunction, in elderly patients, and in patients taking cimetidine. Rifampin, an inducer of hepatic cytochrome P450, decreases the half-life of zolpidem.

Zaleplon

Zaleplon binds selectively to the BZ₁ receptor subtype, facilitating the inhibitory actions of GABA. Zaleplon is rapidly absorbed from the gastrointestinal tract and has an elimination half-life of about 1 hour. The drug is metabolized to inactive metabolites mainly by hepatic aldehyde oxidase and partly by the cytochrome P450 isoform CYP3A4. Dosage should be reduced in patients with hepatic impairment and in the elderly. Metabolism of zaleplon is inhibited by cimetidine; drugs that induce hepatic CYP3A4 increase the clearance of zaleplon.

Zaleplon decreases sleep latency but has little effect on total sleep time or on sleep architecture. Rapid onset and short duration of action are favorable properties for those patients who have

difficulty falling asleep. Amnestic effects and next-day impairment of psychomotor performance may occur, but less commonly than in the case of hypnotic benzodiazepines or zolpidem. The risk of development of tolerance and of withdrawal symptoms indicative of physiologic dependence appears to be low, but the use of high doses (twice the recommended dose) has caused rebound insomnia. Zaleplon potentiates the CNS depressant effects of ethanol and other sedative-hypnotics.

Older Sedative-Hypnotics

These drugs include alcohols (**ethchlorvynol, chloral hydrate**), piperidinediones (**glutethimide, methyprylon**), and carbamates (**meprobamate**). They are rarely used in therapy, though the low cost of chloral hydrate makes it attractive for institutional use. Little is known about their molecular mechanisms of action. Most of these drugs are biotransformed to more water-soluble compounds by hepatic enzymes. Trichloroethanol is the pharmacologically active metabolite of chloral hydrate and has a half-life of 6–10 hours. However, its toxic metabolite, trichloroacetic acid, is cleared very slowly and can accumulate with the nightly administration of chloral hydrate.

Katzung PHARMACOLOGY, 9e > Section V. Drugs That Act in the Central Nervous System > Chapter 22. Sedative-Hypnotic Drugs >

GABA Receptor Heterogeneity & Pharmacologic Selectivity

Studies involving genetically engineered mice have demonstrated that the specific pharmacologic actions elicited by benzodiazepines and other drugs that modulate GABA actions are influenced by the composition of the subunits assembled to form the GABA_A receptor. Benzodiazepines only interact with brain GABA_A receptors in which the α subunits (1,2,3, and 5) have a conserved histidine residue in the N-terminal domain. Strains of mice in which a point mutation has been inserted ("knock-in" strategy), converting histidine to arginine in the α_1 subunit, show resistance to both the sedative and amnestic effects of benzodiazepines, but anxiolytic and muscle relaxing effects are largely unchanged. These animals are also unresponsive to the hypnotic actions of zolpidem and zaleplon, drugs that bind selectively to GABA_A receptors containing α_1 subunits. In contrast, mice with selective histidine-arginine mutations in the α_2 subunit of GABA_A receptors show selective resistance to the antianxiety effects of benzodiazepines. Based on studies of this type it has been suggested that α_1 subunits in GABA_A receptors mediate sedation, amnesia and possibly antiseizure effects of benzodiazepines, while α_2 subunits are involved in their anxiolytic and muscle-relaxing actions. Other transgenic studies have led to suggestions that an α_5 subtype is involved in at least some of the memory impairment caused by benzodiazepines. It should be noted that these studies involving genetic manipulations of the GABA_A receptor utilize rodent models of the anxiolytic and amnestic actions of drugs.

Katzung PHARMACOLOGY, 9e > Section V. Drugs That Act in the Central Nervous System > Chapter 22. Sedative-Hypnotic Drugs >

The Versatility of the Chloride Channel GABA Receptor Complex

The GABA_A-chloride channel macromolecular complex is one of the most versatile drug-responsive machines in the body. In addition to the benzodiazepines, barbiturates and zolpidem, many other drugs with central nervous system effects can modify the function of this important ionotropic receptor. These include alcohol, alphaxolone (a steroid anesthetic), etomidate and propofol (intravenous anesthetics), volatile anesthetics (eg, halothane), several anticonvulsants (eg, gabapentin, vigabatrin), and ivermectin (an anthelmintic agent). Most of these agents facilitate or mimic the action of GABA. (It must be noted that it has not been shown that these drugs act exclusively or even primarily by this mechanism.) Central nervous system excitatory agents that act on the chloride channel include picrotoxin and bicuculline. These convulsant drugs block the

channel directly (picrotoxin) or interfere with GABA binding (bicuculline).

Katzung PHARMACOLOGY, 9e > Section V. Drugs That Act in the Central Nervous System > Chapter 22. Sedative-Hypnotic Drugs >

Clinical Pharmacology of Sedative-Hypnotics

Treatment of Anxiety States

The psychologic, behavioral, and physiologic responses that characterize anxiety can take many forms. Typically, the psychic awareness of anxiety is accompanied by enhanced vigilance, motor tension, and autonomic hyperactivity. Before prescribing sedative-hypnotics, one should analyze the patient's symptoms carefully. Anxiety is in many cases secondary to organic disease states—acute myocardial infarction, angina pectoris, gastrointestinal ulcers, etc—which themselves require specific therapy. Another class of secondary anxiety states (situational anxiety) results from circumstances that may have to be dealt with only once or a few times, including anticipation of frightening medical or dental procedures and family illness or other tragedy. Even though situational anxiety tends to be self-limiting, the short-term use of sedative-hypnotics may be appropriate for the treatment of this and certain disease-associated anxiety states. Similarly, the use of a sedative-hypnotic as premedication prior to surgery or some unpleasant medical procedure is rational and proper (Table 22–2). If the patient presents with chronic anxiety as the primary complaint, it may be appropriate to review the diagnostic criteria set forth in the *Diagnostic & Statistical Manual of Mental Disorders (DSM IV)* to determine whether the diagnosis is correct and if treatment should include drug therapy. For example, excessive or unreasonable anxiety about life circumstances (generalized anxiety disorder), panic disorders, and agoraphobia are amenable to drug therapy, usually in conjunction with psychotherapy. In many cases, anxiety is a symptom of psychiatric problems that may warrant the use of antidepressant or antipsychotic drugs.

Table 22–2. Clinical Uses of Sedative-Hypnotics.

For relief of anxiety
For insomnia
For sedation and amnesia before medical and surgical procedures
For treatment of epilepsy and seizure states
As a component of balanced anesthesia (intravenous administration)
For control of ethanol or other sedative-hypnotic withdrawal states
For muscle relaxation in specific neuromuscular disorders
As diagnostic aids or for treatment in psychiatry

The benzodiazepines continue to be widely used for the management of anxiety states. Since anxiety symptoms may be relieved by many benzodiazepines, it is not always easy to demonstrate the superiority of one drug over another. However, alprazolam is particularly effective in the treatment of panic disorders and agoraphobia and is more selective in this regard than other benzodiazepines. The choice of benzodiazepines for anxiety is based on several sound pharmacologic principles: (1) a relatively high therapeutic index (see drug B in Figure 22–1), plus availability of flumazenil for treatment of overdose; (2) a low risk of drug interactions based on liver enzyme induction; (3) slow elimination rates, which may favor persistence of useful CNS

effects.

Disadvantages of the benzodiazepines include the risk of psychologic dependence, the formation of active metabolites, amnesic effects, and their cost. In addition, the benzodiazepines exert additive central nervous system depression when administered with other drugs, including ethanol. The patient should be warned of this possibility to avoid impairment of performance of any task requiring mental alertness and motor coordination. Many of the disadvantages of benzodiazepines are not shared by buspirone, which appears to be a more selective drug. However, limitations of buspirone include the slow onset of its anxiolytic actions—confining its use to generalized anxiety—and its limited efficacy in anxiety states that feature panic attacks and phobic characteristics. In the treatment of generalized anxiety disorders and certain phobias, newer antidepressants such as paroxetine and venlafaxine are now considered by many authorities to be drugs of first choice (see Chapter 30: Antidepressant Agents). However, these agents have minimal effectiveness in acute anxiety states.

Sedative-hypnotics should be used with appropriate caution so as to minimize adverse effects. A dose should be prescribed that does not impair mentation or motor functions during waking hours. Some patients may tolerate the drug better if most of the daily dose is given at bedtime, with smaller doses during the day. Prescriptions should be written for short periods, since there is little justification for long-term therapy. The physician should make an effort to assess the efficacy of therapy from the patient's subjective responses. Combinations of antianxiety agents should be avoided, and people taking sedatives should be cautioned about the consumption of alcohol and the concurrent use of over-the-counter medications containing antihistaminic or anticholinergic drugs (see Chapter 64: Therapeutic & Toxic Potential of Over-the-Counter Agents).

Phenobarbital, meprobamate, and sedative-autonomic drugs are used occasionally as antianxiety agents. The antihistaminics (diphenhydramine, hydroxyzine, promethazine) continue to be used presurgically for their sedative and muscarinic receptor blocking actions.

Beta-blocking drugs (eg, propranolol) may be used as antianxiety agents in situations such as performance anxiety. The sympathetic nervous system overactivity associated with anxiety appears to be satisfactorily relieved by the β blockers, and a slight improvement in the nonsomatic components of anxiety may also occur. Adverse central nervous system effects of propranolol include lethargy, vivid dreams, and hallucinations.

Treatment of Sleep Problems

Nonpharmacologic therapies that are sometimes useful for sleep problems include proper diet and exercise, avoiding stimulants before retiring, ensuring a comfortable sleeping environment, and retiring at a regular time each night. In some cases, however, the patient will need and should be given a sedative-hypnotic for a limited period. It should be noted that the abrupt discontinuance of most drugs in this class can lead to rebound insomnia.

Benzodiazepines can cause a dose-dependent decrease in both REM and slow wave sleep, though to a lesser extent than the barbiturates. Zolpidem and zaleplon are less likely than the benzodiazepines to change sleep patterns. However, so little is known about the clinical impact of these effects that statements about the desirability of a particular drug based on its effects on sleep architecture have more theoretical than practical significance. Clinical criteria of efficacy in alleviating a particular sleeping problem are more useful. The drug selected should be one that provides sleep of fairly rapid onset (decreased sleep latency) and sufficient duration, with minimal "hangover" effects such as drowsiness, dysphoria, and mental or motor depression the following day. Older drugs such as

chloral hydrate, secobarbital, and pentobarbital continue to be used, but benzodiazepines, zolpidem, or zaleplon are generally preferred. Daytime sedation is more common with benzodiazepines that have slow elimination rates (eg, lorazepam) and those that are biotransformed to active metabolites (eg, flurazepam, quazepam). If hypnotics are used nightly, tolerance can occur, which may lead to dose increases by the patient to produce the desired effect.

Anterograde amnesia occurs to some degree with all hypnotic benzodiazepines. Zaleplon and zolpidem have efficacies similar to those of the hypnotic benzodiazepines in the management of sleep disorders. Favorable clinical features of zolpidem include modest day-after psychomotor depression with few amnestic effects. Zolpidem is currently the most frequently prescribed hypnotic drug in the United States. Zaleplon acts rapidly, and because of its short half-life the drug appears to have value in the management of patients who awaken early in the sleep cycle. At recommended doses, zaleplon appears to cause less amnesia or day-after somnolence than zolpidem or benzodiazepines. The drugs commonly used for sedation and hypnosis are listed in Table 22–3 together with recommended doses. **Note:** Long-term use of hypnotics is irrational and dangerous medical practice.

Sedation		Hypnosis	
Drug	Dosage	Drug	Dosage (at Bedtime)
Alprazolam (Xanax)	0.25–0.5 mg 2–3 times daily	Chloral hydrate	500–1000 mg
Bupirone (BuSpar)	5–10 mg 2–3 times daily	Estazolam (ProSom)	0.5–2 mg
Chlordiazepoxide (Librium)	10–20 mg 2–3 times daily	Flurazepam (Dalmane)	15–30 mg
Clorazepate (Tranxene)	5–7.5 mg twice daily	Lorazepam (Ativan)	2–4 mg
Diazepam (Valium)	5 mg twice daily	Quazepam (Doral)	7.5–15 mg
Halazepam (Paxipam)	20–40 mg 3–4 times daily	Secobarbital	100–200 mg
Lorazepam (Ativan)	1–2 mg once or twice daily	Temazepam (Restoril)	7.5–30 mg
Oxazepam (Serax)	15–30 mg 3–4 times daily	Triazolam (Halcion)	0.125–0.5 mg
Phenobarbital	15–30 mg 2–3 times daily	Zaleplon (Sonata)	5–20 mg
Prazepam (Centrax)	10–20 mg 2–3 times daily	Zolpidem (Ambien)	5–10 mg

Other Therapeutic Uses

Table 22–2 summarizes several other important clinical uses of drugs in the sedative-hypnotic class. Drugs used in the management of seizure disorders and as intravenous agents in anesthesia are discussed in Chapter 24: Antiseizure Drugs and Chapter 25: General Anesthetics.

For sedative and possible amnestic effects during medical or surgical procedures such as endoscopy and bronchoscopy—as well as for premedication prior to anesthesia—oral formulations of shorter-

acting drugs are preferred.

Long-acting drugs such as chlordiazepoxide and diazepam and, to a lesser extent, phenobarbital are administered in progressively decreasing doses to patients during withdrawal from physiologic dependence on ethanol or other sedative-hypnotics.

Meprobamate and, more recently, the benzodiazepines have frequently been used as central muscle relaxants, though evidence for general efficacy without accompanying sedation is lacking. A possible exception is diazepam, which has useful relaxant effects in skeletal muscle spasticity of central origin (see Chapter 27: Skeletal Muscle Relaxants).

Psychiatric uses of benzodiazepines other than treatment of anxiety states include the initial management of mania, the control of drug-induced hyperexcitability states (eg, phencyclidine intoxication), and possibly the treatment of major depressive disorders with alprazolam. Sedative-hypnotics are also used occasionally as diagnostic aids in neurology and psychiatry.

Clinical Toxicology of Sedative-Hypnotics

Direct Toxic Actions

Many of the common adverse effects of drugs in this class are those resulting from dose-related depression of central nervous system functions. Relatively low doses may lead to drowsiness, impaired judgment, and diminished motor skills, sometimes with a significant impact on driving ability, job performance, and personal relationships. Benzodiazepines may cause a significant dose-related anterograde amnesia; they can significantly impair ability to learn new information, particularly that involving effortful cognitive processes, while leaving the retrieval of previously learned information intact. This effect is utilized to clinical advantage in uncomfortable procedures, eg, endoscopy, since the appropriate dose leaves the patient able to cooperate during the procedure but amnesic regarding it afterward. The criminal use of benzodiazepines in cases of "date rape" is based on their dose-dependent amnesic effects. Hangover effects are not uncommon following use of hypnotic drugs with long elimination half-lives. Because elderly patients are more sensitive to the effects of sedative-hypnotics, doses approximately half of those used in younger adults are safer and usually as effective. The most common reversible cause of confusional states in the elderly is overuse of sedative-hypnotics. At higher doses, toxicity may present as lethargy or a state of exhaustion or, alternatively, in the form of gross symptoms equivalent to those of ethanol intoxication. The titration of useful therapeutic effects against such unwanted effects is usually more difficult with sedative-hypnotics that exhibit steep dose-response relationships of the type shown in Figure 22–1 (drug A), including the barbiturates, chloral hydrate, and piperidinediones. The physician should be aware of variability among patients in terms of doses causing adverse effects. An increased sensitivity to sedative-hypnotics is more common in patients with cardiovascular disease, respiratory disease, or hepatic impairment and in older patients. Sedative-hypnotics can exacerbate breathing problems in patients with chronic pulmonary disease and in those with symptomatic sleep apnea.

Sedative-hypnotics are the drugs most frequently involved in deliberate overdoses, in part because of their general availability as very commonly prescribed pharmacologic agents. The benzodiazepines are considered to be "safer" drugs in this respect, since they have flatter dose-response curves. Epidemiologic studies on the incidence of drug-related deaths support this general assumption—eg, 0.3 deaths per million tablets of diazepam prescribed versus 11.6 deaths per million capsules of secobarbital in one study. Of course, many factors other than the specific sedative-hypnotic could influence such data—particularly the presence of other central nervous

system depressants, including ethanol. In fact, most serious cases of drug overdosage, intentional or accidental, do involve polypharmacy; and when combinations of agents are taken, the practical safety of benzodiazepines may be less than the foregoing would imply.

The lethal dose of any sedative-hypnotic varies with the patient and the circumstances (see Chapter 59: Management of the Poisoned Patient). If discovery of the ingestion is made early and a conservative treatment regimen is started, the outcome is rarely fatal, even following very high doses. On the other hand, for most sedative-hypnotics—with the exception of benzodiazepines—a dose as low as ten times the hypnotic dose may be fatal if the patient is not discovered or does not seek help in time. With severe toxicity, the respiratory depression from central actions of the drug may be complicated by aspiration of gastric contents in the unattended patient—an even more likely occurrence if ethanol is present. Loss of brain stem vasomotor control, together with direct myocardial depression, further complicates successful resuscitation. In such patients, treatment consists of ensuring a patent airway, with mechanical ventilation if needed, and maintenance of plasma volume, renal output, and cardiac function. Use of a positive inotropic drug such as dopamine, which preserves renal blood flow, is sometimes indicated. Hemodialysis or hemoperfusion may be used to hasten elimination of some of these drugs.

Flumazenil reverses the sedative actions of benzodiazepines. However, its duration of action is short and its antagonism of respiratory depression unpredictable. Therefore, the use of flumazenil in benzodiazepine overdose *must* be accompanied by adequate monitoring and support of respiratory function.

The extensive clinical use of triazolam has led to reports of serious central nervous system effects including behavioral disinhibition, delirium, aggression, and violence. While behavioral disinhibition may occur with sedative-hypnotic drugs, it does not appear to be more prevalent with triazolam than with other benzodiazepines. Disinhibitory reactions during benzodiazepine treatment are more clearly associated with the use of very high doses and the pretreatment level of patient hostility.

Adverse effects of the sedative-hypnotics that are not referable to their CNS actions occur infrequently. Hypersensitivity reactions, including skin rashes, occur only occasionally with most drugs of this class. Reports of teratogenicity leading to fetal deformation following use of piperidinediones and certain benzodiazepines justify caution in the use of these drugs during pregnancy. Because barbiturates enhance porphyrin synthesis, they are *absolutely contraindicated* in patients with a history of acute intermittent porphyria, variegate porphyria, hereditary coproporphyria, or symptomatic porphyria.

Alterations in Drug Response

Depending on the dosage and the duration of use, tolerance occurs in varying degrees to many of the pharmacologic effects of sedative-hypnotics. However, it should not be assumed that the degree of tolerance achieved is identical for all pharmacologic effects. There is evidence that the lethal dose range is not altered significantly by the chronic use of sedative-hypnotics. Cross-tolerance between the different sedative-hypnotics, including ethanol, can lead to an unsatisfactory therapeutic response when standard doses of a drug are used in a patient with a recent history of excessive use of these agents. However, there have been few reports of tolerance development when zolpidem or zaleplon was used for less than 4 weeks.

With the chronic use of sedative-hypnotics, especially if doses are increased, a state of physiologic dependence can occur. This may develop to a degree unparalleled by any other drug group,

including the opioids. Withdrawal from a sedative-hypnotic can have severe and life-threatening manifestations. Withdrawal symptoms range from restlessness, anxiety, weakness, and orthostatic hypotension to hyperactive reflexes and generalized seizures. The severity of withdrawal symptoms depends to a large extent on the dosage range used immediately prior to discontinuance but also on the particular drug. Symptoms of withdrawal are usually more severe following discontinuance of sedative-hypnotics with shorter half-lives. (Zolpidem and zaleplon appear to be exceptions to this, because withdrawal symptoms are minimal following abrupt discontinuance of these newer short-acting agents.) Symptoms are less pronounced with longer-acting drugs, which may partly accomplish their own "tapered" withdrawal by virtue of their slow elimination. Cross-dependence, defined as the ability of one drug to suppress abstinence symptoms from discontinuance of another drug, is quite marked among sedative-hypnotics. This provides the rationale for therapeutic regimens in the management of withdrawal states: Longer-acting drugs such as chlordiazepoxide, diazepam, and phenobarbital can be used to alleviate withdrawal symptoms of shorter-acting drugs, including ethanol.

Drug Interactions

The most frequent drug interactions involving sedative-hypnotics are interactions with other central nervous system depressant drugs, leading to additive effects. These interactions have some therapeutic utility with respect to the use of these drugs as premedicants or anesthetic adjuvants. However, if not anticipated, they can lead to serious consequences, including enhanced depression with concomitant use of many other drugs. Additive effects can be predicted with concomitant use of alcoholic beverages, opioid analgesics, anticonvulsants, and phenothiazines. Less obvious but just as important is enhanced central nervous system depression with a variety of antihistamines, antihypertensive agents, and antidepressant drugs of the tricyclic class.

Interactions involving changes in the activity of hepatic drug-metabolizing enzyme systems have been discussed (see also Chapter 4: Drug Biotransformation and Appendix II).

Katzung PHARMACOLOGY, 9e > Section V. Drugs That Act in the Central Nervous System > Chapter 22. Sedative-Hypnotic Drugs >

Preparations Available

Benzodiazepines

Alprazolam (generic, Xanax)

Oral: 0.25, 0.5, 1, 2 mg tablets; 0.1, 1.0 mg/mL solution

Chlordiazepoxide (generic, Librium)

Oral: 5, 10, 25 mg capsules; 10, 25 mg tablets

Parenteral: 100 mg powder for injection

Clorazepate (generic, Tranxene)

Oral: 3.75, 7.5, 15 mg tablets and capsules

Oral sustained-release: 11.25, 22.5 mg tablets

Clonazepam (Klonopin)

Oral: 0.5, 1, 2 mg tablets

Diazepam (generic, Valium)

Oral: 2, 5, 10 mg tablets; 1, 5 mg/mL solutions

Parenteral: 5 mg/mL for injection

Estazolam (generic, ProSom)

Oral: 1, 2 mg tablets

Flurazepam (generic, Dalmane)

Oral: 15, 30 mg capsules

Halazepam (Paxipam)

Oral: 20, 40 mg tablets

Lorazepam (generic, Ativan, Alzapam)

Oral: 0.5, 1, 2 mg tablets; 2 mg/mL solution

Parenteral: 2, 4 mg/mL for injection

Midazolam (Versed)

Oral: 2 mg/mL syrup

Parenteral: 1, 5 mg/mL in 1, 2, 5, 10 mL vials for injection

Oxazepam (generic, Serax)

Oral: 10, 15, 30 mg capsules, 15 mg tablets

Quazepam (Doral)

Oral: 7.5, 15 mg tablets

Temazepam (generic, Restoril)

Oral: 7.5, 15, 30 mg capsules

Triazolam (generic, Halcion)

Oral: 0.125, 0.25 mg tablets

Benzodiazepine Antagonist

Flumazenil (Romazicon)

Parenteral: 0.1 mg/mL for IV injection

Barbiturates

Amobarbital (Amytal)

Parenteral: powder in 250, 500 mg vials to reconstitute for injection

Pentobarbital (generic, Nembutal Sodium)

Oral: 50, 100 mg capsules; 4 mg/mL elixir

Rectal: 30, 60, 120, 200 mg suppositories

Parenteral: 50 mg/mL for injection

Phenobarbital (generic, Luminal Sodium)

Oral: 15, 16, 30, 60, 90, 100 mg tablets; 16 mg capsules; 15, 20 mg/5 mL elixirs

Parenteral: 30, 60, 65, 130 mg/mL for injection

Secobarbital (generic, Seconal)

Oral: 100 mg capsules

Miscellaneous Drugs

Bupirone (BuSpar)

Oral: 5, 10, 15 mg tablets

Chloral hydrate (generic, Aquachloral Suppettes)

Oral: 500 mg capsules; 250, 500 mg/5 mL syrups

Rectal: 324, 500, 648 mg suppositories

Ethchlorvynol (Placidyl)

Oral: 200, 500, 750 mg capsules

Hydroxyzine (generic, Atarax, Vistaril)

Oral: 10, 25, 50, 100 mg tablets; 25, 50, 100 mg capsules; 10 mg/5 mL syrup; 25 mg/5 mL suspension

Parenteral: 25, 50 mg/mL for injection

Meprobamate (generic, Equanil, Miltown)

Oral: 200, 400 mg tablets

Oral sustained-release: 200, 400 mg capsules

Paraldehyde (generic)

Oral, rectal liquids

Zaleplon (Sonata)

Oral: 5, 10 mg capsules

Zolpidem (Ambien)

Oral: 5, 10 mg tablets

Chapter 23. The Alcohols

Katzung PHARMACOLOGY, 9e > Section V. Drugs That Act in the Central Nervous System > Chapter 23. The Alcohols >

The Alcohols: Introduction

Alcohol, primarily in the form of ethyl alcohol (ethanol), has occupied an important place in the history of humankind for at least 8000 years. In Western society, beer and wine were a main staple of daily life until the 19th century. These relatively dilute alcoholic beverages were preferred over water, which was known to be associated with acute and chronic illness. They provided important calories and nutrients and served as a main source of daily liquid intake. As systems for improved sanitation and water purification were introduced in the 1800s, beer and wine became less important as components of the human diet, and the consumption of alcoholic beverages, including distilled preparations with higher concentrations of alcohol, shifted toward their present-day role (in many societies) as a socially acceptable form of recreation.

Today, alcohol is widely consumed. Like other sedative-hypnotic drugs, alcohol in low to moderate amounts relieves anxiety and fosters a feeling of well-being or even euphoria. However, alcohol is also the most commonly abused drug in the world, a cause of vast medical and societal costs. In the United States, approximately 75% of the adult population drinks alcohol regularly. The majority of this drinking population is able to enjoy the pleasurable effects of alcohol without allowing their alcohol consumption to become a health risk. However, about 10% of the general population in the United States are unable to limit their ethanol consumption, a condition known as alcohol abuse.

People who continue to drink alcohol in spite of adverse medical or social consequences related directly to their alcohol consumption suffer from **alcoholism**, a complex disorder that appears to have genetic as well as environmental determinants. The societal and medical costs of alcohol abuse are staggering. It is estimated that about 30% of all people admitted to hospitals have coexisting alcohol problems. Once in the hospital, people with chronic alcoholism generally have poorer outcomes. In addition, each year thousands of children are born in the USA with morphologic and functional defects resulting from prenatal exposure to ethanol. Despite the investment of many resources and much basic research, alcoholism remains a common chronic disease that is difficult to treat.

Ethanol and many other alcohols with potentially toxic effects are used in industry, some in enormous quantities. In addition to ethanol, methanol and ethylene glycol toxicity occur with sufficient frequency to warrant discussion in this chapter.

Katzung PHARMACOLOGY, 9e > Section V. Drugs That Act in the Central Nervous System > Chapter 23. The Alcohols >

Basic Pharmacology of Ethanol

Pharmacokinetics

Ethanol is a small water-soluble molecule that is absorbed rapidly from the gastrointestinal tract. After ingestion of alcohol in the fasting state, peak blood alcohol concentrations are reached within 30 minutes. The presence of food in the gut delays absorption by slowing gastric emptying. Distribution is rapid, with tissue levels approximating the concentration in blood. The volume of distribution for ethanol approximates total body water (0.5–0.7 L/kg). For an equivalent oral dose of alcohol, women have a higher peak concentration than men, in part because women have a lower total body water content. In the central nervous system, the concentration of ethanol rises quickly since the brain receives a large proportion of blood flow and ethanol readily crosses biologic membranes.

Over 90% of alcohol consumed is oxidized in the liver; much of the remainder is excreted through the lungs and in the urine. The excretion of a small but consistent proportion of alcohol by the lungs is utilized for breath alcohol tests that serve as a basis for a legal definition of "driving under the influence" in many countries. At levels of ethanol usually achieved in blood, the rate of oxidation follows zero-order kinetics, ie, it is independent of time and concentration of the drug. The typical adult can metabolize 7–10 g (150–220 mmol) of alcohol per hour, the equivalent of approximately 10 oz of beer, 3.5 oz of wine, or 1 oz of distilled 80 proof spirits.

Two major pathways of alcohol metabolism to acetaldehyde have been identified (Figure 23–1). Acetaldehyde is then oxidized by a third metabolic process.

Figure 23–1.

Metabolism of ethanol by alcohol dehydrogenase and the microsomal ethanol-oxidizing system (MEOS). Alcohol dehydrogenase and aldehyde dehydrogenase are inhibited by fomepizole and disulfiram, respectively.

Alcohol Dehydrogenase Pathway

The primary pathway for alcohol metabolism involves alcohol dehydrogenase (ADH), a cytosolic enzyme that catalyzes the conversion of alcohol to acetaldehyde (Figure 23–1, left). This enzyme is located mainly in the liver, but it is also found in other organs such as brain and stomach.

A significant amount of ethanol metabolism by gastric ADH occurs in the stomach in men, but a smaller amount occurs in women, who appear to have lower levels of the gastric enzyme. This difference in gastric metabolism of alcohol in women probably contributes to the sex-related differences in blood alcohol concentrations noted above.

During conversion of ethanol to acetaldehyde, hydrogen ion is transferred from alcohol to the cofactor nicotinamide adenine dinucleotide (NAD^+) to form NADH . As a net result, alcohol oxidation generates an excess of reducing equivalents in the liver, chiefly as NADH . The excess NADH production appears to underlie a number of metabolic disorders that accompany chronic alcoholism.

Microsomal Ethanol Oxidizing System (MEOS)

This enzyme system, also known as the mixed function oxidase system (see Chapter 4: Drug Biotransformation), uses NADPH as a cofactor in the metabolism of ethanol (Figure 23–1, right).

At blood concentrations below 100 mg/dL (22 mmol/L), the MEOS system, which has a relatively high K_m for alcohol, contributes little to the metabolism of ethanol. However, when large amounts of ethanol are consumed, the alcohol dehydrogenase system becomes saturated owing to depletion of the required cofactor, NAD^+ . As the concentration of ethanol increases above 100 mg/dL, there is increased contribution from the MEOS system, which does not rely upon NAD^+ as a cofactor.

During chronic alcohol consumption, MEOS activity increases. As a result, chronic alcohol

consumption results in significant increases not only in ethanol metabolism but also in the clearance of other drugs eliminated by the MEOS system. Similarly, other inducing drugs such as barbiturates may also enhance the rate of blood alcohol clearance slightly. However, the effect of other enzyme-inducing drugs on ethanol clearance is less important because the MEOS is not the primary pathway for ethanol metabolism.

Acetaldehyde Metabolism

Much of the acetaldehyde formed from alcohol appears to be oxidized in the liver in a reaction catalyzed by mitochondrial NAD-dependent aldehyde dehydrogenase. The product of this reaction is acetate (Figure 23–1), which can be further metabolized to CO₂ and water.

Oxidation of acetaldehyde is inhibited by disulfiram, a drug that has been used to deter drinking by alcohol-dependent patients undergoing treatment. When ethanol is consumed in the presence of disulfiram, acetaldehyde accumulates and causes an unpleasant reaction of facial flushing, nausea, vomiting, dizziness, and headache. Several other drugs (eg, metronidazole, cefotetan, trimethoprim) inhibit aldehyde dehydrogenase and can cause a disulfiram-like reaction if combined with ethanol.

Some people, primarily of Asian descent, have a genetic deficiency in the activity of the mitochondrial form of aldehyde dehydrogenase. When these individuals drink alcohol, they develop high blood acetaldehyde concentrations and experience a flushing reaction similar to that seen with the combination of disulfiram and ethanol.

Pharmacodynamics of Acute Ethanol Consumption

Central Nervous System

The central nervous system is markedly affected by acute alcohol consumption. Alcohol causes sedation and relief of anxiety and, at higher concentrations, slurred speech, ataxia, impaired judgment, and disinhibited behavior, a condition usually called intoxication or drunkenness (Table 23–1). These central nervous system effects are most marked as the blood level is rising, because acute tolerance to the effects of alcohol occurs after a few hours of drinking. For chronic drinkers who are tolerant to the effects of alcohol, much higher concentrations are needed to elicit these central nervous system effects. For example, a chronic alcoholic may appear sober or only slightly intoxicated with a blood alcohol concentration of 300–400 mg/dL, whereas this level is associated with marked intoxication or even coma in a nontolerant individual. The propensity of moderate doses of alcohol to inhibit the attention and information processing skills as well as the motor skills required for operation of motor vehicles has profound effects. Approximately half of all traffic accidents resulting in a fatality in the United States involve at least one person with a blood alcohol near or above the legal level of intoxication, and drunken driving is a leading cause of death in young adults.

Table 23–1. Blood Alcohol Concentration (BAC) and Clinical Effects in Nontolerant Individuals.

BAC (mg/dL) ¹	Clinical Effect
50–100	Sedation, subjective "high," increased reaction times
100–200	Impaired motor function, slurred speech, ataxia

200–300	Emesis, stupor
300–400	Coma
> 500	Respiratory depression, death

¹In many parts of the USA, a blood level above 80–100 mg/dL for adults or 10 mg/dL for persons under 21 is sufficient for conviction of driving while "under the influence."

Like other sedative-hypnotic drugs, alcohol is a central nervous system depressant. At high blood concentrations, it induces coma, respiratory depression, and death.

No specific receptor for ethanol has been identified. Instead, ethanol has been shown to affect a large number of membrane proteins that participate in signaling pathways, including neurotransmitter receptors for amines, amino acids, and opioids; enzymes such as Na⁺/K⁺ ATPase, adenylyl cyclase, phosphoinositide-specific phospholipase C; and ion channels such as those for Ca²⁺. Much attention has focused on alcohol's effects upon neurotransmission by glutamate and GABA, the main excitatory and inhibitory neurotransmitters in the central nervous system. Acute ethanol exposure enhances the action of GABA at GABA_A receptors, which is consistent with the ability of GABA-mimetics to intensify many of the acute effects of alcohol and of GABA_A antagonists to attenuate some of the actions of ethanol. Ethanol also inhibits the ability of glutamate to open the cation channel associated with the *N*-methyl-D-aspartate (NMDA) subtype of glutamate receptors. The NMDA receptor is implicated in many aspects of cognitive function, including learning and memory. "Blackouts"—periods of memory loss that occur with high levels of alcohol—may result from inhibition of NMDA receptor activation.

Heart

Significant depression of myocardial contractility has been observed in individuals who acutely consume moderate amounts of alcohol, ie, at a blood concentration above 100 mg/dL. Myocardial biopsies in humans before and after infusion of small amounts of alcohol have shown ultrastructural changes that may be associated with impaired myocardial function. Acetaldehyde is implicated as a cause of cardiac dysfunction by altering myocardial stores of catecholamines.

Smooth Muscle

Ethanol is a vasodilator, probably as a result of both central nervous system effects (depression of the vasomotor center) and direct smooth muscle relaxation caused by its metabolite, acetaldehyde. In cases of severe overdose, hypothermia—caused by vasodilation—may be marked in cold environments. Ethanol also relaxes the uterus and—before the introduction of more effective and safer uterine relaxants (eg, calcium blockers, magnesium ion, NSAIDs, and β₂-adrenoceptor stimulants)—was used intravenously for the suppression of premature labor.

Consequences of Chronic Alcohol Consumption

Chronic alcohol consumption profoundly affects the function of several vital organs—particularly the liver and skeletal muscle—and the nervous, gastrointestinal, cardiovascular, and immune systems. Since ethanol has low potency, it requires concentrations thousands of times higher than other misused drugs (eg, cocaine, opiates, amphetamines) to produce its intoxicating effects. As a result, ethanol is consumed in quantities that are unusually large for a pharmacologically active drug. The tissue damage caused by chronic alcohol ingestion results directly from toxic effects of

ethanol and acetaldehyde and indirectly by making tissues more susceptible to injury. Mechanisms implicated in tissue damage include increased oxidative stress coupled with depletion of glutathione, damage to mitochondria, growth factor dysregulation, and potentiation of cytokine-induced injury.

Chronic consumption of large amounts of alcohol is associated with an increased risk of death. Deaths linked to alcohol consumption are caused by liver disease, cancer, accidents, and suicide.

Liver and Gastrointestinal Tract

Liver disease is the most common medical complication of alcohol abuse; it is estimated that 15–30% of chronic heavy drinkers eventually develop severe liver disease. Clinically significant alcoholic liver disease may be insidious in onset and progress without evidence of overt nutritional abnormalities. Alcoholic fatty liver, a reversible condition, may progress to alcoholic hepatitis and finally to cirrhosis and liver failure. In the USA, chronic alcohol abuse is the leading cause of liver cirrhosis and of the need for liver transplantation. The risk of developing liver disease is related both to the average amount of daily consumption and to the duration of alcohol abuse. Women appear to be more susceptible to alcohol hepatotoxicity than men. Another factor that increases the risk of severe liver disease is concurrent infection with hepatitis B or C virus.

Other portions of the gastrointestinal tract can also be injured. Chronic alcohol ingestion is by far the most common cause of chronic pancreatitis in the Western world. In addition to its direct toxic effect on pancreatic acinar cells, alcohol alters pancreatic epithelial permeability and promotes the formation of protein plugs and calcium carbonate-containing stones.

Chronic alcoholics are prone to develop gastritis and have increased susceptibility to blood and plasma protein loss during drinking, which may contribute to anemia and protein malnutrition. Alcohol also reversibly injures the small intestine, leading to diarrhea, weight loss, and multiple vitamin deficiencies.

Malnutrition from dietary deficiency and vitamin deficiencies due to malabsorption are common in alcoholic individuals. Malabsorption of water-soluble vitamins is especially severe.

Nervous System

Tolerance and Physical Dependence

The consumption of alcohol in high doses over a long period results in tolerance and in physical and psychologic dependence. Tolerance to the intoxicating effects of alcohol is a complex process involving poorly understood changes in the nervous system as well as the metabolic changes described earlier. As with other sedative-hypnotic drugs, there is a limit to tolerance, so that only a relatively small increase in the lethal dose occurs with increasing alcohol use.

Chronic alcohol drinkers, when forced to reduce or discontinue alcohol, experience a withdrawal syndrome, which indicates the existence of physical dependence. Alcohol withdrawal symptoms classically consist of hyperexcitability in mild cases and seizures, toxic psychosis, and **delirium tremens** in severe ones. The dose, rate, and duration of alcohol consumption determine the intensity of the withdrawal syndrome. When consumption has been very high, merely reducing the rate of consumption may lead to signs of withdrawal.

Psychologic dependence upon alcohol is characterized by a compulsive desire to experience the

rewarding effects of alcohol and, for current drinkers, a desire to avoid the negative consequences of withdrawal. People who have recovered from alcoholism and become abstinent still experience periods of intense craving for alcohol that can be set off by environmental cues associated in the past with drinking, such as familiar places, groups of people, or events.

The molecular basis of alcohol tolerance and dependence is not known, nor is it known if the two phenomena reflect opposing effects upon a shared molecular pathway. Tolerance may result from ethanol-induced up-regulation of a pathway in response to the continuous presence of ethanol. Dependence may result from overactivity of that same pathway once the ethanol effect dissipates and before the system has time to return to a normal ethanol-free state. Chronic exposure of animals or cultured cells to alcohol elicits a multitude of adaptive responses involving neurotransmitters and their receptors, ion channels, and enzymes that participate in signal transduction pathways. Up-regulation of the NMDA subtype of glutamate receptors and voltage-sensitive Ca^{2+} channels may underlie the seizures that accompany the alcohol withdrawal syndrome. Based on the ability of sedative-hypnotic drugs that enhance GABAergic neurotransmission to substitute for alcohol during alcohol withdrawal and evidence of down-regulation of GABA_A-mediated responses with chronic alcohol exposure, changes in GABA neurotransmission are believed to play a central role in tolerance and withdrawal.

Neurotransmission events involved in the sensation of reward are also important. Alcohol affects local concentrations of serotonin, opioids, and dopamine—neurotransmitters involved in brain reward circuits. Alcohol also has complex effects on the expression of receptors for these neurotransmitters and their signaling pathways. The discovery that naltrexone, a nonselective opioid receptor antagonist, helps patients who are recovering from alcoholism abstain from drinking supports the idea that the neurochemical reward system is shared by drugs associated with physical and psychological dependence.

Neurotoxicity

Consumption of large amounts of alcohol over extended periods (usually years) often leads to neurologic deficits. The most frequent neurologic abnormality in chronic alcoholism is generalized symmetric peripheral nerve injury that begins with distal paresthesias of the hands and feet. Chronic alcoholics may also exhibit gait disturbances and ataxia that are due to degenerative changes in the central nervous system. Other neurologic disturbances associated with alcoholism include dementia and, rarely, demyelinating disease.

Wernicke-Korsakoff syndrome is a relatively uncommon but important entity characterized by paralysis of the external eye muscles, ataxia, and a confused state that can progress to coma and death. It is associated with thiamin deficiency but is rarely seen in the absence of alcoholism. Wernicke's encephalopathy represents the acute phase of this disease; it may be difficult to distinguish from the acute confused state created by acute alcohol intoxication, which later blends in with the perceptual and behavioral problems associated with alcohol withdrawal. A distinguishing feature of Wernicke's encephalopathy is the longer duration of confusion and the relative absence of the agitation that would be expected during withdrawal. Because of the importance of thiamin in this pathologic condition, all patients suspected of having Wernicke-Korsakoff syndrome should receive thiamine therapy. Often, the ocular signs, ataxia, and confusion improve upon prompt administration of thiamine. However, most patients are left with a chronic disabling memory disorder known as Korsakoff's psychosis.

Alcohol may also impair visual acuity, with painless blurring that occurs over several weeks of heavy alcohol consumption. Changes are usually bilateral and symmetric and may be followed by

optic nerve degeneration. Ingestion of ethanol substitutes such as methanol (see below) causes severe visual disturbances.

Cardiovascular System

Alcohol has complex effects upon the cardiovascular system. Heavy alcohol consumption of long duration is associated with a dilated cardiomyopathy with ventricular hypertrophy and fibrosis. In animals and humans, alcohol induces a number of changes in heart cells that may contribute to cardiomyopathy. They include membrane disruption, depressed function of mitochondria and sarcoplasmic reticulum, intracellular accumulation of phospholipids and fatty acids, and up-regulation of voltage-dependent calcium channels. There is evidence that patients with alcohol-induced dilated cardiomyopathy do significantly worse than patients with idiopathic dilated cardiomyopathy, even though cessation of drinking is associated with a reduction in cardiac size and improved function. The poorer prognosis for patients who continue to drink appears to be due in part to interference of ethanol with the beneficial effects of β -blockers and ACE inhibitors.

Heavy drinking—and especially "binge" drinking—are associated with both atrial and ventricular arrhythmias. Patients undergoing alcohol withdrawal syndrome can develop severe arrhythmias that may reflect abnormalities of potassium or magnesium metabolism as well as enhanced release of catecholamines. Seizures, syncope, and sudden death during alcohol withdrawal may be due to these arrhythmias.

A link between heavier alcohol consumption (more than three drinks per day) and hypertension has been firmly established in epidemiologic studies. Alcohol is estimated to be responsible for approximately 5% of cases of hypertension, making it one of the most common causes of reversible hypertension. This association is independent of obesity, salt intake, coffee drinking, or cigarette smoking. The mechanisms responsible for the sustained increase in blood pressure have not been identified. A reduction in alcohol intake appears to be effective in lowering blood pressure in hypertensives who are also heavy drinkers; the hypertension seen in this population is also responsive to standard blood pressure medications.

While the deleterious effects of excessive alcohol use on the cardiovascular system are well established, there is controversy over the effects of moderate drinking (one to three drinks a day) on the incidence of coronary heart disease (CHD). A number of observational studies concluded that moderate alcohol consumption actually prevents CHD and even reduces mortality. This type of relationship between mortality and the dose of a drug is called a "J-shaped" relationship. Results of these clinical studies are supported by ethanol's ability to raise serum levels of high-density lipoprotein (HDL) cholesterol, the form of cholesterol that appears to protect against atherosclerosis (see Chapter 35: Agents Used in Hyperlipidemia), its ability to inhibit some of the inflammatory processes that underlie atherosclerosis, and the presence in alcoholic beverages (especially red wine) of antioxidants and other substances that may protect against atherosclerosis. More recently, the relationship between moderate drinking and CHD has been called into question (Corrao et al, 2000) based on further investigation of confounders that affected the outcome of earlier epidemiologic studies. For example, moderate drinkers, especially wine drinkers, come from a higher socioeconomic level and may have healthier dietary habits; consumption tends to decrease with age; abstinence often is associated with ill health; and documenting precise amounts of consumption is difficult. Therefore, definitive conclusions regarding a cardioprotective effect of alcohol must await better clinical evidence.

Blood

Alcohol indirectly affects hematopoiesis through metabolic and nutritional effects and may also directly inhibit the proliferation of all cellular elements in bone marrow. The most common hematologic disorder seen in chronic drinkers is mild anemia resulting from alcohol-related folic acid deficiency. Iron deficiency anemia may result from gastrointestinal bleeding. Alcohol has also been implicated as a cause of several hemolytic syndromes, some of which are associated with hyperlipidemia and severe liver disease.

Endocrine System and Electrolyte Balance

Chronic alcohol use has important effects on the endocrine system and on fluid and electrolyte balance. Clinical reports of gynecomastia and testicular atrophy in alcoholics with or without cirrhosis suggest a derangement in steroid hormone balance.

Alcoholics with chronic liver disease may have disorders of fluid and electrolyte balance, including ascites, edema, and effusions. These factors may be related to decreased protein synthesis and portal hypertension. Alterations of whole body potassium induced by vomiting and diarrhea, as well as severe secondary aldosteronism, may contribute to muscle weakness and can be worsened by diuretic therapy. Some alcoholic patients develop hypoglycemia, probably as a result of impaired hepatic gluconeogenesis. Some alcoholics also develop ketosis, caused by excessive lipolytic factors, especially increased cortisol and growth hormone.

Fetal Alcohol Syndrome

Chronic maternal alcohol abuse during pregnancy is associated with teratogenic effects, and alcohol appears to be a leading cause of mental retardation and congenital malformation. The abnormalities that have been characterized as fetal alcohol syndrome include (1) intrauterine growth retardation, (2) microcephaly, (3) poor coordination, (4) underdevelopment of midfacial region (appearing as a flattened face), and (5) minor joint anomalies. More severe cases may include congenital heart defects and mental retardation. Heavy drinking in the first trimester of pregnancy produces the facial features associated with fetal alcohol syndrome. The consequences of heavy drinking in the second and third trimesters are not well defined, but animal studies suggest that the brain is vulnerable to ethanol throughout development. While the level of alcohol intake required for causing serious neurologic deficits appears quite high, the threshold for causing more subtle neurologic deficits is uncertain.

The mechanisms that underlie ethanol's teratogenic effects are unknown. Ethanol rapidly crosses the placenta and reaches concentrations in the fetus that are similar to those in maternal blood. The fetal liver has little or no alcohol dehydrogenase activity, so the fetus must rely upon maternal and placental enzymes for elimination of alcohol.

The neuropathologic abnormalities seen in humans and in animal models of fetal alcohol syndrome indicate that ethanol triggers apoptotic neurodegeneration and also causes aberrant neuronal and glial migration in the developing nervous system. In tissue culture systems, ethanol causes a striking reduction in neurite outgrowth. Alcohol's toxicity to the developing brain may be due to selective interference with the synthesis or function of molecules that are critical for cell recognition and migration, such as L1, an immunoglobulin cell adhesion molecule and gangliosides, major structural components of neuronal plasma membranes.

Immune System

The effects of alcohol on the immune system are complex—immune function in some tissues is

inhibited (eg, the lung), while immune function in other tissues is enhanced (eg, liver, pancreas). In addition, acute and chronic exposure to alcohol have widely different effects on immune function. The types of immunologic changes reported include suppression of the function of alveolar macrophages, inhibition of chemotaxis of granulocytes, and reduced number and function of T cells. In the liver, there is enhanced function of Kupffer cells. What is clear is that chronic heavy alcohol use predisposes to the development of infections, especially of the lung, and that it worsens the morbidity and increases the mortality risk of patients with pneumonia.

Increased Risk of Cancer

Chronic alcohol use increases the risk for cancer of the mouth, pharynx, larynx, esophagus, and liver. Evidence also points to a small increase in the risk of breast cancer in women. Although the methodologic problems of studies relating cancer to alcohol use have been formidable, the consistency of results showing an increase in the risk of gastrointestinal tract cancer is impressive. Much more information is required before a threshold level for alcohol consumption as it relates to cancer can be established. In fact, alcohol itself does not appear to be a carcinogen in most test systems. However, alcoholic beverages may carry potential carcinogens produced in fermentation or processing and may alter liver function so that the activity of potential carcinogens is increased.

Alcohol-Drug Interactions

Interactions between ethanol and other drugs can have important clinical effects that result from alterations in the pharmacokinetics or pharmacodynamics of the second drug.

The most frequent pharmacokinetic alcohol-drug interactions occur as a result of alcohol-induced increases of drug-metabolizing enzymes in liver cells as described in Chapter 4: Drug Biotransformation. Thus, prolonged intake of alcohol without damage to the liver may enhance the metabolic biotransformation of other drugs. Ethanol-mediated induction of hepatic cytochrome P450 enzymes is particularly important with regard to acetaminophen. Chronic consumption at the level of three or more drinks per day increases the risk of hepatotoxicity due to toxic or even high therapeutic levels of acetaminophen. This is probably due to increased P450-mediated conversion of acetaminophen to reactive hepatotoxic metabolites (see Chapter 4: Drug Biotransformation). In 1998, the FDA announced that all OTC products containing acetaminophen must carry a warning about the relationship between chronic ethanol consumption and acetaminophen-induced hepatotoxicity.

In contrast, *acute* alcohol use may inhibit metabolism of other drugs. This inhibition may be due to decreased enzyme activity or decreased liver blood flow. This acute alcohol effect may contribute to the commonly recognized danger of mixing alcohol with other drugs when performing activities requiring some skill, especially driving. Phenothiazines, tricyclic antidepressants, and sedative-hypnotic drugs are the most important drugs that may interact with alcohol by this pharmacokinetic mechanism.

Pharmacodynamic alcohol interactions are also of great clinical significance. Additive central nervous system depression with other sedative-hypnotics is most important. Alcohol also potentiates the pharmacologic effects of many nonsedative drugs, including vasodilators and oral hypoglycemic agents. There is some evidence that alcohol also enhances the antiplatelet action of aspirin.

Katzung PHARMACOLOGY, 9e > Section V. Drugs That Act in the Central Nervous System > Chapter 23. The Alcohols >

Clinical Pharmacology of Ethanol

Ethanol is the cause of more preventable morbidity and mortality than all other drugs combined with the exception of tobacco. The search for specific etiologic factors or the identification of significant predisposing variables for alcohol abuse has generally led to disappointing results. Personality type, severe life stresses, psychiatric disorders, and parental role models are not reliable predictors of alcohol abuse. While environmental factors clearly play a role, evidence suggests that there is a large genetic contribution to the development of alcoholism. Using new genetic markers for humans and animals, an intensive search for genes that predispose toward alcohol dependence is under way (Crabbe, 1999). Not surprisingly, polymorphisms in alcohol dehydrogenase and aldehyde dehydrogenase that lead to increased aldehyde accumulation (and therefore more severe hangover symptoms) appear to protect against alcoholism. Much attention in genetic mapping experiments has focused on membrane-signaling proteins known to be affected by ethanol and on protein constituents of reward pathways in the brain. Early reports of an association of an allele of the dopamine D₂ receptor with alcohol dependence have not been confirmed. Other candidate genes for susceptibility to alcoholism identified in genome-wide screens in humans include the dopamine D₄ receptor, the β_1 subunit of the GABA_A receptor, and tyrosine hydroxylase, an enzyme involved in the synthesis of dopamine, norepinephrine, and epinephrine (see Chapter 6: Introduction to Autonomic Pharmacology).

Genetic mapping studies have also been performed in rodents selectively bred to exhibit high or low voluntary alcohol consumption and to show differences in the severity of alcohol withdrawal seizures. A number of candidate genes have been identified, including neurotransmitter receptors, ion channels, amino acid transporters, and enzymes involved in neurotransmitter synthesis and metabolism. One intriguing candidate is neuropeptide Y (NPY), a small protein expressed in the brain and implicated in the regulation of a variety of behaviors. The role of NPY in behavior related to ethanol has been explored by development of a strain of mice that lack the gene for NPY—NPY knockout mice—and a strain of mice that overexpress NPY. The NPY knockout mice voluntarily consume more ethanol than control mice and are less sensitive to the sedative effects of ethanol. In contrast, mice overexpressing NPY drink less alcohol than the controls even though their total consumption of food and liquid is normal. Much more work is needed to investigate the role of NPY in animal models and in human alcoholism, but these findings illustrate the application of modern genetic techniques for the study of differences in behavioral responses to drugs.

Management of Acute Alcohol Intoxication

Nontolerant individuals who consume alcohol in large quantities develop typical effects of acute sedative-hypnotic drug overdose along with the cardiovascular effects described above (vasodilation, tachycardia) and gastrointestinal irritation. Since tolerance is not absolute, even chronic alcoholics may become severely intoxicated. The degree of intoxication depends upon three factors: the blood ethanol concentration, the rapidity of the rise of the alcohol level, and the time during which the blood level is maintained. The pattern of drinking, the state of the absorptive surface of the gastrointestinal tract, and the presence in the body of other medications also affect the apparent degree of intoxication.

The most important goals in the treatment of acute alcohol intoxication are to prevent severe respiratory depression and aspiration of vomitus. Even with very high blood ethanol levels, survival is probable as long as the respiratory and cardiovascular systems can be supported. The average blood alcohol concentration in fatal cases is above 400 mg/dL; however, the lethal dose of alcohol varies because of varying degrees of tolerance.

Metabolic alterations may require treatment of hypoglycemia and ketosis by administration of glucose. Thiamine is given to protect against the Wernicke-Korsakoff syndrome. Alcoholic patients who are dehydrated and vomiting should also receive electrolyte solutions. If vomiting is severe, large amounts of potassium may be required as long as renal function is normal. Especially important is recognition of decreased serum concentrations of phosphate, which may be aggravated by glucose administration. Low phosphate stores may contribute to poor wound healing, neurologic deficits, and an increased risk of infection.

Management of Alcohol Withdrawal Syndrome

Abrupt alcohol withdrawal leads to a characteristic syndrome of motor agitation, anxiety, insomnia, and reduction of seizure threshold. The severity of the syndrome is usually proportionate to the degree and duration of alcohol abuse. However, this can be greatly modified by the use of other sedatives as well as by associated factors (eg, diabetes, injury). In its mildest form, the alcohol withdrawal syndrome of tremor, anxiety, and insomnia occurs 6–8 hours after alcohol is stopped. These effects usually abate in 1–2 days. In some patients, more severe withdrawal reactions occur in which visual hallucinations, total disorientation, and marked abnormalities of vital signs occur. Alcohol withdrawal is one of the most common causes of seizures in adults. The more severe the withdrawal syndrome, the greater the need for meticulous investigation of possible underlying medical complications. The mortality risks of severe alcohol withdrawal have been overstated in the past. The prognosis is probably related chiefly to the underlying medical complications.

The major objective of drug therapy in the alcohol withdrawal period is prevention of seizures, delirium, and arrhythmias. Potassium, magnesium, and phosphate balance should be restored as rapidly as is consistent with renal function. Thiamine therapy is initiated in all cases. Persons in mild alcohol withdrawal do not need any other pharmacologic assistance.

Specific drug treatment for detoxification in severe cases involves two basic principles: substituting a long-acting sedative-hypnotic drug for alcohol and then gradually reducing ("tapering") the dose of the long-acting drug. Because of their wide margin of safety, benzodiazepines are preferred for treatment of alcohol withdrawal syndrome, though barbiturates such as phenobarbital were used in the past. Since any benzodiazepine will prevent symptoms of alcohol withdrawal, the choice of a specific agent in this class is generally based upon pharmacokinetic or economic considerations. Long-acting benzodiazepines, including chlordiazepoxide, clorazepate, and diazepam, have the advantage of requiring less frequent dosing. Since their pharmacologically active metabolites are eliminated slowly, the long-acting drugs provide a built-in tapering effect. A disadvantage of the long-acting drugs is that they and their pharmacologically active metabolites may accumulate, especially in patients with compromised liver function. Short-acting drugs such as lorazepam and oxazepam are rapidly converted to inactive water-soluble metabolites that will not accumulate, and for this reason the short-acting drugs are especially useful in alcoholic patients with liver disease. Benzodiazepines can be administered orally in mild or moderate cases, or parenterally for patients with more severe withdrawal reactions.

Phenothiazine medications for alcohol withdrawal have potentially serious adverse effects (eg, increasing seizures) that probably outweigh their benefits. Antihistamines have been used but with little justification.

After the alcohol withdrawal syndrome has been treated acutely, sedative-hypnotic medications must be tapered slowly over several weeks. Complete detoxification is not achieved with just a few days of alcohol abstinence. Several months may be required for restoration of normal nervous

system function, especially sleep.

Pharmacotherapy of Alcoholism

Following detoxification, psychosocial therapy either in intensive inpatient or in outpatient rehabilitation programs serves as the primary treatment for alcohol dependence. Since these programs have been only moderately successful, with about 50% of patients relapsing within the first year, there is much interest in finding drugs that can be useful adjuncts to psychosocial counseling. The first approach to pharmacotherapy was to deter drinking with drugs that cause a noxious reaction to alcohol by blocking its metabolism. Disulfiram, an inhibitor of aldehyde dehydrogenase, is the drug most commonly used for this purpose in the USA. More recently, research has focused on identifying drugs that alter brain responses to alcohol, eg, by decreasing the craving of abstinent alcoholics for alcohol or by blunting the pleasurable "high" that comes with renewed drinking. Naltrexone, an inhibitor of opioid receptors, was the first drug of this type to be approved by the FDA for treatment of alcohol dependence.

Other psychiatric problems, most commonly depressive or anxiety disorders, often coexist with alcoholism and, if untreated, can contribute to the tendency of detoxified alcoholics to relapse. Treatment of these associated disorders with counseling and drugs can help decrease the rate of relapse for alcoholic patients.

Disulfiram

Disulfiram (tetraethylthiuram), a widely used antioxidant in the rubber industry, causes extreme discomfort to patients who drink alcoholic beverages. Disulfiram given by itself to nondrinkers has little effect; however, flushing, throbbing headache, nausea, vomiting, sweating, hypotension, and confusion occur within a few minutes after drinking alcohol. The effect may last 30 minutes in mild cases or several hours in severe ones. Disulfiram acts by inhibiting aldehyde dehydrogenase. Thus, alcohol is metabolized as usual, but acetaldehyde accumulates.

Disulfiram is rapidly and completely absorbed from the gastrointestinal tract; however, a period of 12 hours is required for its full action. Its elimination rate is slow, so that its action may persist for several days after the last dose. The drug inhibits the metabolism of many other therapeutic agents, including phenytoin, oral anticoagulants, and isoniazid.

Compliance with disulfiram therapy is often low, and both compliance and clinical outcome can be improved by supervised administration. When the drug is prescribed, the alcohol content of common nonprescription medications should be communicated to the patient; some of these are listed in Table 64–3. Management with disulfiram should be initiated only when the patient has been free of alcohol for at least 24 hours. The drug may cause mild changes in liver function tests. The safety of disulfiram in pregnancy has not been demonstrated. The duration of disulfiram treatment should be individualized and determined by the patient's responsiveness and clinical improvement. The usual oral dose is 250 mg daily taken at bedtime.

Several other drugs, eg, metronidazole, certain cephalosporins, sulfonyleurea hypoglycemic drugs, and chloral hydrate, have disulfiram-like effects on ethanol metabolism. Patients should be warned to avoid drinking ethanol while taking these drugs and for several days after they discontinue them.

Naltrexone

Naltrexone is an orally available opioid receptor antagonist that blocks the effects of exogenous

and, presumably, endogenous opioids (see Chapter 31: Opioid Analgesics & Antagonists). Studies in experimental animals first suggested a link between alcohol consumption and opioids. Injection of small amounts of opioids was followed by an increase in alcohol drinking, whereas administration of opioid antagonists inhibited self-administration of alcohol. Several double-blind, placebo-controlled clinical trials showed that the combination of naltrexone with psychosocial therapy decreased the rate of relapse and reduced alcohol craving (see Manipulating Brain Neurotransmitter Systems to Treat Alcoholism). The subjects taking naltrexone who "slipped," that is, who sampled alcohol during the trial, were better able to control their drinking and avoid relapsing into heavy drinking. The lower alcohol consumption in naloxone-treated subjects was associated with a diminution of the subjective "high" associated with alcohol (Volpicelli et al, 1995). The durability of naltrexone's effect in alcoholism is not clear, since the initial clinical trials were only for 12 weeks. In a follow-up study, the decrease in relapse after 12 weeks of treatment continued for only one month after discontinuation of the naltrexone (O'Malley et al, 1996).

Naltrexone is taken once a day in a dose of 50 mg for treatment of alcoholism. The drug should be used with caution in alcoholic patients with evidence of mild abnormalities in serum aminotransferase activity. The combination of naltrexone plus disulfiram should be avoided since both drugs are potential hepatotoxins. Administration of naltrexone to patients who are physically dependent upon opioids will precipitate an acute withdrawal syndrome so patients must be opioid-free before initiating naltrexone therapy. Naltrexone also blocks the therapeutic effects of usual doses of opioids.

Other Drugs

Preliminary evidence suggests that topiramate, a drug used for partial and generalized tonic-clonic seizures (Chapter 24: Antiseizure Drugs), may be effective in reducing craving in chronic alcoholics.

Katzung PHARMACOLOGY, 9e > Section V. Drugs That Act in the Central Nervous System > Chapter 23. The Alcohols >

Pharmacology of Other Alcohols

Other alcohols related to ethanol have wide applications as industrial solvents and occasionally cause severe poisoning. Of these, **methanol** and **ethylene glycol** are two of the most common causes of intoxication.

Methanol

Methanol (methyl alcohol, wood alcohol) is widely used in the industrial production of synthetic organic compounds and as a constituent of many commercial solvents. In the home, methanol is most frequently found in the form of "canned heat" or in windshield-washing products. Poisonings occur from accidental ingestion of methanol-containing products or when it is used by alcoholics as an ethanol substitute.

Methanol can be absorbed through the skin or from the respiratory or gastrointestinal tract and is then distributed in body water. The primary mechanism of elimination of methanol in humans is by oxidation to formaldehyde, formic acid, and CO₂:

Animal species show great variability in mean lethal doses of methanol. The special susceptibility of humans to methanol toxicity is probably due to folate-dependent production of formate and not to methanol itself or to formaldehyde, the intermediate metabolite.

The most characteristic symptom in methanol poisoning is a visual disturbance, frequently described as "like being in a snowstorm." A complaint of blurred vision with a relatively clear sensorium should strongly suggest the diagnosis of methanol poisoning. Since much of the toxicity is due to metabolites of methanol, there is often a delay of up to 30 hours before development of visual disturbances and other signs of severe intoxication.

Physical findings in methanol poisoning are generally nonspecific. In severe cases, the odor of formaldehyde may be present on the breath or in the urine. Changes in the retina may sometimes be detected on examination, but these are usually late. The development of bradycardia, prolonged coma, seizures, and resistant acidosis all imply a poor prognosis. The cause of death in fatal cases is sudden cessation of respiration.

It is critical that the blood methanol level be determined as soon as possible if the diagnosis is suspected. Methanol concentrations in excess of 50 mg/dL are thought to be an absolute indication for hemodialysis and ethanol treatment, though formate blood levels are a better indication of clinical pathology. Additional laboratory evidence includes metabolic acidosis with an elevated anion gap and osmolar gap (see Chapter 59: Management of the Poisoned Patient). A decrease in serum bicarbonate is a uniform feature of severe methanol poisoning.

The first treatment for methanol poisoning, as in all critical poisoning situations, is support of respiration. For hospitalized patients, gastric lavage should be carried out after the airway has been protected by endotracheal intubation. Activated charcoal is not useful.

There are three specific modalities of treatment for severe methanol poisoning: suppression of metabolism by alcohol dehydrogenase to toxic products, dialysis to enhance removal of methanol and its toxic products, and alkalinization to counteract metabolic acidosis.

The enzyme chiefly responsible for methanol oxidation in the liver is alcohol dehydrogenase. Ethanol has a higher affinity than methanol for alcohol dehydrogenase; thus, saturation of the enzyme with ethanol reduces formate production. Ethanol is often used intravenously as treatment for methanol poisoning. The dose-dependent characteristics of ethanol metabolism and the variability of ethanol metabolism require frequent monitoring of blood ethanol levels to ensure appropriate alcohol concentration. **Fomepizole**, an alcohol dehydrogenase inhibitor, is approved for the treatment of ethylene glycol poisoning (see below) and methanol poisoning.

Hemodialysis rapidly eliminates both methanol and formate. However, ethanol will also be eliminated in the dialysate, requiring alterations in the dose of ethanol. Hemodialysis is discussed in Chapter 59: Management of the Poisoned Patient.

Two other measures are commonly taken. Because of profound metabolic acidosis in methanol poisoning, treatment with bicarbonate often is necessary. Since folate-dependent systems are

responsible for the oxidation of formic acid to CO₂ in humans, it is probably useful to administer folic acid to patients poisoned with methanol, though this has never been fully tested in clinical studies.

Ethylene Glycol

Polyhydric alcohols such as ethylene glycol (CH₂OHCH₂OH) are used as heat exchangers, in antifreeze formulations, and as industrial solvents. Young children and animals are sometimes attracted by the sweet taste of ethylene glycol and, rarely, it is ingested intentionally as an ethanol substitute or in attempted suicide. While ethylene glycol itself is relatively harmless and eliminated by the kidney, it is metabolized to toxic aldehydes and oxalate.

Three stages of ethylene glycol overdose occur. Within the first few hours after ingestion, there is transient excitation followed by central nervous system depression. After a delay of 4–12 hours, severe metabolic acidosis develops from accumulation of acid metabolites and lactate. Finally, delayed renal insufficiency follows deposition of oxalate in renal tubules. The key to the diagnosis of ethylene glycol poisoning is recognition of anion gap acidosis, osmolar gap, and oxalate crystals in the urine in a patient without visual symptoms.

As with methanol poisoning, early ethanol infusion and hemodialysis are standard treatments for ethylene glycol poisoning. Fomepizole, an inhibitor of alcohol dehydrogenase, has FDA approval for treatment of ethylene glycol poisoning in adults based on its ability to decrease concentrations of toxic metabolites in blood and urine and to prevent renal injury. Intravenous treatment with fomepizole is initiated immediately and continued until the patient's serum ethylene glycol concentration drops below a toxic threshold (20 mg/dL). Adverse effects associated with fomepizole are not severe. Headache, nausea, and dizziness are the ones most frequently reported, and a few patients experience minor allergic reactions. Fomepizole is classified as an orphan drug (see Chapter 5: Basic & Clinical Evaluation of New Drugs) because ethylene glycol poisoning is relatively uncommon. Its cost—estimated to be \$4000 per patient—is much higher than the cost of infusible ethanol, but fomepizole offers some advantages over ethanol as an antidote for this potentially fatal poisoning.

Manipulating Brain Neurotransmitter Systems to Treat Alcoholism

Advances in knowledge about the neurochemistry of the brain's reward system have increased the hope that pharmacologic manipulation of brain neurotransmitter systems can help people who become addicted to alcohol and other drugs. The apparent utility of naltrexone, an opioid antagonist, in reducing craving and the incidence of relapse in alcoholic patients provides evidence that the opioid system is an important player in the alcohol response system. The glutamate neurotransmitter system also appears to be important. **Acamprosate**, a competitive inhibitor of the NMDA glutamate receptor, reduces the incidence of relapse and prolongs abstinence. It is widely available in Europe and is being tested in the USA.

Several other neurotransmitter systems are leading targets in studies of pharmacotherapy for alcoholism. Considerable evidence from animal studies indicates that serotonergic and dopaminergic systems participate in the regulation of alcohol consumption. One intriguing clinical trial found that ondansetron reduced drinking in patients with early-onset alcoholism (Johnson et al, 2000). Ondansetron is an antagonist of 5-HT₃ serotonin receptors and a commonly used antiemetic

(see Chapter 16: Histamine, Serotonin, & the Ergot Alkaloids and Chapter 63: Drugs Used in the Treatment of Gastrointestinal Diseases)

Other clinical trials are focusing on selective serotonin reuptake inhibitors (SSRI) such as fluoxetine as well as selective serotonin receptor ligands such as buspirone, a 5-HT_{1A} receptor partial agonist; and ritanserin, a 5-HT₂ receptor antagonist. Of these other drugs, the SSRI drugs have been most thoroughly studied. Results from clinical trials have been mixed, with some studies showing favorable results and others failing to find that SSRIs attenuate alcohol consumption in nondepressed heavy drinkers. A number of dopamine receptor antagonists are also being studied, including selective antagonists of D₁ and D₂ dopamine receptors. Because of their importance in alcohol-related effects, drugs that modify neurotransmission through GABA and glutamate systems are also under investigation. Alcoholism is a heterogeneous disorder. As efforts to classify alcoholic patients into specific subtypes become more sophisticated, it may be possible to identify the subtypes that respond best to specific pharmacotherapies.

Katzung PHARMACOLOGY, 9e > Section V. Drugs That Act in the Central Nervous System > Chapter 23. The Alcohols >

Preparations Available

Drugs for the Treatment of Acute Alcohol Withdrawal Syndrome

Diazepam (generic, Valium, others)

Oral: 2, 3, 10 mg tablets; 5 mg/5 mL solutions (see also Chapter 22: Sedative-Hypnotic Drugs)

Parenteral: 5 mg/mL for injection

Lorazepam (generic, Alzapam, Ativan)

Oral: 0.5, 1, 2 mg tablets

Parenteral: 2, 4 mg/mL for injection

Oxazepam (generic, Serax)

Oral: 10, 15, 30 mg capsules, 15 mg tablets

Thiamine (generic)

Parenteral: 100 mg/mL for IV injection

Drugs for the Prevention of Alcohol Abuse

Disulfiram (generic, Antabuse)

Oral: 250, 500 mg tablets

Naltrexone (ReVia)

Oral: 50 mg tablets

Drugs for the Treatment of Acute Methanol or Ethylene Glycol Poisoning

Ethanol (generic)

Parenteral: 5% or 10% ethanol and 5% dextrose in water for IV infusion

Fomepizole (Antizol)

Parenteral: 1 g/mL for IV injection

Katzung PHARMACOLOGY, 9e > Section V. Drugs That Act in the Central Nervous System > Chapter 24. Antiseizure Drugs^{*} >

Antiseizure Drugs: Introduction

* The authors wish to thank Philip Mayer, PhD, for his assistance in reviewing the pharmacokinetic data in this chapter.

Approximately 1% of the world's population has epilepsy, the second most common neurologic disorder after stroke. Although standard therapy permits control of seizures in 80% of these patients, millions (500,000 people in the USA alone) have uncontrolled epilepsy. Epilepsy is a heterogeneous symptom complex—a chronic disorder characterized by recurrent seizures. Seizures are finite episodes of brain dysfunction resulting from abnormal discharge of cerebral neurons. The causes of seizures are many and include the full range of neurologic diseases, from infection to neoplasm and head injury. In some subgroups, heredity has proved to be a major contributing factor.

The antiseizure drugs described in this chapter are also used in patients with febrile seizures or with seizures occurring as part of an acute illness such as meningitis. The term "epilepsy" is not usually applied to such patients unless chronic seizures develop later. Seizures are occasionally caused by an acute underlying toxic or metabolic disorder, in which case appropriate therapy should be directed toward the specific abnormality, eg, hypocalcemia. In most cases of epilepsy, however, the choice of medication depends on the empiric seizure classification.

Drug Development for Epilepsy

For a long time it was assumed that a single drug could be developed for the treatment of all forms of epilepsy, but the causes of epilepsy are extremely diverse, encompassing genetic and developmental defects and infective, traumatic, neoplastic, and degenerative disease processes, and drug therapy to date shows little evidence of etiologic specificity. There is, however, some specificity according to seizure type. This is most clearly seen with generalized seizures of the

absence type (see Table 24–1), typically with 2–3 Hz spike-and-wave discharges on the electroencephalogram, which respond to ethosuximide and valproate but can be exacerbated by phenytoin and carbamazepine. Drugs acting selectively on absence seizures can be identified by animal screens, using either threshold pentylenetetrazol clonic seizures in mice or rats or mutant mice showing absence-like episodes (so-called lethargic, star-gazer, or tottering mutants). In contrast, the maximal electroshock (MES) test, with suppression of the tonic extensor phase, identifies drugs such as phenytoin, carbamazepine, and lamotrigine that are active against generalized tonic-clonic seizures or complex partial seizures. Use of the maximal electroshock test as the major primary screen for new drugs has probably led to the identification of drugs with a common mechanism of action involving prolonged inactivation of the voltage-sensitive sodium channel. Limbic seizures induced in rats by the process of electrical kindling (involving repeated episodes of focal electrical stimulation) probably provides a better screen for predicting efficacy in complex partial seizures.

Table 24–1. Classification of Seizure Types.

Partial seizures

Simple partial seizures

Complex partial seizures

Partial seizures secondarily generalized

Generalized seizures

Generalized tonic-clonic (grand mal) seizures

Absence (petit mal) seizures

Tonic seizures

Atonic seizures

Clonic and myoclonic seizures

Infantile spasms¹

¹An epileptic syndrome rather than a specific seizure type; drugs useful in infantile spasms will be reviewed separately.

Existing antiseizure drugs provide adequate seizure control in about two thirds of patients. A fraction of the epileptic population is resistant to all available drugs and this may be due to increased expression of the multidrug transporter P-glycoprotein 170, a product of the *ABCB1* gene (Siddiqui, 2003). In children, some severe seizure syndromes associated with progressive brain damage are very difficult to treat. In adults, some focal seizures are refractory to medications. Some, particularly in the temporal lobe, are amenable to surgical resection. Some of the drug-resistant population may respond to vagus-nerve stimulation (VNS), a nonpharmacologic treatment for epilepsy, that is now widely approved for treatment of patients with partial seizures. VNS is indicated for refractory cases or for patients in whom antiseizure drugs are poorly tolerated. Stimulating electrodes are implanted in the left vagus nerve and the pacemaker is implanted in the chest wall or axilla. Use of this device may permit seizure control with lower doses of drugs. New antiseizure drugs are being sought not only by the screening tests noted above but also by more rational approaches. Compounds are sought that act by one of three mechanisms: (1) enhancement

of GABAergic (inhibitory) transmission, (2) diminution of excitatory (usually glutamatergic) transmission, or (3) modification of ionic conductances.

Katzung PHARMACOLOGY, 9e > Section V. Drugs That Act in the Central Nervous System > Chapter 24. Antiseizure Drugs* >

Basic Pharmacology of Antiseizure Drugs

Chemistry

Up to 1990, approximately 16 antiseizure drugs were available, and 13 of them can be classified into five very similar chemical groups: barbiturates, hydantoins, oxazolidinediones, succinimides, and acetylureas. These groups have in common a similar heterocyclic ring structure with a variety of substituents (Figure 24–1). For drugs with this basic structure, the substituents on the heterocyclic ring determine the pharmacologic class, either anti-MES or antipentylentetrazol. Very small changes in structure can dramatically alter the mechanism of action and clinical properties of the compound. The remaining drugs—carbamazepine, valproic acid, and the benzodiazepines—are structurally dissimilar, as are the newer compounds marketed since 1990, ie, felbamate, gabapentin, lamotrigine, oxcarbazepine, tiagabine, topiramate, vigabatrin, and levetiracetam.

Figure 24–1.

Antiseizure heterocyclic ring structure. The "X" varies as follows: hydantoin derivatives, –N–; barbiturates, –C–N–; oxazolidinediones, –O–; succinimides, –C–; acetylureas, –NH₂ (N connected to C₂). R₁, R₂, and R₃ vary within each subgroup.

Pharmacokinetics

The antiseizure drugs exhibit many similar pharmacokinetic properties—even those whose structural and chemical properties are quite diverse. Although many of these compounds are only slightly soluble, absorption is usually good, with 80–100% of the dose reaching the circulation. Most antiseizure drugs are not highly bound to plasma proteins.

Antiseizure drugs are cleared chiefly by hepatic mechanisms, although they have low extraction ratios (see Chapter 3: Pharmacokinetics & Pharmacodynamics: Rational Dosing & the Time Course of Drug Action). Many are converted to active metabolites that are also cleared by the liver. These drugs are predominantly distributed into total body water. Plasma clearance is relatively slow; many anticonvulsants are therefore considered to be medium- to long-acting. For most, half-lives are greater than 12 hours. Phenobarbital and carbamazepine are potent inducers of hepatic microsomal enzyme activity.

Drugs Used in Partial Seizures & Generalized Tonic-Clonic Seizures

The major drugs for partial and generalized tonic-clonic seizures are phenytoin (and congeners), carbamazepine, valproate, and the barbiturates. However, the availability of newer drugs—lamotrigine, gabapentin, oxcarbazepine, topiramate, vigabatrin, and levetiracetam—is altering

clinical practice in countries where these compounds are available.

Phenytoin

Phenytoin is the oldest nonsedative antiseizure drug, introduced in 1938 following a systematic evaluation of compounds such as phenobarbital that altered electrically induced seizures in laboratory animals. It was known for decades as **diphenylhydantoin**.

Chemistry

Phenytoin is a diphenyl-substituted hydantoin with the structure shown below. It has much lower sedative properties than compounds with alkyl substituents at the 5 position. A more soluble prodrug of phenytoin, **fospphenytoin**, is available for parenteral use. This phosphate ester compound is rapidly converted to phenytoin in the plasma.

Phenytoin

Mechanism of Action

Phenytoin has major effects on several physiologic systems. It alters Na^+ , K^+ , and Ca^{2+} conductance, membrane potentials, and the concentrations of amino acids and the neurotransmitters norepinephrine, acetylcholine, and γ -aminobutyric acid (GABA). Studies with neurons in cell culture show that phenytoin blocks sustained high-frequency repetitive firing of action potentials (Figure 24–2). This effect is seen at therapeutically relevant concentrations. It is a use-dependent effect (see Chapter 14: Agents Used in Cardiac Arrhythmias) on Na^+ conductance, arising from preferential binding to—and prolongation of—the inactivated state of the Na^+ channel. This effect is also seen with therapeutically relevant concentrations of carbamazepine and valproate and probably contributes to their antiseizure action in the electroshock model and in partial seizures.

Figure 24–2.

Effects of three antiseizure drugs on sustained high-frequency firing of action potentials by cultured neurons. Intracellular recordings were made from neurons while depolarizing current pulses, approximately 0.75 s in duration, were applied (on-off step changes indicated by arrows). In the absence of drug, a series of high-frequency repetitive action potentials filled the entire duration of the current pulse. Phenytoin, carbamazepine, and sodium valproate all markedly reduced the number of action potentials elicited by the current pulses. (Modified and reproduced, with permission, from Macdonald RL, Meldrum BS: Principles of antiepileptic drug action. In: Levy RH, et al [editors]. *Antiepileptic Drugs*, 4th ed. Raven Press, 1995.)

At high concentrations, phenytoin also inhibits the release of serotonin and norepinephrine, promotes the uptake of dopamine, and inhibits monoamine oxidase activity. The drug interacts with membrane lipids; this binding might promote the stabilization of the membrane. In addition, phenytoin paradoxically causes excitation in some cerebral neurons. A reduction of calcium permeability, with inhibition of calcium influx across the cell membrane, may explain the ability of phenytoin to inhibit a variety of calcium-induced secretory processes, including release of hormones and neurotransmitters. The significance of these biochemical actions and their relationship to phenytoin's clinical activity are unclear.

The mechanism of phenytoin's action probably involves a combination of actions at several levels. At therapeutic concentrations, the major action of phenytoin is to block sodium channels and inhibit the generation of repetitive action potentials.

Clinical Use

Phenytoin is one of the most effective drugs against partial seizures and generalized tonic-clonic seizures. In the latter, it appears to be effective against attacks that are either primary or secondary to another seizure type.

Pharmacokinetics

Absorption of phenytoin is highly dependent on the formulation of the dosage form. Particle size and pharmaceutical additives affect both the rate and the extent of absorption. Absorption of phenytoin sodium from the gastrointestinal tract is nearly complete in most patients, although the time to peak may range from 3 hours to 12 hours. Absorption after intramuscular injection is unpredictable, and some drug precipitation in the muscle occurs; this route of administration is not recommended for phenytoin. In contrast, fosphenytoin, a more soluble phosphate prodrug of phenytoin, is well absorbed after intramuscular administration.

Phenytoin is highly bound to plasma proteins. It appears certain that the total plasma level decreases when the percentage that is bound decreases, as in uremia or hypoalbuminemia, but correlation of free levels with clinical states remains uncertain. Drug concentration in cerebrospinal fluid is

proportionate to the free plasma level. Phenytoin accumulates in brain, liver, muscle, and fat.

Phenytoin is metabolized to inactive metabolites that are excreted in the urine. Only a very small portion of phenytoin is excreted unchanged.

The elimination of phenytoin is dose-dependent. At very low blood levels, phenytoin metabolism follows first-order kinetics. However, as blood levels rise within the therapeutic range, the maximum capacity of the liver to metabolize phenytoin is approached (Figure 24–3). Further increases in dose, even though relatively small, may produce very large changes in phenytoin concentrations. In such cases, the half-life of the drug increases markedly, steady state is not achieved in routine fashion (since the plasma level continues to rise), and patients quickly develop symptoms of toxicity.

Figure 24–3.

Nonlinear relationship of phenytoin dosage and plasma concentrations. Five different patients (identified by different symbols) received increasing dosages of phenytoin by mouth, and the steady-state serum concentration was measured at each dosage. The curves are not linear, since, as the dosage increases, the metabolism is saturable. Note also the marked variation among patients in the serum levels achieved at any dosage. (Modified, with permission, from Jusko WJ: Bioavailability and disposition kinetics of phenytoin in man. In: Kellaway P, Peterson I [editors]. *Quantitative Analytic Studies in Epilepsy*. Raven Press, 1977.)

The half-life of phenytoin varies from 12 hours to 36 hours, with an average of 24 hours for most patients in the low to mid therapeutic range. Much longer half-lives are observed at higher concentrations. At low blood levels, it takes 5–7 days to reach steady-state blood levels after every dosage change; at higher levels, it may be 4–6 weeks before blood levels are stable.

Therapeutic Levels & Dosage

The therapeutic plasma level of phenytoin for most patients is between 10 and 20 $\mu\text{g/mL}$. A loading dose can be given either orally or intravenously; the latter, using fosphenytoin, is the method of choice for convulsive status epilepticus (discussed later). When oral therapy is started, it is common

to begin adults at a dosage of 300 mg/d regardless of body weight. While this may be acceptable in some patients, it frequently yields steady-state blood levels below 10 µg/mL, the minimum therapeutic level for most patients. If seizures continue, higher doses are usually necessary to achieve plasma levels in the upper therapeutic range. Because of its dose-dependent kinetics, some toxicity may occur with only small increments in dose; the phenytoin dosage should be increased each time by only 25–30 mg in adults, and ample time should be allowed for the new steady state to be achieved before further increasing the dose. A common clinical error is to increase the dosage directly from 300 mg/d to 400 mg/d; toxicity frequently occurs at a variable time thereafter. In children, a dosage of 5 mg/kg/d should be followed by readjustment after steady-state plasma levels are obtained.

Two types of oral phenytoin sodium are currently available in the USA, differing in their respective rates of dissolution; one is absorbed rapidly and one more slowly. Only the slow-release extended action formulation can be given in a single daily dosage, and care must be used when changing brands (see Preparations Available). Although a few patients being given phenytoin on a chronic basis have been proved to have low blood levels from poor absorption or rapid metabolism, the most common cause of low levels is poor compliance. Fosphenytoin sodium is available for intravenous or intramuscular use and replaces intravenous phenytoin sodium, a much less soluble form of the drug.

Drug Interactions & Interference with Laboratory Tests

Drug interactions involving phenytoin are primarily related to protein binding or to metabolism. Since phenytoin is 90% bound to plasma protein, other highly bound drugs, such as phenylbutazone or sulfonamides, can displace phenytoin from its binding site. In theory, such displacement may cause a transient increase in free drug. A decrease in protein binding—eg, from hypoalbuminemia—results in a decrease in the total plasma concentration of drug but not the free concentration; intoxication may occur if efforts are made to maintain total drug levels in the therapeutic range by increasing the dose. The protein binding of phenytoin is decreased in the presence of renal disease. The drug has an affinity for thyroid-binding globulin, which confuses some tests of thyroid function; the most reliable screening test of thyroid function in patients taking phenytoin appears to be measurement of TSH.

Phenytoin has been shown to induce microsomal enzymes responsible for the metabolism of a number of drugs. Autostimulation of its own metabolism, however, appears to be insignificant. Other drugs, notably phenobarbital and carbamazepine, cause decreases in phenytoin steady-state concentrations through induction of hepatic microsomal enzymes. On the other hand, isoniazid inhibits the metabolism of phenytoin, resulting in increased steady-state concentrations when the two drugs are given together.

Toxicity

Dose-related adverse effects caused by phenytoin are unfortunately similar to other antiseizure drugs in this group, making differentiation difficult in patients receiving multiple drugs. Nystagmus occurs early, as does loss of smooth extraocular pursuit movements, but neither is an indication for decreasing the dose. Diplopia and ataxia are the most common dose-related adverse effects requiring dosage adjustment; sedation usually occurs only at considerably higher levels. Gingival hyperplasia and hirsutism occur to some degree in most patients; the latter can be especially unpleasant in women. Long-term use is associated in some patients with coarsening of facial features and with mild peripheral neuropathy, usually manifested by diminished deep tendon reflexes in the lower extremities. Long-term use may also result in abnormalities of vitamin D

metabolism, leading to osteomalacia. Low folate levels and megaloblastic anemia have been reported, but the clinical importance of this observation is unknown.

Idiosyncratic reactions to phenytoin are relatively rare. A skin rash may indicate hypersensitivity of the patient to the drug. Fever may also occur, and in rare cases the skin lesions may be severe and exfoliative. Lymphadenopathy may be difficult to distinguish from malignant lymphoma, and although some studies suggest a causal relationship between phenytoin and Hodgkin's disease, the data are far from conclusive. Hematologic complications are exceedingly rare, although agranulocytosis has been reported in combination with fever and rash.

Mephenytoin, Ethotoin, & Phenacemide

Many congeners of phenytoin have been synthesized, but only three have been marketed recently in the USA, and one of these (phenacemide) has been withdrawn from the market. The first two congeners, mephenytoin and ethotoin, like phenytoin, appear to be most effective against generalized tonic-clonic seizures and partial seizures. No well-controlled clinical trials have documented their effectiveness. The incidence of severe reactions such as dermatitis, agranulocytosis, or hepatitis is higher for mephenytoin than for phenytoin.

Ethotoin may be recommended for patients hypersensitive to phenytoin, but larger doses are required. The adverse effects and toxicity are generally less severe than those associated with phenytoin, but the drug appears to be less effective.

Both ethotoin and mephenytoin share with phenytoin the property of saturable metabolism within the therapeutic dosage range. Careful monitoring of the patient during dosage alterations with either drug is essential. Mephenytoin is metabolized to 5,5-ethylphenylhydantoin via demethylation. This metabolite, **nirvanol**, contributes most of the antiseizure activity of mephenytoin. Both mephenytoin and nirvanol are hydroxylated and undergo subsequent conjugation and excretion. Therapeutic levels for mephenytoin range from 5 $\mu\text{g/mL}$ to 16 $\mu\text{g/mL}$, and levels above 20 $\mu\text{g/mL}$ are considered toxic.

Therapeutic blood levels of nirvanol are between 25 and 40 $\mu\text{g/mL}$. A therapeutic range for ethotoin has not been established.

The third congener of phenytoin, phenacemide, is a straight-chain analog of phenytoin. It is a toxic drug of last resort for refractory partial seizures.

Carbamazepine

Closely related to imipramine and other antidepressants, carbamazepine is a tricyclic compound effective in treatment of bipolar depression. It was initially marketed for the treatment of trigeminal neuralgia but has proved useful for epilepsy as well.

Chemistry

Although not obvious from a two-dimensional representation of its structure, carbamazepine has many similarities to phenytoin. The ureide moiety ($-\text{N}-\text{CO}-\text{NH}_2$) present in the heterocyclic ring of most antiseizure drugs is also present in carbamazepine. Three-dimensional structural studies indicate that its spatial conformation is similar to that of phenytoin.

Mechanism of Action

The mechanism of action of carbamazepine appears to be similar to that of phenytoin. Like phenytoin, carbamazepine shows activity against maximal electroshock seizures. Carbamazepine, like phenytoin, blocks sodium channels at therapeutic concentrations and inhibits high-frequency repetitive firing in neurons in culture (Figure 24–2). It also acts presynaptically to decrease synaptic transmission. These effects probably account for the anticonvulsant action of carbamazepine. Binding studies show that carbamazepine interacts with adenosine receptors, but the functional significance of this observation is not known. Carbamazepine also inhibits uptake and release of norepinephrine from brain synaptosomes but does not influence GABA uptake in brain slices. Recent evidence suggests that the postsynaptic action of GABA can be potentiated by carbamazepine.

Clinical Use

Carbamazepine is considered the drug of choice for partial seizures, and many physicians also use it first for generalized tonic-clonic seizures. It can be used with phenytoin in many patients who are difficult to control. Carbamazepine is not sedative in its usual therapeutic range. The drug is also very effective in some patients with trigeminal neuralgia, although older patients may tolerate higher doses poorly, with ataxia and unsteadiness. Carbamazepine is also useful in some patients with mania (bipolar disorder).

Pharmacokinetics

The rate of absorption of carbamazepine varies widely among patients, although almost complete absorption apparently occurs in all. Peak levels are usually achieved 6–8 hours after administration. Slowing absorption by giving the drug after meals helps the patient tolerate larger total daily doses.

Distribution is slow, and the volume of distribution is roughly 1 L/kg. The drug is only 70% bound to plasma proteins; no displacement of other drugs from protein binding sites has been observed.

Carbamazepine has a very low systemic clearance of approximately 1 L/kg/d at the start of therapy. The drug has a notable ability to induce microsomal enzymes. Typically, the half-life of 36 hours observed in subjects following an initial single dose decreases to much less than 20 hours in subjects receiving continuous therapy. Considerable dosage adjustments are thus to be expected during the first weeks of therapy. Carbamazepine also alters the clearance of other drugs (see below).

Carbamazepine is completely metabolized in humans to several derivatives. One of these, carbamazepine-10,11-epoxide, has been shown to have anticonvulsant activity. The contribution of this and other metabolites to the clinical activity of carbamazepine is unknown.

Therapeutic Levels & Dosage

Carbamazepine is considered the drug of choice in partial seizures. It is available only in oral form. The drug is effective in children, in whom a dosage of 15–25 mg/kg/d is appropriate. In adults, daily doses of 1 g or even 2 g are tolerated. Higher dosage is achieved by giving multiple divided doses daily. An extended-release preparation permits twice-daily dosing for most patients. In patients in whom the blood is drawn just before the morning dose (trough level), the therapeutic level is usually 4–8 $\mu\text{g/mL}$; although many patients complain of diplopia at drug levels above 7 $\mu\text{g/mL}$, others can tolerate levels above 10 $\mu\text{g/mL}$, especially with monotherapy.

Drug Interactions

Drug interactions involving carbamazepine are almost exclusively related to the drug's enzyme-inducing properties. As noted previously, the increased metabolic capacity of the hepatic enzymes may cause a reduction in steady-state carbamazepine concentrations and an increased rate of metabolism of other drugs, eg, primidone, phenytoin, ethosuximide, valproic acid, and clonazepam. Other drugs such as propoxyphene, troleandomycin, and valproic acid may inhibit carbamazepine clearance and increase steady-state carbamazepine blood levels. Other anticonvulsants, however, such as phenytoin and phenobarbital, may decrease steady-state concentrations of carbamazepine through enzyme induction. No clinically significant protein-binding interactions have been reported.

Toxicity

The most common dose-related adverse effects of carbamazepine are diplopia and ataxia. The diplopia often occurs first and may last less than an hour during a particular time of day. Rearrangement of the divided daily dose can often remedy this complaint. Other dose-related complaints include mild gastrointestinal upsets, unsteadiness, and, at much higher doses, drowsiness. Hyponatremia and water intoxication have occasionally occurred and may be dose-related.

Considerable concern exists regarding the occurrence of idiosyncratic blood dyscrasias with carbamazepine, including fatal cases of aplastic anemia and agranulocytosis. Most of these have been in elderly patients with trigeminal neuralgia, and most have occurred within the first 4 months of treatment. The mild and persistent leukopenia seen in some patients is not necessarily an indication to stop treatment but requires careful monitoring. The most common idiosyncratic reaction is an erythematous skin rash; other responses such as hepatic dysfunction are unusual.

Oxcarbazepine

Oxcarbazepine is closely related to carbamazepine and useful in the same seizure types, but it may have an improved toxicity profile. Oxcarbazepine has a half-life of only 1–2 hours. Its activity, therefore, resides almost exclusively in the 10-hydroxy metabolite, to which it is rapidly converted and which has a half-life similar to that of carbamazepine, ie, 8–12 hours. The drug is mostly excreted as the glucuronide of the 10-hydroxy metabolite. Oxcarbazepine is less potent than carbamazepine, both in animal models of epilepsy and in epileptic patients; clinical doses of oxcarbazepine may need to be 50% higher than those of carbamazepine to obtain equivalent seizure control. Some studies report fewer hypersensitivity reactions to oxcarbazepine, and cross-reactivity with carbamazepine does not always occur. Furthermore, the drug appears to induce hepatic enzymes to a lesser extent than carbamazepine, minimizing drug interactions. Those adverse effects—such as hyponatremia—that do occur with oxcarbazepine are similar in character to reactions reported with carbamazepine.

Phenobarbital

Aside from the bromides, phenobarbital is the oldest of the currently available antiseizure drugs. Although it has long been considered one of the safest of the antiseizure agents, the use of other medications with lesser sedative effects has been urged. Many consider the barbiturates the drugs of choice for seizures only in infants.

Chemistry

The four derivatives of barbituric acid clinically useful as antiseizure drugs are phenobarbital, mephobarbital, metharbital, and primidone (Figure 24–4). The first three are so similar that they will be considered together. Metharbital is methylated barbital, and mephobarbital is methylated phenobarbital; both are demethylated *in vivo*. The pKa's of these three weak acid compounds range from 7.3 to 7.9. Slight changes in the normal acid-base balance, therefore, can cause significant fluctuation in the ratio of the ionized to the un-ionized species. This is particularly important for phenobarbital, the most commonly used barbiturate, whose pKa is similar to the plasma pH of 7.4.

Figure 24–4.

Primidone and its active metabolites.

The three-dimensional conformations of phenobarbital and *N*-methylphenobarbital are similar to that of phenytoin. Both compounds possess a phenyl ring and are active against partial seizures.

Mechanism of Action

The exact mechanism of action of phenobarbital is unknown, but enhancement of inhibitory processes and diminution of excitatory transmission probably contribute importantly. Recent data indicate that phenobarbital may selectively suppress abnormal neurons, inhibiting the spread and suppressing firing from the foci. Like phenytoin, phenobarbital suppresses high-frequency repetitive firing in neurons in culture through an action on Na⁺ conductance, but only at high concentrations. Also at high concentrations, barbiturates block some Ca²⁺ currents (L-type and N-type). Phenobarbital binds to an allosteric regulatory site on the GABA-benzodiazepine receptor, and it enhances the GABA receptor-mediated current by prolonging the openings of the Cl⁻ channels. Phenobarbital also blocks excitatory responses induced by glutamate, principally those mediated by activation of the AMPA receptor (see Chapter 21: Introduction to the Pharmacology of CNS Drugs). Both the enhancement of GABA-mediated inhibition and the reduction of glutamate-mediated excitation are seen with therapeutically relevant concentrations of phenobarbital.

Clinical Use

Phenobarbital is useful in the treatment of partial seizures and generalized tonic-clonic seizures, although the drug is often tried for virtually every seizure type, especially when attacks are difficult to control. There is little evidence for its effectiveness in generalized seizures such as absence, atonic attacks, or infantile spasms; it may worsen certain patients with these seizure types.

Some physicians prefer either metharbital or mephobarbital—especially the latter—to phenobarbital because of supposed decreased adverse effects. Only anecdotal data are available to support such comparisons.

Pharmacokinetics

See Chapter 22: Sedative-Hypnotic Drugs.

Therapeutic Levels & Dosage

The therapeutic levels of phenobarbital in most patients range from 10 μg/mL to 40 μg/mL. Documentation of effectiveness is best in febrile seizures, and levels below 15 μg/mL appear ineffective for prevention of febrile seizure recurrence. The upper end of the therapeutic range is more difficult to define, as many patients appear to tolerate chronic levels above 40 μg/mL.

Drug Interactions & Toxicity

See Chapter 22: Sedative-Hypnotic Drugs.

Primidone

Primidone, or 2-desoxyphenobarbital (Figure 24–4), was first marketed in the early 1950s. It was later reported that primidone was metabolized to phenobarbital and phenylethylmalonamide (PEMA). All three compounds are active anticonvulsants.

Mechanism of Action

Although primidone is converted to phenobarbital, the mechanism of action of primidone itself may be more like that of phenytoin.

Clinical Use

Primidone, like its metabolites, is effective against partial seizures and generalized tonic-clonic seizures and may be more effective than phenobarbital. It was previously considered to be the drug of choice for complex partial seizures, but the latest studies of partial seizures in adults strongly suggest that carbamazepine and phenytoin are superior to primidone. Attempts to determine the relative potencies of the parent drug and its two metabolites have been conducted in newborn infants, in whom drug-metabolizing enzyme systems are very immature and in whom primidone is only slowly metabolized. Primidone has been shown to be effective in controlling seizures in this group and in older patients beginning treatment with primidone; the latter show seizure control before phenobarbital concentrations reach the therapeutic range. Finally, studies of maximal electroshock seizures in animals suggest that primidone has an anticonvulsant action independent of its conversion to phenobarbital and PEMA (the latter is relatively weak).

Pharmacokinetics

Primidone is completely absorbed, usually reaching peak concentrations about 3 hours after oral administration, although considerable variation has been reported. Primidone is generally confined to total body water, with a volume of distribution of 0.6 L/kg. It is not highly bound to plasma proteins; approximately 70% circulates as unbound drug.

Primidone is metabolized by oxidation to phenobarbital, which accumulates very slowly, and by scission of the heterocyclic ring to form PEMA (Figure 24-4). Both primidone and phenobarbital also undergo subsequent conjugation and excretion.

Primidone has a larger clearance than most other antiseizure drugs (2 L/kg/d), corresponding to a half-life of 6–8 hours. PEMA clearance is approximately half that of primidone, but phenobarbital has a very low clearance. The appearance of phenobarbital corresponds to the disappearance of primidone. Phenobarbital therefore accumulates very slowly but eventually reaches therapeutic concentrations in most patients when therapeutic doses of primidone are administered. During chronic therapy, phenobarbital levels derived from primidone are usually two to three times higher than primidone levels. PEMA, which probably makes a minimal contribution to the efficacy of primidone, has a half-life of 8–12 hours and therefore reaches steady state more rapidly than phenobarbital.

Therapeutic Levels & Dosage

Primidone is most efficacious when plasma levels are in the range of 8–12 $\mu\text{g/mL}$. Concomitant levels of its metabolite, phenobarbital, at steady state will usually vary from 15 $\mu\text{g/mL}$ to 30 $\mu\text{g/mL}$. Dosages of 10–20 mg/kg/d are necessary to obtain these levels. It is very important, however, to start primidone at low doses and gradually increase over days to a few weeks to avoid prominent sedation and gastrointestinal complaints. When adjusting doses of the drug, it is important to remember that the parent drug will rapidly reach steady state (30–40 hours), but the active metabolites phenobarbital (20 days) and PEMA (3–4 days) will reach steady state much more slowly.

Toxicity

The dose-related adverse effects of primidone are similar to those of its metabolite, phenobarbital, except that drowsiness occurs early in treatment and may be prominent if the initial dose is too large; gradual increments are indicated when starting the drug in either children or adults.

Vigabatrin

Current investigations that seek drugs to enhance the effects of GABA include efforts to find GABA agonists and prodrugs, GABA transaminase inhibitors, and GABA uptake inhibitors. Vigabatrin (*r*-vinyl-GABA) is one of these new drugs and has been registered in Europe and South America.

Vigabatrin

Mechanism of Action

Vigabatrin is an irreversible inhibitor of GABA aminotransferase (GABA-T), the enzyme responsible for the degradation of GABA. It apparently acts by increasing the amount of GABA released at synaptic sites, thereby enhancing inhibitory effects. Vigabatrin may also potentiate GABA by inhibiting the GABA transporter. It is effective in a wide range of seizure models. Vigabatrin is marketed as a racemate; the *S*(+) enantiomer is active and the *R*(-) enantiomer appears to be inactive.

Clinical Use

Vigabatrin is useful in the treatment of partial seizures and West's syndrome. The half-life is approximately 6–8 hours, but considerable evidence suggests that the pharmacodynamic activity of the drug is more prolonged and not well correlated with the plasma half-life. In adults, vigabatrin should be started at an oral dosage of 500 mg twice daily; a total of 2–3 g (rarely more) daily may be required for full effectiveness. Typical toxicities include drowsiness, dizziness, and weight gain. Less common but more troublesome adverse reactions are agitation, confusion, and psychosis; preexisting mental illness is a relative contraindication. The drug was delayed in its worldwide introduction by the appearance in rats and dogs of a reversible intramyelinic edema; this phenomenon has not been observed in any patient to date. More recently, unfortunately, long-term therapy with vigabatrin has been associated with development of visual field defects in up to one third of patients. This adverse effect may not be reversible, and vigabatrin may therefore be relegated to use in patients—such as those with infantile spasms—who are refractory to other treatments.

Lamotrigine

Lamotrigine was developed when some investigators thought that the antifolate effects of certain antiseizure drugs (eg, phenytoin) may contribute to their effectiveness. Several phenyltriazines were developed, and although their antifolate properties were weak, some were active in seizure screening tests.

Lamotrigine

Mechanism of Action

Lamotrigine, like phenytoin, suppresses sustained rapid firing of neurons and produces a voltage- and use-dependent inactivation of sodium channels. This action probably explains lamotrigine's efficacy in focal epilepsy. It appears likely that lamotrigine has another mechanism of action to account for its efficacy in primary generalized seizures in childhood, including absence attacks; this mechanism may involve actions on voltage-activated Ca²⁺ channels.

Clinical Use

Although most controlled studies have evaluated lamotrigine as add-on therapy, some also suggest that the drug is effective as monotherapy for partial seizures. Some authorities feel that the drug is also active against absence and myoclonic seizures in children. Adverse effects include dizziness, headache, diplopia, nausea, somnolence, and skin rash. The rash is considered a typical hypersensitivity reaction. Although the risk of rash may be diminished by introducing the drug slowly, pediatric patients are at high risk; some studies suggest that a potentially life-threatening dermatitis will develop in 1–2% of pediatric patients.

Pharmacokinetics & Dosage

Lamotrigine is almost completely absorbed and has a volume of distribution in the range of 1–1.4 L/kg. Protein binding is only about 55%. The drug has linear kinetics and is metabolized primarily by glucuronidation to the 2-*N*-glucuronide, which is excreted in the urine. Lamotrigine has a half-life of approximately 24 hours in normal volunteers; this decreases to 13–15 hours in patients taking enzyme-inducing drugs. Lamotrigine is effective against partial seizures in adults, with dosages typically between 100 mg/d and 300 mg/d and with a therapeutic blood level near 3 µg/mL. Valproate causes a twofold increase in the drug's half-life; in patients receiving valproate, the initial dosage of lamotrigine must be reduced to 25 mg every other day.

Felbamate

Felbamate has been approved and marketed in the USA and in some European countries. Although it is effective in some patients with partial seizures, the drug causes aplastic anemia and severe hepatitis at unexpectedly high rates and has been relegated to the status of a third-line drug for refractory cases.

Felbamate

The mechanism of action of felbamate is not established. The strongest evidence suggests NMDA receptor blockade via the glycine binding site. Felbamate has a half-life of 20 hours (somewhat shorter when administered with either phenytoin or carbamazepine) and is metabolized by hydroxylation and conjugation; a significant percentage of the drug is excreted unchanged in the urine. When added to treatment with other antiseizure drugs, felbamate increases plasma phenytoin and valproic acid levels but decreases levels of carbamazepine.

In spite of the seriousness of the adverse effects, more than 10,000 patients worldwide remain on the medication. Usual dosages are 2000–4000 mg/d in adults, and effective plasma levels range from 30 $\mu\text{g/mL}$ to 100 $\mu\text{g/mL}$. In addition to its usefulness in partial seizures, felbamate has proved effective against the seizures that occur in Lennox-Gastaut syndrome.

Gabapentin

Gabapentin is an amino acid, an analog of GABA, that is effective against partial seizures. Originally planned as a spasmolytic, it was found to be more effective as an antiseizure drug.

GABA

Gabapentin

Mechanism of Action

In spite of its close structural relationship to GABA, gabapentin appears not to act on GABA receptors. It may, however, alter GABA metabolism, its nonsynaptic release, or its reuptake by GABA transporters. An increase in brain GABA concentration is observed in man. Gabapentin is transported into the brain by the L-amino acid transporter. Its anticonvulsant effect in the electroshock model is delayed relative to its peak plasma concentration. The drug also binds to the $\alpha 2\delta$ subunit of voltage-sensitive Ca^{2+} channels.

Clinical Use & Dosage

Gabapentin is effective as an adjunct against partial seizures and generalized tonic-clonic seizures at dosages that range up to 2400 mg/d in controlled clinical trials. Open follow-on studies permitted

dosages up to 4800 mg/d, but data are inconclusive on the effectiveness or tolerability of such doses. Monotherapy studies also document some efficacy. Very high dosages have been needed by some clinicians to achieve improvement in seizure control. Effectiveness in other seizure types has not been well demonstrated. Gabapentin has also been found effective in the treatment of neuropathic pain and is now indicated for postherpetic neuralgia in adults at doses of 1800 mg and above. The most common adverse effects are somnolence, dizziness, ataxia, headache, and tremor.

Pharmacokinetics

Gabapentin is not metabolized and does not induce hepatic enzymes. Absorption is nonlinear and dose-dependent at very high doses, but otherwise the elimination kinetics are linear. The drug is not bound to plasma proteins. Drug-drug interactions are negligible. Elimination is via renal mechanisms; the drug is excreted unchanged. The half-life is short, ranging from 5 hours to 8 hours; the drug is typically administered two or three times per day.

Topiramate

Topiramate is a substituted monosaccharide that is structurally different from all other antiseizure drugs.

Topiramate

Mechanism of Action

Topiramate blocks repetitive firing of cultured spinal cord neurons, as do phenytoin and carbamazepine. Its mechanism of action, therefore, is likely to involve blocking of voltage-dependent sodium channels. Topiramate also appears to potentiate the inhibitory effect of GABA, acting at a site different from the benzodiazepine or barbiturate sites. Topiramate also depresses the excitatory action of kainate on AMPA receptors. It is possible that all three of these actions contribute to topiramate's anticonvulsant effect.

Clinical Use

Clinical trials of topiramate demonstrated a dose-response relationship, and monotherapy trials (using a pseudoplacebo) showed the drug to be effective against partial and generalized tonic-clonic seizures. Some evidence suggests that the drug has a broader spectrum, with effectiveness against Lennox-Gestaut syndrome, West's syndrome, and even absence seizures. Dosages typically ranged from 200 mg/d to 600 mg/d, with a few patients tolerating dosages greater than 1000 mg/d. Most clinicians begin slowly (50 mg/d) and increase slowly to avoid adverse effects. Although no idiosyncratic reactions have been noted, dose-related side effects occur most frequently in the first 4 weeks and include somnolence, fatigue, dizziness, cognitive slowing, paresthesias, nervousness, and confusion. Acute myopia and glaucoma may require prompt drug withdrawal. Urolithiasis has also been reported. However, the discontinuation rate is apparently only about 15%. The drug is teratogenic in animal models, but no human fetal deformities have been noted in the very few

pregnancies that have occurred during the course of topiramate administration.

Pharmacokinetics

Topiramate is rapidly absorbed (about 2 hours) and is 80% bioavailable. There is no food effect on absorption, minimal (15%) plasma protein binding, and only moderate (20–50%) metabolism; no active metabolites are formed. The drug is primarily excreted unchanged in the urine. The half-life is about 20–30 hours. Although increased levels are seen with renal failure and hepatic impairment, there is no age or gender effect, no autoinduction, no inhibition of metabolism, and kinetics are linear. Drug interactions do occur and can be complex, but the major effect is on topiramate levels rather than on the levels of other antiseizure drugs. Birth control pills may be less effective in the presence of topiramate, and higher estrogen doses may be required.

Tiagabine

Tiagabine is a derivative of nipecotic acid and was "rationally designed" as an inhibitor of GABA uptake (as opposed to discovery through random screening).

Tiagabine

Mechanism of Action

Tiagabine is an inhibitor of GABA uptake in both neurons and glia. It preferentially inhibits the transporter isoform 1 (GAT-1) rather than GAT-2 or GAT-3 and increases extracellular GABA levels in the forebrain and hippocampus. It prolongs the inhibitory action of synaptically released GABA. In rodents it is potent against kindled seizures but weak against the maximum electroshock model.

Clinical Use

Tiagabine is indicated for the adjunctive treatment of partial seizures and is effective in doses ranging from 16 mg/d to 56 mg/d. Divided doses as often as four times per day are sometimes required. Some patients appear to do well with tiagabine monotherapy, which is generally well tolerated. Minor adverse events are dose-related and include nervousness, dizziness, tremor, difficulty in concentrating, and depression. Excessive confusion, somnolence, or ataxia may require discontinuation. Psychosis occurs rarely. Rash is an uncommon idiosyncratic adverse effect. Laboratory studies are usually normal.

Pharmacokinetics

Tiagabine is 90–100% bioavailable, has linear kinetics, and is highly protein-bound. The half-life is 5–8 hours and decreases in the presence of enzyme-inducing drugs. Food decreases the peak plasma concentration but not the area under the concentration curve (see Chapter 3: Pharmacokinetics & Pharmacodynamics: Rational Dosing & the Time Course of Drug Action). Hepatic impairment causes a slight decrease in clearance (and may necessitate a lower dose), but the drug does not cause inhibition or induction of hepatic enzymes. The drug is oxidized in the liver by CYP3A. Elimination is primarily in the feces (60–65%) and urine (25%).

Zonisamide

Zonisamide is a sulfonamide derivative. Its primary site of action appears to be on the sodium channel; it may also act on voltage-dependent calcium channels. The drug is effective against partial and generalized tonic-clonic seizures and may also be useful against infantile spasms and certain myoclonias. It has good bioavailability, linear kinetics, low protein-binding, renal excretion, and a half-life of 1–3 days. Doses range from 100 mg/d to 600 mg/d in adults and from 4 mg/d to 12 mg/d in children. Adverse effects include drowsiness, cognitive impairment, and potentially serious skin rashes. Zonisamide does not interact with other antiseizure drugs.

Zonisamide

Levetiracetam

Levetiracetam is a piracetam analog that is ineffective against seizures induced by maximum electroshock or pentylenetetrazol but has prominent activity in the kindling model. Its mechanism of action is unknown. It has a brain-specific binding site and affects allosteric modulations of GABA receptors, high-voltage activated Ca^{2+} channels and some K^+ channels. The drug is marketed for the treatment of partial seizures. Oral absorption is nearly complete; it is rapid and unaffected by food, with peak plasma concentrations in 1.3 hours. Kinetics are linear. Protein binding is less than 10%. The plasma half-life is 6–8 hours, and may be longer in the elderly. Two thirds of the drug is excreted unchanged in the urine. Drug interactions are minimal; levetiracetam is not metabolized by cytochrome P450. Dosing can begin with 500 mg orally twice daily; some patients require up to 3000 mg/d. Adverse effects include somnolence, asthenia, and dizziness. Idiosyncratic reactions are rare.

Levetiracetam

Drugs Used in Generalized Seizures

Ethosuximide

Ethosuximide was introduced in 1960 as the third of three marketed succinimides in the USA. Ethosuximide has very little activity against maximal electroshock but considerable efficacy against pentylenetetrazol seizures and was introduced as a "pure petit mal" drug. Its continued popularity is based on its safety and efficacy, and its role as the first choice anti-absence drug remains undiminished—in part because of the idiosyncratic hepatotoxicity of the alternative drug, valproic acid.

Chemistry

Ethosuximide is the last antiseizure drug to be marketed whose origin is in the cyclic ureide structure. The three antiseizure succinimides marketed in the USA are ethosuximide, phensuximide, and methsuximide. All three are substituted at the 2 position. (See structure below, and note the difference in numbering relative to Figure 24–1.) Methsuximide and phensuximide have phenyl substituents, while ethosuximide is 2-ethyl-2-methylsuccinimide.

Ethosuximide

Mechanism of Action

Ethosuximide has an important effect on Ca²⁺ currents, reducing the low-threshold (T-type) current. This effect is seen at therapeutically relevant concentrations in thalamic neurons. The T-type calcium currents are thought to provide a pacemaker current in thalamic neurons responsible for generating the rhythmic cortical discharge of an absence attack. Inhibition of this current could therefore account for the specific therapeutic action of ethosuximide. Ethosuximide also inhibits Na⁺/K⁺ ATPase, depresses the cerebral metabolic rate, and inhibits GABA aminotransferase. However, none of these actions are seen at therapeutic concentrations.

Clinical Use

As predicted from its activity in laboratory models, ethosuximide is particularly effective against absence seizures. Documentation of its effectiveness required specific advances in quantitation of absence seizures; this was accomplished in the 1970s, when the characteristic generalized 3/s spike-wave electroencephalographic abnormality was correlated with a decrement in consciousness even when the abnormality occurs for only a few seconds. Long-term electroencephalographic recordings, therefore, provided the necessary quantitative method for determining the frequency of absence attacks and allowed rapid and effective evaluation of the efficacy of anti-absence drugs. Although ethosuximide was marketed in advance of the federal requirements for efficacy, these techniques were applied to later drugs such as clonazepam and valproic acid in documentation of their efficacy. This was accomplished by comparison with ethosuximide.

Pharmacokinetics

Absorption is complete following administration of the oral dosage forms. Peak levels are observed 3–7 hours after oral administration of the capsules. Animal studies indicate that chronic administration of the solution may prove irritating to the gastric mucosa. Ethosuximide is uniformly distributed in total body water, ie, 0.7 L/kg and does not penetrate fat. Ethosuximide is not protein-bound, and spinal fluid concentrations are therefore equal to plasma concentrations.

Ethosuximide is completely metabolized, principally by hydroxylation, to inactive metabolites. The drug has a very low total body clearance (0.25 L/kg/d). This corresponds to a half-life of approximately 40 hours, although values from 18 to 72 hours have been reported.

Therapeutic Levels & Dosage

Therapeutic levels of 60–100 $\mu\text{g/mL}$ can be achieved in adults with dosages of 750–1500 mg/d, although lower or higher dosages and blood levels may be necessary and tolerated (up to 125 $\mu\text{g/mL}$) in some patients. Ethosuximide has a linear relationship between dose and steady-state plasma levels. The drug might be administered as a single daily dose were it not for its adverse gastrointestinal effects; twice-a-day dosage is common.

Drug Interactions

Administration of ethosuximide with valproic acid results in a decrease in ethosuximide clearance and higher steady-state concentrations owing to inhibition of metabolism. No other important drug interactions have been reported for the succinimides.

Toxicity

The most common dose-related adverse effect of ethosuximide is gastric distress, including pain, nausea, and vomiting. This can often be avoided by starting therapy at a low dose, with gradual increases into the therapeutic range. When the adverse effect does occur, temporary dosage reductions may allow adaptation. Ethosuximide is a highly efficacious and safe drug for absence seizures; the appearance of relatively mild, dose-related adverse effects should not immediately call for its abandonment. Other dose-related adverse effects include transient lethargy or fatigue and, much less commonly, headache, dizziness, hiccup, and euphoria. Behavioral changes are usually in the direction of improvement.

Non-dose-related or idiosyncratic adverse effects of ethosuximide are extremely uncommon. Skin rashes have been reported, including at least one case of Stevens-Johnson syndrome. A few patients have had eosinophilia, thrombocytopenia, leukopenia, or pancytopenia; it is not entirely certain that ethosuximide was the causal agent. The development of systemic lupus erythematosus has also been reported, but other drugs may have been involved.

Phensuximide & Methsuximide

Phensuximide and methsuximide are phenylsuccinimides that were developed and marketed before ethosuximide. They are used primarily as anti-absence drugs. Methsuximide is generally considered more toxic, and phensuximide less effective, than ethosuximide. Unlike ethosuximide, these two compounds have some activity against maximal electroshock seizures, and methsuximide has been used for partial seizures by some investigators. The desmethyl metabolite of methsuximide has a half-life of 25 hours or more and exerts the major antiseizure effect. The toxicity and reduced effectiveness of phensuximide when compared with methsuximide has been investigated, and the failure of the desmethyl metabolite to accumulate in the former probably explains its relatively

weak effect.

Valproic Acid & Sodium Valproate

Sodium valproate, also used as the free acid, valproic acid, was found to have antiseizure properties when it was used as a solvent in the search for other drugs effective against seizures. It was marketed in France in 1969 but was not licensed in the USA until 1978. Valproic acid is fully ionized at body pH, and for that reason the active form of the drug may be assumed to be the valproate ion regardless of whether valproic acid or a salt of the acid is administered.

Chemistry

Valproic acid is one of a series of fatty carboxylic acids that have antiseizure activity; this activity appears to be greatest for carbon chain lengths of five to eight atoms. Branching and unsaturation do not significantly alter the drug's activity but may increase its lipophilicity, thereby increasing its duration of action. The amides and esters of valproic acid are also active antiseizure agents.

Valproic acid

Mechanism of Action

The time course of valproate's anticonvulsant activity appears to be poorly correlated with blood or tissue levels of the parent drug, an observation giving rise to considerable speculation regarding both the active species and the mechanism of action of valproic acid. Valproate is active against both pentylenetetrazol and maximal electroshock seizures. Like phenytoin and carbamazepine, valproate blocks sustained high-frequency repetitive firing of neurons in culture at therapeutically relevant concentrations. Its action against partial seizures may be a consequence of this effect on Na^+ currents. Blockade of NMDA receptor-mediated excitation may also be important. Much attention has been paid to the effects of valproate on GABA. Several studies have shown increased levels of GABA in the brain after administration of valproate, although the mechanism for this increase remains unclear. An effect of valproate to facilitate glutamic acid decarboxylase (GAD), the enzyme responsible for GABA synthesis, has been described. An inhibitory effect on the GABA transporter GAT-1 may contribute. At very high concentrations, valproate inhibits GABA-T in the brain, thus blocking degradation of GABA. However, at the relatively low doses of valproate needed to abolish pentylenetetrazol seizures, brain GABA levels may remain unchanged. Valproate produces a reduction in the aspartate content of rodent brain, but the relevance of this effect to its anticonvulsant action is not known.

At high concentrations, valproate has been shown to increase membrane potassium conductance. Furthermore, low concentrations of valproate tend to hyperpolarize membrane potentials. These findings have led to speculation that valproate may exert an action through a direct effect on the potassium channels of the membrane.

Valproate probably owes its broad spectrum of action to more than one molecular mechanism. Its action against absence attacks remains to be explained.

Clinical Use

Valproate is very effective against absence seizures. Although ethosuximide is the drug of choice when absence seizures occur alone, valproate is preferred if the patient has concomitant generalized tonic-clonic attacks. The reason for preferring ethosuximide for uncomplicated absence seizures is valproate's idiosyncratic hepatotoxicity, described below. Valproate is unique in its ability to control certain types of myoclonic seizures; in some cases the effect is very dramatic. The drug is effective in generalized tonic-clonic seizures, especially those which are primarily generalized. A few patients with atonic attacks may also respond, and some evidence suggests that the drug is effective in partial seizures.

Other uses of valproate include management of bipolar disorder and migraine prophylaxis.

Pharmacokinetics

Valproate is well absorbed following an oral dose, with bioavailability greater than 80%. Peak blood levels are observed within 2 hours. Food may delay absorption, and decreased toxicity may result if the drug is given after meals.

Valproic acid is 90% bound to plasma proteins, although the fraction bound is somewhat reduced at blood levels greater than 150 $\mu\text{g/mL}$. Since valproate is both highly ionized and highly protein-bound, its distribution is essentially confined to extracellular water, with a volume of distribution of approximately 0.15 L/kg.

Clearance for valproate is low; its half-life varies from 9 hours to 18 hours. At very high blood levels, the clearance of valproate is dose-dependent. There appear to be offsetting changes in the intrinsic clearance and protein binding at higher doses. Approximately 20% of the drug is excreted as a direct conjugate of valproate.

The sodium salt of valproate is marketed in Europe as a tablet protected by aluminum foil, as it is quite hygroscopic. In Central and South America, the magnesium salt is available, which is considerably less hygroscopic. The free acid of valproate was first marketed in the USA in a capsule containing corn oil; the sodium salt is also available in syrup, primarily for pediatric use. An enteric-coated tablet of divalproex sodium is also marketed in the USA. This improved product, a 1:1 coordination compound of valproic acid and sodium valproate, is as bioavailable as the capsule but is absorbed much more slowly and is preferred by most patients. Peak concentrations following administration of the enteric-coated tablets are seen in 3–4 hours.

Therapeutic Levels & Dosage

Dosages of 25–30 mg/kg/d may be adequate in some patients, but others may require 60 mg/kg/d or even more. Therapeutic levels of valproate range from 50 $\mu\text{g/mL}$ to 100 $\mu\text{g/mL}$. In testing efficacy, this drug should not be abandoned until morning trough levels of at least 80 $\mu\text{g/mL}$ have been attained; some patients may require and tolerate trough levels in excess of 100 $\mu\text{g/mL}$.

Drug Interactions

As noted above, the clearance of valproate is dose-dependent, caused by changes in both the intrinsic clearance and protein binding. Valproate inhibits its own metabolism at low doses, thus decreasing intrinsic clearance. At higher doses, there is an increased free fraction of valproate, resulting in lower total drug levels than expected. It may be clinically useful, therefore, to measure both total and free drug levels. Valproate also displaces phenytoin from plasma proteins. In addition to binding interactions, valproate inhibits the metabolism of several drugs, including phenobarbital,

phenytoin, and carbamazepine, leading to higher steady-state concentrations of these agents. The side effects and toxicity of phenytoin are enhanced. The inhibition of phenobarbital metabolism may cause levels of the barbiturate to rise precipitously, causing stupor or coma.

Toxicity

The most common dose-related adverse effects of valproate are nausea, vomiting, and other gastrointestinal complaints such as abdominal pain and heartburn. The drug should be started gradually to avoid these symptoms; a temporary reduction in dose can usually alleviate the problems, and the patient will eventually tolerate higher doses. Sedation is uncommon with valproate alone but may be striking when valproate is added to phenobarbital. A fine tremor is frequently seen at higher levels. Other reversible adverse effects, seen in a small number of patients, include weight gain, increased appetite, and hair loss.

The idiosyncratic toxicity of valproate is largely limited to hepatotoxicity, but this may be severe; there seems little doubt that the hepatotoxicity of valproate has been responsible for more than 50 fatalities in the USA alone. The risk is greatest for patients under the age of 2 years and for those taking multiple medications. Initial aspartate aminotransferase values may not be elevated in susceptible patients, although these levels do eventually become abnormal. Most fatalities have occurred within 4 months after initiation of therapy. Careful monitoring of liver function is recommended when starting the drug; the hepatotoxicity is reversible in some cases if the drug is withdrawn. The other observed idiosyncratic response with valproate is thrombocytopenia, although documented cases of abnormal bleeding are lacking. It should be noted that valproate is an effective and popular antiseizure drug and that only a very small number of patients have had severe toxic effects from its use.

Epidemiologic studies of valproate suggest an increased incidence of spina bifida in the offspring of women who took the drug during pregnancy. In addition, an increased incidence of cardiovascular, orofacial, and digital abnormalities has been reported. These observations, although based on a small number of cases, must be strongly considered in the choice of drugs during pregnancy.

Oxazolidinediones

Trimethadione, the first oxazolidinedione, was introduced as an antiseizure drug in 1945 and remained the drug of choice for absence seizures until the introduction of succinimides in the 1950s. The use of the oxazolidinediones (trimethadione, paramethadione, and dimethadione) is now very limited.

Chemistry

The oxazolidinediones contain an oxazolidine heterocyclic ring (Figure 24–1) and are similar in structure to other antiseizure drugs introduced before 1960. The structure includes only short-chain alkyl substituents on the heterocyclic ring, with no attached phenyl group.

Trimethadione

Mechanism of Action

These compounds are active against pentylenetetrazol-induced seizures. Trimethadione raises the threshold for seizure discharges following repetitive thalamic stimulation. It—or, more notably, its active metabolite dimethadione—has the same effect on thalamic Ca^{2+} currents as ethosuximide (reducing the T-type calcium current). Thus, suppression of absence seizures is likely to depend on inhibiting the pacemaker action of thalamic neurons.

Pharmacokinetics

Trimethadione is rapidly absorbed, with peak levels reached within an hour after drug administration. It is distributed to all perfused tissues, with a volume of distribution that approximates that of total body water. It is not bound to plasma proteins. Trimethadione is completely metabolized in the liver by demethylation to 5,5-dimethyl-2,4-oxazolidinedione (dimethadione), which may exert the major antiseizure activity. The clearance of dimethadione is 0.08 L/kg/d; this metabolite has an extremely long half-life (240 hours).

Therapeutic Levels & Dosage

The therapeutic plasma level range for trimethadione has never been established, although trimethadione blood levels above 20 $\mu\text{g}/\text{mL}$ and dimethadione levels above 700 $\mu\text{g}/\text{mL}$ have been suggested. A dosage of 30 mg/kg/d of trimethadione is necessary to achieve these levels in adults.

Drug Interactions

Relatively few drug interactions involving the oxazolidinediones have been reported, although trimethadione may competitively inhibit the demethylation of other drugs such as metharbital.

Toxicity

The most common and bothersome dose-related adverse effect of the oxazolidinediones is sedation. An unusual adverse effect is hemeralopia, a glare effect in which visual adaptation is impaired; it is reversible upon withdrawal of the drug. Accumulation of dimethadione has been reported to cause a very mild metabolic acidosis. Trimethadione has been associated with many other toxic adverse effects, some of which are severe. These drugs should not be used during pregnancy.

Other Drugs Used in Management of Epilepsy

Some drugs not classifiable by application to seizure type are discussed in this section.

Benzodiazepines

Six benzodiazepines play prominent roles in the therapy of epilepsy (see also Chapter 22: Sedative-Hypnotic Drugs). Although many benzodiazepines are quite similar chemically, subtle structural alterations result in differences in activity. They have two different mechanisms of antiseizure action, which are shown to different degrees by the six compounds. This is evident from the fact that diazepam is relatively more potent against electroshock and clonazepam against pentylenetetrazol (the latter effect correlating with an action at the GABA-benzodiazepine allosteric receptor site). Possible mechanisms of action are discussed in Chapter 22: Sedative-Hypnotic Drugs.

Diazepam given intravenously or rectally is highly effective for stopping continuous seizure activity, especially generalized tonic-clonic status epilepticus (see below). The drug is occasionally given orally on a chronic basis, although it is not considered very effective in this application, probably because of the rapid development of tolerance. A rectal gel is available for refractory patients who need acute control of bouts of seizure activity. **Lorazepam** appears in some studies to be more effective and longer-acting than diazepam in the treatment of status epilepticus.

Clonazepam is a long-acting drug with documented efficacy against absence seizures; it is one of the most potent antiseizure agents known. It is also effective in some cases of myoclonic seizures and has been tried in infantile spasms. Sedation is prominent, especially on initiation of therapy; starting doses should be small. Maximal tolerated doses are usually in the range of 0.1–0.2 mg/kg, but many weeks of gradually increasing daily dosage may be needed to achieve these doses in some patients. Therapeutic blood levels are usually less than 0.1 $\mu\text{g/mL}$ and are not routinely measured in most laboratories. **Nitrazepam** is not marketed in the USA but is used in many other countries, especially for infantile spasms and myoclonic seizures. It is less potent than clonazepam, and its clinical advantages over that drug have not been documented.

Clorazepate dipotassium is approved in the USA as an adjunct to treatment of complex partial seizures in adults. Drowsiness and lethargy are common adverse effects, but as long as the drug is increased gradually, dosages as high as 45 mg/d can be given.

Clobazam is not available in the USA but is marketed in most countries and is widely used in a variety of seizure types. It is a 1,5-benzodiazepine (all other marketed benzodiazepines are 1,4-benzodiazepines) and reportedly has less sedative potential than benzodiazepines marketed in the USA. Whether the drug has significant clinical advantages is not clear. It has a half-life of 18 hours and is effective at dosages of 0.5–1 mg/kg/d. It does interact with some other antiseizure drugs and causes adverse effects typical of the benzodiazepines; efficacy, in some patients, is limited by the development of tolerance.

Pharmacokinetics

The pharmacokinetic properties of the benzodiazepines in part determine their clinical use. In general, the drugs are well absorbed, widely distributed, and extensively metabolized, with many active metabolites. The rate of distribution of benzodiazepines within the body is different from that of other antiseizure drugs. Diazepam and lorazepam in particular are rapidly and extensively distributed to the tissues, with volumes of distribution between 1 L/kg and 3 L/kg. The onset of action is very rapid. Total body clearances of the parent drug and its metabolites are low, corresponding to half-lives of 20–40 hours.

Limitations

Two prominent aspects of benzodiazepines limit their usefulness. The first is their pronounced

sedative effect, which is unfortunate both in the treatment of status epilepticus and in chronic therapy. Children may manifest a paradoxical hyperactivity, as with barbiturates. The second problem is tolerance, in which seizures may respond initially but recur within a few months. The remarkable antiseizure potency of these compounds often cannot be realized because of these limiting factors.

Acetazolamide

Acetazolamide is a diuretic whose main action is the inhibition of carbonic anhydrase (see Chapter 15: Diuretic Agents). Mild acidosis in the brain may be the mechanism by which the drug exerts its antiseizure activity; alternatively, the depolarizing action of bicarbonate ions moving out of neurons via GABA receptor ion channels will be diminished by carbonic anhydrase inhibition.

Acetazolamide has been used for all types of seizures but is severely limited by the rapid development of tolerance, with return of seizures usually within a few weeks. The drug may have a special role in epileptic women who experience seizure exacerbations at the time of menses; seizure control may be improved and tolerance may not develop because the drug is not administered continuously. The usual dosage is approximately 10 mg/kg/d up to a maximum of 1000 mg/d.

Another carbonic anhydrase inhibitor, **sulthiame**, was not found to be effective as an anticonvulsant in clinical trials in the USA. It is marketed in some other countries.

Clinical Pharmacology of Antiseizure Drugs

Seizure Classification

The type of medication utilized for epilepsy depends on the empiric nature of the seizure. For this reason, considerable effort has been expended to classify seizures so that clinicians will be able to make a "seizure diagnosis" and on that basis prescribe appropriate therapy. Errors in seizure diagnosis cause use of the wrong drugs, and an unpleasant cycle ensues in which poor seizure control is followed by increasing drug doses and medication toxicity. As noted above, seizures are divided into two groups: partial and generalized. Drugs used for partial seizures are more or less the same for the entire group, but drugs used for generalized seizures are determined by the individual seizure type. A summary of the international classification of epileptic seizures is presented in Table 24-1.

Partial Seizures

Partial seizures are those in which a localized onset of the attack can be ascertained, either by clinical observation or by electroencephalographic recording; the attack begins in a specific locus in the brain. There are three types of partial seizures, determined to some extent by the degree of brain involvement by the abnormal discharge.

The least complicated partial seizure is the **simple partial seizure**, characterized by minimal spread of the abnormal discharge such that normal consciousness and awareness are preserved. For example, the patient may have a sudden onset of clonic jerking of an extremity lasting 60–90 seconds; residual weakness may last for 15–30 minutes after the attack. The patient is completely aware of the attack and can describe it in detail. The electroencephalogram may show an abnormal discharge highly localized to the involved portion of the brain.

The **complex partial seizure** also has a localized onset, but the discharge becomes more widespread (usually bilateral) and almost always involves the limbic system. Most (not all) complex partial seizures arise from one of the temporal lobes, possibly because of the susceptibility of this area of the brain to insults such as hypoxia or infection. Clinically, the patient may have a brief warning followed by an alteration of consciousness during which some patients may stare and others may stagger or even fall. Most, however, demonstrate fragments of integrated motor behavior called automatisms for which the patient has no memory. Typical automatisms are lip smacking, swallowing, fumbling, scratching, or even walking about. After 30–120 seconds, the patient makes a gradual recovery to normal consciousness but may feel tired or ill for several hours after the attack.

The last type of partial seizure is the **secondarily generalized attack**, in which a partial seizure immediately precedes a generalized tonic-clonic (grand mal) seizure. This seizure type is described below.

Generalized Seizures

Generalized seizures are those in which there is no evidence of localized onset. The group is quite heterogeneous.

Generalized tonic-clonic (grand mal) seizures are the most dramatic of all epileptic seizures and are characterized by tonic rigidity of all extremities, followed in 15–30 seconds by a tremor that is actually an interruption of the tonus by relaxation. As the relaxation phases become longer, the attack enters the clonic phase, with massive jerking of the body. The clonic jerking slows over 60–120 seconds, and the patient is usually left in a stuporous state. The tongue or cheek may be bitten, and urinary incontinence is common. Primary generalized tonic-clonic seizures begin without evidence of localized onset, whereas secondary generalized tonic-clonic seizures are preceded by another seizure type, usually a partial seizure. The medical treatment of both primary and secondary generalized tonic-clonic seizures is the same and uses drugs appropriate for *partial* seizures.

The **absence (petit mal) seizure** is characterized by both sudden onset and abrupt cessation. Its duration is usually less than 10 seconds and rarely more than 45 seconds. Consciousness is altered; the attack may also be associated with mild clonic jerking of the eyelids or extremities, with postural tone changes, autonomic phenomena, and automatisms. The occurrence of automatisms can complicate the clinical differentiation from complex partial seizures in some patients. Absence attacks begin in childhood or adolescence and may occur up to hundreds of times a day. The electroencephalogram during the seizure shows a highly characteristic 2.5–3.5 Hz spike-and-wave pattern. Atypical absence patients have seizures with postural changes that are more abrupt, and such patients are often mentally retarded; the electroencephalogram may show a slower spike-and-wave discharge, and the seizures may be more refractory to therapy.

Myoclonic jerking is seen, to a greater or lesser extent, in a wide variety of seizures, including generalized tonic-clonic seizures, partial seizures, absence seizures, and infantile spasms. Treatment of seizures that include myoclonic jerking should be directed at the primary seizure type rather than at the myoclonus. Some patients, however, have myoclonic jerking as the major seizure type, and some have frequent myoclonic jerking and occasional generalized tonic-clonic seizures without overt signs of neurologic deficit. Many kinds of myoclonus exist, and much effort has gone into attempts to classify this entity.

Atonic seizures are those in which the patient has sudden loss of postural tone. If standing, the patient falls suddenly to the floor and may be injured. If seated, the head and torso may suddenly

drop forward. Although most often seen in children, this seizure type is not unusual in adults. Many patients with atonic seizures wear helmets to prevent head injury.

Infantile spasms are an epileptic syndrome and not a seizure type. The attacks, although sometimes fragmentary, are most often bilateral and are included for pragmatic purposes with the generalized seizures. These attacks are most often characterized clinically by brief, recurrent myoclonic jerks of the body with sudden flexion or extension of the body and limbs; the forms of infantile spasms are, however, quite heterogeneous. Ninety percent of affected patients have their first attack before the age of 1 year. Most patients are mentally retarded, presumably from the same cause as the spasms. The cause is unknown in many patients, but such widely disparate disorders as infection, kernicterus, tuberous sclerosis, and hypoglycemia have been implicated. In some cases, the electroencephalogram is characteristic. Drugs used to treat infantile spasms are effective only in some patients; there is little evidence that the mental retardation is alleviated by therapy, even when the attacks disappear.

Therapeutic Strategy

For most antiseizure drugs, relationships between blood levels and therapeutic effects have been characterized to a high degree. The same is true for the pharmacokinetics of these drugs. These relationships provide significant advantages in the development of therapeutic strategies for the treatment of epilepsy. The therapeutic index for most antiseizure drugs is low, and toxicity is not uncommon. Thus, effective treatment of seizures requires an awareness of the therapeutic levels and pharmacokinetic properties as well as the characteristic toxicities of each agent. Measurements of antiseizure drug plasma levels are extremely useful when combined with clinical observations and pharmacokinetic data (Table 24–2).

Table 24–2. Effective Plasma Levels of Six Antiseizure Drugs.¹

Drug	Effective Level (μg/mL)	High Effective Level ² (μg/mL)	Toxic Level (μg/mL)
Carbamazepine	4–12	7	> 8
Primidone	5–15	10	< 12
Phenytoin	10–20	18	> 20
Phenobarbital	10–40	35	> 40
Ethosuximide	50–100	80	> 100
Valproate	50–100	80	> 100

¹Reprinted, with permission, from Porter RJ: *Epilepsy: 100 Elementary Principles*, 2nd ed. Saunders, 1989.

²Level that should be achieved, if possible, in patients with refractory seizures, assuming that the blood samples are drawn before administration of the morning medication. Higher levels are often possible—without toxicity—when the drugs are used alone, ie, as monotherapy.

Management of Epilepsy

Partial Seizures & Generalized Tonic-Clonic Seizures

Until recently, the choice of drugs was usually limited to phenytoin, carbamazepine, or barbiturates. There has been a strong tendency in the past few years to limit the use of sedative antiseizure drugs such as barbiturates and benzodiazepines to patients who cannot tolerate other medications. In the 1980s, the trend was to increase the use of carbamazepine. Although the choice now appears to be divided between carbamazepine and phenytoin, all of the newer drugs have shown effectiveness against these seizures. The exact role of these drugs remains to be determined, making decisions for the individual patient more complex.

Generalized Seizures

The drugs used for generalized tonic-clonic seizures are the same as for partial seizures; in addition, valproate is clearly useful.

Three drugs are effective against absence seizures. Two are nonsedating and therefore preferred: ethosuximide and valproate. Clonazepam is also highly effective but has disadvantages of dose-related adverse effects and development of tolerance. The drug of choice is ethosuximide, although valproate is effective in some ethosuximide-resistant patients. Lamotrigine and topiramate may also be useful.

Specific myoclonic syndromes are usually treated with valproate; an intravenous formulation can be used acutely as needed. It is nonsedating and can be dramatically effective. Other patients respond to clonazepam, nitrazepam, or other benzodiazepines, although high doses may be necessary, with accompanying sedation and drowsiness. Zonisamide and levetiracetam may be useful. Another specific myoclonic syndrome, juvenile myoclonic epilepsy, can be aggravated by phenytoin or carbamazepine; valproate is the drug of choice followed by lamotrigine and topiramate.

Atonic seizures are often refractory to all available medications, although some reports suggest that valproate may be beneficial, as may lamotrigine. Benzodiazepines have been reported to improve seizure control in some of these patients but may worsen the attacks in others. Felbamate has been demonstrated to be effective in some patients, although the drug's idiosyncratic toxicity limits its use. If the loss of tone appears to be part of another seizure type (such as absence or complex partial seizures), every effort should be made to treat the other seizure type vigorously, hoping for simultaneous alleviation of the atonic component of the seizure. The ketogenic diet may also be useful.

Drugs Used in Infantile Spasms

The treatment of infantile spasms is unfortunately limited to improvement of control of the seizures rather than other features of the disorder, such as retardation. Most patients receive a course of intramuscular corticotropin, although some clinicians note that prednisone may be equally effective and can be given orally. Clinical trials have been unable to settle the matter. In either case, therapy must often be discontinued because of adverse effects. If seizures recur, repeat courses of corticotropin or corticosteroids can be given, or other drugs may be tried. Other drugs widely used are the benzodiazepines such as clonazepam or nitrazepam; their efficacy in this heterogeneous syndrome may be nearly as good as that of corticosteroids. Vigabatrin may also be effective. The mechanism of action of corticosteroids or corticotropin in the treatment of infantile spasms is unknown. Further details may be sought in more specialized texts.

Status Epilepticus

There are many forms of status epilepticus. The most common, generalized tonic-clonic status epilepticus, is a life-threatening emergency, requiring immediate cardiovascular, respiratory, and metabolic management as well as pharmacologic therapy. The latter virtually always requires intravenous administration of antiseizure medications. Diazepam is the most effective drug in most patients for stopping the attacks and is given directly by intravenous push to a maximum total dose of 20–30 mg in adults. Intravenous diazepam may depress respiration (less frequently, cardiovascular function), and facilities for resuscitation must be immediately at hand during its administration. The effect of diazepam is not lasting, but the 30- to 40-minute seizure-free interval allows more definitive therapy to be initiated. For patients who are not actually in the throes of a seizure, diazepam therapy can be omitted and the patient treated at once with a long-acting drug such as phenytoin. Some physicians prefer lorazepam, which is equivalent to diazepam in effect and perhaps somewhat longer-acting.

Until the introduction of fosphenytoin, the mainstay of continuing therapy for status epilepticus was intravenous phenytoin, which is effective and nonsedating. It should be given as a loading dose of 13–18 mg/kg in adults; the usual error is to give too little. Administration should be at a maximum rate of 50 mg/min. It is safest to give the drug directly by intravenous push, but it can also be diluted in saline; it precipitates rapidly in the presence of glucose. Careful monitoring of cardiac rhythm and blood pressure is necessary, especially in elderly people. At least part of the cardiotoxicity is from the propylene glycol in which the phenytoin is dissolved. Fosphenytoin, which is freely soluble in intravenous solutions without the need for propylene glycol or other solubilizing agents, is a better parenteral agent. Because of its greater molecular weight, this prodrug is two thirds to three quarters as potent as phenytoin on a milligram basis.

In previously treated epileptic patients, the administration of a large loading dose of phenytoin may cause some dose-related toxicity such as ataxia. This is usually a relatively minor problem during the acute status episode and is easily alleviated by later adjustment of plasma levels.

For patients who do not respond to phenytoin, phenobarbital can be given in large doses: 100–200 mg intravenously to a total of 400–800 mg. Respiratory depression is a common complication, especially if benzodiazepines have already been given, and there should be no hesitation in instituting intubation and ventilation.

Although other drugs such as lidocaine have been recommended for the treatment of generalized tonic-clonic status epilepticus, general anesthesia is usually necessary in highly resistant cases.

For patients in absence status, benzodiazepines are still drugs of first choice. Rarely, intravenous valproate may be required.

Special Aspects of the Toxicology of Antiseizure Drugs

Teratogenicity

The potential teratogenicity of antiseizure drugs is controversial and important. It is important because teratogenicity resulting from long-term drug treatment of millions of people throughout the world may have a profound effect even if the effect occurs in only a small percentage of cases. It is controversial because both epilepsy and antiseizure drugs are heterogeneous, and few epileptic patients are available for study who are not receiving these drugs. Furthermore, patients with severe epilepsy, in whom genetic factors rather than drug factors may be of greater importance in the

occurrence of fetal malformations, are often receiving multiple antiseizure drugs in high doses.

In spite of these limitations, it appears—from whatever cause—that children born to mothers taking antiseizure drugs have an increased risk, perhaps twofold, of congenital malformations. Phenytoin has been implicated in a specific syndrome called **fetal hydantoin syndrome**, although not all investigators are convinced of its existence and a similar syndrome has been attributed both to phenobarbital and to carbamazepine. Valproate, as noted above, has also been implicated in a specific malformation, spina bifida. It is estimated that a pregnant woman taking valproic acid or sodium valproate has a 1–2% risk of having a child with spina bifida. Topiramate has shown some teratogenicity in animal testing.

In dealing with the clinical problem of a pregnant woman with epilepsy, most epileptologists agree that while it is important to minimize exposure to antiseizure drugs, both in numbers and dosages, it is also important not to allow maternal seizures to go unchecked.

Withdrawal

Withdrawal of antiseizure drugs, whether by accident or by design, can cause increased seizure frequency and severity. There are two factors to consider: the effects of the withdrawal itself and the need for continued drug suppression of seizures in the individual patient. In many patients, both factors must be considered. It is important to note, however, that the abrupt discontinuance of antiseizure drugs ordinarily does not cause seizures in nonepileptic patients provided the drug levels are not above the usual therapeutic range when the drug is stopped.

Some drugs are more easily withdrawn than others. In general, withdrawal of anti-absence drugs is easier than withdrawal of drugs needed for partial or generalized tonic-clonic seizures. Barbiturates and benzodiazepines are the most difficult to discontinue; weeks or months may be required, with very gradual dosage decrements, to accomplish their complete removal, especially if the patient is not hospitalized.

Because of the heterogeneity of epilepsy, complete discontinuance of antiseizure drug administration is an especially difficult problem. If a patient is seizure-free for 3 or 4 years, gradual discontinuance is usually warranted.

Overdose

Antiseizure drugs are central nervous system depressants but are rarely lethal. Very high blood levels are usually necessary before overdoses can be considered life-threatening. The most dangerous effect of antiseizure drugs after large overdoses is respiratory depression, which may be potentiated by other agents, such as alcohol. Treatment of antiseizure drug overdose is supportive; stimulants should not be used. Efforts to hasten removal of antiseizure drugs, such as alkalinization of the urine (phenytoin is a weak acid), are usually ineffective.

Katzung PHARMACOLOGY, 9e > Section V. Drugs That Act in the Central Nervous System > Chapter 24. Antiseizure Drugs* >

Preparations Available

Carbamazepine (generic, Tegretol)

Oral: 200 mg tablets; 100 mg chewable tablets; 100 mg/5 mL suspension

Oral extended-release: 100, 200, 400 mg tablets; 200, 300 mg capsules

Clonazepam (generic, Klonopin)

Oral: 0.5, 1, 2 mg tablets

Clorazepate dipotassium (generic, Tranxene)

Oral: 3.75, 7.5, 15 mg tablets, capsules

Oral sustained-release (Tranxene-SD): 11.25, 22.5 mg tablets

Diazepam (generic, Valium, others)

Oral: 2, 5, 10 mg tablets; 5 mg/5 mL, 5 mg/mL solutions

Parenteral: 5 mg/mL for IV injection

Rectal: 2.5, 5, 10, 15, 20 mg diazepam viscous rectal solution

Ethosuximide (generic, Zarontin)

Oral: 250 mg capsules; 250 mg/5 mL syrup

Ethotoin (Peganone)

Oral: 250, 500 mg tablets

Felbamate (Felbatol)

Oral: 400, 600 mg tablets; 600 mg/5 mL suspension

Fosphenytoin (Cerebyx)

Parenteral: 75 mg/mL for IV or IM injection

Gabapentin (Neurontin)

Oral: 100, 300, 400 mg capsules; 600, 800 mg filmtabs; 50 mg/mL solution

Lamotrigine (Lamictal)

Oral: 25, 100, 150, 200 mg tablets; 2, 5, 25 mg chewable tablets

Levetiracetam (Keppra)

Oral: 250, 500, 750 mg tablets

Lorazepam (generic, Ativan)

Oral: 0.5, 1, 2 mg tablets; 2 mg/mL solution

Parenteral: 2, 4 mg/mL for IV or IM injection

Mephenytoin (Mesantoin)

Oral: 100 mg tablets

Mephobarbital (Mebaral)

Oral: 32, 50, 100 mg tablets

Oxycarbazepine (Trileptal)

Oral: 100, 300, 600 mg tablets; 60 mg/mL suspension

Pentobarbital sodium (generic, Nembutal)

Parenteral: 50 mg/mL for IV or IM injection

Phenobarbital (generic, Luminal Sodium, others)

Oral: 15, 16, 30, 60, 90, 100 mg tablets; 16 mg capsules; 15, 20 mg/5 mL elixirs

Parenteral: 30, 60, 65, 130 mg/mL for IV or IM injection

Phenytoin (generic, Dilantin, others)

Oral (prompt release): 100 mg capsules; 50 mg chewable tablets; 30, 125 mg/5 mL suspension

Oral extended-action: 30, 100 mg capsules

Oral slow release (Phenytek): 200, 300 mg capsules

Parenteral: 50 mg/mL for IV injection

Primidone (generic, Mysoline)

Oral: 50, 250 mg tablets; 250 mg/5 mL suspension

Tiagabine (Gabitril)

Oral: 4, 12, 16, 20 mg tablets

Topiramate (Topamax)

Oral: 25, 100, 200 mg tablets; 15, 25 mg sprinkle capsules

Trimethadione (Tridione)

Oral: 150 mg chewable tablets; 300 mg capsules; 40 mg/mL solution

Valproic acid (generic, Depakene)

Oral: 250 mg capsules; 250 mg/5 mL syrup (sodium valproate)

Oral sustained-release (Depakote): 125, 250, 500 mg tablets (as divalproex sodium)

Parenteral (Depacon): 100 mg/mL in 5 mL vial for IV injection

Chapter 25. General Anesthetics

Katzung PHARMACOLOGY, 9e > Section V. Drugs That Act in the Central Nervous System > Chapter 25. General Anesthetics >

General Anesthetics: Introduction

The physiologic state of general anesthesia typically includes analgesia, amnesia, loss of consciousness, inhibition of sensory and autonomic reflexes, and skeletal muscle relaxation. The extent to which any individual anesthetic drug can exert these effects varies with the drug, the dosage, and the clinical situation.

An ideal anesthetic drug would induce anesthesia smoothly and rapidly while allowing for prompt recovery after its administration is discontinued. The drug would also possess a wide margin of safety and be devoid of adverse effects. No single anesthetic agent is capable of achieving all of these desirable effects without some disadvantages when used alone. The modern practice of anesthesiology most commonly involves the use of combinations of intravenous and inhaled drugs, taking advantage of their individual favorable properties while attempting to minimize their potential for causing adverse reactions.

The anesthetic technique will vary depending on the proposed type of diagnostic, therapeutic, or surgical intervention. For minor procedures, so-called monitored anesthesia care or conscious sedation is used, employing oral or parenteral sedatives in conjunction with local anesthetics (see Chapter 26: Local Anesthetics). These techniques provide profound analgesia, but with retention of the patient's ability to maintain a patent airway and to respond to verbal commands. For more extensive surgical procedures, anesthesia frequently includes the use of preoperative benzodiazepines, induction of anesthesia with intravenous thiopental or propofol, and maintenance of anesthesia with a combination of inhaled and intravenous anesthetic drugs. Such protocols also often include the use of neuromuscular blocking drugs (see Chapter 27: Skeletal Muscle Relaxants).

Types of General Anesthetics

General anesthetics are usually given by inhalation or by intravenous injection.

Inhaled Anesthetics

The chemical structures of the currently available inhaled anesthetics are shown in Figure 25–1. Nitrous oxide, a gas at ambient temperature and pressure, continues to be an important component of many anesthesia regimens. Halothane, enflurane, isoflurane, desflurane, sevoflurane, and methoxyflurane are volatile liquids.

Figure 25–1.

Intravenous Anesthetics

Several drugs are used intravenously, alone or in combination with other drugs, to achieve an anesthetic state (as components of balanced anesthesia) or to sedate patients in intensive care units who must be mechanically ventilated. These drugs include the following: (1) barbiturates (thiopental, methohexital); (2) benzodiazepines (midazolam, diazepam); (3) opioid analgesics (morphine, fentanyl, sufentanil, alfentanil, remifentanyl); (4) propofol; (5) ketamine; and (6) miscellaneous drugs (droperidol, etomidate, dexmedetomidine). Figure 25–2 shows the structures of

commonly used intravenous anesthetics.

Figure 25–2.

Signs & Stages of Anesthesia

The traditional description of the signs and stages of anesthesia (Guedel's signs) were derived from observations of the effects of diethyl ether, which has a slow onset of central action owing to its high solubility in blood. With these signs, anesthetic effects can be divided into four stages of increasing depth of central nervous system depression.

I. Stage of Analgesia: The patient initially experiences analgesia without amnesia. Later in stage I, both analgesia and amnesia are produced.

II. Stage of Excitement: During this stage, the patient often appears to be delirious and excited but definitely is amnesic. Respiration is irregular both in volume and rate, and retching and vomiting may occur. The patient may struggle and is sometimes incontinent. For these reasons, efforts are made to limit the duration and severity of this stage, which ends with the reestablishment of regular breathing.

III. Stage of Surgical Anesthesia: This stage begins with the recurrence of regular respiration

and extends to complete cessation of spontaneous respiration. Four planes of stage III have been described in terms of changes in ocular movements, eye reflexes, and pupil size, which under specified conditions may represent signs of increasing depth of anesthesia.

IV. Stage of Medullary Depression: This stage of anesthesia includes severe depression of the vasomotor center in the medulla as well as the respiratory center. Without full circulatory and respiratory support, death rapidly ensues.

In modern anesthesia practice, the distinctive signs of each of the four stages described above are usually obscured. Reasons for this include the relatively rapid onset of action of many intravenous and inhaled anesthetics compared with ether and the fact that respiratory activity is often controlled mechanically with muscle relaxants. In addition, the practice of administering other pharmacologic agents preoperatively or intraoperatively can also alter the clinical signs of anesthesia. Atropine and glycopyrrrolate are used to decrease secretions; however, they also dilate the pupils. Drugs such as tubocurarine and succinylcholine affect muscle tone, and the opioid analgesics exert depressant effects on respiration. The most reliable indication that stage III (surgical anesthesia) has been achieved is loss of the eyelash reflex and establishment of a regular respiratory pattern. The adequacy of depth of anesthesia for the specific surgical requirements is assessed by changes in respiratory and cardiovascular responses with surgical stimulation.

While vital sign monitoring remains a common method of assessing depth of anesthesia during surgery, newer techniques involving computer-assisted monitoring of cerebral function appear to offer some advantages. Automated techniques available include those based on the bispectral index (BIS), the physical state index (PSI) and the middle-latency auditory evoked potential (MLAEP), all of which are processed variables derived from established effects of anesthetics on the electroencephalogram. The application of such real-time cerebral monitoring techniques has been shown to reduce the volatile anesthetic requirement, contributing to a more rapid recovery from general anesthesia.

Katzung PHARMACOLOGY, 9e > Section V. Drugs That Act in the Central Nervous System > Chapter 25. General Anesthetics >

Inhaled Anesthetics

Pharmacokinetics

Depth of anesthesia is dependent upon the concentration of anesthetic in the central nervous system. The rate at which an effective brain concentration is reached (the rate of induction of anesthesia) depends on multiple pharmacokinetic factors that influence the uptake and distribution of the anesthetic. Certain of these factors also influence the rate of recovery from anesthesia when the anesthetic is discontinued.

Uptake & Distribution

The concentration of an individual gas in a mixture of gases is proportionate to its **partial pressure** or **tension**. These terms are often used interchangeably in discussing the various transfer processes of anesthetic gases in the body. Achievement of a brain concentration of an inhaled anesthetic adequate to cause anesthesia requires transfer of that anesthetic from the alveolar air to blood and then to brain. The rate at which a given concentration of anesthetic in the brain is reached depends on the solubility properties of the anesthetic, its concentration in the inspired air, pulmonary ventilation rate, pulmonary blood flow, and the partial pressure gradient of the anesthetic between arterial and mixed venous blood.

Solubility

One of the most important factors influencing the transfer of an anesthetic from the lungs to the arterial blood is its solubility. The blood:gas partition coefficient is a useful index of solubility and defines the relative affinity of an anesthetic for the blood compared to air. The partition coefficients for desflurane and nitrous oxide, which are not very soluble in the blood, are low (< 0.5). Halothane has a value greater than 2, and methoxyflurane, which is rarely used, has a coefficient of more than 10 (Table 25–1). When an anesthetic with low blood solubility diffuses from the lung into the arterial blood, relatively few molecules are required to raise its partial pressure, and therefore the arterial tension rises quickly (Figure 25–3, top, nitrous oxide). Conversely, for anesthetics with moderate to high solubility, more molecules dissolve before partial pressure changes significantly, and arterial tension of the gas increases less rapidly (Figure 25–3, bottom, halothane). This inverse relationship between the blood solubility of an anesthetic and the rate of rise of its tension in arterial blood is illustrated in Figure 25–4. Nitrous oxide with low solubility in blood, reaches high arterial tensions rapidly, which in turn results in rapid equilibration with the brain and fast onset of action. A rapid onset of anesthetic action is also characteristic of desflurane and sevoflurane, compounds that also have a low blood:gas partition coefficient.

Table 25–1. Properties of Inhaled Anesthetics.

Anesthetic	Blood:Gas Partition Coefficient ¹	Brain:Blood Partition Coefficient ¹	Minimal Alveolar Conc (MAC) (%) ²	Metabolism	Comments
Nitrous oxide	0.47	1.1	> 100	None	Incomplete anesthetic; rapid onset and recovery
Desflurane	0.42	1.3	6–7	< 0.05%	Low volatility; poor induction agent; rapid recovery
Sevoflurane	0.69	1.7	2.0	2–5% (fluoride)	Rapid onset and recovery; unstable in soda-lime
Isoflurane	1.40	2.6	1.4	< 2%	Medium rate of onset and recovery
Enflurane	1.80	1.4	1.7	8%	Medium rate of onset and recovery
Halothane	2.30	2.9	0.75	> 40%	Medium rate of onset and recovery
Methoxyflurane	12	2.0	0.16	> 70%	Slow onset and

¹Partition coefficients (at 37 °C) are from multiple literature sources.

²MAC is the anesthetic concentration that produces immobility in 50% of patients exposed to a noxious stimulus.

Figure 25–3.

Why induction of anesthesia is slower with more soluble anesthetic gases. In this schematic diagram, solubility in blood is represented by the relative size of the blood compartment (the more soluble, the larger the compartment). Relative partial pressures of the agents in the compartments are indicated by the degree of filling of each compartment. For a given concentration or partial pressure of the two anesthetic gases in the inspired air, it will take much longer for the blood partial pressure of the more soluble gas (halothane) to rise to the same partial pressure as in the alveoli. Since the concentration of the anesthetic agent in the brain can rise no faster than the concentration in the blood, the onset of anesthesia will be slower with halothane than with nitrous oxide.

Figure 25–4.

Tensions of three anesthetic gases in arterial blood as a function of time after beginning inhalation. Nitrous oxide is relatively insoluble (blood:gas partition coefficient = 0.47); methoxyflurane is much more soluble (coefficient = 12); and halothane is intermediate (2.3).

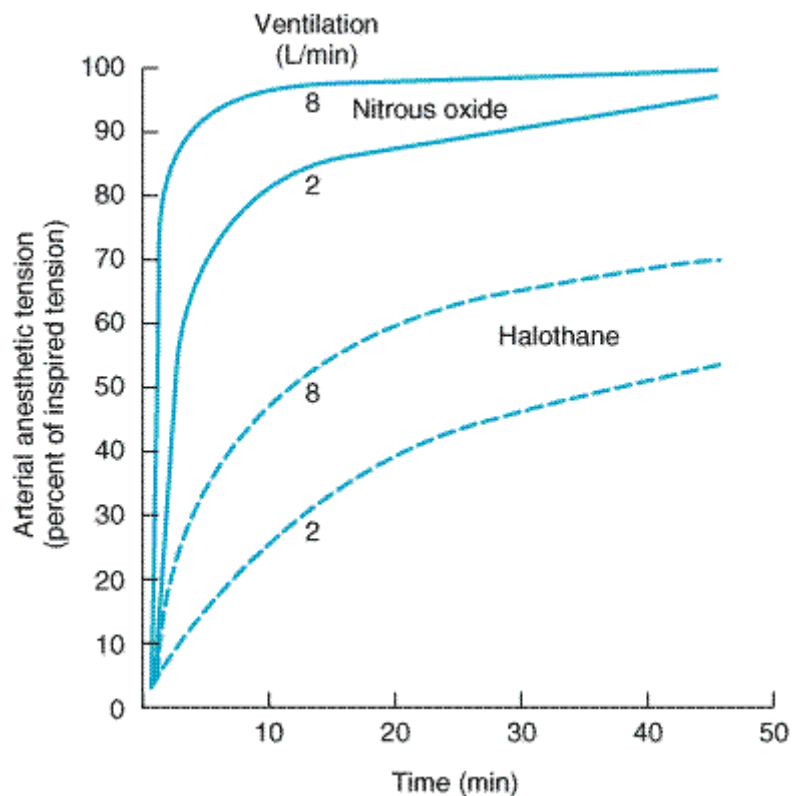

Anesthetic Concentration in the Inspired Air

The concentration of an inhaled anesthetic in the inspired gas mixture has direct effects on both the maximum tension that can be achieved in the alveoli and the rate of increase in its tension in arterial blood. Increases in the inspired anesthetic concentration will increase the rate of induction of anesthesia by increasing the rate of transfer into the blood according to Fick's law (see Chapter 1: Introduction). Advantage is taken of this effect in anesthetic practice with inhaled anesthetics of moderate blood solubility such as enflurane, isoflurane, and halothane, which have a relatively slow onset of anesthetic effect. For example, a 3–4% concentration of halothane may be administered initially to increase the rate of induction; this is reduced to 1–2% for maintenance when adequate anesthesia is achieved. In addition, these anesthetics are often administered in combination with a less soluble agent (eg, nitrous oxide) to reduce the time required for loss of consciousness.

Pulmonary Ventilation

The rate of rise of anesthetic gas tension in arterial blood is directly dependent on both the rate and depth of ventilation (ie, minute ventilation). The magnitude of the effect varies according to the blood:gas partition coefficient. An increase in pulmonary ventilation is accompanied by only a slight increase in arterial tension of an anesthetic with low blood solubility or low coefficient but can significantly increase tension of agents with moderate or high blood solubility (Figure 25–5). For example, a fourfold increase in ventilation rate almost doubles the arterial tension of halothane during the first 10 minutes of anesthesia but increases the arterial tension of nitrous oxide by only 15%. Therefore, hyperventilation increases the speed of induction of anesthesia with inhaled anesthetics that would normally have a slow onset. Depression of respiration by opioid analgesics will slow the onset of anesthesia of some inhaled anesthetics if ventilation is not assisted.

Figure 25–5.

Ventilation rate and arterial anesthetic tensions. Increased ventilation (8 versus 2 L/min) has a much greater effect on equilibration of halothane than nitrous oxide.

Pulmonary Blood Flow

Changes in blood flow to and from the lungs influence transfer processes of the anesthetic gases. An increase in pulmonary blood flow (increased cardiac output) slows the rate of rise in arterial tension, particularly for those anesthetics with moderate to high blood solubility. This is because increased pulmonary blood flow exposes a larger volume of blood to the anesthetic; thus, blood "capacity" increases and the anesthetic tension rises slowly. A decrease in pulmonary blood flow has the opposite effect and increases the rate of rise of arterial tension of inhaled anesthetics. In a patient with circulatory shock, the combined effects of decreased cardiac output (resulting in decreased pulmonary flow) and increased ventilation will accelerate the induction of anesthesia with halothane and isoflurane. This is not likely to occur with nitrous oxide, desflurane, or sevoflurane because of their low blood solubility.

Arteriovenous Concentration Gradient

The anesthetic concentration gradient between arterial and mixed venous blood is dependent mainly on uptake of the anesthetic by the tissues, including nonneural tissues. Depending on the rate and extent of tissue uptake, venous blood returning to the lungs may contain significantly less anesthetic than arterial blood. The greater this difference in anesthetic tensions, the more has been taken up by viscera, muscle, etc, and the more time it will take to achieve equilibrium with brain tissue. Anesthetic entry into tissues is influenced by factors similar to those that determine transfer from lung to blood, including tissue:blood partition coefficient, rates of blood flow to the tissues, and

concentration gradients.

During the induction phase of anesthesia, the tissues that exert greatest influence on the arterial-venous anesthetic concentration gradient are those which are highly perfused. These include the brain, heart, liver, kidneys, and splanchnic bed, which together receive over 75% of the resting cardiac output. In the case of anesthetics with relatively high solubility in these tissues, venous blood concentration will initially be very low, and equilibrium with arterial blood is achieved slowly.

During maintenance of anesthesia with inhaled anesthetics, these drugs may continue to be transferred between various tissues at rates dependent on solubility and blood flow. Muscle and skin, which together constitute 50% of body mass, accumulate anesthetics more slowly than the highly vascularized tissues (eg, brain), since they receive only one-fifth the blood flow of the latter groups. Although most anesthetic gases have high solubility in adipose tissues, low blood perfusion rates to these tissues delay accumulation, and equilibrium is unlikely to occur with most anesthetics during the time usually required for surgery.

Elimination

The time to recovery from inhalation anesthesia depends on the rate of elimination of anesthetics from the brain after the inspired concentration of anesthetic has been decreased. Many of the processes of anesthetic transfer during recovery are similar to those that occur during induction of anesthesia. One of the most important factors governing rate of recovery is the blood:gas partition coefficient of the anesthetic agent (see below). Other factors controlling rate of recovery include the pulmonary blood flow, the magnitude of ventilation, and the solubility of the anesthetic in the tissues. Two features of recovery, however, are quite different from what happens during induction of anesthesia. First, while transfer of an anesthetic from the lungs to blood can be enhanced by increasing its concentration in inspired air, the reverse transfer process cannot be enhanced, since the concentration in the lungs cannot be reduced below zero. Second, at the beginning of recovery, the anesthetic gas tension in different tissues may be quite variable, depending on the specific agent and the duration of anesthesia. With induction of anesthesia, the initial anesthetic tension in all tissues is zero.

Inhaled anesthetics that are relatively insoluble in blood (low blood:gas partition coefficient) and brain are eliminated at faster rates than more soluble anesthetics. The washout of nitrous oxide, desflurane, and sevoflurane occurs at a rapid rate, which leads to a more rapid recovery from their anesthetic effects compared to halothane and isoflurane. Halothane is approximately twice as soluble in brain tissue and five times more soluble in blood than nitrous oxide and desflurane; its elimination therefore takes place more slowly, and recovery from halothane anesthesia is predictably less rapid. The duration of exposure to the anesthetic can also have a marked effect on the time of recovery, especially in the case of more soluble anesthetics. Accumulation of anesthetics in tissues, including muscle, skin, and fat, increases with continuous inhalation (especially in obese patients), and blood tension may decline slowly during recovery as the anesthetic is gradually eliminated from these tissues. Thus, if exposure to the anesthetic is short, recovery may be rapid even with the more soluble agents. However, after prolonged anesthesia, recovery may be delayed even with anesthetics of moderate solubility such as isoflurane.

Clearance of inhaled anesthetics by the lungs into the expired air is the major route of their elimination from the body. However, metabolism by enzymes of the liver and other tissues may also contribute to the elimination of volatile anesthetics. For example, the elimination of halothane during recovery is more rapid than that of enflurane, which would not be predicted from their

respective solubilities. However, over 40% of inspired halothane is metabolized during an average anesthetic procedure, while less than 10% of enflurane is metabolized over the same period. Oxidative metabolism of halothane results in the formation of trifluoroacetic acid and release of bromide and chloride ions. Under conditions of low oxygen tension, halothane is metabolized to the chlorotrifluoroethyl free radical, which is capable of reacting with hepatic membrane components. Isoflurane and desflurane are the least metabolized of the fluorinated anesthetics, only traces of trifluoroacetic acid appearing in the urine even after prolonged administration. The metabolism of enflurane and sevoflurane results in the formation of fluoride ion, which does not appear to reach toxic levels under normal circumstances. In addition, sevoflurane is degraded by contact with the carbon dioxide absorbent in anesthesia machines, yielding a vinyl ether called "compound A" that can cause renal damage if high concentrations are absorbed. (See Do We Need Another Inhaled Anesthetic?) Over 70% of absorbed methoxyflurane is metabolized by the liver with the release of fluoride ions at concentrations that can be nephrotoxic. In terms of the extent of metabolism of inhaled anesthetics, the rank order is: methoxyflurane > halothane > enflurane > sevoflurane > isoflurane > desflurane > nitrous oxide (Table 25–1). Nitrous oxide is probably not metabolized by human tissues.

Pharmacodynamics

Mechanism of Action

The inhaled anesthetics—and most of the intravenous agents—depress spontaneous and evoked activity of neurons in many regions of the brain. Older concepts of the mechanism of anesthesia invoked nonspecific interactions of these agents with the lipid matrix of the nerve membrane (the Meyer-Overton principle)—interactions that were thought to lead to secondary changes in ion flux. More recently, evidence has accumulated suggesting that the modification of ion currents by anesthetics results from more specific interactions with nerve membrane components. The ionic mechanisms involved for different anesthetics may vary, but at clinically relevant concentrations they appear to involve interactions with members of the ligand-gated ion channel family.

In the past decade, considerable evidence has accumulated that a primary molecular target of many general anesthetics is the GABA_A receptor-chloride channel, a major mediator of inhibitory synaptic transmission. Inhaled anesthetics, barbiturates, benzodiazepines, etomidate, and propofol facilitate GABA-mediated inhibition at GABA_A receptor sites. These receptors are sensitive to clinically relevant concentrations of the anesthetic agents and exhibit the appropriate stereospecific effects in the case of enantiomeric drugs. The GABA_A receptor-chloride channel is a pentameric assembly of five proteins derived from several polypeptide subclasses (see Chapter 22: Sedative-Hypnotic Drugs). Combinations of three major subunits— α , β , and γ —are necessary for normal physiologic and pharmacologic functions. GABA_A receptors in different areas of the central nervous system contain different subunit combinations conferring different pharmacologic properties on each receptor subtype. Inhaled anesthetics and intravenous agents with general anesthetic properties directly activate GABA_A receptors, but at low concentrations they can also facilitate the action of GABA to increase chloride ion flux. In contrast, sedative benzodiazepines lacking general anesthetic properties (eg, midazolam) facilitate GABA action but have no direct actions on GABA_A receptors even at high concentrations in the absence of GABA.

Reconstitution studies with transfected cells utilizing chimeric and mutated GABA_A receptors reveal that anesthetic molecules do not interact directly with the GABA binding site but with specific sites in the transmembrane domains of both α and β subunits. Two specific amino acid residues in transmembrane segments 2 and 3 of the GABA_A receptor α_2 subunit, Ser270 and Ala291, are critical for the enhancement of GABA_A receptor function by inhaled anesthetics. One

consequence of the interaction of isoflurane with this domain is an alteration in the gating of the chloride ion channel. However, differences occur in the precise binding sites of individual anesthetics. For example, a specific aspartate residue within transmembrane segment 2 of the GABA_A receptor α_2 subunit is required for etomidate activity but is not essential for the activity of barbiturates or propofol.

Ketamine does not produce its effects via facilitation of GABA_A receptor functions, but it may function via antagonism of the action of the excitatory neurotransmitter glutamic acid on the NMDA receptor.

In addition to actions on GABA_A chloride channels, inhaled anesthetics have been reported to cause membrane hyperpolarization (an inhibitory action) via their activation of ligand-gated potassium channels. These channels are ubiquitous in the central nervous system and are linked to several neurotransmitters, including acetylcholine, dopamine, norepinephrine, and serotonin. Electrophysiologic analyses of membrane ion flux in cultured cells have shown that inhaled anesthetics decrease the duration of opening of nicotinic receptor-activated cation channels—an action that decreases the excitatory effects of acetylcholine at cholinergic synapses. Most inhaled anesthetics inhibit nicotinic acetylcholine receptor isoforms, particularly those containing the α_4 subunit, though such actions do not appear to be involved in their immobilizing actions. The strychnine-sensitive glycine receptor is another ligand-gated ion channel that may function as a target for inhaled anesthetics which can elicit channel opening directly and independently of their facilitatory effects on neurotransmitter binding.

The neuropharmacologic basis for the effects that characterize the stages of anesthesia appears to be differential sensitivity of specific neurons or neuronal pathways to the anesthetic drugs. Neurons in the substantia gelatinosa of the dorsal horn of the spinal cord are very sensitive to relatively low anesthetic concentrations. Interaction with neurons in this region interrupts sensory transmission in the spinothalamic tract, including transmission of nociceptive (pain) stimuli. These effects contribute to stage I analgesia and conscious sedation. The disinhibitory effects of general anesthetics (stage II), which occur at higher brain concentrations, result from complex neuronal actions including blockade of many small inhibitory neurons such as Golgi type II cells, together with a paradoxical facilitation of excitatory neurotransmitters. A progressive depression of ascending pathways in the reticular activating system occurs during stage III of anesthesia, together with suppression of spinal reflex activity, which contributes to muscle relaxation. Neurons in the respiratory and vasomotor centers of the medulla are relatively insensitive to the effects of the general anesthetics, but at high concentrations their activity is depressed, leading to cardiorespiratory collapse (stage IV). It remains to be determined whether regional variation in anesthetic actions corresponds with the regional variation in the subtypes of GABA_A receptor. The differential sensitivity of specific neurons or neuronal pathways to anesthetics could reflect their interactions with other molecules in the fast ligand-gated ion channel family or could represent the existence of other molecular targets that have yet to be characterized.

Dose-Response Characteristics: The Minimum Alveolar Anesthetic Concentration (MAC)

Inhaled anesthetics are delivered to the lungs in gas mixtures in which concentrations and flow rates are easy to measure and control. However, dose-response characteristics of gaseous anesthetics are difficult to measure. Although achievement of an anesthetic state depends on the concentration of the anesthetic in the brain, that concentration is impossible to measure under clinical conditions. Furthermore, neither the lower nor the upper ends of the graded dose-response curve can be ethically determined, since at very low concentrations severe pain might be experienced while at high concentrations there would be a high risk of fatal cardiovascular and respiratory depression.

Nevertheless, a useful estimate of anesthetic potency can be obtained using quantal dose-response principles.

During general anesthesia, the partial pressure of an inhaled anesthetic in the brain equals that in the lung when steady state is reached. Therefore, at a given level of anesthesia, the measurement of the steady-state alveolar concentrations of different anesthetics provides a comparison of their relative potencies. The minimum alveolar anesthetic concentration (MAC) is defined as the median concentration (ie, the percentage of the alveolar gas mixture, or partial pressure of the anesthetic as a percentage of 760 mm Hg) that results in immobility in 50% of patients when exposed to a noxious stimulus (eg, surgical incision). Therefore, MAC represents one point (the ED₅₀) on a conventional quantal dose-response curve (see Figure 2–16). Table 25–1 shows some properties of the common inhaled anesthetics, permitting comparison of their relative anesthetic potencies. The MAC value greater than 100% for nitrous oxide demonstrates that it is the least potent anesthetic, since at normal barometric pressure even 760 mm Hg partial pressure of nitrous oxide (100% of the inspired gas) is still not equal to 1 MAC.

The dose of anesthetic gas that is being administered can be stated in multiples of MAC. While a dose of 1 MAC of any anesthetic prevents movement in response to surgical incision in 50% of patients, individual patients may require 0.5–1.5 MAC. Unfortunately, the MAC gives no information about the slope of the dose-response curve. In general, however, the dose-response relationship for inhaled anesthetics is very steep. Therefore, over 95% of patients may fail to respond to a noxious stimulus at 1.1 MAC. The measurement of MAC values under controlled conditions has permitted quantitation of the effects of a number of variables on anesthetic requirements. For example, MAC values decrease in elderly patients and with hypothermia, but are not affected greatly by sex, height, and weight. Of particular importance is the presence of adjuvant drugs, which can change anesthetic requirement. For example, when drugs such as the opioid analgesics, sympatholytics, or sedative-hypnotics are present, the MAC is decreased in a dose-related fashion. The inspired concentration of anesthetic should be decreased in these situations. MAC values of the inhaled anesthetics are additive. For example, nitrous oxide can be used as a "carrier" gas at 40% of its MAC, decreasing the anesthetic requirement of other inhaled anesthetics; 70% of their MAC would yield a total of 110% of one MAC, which is sufficient for surgical anesthesia in most patients.

Organ System Effects of Inhaled Anesthetics

Effects on Cardiovascular System

Halothane, desflurane, enflurane, sevoflurane, and isoflurane all decrease mean arterial pressure in direct proportion to their alveolar concentration. With halothane and enflurane, the reduced arterial pressure appears to be caused by a reduction in cardiac output because there is little change in systemic vascular resistance despite marked changes in individual vascular beds (eg, increase in cerebral blood flow). In contrast, isoflurane, desflurane, and sevoflurane have a depressant effect on arterial pressure as a result of a decrease in systemic vascular resistance with minimal effect on cardiac output.

Inhaled anesthetics change heart rate either directly by altering the rate of sinus node depolarization or indirectly by shifting the balance of autonomic nervous system activity. Bradycardia is often seen with halothane, probably through vagal stimulation. In contrast, enflurane, and sevoflurane have little effect, and both desflurane and isoflurane increase heart rate. In the case of desflurane, cardiovascular responses include a transient sympathetic activation that can lead to marked increases in heart rate and blood pressure when high inspired gas concentrations are administered.

All inhaled anesthetics tend to increase right atrial pressure in a dose-related fashion, which reflects depression of myocardial function. In general, enflurane and halothane have greater myocardial depressant effects than isoflurane and the newer less soluble halogenated anesthetics. Inhaled anesthetics reduce myocardial oxygen consumption, primarily by decreasing the variables that control oxygen demand, such as arterial blood pressure and contractile force. Although certainly less depressant than the other inhaled anesthetics, nitrous oxide has also been found to depress the myocardium in a dose-dependent manner. However, nitrous oxide in combination with potent inhaled anesthetics produces sympathetic stimulation that minimizes cardiac depressant effects. The combination of nitrous oxide with halothane or enflurane, for example, appears to produce less cardiac depression at a given depth of anesthesia than either of the more potent anesthetics given alone.

Several factors influence the cardiovascular effects of inhaled anesthetics. Surgical stimulation, volume status, ventilatory status, and duration of anesthesia will alter the depressant effects of these drugs. Hypercapnia releases catecholamines, which attenuate the decrease in blood pressure. The blood pressure decrease after 5 hours of anesthesia is less than it is after 1 hour; concomitant use of beta-blockers reduces this adaptive effect. Halothane (and, to a lesser extent, isoflurane) sensitizes the myocardium to catecholamines. Ventricular arrhythmias may occur in patients with cardiac disease who are given sympathomimetic drugs or have high circulating levels of endogenous catecholamines (eg, anxious patients, patients with pheochromocytoma). The newer, less soluble inhaled anesthetics appear to be less arrhythmogenic.

Effects on the Respiratory System

With the exception of nitrous oxide, all inhaled anesthetics in current use cause a dose-dependent decrease in tidal volume and an increase in respiratory rate. However, the increase in rate is insufficient to compensate for the decrease in volume, resulting in a decrease in minute ventilation. All inhaled anesthetics are respiratory depressants, as indicated by a reduced response to increased levels of carbon dioxide. The degree of ventilatory depression varies among the volatile agents, with isoflurane and enflurane being the most depressant. All inhaled anesthetics in current use increase the resting level of PaCO₂ (the partial pressure of carbon dioxide in arterial blood).

Inhaled anesthetics increase the apneic threshold (PaCO₂ level below which apnea occurs through lack of CO₂-driven respiratory stimulation) and decrease the ventilatory response to hypoxia. The latter effect is especially important because subanesthetic concentrations (ie, those that exist during recovery) depress the normal compensating increase in ventilation that occurs during hypoxia. Respiratory depressant effects of anesthetics are overcome by assisting or controlling ventilation mechanically. Furthermore, the ventilatory depressant effects of the inhaled anesthetics are lessened by surgical stimulation.

Inhaled anesthetics also depress mucociliary function in the airway. Thus, prolonged anesthesia may lead to pooling of mucus and then result in atelectasis and postoperative respiratory infections. However, inhaled anesthetics tend to be bronchodilators, an effect of value in the treatment of status asthmaticus. The bronchodilating action of halothane and sevoflurane makes them the induction agents of choice in patients with underlying airway problems. Airway irritation, which may provoke coughing or breath holding, is rarely a problem with most inhaled anesthetics. However, it is relatively common with desflurane, making induction of anesthesia more difficult to accomplish with this anesthetic despite its low blood:gas partition coefficient. Similarly, the pungency of enflurane may elicit breath holding, which can decrease the speed of induction.

Effects on Brain

Inhaled anesthetics decrease the metabolic rate of the brain. Nevertheless, most volatile agents increase cerebral blood flow because they decrease cerebral vascular resistance. The increase in cerebral blood flow is often clinically undesirable. For example, in patients who have an increased intracranial pressure because of a brain tumor or head injury, administration of a volatile anesthetic may increase cerebral blood flow, which in turn will increase cerebral blood volume and further increase intracranial pressure.

Of the inhaled anesthetics, nitrous oxide increases cerebral blood flow the least. However, when 60% nitrous oxide is added to halothane anesthesia, cerebral blood flow usually increases more than with halothane alone. At low doses, all of the halogenated agents have similar effects on cerebral blood flow. At larger doses, enflurane and isoflurane increase cerebral blood flow less than halothane. If the patient is hyperventilated before the anesthetic is given (reducing PaCO₂), the increase in intracranial pressure from inhaled anesthetics can be minimized.

Halothane, isoflurane, and enflurane have similar effects (eg, burst suppression) on the EEG up to doses of 1–1.5 MAC. At higher doses, the cerebral irritant effects of enflurane may lead to development of a spike-and-wave pattern during which auditory stimuli can precipitate mild generalized muscle twitching that is augmented by hyperventilation. Enflurane-induced EEG seizure activity has never been shown to have any adverse clinical consequences, though it may be prudent to avoid the use of enflurane in patients with a history of seizure disorders. This effect is not seen clinically with the newer volatile anesthetics. Although nitrous oxide has low anesthetic potency, it does exert analgesic and amnesic actions, desirable properties when used in combination with other agents in general anesthesia and dental anesthesia.

Effects on the Kidney

To varying degrees, all inhaled anesthetics decrease glomerular filtration rate and effective renal plasma flow and increase filtration fraction. All the anesthetics tend to increase renal vascular resistance. Since renal blood flow decreases during general anesthesia in spite of well-maintained or even increased perfusion pressures, autoregulation of renal flow is probably impaired.

Effects on the Liver

All volatile anesthetics cause a decrease in hepatic blood flow, ranging from 15% to 45% of the preanesthetic flow rate. Despite transient intraoperative changes in liver function tests, permanent changes in liver function rarely occur from the use of these agents. The hepatotoxicity of halothane is discussed below.

Effects on Uterine Smooth Muscle

Nitrous oxide appears to have little effect on uterine musculature. However, the halogenated hydrocarbon anesthetics are potent uterine muscle relaxants. This pharmacologic effect can be used to advantage when profound uterine relaxation is required for intrauterine fetal manipulation or manual extraction of a retained placenta during delivery.

Toxicity

Hepatotoxicity (Halothane)

Postoperative hepatic dysfunction is usually associated with factors such as blood transfusions, hypovolemic shock, and other surgical stresses rather than anesthetic toxicity. However, a very

small subset of individuals exposed to halothane may develop a potentially severe and life-threatening hepatitis. The incidence of severe hepatotoxicity following exposure to halothane is probably in the range of one in 20,000–35,000. Obese patients having more than one exposure to halothane during a short time interval may be more susceptible. There is no specific treatment for halothane hepatitis, and liver transplantation may ultimately be required.

The mechanisms underlying hepatotoxicity from halothane remain unclear, but studies in animals have implicated the formation of reactive metabolites that either cause direct hepatocellular damage (eg, free radical intermediates) or initiate immune-mediated responses. With regard to the latter mechanism, serum from patients with halothane hepatitis contains a variety of autoantibodies against hepatic proteins, many of which are in a trifluoroacetylated form. These trifluoroacetylated proteins could be formed in the hepatocyte during the biotransformation of halothane by liver drug-metabolizing enzymes. However, TFA proteins have also been identified in the sera of patients who did not develop hepatitis after halothane anesthesia.

Nephrotoxicity

Metabolism of enflurane and sevoflurane leads to the formation of fluoride ions, and this has raised questions concerning the potential nephrotoxicity of these anesthetics. Changes in renal concentrating ability have been observed with prolonged exposure to enflurane but not sevoflurane. Differences between the two agents may be related to the fact that enflurane (but not sevoflurane) is metabolized in part by renal enzymes, generating fluoride ions intrarenally. Sevoflurane degradation by carbon dioxide absorbents in anesthesia machines leads to formation of a haloalkene, compound A, that causes a proximal tubular necrosis when administered to rats. However, there have been no reports of renal injury in humans undergoing sevoflurane anesthesia, and the anesthetic does not appear to change standard markers of renal function. Renal dysfunction following methoxyflurane is caused by inorganic fluoride released during the extensive metabolism of this anesthetic by hepatic and renal enzymes. As a result, methoxyflurane is considered obsolete for most purposes.

Malignant Hyperthermia

Malignant hyperthermia is an autosomal dominant genetic disorder of skeletal muscle that occurs in susceptible individuals undergoing general anesthesia with inhaled agents and muscle relaxants (eg, succinylcholine). The malignant hyperthermia syndrome consists of the rapid onset of tachycardia and hypertension, severe muscle rigidity, hyperthermia, hyperkalemia, and acid-base imbalance with acidosis, following exposure to a triggering agent. Malignant hyperthermia is a rare but important cause of anesthetic morbidity and mortality. The specific biochemical abnormality is an increase in free calcium concentration in skeletal muscle cells. Treatment includes administration of dantrolene (which prevents calcium release from the sarcoplasmic reticulum) and appropriate measures to reduce body temperature and restore electrolyte and acid-base balance.

Malignant hyperthermia susceptibility is characterized by genetic heterogeneity, and several predisposing clinical myopathies have been identified. It has been associated with mutations in the gene loci corresponding to the skeletal muscle ryanodine receptor (RYR1), the calcium release channel of the sarcoplasmic reticulum. Mutations in the ryanodine receptor gene are inherited as mendelian dominant characteristics. Other chromosomal loci for malignant hyperthermia susceptibility include mutant alleles of the gene encoding the α_1 subunit of the human skeletal muscle dihydropyridine-sensitive L-type voltage-dependent calcium channel. However, the genetic loci identified to date account for no more than 50% of malignant hyperthermia-susceptible individuals. Given such genetic heterogeneity, it seems premature to utilize genetic testing methods

for malignant hyperthermia susceptibility at this time. Currently, the most reliable test to establish such susceptibility is the in vitro caffeine-halothane contracture test utilizing skeletal muscle biopsy tissue.

Chronic Toxicity

Mutagenicity

Under normal conditions, most modern and many older inhaled anesthetics are neither mutagens nor carcinogens.

Carcinogenicity

Some epidemiologic studies have suggested an increase in the cancer rate in operating room personnel who have been exposed to trace concentrations of anesthetic agents. However, no study has demonstrated the existence of a cause-and-effect relationship between anesthetics and cancer. Many other factors might account for the questionably positive results seen after a careful review of epidemiologic data. Most operating room theaters remove trace concentrations of anesthetics released from anesthetic machines via vents to the outdoors.

Effects on Reproduction

The most consistent finding reported from surveys conducted to determine the reproductive performance of female operating room personnel has been a higher than expected incidence of miscarriages. However, there are several problems in interpreting these studies, and the evidence is not strong.

The association of obstetric problems with surgery and anesthesia in pregnant patients is an important consideration. In the USA, at least 50,000 pregnant women each year undergo anesthesia and surgery for indications unrelated to pregnancy. The risk of abortion is clearly higher following this experience. It is not obvious whether the underlying disease, surgery, anesthesia, or a combination of these factors is the cause of the increased risk. Another concern is that anesthesia during pregnancy may lead to an increased incidence of congenital anomalies. Since anesthetics do not appear to be teratogenic, the risk must be very small.

Hematotoxicity

Prolonged exposure to nitrous oxide decreases methionine synthase activity and causes megaloblastic anemia. This is a potential occupational hazard for staff working in poorly ventilated dental operating suites.

Clinical Use of Inhaled Anesthetics

Volatile anesthetics are rarely used as the sole agents for both induction and maintenance of anesthesia. Most commonly, they are combined with intravenous agents in regimens of so-called balanced anesthesia. Of the inhaled anesthetics, nitrous oxide, desflurane, sevoflurane, and isoflurane are the most commonly used in the USA. Use of the more soluble volatile anesthetics has declined during the last decade as more surgical procedures are performed on an outpatient ("short-stay") basis. The low blood:gas coefficients of desflurane and sevoflurane afford more rapid recovery and fewer postoperative adverse effects than halothane or isoflurane. Although halothane is still used in pediatric anesthesia, sevoflurane is rapidly replacing halothane in this setting. As

indicated previously, nitrous oxide lacks sufficient potency to produce surgical anesthesia by itself and therefore is used with volatile or intravenous anesthetics to produce a general anesthetic state.

Despite the advantages of the inhaled anesthetics now available, there is reason to believe that better ones might be developed. (See Do We Need Another Inhaled Anesthetic?)

Katzung PHARMACOLOGY, 9e > Section V. Drugs That Act in the Central Nervous System > Chapter 25. General Anesthetics >

Do We Need Another Inhaled Anesthetic?

For almost 30 years, from its introduction in 1956, halothane was the standard of comparison for inhaled anesthetics. However, the onset of its anesthetic action is slow compared with many intravenous agents, and the rate of recovery from its anesthetic effects is not rapid. In addition, its hepatic metabolism to a reactive compound may lead to development of halothane-associated hepatitis.

The newer inhaled anesthetics, desflurane and sevoflurane, have physicochemical characteristics (low blood:gas partition coefficients) favorable to a more rapid onset and a shorter duration of anesthetic actions than older agents such as isoflurane and halothane. However, both of these newer agents also have certain limitations. The low volatility of desflurane necessitates the use of a specialized vaporizer, and the pungency of the drug leads to a high incidence of coughing—and sometimes laryngospasm—such that it cannot be used for induction of anesthesia. In addition, desflurane causes a centrally mediated sympathetic activation leading to elevations of blood pressure and heart rate.

In the case of the newest agent, sevoflurane, induction of anesthesia is achieved rapidly and smoothly, and recovery is more rapid than most other inhaled anesthetics including isoflurane. However, sevoflurane is chemically unstable when exposed to carbon dioxide absorbents, degrading to an olefinic compound (fluoromethyl-2,2-difluoro-1-[trifluoromethyl]vinyl ether, compound A) that is potentially nephrotoxic. In addition, sevoflurane is metabolized by the liver to release fluoride ions, raising concerns about possible renal damage similar to that caused by methoxyflurane. Sevoflurane comes close to having the characteristics of an ideal gas anesthetic, but a relatively insoluble compound that has greater chemical stability could be a useful alternative in the future.

Katzung PHARMACOLOGY, 9e > Section V. Drugs That Act in the Central Nervous System > Chapter 25. General Anesthetics >

Intravenous Anesthetics

In the last 2 decades there has been increasing use of intravenous drugs in anesthesia, both as adjuncts to inhaled anesthetics and in techniques that do not include inhaled anesthetics (eg, total intravenous anesthesia). Unlike inhaled anesthetics, intravenous agents do not require specialized vaporizer equipment for their delivery or expensive facilities for the recovery and disposal of exhaled gases. Intravenous drugs such as thiopental, etomidate, ketamine, and propofol have an onset of anesthetic action faster than the fastest of the inhaled gaseous agents such as desflurane and sevoflurane. Therefore, intravenous agents are commonly used for induction of anesthesia. Recovery is sufficiently rapid with many intravenous drugs to permit their extensive use for short ambulatory (outpatient) surgical procedures. In the case of propofol, recovery times are similar to those seen with the shortest-acting inhaled anesthetics. The anesthetic potency of intravenous anesthetics, including thiopental, ketamine, and propofol, is adequate to permit their use as the sole anesthetic in short surgical procedures when combined with nitrous oxide and opioid analgesics.

Adjunctive use of potent opioids (eg, fentanyl and related compounds) contributes cardiovascular stability, enhanced sedation, and profound analgesia. Other intravenous agents such as the benzodiazepines (eg, midazolam, diazepam) have slower onset and recovery features and are rarely used for induction of anesthesia. However, preanesthetic administration of benzodiazepines can be used to provide a basal level of sedation and amnesia when used in conjunction with other anesthetic agents.

Pharmacokinetic properties of the intravenous anesthetics are summarized in Table 25–2.

Table 25–2. Characteristics of Intravenous Anesthetics.		
Drug	Induction and Recovery	Comments
Etomidate	Rapid onset and moderately fast recovery	Cardiovascular stability; decreased steroidogenesis; involuntary muscle movements
Ketamine	Moderately rapid onset and recovery	Cardiovascular stimulation; increased cerebral blood flow; emergence reactions impair recovery
Midazolam	Slow onset and recovery; flumazenil reversal available	Used in balanced anesthesia and conscious sedation; cardiovascular stability; marked amnesia
Propofol	Rapid onset and rapid recovery	Used in induction and for maintenance; hypotension; useful antiemetic action
Thiopental	Rapid onset and rapid recovery (bolus dose)—slow recovery following infusion	Standard induction agent; cardiovascular depression; avoid in porphyrias
Fentanyl	Slow onset and recovery; naloxone reversal available	Used in balanced anesthesia and conscious sedation; marked analgesia

Short-Acting Barbiturates

Thiopental is a short-acting barbiturate commonly used for induction of anesthesia. The general pharmacology of the barbiturates is discussed in Chapter 22: Sedative-Hypnotic Drugs.

Following an intravenous bolus injection, thiopental rapidly crosses the blood-brain barrier and, if given in sufficient dosage, produces loss of consciousness (hypnosis) in one circulation time. Similar effects occur with another short-acting barbiturate, methohexital. With these barbiturates, plasma:brain equilibrium occurs rapidly (< 1 minute) because of their high lipid solubility. Thiopental rapidly diffuses out of the brain and other highly vascular tissues and is redistributed to muscle, fat, and eventually all body tissues (Figure 25–6). It is because of this rapid removal from brain tissue that a single dose of thiopental is so short-acting. Thiopental is metabolized at the rate of 12–16% per hour in humans following a single dose. Less than 1% of an administered dose of thiopental is excreted unchanged by the kidney.

Figure 25–6.

Redistribution of thiopental after an intravenous bolus administration. Note that the time axis is not linear.

With large doses, thiopental causes dose-dependent decreases in arterial blood pressure, stroke volume, and cardiac output. This is due primarily to its myocardial depressant effect and increased venous capacitance; there is little change in total peripheral resistance. Thiopental is also a potent respiratory depressant, lowering the sensitivity of the medullary respiratory center to carbon dioxide.

Cerebral metabolism and oxygen utilization are decreased after thiopental administration in proportion to the degree of cerebral depression. Cerebral blood flow is also decreased, but much less so than oxygen consumption. This makes thiopental a desirable drug for use in patients with cerebral swelling (eg, head trauma, brain tumors), since intracranial pressure and blood volume are not increased (in contrast to the volatile anesthetics).

Thiopental may reduce hepatic blood flow and glomerular filtration rate, but it produces no lasting effects on hepatic and renal function. Barbiturates may exacerbate acute intermittent porphyria by inducing the synthesis of hepatic ALA synthase (see Chapter 22: Sedative-Hypnotic Drugs). Thiopental has precipitated porphyric crisis when used as an induction agent in susceptible individuals.

Benzodiazepines

Diazepam, lorazepam, and midazolam are used in anesthetic procedures. The primary indication is for premedication because of their sedative and amnestic properties. (The basic pharmacology of benzodiazepines is discussed in Chapter 22: Sedative-Hypnotic Drugs.) Diazepam and lorazepam are not water-soluble, and their intravenous use necessitates nonaqueous vehicles, which may cause local irritation. Midazolam formulations are water-soluble and thus produce less irritation, but the drug becomes lipid-soluble at physiologic pH and readily crosses the blood-brain barrier.

Compared with intravenous barbiturates, benzodiazepines produce a slower onset of central nervous

system effects and induce a plateau of central depression less than that required for a true anesthetic state. Large doses of benzodiazepines can prolong the postanesthetic recovery period (an undesirable effect), but they can produce a high incidence of anterograde amnesia which is clinically useful. Because it causes a high incidence of amnesia (> 50%), midazolam is frequently given intravenously before induction of general anesthesia. Midazolam has a more rapid onset, a shorter elimination half-life (2–4 hours), and a steeper dose-response curve than do the other benzodiazepines used in anesthesia.

The benzodiazepine antagonist flumazenil is sometimes used to accelerate recovery from excessive sedative actions of intravenous benzodiazepines, but reversal of respiratory depression by flumazenil is less predictable. Its short duration of action (< 90 minutes) may necessitate multiple doses to prevent recurrence of central nervous system depressant effects of longer-acting benzodiazepines.

Opioid Analgesics

Large doses of opioid analgesics have been used to achieve general anesthesia, particularly in patients undergoing cardiac surgery or other major surgery when their circulatory reserve is minimal. Intravenous morphine, 1–3 mg/kg, or the high-potency opioid fentanyl, 100–150 μ g/kg, have been used in such situations with minimal evidence of cardiovascular deterioration. More recently, several congeners of fentanyl, namely sufentanil, alfentanil, and remifentanil, have also been used. Despite the use of high doses of these potent opioids (see Table 31–2 for conventional analgesic doses), awareness during anesthesia and unpleasant postoperative recall have occurred.

Furthermore, high intravenous doses of opioids can cause chest wall rigidity, thereby acutely impairing ventilation, as well as postoperative respiratory depression requiring prolonged assisted ventilation and the administration of opioid antagonists (eg, naloxone). Low doses of fentanyl have been used as premedication and as an adjunct to both intravenous and inhaled anesthetics. Alfentanil and remifentanil have been used as induction agents since they both have a rapid onset of action. Remifentanil has an extremely short duration of action because it is rapidly metabolized by esterases in the blood (not plasma cholinesterase) and muscle tissues. The metabolism of remifentanil is not subject to genetic variability, and the drug does not interfere with the clearance of compounds metabolized by plasma cholinesterase (eg, esmolol, mivacurium, or succinylcholine). Rapid recovery following remifentanil is important regarding its potential utility in anesthesia regimens for ambulatory surgery. Fentanyl and droperidol (a butyrophenone related to haloperidol) together produce analgesia and amnesia and are sometimes used with nitrous oxide to provide a state of **neuroleptanesthesia**.

Opioid analgesics can also be used at low doses by the epidural and spinal routes of administration to produce excellent postoperative analgesia.

Propofol

Propofol (2,6-diisopropylphenol) is an extremely popular intravenous anesthetic. Its rate of onset of action is similar to that of the intravenous barbiturates; recovery is more rapid; and patients are able to ambulate sooner after propofol. Furthermore, patients subjectively "feel better" in the immediate postoperative period after propofol as compared with other intravenous anesthetics. Postoperative nausea and vomiting is less common because propofol has antiemetic actions. Propofol is used for both induction and maintenance of anesthesia; however, cumulative effects can delay arousal following prolonged infusion. These favorable properties are responsible for the extensive use of propofol as a component of balanced anesthesia and for its great popularity as an anesthetic for use

in day surgery outpatient procedures. The drug is also effective in producing prolonged sedation in patients in critical care settings (see Conscious Sedation and Deep Sedation). However, use of propofol for the sedation of children under intensive care has led to severe acidosis in the presence of respiratory infections and possible neurological sequelae on withdrawal.

After intravenous administration of propofol, the distribution half-life is 2–8 minutes; the elimination half-life is approximately 30–60 minutes. The drug is rapidly metabolized in the liver (ten times faster than thiopental) and excreted in the urine as glucuronide and sulfate conjugates. Less than 1% of the drug is excreted unchanged. Total body clearance of the anesthetic is greater than hepatic blood flow, suggesting that its elimination includes extrahepatic mechanisms in addition to metabolism by liver enzymes. This property is useful in patients with impaired ability to metabolize other sedative-anesthetic drugs.

Effects on respiration are similar to those of thiopental at usual anesthetic doses. However, propofol causes a marked decrease in systemic blood pressure during induction of anesthesia, primarily through decreased peripheral resistance. In addition, propofol has greater negative inotropic effects on the heart than etomidate and thiopental. Apnea and pain at the site of injection are common adverse effects of bolus administration. Muscle movements, hypotonus, and (rarely) tremors have also been reported following its use. Clinical infections due to bacterial contamination of the propofol emulsion have led to the addition of antimicrobial adjuvants (eg, ethylenediaminetetraacetic acid and metabisulfite).

Etomidate

Etomidate is a carboxylated imidazole that can be used for induction of anesthesia in patients with limited cardiovascular reserve. Its major advantage over other intravenous agents is that it causes minimal cardiovascular and respiratory depression. Etomidate produces a rapid loss of consciousness, with minimal hypotension. The heart rate is usually unchanged, and the incidence of apnea is low. The drug has no analgesic effects, and coadministration of opioids may be required to decrease cardiac responses during tracheal intubation and to lessen spontaneous muscle movements. Following an induction dose, recovery is rapid (< 5 minutes).

Distribution of etomidate is rapid, with a biphasic plasma concentration curve showing distribution half-lives of 3 and 29 minutes. Redistribution of the drug from brain to highly perfused tissues appears to be responsible for the short duration of its anesthetic effects. Etomidate is extensively metabolized in the liver and plasma to inactive metabolites with only 2% of the drug excreted unchanged in the urine.

Etomidate causes a high incidence of pain on injection, myoclonus, and postoperative nausea and vomiting. The involuntary muscle movements are not associated with electroencephalographic epileptiform activity. Etomidate may also cause adrenocortical suppression via inhibitory effects on steroidogenesis, with decreased plasma levels of hydrocortisone after a single dose. Prolonged infusion of etomidate in critically ill patients may result in hypotension, electrolyte imbalance, and oliguria due to its adrenal suppressive effects.

Ketamine

Ketamine (Figure 25–2) produces **dissociative anesthesia**, which is characterized by catatonia, amnesia, and analgesia, with or without actual loss of consciousness. The drug is an arylcyclohexylamine chemically related to phencyclidine (PCP), a drug frequently abused because of its psychoactive properties. The mechanism of action of ketamine may involve blockade of the

membrane effects of the excitatory neurotransmitter glutamic acid at the NMDA (*N*-methyl-D-aspartate) receptor subtype (see Chapter 21: Introduction to the Pharmacology of CNS Drugs).

Ketamine is a highly lipophilic drug and is rapidly distributed into highly vascular organs, including the brain, and subsequently redistributed to less well perfused tissues with concurrent hepatic metabolism and both urinary and biliary excretion.

Ketamine is the only intravenous anesthetic that possesses analgesic properties and produces cardiovascular stimulation. Heart rate, arterial blood pressure, and cardiac output are usually significantly increased. The peak increases in these variables occur 2–4 minutes after intravenous injection and then slowly decline to normal over the next 10–20 minutes. Ketamine produces its cardiovascular stimulation by excitation of the central sympathetic nervous system and possibly by inhibition of the reuptake of norepinephrine at sympathetic nerve terminals. Increases in plasma epinephrine and norepinephrine levels occur as early as 2 minutes after intravenous ketamine and return to baseline levels 15 minutes later.

Ketamine markedly increases cerebral blood flow, oxygen consumption, and intracranial pressure. In this regard ketamine resembles the volatile anesthetics as a potentially dangerous drug when intracranial pressure is elevated. In most patients, ketamine decreases the respiratory rate. However, upper airway muscle tone is well maintained, and airway reflexes are usually preserved.

Although it is a desirable anesthetic in many respects, ketamine has been associated with postoperative disorientation, sensory and perceptual illusions, and vivid dreams (so-called emergence phenomena). Diazepam, 0.2–0.3 mg/kg, or midazolam, 0.025–0.05 mg intravenously, given prior to the administration of ketamine reduces the incidence of these adverse effects. Because of the high incidence of postoperative psychic phenomena associated with its use, ketamine is not commonly used in general surgery in the USA. It is considered useful for poor-risk geriatric patients and in unstable patients (eg, cardiogenic or septic shock) because of its cardiostimulatory properties. It is also used in low doses for outpatient anesthesia in combination with propofol and in children undergoing painful procedures (eg, dressing changes for burns).

Conscious Sedation & Deep Sedation

Many diagnostic, therapeutic, and minor surgical procedures require neither general anesthesia nor the availability of specialized equipment and facilities necessary for inhaled anesthesia. In this setting, regional or local anesthesia supplemented with midazolam or propofol and opioid analgesics may be a more appropriate and safer approach than general anesthesia.

Another approach has been the development of protocols to provide a state of **conscious sedation** or drug-induced alleviation of anxiety and pain in combination with an altered level of consciousness, but with retention of the ability of the patient to maintain a patent airway and to respond to verbal commands. A wide variety of intravenous anesthetic agents have proved to be useful drugs in conscious sedation techniques. For example, intravenous benzodiazepines, propofol, and opioid analgesics can provide amnestic, sedative, and analgesic effects without loss of consciousness. Use of benzodiazepines and opioid analgesics in conscious sedation protocols has the advantage of being reversible by the specific receptor antagonist drugs (eg, flumazenil and naloxone, respectively).

A special form of conscious sedation is sometimes needed in the ICU, when patients are under

severe stress and often require mechanical ventilation for long periods (days) with an endotracheal tube in place. In this situation, sedative drugs or intravenous anesthetics in low dosage, neuromuscular blockers, and **dexmedetomidine** may be combined. Dexmedetomidine is an α_2 agonist with strong sedative properties. It has a half-life of 2–3 hours and is metabolized in the liver and excreted, mainly as metabolites, in the urine.

Deep sedation is a controlled state of anesthesia involving decreased consciousness from which the patient is not easily aroused. Since deep sedation is often accompanied by a loss of protective reflexes, an inability to maintain a patent airway, and lack of response to surgical stimuli, the state may be indistinguishable from that of general anesthesia. Intravenous agents used in deep sedation protocols include thiopental, ketamine, propofol, and certain intravenous opioid analgesics.

Preparations Available¹

Desflurane (Suprane)

Liquid: 240 mL for inhalation

Dexmedetomidine (Precedex)

Parenteral: 100 μ g/mL for IV infusion

Diazepam (generic, Valium)

Oral: 2, 5, 10 mg tablets; 5 mg/5 mL and 5 mg/mL solution

Oral sustained-release: 15 mg capsules

Parenteral: 5 mg/mL for injection

Droperidol (generic, Inapsine)

Parenteral: 2.5 mg/mL for IV or IM injection

Enflurane (Enflurane, Ethrane)

Liquid: 125, 250 mL for inhalation

Etomidate (Amidate)

Parenteral: 2 mg/mL for injection

Halothane (generic, Fluothane)

Liquid: 125, 250 mL for inhalation

Isoflurane (Isoflurane, Forane)

Liquid: 100 mL for inhalation

Ketamine (generic, Ketalar)

Parenteral: 10, 50, 100 mg/mL for injection

Lorazepam (generic, Ativan)

Oral: 0.5, 1, 2 mg tablets; 2 mg/mL solution

Parenteral: 2, 4 mg/mL for injection

Methohexital (Brevital Sodium)

Parenteral: 0.5, 2.5, 5 g powder to reconstitute for injection

Methoxyflurane (Penthrane)

Liquid: 15, 125 mL for inhalation

Midazolam (generic, Versed)

Parenteral: 1, 5 mg/mL for injection in 1, 2, 5, 10 mL vials

Oral: 2 mg/mL syrup

Nitrous oxide (gas, supplied in blue cylinders)

Propofol (generic, Diprivan)

Parenteral: 10 mg/mL for IV injection

Sevoflurane (Ultane)

Liquid: 250 mL for inhalation

Thiopental (generic, Pentothal)

Parenteral: powder to reconstitute 20, 25 mg/mL for IV injection

¹See Chapter 31: Opioid Analgesics & Antagonists for formulations of opioid agents used in anesthesia.

Chapter 26. Local Anesthetics

Katzung PHARMACOLOGY, 9e > Section V. Drugs That Act in the Central Nervous System > Chapter 26. Local Anesthetics >

Local Anesthetics: Introduction

Local anesthetics reversibly block impulse conduction along nerve axons and other excitable membranes that utilize sodium channels as the primary means of action potential generation. This action can be used clinically to block pain sensation from—or sympathetic vasoconstrictor impulses to—specific areas of the body. Cocaine, the first such agent, was isolated by Niemann in 1860. It was introduced into clinical use by Koller in 1884 as an ophthalmic anesthetic. Cocaine was soon found to be strongly addicting but was widely used, nevertheless, for 30 years, since it was the only local anesthetic drug available. In an attempt to improve the properties of cocaine, Einhorn in 1905 synthesized procaine, which became the dominant local anesthetic for the next 50 years. Since 1905, many local anesthetic agents have been synthesized. The goals of these efforts were reduction of local irritation and tissue damage, minimization of systemic toxicity, faster onset of action, and longer duration of action. Lidocaine, still a popular agent, was synthesized in 1943 by Löfgren and may be considered the prototype local anesthetic agent.

None of the currently available local anesthetics are ideal, and development of newer agents continues. However, while it is relatively easy to synthesize a chemical with local anesthetic effects, it is very difficult to reduce the toxicity significantly below that of the current agents. The major reason for this difficulty is the fact that the much of the serious toxicity of local anesthetics represents extensions of the therapeutic effect on the brain and the circulatory system. However, new research into the mechanisms of cardiac and spinal toxicity and alternative drug targets for spinal analgesia (eg, μ_2 receptors) suggest that it may be possible to find better drugs, at least for spinal anesthesia. In an attempt to extend the duration of the local anesthetic action, a variety of novel delivery systems are in development (eg, polymers). Transdermal local anesthetic delivery systems are also being investigated.

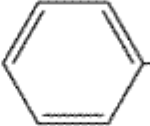

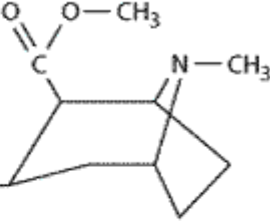

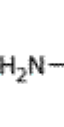

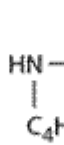

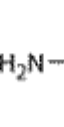

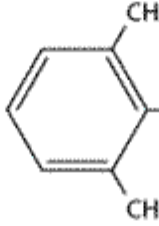

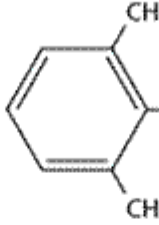

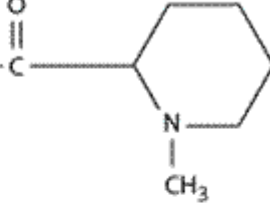

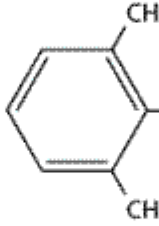

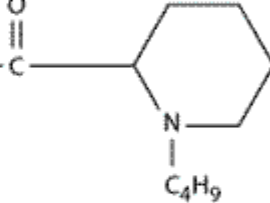

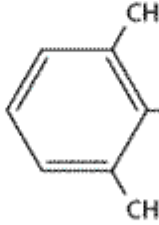

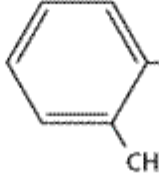

Katzung PHARMACOLOGY, 9e > Section V. Drugs That Act in the Central Nervous System > Chapter 26. Local Anesthetics >

Basic Pharmacology of Local Anesthetics

Chemistry

Most local anesthetic agents consist of a lipophilic group (frequently an aromatic ring) connected by an intermediate chain (commonly including an ester or amide) to an ionizable group (usually a tertiary amine; Table 26–1). In addition to the general physical properties of the molecules, specific stereochemical configurations are associated with differences in the potency of stereoisomers for a few compounds, eg, bupivacaine, ropivacaine. Since ester links (as in procaine) are more prone to hydrolysis than amide links, esters usually have a shorter duration of action.

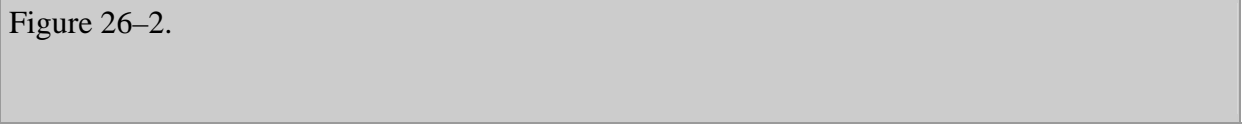

Table 26–1. Structure and Properties of Some Ester and Amide Local Anesthetics.¹

	Lipophilic Group	Intermediate Chain	Amine Substituents	(P)
Esters				
Cocaine		$\text{C}(=\text{O})\text{O}$		
Procaine (Novocain)		$\text{C}(=\text{O})\text{O}$	$\text{CH}_2\text{CH}_2\text{N}(\text{C}_2\text{H}_5)_2$	
Tetracaine (Pontocaine)		$\text{C}(=\text{O})\text{O}$	$\text{CH}_2\text{CH}_2\text{N}(\text{CH}_3)_2$	
Benzocaine		$\text{C}(=\text{O})\text{O}$	CH_2CH_3	
Amides				
Lidocaine (Xylocaine)		$\text{NH}-\text{C}(=\text{O})$	$\text{CH}_2\text{N}(\text{C}_2\text{H}_5)_2$	
Mepivacaine (Carbocaine, Isocaine)		$\text{NH}-\text{C}(=\text{O})$		
Bupivacaine (Marcaine), levobupivacaine (Chirocaine)		$\text{NH}-\text{C}(=\text{O})$		
Etidocaine (Duranest)		$\text{NH}-\text{C}(=\text{O})$	$\text{CH}(\text{C}_2\text{H}_5)\text{N}(\text{C}_2\text{H}_5)(\text{C}_3\text{H}_7)$	
Prilocaine (Citanest)		$\text{NH}-\text{C}(=\text{O})$	$\text{CH}(\text{CH}_3)\text{NHC}_3\text{H}_7$	

Clinical Pharmacology of Local Anesthetics

Local anesthetics can provide highly effective analgesia in well-defined regions of the body. The usual routes of administration include topical application (eg, nasal mucosa, wound margins), injection in the vicinity of peripheral nerve endings and major nerve trunks (infiltration), and injection into the epidural or subarachnoid spaces surrounding the spinal cord (Figure 26–2). Intravenous regional anesthesia of the arm or leg (Bier block) is used for short surgical procedures (< 45 minutes). This is accomplished by intravenous injection of the anesthetic agent into a distal vein while the circulation of the limb is isolated with a proximally placed tourniquet. Finally, an infiltration block of autonomic sympathetic fibers can be used to evaluate the role of sympathetic tone in patients with peripheral vasospasm.

Figure 26–2.

The choice of local anesthetic for a specific procedure is usually based on the duration of action

an intermediate duration of action; and tetracaine, bupivacaine, levobupivacaine, etidocaine, and ropivacaine are long-acting drugs (Table 26–1).

The anesthetic effect of the agents with short and intermediate durations of action can be prolonged by increasing the dose or by adding a vasoconstrictor agent (eg, epinephrine or phenylephrine). The vasoconstrictor retards the removal of drug from the injection site. In addition, it decreases the blood level and hence the probability of central nervous system toxicity.

The onset of local anesthesia can be accelerated by the use of solutions saturated with carbon dioxide ("carbonated"). The high tissue level of CO₂ results in intracellular acidosis (CO₂ crosses membranes readily), which in turn results in intracellular accumulation of the cationic form of the local anesthetic.

Repeated injection of local anesthetics can result in loss of effectiveness (ie, tachyphylaxis) due to extracellular acidosis. Local anesthetics are commonly marketed as hydrochloride salts (pH 4.0–6.0). After injection, the salts are buffered in the tissue to physiologic pH, thereby providing sufficient free base for diffusion through axonal membranes. However, repeated injections deplete the buffering capacity of the local tissues. The ensuing acidosis increases the extracellular cationic form, which diffuses poorly into axons. The clinical result is apparent tachyphylaxis, especially in areas of limited buffer reserve, such as the cerebrospinal fluid.

Pregnancy appears to increase susceptibility to local anesthetic toxicity in that median doses required for nerve block or to induce toxicity are reduced. Cardiac arrest leading to death following the epidural administration of 0.75% bupivacaine to women in labor resulted in the temporary withdrawal from the market of the high concentration of this long-acting local anesthetic and subsequent introduction of potentially less cardiotoxic alternatives (ie, ropivacaine and levobupivacaine) for this high-risk population. It is not clear whether the increased sensitivity during pregnancy is due to elevated estrogen, elevated progesterone, or some other factor.

Topical local anesthesia is often used for eye, ear, nose, and throat procedures and for cosmetic surgery. Satisfactory local anesthesia requires an agent capable of rapid penetration of the skin or mucosa and with limited tendency to diffuse away from the site of application. Cocaine, because of its excellent penetration and vasoconstrictor effects, has been used extensively for nose and throat procedures. It is somewhat irritating, however, and is thus much less popular for ophthalmic procedures. Recent concerns about its potential cardiotoxicity when combined with epinephrine has led most otolaryngologists and plastic surgeons to switch to a combination containing lidocaine and epinephrine. Other drugs used for topical anesthesia include lidocaine, tetracaine, pramoxine, dibucaine, benzocaine, and dyclonine.

Since local anesthetics are membrane-stabilizing drugs, both parenteral (eg, intravenous lidocaine) and oral (eg, mexiletine, tocainide) formulations of these drugs have been used to treat patients with neuropathic pain syndromes. Systemic local anesthetic drugs are commonly used as adjuvants to the combination of a tricyclic antidepressant (eg, amitriptyline) and an anticonvulsant (eg, carbamazepine) in patients who fail to respond to the standard tricyclic plus anticonvulsant combination. One to 3 weeks are required to observe a therapeutic effect after introduction of the local anesthetic in patients with neuropathic pain.

Toxicity

Two major forms of local anesthetic toxicity are recognized: direct neurotoxicity from the local effects of certain agents administered around the cord or other major nerve trunks, and systemic

effects, since ultimately, local anesthetic agents are absorbed from the site of administration. If blood levels rise too high, effects on several organ systems may be observed.

Central Nervous System

All Local Anesthetics

Central nervous system effects at low doses include sleepiness, light-headedness, visual and auditory disturbances, and restlessness. An early symptom of local anesthetic toxicity is circumoral and tongue numbness and a metallic taste. At higher concentrations, nystagmus and muscular twitching occur. Finally, overt tonic-clonic convulsions followed by central nervous system depression and death may occur. Local anesthetics apparently cause depression of cortical inhibitory pathways, thereby allowing unopposed activity of excitatory components. This transitional stage of unbalanced excitation is then followed by generalized central nervous system depression at higher blood levels of local anesthetic.

Convulsions due to excessive blood levels can usually be prevented by administering the smallest dose of local anesthetic required for adequate anesthesia and by avoiding inadvertent intravascular injection or injection into highly perfused tissues. When large doses must be administered, premedication with a benzodiazepine, eg, oral diazepam or midazolam parenterally, appears to provide significant prophylaxis against local anesthetic seizures by raising the seizure threshold. If seizures do occur, it is important to prevent hypoxemia and acidosis. Although administration of oxygen does not prevent seizure activity, hyperoxemia may be beneficial after onset of seizures. Since hypercapnia and acidosis may lower the seizure threshold, hyperventilation is recommended during treatment of seizures. In addition, hyperventilation increases blood pH, which in turn lowers extracellular potassium. This action hyperpolarizes the transmembrane potential of axons, which favors the rested or low-affinity state of the sodium channels, resulting in decreased local anesthetic toxicity.

Seizures induced by local anesthetics can also be treated with small doses (given intravenously) of thiopental 1–2 mg/kg, propofol 0.5–1 mg/kg, midazolam 2–4 mg total dose, or diazepam 0.1 mg/kg. The muscular manifestations of seizures can be suppressed by a short-acting neuromuscular blocking agent (eg, succinylcholine, 0.5–1 mg/kg IV). It should be emphasized that succinylcholine does not obliterate central nervous system manifestations of seizure activity. Rapid tracheal intubation and mechanical ventilation can prevent pulmonary aspiration of gastric contents and facilitate hyperventilation therapy.

Cocaine

Since prehistoric times, the natives of Peru have chewed the leaves of the indigenous plant *Erythroxylon coca*, the source of cocaine, to obtain a feeling of well-being and reduce fatigue. Intense central nervous system effects can be achieved by sniffing cocaine powder and smoking cocaine base. Cocaine has become one of the most widely abused drugs (see Chapter 32: Drugs of Abuse). High doses of inhaled cocaine as well as injected cocaine have all of the toxicities described for other local anesthetics in general. In addition, cocaine can produce severe cardiovascular toxicity, including hypertension and arrhythmias.

Neurotoxicity

When applied at excessively high concentrations, all local anesthetics can be toxic to nerve tissue. Chlorprocaine and lidocaine appear to be more neurotoxic than other local anesthetics when used

for spinal anesthesia, producing so-called transient radicular irritation. It has been suggested that this toxicity results from pooling of high concentrations of the local anesthetic in the cauda equina. Although the mechanism of this neurotoxic action has not been established, both interference with axonal transport and disruption of calcium homeostasis have been shown to occur and could be responsible. Spinal neurotoxicity does not result from excessive sodium channel blockade.

Cardiovascular System

The cardiovascular effects of local anesthetics result partly from direct effects upon the cardiac and smooth muscle membranes and partly from indirect effects upon the autonomic nerves. As described in Chapter 14: Agents Used in Cardiac Arrhythmias, local anesthetics block cardiac sodium channels and thus depress abnormal cardiac pacemaker activity, excitability, and conduction. At very high concentrations, they may also block calcium channels. With the notable exception of cocaine, local anesthetics also depress the strength of cardiac contraction and cause arteriolar dilation, both effects leading to severe hypotension. Cardiovascular collapse and death are rare and usually occur only after large doses of 0.75% bupivacaine.

As noted above, cocaine differs from the other local anesthetics in its cardiovascular effects. Cocaine's blockade of norepinephrine reuptake results in vasoconstriction and hypertension. It may also precipitate cardiac arrhythmias. The vasoconstriction produced by cocaine can lead to ischemia and, in chronic abusers, to ulceration of the mucous membrane and even damage to the nasal septum when "snorted." This vasoconstrictor property of cocaine can be used clinically to decrease bleeding from mucosal damage in the nasopharynx.

Bupivacaine is more cardiotoxic than other local anesthetics. This reflects the fact that bupivacaine block of sodium channels is potentiated by the long action potential duration of cardiac cells (as compared to nerve fibers). Studies have shown that the most common electrocardiographic finding in patients with bupivacaine intoxication is slow idioventricular rhythm with broad QRS complexes and eventually, electromechanical dissociation.

Resuscitation from bupivacaine cardiovascular toxicity is extremely difficult. However, prompt resuscitation has been successful with standard cardiopulmonary support, including the prompt correction of acidosis by hyperventilation and administration of bicarbonate as well as epinephrine, atropine, and bretylium. Local anesthetics, especially bupivacaine, also inhibit basal and epinephrine-stimulated cAMP production. This finding places greater emphasis on aggressive epinephrine therapy during bupivacaine-induced cardiotoxicity. The (*S*)-isomer, levobupivacaine, appears to have a lower propensity for cardiovascular toxicity than the racemic mixture or the (*R*)-isomer and has recently been approved for clinical use. **Ropivacaine**, another newer local anesthetic, has clinical effects similar to those of bupivacaine but may be associated with a lower potential for cardiovascular toxicity. Ropivacaine is available only as the (*S*)-stereoisomer, which has inherently less affinity for the cardiac sodium channel.

Hematologic Effects

The administration of large doses (> 10 mg/kg) of prilocaine during regional anesthesia may lead to accumulation of the metabolite *o*-toluidine, an oxidizing agent capable of converting hemoglobin to methemoglobin. When sufficient methemoglobin is present (3–5 mg/dL), the patient may appear cyanotic and the blood chocolate-colored. Although moderate levels of methemoglobinemia are well-tolerated by healthy individuals, they may cause decompensation in patients with cardiac or pulmonary disease. The treatment of methemoglobinemia involves the intravenous administration of reducing agents (eg, methylene blue or ascorbic acid), which rapidly convert methemoglobin to

hemoglobin.

Allergic Reactions

The ester type local anesthetics are metabolized to *p*-aminobenzoic acid derivatives. These metabolites are responsible for allergic reactions in a small percentage of the population. Amides are not metabolized to *p*-aminobenzoic acid, and allergic reactions to agents of the amide group are extremely rare.

Katzung PHARMACOLOGY, 9e > Section V. Drugs That Act in the Central Nervous System > Chapter 26. Local Anesthetics >

Preparations Available

Articaine (Septocaine)

Parenteral: 4% with 1:100,000 epinephrine

Benzocaine (generic, others)

Topical: 5, 6% creams; 15, 20% gels; 5, 20% ointments; 0.8% lotion; 20% liquid; 20% spray

Bupivacaine (generic, Marcaine, Sensorcaine)

Parenteral: 0.25, 0.5, 0.75% for injection; 0.25, 0.5, 0.75% with 1:200,000 epinephrine

Butamben picrate (Butesin Picrate)

Topical: 1% ointment

Chloroprocaine (generic, Nesacaine)

Parenteral: 1, 2, 3% for injection

Cocaine (generic)

Topical: 40, 100 mg/mL solutions; 5, 25 g powder

Dibucaine (generic, Nupercainal)

Topical: 0.5% cream; 1% ointment

Dyclonine (Dyclone)

Topical: 0.5, 1% solution

Levobupivacaine (Chirocaine)

Parenteral: 2.5, 5, 7.5 mg/mL

Lidocaine (generic, Xylocaine, others)

Parenteral: 0.5, 1, 1.5, 2, 4% for injection; 0.5, 1, 1.5, 2% with 1:200,000 epinephrine; 1, 2% with 1:100,000 epinephrine, 2% with 1:50,000 epinephrine

Topical: 2.5, 5% ointments; 0.5, 4% cream; 0.5, 2.5% gel; 2, 2.5, 4% solutions; 23, 46 mg/2 cm² patch

Lidocaine and etidocaine eutectic mixture (EMLA cream)

Topical: lidocaine 2.5% plus etidocaine 2.5%

Mepivacaine (generic, Carbocaine, others)

Parenteral: 1, 1.5, 2, 3% for injection; 2% with 1:20,000 levonordefrin

Pramoxine (Tronothane, others)

Topical: 1% cream, lotion, spray, and gel

Prilocaine (Citanest)

Parenteral: 4% for injection; 4% with 1:200,000 epinephrine

Procaine (generic, Novocain)

Parenteral: 1, 2, 10% for injection

Proparacaine (generic, Alcain, others)

0.5% solution for ophthalmic use

Ropivacaine (Naropin)

Parenteral: 0.2, 0.5, 0.75, 1.0 % solution for injection

Tetracaine (Pontocaine)

Parenteral: 1% for injection; 0.2, 0.3% with 6% dextrose for spinal anesthesia

Topical: 1% ointment; 0.5% solution (ophthalmic); 1, 2% cream; 2% solution for nose and throat; 2% gel

Chapter 27. Skeletal Muscle Relaxants

Katzung PHARMACOLOGY, 9e > Section V. Drugs That Act in the Central Nervous System > Chapter 27. Skeletal Muscle Relaxants >

Skeletal Muscle Relaxants: Introduction

Drugs that affect skeletal muscles fall into two major therapeutic groups: those used during surgical procedures and in intensive care units to cause paralysis (ie, **neuromuscular blockers**), and those used to reduce spasticity in a variety of neurologic conditions (ie, **spasmolytics**). Neuromuscular blocking drugs interfere with transmission at the neuromuscular end plate and lack central nervous system activity. These compounds are used primarily as adjuncts to general anesthesia. Drugs in the spasmolytic group have traditionally been called "centrally acting" muscle relaxants. However, at least one of these latter agents (dantrolene) has no significant central effects.

Neuromuscular Blocking Drugs

History

During the 16th century, European explorers found that natives of the Amazon Basin of South America were using an arrow poison (curare) that produced death by skeletal muscle paralysis. The active compound from curare, *d*-tubocurarine, and its synthetic derivatives have had an enormous influence on the practice of anesthesia and surgery and have been very useful in defining normal neuromuscular physiologic mechanisms.

Normal Neuromuscular Function

The mechanism of neuromuscular transmission at the end plate is similar to that described for preganglionic cholinergic nerves in Chapter 6: Introduction to Autonomic Pharmacology, with arrival of an impulse at the motor nerve terminal, influx of calcium, and release of acetylcholine. Acetylcholine then diffuses across the synaptic cleft to the nicotinic receptor located on the motor end plate. As noted in Chapter 7: Cholinergic-Activating & Cholinesterase-Inhibiting Drugs, this receptor is composed of five peptides: two alpha peptides, one beta, one gamma, and one delta peptide. Combination of two acetylcholine molecules with receptors on the two α subunits causes opening of the channel. The resulting movements of sodium and potassium are associated with a graded depolarization of the end plate membrane. This change in voltage is termed the motor end plate potential. The magnitude of the end plate potential is directly related to the amount of acetylcholine released. If the potential is small, the permeability and the end plate potential return to normal without an impulse being propagated from the end plate region to the rest of the muscle membrane. However, if the end plate potential is large, the adjacent muscle membrane is depolarized, and an action potential will be propagated along the entire muscle fiber. Muscle contraction is then initiated by excitation-contraction coupling. The released acetylcholine is quickly removed from the end plate region by diffusion and enzymatic destruction by the local acetylcholinesterase enzyme.

At least two additional types of acetylcholine receptors are associated with the neuromuscular apparatus. One is located on the presynaptic motor axon terminal; activation of these receptors mobilizes additional transmitter for subsequent release, perhaps by mobilizing more acetylcholine vesicles within the ending. The second type of receptor is found on perijunctional cells and is not normally involved in neuromuscular transmission. However, under certain conditions (eg, prolonged immobilization, burns), these receptors may proliferate sufficiently to affect subsequent neuromuscular transmission.

Skeletal muscle relaxation and paralysis can occur from interruption of function at several different sites, including the central nervous system, myelinated somatic nerves, unmyelinated motor nerve terminals, nicotinic acetylcholine receptors, the motor end plate, and the muscle membrane or

intracellular contractile apparatus itself (Figure 27–1).

Figure 27–1.

Schematic representation of the neuromuscular junction. (V, transmitter vesicle; M, mitochondrion; ACh, acetylcholine; AChE, acetylcholinesterase; JF, junctional folds.) (Reproduced, with permission, from Drachman DB: Myasthenia gravis. *N Engl J Med* 1978;298:135.)

In practice, blockade of end plate function is accomplished by two basic mechanisms. Pharmacologic blockade of the physiologic agonist acetylcholine is characteristic of the *antagonist* neuromuscular blocking drugs. These drugs prevent access of the transmitter to its receptor and prevent depolarization. The prototype of this *nondepolarizing* subgroup is ***d*-tubocurarine**. Block of transmission can also be produced by an excess of the depolarizing *agonist*, namely acetylcholine. This paradoxical effect of acetylcholine also occurs at the ganglionic nicotinic acetylcholine receptor. The clinically useful prototypical *depolarizing* blocking drug is **succinylcholine**. A similar depolarizing block can be produced by acetylcholine itself if very high local concentrations are achieved in the synaptic cleft (eg, in cholinesterase inhibitor intoxication), by nicotine, and by other nicotinic agonists. However, because the block produced by these drugs cannot be controlled adequately, they are of no clinical value in this application.

Katzung PHARMACOLOGY, 9e > Section V. Drugs That Act in the Central Nervous System > Chapter 27. Skeletal Muscle Relaxants >

Basic Pharmacology of Neuromuscular Blocking Drugs

Chemistry

All of the available neuromuscular blocking drugs bear a structural resemblance to acetylcholine. In fact, succinylcholine is two acetylcholine molecules linked end-to-end (Figure 27–2). In contrast to the single linear structure of succinylcholine and other depolarizing drugs, the nondepolarizing

agents (eg, pancuronium) conceal the "double-acetylcholine" structure in one of two types of bulky, semi-rigid ring systems (Figure 27–2). The two major families of nondepolarizing blocking drugs—the isoquinoline and steroid derivatives—are shown in Figures 27–3 and 27–4. Another feature common to all currently used neuromuscular blockers is the presence of one or two quaternary nitrogens, which makes them poorly lipid-soluble and limits entry into the central nervous system.

Figure 27–2.

Structural relationship of succinylcholine, a depolarizing agent, and pancuronium, a nondepolarizing agent, to acetylcholine, the neuromuscular transmitter. Succinylcholine, originally called diacetylcholine, is simply two molecules of acetylcholine linked through the acetate methyl groups. Pancuronium may be viewed as two acetylcholine-like fragments (*outlined in color*) oriented on a steroid nucleus.

Clinical Pharmacology of Neuromuscular Blocking Drugs

Skeletal Muscle Paralysis

Before the introduction of neuromuscular blocking drugs, profound skeletal muscle relaxation for intracavitary operations could be achieved only by producing deep levels of anesthesia that was often associated with profound depressant effects on the cardiovascular and respiratory systems. The adjunctive use of neuromuscular blocking drugs makes it possible to achieve adequate muscle relaxation for all types of surgical procedures without the cardiorespiratory depressant effects of deep anesthesia.

Assessment of Neuromuscular Transmission

Monitoring the effect of muscle relaxants during surgery (and recovery following the use of cholinesterase inhibitors) typically involves the use of a device that produces transdermal electrical stimulation of one of the peripheral nerves to the hand and recording of the evoked contractions (twitches; Figure 27–6). The motor responses to different patterns of peripheral nerve stimulation are measured. The three most commonly used patterns include (1) single-twitch stimulation, (2) train-of-four (TOF) stimulation, and (3) tetanic stimulation. Two newer modalities are also available to monitor neuromuscular transmission: double-burst stimulation and posttetanic count.

With single-twitch stimulation, a single supramaximal electrical stimulus is applied to a peripheral nerve at frequencies from 0.1 Hz to 1.0 Hz. The higher frequency is often used during induction and reversal to more accurately determine the peak (maximal) drug effect. TOF stimulation involves four successive supramaximal stimuli given at intervals of 0.5 second (2 Hz). Each stimulus in the TOF causes the muscle to contract, and the relative magnitude of the response of the fourth twitch compared to the first twitch is the TOF ratio. With a depolarizing block, all four twitches are reduced in a dose-related fashion. With a nondepolarizing block, the TOF ratio decreases ("fades") and is inversely proportionate to the degree of blockade. During recovery from nondepolarizing block, the amount of fade decreases as the TOF ratio approaches 1.0. Fade in the TOF response after administration of succinylcholine signifies the development of a phase II block.

Finally, tetanic stimulation consists of very rapid (30–100 Hz) delivery of electrical stimuli for several seconds. During a nondepolarizing block and a phase II block after succinylcholine, the response will not be sustained and fade is observed. Fade in response to tetanic stimulation is normally considered a presynaptic event. However, the degree of fade depends primarily on the degree of neuromuscular blockade. During a partial nondepolarizing blockade, tetanic nerve stimulation is followed by a posttetanic increase in the twitch response, a manifestation of so-called posttetanic facilitation of neuromuscular transmission. During very intense neuromuscular blockade, there is no response to either tetanic or posttetanic stimulation. As the intensity of the block diminishes, the response to posttetanic twitch stimulation reappears. The time to reappearance of the first response to TOF stimulation is related to the posttetanic count.

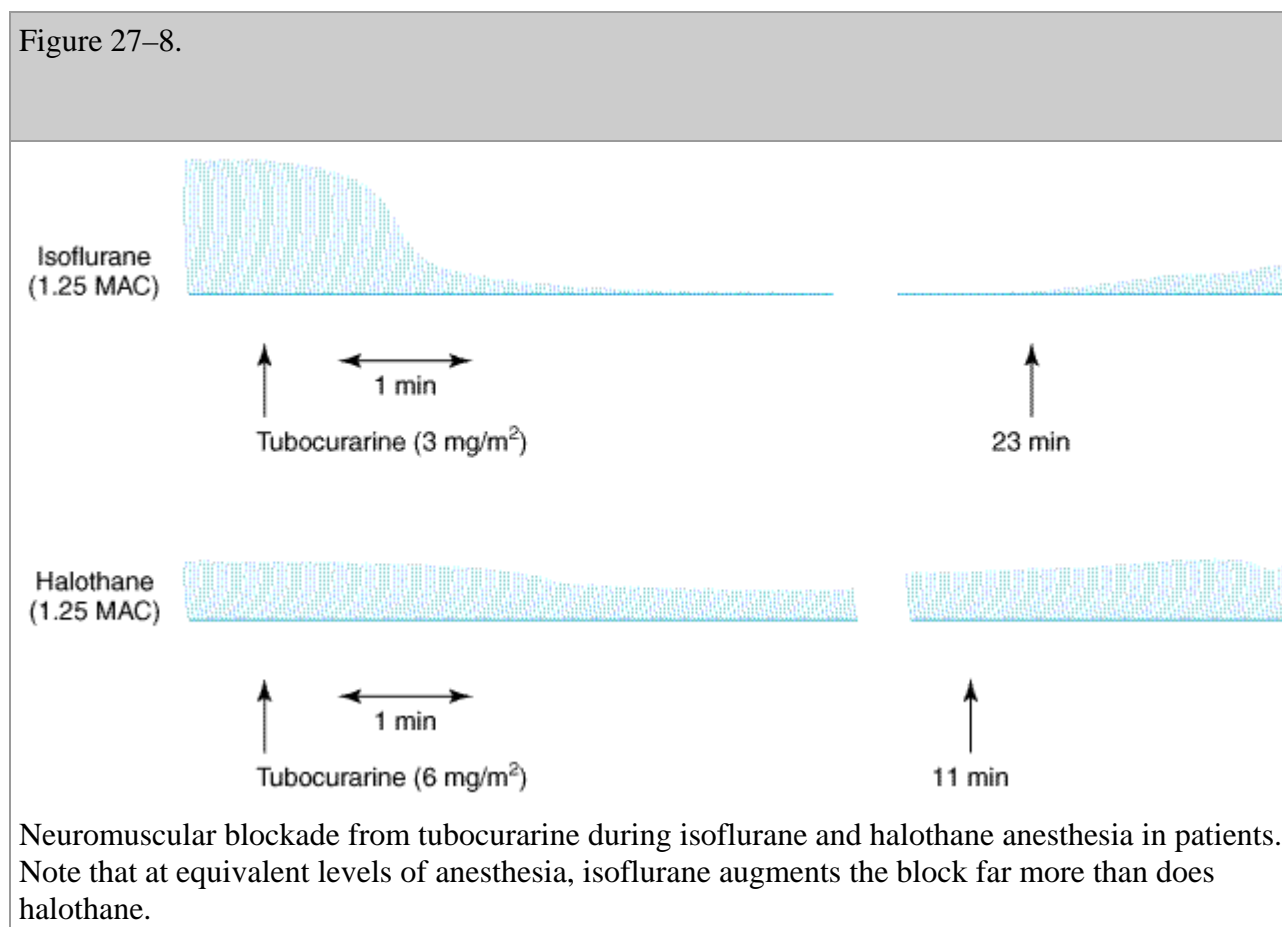

The double-burst stimulation pattern is a newer mode of electrical nerve stimulation developed with the goal of allowing for manual detection of residual neuromuscular blockade when it is not possible to record the responses to single-twitch, TOF, or tetanic stimulation. In this pattern, three nerve stimuli are delivered at 50 Hz followed by a 700 ms rest period and then by two or three additional stimuli at 50 Hz. It is easier to detect fade in the responses to double-burst stimulation

than in the responses to TOF stimulation. Note that the absence of fade in the responses to double-burst stimulation implies that clinically significant residual neuromuscular blockade does not exist.

Nondepolarizing Drugs

During anesthesia, the intravenous administration of tubocurarine, 0.1–0.4 mg/kg, will initially cause motor weakness, followed by the skeletal muscles becoming totally flaccid and inexcitable to electrical stimulation (Figure 27–8). In general, larger muscles (eg, abdominal, trunk, paraspinous, diaphragm) are more resistant to blockade and recover more rapidly than smaller muscles (eg, facial, foot, hand). The diaphragm is usually the last muscle to be paralyzed. Assuming that ventilation is adequately maintained, no adverse effects occur. When administration of muscle relaxants is discontinued, recovery of muscles usually occurs in reverse order, with the diaphragm regaining function first, depending on the relaxant's elimination half-life. The pharmacologic effect of tubocurarine, 0.3 mg/kg IV, usually lasts 45–60 minutes. However, subtle evidence of residual muscle paralysis detected using a neuromuscular monitor may last for another hour. Potency and duration of action of the other nondepolarizing drugs are shown in Table 27–1. In addition to the duration of action, the most important property distinguishing the nondepolarizing relaxants is the time to onset of effect, which determines how rapidly the patient's trachea can be intubated with a tracheal tube. Of the nondepolarizing drugs, rapacuronium has the fastest onset of effect (45–90 seconds) followed by rocuronium (60–120 seconds). As earlier noted, rapacuronium is no longer available.

Figure 27–8.

Depolarizing Drugs

Following the intravenous administration of succinylcholine, 0.75–1.5 mg/kg, transient muscle

fasciculations occur, especially over the chest and abdomen, though general anesthesia tends to attenuate them. As complete paralysis develops, the arm, neck, and leg muscles are involved at a time when there is only slight weakness of the facial and pharyngeal muscles. However, respiratory muscle weakness follows rapidly, usually within 60 seconds (Figure 27–9). As a result of succinylcholine's rapid hydrolysis by cholinesterase in the plasma and liver, the duration of neuromuscular block typically lasts 5–10 minutes (Table 27–1).

Figure 27–9.

Cardiovascular Effects

Vecuronium, pipecuronium, doxacurium, cisatracurium, and rocuronium have minimal cardiovascular effects. The other currently used nondepolarizing muscle relaxants (pancuronium, atracurium, mivacurium) produce some cardiovascular effects that are mediated by autonomic or histamine receptors or both (Table 27–3). Tubocurarine and, to a lesser extent, metocurine, mivacurium, and atracurium, can produce hypotension as a result of systemic histamine release, and with larger doses ganglionic blockade may occur with tubocurarine and metocurine. Premedication with an antihistamine drug will attenuate tubocurarine- and mivacurium-induced hypotension. Pancuronium causes a moderate increase in heart rate and a smaller increase in cardiac output, with little or no change in systemic vascular resistance. Although pancuronium-induced tachycardia is primarily due to a vagolytic action, release of norepinephrine from adrenergic nerve endings and blockade of neuronal uptake of norepinephrine have been suggested as secondary mechanisms. Effects of nondepolarizing blockers on the airways are discussed in Bronchospasm Induced by Neuromuscular Blockers.

Table 27–3. Effects of Neuromuscular Blocking Drugs on Other Tissues.

Drug	Effect on Autonomic Ganglia	Effect on Cardiac Muscarinic Receptors	Tendency to Cause Histamine Release
Isoquinoline derivatives			
Atracurium	None	None	Slight
Cisatracurium	None	None	None
Doxacurium	None	None	None

Metocurine	Weak block	None	Slight
Mivacurium	None	None	Moderate
Tubocurarine	Weak block	None	Moderate
Steroid derivatives			
Pancuronium	None	Moderate block	None
Pipecuronium	None	None	None
Rapacuronium ¹	None	Very slight block	None
Rocuronium ²	None	Slight	None
Vecuronium	None	None	None
Other agents			
Gallamine	None	Strong block	None
Succinylcholine	Stimulation	Stimulation	Slight

¹Withdrawn from clinical use.

²Allergic reactions have been reported.

Succinylcholine can cause cardiac arrhythmias when administered during halothane anesthesia. The drug stimulates all autonomic cholinergic receptors, including the nicotinic receptors in both sympathetic and parasympathetic ganglia and muscarinic receptors in the heart (eg, sinus node). The negative inotropic and chronotropic responses to succinylcholine can be attenuated by administration of an anticholinergic drug (eg, glycopyrrolate, atropine). With large doses of succinylcholine, positive inotropic and chronotropic effects may result. On the other hand, bradycardia has been repeatedly observed when a second dose of succinylcholine is given less than 5 minutes after the first dose. This transient bradycardia can be prevented by thiopental, atropine, ganglionic-blocking drugs, and even nondepolarizing muscle relaxants. Direct myocardial effects, increased muscarinic stimulation, and ganglionic stimulation may all be involved in this bradycardic response.

Other Adverse Effects of Depolarizing Blockade

Hyperkalemia

Patients with burns, nerve damage or neuromuscular disease, closed head injury, and other trauma can respond to succinylcholine by an exaggerated release of potassium into the blood, occasionally resulting in cardiac arrest. As a result of the cardiac arrests (presumably caused by hyperkalemia), the Food and Drug Administration recommended in 1993 that succinylcholine no longer be used in children. However, this highly controversial contraindication was subsequently modified to a simple warning because no acceptable alternative to succinylcholine was available for rapid-sequence inductions.

Increased Intraocular Pressure

Administration of succinylcholine is followed by a transient increase in intraocular pressure that is manifested less than 60 seconds after intravenous injection, peaks at 2–4 minutes, and declines after

5 minutes. The mechanism for this effect has not been clearly defined, but it may involve contraction of tonic myofibrils or transient dilation of choroidal blood vessels. Despite the increase in intraocular pressure, the use of succinylcholine for ophthalmologic operations is not contraindicated unless the anterior chamber is to be opened.

Increased Intra gastric Pressure

In heavily muscled patients, the fasciculations associated with succinylcholine will cause an increase in intra gastric pressure ranging from 5 cm to 40 cm H₂O. This may make emesis more likely, with the potential hazard of aspiration of gastric contents. This complication is more likely to occur in patients with delayed gastric emptying (eg, diabetes, esophageal dysfunction, obesity).

Muscle Pain

This is a common postoperative complaint of heavily muscled patients and those who have received large doses of succinylcholine. The true incidence of this symptom is difficult to establish because of subjective factors and differences in study design, but it has been reported in 0.2–20% of patients in different studies. It occurs more frequently in ambulatory than in bedridden patients. The pain is thought to be secondary to the unsynchronized contractions of adjacent muscle fibers just before the onset of paralysis. However, there is controversy over whether the incidence of muscle pain following succinylcholine is really higher than that following nondepolarizing muscle relaxants when other potentially confounding factors are considered.

Interactions with Other Drugs

Anesthetics

Inhaled anesthetics augment the neuromuscular blockade produced by nondepolarizing muscle relaxants in a dose-dependent fashion. Of the anesthetics that have been studied, inhaled anesthetics augment the effects of muscle relaxants in the following order: isoflurane (most); then sevoflurane, desflurane, enflurane, and halothane (Figure 27–8); and finally nitrous oxide (least). The most important factors involved in this interaction are the following: (1) nervous system depression at sites proximal to the neuromuscular junction (ie, central nervous system); (2) increased muscle blood flow (ie, due to peripheral vasodilation), which allows a larger fraction of the injected muscle relaxant to reach the neuromuscular junction; and (3) decreased sensitivity of the postjunctional membrane to depolarization.

Antibiotics

Numerous reports have appeared describing enhancement of neuromuscular blockade by antibiotics, especially the aminoglycosides. Many of the antibiotics have been shown to cause a depression of evoked release of acetylcholine similar to that caused by magnesium. The mechanism of this prejunctional effect appears to be blockade of specific P-type calcium channels. These antibiotics also have postjunctional activity.

Local Anesthetics and Antiarrhythmic Drugs

In large doses, most local anesthetics block neuromuscular transmission. However, in smaller doses, they enhance the neuromuscular block produced by both nondepolarizing and depolarizing muscle relaxants. In small doses, local anesthetics depress posttetanic potentiation, and this is thought to be a prejunctional neural effect. With higher doses, local anesthetics block acetylcholine-induced

muscle contractions. This stabilizing effect is the result of blockade of the nicotinic receptor ion channels. Experimentally, similar effects can be demonstrated with sodium channel-blocking antiarrhythmic drugs such as quinidine. However, at the doses used for cardiac arrhythmias, this interaction is of little or no clinical significance. Higher concentrations of bupivacaine (0.75%) have been associated with cardiac arrhythmias independent of the muscle relaxant used.

Other Neuromuscular Blocking Drugs

The end plate-depolarizing effect of succinylcholine can be antagonized by administering a small dose of a nondepolarizing blocker. To prevent the fasciculations associated with succinylcholine administration, a small nonparalyzing dose of a nondepolarizer can be given before succinylcholine (eg, *d*-tubocurarine 2 mg intravenously or pancuronium 0.5 mg intravenously). While this dose usually reduces fasciculations and postoperative pain, it can increase the amount of succinylcholine required for relaxation by 50–90% and may produce a feeling of weakness in awake patients. Therefore, preventive curarization prior to succinylcholine is no longer widely practiced.

Effects of Diseases & Aging on the Neuromuscular Response

Several diseases can diminish or augment the neuromuscular blockade produced by nondepolarizing muscle relaxants. Myasthenia gravis strongly enhances the neuromuscular blockade produced by these drugs. Advanced age (> 70 years) is associated with a prolonged duration of action from nondepolarizing relaxants as a result of decreased clearance of the drugs by the liver and kidneys. As a result, the dose of neuromuscular blocking drugs should be reduced in elderly patients.

Conversely, patients with severe burns and those with upper motor neuron disease are resistant to nondepolarizing muscle relaxants. This "desensitization" is probably caused by proliferation of extrajunctional receptors, which results in an increased dose requirement for the nondepolarizing relaxant to block a sufficient number of receptors.

Reversal of Nondepolarizing Neuromuscular Blockade

The cholinesterase inhibitors effectively antagonize the neuromuscular blockade caused by nondepolarizing drugs. Their general pharmacology is discussed in Chapter 7: Cholinergic-Activating & Cholinesterase-Inhibiting Drugs. Neostigmine and pyridostigmine antagonize nondepolarizing neuromuscular blockade by increasing the availability of acetylcholine at the motor end plate, mainly by inhibition of acetylcholinesterase. To a lesser extent, these cholinesterase inhibitors also increase release of transmitter from the motor nerve terminal. In contrast, edrophonium antagonizes neuromuscular blockade purely by inhibiting acetylcholinesterase. Edrophonium may be less effective than neostigmine in reversing the effects of most nondepolarizing blockers in the presence of a more profound degree of neuromuscular blockade. These differences are important in determining recovery from "residual block," the neuromuscular blockade remaining after completion of surgery and movement of the patient to the recovery room. Unsuspected residual block may result in hypoxia and even apnea, especially if patients receive other depressant medications during the recovery period.

Since mivacurium is metabolized by plasma cholinesterase, the interaction with the reversal drugs is unpredictable. On one hand, the neuromuscular blockade is antagonized because of increased acetylcholine concentrations in the synapse. On the other hand, mivacurium concentration may be higher because of decreased plasma cholinesterase breakdown of the muscle relaxant. The former effect usually dominates clinically, and mivacurium block is reversed by neostigmine.

Uses of Neuromuscular Blocking Drugs

Surgical Relaxation

By far the most important application of the neuromuscular blockers is in facilitating surgery. This is especially important in intra-abdominal and intrathoracic procedures.

Control of Ventilation

In critically ill patients who have ventilatory failure from various causes (eg, severe bronchospasm, pneumonia, chronic obstructive airway disease), it may be necessary to control ventilation to provide adequate gas exchange and to prevent atelectasis. Muscle paralysis is produced by administration of neuromuscular blocking drugs to eliminate chest wall resistance and ineffective spontaneous ventilation.

Treatment of Convulsions

Neuromuscular blocking drugs are sometimes used to attenuate or eliminate the peripheral manifestations of convulsions associated with epilepsy or local anesthetic toxicity. Although this approach is effective in eliminating the muscular manifestations of the seizures, it has no effect on the central processes involved since neuromuscular blocking drugs do not cross the blood-brain barrier.

Spasmolytic Drugs

Spasticity is characterized by an increase in tonic stretch reflexes and flexor muscle spasms (ie, increased basal muscle tone), together with muscle weakness. It is often associated with cerebral palsy, multiple sclerosis, and stroke. These conditions often involve abnormal function of the bowel and bladder as well as skeletal muscle. The mechanisms underlying clinical spasticity appear to involve not only the stretch reflex arc itself but also higher centers in the central nervous system (upper motor neuron lesion), with damage to descending pathways in the spinal cord, resulting in hyperexcitability of the alpha motoneurons in the cord. Nevertheless, pharmacologic therapy may ameliorate some of the symptoms of spasticity by modifying the stretch reflex arc or by interfering directly with skeletal muscle (ie, excitation-contraction coupling). The important components involved in these processes are shown in Figure 27–10.

Figure 27–10.

Drugs that modify this reflex arc may modulate excitatory or inhibitory synapses (Chapter 21: Introduction to the Pharmacology of CNS Drugs). Thus, to reduce the hyperactive stretch reflex, it is desirable to reduce the activity of the Ia fibers that excite the primary motoneuron or to enhance the activity of the inhibitory internuncial neurons. These structures are shown in greater detail in Figure 27–11.

Figure 27–11.

A variety of pharmacologic agents described as depressants of the spinal "polysynaptic" reflex arc (eg, barbiturates [phenobarbital] and glycerol ethers [mephenesin]) have been used to treat these conditions of excess skeletal tone. However, as illustrated in Figure 27–11, nonspecific depression of synapses involved in the stretch reflex could reduce the desired inhibitory activity as well as the excitatory transmission. During the past several decades, more specific therapies have become available. Unfortunately, the lack of convenient and quantifiable measures of clinical response and of appropriate experimental models has hampered development of better agents for this heterogeneous group of medical conditions. Furthermore, while currently available drugs do provide significant relief from painful muscle spasms, they are all less effective in improving meaningful function (eg, mobility and return to work).

Diazepam

As described in Chapter 22: Sedative-Hypnotic Drugs, benzodiazepines facilitate the action of γ -aminobutyric acid (GABA) in the central nervous system. Diazepam acts at all GABA_A synapses, but its action in reducing spasticity is at least partly mediated in the spinal cord because it is somewhat effective in patients with cord transection. It can be used in patients with muscle spasm of almost any origin, including local muscle trauma. However, it produces sedation in most patients at the doses required to significantly reduce muscle tone. Dosage is usually begun at 4 mg/d and gradually increased to a maximum of 60 mg/d. Other benzodiazepines have been used as

spasmolytics, but experience with them is much more limited.

Baclofen

Baclofen (*p*-chlorophenyl-GABA) was designed to be an orally active GABA-mimetic agent. The structure is shown below.

Baclofen

Baclofen exerts its spasmolytic activity at GABA_B receptors. Activation of these receptors in the brain by baclofen results in hyperpolarization, probably by increased K⁺ conductance. It has been suggested that hyperpolarization (in the spinal cord as well as in the brain) causes presynaptic inhibition by reducing calcium influx (Figure 27–11) and reduces the release of excitatory transmitters in both the brain and the spinal cord. Baclofen may also reduce pain in patients with spasticity, perhaps by inhibiting the release of substance P in the spinal cord.

Baclofen is at least as effective as diazepam in reducing spasticity and produces much less sedation. In addition, baclofen does not reduce overall muscle strength as much as dantrolene. It is rapidly and completely absorbed after oral administration and has a plasma half-life of 3–4 hours. Dosage is started at 15 mg twice daily, increasing as tolerated to 100 mg daily. Adverse effects of this drug include drowsiness, to which the patient may become tolerant with chronic administration. Increased seizure activity has been reported in epileptic patients. Therefore, withdrawal of baclofen must be done very slowly.

Studies have confirmed that intrathecal administration of baclofen can control severe spasticity and muscle pain that is not responsive to medication by other routes of administration. Owing to the poor egress of baclofen from the spinal cord, peripheral symptoms are rare. Therefore, higher central concentrations of the drug may be tolerated. Partial tolerance to the effect of the drug may occur after several months of therapy but can be overcome by upward dosage adjustments to maintain the beneficial effect. Several cases of excessive somnolence, respiratory depression, and even coma have been reported. Although a major disadvantage of this therapeutic approach is the difficulty of maintaining the drug delivery catheter in the subarachnoid space, long-term intrathecal baclofen therapy can improve the quality of life for patients with severe spastic disorders.

Oral baclofen has been studied in several other medical conditions. Preliminary studies suggest that it may be effective in reducing craving in recovering alcoholics. It has also been found effective in preventing migraine attacks in some patients.

Tizanidine

As noted in Chapter 11: Antihypertensive Agents, α_2 agonists such as clonidine and other imidazoline compounds have a variety of effects on the central nervous system that are not fully understood. Among these effects is the ability to reduce muscle spasm. Tizanidine is a congener of clonidine that has been studied for its spasmolytic actions. Tizanidine has significant α_2 -adrenoceptor agonist effects, but it reduces spasticity in experimental models at doses that cause less cardiovascular effect than clonidine. Neurophysiologic studies in animals and humans suggest that tizanidine reinforces both presynaptic and postsynaptic inhibition in the cord. It also inhibits

nociceptive transmission in the spinal dorsal horn.

Clinical trials suggest that tizanidine may produce a significant benefit in patients with spasticity. These trials report comparable efficacy in relieving muscle spasm to diazepam, baclofen, and dantrolene. However, tizanidine produces a different spectrum of adverse effects, including drowsiness, hypotension, dry mouth, and asthenia. The dosage requirements vary markedly among patients, suggesting that individual dosage titration is necessary to achieve an optimal effect.

Other Centrally Active Spasmolytic Drugs

Gabapentin is an antiepileptic drug (see Chapter 24: Antiseizure Drugs) that has shown considerable promise as a spasmolytic agent in several studies involving patients with multiple sclerosis. **Progabide** and **glycine** have also been found in preliminary studies to reduce spasticity. Progabide is a GABA_A and GABA_B agonist and has active metabolites, including GABA itself. **Glycine** is another inhibitory amino acid neurotransmitter (see Chapter 21: Introduction to the Pharmacology of CNS Drugs). It appears to possess pharmacologic activity when given orally and readily passes the blood-brain barrier. **Idrocilamide** and **riluzole** are newer drugs for the treatment of amyotrophic lateral sclerosis that appear to have spasm-reducing effects, possibly through inhibition of glutamatergic transmission in the central nervous system.

Dantrolene

Dantrolene is a hydantoin derivative related to phenytoin that has a unique mechanism of spasmolytic activity. In contrast to the centrally active drugs, dantrolene reduces skeletal muscle strength by interfering with excitation-contraction coupling in the muscle fibers. The normal contractile response involves release of calcium from its stores in the sarcoplasmic reticulum (see Figures 13–1 and 27–10). This activator calcium brings about the tension-generating interaction of actin with myosin. Calcium is released from the sarcoplasmic reticulum via a calcium channel, sometimes called the ryanodine receptor channel because the plant alkaloid **ryanodine** combines with a receptor on the channel protein and, in the case of the skeletal muscle channel, locks it in the open position.

Dantrolene interferes with the release of activator calcium through this sarcoplasmic reticulum calcium channel by binding to the ryanodine receptor. Motor units that contract rapidly are more sensitive to the drug's effects than are slower-responding units. Cardiac muscle and smooth muscle are depressed only slightly, perhaps because the release of calcium from their sarcoplasmic reticulum involves a somewhat different process.

Treatment with dantrolene is usually initiated with 25 mg daily as a single dose, increasing to a maximum of 100 mg four times daily as tolerated. Only about one third of an oral dose of dantrolene is absorbed, and the elimination half-life of the drug is about 8 hours. Major adverse effects are generalized muscle weakness, sedation, and occasionally hepatitis.

A special application of dantrolene is in the treatment of **malignant hyperthermia**, a rare heritable

disorder that can be triggered by a variety of stimuli, including general anesthetics (eg, volatile anesthetics) and neuromuscular blocking drugs (eg, succinylcholine). Patients at risk for this condition have a hereditary impairment in the ability of the sarcoplasmic reticulum to sequester calcium. Following administration of one of the triggering agents, there is a sudden and prolonged release of calcium, with massive muscle contraction, lactic acid production, and increased body temperature. Prompt treatment is essential to control acidosis and body temperature and to reduce calcium release. The latter is accomplished with intravenous dantrolene, starting with a dose of 1 mg/kg intravenously and repeating as necessary to a maximum dose of 10 mg/kg.

Botulinum Toxin

The therapeutic use of botulinum toxin for ophthalmic purposes and for local muscle spasm was mentioned in Chapter 6: Introduction to Autonomic Pharmacology. Local injection of botulinum toxin has become popular for the treatment of generalized spastic disorders (eg, cerebral palsy). Most clinical studies to date have involved administration in one or two limbs, and the benefits appear to persist for weeks to several months after a single treatment. Most studies to date have utilized type A botulinum toxin, but type B is also available.

Drugs Used to Treat Acute Local Muscle Spasm

A large number of drugs (eg, **carisoprodol**, **chlorphenesin**, **chlorzoxazone**, **cyclobenzaprine**, **metaxalone**, **methocarbamol**, and **orphenadrine**) are promoted for the relief of acute muscle spasm caused by local tissue trauma or muscular strains. It has been suggested that these drugs act primarily at the level of the brain stem. Cyclobenzaprine may be regarded as the prototype of the group. Cyclobenzaprine is structurally related to the tricyclic antidepressants and possesses antimuscarinic effects. It is ineffective in treating muscle spasm due to cerebral palsy or spinal cord injury. The drug has strong antimuscarinic actions and may cause significant sedation as well as confusion and transient visual hallucinations. The dosage of cyclobenzaprine for acute injury-related muscle spasm is 20–40 mg/d in divided doses.

Katzung PHARMACOLOGY, 9e > Section V. Drugs That Act in the Central Nervous System > Chapter 27. Skeletal Muscle Relaxants >

Bronchospasm Induced by Neuromuscular Blockers

Skeletal muscle relaxants have no direct effect on bronchial smooth muscle, but tubocurarine and mivacurium have been known to cause bronchoconstriction through the release of histamine. It was therefore unexpected that rapacuronium, which does not release histamine, caused severe bronchospasm in a significant number of patients during rapid-sequence induction for intubation. This dangerous (and in several cases fatal) effect was associated with young age (especially infants and children) and a history of reactive airway disease. Research indicates that rapacuronium blocks presynaptic M₂ muscarinic receptors (which modulate acetylcholine release) more effectively than postsynaptic M₃ receptors (which evoke bronchial smooth muscle contraction). This suggests that in reactive airways, rapacuronium might greatly enhance the release of acetylcholine onto inadequately blocked postsynaptic muscarinic receptors.

Katzung PHARMACOLOGY, 9e > Section V. Drugs That Act in the Central Nervous System > Chapter 27. Skeletal Muscle Relaxants >

Preparations Available

Neuromuscular Blocking Drugs

Atracurium (Tracrium)

Parenteral: 10 mg/mL for injection

Cisatracurium (Nimbex)

Parenteral: 2, 10 mg/mL for IV injection

Doxacurium (Nuromax)

Parenteral: 1 mg/mL for IV injection

Metocurine (generic, Metubine Iodide)

Parenteral: 2 mg/mL for injection

Mivacurium (Mivacron)

Parenteral: 0.5, 2 mg/mL for injection

Pancuronium (generic, Pavulon)

Parenteral: 1, 2 mg/mL for injection

Pipecuronium (Arduan)

Parenteral: 1 mg/mL for IV injection

Rocuronium (Zemuron)

Parenteral: 10 mg/mL for IV injection

Succinylcholine (generic, Anectine)

Parenteral: 20, 50, 100 mg/mL for injection; 100, 500 mg per vial powders to reconstitute for injection

Tubocurarine (generic)

Parenteral: 3 mg (20 units)/mL for injection

Vecuronium (generic, Norcuron)

Parenteral: 10, 20 mg powder to reconstitute for injection

Muscle Relaxants (Spasmolytics)

Baclofen (generic, Lioresal)

Oral: 10, 20 mg tablets

Intrathecal: 0.05, 0.5, 2 mg/mL

Botulinum toxin type A (Botox)

Parenteral: Powder for solution, 100 units/vial

Botulinum toxin type B (Myobloc)

Parenteral: 5000 units/mL for injection

Carisoprodol (generic, Soma)

Oral: 350 mg tablets

Chlorphenesin (Maolate)

Oral: 400 mg tablets

Chlorzoxazone (generic, Paraflex)

Oral: 250, 500 mg tablets, caplets

Cyclobenzaprine (generic, Flexeril)

Oral: 10 mg tablets

Dantrolene (Dantrium)

Oral: 25, 50, 100 mg capsules

Parenteral: 20 mg per vial powder to reconstitute for injection

Diazepam (generic, Valium)

Oral: 2, 5, 10 mg tablets; 5 mg/5 mL, 5 mg/mL solutions

Parenteral: 5 mg/mL for injection

Gabapentin (Neurontin)

Oral: 100, 300, 400 mg capsules; 600, 800 mg tablets

Note: This drug is labeled for use only in epilepsy.

Metaxalone (Skelaxin)

Oral: 400 mg tablets

Methocarbamol (generic, Robaxin)

Oral: 500, 750 mg tablets

Parenteral: 100 mg/mL for IM, IV injection

Orphenadrine (generic, Norflex)

Oral: 100 mg tablets; 100 mg sustained-release tablets

Parenteral: 30 mg/mL for IM, IV injection

Riluzole (Rilutek)

Oral: 50 mg tablets

Note: This drug is labeled only for use in amyotrophic lateral sclerosis.

Tizanidine (Zanaflex)

Oral: 4 mg tablets

Chapter 28. Pharmacologic Management of Parkinsonism & Other Movement Disorders

Katzung PHARMACOLOGY, 9e > Section V. Drugs That Act in the Central Nervous System > Chapter 28. Pharmacologic Management of Parkinsonism & Other Movement Disorders >

Pharmacologic Management of Parkinsonism & Other Movement Disorders: Introduction

Several different types of abnormal movement are recognized. **Tremor** consists of a rhythmic oscillatory movement around a joint and is best characterized by its relation to activity. Tremor present at rest is characteristic of parkinsonism, when it is often associated with rigidity and an impairment of voluntary activity. Tremor may occur during maintenance of sustained posture (postural tremor) or during movement (intention tremor). A conspicuous postural tremor is the cardinal feature of benign essential or familial tremor. Intention tremor occurs in patients with a lesion of the brainstem or cerebellum, especially when the superior cerebellar peduncle is involved, and may also occur as a manifestation of toxicity from alcohol or certain other drugs.

Chorea consists of irregular, unpredictable, involuntary muscle jerks that occur in different parts of the body and impair voluntary activity. In some instances, the proximal muscles of the limbs are most severely affected, and because the abnormal movements are then particularly violent, the term ballismus has been used to describe them. Chorea may be hereditary or may occur as a complication

of a number of general medical disorders and of therapy with certain drugs.

Abnormal movements may be slow and writhing in character (**athetosis**) and in some instances are so sustained that they are more properly regarded as abnormal postures (**dystonia**). Athetosis or dystonia may occur with perinatal brain damage, with focal or generalized cerebral lesions, as an acute complication of certain drugs, as an accompaniment of diverse neurologic disorders, or as an isolated inherited phenomenon of uncertain cause known as idiopathic torsion dystonia or dystonia musculorum deformans. Its physiologic basis is uncertain, and treatment is unsatisfactory.

Tics are sudden coordinated abnormal movements that tend to occur repetitively, particularly about the face and head, especially in children, and can be suppressed voluntarily for short periods of time. Common tics include, for example, repetitive sniffing or shoulder shrugging. Tics may be single or multiple and transient or chronic. Gilles de la Tourette's syndrome is characterized by chronic multiple tics; its pharmacologic management is discussed at the end of this chapter.

Many of the movement disorders have been attributed to disturbances of the basal ganglia, but the precise function of these anatomic structures is not yet fully understood, and it is not possible to relate individual symptoms to involvement at specific sites.

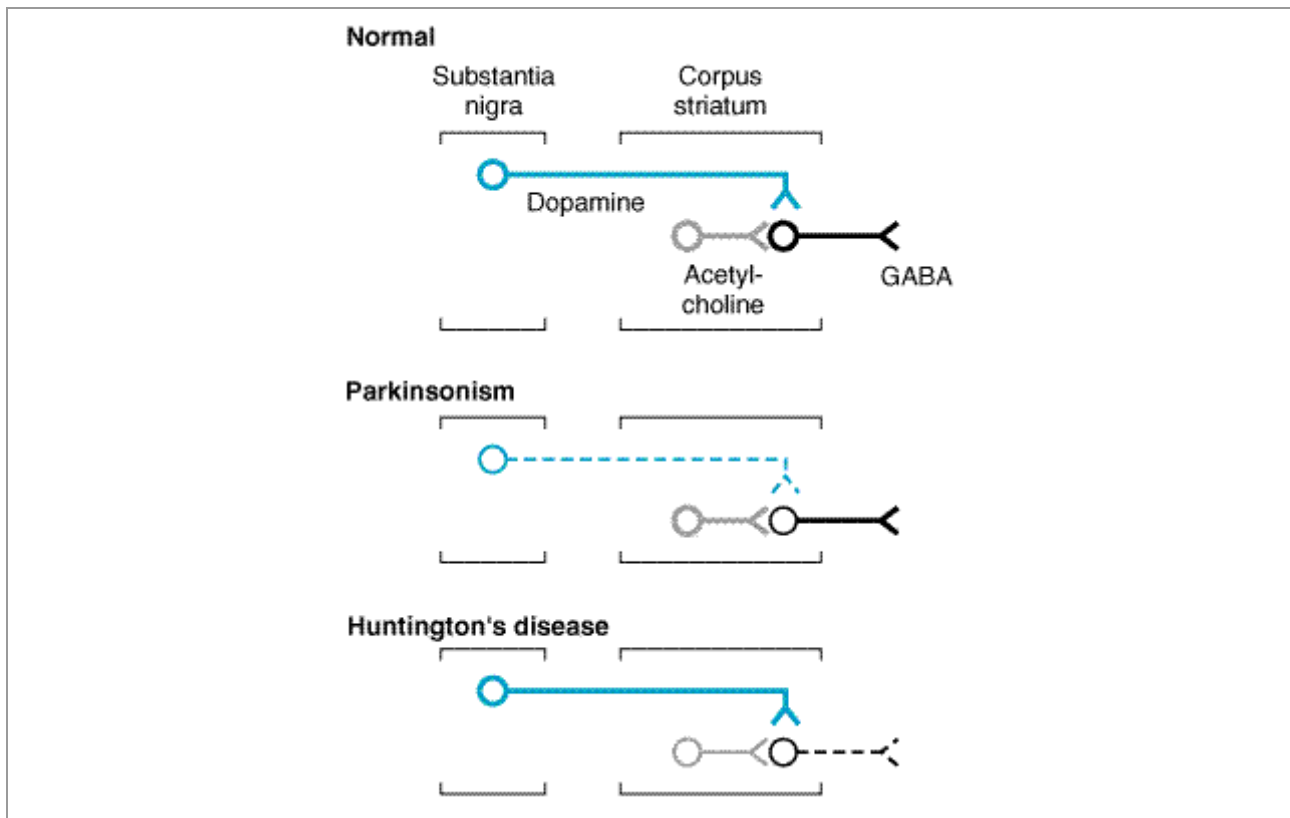

Katzung PHARMACOLOGY, 9e > Section V. Drugs That Act in the Central Nervous System > Chapter 28. Pharmacologic Management of Parkinsonism & Other Movement Disorders >

Parkinsonism (Paralysis Agitans)

Parkinsonism is characterized by a combination of rigidity, bradykinesia, tremor, and postural instability that can occur for a wide variety of reasons but is usually idiopathic. The pathophysiologic basis of the idiopathic disorder may relate to exposure to some unrecognized neurotoxin or to the occurrence of oxidation reactions with the generation of free radicals. Studies in twins suggest that genetic factors may also be important, especially when the disease occurs in patients under age 50. Parkinson's disease is generally progressive, leading to increasing disability unless effective treatment is provided.

The normally high concentration of dopamine in the basal ganglia of the brain is reduced in parkinsonism, and pharmacologic attempts to restore dopaminergic activity with levodopa and dopamine agonists have been successful in alleviating many of the clinical features of the disorder. An alternative but complementary approach has been to restore the normal balance of cholinergic and dopaminergic influences on the basal ganglia with antimuscarinic drugs. The pathophysiologic basis for these therapies is that in idiopathic parkinsonism, dopaminergic neurons in the substantia nigra that normally inhibit the output of GABAergic cells in the corpus striatum are lost (Figure 28–1). (In contrast, Huntington's chorea involves the loss of some cholinergic neurons and an even greater loss of the GABAergic cells that exit the corpus striatum.) Drugs that *induce* parkinsonian syndromes either are dopamine receptor antagonists (eg, antipsychotic agents; see Chapter 29: Antipsychotic Agents & Lithium) or lead to the destruction of the dopaminergic nigrostriatal neurons (eg, 1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine [MPTP]; see below).

Figure 28–1.

Schematic representation of the sequence of neurons involved in parkinsonism and Huntington's chorea. **Top:** Dopaminergic neurons (color) originating in the substantia nigra normally inhibit the GABAergic output from the striatum, whereas cholinergic neurons (gray) exert an excitatory effect. **Middle:** In parkinsonism, there is a selective loss of dopaminergic neurons (dashed, color). **Bottom:** In Huntington's chorea, some cholinergic neurons may be lost (gray), but even more GABAergic neurons (black, dashed) degenerate.

Levodopa

Dopamine does not cross the blood-brain barrier and if given into the peripheral circulation has no therapeutic effect in parkinsonism. However, (–)-3-(3,4-dihydroxyphenyl)-L-alanine (levodopa), the immediate metabolic precursor of dopamine, does penetrate the brain, where it is decarboxylated to dopamine (see Figure 6–5). Several dopamine agonists have also been developed and may lead to clinical benefit, as discussed below.

Dopamine receptors are discussed in detail in Chapter 21: Introduction to the Pharmacology of CNS Drugs and Chapter 29: Antipsychotic Agents & Lithium. Dopamine receptors of the D_1 type are located in the zona compacta of the substantia nigra and presynaptically on striatal axons coming from cortical neurons and from dopaminergic cells in the substantia nigra. The D_2 receptors are located postsynaptically on striatal neurons and presynaptically on axons in the substantia nigra belonging to neurons in the basal ganglia. The benefits of dopaminergic antiparkinsonism drugs appear to depend mostly on stimulation of the D_2 receptors, but D_1 -receptor stimulation may also be required for maximal benefit. Dopamine agonist or partial agonist ergot derivatives such as lergotriple and bromocriptine that are powerful stimulators of the D_2 receptors have antiparkinsonism properties, whereas certain dopamine blockers that are selective D_2 antagonists can induce parkinsonism.

Chemistry

As discussed in Chapter 6: Introduction to Autonomic Pharmacology, dopa is the precursor of dopamine and norepinephrine. Its structure is shown in Figure 28–2. Levodopa is the levorotatory stereoisomer of dopa.

Figure 28–2.

**Dihydroxyphenylalanine
(dopa)**

Carbidopa

Selegiline

Some drugs used in the treatment of parkinsonism.

Pharmacokinetics

Levodopa is rapidly absorbed from the small intestine, but its absorption depends on the rate of gastric emptying and the pH of the gastric contents. Food will delay the appearance of levodopa in the plasma. Moreover, certain amino acids from ingested food can compete with the drug for absorption from the gut and for transport from the blood to the brain. Plasma concentrations usually peak between 1 and 2 hours after an oral dose, and the plasma half-life is usually between 1 and 3 hours, although it varies considerably between individuals. About two thirds of the dose appears in the urine as metabolites within 8 hours of an oral dose, the main metabolic products being 3-methoxy-4-hydroxyphenylacetic acid (homovanillic acid, HVA) and dihydroxy-phenylacetic acid (DOPAC). Unfortunately, only about 1–3% of administered levodopa actually enters the brain unaltered, the remainder being metabolized extracerebrally, predominantly by decarboxylation to dopamine, which does not penetrate the blood-brain barrier. This means that levodopa must be given in large amounts when it is used alone. However, when it is given in combination with a dopa decarboxylase inhibitor that does not penetrate the blood-brain barrier, the peripheral metabolism of levodopa is reduced, plasma levels of levodopa are higher, plasma half-life is longer, and more dopa is available for entry into the brain (Figure 28–3). Indeed, concomitant administration of a peripheral dopa decarboxylase inhibitor may reduce the daily requirements of levodopa by

approximately 75%.

Figure 28–3.

Fate of orally administered levodopa and the effect of carbidopa, estimated from animal data. The width of each pathway indicates the absolute amount of the drug present at each site, while the percentages shown denote the relative proportion of the administered dose. The benefits of coadministration of carbidopa include reduction of the amount of levodopa diverted to peripheral tissues and an increase in the fraction of the dose that reaches the brain. (GI, gastrointestinal.) (Data from Nutt JG, Fellman JH: Pharmacokinetics of levodopa. Clin Neuropharmacol 1984;7:35.)

Clinical Use

The best results of levodopa treatment are obtained in the first few years of treatment. This is sometimes because the daily dose of levodopa must be reduced with time in order to avoid side effects at doses that were well tolerated at the outset. The reason that adverse effects develop in this way is unclear, but selective denervation or drug-induced supersensitivity may be responsible. Some patients also become less responsive to levodopa, so that previously effective doses eventually fail to produce any therapeutic benefit. Responsiveness to levodopa may ultimately be lost completely, perhaps because of the disappearance of dopaminergic nigrostriatal nerve terminals or some pathologic process directly involving the striatal dopamine receptors. For such reasons, the benefits of levodopa treatment often begin to diminish after about 3 or 4 years of therapy irrespective of the initial therapeutic response. Although levodopa therapy does not stop the progression of parkinsonism, its early initiation lowers the mortality rate. However, long-term therapy may lead to a number of problems in management such as development of the on-off phenomenon discussed below. The most appropriate time to introduce levodopa therapy must therefore be determined individually.

When levodopa is used, it is generally given in combination with carbidopa (Figure 28–2), a peripheral dopa decarboxylase inhibitor, for the reasons set forth above. **Sinemet** is a dopa preparation containing carbidopa and levodopa in fixed proportion (1:10 or 1:4). Treatment is started with a small dose, eg, Sinemet-25/100 (carbidopa 25 mg, levodopa 100 mg) three times daily, and gradually increased depending on the therapeutic response and development of adverse effects. It should be taken 30–60 minutes before meals. Most patients ultimately require Sinemet-25/250 (carbidopa 25 mg, levodopa 250 mg) three or four times daily. It is generally preferable to keep treatment with this agent at a low level (eg, Sinemet-25/100 three times daily) and to increase dopaminergic therapy by the addition of a dopamine agonist if necessary, in order to reduce the risk of development of response fluctuations, as discussed below. A controlled-release formulation of Sinemet is available and may be helpful in patients with established response fluctuations or as a means of reducing dosing frequency.

Levodopa can ameliorate all of the clinical features of parkinsonism, but it is particularly effective in relieving bradykinesia and any disabilities resulting from it. When it is first introduced, about one third of patients respond very well and one third less well. Most of the remainder either are unable to tolerate the medication or simply do not respond at all.

Adverse Effects

Gastrointestinal Effects

When levodopa is given without a peripheral decarboxylase inhibitor, anorexia and nausea and vomiting occur in about 80% of patients. These adverse effects can be minimized by taking the drug in divided doses, with or immediately after meals, and by increasing the total daily dose very slowly; antacids taken 30–60 minutes before levodopa may also be beneficial. The vomiting has been attributed to stimulation of an emetic center located in the brainstem but outside the blood-brain barrier to dopamine and to peripheral decarboxylase inhibitors. Fortunately, tolerance to this emetic effect develops in many patients after several months. Antiemetics such as phenothiazines should be avoided because they reduce the antiparkinsonism effects of levodopa and may exacerbate the disease.

When levodopa is given in combination with carbidopa to reduce its extracerebral metabolism, adverse gastrointestinal effects are much less frequent and troublesome, occurring in fewer than 20% of cases, so that patients can tolerate proportionately higher doses.

Cardiovascular Effects

A variety of cardiac arrhythmias have been described in patients receiving levodopa, including tachycardia, ventricular extrasystoles and, rarely, atrial fibrillation. This effect has been attributed to increased catecholamine formation peripherally. The incidence of such arrhythmias is low, even in the presence of established cardiac disease, and may be reduced still further if the levodopa is taken in combination with a peripheral decarboxylase inhibitor. In parkinsonism patients who also have heart disease, the anticipated benefits of levodopa, especially when combined with carbidopa, generally outweigh the slight risk of inducing a cardiac arrhythmia.

Postural hypotension is common and often asymptomatic, and tends to diminish with continuing treatment. Hypertension may also occur, especially in the presence of nonselective monoamine oxidase inhibitors or sympathomimetics or when massive doses of levodopa are being taken.

Dyskinesias

Dyskinesias occur in up to 80% of patients receiving levodopa therapy for long periods. The form and nature of dopa dyskinesias vary widely in different patients but tend to remain constant in character in individual patients. Chorea, ballismus, athetosis, dystonia, myoclonus, tics, and tremor may occur individually or in any combination in the face, trunk, or limbs. Choreoathetosis of the face and distal extremities is the most common presentation. The development of dyskinesias is dose-related, but there is considerable individual variation in the dose required to produce them.

Behavioral Effects

A wide variety of adverse mental effects have been reported including depression, anxiety, agitation, insomnia, somnolence, confusion, delusions, hallucinations, nightmares, euphoria, and other changes in mood or personality. Such adverse effects are more common in patients taking levodopa in combination with a decarboxylase inhibitor rather than levodopa alone, presumably because higher levels are reached in the brain. They may be precipitated by intercurrent illness or operation. It may be necessary to reduce or withdraw the medication. Several atypical antipsychotic agents are now available and may be particularly helpful in counteracting the behavioral complications of levodopa. Clozapine requires weekly blood counts because it leads to marrow suppression in rare instances. The starting dose is 6.25 mg at bedtime, with subsequent increments depending on response and tolerance; doses of 25–100 mg/d are typical. Olanzapine, quetiapine, and risperidone have also been used; they are less expensive than clozapine and do not cause marrow suppression but sometimes seem less effective.

Fluctuations in Response

Certain fluctuations in clinical response to levodopa occur with increasing frequency as treatment continues. In some patients, these fluctuations relate to the timing of levodopa intake, and they are then referred to as wearing-off reactions or end-of-dose akinesia. In other instances, fluctuations in clinical state are unrelated to the timing of doses (on-off phenomenon). In the on-off phenomenon, off-periods of marked akinesia alternate over the course of a few hours with on-periods of improved mobility but often marked dyskinesia. The phenomenon is most likely to occur in patients who responded well to treatment initially. The exact mechanism is unknown.

Miscellaneous Adverse Effects

Mydriasis may occur and may precipitate an attack of acute glaucoma in some patients. Other

reported but rare adverse effects include various blood dyscrasias; a positive Coombs test with evidence of hemolysis; hot flushes; aggravation or precipitation of gout; abnormalities of smell or taste; brownish discoloration of saliva, urine, or vaginal secretions; priapism; and mild—usually transient—elevations of blood urea nitrogen and of serum transaminases, alkaline phosphatase, and bilirubin.

Drug Holidays

A drug holiday (for 3–21 days) may alleviate some of the neurologic and behavioral adverse effects of levodopa but is usually of little help in the management of the on-off phenomenon. Up to two thirds of patients show temporary improved responsiveness to levodopa when the drug is reinstated, and—because they can be managed on lower doses than before—adverse mental effects and dyskinesias are less troublesome. Fluctuations in response (on-off phenomenon) are reduced in many instances, but any benefit in this regard is usually short-lived. Furthermore, a drug holiday carries the risks of aspiration pneumonia, venous thrombosis, pulmonary embolism, and depression resulting from the immobility accompanying severe parkinsonism. For these reasons and because of the temporary nature of any benefit, drug holidays are no longer recommended.

Drug Interactions

Pharmacologic doses of pyridoxine (vitamin B6) enhance the extracerebral metabolism of levodopa and may therefore prevent its therapeutic effect unless a peripheral decarboxylase inhibitor is also taken. Levodopa should not be given to patients taking monoamine oxidase A inhibitors or within 2 weeks of their discontinuance, because such a combination can lead to hypertensive crises.

Contraindications

Levodopa should not be given to psychotic patients, as it may exacerbate the mental disturbance. It is also contraindicated in patients with angle-closure glaucoma, but those with chronic open-angle glaucoma may be given levodopa if intraocular pressure is well controlled and can be monitored. It is best given combined with carbidopa to patients with cardiac disease, but even so the risk of cardiac dysrhythmia is slight. Patients with active peptic ulcer must also be managed carefully, since gastrointestinal bleeding has occasionally occurred with levodopa. Because levodopa is a precursor of skin melanin and conceivably may activate malignant melanoma, its use should be avoided in patients with a history of melanoma or with suspicious undiagnosed skin lesions.

Dopamine Agonists

Drugs acting directly on dopamine receptors may have a beneficial effect additional to that of levodopa. Unlike levodopa, they do not require enzymatic conversion to an active metabolite, have no potentially toxic metabolites, and do not compete with other substances for active transport into the blood and across the blood-brain barrier. Moreover, drugs selectively affecting certain (but not all) dopamine receptors may have more limited adverse effects than levodopa. There are a number of dopamine agonists with antiparkinsonism activity. The older dopamine agonists (bromocriptine and pergolide) are ergot derivatives (see Chapter 16: Histamine, Serotonin, & the Ergot Alkaloids), unlike the newer agents (pramipexole and ropinirole). There is no evidence that one agonist is superior to another; individual patients, however, may respond to one but not another of these agents.

Dopamine agonists have an important role as first-line therapy for Parkinson's disease, and their use is associated with a lower incidence of the response fluctuations and dyskinesias occurring with

long-term levodopa therapy. In consequence, dopaminergic therapy may best be initiated with a dopamine agonist. Alternatively, a low dose of carbidopa plus levodopa (eg, Sinemet-25/100 three times daily) is introduced and a dopamine agonist is then added. In either case, the dose of the dopamine agonist is built up gradually depending on response and tolerance. Dopamine agonists may also be given to parkinsonian patients taking levodopa who have end-of-dose akinesia or on-off phenomenon or who are becoming resistant to treatment with levodopa. In such circumstances, it is generally necessary to lower the dose of levodopa to prevent intolerable adverse effects. The response to a dopamine agonist is generally disappointing in patients who have never responded to levodopa.

Bromocriptine

Bromocriptine is a D₂ agonist; its structure is shown in Table 16–4. This drug has been widely used to treat Parkinson's disease and has also been used to treat certain endocrinologic disorders, especially hyperprolactinemia (see Chapter 37: Hypothalamic & Pituitary Hormones), but in lower doses than for parkinsonism. Bromocriptine is absorbed to a variable extent from the gastrointestinal tract; peak plasma levels are reached within 1–2 hours after an oral dose. It is excreted in the bile and feces. The usual daily dose of bromocriptine in the treatment of parkinsonism is between 7.5 and 30 mg, depending on response and tolerance. In order to minimize adverse effects, the dose is built up slowly over 2 or 3 months from a starting level of 1.25 mg twice daily after meals; the daily dose is then increased by 2.5 mg every 2 weeks depending on the response or the development of adverse reactions.

Pergolide

Pergolide, another ergot derivative, directly stimulates both D₁ and D₂ receptors. It too has been widely used for parkinsonism, and comparative studies suggest that it is more effective than bromocriptine in relieving the symptoms and signs of parkinsonism, increasing "on-time" among response fluctuators, and permitting the levodopa dose to be reduced. The average therapeutic dose is 3 mg daily. Patients are generally started on 0.05 mg daily and the dose is built up over about 4 weeks by increments until benefit occurs or side effects limit further increments.

Pramipexole

Pramipexole, which is not an ergot derivative, has preferential affinity for the D₃ family of receptors. It is effective when used as monotherapy for mild parkinsonism. It is also helpful in patients with advanced disease, permitting the dose of levodopa to be reduced and smoothing out response fluctuations. It may ameliorate affective symptoms. A possible neuroprotective effect has been suggested by its ability to scavenge hydrogen peroxide and enhance neurotrophic activity in mesencephalic dopaminergic cell cultures. Pramipexole is rapidly absorbed, reaching peak plasma concentrations in approximately 2 hours, and is excreted largely unchanged in the urine. It is started at a dose of 0.125 mg three times daily; the dose is doubled after 1 week and again after another week. Further increments in the daily dose are by 0.75 mg at weekly intervals depending on response and tolerance. Most patients require between 0.5 and 1.5 mg three times daily. Renal insufficiency may necessitate dosage adjustment.

Pramipexole

Ropinirole

Ropinirole, another nonergoline derivative, is a relatively pure D_2 receptor agonist that is effective as monotherapy in patients with mild disease and as a means of smoothing the response to levodopa in patients with more advanced disease and response fluctuations. It is introduced in a dose of 0.25 mg three times daily, and the total daily dose is then increased by 0.75 mg at weekly intervals until the fourth week and by 1.5 mg thereafter. In most instances, a dose of between 2 and 8 mg three times daily is necessary. Ropinirole is metabolized by CYP1A2; drugs metabolized by the liver may significantly reduce its clearance.

Ropinirole

Adverse Effects of Dopamine Agonists

Gastrointestinal Effects

Anorexia and nausea and vomiting may occur when a dopamine agonist is introduced and can be minimized by taking the medication with meals. Constipation, dyspepsia, and symptoms of reflux esophagitis may also occur. Bleeding from peptic ulceration has been reported.

Cardiovascular Effects

Postural hypotension may occur, particularly at the initiation of therapy. Painless digital vasospasm is a dose-related complication of long-term treatment with the ergot derivatives (bromocriptine or pergolide). When cardiac arrhythmias occur, they are an indication for discontinuing treatment. Peripheral edema is sometimes problematic.

Dyskinesias

Abnormal movements similar to those introduced by levodopa may occur and are reversed by reducing the total dose of dopaminergic drugs being taken.

Mental Disturbances

Confusion, hallucinations, delusions, and other psychiatric reactions are other complications of dopaminergic treatment and are more common and severe with dopamine agonists than levodopa. They clear on withdrawal of the offending medication.

Miscellaneous

Headache, nasal congestion, increased arousal, pulmonary infiltrates, pleural and retroperitoneal fibrosis, and erythromelalgia are other reported side effects of the ergot-derived dopamine agonists. Erythromelalgia consists of red, tender, painful, swollen feet and, occasionally, hands, at times associated with arthralgia; symptoms and signs clear within a few days of withdrawal of the causal drug. In rare instances, an uncontrollable tendency to fall asleep at inappropriate times has occurred, particularly in patients receiving pramipexole or ropinirole, requiring the discontinuation of medication.

Contraindications

Dopamine agonists are contraindicated in patients with a history of psychotic illness or recent myocardial infarction, or with active peptic ulceration. The ergot-derived agonists are best avoided in patients with peripheral vascular disease.

Monoamine Oxidase Inhibitors

Two types of monoamine oxidase have been distinguished. Monoamine oxidase A metabolizes norepinephrine and serotonin; monoamine oxidase B metabolizes dopamine. **Selegiline** (deprenyl) (Figure 28–2), a selective inhibitor of monoamine oxidase B, retards the breakdown of dopamine; in consequence, it enhances and prolongs the antiparkinsonism effect of levodopa (thereby allowing the dose of levodopa to be reduced) and may reduce mild on-off or wearing-off phenomena. It is therefore used as adjunctive therapy for patients with a declining or fluctuating response to levodopa. The standard dose is 5 mg with breakfast and 5 mg with lunch. Selegiline may cause insomnia when taken later during the day. It should not be taken by patients receiving meperidine, tricyclic antidepressants, or serotonin reuptake inhibitors because of the risk of acute toxic interactions. The adverse effects of levodopa may be increased by selegiline. Selegiline has only a minor therapeutic effect on parkinsonism when given alone, but studies in animals suggest that it may reduce disease progression. Such an effect of antioxidative therapy on disease progression may be expected if Parkinson's disease is associated with the oxidative generation of free radicals. However, any neuroprotective effect of selegiline may relate to its metabolite, desmethylselegiline, and involve antiapoptotic mechanisms. Studies to test the effect of selegiline on the progression of parkinsonism in humans have yielded ambiguous results. The findings in a large multicenter study have been taken to suggest a beneficial effect in slowing disease progression but may simply have reflected a symptomatic response.

Rasagiline, another monoamine oxidase B inhibitor, is more potent than selegiline in preventing MPTP-induced parkinsonism and is currently under study as a neuroprotective agent.

The combined administration of levodopa and an inhibitor of both forms of monoamine oxidase must be avoided, since it may lead to hypertensive crises, probably because of the peripheral accumulation of norepinephrine.

Catechol-O-Methyltransferase Inhibitors

Inhibition of dopa decarboxylase is associated with compensatory activation of other pathways of

levodopa metabolism, especially catechol-*O*-methyltransferase (COMT), and this increases plasma levels of 3-*O*-methyldopa (3OMD). Elevated levels of 3OMD have been associated with a poor therapeutic response to levodopa, perhaps in part because 3OMD competes with levodopa for an active carrier mechanism that governs its transport across the intestinal mucosa and the blood-brain barrier. Selective COMT inhibitors such as **tolcapone** and **entacapone** also prolong the action of levodopa by diminishing its peripheral metabolism. Levodopa clearance is decreased, and relative bioavailability of levodopa is thus increased. Neither the time to reach peak concentration nor the maximal concentration of levodopa is increased. These agents may be helpful in patients receiving levodopa who have developed response fluctuations—leading to a smoother response, more prolonged "on-time," and the option of reducing total daily levodopa dose. Tolcapone and entacapone are both widely available, but entacapone is generally preferred because it has not been associated with hepatotoxicity.

The pharmacologic effects of tolcapone and entacapone are similar, and both are rapidly absorbed, bound to plasma proteins, and metabolized prior to excretion. However, tolcapone has both central and peripheral effects, whereas the effect of entacapone is peripheral. The half-life of both drugs is approximately 2 hours, but tolcapone is slightly more potent and has a longer duration of action. Tolcapone is taken in a standard dose of 100 mg three times daily; some patients require a daily dose of twice that amount. By contrast, entacapone (200 mg) needs to be taken with each dose of levodopa, up to five times daily.

Adverse effects of the COMT inhibitors relate in part to increased levodopa exposure and include dyskinesias, nausea, and confusion. It is often necessary to lower the daily dose of levodopa by about 30% in the first 48 hours to avoid or reverse such complications. Other side effects include diarrhea, abdominal pain, orthostatic hypotension, sleep disturbances, and an orange discoloration of the urine. Tolcapone may cause an increase in liver enzyme levels and has been rarely associated with death from acute hepatic failure; accordingly, its use in the USA requires signed patient consent (as provided in the product labeling) plus monitoring of liver function tests every 2 weeks during the first year and less frequently thereafter. No such toxicity has been reported with entacapone.

Amantadine

Amantadine, an antiviral agent, was by chance found to have antiparkinsonism properties. Its mode of action in parkinsonism is unclear, but it may potentiate dopaminergic function by influencing the synthesis, release, or reuptake of dopamine. Release of catecholamines from peripheral stores has been documented.

Pharmacokinetics

Peak plasma concentrations of amantadine are reached 1–4 hours after an oral dose. The plasma half-life is between 2 and 4 hours, most of the drug being excreted unchanged in the urine.

Clinical Use

Amantadine is less potent than levodopa and its benefits may be short-lived, often disappearing after only a few weeks of treatment. Nevertheless, during that time it may favorably influence the bradykinesia, rigidity, and tremor of parkinsonism. The standard dose is 100 mg orally twice or three times daily.

Adverse Effects

Amantadine has a number of undesirable central nervous system effects, all of which can be reversed by stopping the drug. These include restlessness, depression, irritability, insomnia, agitation, excitement, hallucinations, and confusion. Overdosage may produce an acute toxic psychosis. With doses several times higher than recommended, convulsions have occurred.

Livedo reticularis sometimes occurs in patients taking amantadine and usually clears within a month after the drug is withdrawn. Other dermatologic reactions have also been described. Peripheral edema, another well-recognized complication, is not accompanied by signs of cardiac, hepatic, or renal disease and responds to diuretics. Other adverse reactions include headache, heart failure, postural hypotension, urinary retention, and gastrointestinal disturbances (eg, anorexia, nausea, constipation, and dry mouth).

Contraindications

Amantadine should be used with caution in patients with a history of seizures or heart failure.

Acetylcholine-Blocking Drugs

A number of centrally acting antimuscarinic preparations are available that differ in their potency and in their efficacy in different patients.

Clinical Use

Treatment is started with a low dose of one of the drugs in this category, the level of medication gradually being increased until benefit occurs or adverse effects limit further increments. Antimuscarinic drugs may improve the tremor and rigidity of parkinsonism but have little effect on bradykinesia. If patients do not respond to one drug, a trial with another is warranted and may be successful. Some of the more commonly used drugs are listed in Table 28–1.

Drug	Usual Daily Dose (mg)
Benztropine mesylate	1–6
Biperiden	2–12
Orphenadrine	150–400
Procyclidine	7.5–30
Trihexyphenidyl	6–20

Adverse Effects

Antimuscarinic drugs have a number of central nervous system effects, including drowsiness, mental slowness, inattention, restlessness, confusion, agitation, delusions, hallucinations, and mood changes. Other common effects include dryness of the mouth, blurring of vision, mydriasis, urinary retention, nausea and vomiting, constipation, tachycardia, tachypnea, increased intraocular pressure, palpitations, and cardiac arrhythmias. Dyskinesias occur in rare cases. Acute suppurative parotitis sometimes occurs as a complication of dryness of the mouth.

If medication is to be withdrawn, this should be accomplished gradually rather than abruptly in order to prevent acute exacerbation of parkinsonism.

Contraindications

Acetylcholine-blocking drugs should be avoided in patients with prostatic hyperplasia, obstructive gastrointestinal disease (eg, pyloric stenosis or paralytic ileus), or angle-closure glaucoma. In parkinsonism patients receiving antimuscarinic medication, concomitant administration of other drugs with antimuscarinic properties (eg, tricyclic antidepressants or antihistamines) may precipitate some of the complications mentioned above.

Surgical Procedures

In patients with advanced disease that is poorly responsive to pharmacotherapy, worthwhile benefit may follow thalamotomy (for conspicuous tremor) or posteroventral pallidotomy. Ablative surgical procedures, however, are being replaced by functional, reversible lesions induced by high-frequency deep-brain stimulation, which has a lower morbidity. Thalamic stimulation by an implanted electrode and stimulator is very effective for the relief of tremor, and stimulation of the subthalamic nucleus or globus pallidus internus has yielded good results for management of the clinical fluctuation occurring in advanced parkinsonism. The anatomic substrate for such therapy is indicated in Figure 28–4. Such procedures are contraindicated in patients with secondary or atypical parkinsonism. Transplantation of dopaminergic tissue (fetal substantia nigra tissue) has been reported to confer benefit in some parkinsonism patients, but the results are conflicting and uncontrollable dyskinesias have occurred in some patients. Such procedures are best regarded as investigational.

Figure 28–4.

Neuroprotective Therapy

A number of different compounds are currently under investigation as potential neuroprotective agents that may slow disease progression. These include antioxidants, antiapoptotic agents, glutamate antagonists, intraparenchymally administered glial-derived neurotrophic factor, coenzyme Q10, and anti-inflammatory drugs. The role of these agents remains to be established, however, and their use for therapeutic purposes is not indicated at this time.

General Comments on Drug Management of Patients with Parkinsonism

Parkinson's disease generally follows a progressive course. Moreover, the benefits of levodopa therapy often seem to diminish with time and certain adverse effects may complicate long-term levodopa treatment. Nevertheless, evidence is accumulating that dopaminergic therapy at a relatively early stage may be most effective in alleviating symptoms of parkinsonism and may also favorably affect the mortality rate due to the disease. Symptomatic treatment of mild parkinsonism is probably best avoided until there is some degree of disability or until symptoms begin to have a significant impact on the patient's lifestyle. When treatment becomes necessary, a trial of

amantadine or an antimuscarinic drug (or both) may be worthwhile. With disease progression, dopaminergic therapy becomes necessary. This can conveniently be initiated with a dopamine agonist, either alone or in combination with low-dose Sinemet therapy. Physical therapy is helpful in improving mobility. In patients with severe parkinsonism and long-term complications of levodopa therapy, such as the on-off phenomena, a trial of treatment with a COMT inhibitor may be worthwhile. Regulation of dietary protein intake may also improve response fluctuations. Pallidotomy or deep-brain stimulation may be helpful in patients who fail to respond adequately to these measures. Treating patients who are young or have mild parkinsonism with selegiline may delay disease progression and merits consideration.

Drug-Induced Parkinsonism

Reserpine and the related drug tetrabenazine deplete biogenic monoamines from their storage sites, while haloperidol and the phenothiazines block dopamine receptors. These drugs may therefore produce a parkinsonian syndrome, usually within 3 months after introduction, which is related to high dosage and clears over a few weeks or months after withdrawal. If treatment is necessary, antimuscarinic agents are preferred. Levodopa is of no help if neuroleptic drugs are continued and may in fact aggravate the mental disorder for which antipsychotic drugs were prescribed originally.

In 1983, a drug-induced form of parkinsonism was discovered in individuals who attempted to synthesize and use a narcotic drug related to meperidine but actually synthesized and self-administered MPTP, as discussed in the MPTP & Parkinsonism.

Katzung PHARMACOLOGY, 9e > Section V. Drugs That Act in the Central Nervous System > Chapter 28. Pharmacologic Management of Parkinsonism & Other Movement Disorders >

MPTP & Parkinsonism

Reports in the early 1980s of a rapidly progressive form of parkinsonism in young persons opened a new area of research in the etiology and treatment of parkinsonism. The initial report described apparently healthy young people who attempted to support their opioid habit with a meperidine analog synthesized by an amateur chemist. They unwittingly self-administered 1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine (MPTP) and subsequently developed a very severe form of parkinsonism.

MPTP is a protoxin that is converted by monoamine oxidase B to *N*-methyl-4-phenylpyridinium (MPP⁺). MPP⁺ is selectively taken up by cells in the substantia nigra through an active mechanism normally responsible for dopamine reuptake. MPP⁺ inhibits mitochondrial complex I, thereby inhibiting oxidative phosphorylation. The interaction of MPP⁺ with complex I probably leads to cell death and thus to striatal dopamine depletion and parkinsonism.

Recognition of the effects of MPTP suggested that spontaneously occurring Parkinson's disease may result from exposure to an environmental toxin that is similarly selective in its target. However, no such toxin has yet been identified. It also suggested a successful means of producing an experimental model of Parkinson's disease in animals, especially nonhuman primates. This model is assisting in the development of new antiparkinsonism drugs. Pretreatment of exposed animals with a monoamine oxidase B inhibitor such as selegiline prevents the conversion of MPTP to MPP⁺ and thus protects against the occurrence of parkinsonism. This observation has provided one reason to believe that selegiline may retard the progression of Parkinson's disease in humans.

Other Movement Disorders

Tremor

Tremor consists of rhythmic oscillatory movements. Physiologic postural tremor, which is a normal phenomenon, is enhanced in amplitude by anxiety, fatigue, thyrotoxicosis, and intravenous epinephrine or isoproterenol. Propranolol reduces its amplitude and, if administered intra-arterially, prevents the response to isoproterenol in the perfused limb, presumably through some peripheral action. Certain drugs—especially the bronchodilators, valproate, tricyclic antidepressants, and lithium—may produce a dose-dependent exaggeration of the normal physiologic tremor that is reversed by discontinuing the drug. Although the tremor produced by sympathomimetics such as terbutaline (a bronchodilator) is blocked by propranolol, which antagonizes both β_1 and β_2 receptors, it is not blocked by metoprolol, a β_1 -selective antagonist, suggesting that such tremor is mediated mainly by the β_2 receptors.

Essential tremor is a postural tremor, sometimes familial, that is clinically similar to physiologic tremor. Dysfunction of β_1 receptors has been implicated in some instances, since the tremor may respond dramatically to standard doses of metoprolol as well as to propranolol. The most useful approach is with propranolol, but whether the response depends on a central or peripheral action is unclear. The pharmacokinetics, pharmacologic effects, and adverse reactions of propranolol are discussed in Chapter 10: Adrenoceptor Antagonist Drugs. Daily doses of propranolol on the order of 120 mg (range, 60–240 mg) are usually required, and reported adverse effects have been few. Propranolol should be used with caution in patients with heart failure, heart block, asthma, and hypoglycemia. Patients can be instructed to take their own pulse and call the physician if significant bradycardia develops. Metoprolol is sometimes useful in treating tremor when patients have concomitant pulmonary disease that contraindicates use of propranolol. Primidone (an antiepileptic drug; see Chapter 24: Antiseizure Drugs), in gradually increasing doses up to 250 mg three times daily, is also effective in providing symptomatic control in some cases. Patients with tremor are very sensitive to primidone and often cannot tolerate the doses used to treat seizures; they should be started on 50 mg once daily and the daily dose increased by 50 mg every 2 weeks depending on response. Topiramate, another antiepileptic drug, may also be helpful in a dose of 400 mg daily, built up gradually. Small quantities of alcohol may suppress essential tremor but only for a short time and by an unknown mechanism. Diazepam, chlordiazepoxide, mephenesin, and antiparkinsonism agents have been advocated in the past but are generally worthless. Alprazolam (in doses up to 3 mg daily) is helpful in some patients. Thalamic stimulation (discussed earlier) is often worthwhile in advanced cases refractory to pharmacotherapy.

Intention tremor is present during movement but not at rest; sometimes it occurs as a toxic manifestation of alcohol or drugs such as phenytoin. Withdrawal or reduction in dosage provides dramatic relief. There is no satisfactory pharmacologic treatment for intention tremor due to other neurologic disorders.

Rest tremor is usually due to parkinsonism.

Huntington's Disease

This dominantly inherited disorder is characterized by progressive chorea and dementia that usually

begin in adulthood. The development of chorea seems to be related to an imbalance of dopamine, acetylcholine, GABA, and perhaps other neurotransmitters in the basal ganglia (Figure 28–1). Pharmacologic studies indicate that chorea results from functional overactivity in dopaminergic nigrostriatal pathways, perhaps because of increased responsiveness of postsynaptic dopamine receptors or deficiency of a neurotransmitter that normally antagonizes dopamine. Drugs that impair dopaminergic neurotransmission, either by depleting central monoamines (eg, reserpine, tetrabenazine) or by blocking dopamine receptors (eg, phenothiazines, butyrophenones), often alleviate chorea, whereas dopamine-like drugs such as levodopa tend to exacerbate it.

Both GABA and the enzyme (glutamic acid decarboxylase) concerned with its synthesis are markedly reduced in the basal ganglia of patients with Huntington's disease, and GABA receptors are usually implicated in inhibitory pathways. There is also a significant decline in concentration of choline acetyltransferase, the enzyme responsible for synthesizing acetylcholine, in the basal ganglia of these patients. These findings may be of pathophysiologic significance and have led to attempts to alleviate chorea by enhancing central GABA or acetylcholine activity. Unfortunately, such pharmacologic manipulations have been disappointing, yielding no consistently beneficial response, and as a consequence the most commonly used drugs for controlling dyskinesia in patients with Huntington's disease are still those that interfere with dopamine activity. With all of the latter drugs, however, reduction of abnormal movements may be associated with iatrogenic parkinsonism.

Reserpine depletes cerebral dopamine by preventing intraneuronal storage; it is introduced in low doses (eg, 0.25 mg daily), and the daily dose is then built up gradually (eg, by 0.25 mg every week) until benefit occurs or adverse effects become troublesome. A daily dose of 2–5 mg is often effective in suppressing abnormal movements, but adverse effects may include hypotension, depression, sedation, diarrhea, and nasal congestion. Tetrabenazine resembles reserpine in depleting cerebral dopamine and has less troublesome adverse effects, but it is not available in the USA. Treatment with postsynaptic dopamine receptor blockers such as phenothiazines and butyrophenones may also be helpful. Haloperidol is started in a small dose, eg, 1 mg twice daily, and increased every 4 days depending on the response. If haloperidol is not helpful, treatment with increasing doses of perphenazine up to a total of about 20 mg daily sometimes helps. Several recent reports suggest that olanzapine may also be helpful; the dose varies with the patient, but 10 mg daily is often sufficient although doses as high as 30 mg daily are sometimes required. The pharmacokinetics and clinical properties of these drugs are considered in greater detail elsewhere in this book.

Other Forms of Chorea

Treatment is directed at the underlying cause when chorea occurs as a complication of general medical disorders such as thyrotoxicosis, polycythemia vera rubra, systemic lupus erythematosus, hypocalcemia, and hepatic cirrhosis. Drug-induced chorea is managed by withdrawal of the offending substance, which may be levodopa, an antimuscarinic drug, amphetamine, lithium, phenytoin, or an oral contraceptive. Neuroleptic drugs may also produce an acute or tardive dyskinesia (discussed below). Sydenham's chorea is temporary and usually so mild that pharmacologic management of the dyskinesia is unnecessary, but dopamine-blocking drugs are effective in suppressing it.

Ballismus

The biochemical basis of ballismus is unknown, but the pharmacologic approach to management is the same as for chorea. Treatment with haloperidol, perphenazine, or other dopamine-blocking

drugs may be helpful.

Athetosis & Dystonia

The pharmacologic basis of these disorders is unknown, and there is no satisfactory medical treatment for them. Occasional patients with dystonia may respond to diazepam, amantadine, antimuscarinic drugs (in high dosage), levodopa, carbamazepine, baclofen, haloperidol, or phenothiazines. A trial of these pharmacologic approaches is worthwhile even though often not successful. Patients with focal dystonias such as blepharospasm or torticollis may benefit from injection of botulinum toxin into the overactive muscles.

Tics

The pathophysiologic basis of tics is unknown. Chronic multiple tics (Gilles de la Tourette's syndrome) may require treatment if the disorder is severe or is having a significant impact on the patient's life. The most effective pharmacologic approach is with haloperidol, and patients are better able to tolerate this drug if treatment is started with a small dosage (eg, 0.25 or 0.5 mg daily) and then increased very gradually over the following weeks. Most patients ultimately require a total daily dose of 3–8 mg. If haloperidol is not helpful, fluphenazine, clonazepam, clonidine, or carbamazepine should be tried. The pharmacologic properties of these drugs are discussed elsewhere in this book. Pimozide, an oral dopamine blocker, may help patients intolerant or unresponsive to haloperidol. The role of the newer atypical antipsychotic agents, such as risperidone, is unclear.

Drug-Induced Dyskinesias

The pharmacologic basis of the acute dyskinesia or dystonia sometimes precipitated by the first few doses of a phenothiazine is not clear. In most instances, parenteral administration of an antimuscarinic drug such as benztropine (2 mg intravenously), diphenhydramine (50 mg intravenously), or biperiden (2–5 mg intravenously or intramuscularly) is helpful, while in other instances diazepam (10 mg intravenously) alleviates the abnormal movements.

Tardive dyskinesia, a disorder characterized by a variety of abnormal movements, is a common complication of long-term neuroleptic drug treatment (see Chapter 29: Antipsychotic Agents & Lithium). Unfortunately, its precise pharmacologic basis is unclear. A reduction in dose of the offending medication, a dopamine receptor blocker, commonly worsens the dyskinesia, while an increase in dose may suppress it. The drugs most likely to provide immediate symptomatic benefit are those interfering with dopaminergic function, either by depletion (eg, reserpine, tetrabenazine) or receptor blockade (eg, phenothiazines, butyrophenones). Paradoxically, the receptor-blocking drugs are the very ones that also cause the dyskinesia, and they are probably best avoided to prevent the development of a spiral phenomenon in which continuing aggravation of the dyskinesia by the drugs used to control it necessitates increasingly higher doses for its temporary suppression.

Because tardive dyskinesia developing in adults is usually irreversible and has no satisfactory treatment, care must be taken to reduce the likelihood of its occurrence. Antipsychotic medication should be prescribed only when necessary and should be withheld periodically to assess the need for continued treatment and to unmask incipient dyskinesia. Thioridazine, a phenothiazine with a piperidine side chain, is an effective antipsychotic that seems less likely than most to cause extrapyramidal reactions, perhaps because it has little effect on dopamine receptors in the striatal system. Finally, antimuscarinic drugs should not be prescribed routinely in patients receiving

neuroleptics, since the combination may increase the likelihood of dyskinesia.

Wilson's Disease

Wilson's disease, a recessively inherited disorder of copper metabolism, is characterized biochemically by reduced serum copper and ceruloplasmin concentrations, pathologically by markedly increased concentration of copper in the brain and viscera, and clinically by signs of hepatic and neurologic dysfunction. Treatment involves the removal of excess copper, followed by maintenance of copper balance. A commonly used agent for this purpose is **penicillamine** (dimethylcysteine), a chelating agent that forms a ring complex with copper. It is readily absorbed from the gastrointestinal tract and rapidly excreted in the urine. A common starting dose in adults is 500 mg three or four times daily. After remission occurs, it may be possible to lower the maintenance dose, generally to not less than 1 g daily, which must thereafter be continued indefinitely. Adverse effects include nausea and vomiting, nephrotic syndrome, a lupus-like syndrome, pemphigus, myasthenia, arthropathy, optic neuropathy, and various blood dyscrasias. Treatment should be monitored by frequent urinalysis and complete blood counts. Dietary copper should also be kept below 2 mg daily. Potassium disulfide, 20 mg three times daily with meals, reduces the intestinal absorption of copper and should also be prescribed.

For those patients who are unable to tolerate penicillamine, **trientine**, another chelating agent, may be used in a daily dose of 1–1.5 g. Trientine appears to have few adverse effects other than mild anemia due to iron deficiency in a few patients. **Zinc acetate** administered orally increases the fecal excretion of copper and is sometimes used for maintenance therapy. The dose is 50 mg three times a day. **Zinc sulfate** (200 mg/d orally) has also been used to decrease copper absorption. Zinc blocks copper absorption from the gastrointestinal tract by induction of intestinal cell metallothionein. Its main advantage is its low toxicity compared with other anticopper agents, although it may cause gastric irritation when first introduced.

Katzung PHARMACOLOGY, 9e > Section V. Drugs That Act in the Central Nervous System > Chapter 28. Pharmacologic Management of Parkinsonism & Other Movement Disorders >

Preparations Available

Amantadine (Symmetrel, others)

Oral: 100 mg capsules; 10 mg/mL syrup

Benzotropine (Cogentin, others)

Oral: 0.5, 1, 2 mg tablets

Parenteral: 1 mg/mL for injection

Biperiden (Akineton)

Oral: 2 mg tablets

Parenteral: 5 mg/mL for injection

Bromocriptine (Parlodel)

Oral: 2.5 mg tablets; 5 mg capsules

Carbidopa (Lodosyn)

Oral: 25 mg tablets

Carbidopa/levodopa (Sinemet)

Oral: 10 mg carbidopa and 100 mg levodopa, 25 mg carbidopa and 100 mg levodopa, 25 mg carbidopa and 250 mg levodopa tablets

Oral sustained-release (Sinemet CR): 25 mg carbidopa and 100 mg levodopa; 50 mg carbidopa and 200 mg levodopa

Entacapone (Comtan)

Oral: 200 mg tablets

Levodopa (Dopar, Larodopa)

Oral: 100, 250, 500 mg tablets, capsules

Orphenadrine (various)

Oral: 100 mg tablets

Oral sustained-release: 100 mg tablets

Parenteral: 30 mg/mL for injection

Penicillamine (Cuprimine, Depen)

Oral: 125, 250 mg capsules; 250 mg tablets

Pergolide (Permax)

Oral: 0.05, 0.25, 1 mg tablets

Pramipexole (Mirapex)

Oral: 0.125, 0.25, 1, 1.5 mg tablets

Procyclidine (Kemadrin)

Oral: 5 mg tablets

Ropinirole (Requip)

Oral: 0.25, 0.5, 1, 2, 5 mg tablets

Selegiline (deprenyl) (generic, Eldepryl)

Oral: 5 mg tablets

Tolcapone (Tasmar)

Oral: 100, 200 mg tablets

Trientine (Syprine)

Oral: 250 mg capsules

Trihexyphenidyl (Artane, others)

Oral: 2, 5 mg tablets; 2 mg/5 mL elixir

Oral sustained-release (Artane Sequels): 5 mg capsules

Chapter 29. Antipsychotic Agents & Lithium

Katzung PHARMACOLOGY, 9e > Section V. Drugs That Act in the Central Nervous System > Chapter 29. Antipsychotic Agents & Lithium >

Antipsychotic Agents

*Deceased

The terms **antipsychotic** and **neuroleptic** are used interchangeably to denote a group of drugs that have been used mainly for treating schizophrenia but are also effective in some other psychoses and agitated states.

History

Antipsychotic drugs have been used in western medicine for 50 years. Reserpine and chlorpromazine were the first drugs found to be useful in schizophrenia. Although chlorpromazine is still sometimes used for the treatment of psychoses, these forerunner drugs have been superseded by many newer agents. Their impact on psychiatry, however—especially on the treatment of schizophrenia—has been enormous: The number of patients requiring hospitalization in mental institutions has markedly decreased, and psychiatric thinking has shifted to a more biologic basis.

Nature of Psychosis & Schizophrenia

The term "psychosis" denotes a variety of mental disorders. Schizophrenia is a particular kind of psychosis characterized mainly by a clear sensorium but a marked thinking disturbance.

The pathogenesis of schizophrenia is unknown. Largely as a result of research stimulated by the discovery of antipsychotic drugs, a genetic predisposition has been proposed as a necessary but not always sufficient condition underlying psychotic disorder. This assumption has been supported by the observed familial incidence of schizophrenia. Completion of the first phase of the human genome project increases the likelihood of identifying multiple genes that contribute to the various clinical phenotypes subsumed under the broad diagnostic classification of schizophrenia. At least one gene—that which encodes for neuregulin 1—is associated with schizophrenia in Icelandic and northern European populations. In what way it actually contributes to schizophrenia and whether it applies to other populations have yet to be determined. The molecular basis for schizophrenia thus continues to elude definition, but a great deal of effort has been expended in attempting to link the disorder with abnormalities of amine neurotransmitter function, especially that of dopamine (see The Dopamine Hypothesis). The defects of this hypothesis are significant, and it is now appreciated that the disorder is far more complex than originally supposed.

Basic Pharmacology of Antipsychotic Agents

Chemical Types

A number of chemical structures have been associated with antipsychotic properties. The drugs can be classified into several groups as shown in Figures 29–1 and 29–2.

Figure 29–1.

PHENOTHIAZINE DERIVATIVES

Piperazine side chain

THIOXANTHENE DERIVATIVE

BUTYROPHENONE

Haloperidol

Structural formulas of some older antipsychotic drugs: phenothiazines, thioxanthenes, and butyrophenones. Only representative members of each type are shown.

Molindone

Pimozide

Loxapine

Clozapine

Risperidone

Quetiapine

Olanzapine

Ziprasidone

Aripiprazole

Structural formulas of some newer antipsychotic drugs.

The Dopamine Hypothesis

The dopamine hypothesis for schizophrenia is the most fully developed of several hypotheses and is the basis for much of the rationale for drug therapy. Several lines of circumstantial evidence suggest that excessive dopaminergic activity plays a role in the disorder: (1) most antipsychotic drugs strongly block postsynaptic D₂ receptors in the central nervous system, especially in the mesolimbic-frontal system; (2) drugs that increase dopaminergic activity, such as levodopa (a precursor), amphetamines (releasers of dopamine), or apomorphine (a direct dopamine receptor agonist), either aggravate schizophrenia or produce psychosis de novo in some patients; (3) dopamine receptor density has been found, postmortem, to be increased in the brains of schizophrenics who have not been treated with antipsychotic drugs; (4) positron emission tomography (PET) has shown increased dopamine receptor density in both treated and untreated schizophrenics when compared with such scans of nonschizophrenic persons; and (5) successful treatment of schizophrenic patients has been reported to change the amount of homovanillic acid (HVA), a metabolite of dopamine, in the cerebrospinal fluid, plasma, and urine.

The dopamine hypothesis is far from complete, however. If an abnormality of dopamine physiology were completely responsible for the pathogenesis of schizophrenia, antipsychotic drugs would do a much better job of treating patients—but they are only partially effective for most and ineffective for some patients. Moreover, it appears that antagonists of the NMDA receptor such as phencyclidine, when administered to nonpsychotic subjects, produce much more "schizophrenia-like" symptoms than do dopamine agonists. The recent cloning and characterization of multiple dopamine receptor types may permit more direct testing of the dopamine hypothesis if drugs can be developed that act selectively on each receptor type. The traditional antipsychotics bind D₂ 50 times more avidly than D₁ or D₃ receptors. Until recently, the main thrust in drug development was to find agents that were more potent and more selective in blocking D₂ receptors. The fact that several of the atypical antipsychotic drugs have much less effect on D₂ receptors and yet are effective in schizophrenia has redirected attention to the role of other dopamine receptors and to nondopamine receptors, especially serotonin receptor subtypes that may mediate synergistic effects or protect against the extrapyramidal consequences of D₂ antagonism. As a result of these considerations, the direction of research has changed to a greater focus on compounds that may act on several transmitter-receptor systems. The great hope is to produce drugs with greater efficacy and fewer adverse effects, especially extrapyramidal toxicity.

Lithium & Other Mood-Stabilizing Drugs

Lithium carbonate is often referred to as an "antimanic" drug, but in many parts of the world it is considered a "mood-stabilizing" agent because of its primary action of preventing mood swings in patients with bipolar affective (manic-depressive) disorder. Discovery of its benefits was based on an incorrect hypothesis and extremely good fortune in choosing the correct dosage. Carbamazepine has also been recognized as effective in some groups of manic-depressive patients despite not being formally approved for such use. Valproate has recently been approved for the treatment of mania and is being evaluated as a mood stabilizer. Atypical antipsychotics, beginning with olanzapine, are being investigated and approved as antimanic agents and potential mood stabilizers.

Nature of Bipolar Affective Disorder

Bipolar affective (manic-depressive) disorder is a frequently diagnosed and very serious psychiatric disorder. Patients with cyclic attacks of mania have many symptoms of paranoid schizophrenia (grandiosity, bellicosity, paranoid thoughts, and overactivity). The gratifying response to lithium therapy of patients with bipolar disorder has made such diagnostic distinctions important.

The episodes of mood swings characteristic of this condition are generally unrelated to life events. The exact biologic disturbance has not been identified, but a preponderance of catecholamine-related activity is thought to be present. Drugs that increase this activity tend to exacerbate mania, whereas those that reduce activity of dopamine or norepinephrine relieve mania. Acetylcholine or glutamate may also be involved. The nature of the abrupt switch from mania to depression experienced by some patients is uncertain. Bipolar disorder has a strong familial component. Genetic studies have identified at least three possible linkages to different chromosomes.

Basic Pharmacology of Lithium

Pharmacokinetics

Lithium is a small monovalent cation. Its pharmacokinetics are summarized in Table 29–5.

Absorption	Virtually complete within 6–8 hours; peak plasma levels in 30 minutes to 2 hours
Distribution	In total body water; slow entry into intracellular compartment. Initial volume of distribution is 0.5 L/kg, rising to 0.7–0.9 L/kg; some sequestration in bone. No protein binding.
Metabolism	None
Excretion	Virtually entirely in urine. Lithium clearance about 20% of creatinine. Plasma half-life about 20 hours.
Target plasma concentration	0.6–1.4 meq/L
Dosage	0.5 meq/kg/d in divided doses

Pharmacodynamics

Despite considerable investigation, the mode of action of lithium remains unclear. The major possibilities being investigated include (1) effects on electrolytes and ion transport; (2) effects on neurotransmitters and their release; and (3) effects on second messengers and intracellular enzymes that mediate transmitter action. The last of these three approaches appears to be the most promising.

Effects on Electrolytes and Ion Transport

Lithium is closely related to sodium in its properties. It can substitute for sodium in generating action potentials and in Na^+ - Na^+ exchange across the membrane. It inhibits the latter process, ie,

Li^+ - Na^+ exchange is gradually slowed after lithium is introduced into the body. At therapeutic concentrations (around 1 mmol/L), it does not significantly affect the $\text{Na}^+/\text{Ca}^{2+}$ exchange process or the Na^+/K^+ ATPase sodium pump.

Effects on Neurotransmitters

Lithium appears to enhance some of the actions of serotonin, though findings have been contradictory. Its effects on norepinephrine are variable. The drug may decrease norepinephrine and dopamine turnover, and these effects, if confirmed, might be relevant to its antimanic action. Lithium also appears to block the development of dopamine receptor supersensitivity that may accompany chronic therapy with antipsychotic agents. Finally, lithium may augment the synthesis of acetylcholine, perhaps by increasing choline uptake into nerve terminals. Some clinical studies have suggested that increasing cholinergic activity may mitigate mania. However, as noted below, a second-messenger effect of lithium may obviate any effect of increased acetylcholine release.

Effects on Second Messengers

One of the best-defined effects of lithium is its action on inositol phosphates. Early studies of lithium demonstrated changes in brain inositol phosphate levels, but the significance of these changes was not appreciated until the second-messenger roles of inositol-1,4,5-trisphosphate (IP_3) and diacylglycerol (DAG) were discovered. As described in Chapter 2: Drug Receptors & Pharmacodynamics, IP_3 and DAG are important second messengers for both α -adrenergic and muscarinic transmission. Lithium inhibits several important enzymes in the normal recycling of membrane phosphoinositides, including conversion of IP_2 to IP_1 (inositol monophosphate) and the conversion of IP to inositol (Figure 29–4). This block leads to a depletion of phosphatidylinositol-4,5-bisphosphate (PIP_2), the membrane precursor of IP_3 and DAG. Over time, the effects of transmitters on the cell will diminish in proportion to the amount of activity in the PIP_2 -dependent pathways. Before therapy, such activity might be greatly increased in mania; thus, lithium could cause a selective depression of the overactive circuits.

Figure 29–4.

Effect of lithium on the IP_3 and DAG second-messenger system. The schematic diagram shows the synaptic membrane of a neuron. (PIP_2 , phosphatidylinositol-4,5-bisphosphate; PLC, phospholipase-C; G, coupling protein; EFFECTS, activation of protein kinase C, mobilization of intracellular Ca^{2+} , etc.) Lithium, by inhibiting the recycling of inositol substrates, may cause

depletion of the second-messenger source PIP_2 and therefore reduce the release of IP_3 and DAG. Lithium may also act by other mechanisms.

Studies of noradrenergic effects in isolated brain tissue indicate that lithium can inhibit norepinephrine-sensitive adenylyl cyclase. Such an effect could relate to both its antidepressant and its antimanic effects. The relationship of these effects to lithium's actions on IP_3 mechanisms is currently unknown.

Since lithium affects second-messenger systems involving both activation of adenylyl cyclase and phosphoinositol turnover, it is not surprising that G proteins are also found to be affected. Several studies suggest that lithium may uncouple receptors from their G proteins; indeed, two of lithium's most common side effects, polyuria and subclinical hypothyroidism, may be due to uncoupling of the vasopressin and TSH receptors from their G proteins.

The major current working hypothesis for lithium's therapeutic mechanism of action supposes that its effects on phosphoinositol turnover, leading to an early relative reduction of myoinositol in human brain, are part of an initiating cascade of intracellular changes. Effects on specific isoforms of protein kinase C may be most relevant. Alterations of protein kinase C-mediated signaling alter gene expression and the production of proteins implicated in long-term neuroplastic events that could underlie long-term mood stabilization.

Clinical Pharmacology of Lithium

Bipolar Affective Disorder

Until recently, lithium carbonate was the universally preferred treatment for bipolar disorder, especially in the manic phase. With the approval of valproate and olanzapine for this indication, a smaller fraction of bipolar patients now receive lithium. This trend is reinforced by the slow onset of action of lithium, which has often been supplemented with concurrent use of antipsychotic drugs or potent benzodiazepines in severely manic patients. The overall success rate for achieving remission from the manic phase of bipolar disorder has been reported to be 60–80%. However, among patients who require hospitalization, success rates are considerably lower. A similar situation applies to maintenance treatment, which is about 60% effective overall but less in severely ill patients. These considerations have led to increased use of combined treatment in severe cases. After mania is controlled, the antipsychotic drug may be stopped, then the benzodiazepine and lithium continued as maintenance therapy.

The depressive phase of manic-depressive disorder often requires concurrent use of an antidepressant drug (see Chapter 30: Antidepressant Agents). Tricyclic antidepressant agents have been linked to precipitation of mania, with more rapid cycling of mood swings, although most patients do not show this effect. Selective serotonin reuptake inhibitors are less likely to induce mania but may have limited efficacy. Bupropion has shown some promising effects but may induce mania—like tricyclic antidepressants—at higher doses. As shown in recent controlled trials, the anticonvulsant lamotrigine is effective for many patients with bipolar depression. For some patients, however, one of the older MAO inhibitors may be the antidepressant of choice.

Unlike antipsychotic or antidepressant drugs, which exert several actions on the central or autonomic nervous system, lithium ion at therapeutic concentrations is devoid of autonomic blocking effects and of activating or sedating effects, though it can produce nausea and tremor.

Another attribute of considerable interest has been the prophylactic use of lithium in preventing

both mania and depression. It is indeed remarkable that a so-called functional psychosis can be controlled so easily by such a simple chemical as lithium carbonate.

Other Applications

Acute endogenous depression is not generally considered to be an indication for treatment with lithium. Alcohol and substance abuse have a high association with bipolar illness. However, recurrent endogenous depressions with a cyclic pattern are controlled by either lithium or imipramine, both of which are superior to a placebo.

Schizoaffective disorders are characterized by a mixture of schizophrenic symptoms and altered affect in the form of depression or excitement. Antipsychotic drugs alone or combined with lithium are used in the excited as well as in the maintenance phases; clozapine may be particularly effective. Various antidepressants are added if depression is present, but none has been adequately studied in this condition.

While lithium alone is rarely successful in treating schizophrenia, adding it to an antipsychotic may salvage an otherwise treatment-resistant patient. Carbamazepine may work equally well when added to an antipsychotic.

An interesting application of lithium that is relatively well supported by controlled studies is as an adjunct to tricyclic antidepressants and selective serotonin reuptake inhibitors in patients with unipolar depression who do not respond fully to monotherapy with the antidepressant. For this application, concentrations of lithium at the lower end of the recommended range for manic depressive illness appear to be adequate.

Monitoring Treatment

Clinicians have relied heavily on measurements of serum concentrations for assessing both the dosage required for satisfactory treatment of acute mania and the adequacy of maintenance treatment. These measurements are customarily taken 10–12 hours after the last dose, so all data in the literature pertaining to these concentrations reflect this interval.

An initial determination of serum lithium concentration should be obtained about 5 days after the start of treatment, at which time steady-state conditions should have been attained for the dosage chosen. If the clinical response suggests a change in dosage, simple arithmetic (new dose equals present dose times desired blood level divided by present blood level) should produce the desired level. The serum concentration attained with the adjusted dosage can be checked in another 5 days. Once the desired concentration has been achieved, levels can be measured at increasing intervals unless the schedule is influenced by intercurrent illness or the introduction of a new drug into the treatment program.

Maintenance Treatment

The decision to use lithium as *prophylactic* treatment depends on many factors: the frequency and severity of previous episodes, a crescendo pattern of appearance, and the degree to which the patient is willing to follow a program of indefinite maintenance therapy. If the present attack was the patient's first or if the patient is unreliable, one might prefer to terminate treatment after the attack has subsided. Patients who have one or more episodes of illness per year are candidates for maintenance treatment. While some patients can be maintained with serum levels as low as 0.6 meq/L, the best results in groups of patients have been obtained with higher levels, such as 0.9

meq/L.

Drug Interactions

Renal clearance of lithium is reduced about 25% by diuretics (eg, thiazides), and doses may need to be reduced by a similar amount. A similar reduction in lithium clearance has been noted with several of the newer nonsteroidal anti-inflammatory drugs that block synthesis of prostaglandins. This interaction has not been reported for either aspirin or acetaminophen. All neuroleptics tested to date, with the possible exception of clozapine and the newer antipsychotics, may produce more severe extrapyramidal syndromes when combined with lithium.

Adverse Effects & Complications

Many adverse effects associated with lithium treatment occur at varying times after treatment is started. Some are harmless, but it is important to be alert to adverse effects that may signify impending serious toxic reactions.

Neurologic and Psychiatric Adverse Effects

Tremor is one of the most frequent adverse effects of lithium treatment, occurring at therapeutic dosage levels. Propranolol and atenolol, which have been reported to be effective in essential tremor, also alleviate lithium-induced tremor. Other reported neurologic abnormalities include choreoathetosis, motor hyperactivity, ataxia, dysarthria, and aphasia. Psychiatric disturbances at toxic concentrations are generally marked by mental confusion and withdrawal or bizarre motor movements. Appearance of any new neurologic or psychiatric symptoms or signs is a clear indication for temporarily stopping treatment with lithium and close monitoring of serum levels.

Effects on Thyroid Function

Lithium probably decreases thyroid function in most patients exposed to the drug, but the effect is reversible or nonprogressive. Few patients develop frank thyroid enlargement, and fewer still show symptoms of hypothyroidism. Although initial thyroid testing followed by regular monitoring of thyroid function has been proposed, such procedures are not cost-effective. Obtaining a serum TSH concentration every 6–12 months, however, is prudent.

Renal Adverse Effects

Polydipsia and polyuria are frequent but reversible concomitants of lithium treatment, occurring at therapeutic serum concentrations. The principal physiologic lesion involved is loss of the ability of the collecting tubule to conserve water under the influence of antidiuretic hormone, resulting in excessive free water clearance (**nephrogenic diabetes insipidus**). Lithium-induced diabetes insipidus is resistant to vasopressin but responds to amiloride.

An extensive literature has accumulated concerning other forms of renal dysfunction during long-term lithium therapy, including **chronic interstitial nephritis** and **minimal change glomerulopathy** with nephrotic syndrome. Some instances of decreased glomerular filtration rate have been encountered but no instances of marked azotemia or renal failure.

Patients receiving lithium should avoid dehydration and the associated increased concentration of lithium in urine. Periodic tests of renal concentrating ability should be performed to detect changes.

Edema

Edema is a frequent adverse effect of lithium treatment and may be related to some effect of lithium on sodium retention. Although weight gain may be expected in patients who become edematous, water retention does not account for the weight gain observed in up to 30% of patients taking lithium.

Cardiac Adverse Effects

The bradycardia-tachycardia ("sick sinus") syndrome is a definite contraindication to the use of lithium because the ion further depresses the sinus node. T wave flattening is often observed on the ECG but is of questionable significance.

Use during Pregnancy

Renal clearance of lithium increases during pregnancy and reverts to lower levels immediately after delivery. A patient whose serum lithium concentration is in a good therapeutic range during pregnancy may develop toxic levels following delivery. Special care in monitoring lithium levels is needed at these times. Lithium is transferred to nursing infants through breast milk, in which it has a concentration about one-third to one-half that of serum. Lithium toxicity in newborns is manifested by lethargy, cyanosis, poor suck and Moro reflexes, and perhaps hepatomegaly.

The issue of dysmorphogenesis is not settled. An earlier report suggested an increase in the frequency of cardiac anomalies, especially Ebstein's anomaly, in lithium babies, but the most recent data suggest that lithium carries a relatively low risk of teratogenic effects.

Miscellaneous Adverse Effects

Transient acneiform eruptions have been noted early in lithium treatment. Some of them subside with temporary discontinuance of treatment and do not recur with its resumption. Folliculitis is less dramatic and probably occurs more frequently. Leukocytosis is always present during lithium treatment, probably reflecting a direct effect on leukopoiesis rather than mobilization from the marginal pool. This "adverse effect" has now become a therapeutic effect in patients with low leukocyte counts.

Overdoses

Therapeutic overdoses are more common than those due to deliberate or accidental ingestion of the drug. Therapeutic overdoses are usually due to accumulation of lithium resulting from some change in the patient's status, such as diminished serum sodium, use of diuretics, or fluctuating renal function. Since the tissues will have already equilibrated with the blood, the plasma concentrations of lithium may not be excessively high in proportion to the degree of toxicity; any value over 2 meq/L must be considered as indicating likely toxicity. As lithium is a small ion, it is dialyzed readily. Both peritoneal dialysis and hemodialysis are effective, though the latter is preferred. Dialysis should be continued until the plasma concentration falls below the usual therapeutic range.

Valproic Acid

Valproic acid (valproate), discussed in detail elsewhere as an antiepileptic (see Chapter 24: Antiseizure Drugs), has been demonstrated to have antimanic effects and is now being widely used for this indication in the USA. Overall, it shows efficacy equivalent to that of lithium during the

early weeks of treatment. Importantly, valproic acid has been effective in some patients who have failed to respond to lithium. Moreover, its side effect profile is such that one can rapidly increase the dose over a few days to produce blood levels in the apparent therapeutic range, with nausea being the only limiting factor in some patients. The starting dose is 750 mg/d, increasing rapidly to the 1500–2000 mg range with a recommended maximum dose of 60 mg/kg/d.

Combinations of valproic acid with other psychotropic medications likely to be used in the management of either phase of bipolar illness are generally well tolerated. Valproic acid is becoming recognized as an appropriate first-line treatment for mania, though it is not clear that it will be as effective as lithium as a maintenance treatment in all subsets of patients. Many clinicians argue for combining valproic acid and lithium in patients who do not fully respond to either agent alone.

Carbamazepine

Carbamazepine has been considered to be a reasonable alternative to lithium when the latter is less than optimally efficacious. It may be used to treat acute mania and also for prophylactic therapy. Adverse effects (discussed in Chapter 24: Antiseizure Drugs) are generally no greater and sometimes are less than those associated with lithium. Carbamazepine may be used alone or, in refractory patients, in combination with lithium or, rarely, valproate. The mode of action of carbamazepine is unclear, but it may reduce the sensitization of the brain to repeated episodes of mood swing. Such a mechanism might be similar to its anticonvulsant effect.

The use of carbamazepine as a mood stabilizer is similar to its use as an anticonvulsant (see Chapter 24: Antiseizure Drugs). Dosage usually begins with 200 mg twice daily, with increases as needed. Maintenance dosage is similar to that used for treating epilepsy, ie, 800–1200 mg/d. Plasma concentrations between 3 and 14 mg/L are considered desirable, though no therapeutic range has been established. Although blood dyscrasias have figured prominently in the adverse effects of carbamazepine when it is used as an anticonvulsant, they have not been a major problem with its use as a mood stabilizer. Overdoses of the drug are a major emergency and should be managed in general like overdoses of tricyclic antidepressants.

Katzung PHARMACOLOGY, 9e > Section V. Drugs That Act in the Central Nervous System > Chapter 29. Antipsychotic Agents & Lithium >

Preparations Available

Antipsychotic Agents

Aripiprazole (Abilify)

Oral: 10, 15, 20, 30 mg tablets

Chlorpromazine (generic, Thorazine, others)

Oral: 10, 25, 50, 100, 200 mg tablets; 10 mg/5 mL syrup; 30, 100 mg/mL concentrate

Oral sustained-release: 30, 75, 150 mg capsules

Rectal: 25, 100 mg suppositories

Parenteral: 25 mg/mL for IM injection

Clozapine (generic, Clozaril)

Oral: 25, 100 mg tablets

Fluphenazine (generic, Permitil, Prolixin)

Oral: 1, 2.5, 5, 10 mg tablets; 2.5 mg/5 mL elixir; 5 mg/mL concentrate

Parenteral: 2.5 mg/mL for IM injection

Fluphenazine esters (generic [decanoate only], Prolixin Enanthate, Prolixin Decanoate)

Parenteral: 25 mg/mL

Haloperidol (generic, Haldol)

Oral: 0.5, 1, 2, 5, 10, 20 mg tablets; 2 mg/mL concentrate

Parenteral: 5 mg/mL for IM injection

Haloperidol ester (Haldol Decanoate)

Parenteral: 50, 100 mg/mL for IM injection

Loxapine (Loxitane)

Oral: 5, 10, 25, 50 mg capsules; 25 mg/mL concentrate

Parenteral: 50 mg/mL for IM injection

Mesoridazine (Serentil)

Oral: 10, 25, 50, 100 mg tablets; 25 mg/mL concentrate

Parenteral: 25 mg/mL for IM injection

Molindone (Moban)

Oral: 5, 10, 25, 50, 100 mg tablets; 20 mg/mL concentrate

Olanzapine (Zyprexa)

Oral: 2.5, 5, 7.5, 10, 15, 20 mg tablets; 5, 10, 15, 20 mg orally disintegrating tablets.

Perphenazine (generic, Trilafon)

Oral: 2, 4, 8, 16 mg tablets; 16 mg/5 mL concentrate

Parenteral: 5 mg/mL for IM or IV injection

Pimozide (Orap)

Oral: 1, 2 mg tablets

Prochlorperazine (generic, Compazine)

Oral: 5, 10, mg tablets; 5 mg/5 mL syrup

Oral sustained-release: 10, 15 mg capsules

Rectal: 2.5, 5, 25 mg suppositories

Parenteral: 5 mg/mL for IM injection

Promazine (generic, Sparine)

Oral: 25, 50 mg tablets

Parenteral: 25, 50 mg/mL for IM injection

Quetiapine (Seroquel)

Oral: 25, 100, 200, 300 mg tablets

Risperidone (Risperdal)

Oral: 0.25, 0.5, 1, 2, 3, 4 mg tablets; 1 mg/mL oral solution

Thioridazine (generic, Mellaril, others)

Oral: 10, 15, 25, 50, 100, 150, 200 mg tablets; 30, 100 mg/mL concentrate; 25, 100 mg/5 mL suspension

Thiothixene (generic, Navane)

Oral: 1, 2, 5, 10, 20 mg capsules; 5 mg/mL concentrate

Trifluoperazine (generic, Stelazine)

Oral: 1, 2, 5, 10 mg tablets; 10 mg/mL concentrate

Parenteral: 2 mg/mL for IM injection

Triflupromazine (Vesprin)

Parenteral: 10, 20 mg/mL for IM injection

Ziprasidone (Geodon)

Oral: 20, 40, 60, 80 mg capsules

Parenteral: 20 mg/mL for IM injection

Mood Stabilizers

Carbamazepine (generic, Tegretol, others)

Oral: 200 mg tablets, 100 mg chewable tablets; 100 mg/5 mL oral suspension.

Oral extended-release: 100, 200, 400 mg tablets; 200, 300 mg capsules

Divalproex (Depakote)

Oral: 125, 250, 500 mg delayed-release tablets

Lithium carbonate (generic, Eskalith) (Note: 300 mg lithium carbonate = 8.12 meq Li⁺.)

Oral: 150, 300, 600 mg capsules; 300 mg tablets; 8 meq/5 mL syrup

Oral sustained-release: 300, 450 mg tablets

Valproic acid (generic, Depakene)

Oral: 250 mg capsules; 250 mg/5 mL syrup

Chapter 30. Antidepressant Agents

Katzung PHARMACOLOGY, 9e > Section V. Drugs That Act in the Central Nervous System > Chapter 30. Antidepressant Agents >

Antidepressant Agents: Introduction

Major depression is one of the most common psychiatric disorders. At any given moment, about 5–6% of the population is depressed (point prevalence), and an estimated 10% of people may become depressed during their lives (lifetime prevalence). The symptoms of depression are often subtle and unrecognized both by patients and by physicians. Patients with vague complaints that resist explanation as manifestations of somatic disorders and those who might be simplistically described as "neurotic" should be suspected of being depressed.

Depression is a heterogeneous disorder that has been characterized and classified in a variety of ways. According to the American Psychiatric Association's fourth edition (1994) of the *Diagnostic and Statistical Manual of Mental Disorders (DSM-IV)*, several diagnoses of affective disorders are possible. Major depression and dysthymia (minor) are pure depressive syndromes, whereas bipolar disorder and cyclothymic disorder signify depression in association with mania. A simplified classification based on presumed origin is as follows: (1) "reactive" or "secondary" depression (most common), occurring in response to real stimuli such as grief, illness, etc; (2) "endogenous" depression, a genetically determined biochemical disorder manifested by inability to experience ordinary pleasure or to cope with ordinary life events; and (3) depression associated with bipolar affective (manic-depressive) disorder. Drugs discussed in this chapter are used chiefly in

management of the second type. Table 30–1 indicates how the three types may be differentiated.

Table 30–1. Differentiation of Types of Depression.		
Type	Diagnostic Features	Comments
Reactive	Loss (adverse life events). Physical illness (myocardial infarct, cancer). Drugs (antihypertensives, alcohol, hormones). Other psychiatric disorders (senility).	More than 60% of all depressions. Core depressive syndrome: depression, anxiety, bodily complaints, tension, guilt. May respond spontaneously or to a variety of ministrations.
Major depressive (endogenous)	Precipitating life event not adequate for degree of depression. Autonomous (unresponsive to changes in life). May occur at any age (childhood to old age). Biologically determined (family history).	About 25% of all depressions. Core depressive syndrome plus "vital" signs: abnormal rhythms of sleep, motor activity, libido, appetite. Usually responds specifically to antidepressants or electroconvulsive therapy. Tends to recur throughout life.
Bipolar affective (manic-depressive)	Characterized by episodes of mania. Cyclic; mania alone, rare; depression alone, occasional; mania-depression, usual.	About 10–15% of all depressions. May be misdiagnosed as endogenous if hypomanic episodes are missed. Lithium carbonate stabilizes mood. Mania may require antipsychotic drugs as well; depression managed with antidepressants.

An intensive effort to formalize guidelines for the treatment of depression is provided by the cross-disciplinary publication of the Depression Guideline Panel (1993) and its update on newer pharmacotherapies (Mulrow et al, 1999). Pharmacologic treatment is emphasized, though a continuing role for electroconvulsive therapy for delusional or severe forms of life-threatening depression is noted. Despite intensive research, the mechanisms of action of various pharmacologic treatments are still not understood, though most are believed to involve effects on two monoamine neurotransmitters: serotonin and norepinephrine.

The Pathogenesis of Major Depression: The Amine Hypothesis

Soon after the introduction of reserpine in the early 1950s, it became apparent that the drug could induce depression in patients being treated for hypertension and schizophrenia as well as in normal subjects. Within the next few years, pharmacologic studies revealed that the principal mechanism of action of reserpine was to inhibit the storage of amine neurotransmitters such as serotonin and norepinephrine in the vesicles of presynaptic nerve endings. Reserpine induced depression and depleted stores of amine neurotransmitters; therefore, it was reasoned, depression must be associated with decreased functional amine-dependent synaptic transmission. This idea provided the basis for what became known as the amine hypothesis of depression. A major puzzle in applying this hypothesis was the fact that although the pharmacologic actions of both tricyclic and MAO inhibitor classes of antidepressants are prompt, the clinical effects require weeks to become manifest. Attempts have been made to explain this observation by invoking slow compensatory responses to the initial blockade of amine reuptake or MAO inhibition (see below).

While the amine hypothesis is undoubtedly too simplistic, it has provided the major experimental models for the discovery of new antidepressant drugs. As a result, all the currently available antidepressant drugs—except bupropion—are classified as having their primary actions on the metabolism, reuptake, or selective receptor antagonism of serotonin, norepinephrine, or both.

Katzung PHARMACOLOGY, 9e > Section V. Drugs That Act in the Central Nervous System > Chapter 30. Antidepressant Agents >

Basic Pharmacology of Antidepressants

Chemistry

A variety of different chemical structures have been found to have antidepressant activity. With the possible exception of bupropion, however, the core antidepressant action of even the newest agents derives from mechanisms engaged by antidepressants introduced 4 decades ago.

Tricyclic Antidepressants (TCAs)

Tricyclic antidepressants—so called because of the characteristic three-ring nucleus—have been used clinically for four decades (Figure 30–1). They closely resemble the phenothiazines chemically and, to a lesser extent, pharmacologically. Like the latter drugs, they were first thought to be useful as antihistamines with sedative properties and later as antipsychotics. The discovery of their antidepressant properties was a fortuitous clinical observation. **Imipramine** and **amitriptyline** are the prototypical drugs of the class as mixed norepinephrine and serotonin uptake inhibitors though they also have several other properties.

Figure 30–1.

Heterocyclics; Second- and Third-Generation Drugs

Between 1980 and 1996, a number of heterocyclic agents denoted as second-generation and third-generation or heterocyclic antidepressants were introduced. Four of the agents classified as "second-generation" are available for clinical use in the USA and are shown in Figure 30–2. **Amoxapine** and **maprotiline** resemble the structure of the tricyclic agents, while **trazodone** and **bupropion** are distinctive. The heterocyclic agents are not notably different from the older agents in potency. Since 1990, **venlafaxine**, a chemically unique third-generation agent; **mirtazapine**, an analog of a widely used European antidepressant; and **nefazodone**, developed on the basis of trazodone, have been introduced. The structures of these compounds are shown in Figure 30–3.

Figure 30–2.

Figure 30-3.

Selective Serotonin Reuptake Inhibitors (SSRIs)

Among the major drawbacks of most first-generation antidepressants have been their many "irrelevant" pharmacologic actions, a trait inherited from the phenothiazine antipsychotic agents. As far as has been determined, the antimuscarinic, antihistaminic, and α -adrenoceptor-blocking actions of tricyclic antidepressants contribute only to the toxicity of these agents. Since the introduction of **fluoxetine**—an effective and more selective antidepressant with minimal autonomic toxicity—four more selective serotonin reuptake inhibitors have been introduced as well as the active enantiomeric form of one, (*S*)-citalopram. All are structurally distinct from the tricyclic molecules (Figure 30–4).

Figure 30–4.

Monoamine Oxidase (MAO) Inhibitors

MAO inhibitors may be classified as hydrazides, exemplified by the C–N–N moiety, as is the case

with **phenelzine** and **isocarboxazid** (no longer marketed); or nonhydrazides, which lack such a moiety, as with **tranylcypromine** (Figure 30–5). Tranylcypromine closely resembles dextroamphetamine, which is itself a weak inhibitor of MAO. Tranylcypromine retains some of the sympathomimetic characteristics of the amphetamines. The hydrazides appear to combine irreversibly with the enzyme, while tranylcypromine has a prolonged duration of effect even though it is not bound irreversibly. These older MAO inhibitors are nonselective inhibitors of both MAO-A and MAO-B.

Figure 30–5.

Phenelzine

Tranylcypromine

Some monoamine oxidase inhibitors. Phenelzine is the hydrazide of phenylethylamine (Figure 9–3), while tranylcypromine has a cyclopropyl amine side chain and closely resembles dextroamphetamine (see Figure 9–4). These agents are unselective and produce an extremely long-lasting inhibition of the enzyme.

Pharmacokinetics

Tricyclics

Most tricyclics are incompletely absorbed and undergo significant first-pass metabolism. As a result of high protein binding and relatively high lipid solubility, volumes of distribution tend to be very large. Tricyclics are metabolized by two major routes: transformation of the tricyclic nucleus and alteration of the aliphatic side chain. Monodemethylation of tertiary amines leads to active metabolites such as desipramine and nortriptyline (which are themselves available as drugs; Figure 30–1). The pharmacokinetic parameters of various antidepressants are summarized in Table 30–2.

Table 30–2. Pharmacokinetic Parameters of Various Antidepressants.^{1,2}

Drug	Bioavailability (percent)	Protein Binding (percent)	Plasma $t_{1/2}$ (hours)	Active Metabolites	Volume of Distribution (L/kg)	Therapeutic Plasma Concentrations (ng/mL)
Amitriptyline	31–61	82–96	31–46	Nortriptyline	5–10	80–200 total

Amoxapine	nd	nd	8	7-,8-Hydroxy	nd	nd
Bupropion	60–80	85	14–37	Hydroxy, threohydro, erythrohydro	20–30	25–100
Citalopram	51–93	70–80	23–75	Desmethyl	12–16	nd
Clomipramine	nd	nd	22–84	Desmethyl	7–20	240–700
Desipramine	60–70	73–90	14–62	Hydroxy	22–59	> 125
Doxepin	13–45	nd	8–24	Desmethyl	9–33	30–150
Escitalopram	80	56	27–59	5-Desmethyl	12	nd
Fluoxetine	70	94	24–96	Norfluoxetine	12–97	nd
Fluvoxamine	> 90	77	7–63	None	> 5	nd
Imipramine	29–77	76–95	9–24	Desipramine	15–30	> 180 total
Maprotiline	66–75	88	21–52	Desmethyl	15–28	200–300
Mirtazapine	nd	nd	20–40	Desmethyl	nd	nd
Nefazodone	15–23	98	2–4	Hydroxy, <i>m</i> -chlorophenyl piperazine	nd	nd
Nortriptyline	32–79	93–95	18–93	10-Hydroxy	21–57	50–150

Venlafaxine	nd	27–30	4–10	<i>O</i> -Desmethyl	nd	nd

¹Range includes active metabolites.

²nd = no data found.

Heterocyclics

The pharmacokinetics of these drugs are similar to those of the tricyclics (Table 30–2). Some may have active metabolites. Trazodone and venlafaxine have short plasma half-lives, which mandates divided doses during the day when beginning treatment, though once-a-day dosing may be possible later. Extended-release forms of bupropion and venlafaxine allow for once-a-day dosing in some patients from the outset.

Selective Serotonin Reuptake Inhibitors (SSRIs)

The pharmacokinetic parameters of these drugs are summarized in Table 30–2. Fluoxetine is notable for the long half-life of its active metabolite, norfluoxetine (7–9 days at steady state). This long $t_{1/2}$ has allowed for the introduction of a formulation for once-weekly dosing. Fluoxetine

inhibits various drug-metabolizing enzymes, which has led to a number of significant drug-drug interactions with other antidepressants and with other drugs as well. Sertraline and paroxetine have pharmacokinetic parameters similar to those of tricyclics. Citalopram and fluvoxamine resemble fluoxetine.

MAO Inhibitors

The monoamine oxidase inhibitors (MAOIs) are readily absorbed from the gastrointestinal tract. The hydrazide inhibitor phenelzine is acetylated in the liver and manifests differences in elimination depending on the acetylation phenotype of the individual (see Chapter 4: Drug Biotransformation). However, inhibition of MAO persists even after these drugs are no longer detectable in plasma. Therefore, conventional pharmacokinetic parameters (half-life, etc) are not very helpful in governing dosage. It is prudent to assume that the drug effect will persist for from 7 days (tranylcypromine) to 2 or 3 weeks (phenelzine) after discontinuance of the drug.

Pharmacodynamics

Action of Antidepressants on Biogenic Amine Neurotransmitters

The amine hypothesis was buttressed by studies on the mechanism of action of various types of antidepressant drugs (Figure 30–6). Tricyclics block the amine (norepinephrine or serotonin) reuptake pumps, which terminate amine neurotransmission (see Table 30–3 and Chapter 6: Introduction to Autonomic Pharmacology). Such an action presumably permits a longer sojourn of neurotransmitter at the receptor site. MAO inhibitors block a major degradative pathway for the amine neurotransmitters, which permits more amines to accumulate in presynaptic stores and more to be released. Some of the second-generation antidepressants have similar effects on amine neurotransmitters, while others have mild or minimal effects on reuptake or metabolism. In contrast, trazodone, nefazodone, and mirtazapine stand out as agents in which antagonism of subtypes of serotonin receptors (5-HT_{2A} or 5-HT_{2C}) may be important in their action. Mirtazapine is unique in including antagonism of α_2 norepinephrine receptors as presumably contributing to its therapeutic effects. Bupropion has been found to alter the output of norepinephrine in humans following chronic administration through some as yet unidentified primary mechanism as well as occupying about 25% of dopamine uptake pumps in the brain as revealed by positron emission tomography. Since it has been shown that effective doses of SSRIs occupy 80% of serotonin uptake sites, the clinical relevance of 25% dopamine uptake occupancy is uncertain. Thus, even the newest antidepressants can still be categorized as working through serotonergic and noradrenergic effects with the possibility of a role for dopamine. A potential dopaminergic mechanism has often been invoked as relevant to the efficacy of MAOIs.

Figure 30–6.

Schematic diagram showing some of the potential sites of action of antidepressant drugs. Chronic therapy with these drugs has been proved to reduce reuptake of norepinephrine or serotonin (or both), reduce the number of postsynaptic β receptors, and reduce the generation of cAMP. The MAO inhibitors act on MAO in the nerve terminals and cause the same effects on β receptors and cAMP generation.

Receptor and Postreceptor Effects

Considerable attention has been paid to the ultimate postsynaptic effects of increased neurotransmitters in the synapses. In tests of postsynaptic effects, cAMP concentrations have consistently *decreased* rather than increased, in spite of the presumably longer duration of action of the transmitters. In addition, the number of postsynaptic β -adrenoceptors has shown a measurable decrease that follows the same delayed time course as clinical improvement in patients. Thus, the initial increase in neurotransmitter seen with some antidepressants appears to produce, over time, a compensatory decrease in receptor activity, i.e., down-regulation of receptors. Decreases in norepinephrine-stimulated cAMP and in β -adrenoceptor binding have been conclusively shown for selective norepinephrine uptake inhibitors, those with mixed action on norepinephrine and serotonin, monoamine oxidase inhibitors, and even electroconvulsive therapy. Such changes do not consistently occur after the selective serotonin uptake inhibitors, α_2 receptor antagonists, and mixed serotonin antagonists.

It has also been emphasized that enhanced serotonergic transmission, albeit mediated through diverse mechanisms, might be a common (but not universal) long-term effect of antidepressants. This could occur, for instance, without increasing the concentration of neurotransmitter at the receptor site if there were an increase in serotonin receptor sensitivity. Thus, chronic treatment with tricyclic agents or electroconvulsive shock increases the electrophysiologic response to microiontophoretically applied serotonin in various areas of the rat brain. And selective receptor antagonism of either norepinephrine or serotonin receptors may lead to enhanced extracellular serotonin due to the complex manner in which these neurotransmitters are interregulated. One current hypothesis holds that enhanced stimulation or responsiveness of postsynaptic 5-HT_{1A} receptors is particularly important in the action of antidepressants.

Most recently, long-term intracellular changes involving phosphorylation of various regulatory elements, including those within the nucleus, have been implicated as relevant to antidepressant action. It is possible that effects on certain neurotrophic factors—factors critical to sustained survival and function of neurons in the adult nervous system—may be central to the actions of antidepressants.

No clinical studies have directly tested the relevance of these findings from animals for norepinephrine and serotonin function in humans and their relationship to the mode of action of antidepressants. One of the most interesting approaches has been to reduce the amino acid precursor of serotonin, tryptophan, in the diet and, by implication, the amount of available neurotransmitter in the brain, since tryptophan availability can be rate-limiting in the formation of serotonin under certain experimental conditions. Using this approach, it was found that a tryptophan-depleted diet produces low plasma tryptophan and acutely reverses antidepressant responses to SSRIs but not to selective or mixed norepinephrine uptake inhibitors. Similarly, depletion of the norepinephrine amino acid precursor tyrosine can reverse antidepressant effects of the relatively selective norepinephrine reuptake inhibitor, desipramine. These findings indirectly support the hypothesis that enhanced serotonin throughput is necessary for the antidepressant action of serotonin but not norepinephrine uptake inhibitors. The same appears to be true of norepinephrine throughput and norepinephrine reuptake inhibitors. However, tryptophan depletion does not consistently worsen the condition of unmedicated depressed patients. Thus, there is no clear relationship between serotonin and depression or antidepressant mechanisms in general.

Effects of Specific Antidepressants

Tricyclics

The first-generation antidepressants demonstrate varying degrees of selectivity for the reuptake pumps for norepinephrine and serotonin (Table 30–3). They also have numerous autonomic actions, as described below under Adverse Effects.

Table 30–3. Pharmacologic Differences among Several Antidepressants.¹

Drug	Sedative Action	Antimuscarinic Action	Block of Amine Pump for:		
			Serotonin	Norepinephrine	Dopamine
Amitriptyline	+++	+++	+++	++	0
Amoxapine	++	++	+	++	+
Bupropion	0	0	+, 0	+, 0	+
Citalopram, escitalopram	0	0	+++	0	0
Clomipramine	+++	++	+++	+++	0
Desipramine	+	+	0	+++	0
Doxepin	+++	+++	++	+	0
Fluoxetine	+	+	+++	0, +	0, +

Venlafaxine	0	0	+++	++	0, +

¹0 = none; + = slight; ++ = moderate; +++ = high; ? = uncertain.

²Significant α_2 -adrenoceptor antagonism.

Second-Generation Agents

Amoxapine is a metabolite of the antipsychotic drug loxapine and retains some of its antipsychotic action and dopamine receptor antagonism. A combination of antidepressant and antipsychotic actions might make it a suitable drug for depression in psychotic patients. However, the dopamine antagonism may cause akathisia, parkinsonism, amenorrhea-galactorrhea syndrome, and perhaps tardive dyskinesia.

Maprotiline (a tetracyclic drug) is most like desipramine in terms of its potent norepinephrine uptake inhibition. Like the latter drug, it has fewer sedative and antimuscarinic actions than the older tricyclics.

Clinical experience with trazodone has indicated unpredictable efficacy for depression though it has proved very useful as a hypnotic, sometimes being combined with MAOIs, which disturb sleep.

Third-Generation Agents

Three antidepressants—nefazodone, venlafaxine, and mirtazapine—are all related to earlier agents in either structure or mechanism of action. Nefazodone is closely related to trazodone but is less sedating. It produces fewer adverse sexual effects than the SSRIs but is a potent inhibitor of CYP3A4. (Fluvoxamine causes the same inhibition of CYP3A4.)

Venlafaxine is a potent inhibitor of serotonin reuptake and a weaker inhibitor of norepinephrine transport such that at lower therapeutic doses it behaves like an SSRI. At high doses (more than 225 mg/d) it produces mild to moderate increases of heart rate and blood pressure attributable to norepinephrine reuptake inhibition. Doses in the range of 300 mg/d or greater may confer broader therapeutic effects than SSRIs, but a careful titration up to these doses is needed to control adverse effects.

Mirtazapine, a drug derived from mianserin—an antidepressant available outside the USA—is a

potent antihistaminic with greater sedating effects than the other second- and third-generation antidepressants. Its use is also more likely to be associated with weight gain. The hypothesized mechanism of action of mirtazapine combines 5-HT₂ receptor and α -adrenoceptor antagonism and, if established in humans, would be unique among available drugs. Thus, mirtazapine may prove beneficial in patients who can tolerate its sedative effects and do not respond well to SSRIs or cannot tolerate the sexual or other adverse effects of the other antidepressants.

Selective Serotonin Reuptake Inhibitors

Fluoxetine was the first SSRI to reach general clinical use. Paroxetine and sertraline differ mainly in having shorter half-lives and different potencies as inhibitors of specific P450 isoenzymes. While the SSRIs have not been shown to be more effective overall than prior drugs, they lack many of the toxicities of the tricyclic and heterocyclic antidepressants. Thus, patient acceptance has been high despite adverse effects such as nausea, decreased libido, and even decreased sexual function.

A dangerous pharmacodynamic interaction may occur when fluoxetine or one of the newer selective serotonin reuptake inhibitors is used in the presence of a monoamine oxidase inhibitor. The combination of increased stores of the monoamine plus inhibition of reuptake after release is thought to result in marked increases of serotonin in the synapses, leading to a **serotonin syndrome**. This sometimes fatal syndrome includes hyperthermia, muscle rigidity, myoclonus, and rapid changes in mental status and vital signs.

MAO Inhibitors

MAO-A (isoform A) is the amine oxidase primarily responsible for norepinephrine, serotonin, and tyramine metabolism. MAO-B is more selective for dopamine. The irreversible inhibitors available in the USA are nonselective and block both forms of the enzyme. Irreversible block of MAO, characteristic of the older MAO inhibitors, allows significant accumulation of tyramine and loss of the first-pass metabolism that protects against tyramine in foods. As a result, the irreversible MAO inhibitors are subject to a very high risk of hypertensive reactions to tyramine ingested in food. From the evidence available to date, the reversible, short-acting MAO inhibitor moclobemide, which is available in several countries (but not the USA), appears to be relatively free of this interaction. (The selective MAO-B inhibitor selegiline loses selectivity at antidepressant dosage. Because its action is on the enzyme that metabolizes dopamine, it is most useful in the treatment of Parkinson's disease [Chapter 28: Pharmacologic Management of Parkinsonism & Other Movement Disorders].)

Katzung PHARMACOLOGY, 9e > Section V. Drugs That Act in the Central Nervous System > Chapter 30. Antidepressant Agents >

Clinical Pharmacology of Antidepressants

Clinical Indications

The major indication for these drugs is to treat depression, but a number of other uses have been established by clinical experience and controlled trials.

Depression

This indication has been kept broad deliberately, even though evidence from clinical studies strongly suggests that the drugs are specifically useful only in major depressive episodes. Major

depressive episodes are diagnosed not so much by their severity as by their quality. Formerly, they were referred to as "endogenous," "vital," or "vegetative"—reflecting the characteristic disturbances of major body rhythms of sleep, hunger and appetite, sexual drive, and motor activity. The diagnosis of major depression may be uncertain in individual patients, so that on balance this condition is underdiagnosed and undertreated. The depressed phase of bipolar illness definitely requires pharmacologic treatment given the high rate of suicide in persons with this disorder. Standard antidepressants are usually added to lithium or another antimanic agent; SSRIs are less likely to induce mania than the older tricyclic agents. There are, however, few controlled studies on their relative efficacy or proper duration of use. Recent controlled studies provide evidence that the anticonvulsant lamotrigine may have special promise in bipolar depression.

Panic Disorder

Imipramine was first shown in 1962 to have a beneficial effect in the acute episodes of anxiety that have come to be known as panic attacks. Recent studies have shown it to be as effective as MAO inhibitors and benzodiazepines. It has also been demonstrated that SSRIs are effective in panic disorder. In some instances, benzodiazepines are preferred, as they are well tolerated and their clinical effects become evident promptly. Alternatively, if one wishes to avoid the physiologic dependence associated with chronic benzodiazepine use, SSRIs are acceptable for many patients though they require several weeks to produce full therapeutic effects.

Obsessive-Compulsive Disorders

The serotonin reuptake inhibitors have been shown to be uniquely effective for treating these disorders. Recent studies have focused on fluoxetine and other selective serotonin reuptake-inhibiting drugs, although clomipramine, a mixed serotonin and norepinephrine uptake inhibitor, may be more potent. Fluvoxamine is marketed exclusively for this disorder in the United States.

Enuresis

Enuresis is an established indication for tricyclics. Proof of efficacy for this indication is substantial, but drug therapy is not the preferred approach. The beneficial effect of drug treatment lasts only as long as drug treatment is continued. Institutionalized elderly patients with incontinence are often treated with imipramine. Unfortunately, this age group is also the most sensitive to the anticholinergic hallucinogenic effects of the drug.

Chronic Pain

Clinicians in pain clinics have found tricyclics to be especially useful for treating a variety of chronically painful states that often cannot be definitively diagnosed. Whether such painful states represent depressive equivalents or whether such patients become secondarily depressed after some initial pain-producing insult is not clear. It is even possible that the tricyclics work directly on pain pathways.

Controlled studies of higher doses of venlafaxine, which inhibit both norepinephrine and serotonin uptake, show efficacy in pain. **Duloxetine**, a mixed uptake inhibitor soon to be marketed, has similar effects. SSRIs, however, are not effective for chronic pain.

Other Indications

Certain antidepressants have been shown to be effective for eating disorders, especially bulimia

(fluoxetine), and attention deficit hyperkinetic disorder (imipramine, desipramine). **Atomoxetine** was recently introduced for the treatment of attention deficit hyperactivity disorder (ADHD). This selective inhibitor of norepinephrine reuptake was shown to be as effective as a standard drug in this condition (methylphenidate; see Chapter 9: Adrenoceptor-Activating & Other Sympathomimetic Drugs) and possibly better tolerated. This drug should not be used concurrently with MAO inhibitors.

SSRIs show efficacy in social phobia, and combined serotonin and norepinephrine uptake inhibitors are effective in generalized anxiety disorder.

Drug Choice

Controlled comparisons of the available antidepressants have usually led to the conclusion that they are roughly equivalent drugs. Although this may be true for groups of patients, individual patients may for uncertain reasons fare better on one drug than on another. European studies show that patients depressed enough to be hospitalized respond better to classic tricyclics than to monotherapy with SSRIs. Meta-analyses of outpatient studies also show greater efficacy of tricyclics than SSRIs in patients who complete trials. The greater tolerability of the SSRIs, however, makes them the preferred agent for most patients. At high doses (> 225 mg), venlafaxine also shows greater efficacy than the SSRIs. Thus, finding the right drug and the right dose for the individual patient must be accomplished empirically. The past history of the patient's drug experience is the most valuable guide. At times such a history may lead to the exclusion of tricyclics, as in the case of patients who have responded well in the past to MAO inhibitors.

Tricyclics and the second- and third-generation agents differ mainly in the degree of sedation they produce (greatest with amitriptyline, doxepin, trazodone, and mirtazapine) and their antimuscarinic effects (greatest with amitriptyline and doxepin; Table 30–3). SSRIs are generally free of sedative effects and remarkably safe in overdose. Combined with the ease of once-a-day dosing, these qualities may explain why they have become the most widely prescribed antidepressants.

None of the newer antidepressants have been shown to be more effective overall than the tricyclics with which they have been compared. Solid evidence to support a claim of more rapid onset of action has been difficult to obtain. Amoxapine and maprotiline seem to have as many sedative and autonomic actions as most tricyclics; more recently introduced antidepressants such as bupropion and venlafaxine have fewer, although nefazodone and mirtazapine are very sedating. Amoxapine and maprotiline are at least as dangerous as the tricyclics when taken in overdoses; the other newer agents seem to be safer.

No special indications for particular types of depression have been found for the selective serotonin reuptake inhibitors or other newer antidepressants. The popularity of these drugs, despite their higher cost, is due principally to their greater acceptance by patients. A provocative clinical report that fluoxetine use increased suicidal or aggressive ideation was not supported by subsequent analyses of massive data bases. Suicidal thoughts are part of the depressive syndrome.

Clinical reports, prescription databases, and a few trials support the use of selective serotonin reuptake inhibitors in combination with the older tricyclics, especially desipramine; with bupropion; and, most recently, with mirtazapine in patients who do not show an adequate response to a single agent.

MAO inhibitors are helpful in patients described as having "atypical" depressions—usually patients with considerable attendant anxiety, phobic features, and hypochondriasis.

Few clinicians use lithium, an antimanic agent, as primary treatment for depression. However, some have found that lithium along with one of the other antidepressants may achieve a favorable response not obtained by the antidepressant alone. Another potential use of lithium is to prevent relapses of depression.

Dosages

The usual daily dose ranges of antidepressants are shown in Table 30–4. Doses are almost always determined empirically; the patient's acceptance of adverse effects is the usual limiting factor. Tolerance to some of the objectionable effects may develop, so that the usual pattern of treatment has been to start with small doses, increasing either to a predetermined daily dose, or to one that produces relief of depression, or to the maximum tolerated dose (except in the case of nortriptyline, which loses efficacy at plasma concentrations over 150 ng/mL).

Drug	Dose (mg)
Tricyclics	
Amitriptyline	75–200
Clomipramine	75–300
Desipramine	75–200
Doxepin	75–300
Imipramine	75–200
Nortriptyline	75–150
Protriptyline	20–40
Trimipramine	75–200
Second- and third-generation agents	
Amoxapine	150–300
Bupropion	200–400
Maprotiline	75–300
Mirtazapine	15–60
Nefazodone	200–600
Trazodone	50–600
Venlafaxine	75–225
Monoamine oxidase inhibitors	
Phenelzine	45–75
Tranlycypromine	30–60
Selective serotonin reuptake inhibitors	
Citalopram	20–60
Escitalopram	10–30

Fluoxetine	10–60
Fluvoxamine	100–300
Paroxetine	20–50
Sertraline	50–200

MAO inhibitors, bupropion, fluoxetine, sertraline, paroxetine, citalopram, and venlafaxine are customarily given early in the day when initiating treatment, as they can be somewhat stimulating and may cause insomnia if given late. After a few weeks on the drug, however, any such effects should disappear and time of day administered is rarely important. Virtually all the other antidepressants have varying degrees of sedative effects and are best given near bedtime. Autonomic adverse effects also tend to be less troublesome if the dose is given late.

Maintenance Treatment

Whether or not to undertake long-term maintenance treatment of a depressed patient depends entirely on the natural history of the disorder. If the depressive episode was the patient's first and if it responded quickly and satisfactorily to drug therapy, it is rational to gradually withdraw treatment over a period of a few weeks after treating for 6–9 months. If relapse does not occur, drug treatment can be stopped until another episode occurs, which is unpredictable but highly probable. Pooled data from randomized trials covering 6–36 months reveal more than 50% reduction in relapses or recurrences if patients are maintained on an antidepressant. Thus, a patient who has had previous episodes of depression—especially if each succeeding one was more severe and more difficult to treat—is a candidate for maintenance therapy. Maintenance therapy requires the full dosage used to obtain the initial response. The duration of treatment varies, though many patients require maintenance treatment indefinitely.

Monitoring Plasma Concentrations

Routine monitoring of plasma concentrations of antidepressants, while technically feasible for most drugs, is of uncertain value (except for nortriptyline). However, studies suggest that at least 20% of patients become noncompliant at some time or other. Thus, a "poor response" in a patient for whom an adequate dosage of drug has been prescribed may be shown by measurement of the plasma drug concentration to be due merely to failure to take the drug.

Unresponsive Patients

One third or more of patients do not respond (defined as 50% or more improvement), and over half fail to achieve or maintain full remission on any single treatment. In evaluating a patient's resistance to treatment, one should consider the five D's: diagnosis, drug, dose, duration of treatment, and different treatment.

Diagnosis might be reassessed if the patient shows little response over a period of 2–3 weeks of adequate dosage or plasma concentrations. Whether or not the patient is bipolar, lithium might be added (see Chapter 29: Antipsychotic Agents & Lithium); if psychotic, treatment might be augmented with an antipsychotic. Combination of an SSRI with desipramine or bupropion appears relatively safe and effective for some patients. Similarly, mirtazapine can be effectively combined with SSRIs. There is no good pharmacologic rationale for combining venlafaxine with SSRIs since it is itself a potent serotonin reuptake inhibitor; rather, it might be considered for combination with bupropion or mirtazapine. Some clinicians believe that several weeks or months of treatment should

be tried before giving up on a drug or combination. The morbidity of depression, however, is such that long delays in attaining relief are demoralizing.

A generally accepted strategy is to begin treatment with an SSRI in mild to moderate outpatient depression and then augment by adding a drug of a different class for more impaired patients. Otherwise, switch to a drug of different class. Most clinicians would prefer to move through various antidepressant drug classes in the search for the right drug rather than through various drugs within a class.

Dose and duration of treatment must be considered. Many treatment failures are due to inadequate dosage, which should be pushed to the limits of the patient's tolerance in refractory cases. The duration of treatment before giving up on a drug is a matter of clinical judgment.

Finally, some patients may need a completely different type of treatment, such as electroconvulsive therapy (ECT). ECT is often viewed as a treatment of last resort, but it should not be withheld from patients with this disorder who cannot be helped by drug therapy. For patients with psychotic depression, ECT may be a treatment of first choice.

Noncompliance is an important cause of lack of response to drugs. Patients should be warned also that noticeable improvement may be slow, perhaps taking 3 weeks or more. Inability to tolerate adverse effects and discouragement with treatment are two major causes for noncompliance and for failure of antidepressants to show efficacy.

Adverse Effects

Adverse effects of various antidepressants are summarized in Table 30–5. Most common unwanted effects are minor, but they may seriously affect patient compliance; the more seriously depressed the patient is, the more likely it is that unwanted effects will be tolerated. Most normal persons find that even moderate doses of many antidepressants cause disagreeable symptoms, especially the classic tertiary amine tricyclics: amitriptyline, imipramine, clomipramine, and doxepin. With the SSRIs, transient nausea is the most frequent complaint, and decreased libido and sexual dysfunction create the greatest concerns during maintenance treatment.

Tricyclics	Sedation (sleepiness, additive effects with other sedative drugs)
	Sympathomimetic (tremor, insomnia)
	Antimuscarinic (blurred vision, constipation, urinary hesitancy, confusion)
	Cardiovascular (orthostatic hypotension, conduction defects, arrhythmias)
	Psychiatric (aggravation of psychosis, withdrawal syndrome)
	Neurologic (seizures)
	Metabolic-endocrine (weight gain, sexual disturbances)
Monoamine oxidase inhibitors	Sleep disturbances, weight gain, postural hypotension, sexual disturbances (phenelzine)

Amoxapine	Similar to the tricyclics with the addition of some effects associated with the antipsychotics (Chapter 29: Antipsychotic Agents & Lithium)
Maprotiline	Similar to tricyclics; seizures are dose-related
Mirtazapine	Somnolence, increased appetite, weight gain, dizziness
Trazodone, nefazadone	Drowsiness, dizziness, insomnia, nausea, agitation
Venlafaxine	Nausea, somnolence, sweating, dizziness, sexual disturbances, hypertension, anxiety
Bupropion	Dizziness, dry mouth, sweating, tremor, aggravation of psychosis, potential for seizures at high doses
Fluoxetine and other serotonin reuptake inhibitors	Gastrointestinal symptoms, decreased libido, sexual dysfunction, anxiety (acutely), insomnia, tremor

Drug Interactions

Pharmacodynamic Interactions

Many of the pharmacodynamic interactions of antidepressants with other drugs have already been discussed. Sedative effects may be additive with other sedatives, especially alcohol. Patients taking tricyclics should be warned that use of alcohol may lead to greater than expected impairment of driving ability. MAO inhibitors, by increasing stores of catecholamines, sensitize the patient to indirectly acting sympathomimetics such as tyramine, which is found in some fermented foods and beverages, and to sympathomimetic drugs such as diethylpropion, phenylpropanolamine, or botanicals containing ephedrine. Such sensitization can result in dangerous and—rarely—fatal hypertensive reactions. The serious interaction between MAO inhibitors and selective serotonin reuptake inhibitors has been mentioned; the serotonin syndrome is potentially lethal and must be avoided.

Pharmacokinetic Interactions

The most likely pharmacokinetic interactions are between the potent inhibitors of P450 2D6, paroxetine and fluoxetine, and those drugs highly dependent on this pathway for clearance (eg, desipramine, nortriptyline, flecainide; see also Chapter 4: Drug Biotransformation). Actual instances of clinically significant interactions are extremely rare, there being only a handful of case reports after cumulative exposure of more than 50 million patients to these SSRI drugs. Inhibition of P450 3A4 could possibly occur at high concentrations of nefazodone and fluvoxamine and block the metabolism of the many substrates of this isoform.

Overdoses

Tricyclics

Tricyclics are extremely dangerous when taken in overdose quantities, and depressed patients are more likely than others to be suicidal. Prescriptions should therefore be limited to amounts less than 1.25 g, or 50 dose units of 25 mg, on a "no refill" basis. If suicide is a serious possibility, the tablets should be entrusted to a family member. The drugs must be kept away from children. Both

accidental and deliberate overdoses continue to occur and are serious medical emergencies. Major effects and management of overdosage are discussed in Chapter 59: Management of the Poisoned Patient.

Second- and Third-Generation Drugs

Overdoses of amoxapine are characterized by severe neurotoxicity, with seizures that are difficult to control. Overdoses of maprotiline also have a tendency to cause seizures as well as cardiotoxicity. Overdoses of the other heterocyclic drugs appear to create only minor problems and can usually be managed with purely supportive measures. For example, in one recorded case even 11 g of nefazodone failed to cause serious injury.

MAO Inhibitors

Intoxication with MAO inhibitors is unusual. Agitation, delirium, and neuromuscular excitability are followed by obtunded consciousness, seizures, shock, and hyperthermia. Supportive treatment is usually all that is required, though sedative phenothiazines with α -adrenoceptor-blocking action, such as chlorpromazine, may be useful.

Selective Serotonin Reuptake Inhibitors

A few deaths have occurred during overdosage of SSRIs when other drugs were also being taken. The likelihood of fatalities from SSRI overdoses is extremely low. In case of overdose, only supportive treatment can be offered, since the high volume of distribution, as with other antidepressants, rules out removal of drug by dialysis. As much as 2.6 g of sertraline has been taken with survival. Overdoses of paroxetine are relatively benign: Up to 850 mg has been taken with no evidence of cardiotoxicity.

Katzung PHARMACOLOGY, 9e > Section V. Drugs That Act in the Central Nervous System > Chapter 30. Antidepressant Agents >

Preparations Available

Tricyclics

Amitriptyline (generic, Elavil, others)

Oral: 10, 25, 50, 75, 100, 150 mg tablets

Parenteral: 10 mg/mL for IM injection

Clomipramine (generic, Anafranil; labeled only for obsessive-compulsive disorder)

Oral: 25, 50, 75 mg capsules

Desipramine (generic, Norpramin, Pertofrane)

Oral: 10, 25, 50, 75, 100, 150 mg tablets

Doxepin (generic, Sinequan, others)

Oral: 10, 25, 50, 75, 100, 150 mg capsules; 10 mg/mL concentrate

Imipramine (generic, Tofranil, others)

Oral: 10, 25, 50 mg tablets (as hydrochloride); 75, 100, 125, 150 mg capsules (as pamoate)

Parenteral: 25 mg/2 mL for IM injection

Nortriptyline (generic, Aventyl, Pamelor)

Oral: 10, 25, 50, 75 mg capsules; 10 mg/5 mL solution

Protriptyline (generic, Vivactil)

Oral: 5, 10 mg tablets

Trimipramine (Surmontil)

Oral: 25, 50, 100 mg capsules

Second- & Third-Generation Drugs

Amoxapine (generic, Asendin)

Oral: 25, 50, 100, 150 mg tablets

Bupropion (generic, Wellbutrin)

Oral: 75, 100 mg tablets; 100, 150 mg sustained-release tablets

Maprotiline (generic, Ludiomil)

Oral: 25, 50, 75 mg tablets

Mirtazapine (Remeron)

Oral: 15, 30, 45 mg tablets

Nefazodone (Serzone)

Oral: 50, 100, 150, 200, 250 mg tablets

Trazodone (generic, Desyrel)

Oral: 50, 100, 150, 300 mg tablets

Venlafaxine (Effexor)

Oral: 25, 37.5, 50, 75, 100 mg tablets; 37.5, 75, 150 mg extended-release tablets

Selective Serotonin Reuptake Inhibitors

Citalopram (Celexa)

Oral: 20, 40 mg tablets

Escitalopram (Lexapro)

Oral: 5, 10, 20 mg tablets

Fluoxetine (generic, Prozac)

Oral: 10, 20 mg pulvules; 10 mg tablets; 20 mg/5 mL liquid

Oral delayed release (Prozac Weekly): 90 mg capsules

Fluvoxamine (Luvox, labeled only for obsessive- compulsive disorder)

Oral: 25, 50, 100 mg tablets

Paroxetine (Paxil)

Oral: 10, 20, 30, 40 mg tablets; 10 mg/5 mL suspension; 12.5, 25, 37.5 mg controlled-release tablets

Sertraline (Zoloft)

Oral: 25, 50, 100 mg tablets

Monoamine Oxidase Inhibitors

Phenelzine (Nardil)

Oral: 15 mg tablets

Tranlycypromine (Parnate)

Oral: 10 mg tablets

Other

Atomoxetine (Strattera)

Oral: 10, 18, 25, 40, 60 mg capsules

Chapter 31. Opioid Analgesics & Antagonists

Katzung PHARMACOLOGY, 9e > Section V. Drugs That Act in the Central Nervous System > Chapter 31. Opioid Analgesics & Antagonists >

Opioid Analgesics & Antagonists: Introduction

Morphine, the prototypical opioid agonist, has long been known to relieve severe pain with remarkable efficacy. The opium poppy is the source of crude opium from which Serturmer in 1803 isolated the pure alkaloid morphine—named after Morpheus, the Greek god of dreams. It remains the standard against which all drugs that have strong analgesic action are compared. These drugs are collectively known as "opioid analgesics" and include not only the natural and semisynthetic alkaloid derivatives from opium but also include synthetic surrogates, other opioid-like drugs whose actions are blocked by the nonselective antagonist naloxone, plus several endogenous peptides that interact with the several subtypes of opioid receptors.

Katzung PHARMACOLOGY, 9e > Section V. Drugs That Act in the Central Nervous System > Chapter 31. Opioid Analgesics & Antagonists >

Basic Pharmacology of the Opioid Analgesics

Source

Incision of the poppy seed pod reveals a white substance that turns into a brown gum that is crude opium. Opium contains many alkaloids, the principle one being morphine which is present in a concentration of about 10%. Codeine is synthesized commercially from morphine.

Classification & Chemistry

Opioid drugs include full agonists, partial agonists, and antagonists (see Chapter 2: Drug Receptors & Pharmacodynamics for definitions). Figure 31–1 shows the chemical structures of morphine, a natural opioid; codeine, a semisynthetic opioid; fentanyl, a pharmacologically similar synthetic; and naloxone, a nonselective opioid antagonist. Morphine is a full agonist at the μ (mu) opioid receptor, whereas codeine functions as a partial (or "weak") μ receptor agonist. As shown in Figure 31–1, simple substitution of an allyl group on the nitrogen of the full *agonist* morphine plus addition of a single hydroxyl group results in naloxone, a strong μ receptor *antagonist*. Some opioids, eg, nalbuphine, are capable of producing an agonist (or partial agonist) effect at one opioid receptor subtype and an antagonist effect at another. Not only can the activating properties of opioid analgesics be manipulated by pharmaceutical chemistry, certain opioid analgesics are modified in the liver resulting in compounds with greater analgesic action (see below, Pharmacokinetics, Metabolism).

Figure 31–1.

Endogenous Opioid Peptides

Opioid alkaloids (eg, morphine) produce analgesia through actions at regions in the brain that contain peptides which have opioid-like pharmacologic properties. The general term currently used for these endogenous substances is **endogenous opioid peptides**, which replaces the previous term **endorphin**.

Three families of endogenous opioid peptides have been described in detail. The best-characterized of the opioid peptides possessing analgesic activity are the pentapeptides methionine-enkephalin (**met-enkephalin**) and leucine-enkephalin (**leu-enkephalin**). Leu- and met-enkephalin have slightly higher affinity for the δ (delta) than for the μ opioid receptor (Table 31–1). These endogenous opioid peptides are derived from three precursor proteins: prepro-opiomelanocortin (POMC), preproenkephalin (proenkephalin A), and preprodynorphin (proenkephalin B). POMC contains the met-enkephalin sequence, β -**endorphin**, and several nonopioid peptides, including adrenocorticotrophic hormone (ACTH), β -lipotropin, and melanocyte-stimulating hormone. Preproenkephalin contains six copies of met-enkephalin and one copy of leu-enkephalin. Preprodynorphin yields several active opioid peptides that contain the leu-enkephalin sequence. These are **dynorphin A**, **dynorphin B**, and α and β neoendorphins. More recently, the endogenous peptides **endomorphin-1** and **endomorphin-2**, have been found to possess many of the properties of opioid peptides, notably analgesia and high affinity binding to the μ receptor. Current research is focused on whether endomorphins selectively activate μ receptor subtypes. Both the endogenous opioid precursor molecules and the endomorphins are present at central nervous system (CNS) sites that have been implicated in pain modulation. Evidence suggests that they can be released during stressful conditions such as pain or the anticipation of pain to diminish the sensation of noxious stimuli.

Table 31–1. Opioid Receptor Subtypes, Endogenous Opioid Peptide Affinity, and Some of Their Functions.

Receptor Subtype	Functions	Endogenous Opioid Peptide Affinity
μ (μ)	Supraspinal and spinal analgesia; sedation; inhibition of respiration; slowed GI transit; modulation of hormone and neurotransmitter release	Endorphin > enkephalins > dynorphins

δ(delta)	Supraspinal and spinal analgesia; modulation of hormone and neurotransmitter release	Enkephalins >> endorphins and dynorphins
κ(kappa)	Supraspinal and spinal analgesia; psychotomimetic effects; slowed GI transit	Dynorphins >> endorphin and enkephalins

GI, gastrointestinal.

In contrast to the analgesic role of leu- and met-enkephalin, an analgesic action of dynorphin A—through its binding to κ(kappa) opioid receptors—remains controversial. Dynorphin A is also found in the dorsal horn of the spinal cord where it plays a critical role in the *sensitization* of nociceptive neurotransmission. Increased levels of dynorphin can be found in the dorsal horn following tissue injury and inflammation. This elevated dynorphin level is believed to increase pain and induce a state of long-lasting hyperalgesia. The pro-nociceptive action of dynorphin in the spinal cord appears to be independent of the opioid receptor system. Rather, dynorphin A can bind and activate the *N*-methyl-D-aspartate (NMDA) receptor complex, a site of action that is the focus of intense therapeutic development.

Recently, a novel receptor-ligand system homologous to the opioid peptides has been found. The principle receptor for this system is the G protein-coupled **orphanin opioid-receptor-like subtype 1 (ORL1)**. Its endogenous ligand has been termed **nociceptin** by one group of investigators and **orphanin FQ** by another group. This ligand-receptor system is currently known as the **N/O/FQ** system. Nociceptin is structurally similar to dynorphin but acts only at the ORL1 receptor. Although widely expressed in the CNS and periphery, this system has a diverse pharmacology, capable of opposing classic κ-receptor-mediated analgesia as well as modulating drug reward, reinforcement, learning, and memory processes.

Pharmacokinetics

Some of the pharmacologic properties of clinically important opioids are summarized in Table 31–2.

Generic Name	Trade Name	Approximate Dose (mg)	Oral:Parenteral Potency Ratio	Duration of Analgesia (hours)	Intrinsic Activity
Morphine ¹		10	Low	4–5	High
Hydromorphone	Dilaudid	1.5	Low	4–5	High
Oxymorphone	Numorphan	1.5	Low	3–4	High
Methadone	Dolophine	10	High	4–6	High
Meperidine	Demerol	60–100	Medium	2–4	High
Fentanyl	Sublimaze	0.1	Low	1–1.5	High

Sufentanil	Sufenta	0.02	Parenteral only	1–1.5	High
Alfentanil	Alfenta	Titrated	Parenteral only	0.25–0.75	High
Levorphanol	Levo-Dromoran	2–3	High	4–5	High
Codeine		30–60 ⁴	High	3–4	Low
Hydrocodone ²		5–10	Medium	4–6	Moderate
Oxycodone ^{1,3}	Percodan	4.5 ⁴	Medium	3–4	Moderate
Propoxyphene	Darvon	60–120 ^{3,4}	Oral only	4–5	Very low
Pentazocine	Talwin	30–50 ⁴	Medium	3–4	Moderate
Nalbuphine	Nubain	10	Parenteral only	3–6	High
Buprenorphine	Buprenex	0.3	Low	4–8	High
Butorphanol	Stadol	2	Parenteral only	3–4	High

¹ Available in sustained-release forms, morphine (MSContin); oxycodone (OxyContin).

² Available in tablets containing acetaminophen (Norco, Vicodin, Lortab, others).

³ Available in tablets containing acetaminophen (Percocet); aspirin (Percodan).

⁴ Analgesic efficacy at this dose not equivalent to 10 mg of morphine. See text for explanation.

Absorption

Most opioid analgesics are well absorbed when given by subcutaneous, intramuscular, and oral routes. However, because of the first-pass effect, the oral dose of the opioid (eg, morphine) may need to be much higher than the parenteral dose to elicit a therapeutic effect. Considerable interpatient variability exists in first-pass opioid metabolism, making prediction of an effective oral dose difficult. Certain analgesics such as codeine and oxycodone are effective orally because they have reduced first-pass metabolism, which is primarily due to a methyl group on their aromatic hydroxyl group. Nasal insufflation of certain opioids can result in rapid therapeutic blood levels by avoiding first-pass metabolism. Other routes of opioid administration include oral mucosal and the application of transdermal patches, which can provide delivery of potent analgesics over days.

Distribution

The uptake of opioids by various organs and tissues is a function of both physiologic and chemical factors. Although all opioids bind to plasma proteins with varying affinity, the drugs rapidly leave the blood compartment and localize in highest concentrations in tissues that are highly perfused such as the brain, lungs, liver, kidneys, and spleen. Drug concentrations in skeletal muscle may be much lower, but this tissue serves as the main reservoir because of its greater bulk. Even though blood flow to fatty tissue is much lower than to the highly perfused tissues, accumulation can be

very important particularly after frequent high-dose administration or continuous infusion of highly lipophilic opioids that are slowly metabolized, eg, fentanyl.

Metabolism

The opioids are converted in large part to polar metabolites (mostly glucuronides), which are then readily excreted by the kidneys. For example, morphine, which contains free hydroxyl groups, is primarily conjugated to morphine-3-glucuronide (M3G), a compound with neuroexcitatory properties. Moreover, approximately 10% of morphine is metabolized to morphine-6-glucuronide (M6G), an active metabolite with greater analgesic potency than morphine. Despite their limited ability to cross the blood-brain barrier, accumulation of these metabolites may produce unexpected side effects in patients with renal failure or when exceptionally large doses of morphine are administered. This can result in M3G-induced CNS excitation (seizures) or enhanced and prolonged opioid action produced by M6G. Similarly, hydromorphone is metabolized to hydromorphone-3-glucuronide (H3G), which has CNS excitatory properties. However, hydromorphone has not been shown to form the 6-glucuronide metabolite.

Esters (eg, heroin, remifentanyl) are rapidly hydrolyzed by common tissue esterases. Heroin (diacetylmorphine) is hydrolyzed to monoacetylmorphine and finally to morphine, which is then conjugated with glucuronic acid.

Hepatic oxidative metabolism is the primary route of degradation of the phenylpiperidine opioids (fentanyl, alfentanil, sufentanil) and eventually leaves only small quantities of the parent compound unchanged for excretion. No active metabolites of fentanyl have been reported. The P450 isozyme CYP3A4 metabolizes fentanyl by N-dealkylation in the liver. CYP3A4 is also present in the mucosa of the small intestine and contributes to the first-pass metabolism of fentanyl when it is taken orally. Codeine, oxycodone, and hydrocodone undergo metabolism in the liver by P450 isozyme CYP2D6, resulting in the production of metabolites of greater potency. Genetic polymorphism of CYP2D6 has been documented and linked to the variation in analgesic response seen among patients. Nevertheless, these metabolites may be of minor consequence because the parent compounds (codeine, oxycodone, hydrocodone) are currently believed to be directly responsible for the majority of their analgesic actions.

Accumulation of a demethylated metabolite of meperidine, normeperidine, may occur in patients with decreased renal function or those receiving multiple high doses of the drug. In sufficiently high concentrations, normeperidine may cause seizures.

Excretion

Polar metabolites, including glucuronide conjugates of opioid analgesics, are excreted mainly in the urine. Small amounts of unchanged drug may also be found in the urine. Glucuronide conjugates are also found in the bile, but enterohepatic circulation represents only a small portion of the excretory process.

Pharmacodynamics

Mechanism of Action

Opioid agonists produce analgesia by binding to specific G protein-coupled receptors, located primarily in brain and spinal cord regions involved in the transmission and modulation of pain.

Receptor Types

As noted above, three major classes of opioid receptors (μ , δ , and κ) have been identified in various nervous system sites and in other tissues (Table 31–1). Each of the three major receptors has now been cloned. All are members of the G protein-coupled family of receptors and show significant amino acid sequence homologies. Multiple receptor subtypes have been proposed based on pharmacologic criteria, including μ_1 , μ_2 , δ_1 , δ_2 , κ_1 , κ_2 , and κ_3 . However, genes encoding only one subtype from each of the μ , δ , and κ receptor families have been isolated and characterized thus far. One plausible explanation is that μ receptor subtypes arise from alternate splice variants of a common gene. Since an opioid drug may function with different potencies as an agonist, partial agonist, or antagonist at more than one receptor class or subtype, it is not surprising that these agents are capable of diverse pharmacologic effects.

Cellular Actions

At the molecular level, opioid receptors form a family of proteins that physically couple to G proteins and through this interaction affect ion channel gating, modulate intracellular Ca^{2+} disposition, and alter protein phosphorylation (see Chapter 2: Drug Receptors & Pharmacodynamics). The opioids have two well-established direct actions on neurons: (1) they close voltage-gated Ca^{2+} channels on presynaptic nerve terminals and thereby reduce transmitter release and (2) they hyperpolarize and thus inhibit postsynaptic neurons by opening K^+ channels. Figure 31–2 schematically illustrates the presynaptic action at all three receptor types and the postsynaptic effect at μ receptors on nociceptive afferents in the spinal cord. The presynaptic action—depressed transmitter release—has been demonstrated for release of a large number of neurotransmitters including glutamate, the principle excitatory amino acid released from nociceptive nerve terminals, as well as acetylcholine, norepinephrine, serotonin, and substance P.

Figure 31–2.

Relation of Physiologic Effects to Receptor Type

The majority of currently available opioid analgesics act primarily at the μ opioid receptor. Analgesia, as well as the euphoriant, respiratory depressant, and physical dependence properties of

morphine result principally from actions at μ receptors. In fact, the μ receptor was originally defined using the relative potencies for clinical analgesia of a series of opioid alkaloids. However, opioid analgesic effects are complex and include interaction with δ and κ receptors. This is supported by the study of genetic knockouts of the μ , δ , and κ genes in mice. Delta receptor agonists retain analgesic properties in μ receptor knockout mice. The development of δ receptor-selective agonists could be clinically useful if their side-effect profiles (respiratory depression, risk of dependence) were more favorable than those found with current μ receptor agonists, such as morphine. Although morphine does act at κ and δ receptor sites, it is unclear to what extent this contributes to its analgesic action. The endogenous opioid peptides differ from most of the alkaloids in their affinity for the δ and κ receptors (Table 31-1). For example, leu-enkephalin has a high affinity for the δ receptor and dynorphin for the κ receptor.

In an effort to develop opioid analgesics with a reduced incidence of respiratory depression or propensity for addiction and dependence, compounds that show preference for μ opioid receptors have been developed. Butorphanol and nalbuphine have shown some clinical success as analgesics, but they can cause dysphoric reactions and have limited potency. Interestingly, butorphanol has also been shown to cause significantly greater analgesia in women than in men. The reason for this difference is not known.

Receptor Distribution and Neural Mechanisms of Analgesia

Opioid receptor binding sites have been localized autoradiographically using high-affinity radioligand binding with antibodies to unique peptide sequences in each receptor subtype. All three major receptors are present in high concentrations in the dorsal horn of the spinal cord (site **B**, Figure 31-3). Receptors are present both on spinal cord pain transmission neurons and on the primary afferents that relay the pain message to them (Figure 31-3, left side). Opioid agonists inhibit the release of excitatory transmitters from these primary afferents, and they directly inhibit the dorsal horn pain transmission neuron. Thus, opioids exert a powerful analgesic effect directly upon the spinal cord. This **spinal action** has been exploited clinically by direct application of opioid agonists to the spinal cord, which provides a regional analgesic effect while reducing the unwanted respiratory depression, nausea and vomiting, and sedation that may occur from the **supraspinal actions** of systemically administered opioids.

Figure 31-3.

Under most circumstances, opioids are given systemically and so act simultaneously at both spinal and supraspinal sites; interaction at these two sites tends to increase their overall analgesic efficacy. Different combinations of opioid receptors are found in the supraspinal regions implicated in pain transmission and modulation (Figure 31-3). Of particular importance are opioid binding sites in pain-modulating descending pathways (Figure 31-3, right), including the rostral ventral medulla, the locus ceruleus, and the midbrain periaqueductal gray area. At these sites as at others, opioids directly inhibit neurons, yet neurons that send processes to the spinal cord and inhibit pain transmission neurons are activated by the drugs. This activation has been shown to result from the inhibition of inhibitory neurons in several locations (Figure 31-4).

Figure 31–4.

Brainstem local circuitry underlying μ opioid receptor (MOR)–mediated analgesia. The pain inhibitory neuron (*I*) is indirectly excited by opioids (exogenous or endogenous) that inhibit an inhibitory (GABAergic) interneuron (*GABA*).

When pain-relieving opioid drugs are given systemically, they presumably act upon brain circuits normally regulated by endogenous opioid peptides. Part of the pain-relieving action of exogenous opioids involves the release of endogenous opioid peptides. An exogenous opioid agonist (eg, morphine) may act primarily and directly at the μ receptor, but this action may evoke the release of endogenous opioids that additionally act at δ and κ receptors. Thus, even a receptor-selective ligand can initiate a complex sequence of events involving multiple synapses, transmitters, and receptor types.

Animal and human clinical studies demonstrate that both endogenous and exogenous opioids can also produce opioid-mediated analgesia at sites *outside* the CNS. Pain associated with inflammation seems especially sensitive to these peripheral opioid actions. The identification of functional μ receptors on the peripheral terminals of sensory neurons supports this hypothesis. Furthermore, activation of peripheral μ receptors results in a decrease in sensory neuron activity and transmitter release. Peripheral administration of opioids, eg, into the knees of patients undergoing arthroscopic knee surgery, has shown some clinical benefit. If they can be developed, opioids selective for a peripheral site would be useful adjuncts in the treatment of inflammatory pain (see Ion Channels & Novel Analgesics). Moreover, new peripherally acting dynorphins may provide a novel means to treat visceral pain.

Tolerance and Physical Dependence

With frequently repeated administration of therapeutic doses of morphine or its surrogates, there is a gradual loss in effectiveness, ie, tolerance. To reproduce the original response, a larger dose must be administered. Along with tolerance, physical dependence develops. Physical dependence is defined as the occurrence of a characteristic withdrawal or **abstinence syndrome** when the drug is stopped or an antagonist is administered.

The mechanism of development of tolerance and physical dependence is poorly understood, but persistent activation of μ receptors such as occurs with the treatment of severe chronic pain appears to play a primary role in its induction and maintenance. Current concepts have shifted away from tolerance being driven by a simple up-regulation of the cyclic adenosine monophosphate (cAMP) system or a down-regulation and recycling of μ receptors from the cell surface to cryptic

intracellular sites. Although these processes are associated with tolerance, they are not sufficient to explain it. Recent research suggests that the μ opioid receptor is an important component in the maintenance of tolerance. In addition, the concept of **receptor uncoupling** has gained prominence. Under this hypothesis, tolerance is due to a dysfunction of structural interactions between the μ receptor and G-proteins, second messenger systems, and their target ion channels. Moreover, a particular ion channel complex, the NMDA receptor, has been shown to play a critical role in tolerance development and maintenance because NMDA receptor antagonists such as ketamine can block tolerance development. The development of novel NMDA receptor antagonists or other strategies to recouple μ receptors to their target ion channels provides hope for achieving a clinically effective means to prevent or reverse opioid analgesic tolerance. In addition to the development of tolerance, persistent administration of opioid analgesics has been observed to *increase* the sensation of pain. Spinal dynorphin is a leading candidate for the mediation of opioid-induced pain and hyperalgesia.

Organ System Effects of Morphine and Its Surrogates

The actions described below for morphine, the prototypic opioid agonist, can also be observed with other opioid agonists even though some variation between individual agents does occur. Agents with partial agonist or mixed receptor effects, when given to a patient who has not recently received an agonist agent, also produce analgesia but with minor additional variations in effects as noted below. Characteristics of specific members of these two groups are discussed below. When given to a subject who *has* received an agonist, the pure antagonists and the mixed agents have very different effects from those observed in a subject who *has not* received an agonist. This is discussed further at the end of this chapter.

Central Nervous System Effects

The principal effects of opioid analgesics with affinity for μ receptors are on the CNS; the more important ones include analgesia, euphoria, sedation, and respiratory depression. With repeated use, a high degree of tolerance occurs to all of these effects (Table 31–3).

High	Moderate	Minimal or None
Analgesia	Bradycardia	Miosis
Euphoria, dysphoria		Constipation
Mental clouding		Convulsions
Sedation		
Respiratory depression		
Antidiuresis		
Nausea and vomiting		
Cough suppression		

Analgesia

Pain consists of both sensory and affective (emotional) components. Opioid analgesics are unique in that they can reduce both aspects of the pain experience, especially the affective aspect.

Euphoria

Typically, patients or intravenous drug users who receive intravenous morphine experience a pleasant floating sensation with lessened anxiety and distress. However, dysphoria, an unpleasant state characterized by restlessness and malaise, may sometimes occur.

Sedation

Drowsiness and clouding of mentation are frequent concomitants of opioid action. There is little or no amnesia. Sleep is induced by opiates more frequently in the elderly than in young, healthy individuals. Ordinarily, the patient can be easily aroused from this sleep. However, the combination of morphine with other central depressant drugs such as the sedative-hypnotics may result in very deep sleep. Marked sedation occurs more frequently with compounds closely related to the phenanthrene derivatives and less frequently with the synthetic agents such as meperidine and fentanyl. In standard analgesic doses, morphine (a phenanthrene) disrupts normal REM and non-REM sleep patterns. This disrupting effect is probably characteristic of all opioids. In contrast to humans, a number of species (cats, horses, cows, pigs) may manifest excitation rather than sedation when given opioids. These paradoxical effects are at least partially dose-dependent.

Respiratory Depression

All of the opioid analgesics can produce significant respiratory depression by inhibiting brainstem respiratory mechanisms. Alveolar PCO_2 may increase, but the most reliable indicator of this depression is a depressed response to a carbon dioxide challenge. The respiratory depression is dose-related and is influenced significantly by the degree of sensory input occurring at the time. For example, it is possible to partially overcome opioid-induced respiratory depression by stimulation of various sorts. When strongly painful stimuli that have prevented the depressant action of a large dose of an opioid are relieved, respiratory depression may suddenly become marked. A small to moderate decrease in respiratory function, as measured by $PaCO_2$ elevation, may be well-tolerated in the patient without prior respiratory impairment. However, in individuals with increased intracranial pressure, asthma, chronic obstructive pulmonary disease, or cor pulmonale, this decrease in respiratory function may not be tolerated.

Cough Suppression

Suppression of the cough reflex is a well-recognized action of opioids. Codeine in particular has been used to advantage in persons suffering from pathologic cough and in patients in whom it is necessary to maintain ventilation via an endotracheal tube. However, cough suppression by opioids may allow accumulation of secretions and thus lead to airway obstruction and atelectasis.

Miosis

Constriction of the pupils is seen with virtually all opioid agonists. Miosis is a pharmacologic action to which little or no tolerance develops (Table 31–3); thus, it is valuable in the diagnosis of opioid overdose. Even in highly tolerant addicts, miosis will be seen. This action, which can be blocked by opioid antagonists, is mediated by parasympathetic pathways, which, in turn, can be blocked by atropine.

Truncal Rigidity

An intensification of tone in the large trunk muscles has been noted with a number of opioids. It was originally believed that truncal rigidity involved a spinal cord action of these drugs, but there is now evidence that it results from an action at supraspinal levels. Truncal rigidity reduces thoracic compliance and thus interferes with ventilation. The effect is most apparent when high doses of the highly lipid-soluble opioids (eg, fentanyl, sufentanil, alfentanil) are rapidly administered intravenously. Truncal rigidity may be overcome by administration of an opioid antagonist, which of course will also antagonize the analgesic action of the opioid. Preventing truncal rigidity while preserving analgesia requires the concomitant use of neuromuscular blocking agents.

Nausea and Vomiting

The opioid analgesics can activate the brainstem chemoreceptor trigger zone to produce nausea and vomiting. There may also be a vestibular component in this effect because ambulation seems to increase the incidence of nausea and vomiting.

Peripheral Effects

Cardiovascular System

Most opioids have no significant *direct* effects on the heart and no major effects on cardiac rhythm (except bradycardia). Meperidine is an exception to this generalization because its antimuscarinic action may result in tachycardia. Blood pressure is usually well maintained in subjects receiving opioids unless the cardiovascular system is stressed, in which case hypotension may occur. This hypotensive effect is probably due to peripheral arterial and venous dilation, which has been attributed to a number of mechanisms including central depression of vasomotor-stabilizing mechanisms and release of histamine. No consistent effect on cardiac output is seen, and the electrocardiogram is not significantly affected. However, caution should be exercised in patients with decreased blood volume, since the above mechanisms make these patients quite susceptible to hypotension. Opioid analgesics affect cerebral circulation minimally except when PCO₂ rises as a consequence of respiratory depression. Increased PCO₂ leads to cerebral vasodilation associated with a decrease in cerebral vascular resistance, an increase in cerebral blood flow, and an increase in intracranial pressure.

Gastrointestinal Tract

Constipation has long been recognized as an effect of opioids. Opioid receptors exist in high density in the gastrointestinal tract, and the constipating effects of the opioids are mediated through an action on the local enteric nervous system (see Chapter 6: Introduction to Autonomic Pharmacology) as well as the CNS. In the stomach, motility (rhythmic contraction and relaxation) may decrease but tone (persistent contraction) may increase—particularly in the central portion; gastric secretion of hydrochloric acid is decreased. Small intestine resting tone is increased, with periodic spasms, but the amplitude of nonpropulsive contractions is markedly decreased. In the large intestine, propulsive peristaltic waves are diminished and tone is increased; this delays passage of the fecal mass and allows increased absorption of water, which leads to constipation. The large bowel actions are the basis for the use of opioids in management of diarrhea.

Biliary Tract

The opioids constrict biliary smooth muscle, which may result in biliary colic. The sphincter of

Oddi may constrict, resulting in reflux of biliary and pancreatic secretions and elevated plasma amylase and lipase levels.

Renal

Renal function is depressed by opioids. It is believed that in humans this is chiefly due to decreased renal plasma flow. Opioids can decrease systemic blood pressure and glomerular filtration rate. In addition, opioids have been found to have an antidiuretic effect in humans. Mechanisms may involve both the CNS and peripheral sites, but the relative contributions of each are unknown. Opioids also enhance renal tubular sodium reabsorption. The role of opioid-induced changes in antidiuretic hormone (ADH) release is controversial. Ureteral and bladder tone are increased by therapeutic doses of the opioid analgesics. Increased sphincter tone may precipitate urinary retention, especially in postoperative patients. Occasionally, ureteral colic caused by a renal calculus is made worse by opioid-induced increase in ureteral tone.

Uterus

The opioid analgesics may prolong labor. The mechanism for this action is unclear, but both peripheral and central effects of the opioids can reduce uterine tone.

Neuroendocrine

Opioid analgesics stimulate the release of ADH, prolactin, and somatotropin but inhibit the release of luteinizing hormone. These effects suggest that endogenous opioid peptides, through effects in the hypothalamus, play regulatory roles in these systems (Table 31-1).

Pruritus

Therapeutic doses of the opioid analgesics produce flushing and warming of the skin accompanied sometimes by sweating and itching; CNS effects and peripheral histamine release may be responsible for these reactions. Opioid-induced pruritus and occasionally urticaria appear more frequently when opioid analgesics are administered parenterally. In addition, when opioids such as morphine are administered to the neuraxis by the spinal or epidural route, their usefulness may be limited by intense pruritus over the lips and torso.

Miscellaneous

The opioids may modulate the actions of the immune system by effects on lymphocyte proliferation, antibody production, and chemotaxis. Natural killer cell cytolytic activity and lymphocyte proliferative responses to mitogens are usually inhibited by opioids. Although the mechanisms involved are complex, activation of central opioid receptors could mediate a significant component of the changes observed in peripheral immune function. In general, these effects are mediated by the sympathetic nervous system in the case of acute administration and by the hypothalamic-pituitary-adrenal system in the case of prolonged administration of opioids.

Effects of Drugs with Both Agonist and Antagonist Actions

Buprenorphine is an opioid agonist that displays high binding affinity but low intrinsic activity at the μ -receptor. Its slow rate of dissociation from the μ -receptor has also made it an attractive alternative to methadone for the management of opioid withdrawal. It functions as an *antagonist* at the δ and κ -receptors and for this reason is referred to as a "mixed agonist-antagonist." Although

buprenorphine is used as an analgesic, it can antagonize the action of more potent μ agonists such as morphine. Buprenorphine also binds to ORL1, the orphanin receptor. Whether this property also participates in opposing μ receptor function is under study. Pentazocine and nalbuphine are other examples of opioid analgesics with mixed agonist-antagonist properties. Psychotomimetic effects, with hallucinations, nightmares, and anxiety, have been reported following use of drugs with mixed agonist-antagonist actions.

Katzung PHARMACOLOGY, 9e > Section V. Drugs That Act in the Central Nervous System > Chapter 31. Opioid Analgesics & Antagonists >

Ion Channels & Novel Analgesics

Even the most severe acute pain (that lasting hours to days) can usually be well controlled—with significant but tolerable adverse effects—with currently available analgesics, especially the opioids. Chronic pain (lasting weeks to months), however, is not very satisfactorily managed with opioids. It is now known that in chronic pain, presynaptic receptors on sensory nerve terminals in the periphery contribute to increased excitability of sensory nerve endings (peripheral sensitization). The hyperexcitable sensory neuron bombards the spinal cord, leading to increased excitability and synaptic alterations in the dorsal horn (central sensitization). Such changes appear to be important in chronic inflammatory and neuropathic pain states (Basbaum, 1999; Woolf, 2000).

In the effort to discover better analgesic drugs for chronic pain, renewed attention is being paid to synaptic transmission in nociception and sensory processing. Potentially important ion channels associated with these processes in the periphery include members of the transient receptor potential family as TRPV1 (capsaicin receptor) that is activated by heat and products of inflammation as well as P2X receptors (responsive to purines released from tissue damage). A special type of tetrodotoxin-resistant voltage-gated sodium channel (Nav1.8), also known as the PN3/SNS channel, is apparently uniquely associated with nociceptive neurons in dorsal root ganglia. Mexiletine, which is useful in some chronic pain states, may act by blocking this channel. Certain blockers of voltage-gated N-type calcium channels have shown analgesic effects. A synthetic peptide related to the marine snail toxin ω -conotoxin, which selectively blocks these calcium channels, is in clinical trials as an analgesic. Gabapentin, an anticonvulsant analog of GABA (see Chapter 24: Antiseizure Drugs), is an effective treatment for neuropathic (nerve injury) pain. It has recently been shown to block the pain and hyperalgesia associated with inflammation. Potential sites of action of gabapentin include the α -2-delta family of calcium channels.

N-methyl-D-aspartate (NMDA) receptors appear to play a very important role in central sensitization at both spinal and supraspinal levels. Although certain NMDA antagonists have demonstrated analgesic activity (eg, ketamine), it has been difficult to find agents with an acceptably low profile of side effects or neurotoxicity. GABA and acetylcholine (through nicotinic receptors) appear to control the central synaptic release of several transmitters involved in nociception. Nicotine itself and certain nicotine analogs cause analgesia. A nicotinic agonist found in certain frogs (epibatidine) has significant analgesic effect.

Although none of the studies described has yet yielded an approved analgesic drug, they have already provided a better understanding of nociception and analgesia.

Katzung PHARMACOLOGY, 9e > Section V. Drugs That Act in the Central Nervous System > Chapter 31. Opioid Analgesics & Antagonists >

Clinical Pharmacology of the Opioid Analgesics

Successful treatment of pain is a challenging task that begins with careful attempts to assess the source and magnitude of the pain. The amount of pain experienced by the patient is often described in terms of a numeric visual analog scale (VAS) with word descriptors ranging from no pain (0) to excruciating pain (10). A similar scale can be used with children and with patients who cannot speak; this scale depicts five faces ranging from smiling (no pain) to crying (maximum pain).

In severe pain, the administration of an opioid analgesic is usually considered a primary part of the overall management plan. Determining the route of administration (oral, parenteral, neuraxial), duration of drug action, ceiling effect (maximal intrinsic activity), duration of therapy, potential for unwanted side effects, and the patient's past experience with opioids should all be addressed. One of the principal errors made by physicians in this setting is a failure to adequately assess a patient's pain and to match its severity with an appropriate level of therapy. Just as important is the principle that following delivery of the therapeutic plan, its effectiveness must be reevaluated and the plan modified if necessary if the response was excessive or inadequate.

Use of opioid drugs in acute situations may be contrasted with their use in chronic pain management, where a multitude of other factors must be considered, including the development of tolerance to and physical dependence on to opioid analgesics.

Clinical Use of Opioid Analgesics

Analgesia

Severe, *constant* pain is usually relieved with opioid analgesics with high intrinsic activity (see Table 31–2); whereas sharp, intermittent pain does not appear to be as effectively controlled.

The pain associated with cancer and other terminal illnesses must be treated aggressively and often requires a multidisciplinary approach for effective management. Such conditions may require continuous use of potent opioid analgesics and will be associated with some degree of tolerance and dependence. However, this should not be used as a barrier to providing patients with the best possible care and quality of life. Research in the hospice movement has demonstrated that fixed-interval administration of opioid medication (ie, a regular dose at a scheduled time) is more effective in achieving pain relief than dosing on demand. New dosage forms of opioids that allow slower release of the drug are now available (eg, sustained-release forms of morphine (MSContin) and oxycodone (OxyContin). Their purported advantage is a longer and more stable level of analgesia.

If disturbances of gastrointestinal function prevent the use of oral sustained-release morphine, the fentanyl transdermal system (fentanyl patch) can be used over long periods. Furthermore, buccal transmucosal fentanyl can be used for episodes of breakthrough pain (see Alternative Routes of Administration, below). Administration of strong opioids by nasal insufflation has been shown to be efficacious, and nasal preparations are now available in some countries. Approval of such formulations in the USA is growing. In addition, stimulant drugs such as the amphetamines have been shown to enhance the analgesic actions of the opioids and thus may be very useful adjuncts in the patient with chronic pain.

Opioid analgesics are often used during obstetric labor. Because opioids cross the placental barrier and reach the fetus, care must be taken to minimize neonatal depression. If this occurs, immediate injection of the antagonist naloxone will reverse the depression. The phenylpiperidine drugs (eg,

meperidine) appear to produce less depression, particularly respiratory depression, in newborn infants than does morphine; this may justify their use in obstetric practice.

The acute, severe pain of renal and biliary colic often requires a strong agonist opioid for adequate relief. However, the drug-induced increase in smooth muscle tone may cause a paradoxical *increase* in pain secondary to increased spasm. An increase in the dose of opioid is usually successful in providing adequate analgesia.

Acute Pulmonary Edema

The relief produced by intravenous morphine in dyspnea from pulmonary edema associated with left ventricular failure is remarkable. The mechanism is not clear but probably involves reduced *perception* of shortness of breath and reduced patient anxiety as well as reduced cardiac preload (reduced venous tone) and afterload (decreased peripheral resistance). Morphine can be particularly useful when treating painful myocardial ischemia with pulmonary edema.

Cough

Suppression of cough can be obtained at doses lower than those needed for analgesia. However, in recent years the use of opioid analgesics to allay cough has diminished largely because a number of effective synthetic compounds have been developed that are neither analgesic nor addictive. These agents are discussed below.

Diarrhea

Diarrhea from almost any cause can be controlled with the opioid analgesics, but if diarrhea is associated with infection such use must not substitute for appropriate chemotherapy. Crude opium preparations (eg, paregoric) were used in the past to control diarrhea, but now synthetic surrogates with more selective gastrointestinal effects and few or no CNS effects, eg, diphenoxylate, are used. Several preparations are available specifically for this purpose.

Applications in Anesthesia

The opioids are frequently used as premedicant drugs before anesthesia and surgery because of their sedative, anxiolytic, and analgesic properties. The opioids are also used intraoperatively both as adjuncts to other anesthetic agents and, in high doses (eg, 0.02–0.075 mg/kg of fentanyl), as a primary component of the anesthetic regimen (see Chapter 25: General Anesthetics), most commonly in cardiovascular surgery and other types of high-risk surgery where a primary goal is to minimize cardiovascular depression. In such situations, mechanical respiratory assistance must be provided.

Because of their direct action on the superficial neurons of the spinal cord dorsal horn, opioids can also be used as regional analgesics, by administration into the epidural or subarachnoid spaces of the spinal column. A number of studies have demonstrated that long-lasting analgesia with minimal adverse effects can be achieved by epidural administration of 3–5 mg of morphine, followed by slow infusion through a catheter placed in the epidural space. It was initially assumed that the epidural application of opioids might selectively produce analgesia without impairment of motor, autonomic, or sensory functions other than pain. However, respiratory depression may occur after the drug is injected into the epidural space and may require reversal with naloxone. Other effects such as pruritus and nausea and vomiting are common after epidural and subarachnoid administration of opioids and may also be reversed with naloxone if necessary. Currently, the

epidural route is favored because adverse effects are less common. Morphine is the most frequently used agent, but the use of low doses of local anesthetics in combination with fentanyl infused through a thoracic epidural catheter has also become an accepted method of pain control in patients recovering from major upper abdominal surgery. In rare cases, chronic pain management specialists may elect to surgically implant a programmable infusion pump connected to a spinal catheter for continuous infusion of opioids or other analgesic compounds.

Alternative Routes of Administration

Rectal suppositories of morphine and hydromorphone have long been used when oral and parenteral routes are undesirable. The **transdermal patch** provides stable blood levels of drug and better pain control while avoiding the need for repeated parenteral injections. Fentanyl has been the most successful opioid in transdermal application and finds great use in patients experiencing chronic pain. The **intranasal** route avoids repeated parenteral drug injections and the first-pass metabolism of orally administered drugs. Butorphanol is the only opioid currently available in the USA in a nasal formulation but more are expected. Another alternative to parenteral administration is the **buccal transmucosal** route, which uses a fentanyl citrate lozenge or a "lollipop" mounted on a stick.

Another type of pain control called **patient-controlled analgesia (PCA)** is now in widespread use. With PCA, the patient controls a parenteral (usually intravenous) infusion device by depressing a button to deliver a preprogrammed dose of the desired opioid analgesic. Claims of better pain control using less opioid are supported by well-designed clinical trials, making this approach very useful in postoperative pain control. However, health care personnel must be very familiar with the use of PCAs to avoid overdosage secondary to misuse or improper programming. There is a proven risk of respiratory depression with hypoxia that requires careful monitoring of vital signs and sedation level.

Toxicity & Undesired Effects

Direct toxic effects of the opioid analgesics that are extensions of their acute pharmacologic actions include respiratory depression, nausea, vomiting, and constipation (Table 31–4). In addition, tolerance and dependence, diagnosis and treatment of overdosage, as well as contraindications must be considered.

Table 31–4. Adverse Effects of the Opioid Analgesics.
Behavioral restlessness, tremulousness, hyperactivity (in dysphoric reactions)
Respiratory depression
Nausea and vomiting
Increased intracranial pressure
Postural hypotension accentuated by hypovolemia
Constipation
Urinary retention
Itching around nose, urticaria (more frequent with parenteral and spinal administration)

Tolerance and Dependence

Drug dependence of the opioid type is marked by a relatively specific withdrawal or abstinence syndrome. Just as there are pharmacologic differences between the various opioids, there are also differences in psychologic dependence and the severity of withdrawal effects. For example, withdrawal from dependence upon a strong agonist is associated with more severe withdrawal signs and symptoms than withdrawal from a mild or moderate agonist. Administration of an opioid *antagonist* to an opioid-dependent person is followed by brief but severe withdrawal symptoms (see antagonist-precipitated withdrawal, below). The potential for physical and psychologic dependence of the partial agonist-antagonist opioids appear to be less than that of the agonist drugs.

Tolerance

Although development of tolerance begins with the first dose of an opioid, tolerance generally does not become clinically manifest until after 2–3 weeks of frequent exposure to ordinary therapeutic doses. Tolerance develops most readily when large doses are given at short intervals and is minimized by giving small amounts of drug with longer intervals between doses.

Depending on the compound and the effect measured, the degree of tolerance may be as great as 35-fold. Marked tolerance may develop to the analgesic, sedating, and respiratory depressant effects. It is possible to produce respiratory arrest in a nontolerant person with a dose of 60 mg of morphine, whereas in addicts maximally tolerant to opioids as much as 2000 mg of morphine taken over a 2- or 3-hour period may not produce significant respiratory depression. Tolerance also develops to the antidiuretic, emetic, and hypotensive effects but not to the miotic, convulsant, and constipating actions (Table 31–3).

Tolerance to the sedating and respiratory effects of the opioids dissipates within a few days after the drugs are discontinued. Tolerance to the emetic effects may persist for several months after withdrawal of the drug. The rates at which tolerance appears and disappears, as well as the degree of tolerance, may also differ considerably among the different opioid analgesics and among individuals using the same drug. For instance, tolerance to methadone develops more slowly and to a lesser degree than to morphine.

Tolerance develops also to analgesics with mixed receptor effects but to a lesser extent than to the agonists. Such effects as hallucinations, sedation, hypothermia, and respiratory depression are reduced after repeated administration of the mixed receptor drugs. However, tolerance to the latter agents does not generally include cross-tolerance to the agonist opioids. It is also important to note that tolerance does not develop to the antagonist actions of the mixed agents nor to those of the pure antagonists.

Cross-tolerance is an extremely important characteristic of the opioids, ie, patients tolerant to morphine show a reduction in analgesic response to other agonist opioids. This is particularly true of those agents with primarily μ -receptor agonist activity. Morphine and its congeners exhibit cross-tolerance not only with respect to their analgesic actions but also to their euphoriant, sedative, and respiratory effects. However, the cross-tolerance existing among the μ -receptor agonists can often be partial or incomplete. This clinical observation has led to the concept of "opioid rotation," which has been used in the treatment of cancer pain for many years. A patient who is experiencing decreasing effectiveness of one opioid analgesic regimen is "rotated" to a different opioid analgesic (eg, morphine to hydromorphone; hydromorphone to methadone) and typically experiences significantly improved analgesia at a reduced overall equivalent dosage. Another approach is to

"recouple" opioid receptor function through the use of adjunctive nonopioid agents. NMDA receptor antagonists (eg, ketamine, dextromethorphan) have shown promise in preventing or reversing opioid-induced tolerance in animals and humans. Routine use of these agents awaits the outcome of well-controlled studies to determine their clinical effectiveness in reducing postoperative pain and morphine requirements.

Physical Dependence

The development of physical dependence is an invariable accompaniment of tolerance to repeated administration of an opioid of the μ type. Failure to continue administering the drug results in a characteristic withdrawal or **abstinence syndrome** that reflects an exaggerated rebound from the acute pharmacologic effects of the opioid.

The signs and symptoms of withdrawal include rhinorrhea, lacrimation, yawning, chills, gooseflesh (piloerection), hyperventilation, hyperthermia, mydriasis, muscular aches, vomiting, diarrhea, anxiety, and hostility (see Chapter 32: Drugs of Abuse). The number and intensity of the signs and symptoms are largely dependent on the degree of physical dependence that has developed. Administration of an opioid at this time suppresses abstinence signs and symptoms almost immediately.

The time of onset, intensity, and duration of abstinence syndrome depend on the drug used and may be related to its biologic half-life. With morphine or heroin, withdrawal signs usually start within 6–10 hours after the last dose. Peak effects are seen at 36–48 hours, after which most of the signs and symptoms gradually subside. By 5 days, most of the effects have disappeared, but some may persist for months. In the case of meperidine, the withdrawal syndrome largely subsides within 24 hours, whereas with methadone several days are required to reach the peak of the abstinence syndrome, and it may last as long as 2 weeks. The slower subsidence of methadone effects is associated with a less intense immediate syndrome, and this is the basis for its use in the detoxification of heroin addicts. After the abstinence syndrome subsides, tolerance also disappears as evidenced by a restoration in sensitivity to the opioid agonist. However, despite the loss of physical dependence on the opioid, craving for it may persist for many months.

A transient, explosive abstinence syndrome—**antagonist-precipitated withdrawal**—can be induced in a subject physically dependent on opioids by administering naloxone or other antagonist. Within 3 minutes after injection of the antagonist, signs and symptoms similar to those seen after abrupt discontinuance appear, peaking in 10–20 minutes and largely subsiding after 1 hour. Even in the case of methadone, withdrawal of which results in a relatively mild abstinence syndrome, the antagonist-precipitated abstinence syndrome may be very severe.

In the case of agents with mixed effects, withdrawal signs and symptoms can be induced after repeated administration followed by abrupt discontinuance of pentazocine, cyclazocine, or nalorphine, but the syndrome appears to be somewhat different from that produced by morphine and other agonists. Anxiety, loss of appetite and body weight, tachycardia, chills, increase in body temperature, and abdominal cramps have been noted.

Psychologic Dependence

The euphoria, indifference to stimuli, and sedation usually caused by the opioid analgesics, especially when injected intravenously, tend to promote their compulsive use. In addition, the addict experiences abdominal effects that have been likened to an intense sexual orgasm. These factors constitute the primary reasons for opioid abuse liability and are strongly reinforced by the

development of physical dependence.

Obviously, the risk of causing dependence is an important consideration in the therapeutic use of these drugs. *Despite that risk, under no circumstances should adequate pain relief ever be withheld simply because an opioid exhibits potential for abuse or because legislative controls complicate the process of prescribing narcotics.* Furthermore, certain principles can be observed by the clinician to minimize problems presented by tolerance and dependence when using opioid analgesics:

Establish therapeutic goals before starting opioid therapy. This tends to limit the potential for physical dependence. The patient should be included in this process.

Once a therapeutic dose is established, attempt to limit dosage to this level. This goal is facilitated by use of a written treatment contract which specifically prohibits early refills and having multiple prescribing physicians.

Instead of opioid analgesics—especially in chronic management—consider using other types of analgesics or compounds exhibiting less pronounced withdrawal symptoms on discontinuance.

Frequently evaluate continuing analgesic therapy and the patient's need for opioids.

Diagnosis and Treatment of Opioid Overdosage

Intravenous injection of naloxone dramatically reverses coma due to opioid overdose but not that due to other CNS depressants. Use of the antagonist should not, of course, delay the institution of other therapeutic measures, especially respiratory support.

See also following Antagonists section and Chapter 59: Management of the Poisoned Patient.

Contraindications and Cautions in Therapy

Use of Pure Agonists with Weak Partial Agonists

When a weak partial agonist such as pentazocine is given to a patient also receiving a full agonist (eg, morphine), there is a risk of diminishing analgesia or even inducing a state of withdrawal; combining full agonist with partial agonist opioids should be avoided.

Use in Patients with Head Injuries

Carbon dioxide retention caused by respiratory depression results in cerebral vasodilation. In patients with elevated intracranial pressure, this may lead to lethal alterations in brain function.

Use during Pregnancy

In pregnant women who are chronically using opioids, the fetus may become physically dependent in utero and manifest withdrawal symptoms in the early postpartum period. A daily dose as small as 6 mg of heroin (or equivalent) taken by the mother will result in a mild withdrawal syndrome in the infant, and twice that much may result in severe signs and symptoms, including irritability, shrill crying, diarrhea, or even seizures. Recognition of the problem is aided by a careful history and physical examination. When withdrawal symptoms are judged to be relatively mild, treatment is aimed at control of these symptoms with such drugs as diazepam; with more severe withdrawal, camphorated tincture of opium (paregoric; 0.4 mg of morphine/mL) in an oral dose of 0.12–0.24

mL/kg is used. Oral doses of methadone (0.1–0.5 mg/kg) have also been used.

Use in Patients with Impaired Pulmonary Function

In patients with borderline respiratory reserve, the depressant properties of the opioid analgesics may lead to acute respiratory failure.

Use in Patients with Impaired Hepatic or Renal Function

Because morphine and its congeners are metabolized primarily in the liver, their use in patients in prehepatic coma may be questioned. Half-life is prolonged in patients with impaired renal function, and morphine and its active glucuronide metabolite, may accumulate; dosage can often be reduced in such patients.

Use in Patients with Endocrine Disease

Patients with adrenal insufficiency (Addison's disease) and those with hypothyroidism (myxedema) may have prolonged and exaggerated responses to opioids.

Drug Interactions

Because seriously ill or hospitalized patients may require a large number of drugs, there is always a possibility of drug interactions when the opioid analgesics are administered. Table 31–5 lists some of these drug interactions and the reasons for not combining the named drugs with opioids.

Table 31–5. Opioid Drug Interactions.	
Drug Group	Interaction With Opioids
Sedative-hypnotics	Increased central nervous system depression, particularly respiratory depression.
Antipsychotic tranquilizers	Increased sedation. Variable effectson respiratory depression. Accentuation of cardiovascular effects (antimuscarinic and α -blocking actions).
MAO inhibitors	Relative contraindication to all opioid analgesics because of the high incidence of hyperpyrexia; hypertension has also been reported.

MAO, monoamine oxidase.

Specific Agents

The following section describes the most important widely used opioid analgesics, along with features peculiar to specific agents. Data about doses approximately equivalent to 10 mg of intramuscular morphine, oral versus parenteral efficacy, duration of analgesia, and intrinsic activity (maximum efficacy) are presented in Table 31–2.

Strong Agonists

Phenanthrenes

Morphine, hydromorphone, and oxycodone are strong agonists useful in treating severe pain. These prototypic agents have been described in detail above. **Heroin** (diamorphine, diacetylmorphine) is potent and fast-acting, but its use is prohibited in the USA and Canada. In recent years, there has been considerable agitation to revive its use. However, double-blind studies have not supported the claim that heroin is more effective than morphine in relieving severe chronic pain, at least when given by the intramuscular route.

Phenylheptylamines

Methadone has undergone a dramatic revival as a potent and clinically useful analgesic. It can be administered by the oral, intravenous, subcutaneous, and rectal routes. It is well absorbed from the gastrointestinal tract and its bioavailability far exceeds that of oral morphine. Methadone is not only a potent μ -receptor agonist but its racemic mixture of d- and l-methadone isomers can block both NMDA receptors and monoaminergic reuptake. These nonopioid receptor properties may help explain its ability to relieve difficult-to-treat pain (neuropathic, cancer pain), especially when a previous trial of morphine has failed. In this regard, when analgesic tolerance or intolerable side effects have developed with the use of increasing doses of morphine or hydromorphone, "opioid rotation" to methadone has provided superior analgesia at 10–20% of the morphine-equivalent daily dose. In contrast to its use in suppressing symptoms of opioid withdrawal, use of methadone as an analgesic typically requires administration at intervals of at least every 8 hours. However, given methadone's highly variable pharmacokinetics and long half-life (25–52 hours), initial administration should be closely monitored to avoid potentially harmful side effects, such as respiratory depression.

Methadone is widely known for its use in the treatment of opioid abuse. Tolerance and physical dependence develop more slowly with methadone than with morphine. The withdrawal signs and symptoms occurring after abrupt discontinuance of methadone are milder, although more prolonged, than those of morphine. These properties make methadone a useful drug for detoxification and for maintenance of the chronic relapsing heroin addict.

For detoxification of a heroin-dependent addict, low doses of methadone (5–10 mg orally) are given two or three times daily for 2 or 3 days. Upon discontinuing methadone, the addict experiences a mild but endurable withdrawal syndrome.

For maintenance therapy of the opioid recidivist, tolerance to 50–100 mg/d of oral methadone may be deliberately produced; in this state, the addict experiences cross-tolerance to heroin that prevents most of the addiction-reinforcing effects of heroin. One rationale of maintenance programs is that blocking the reinforcement obtained from abuse of illicit opioids removes the drive to obtain them, thereby reducing criminal activity and making the addict more amenable to psychiatric and rehabilitative therapy. The pharmacologic basis for the use of methadone in maintenance programs is sound and the sociologic basis is rational, but some methadone programs fail because nonpharmacologic management is inadequate.

The concurrent administration of methadone to heroin addicts known to be recidivists has been questioned due to the increased risk of overdose death secondary to respiratory arrest. Buprenorphine, a partial μ -receptor agonist with long-acting properties, has been found to be effective in opioid detoxification and maintenance programs and is presumably associated with a lower risk of such overdose fatalities.

Phenylpiperidines

Meperidine and **fentanyl** are the most widely used agents in this family of synthetic opioids. Meperidine has significant antimuscarinic effects, which may be a contraindication if tachycardia would be a problem. It is also reported to have a negative inotropic action on the heart. The potential for producing seizures secondary to accumulation of normeperidine in patients receiving high doses of meperidine or with renal compromise must be considered. The fentanyl subgroup now includes **sufentanil**, **alfentanil**, and **remifentanil** in addition to the parent compound, fentanyl. These opioids differ mainly in their potency and biodisposition. Sufentanil is five to seven times more potent than fentanyl. Alfentanil is considerably less potent than fentanyl, acts more rapidly, and has a markedly shorter duration of action. Remifentanil is metabolized very rapidly by blood and nonspecific tissue esterases, making its pharmacokinetic and pharmacodynamic half-lives extremely short.

Morphinans

Levorphanol is a synthetic opioid analgesic closely resembling morphine in its action.

Mild to Moderate Agonists

Phenanthrenes

Codeine (Figure 31–1), **oxycodone**, **dihydrocodeine**, and **hydrocodone** are all somewhat less efficacious than morphine (they are partial agonists) or have adverse effects that limit the maximum tolerated dose when one attempts to achieve analgesia comparable to that of morphine. These compounds are rarely used alone but are combined in formulations containing aspirin or acetaminophen and other drugs.

Phenylheptylamines

Propoxyphene is chemically related to methadone but has low analgesic activity. Various studies have reported its potency at levels ranging from no better than placebo to half as potent as codeine, ie, 120 mg propoxyphene = 60 mg codeine. Its true potency probably lies somewhere between these extremes, and its analgesic effect is additive to that of an optimal dose of aspirin. However, its low efficacy makes it unsuitable, even in combination with aspirin, for severe pain. Although propoxyphene has a low abuse liability, the increasing incidence of deaths associated with its misuse has caused it to be scheduled as a controlled substance with low potential for abuse.

Phenylpiperidines

Diphenoxylate and its metabolite, **difenoxin**, are not used for analgesia but for the treatment of diarrhea. They are scheduled for minimal control (difenoxin is schedule IV, diphenoxylate schedule V; see inside front cover) because the likelihood of their abuse is remote. The poor solubility of the compounds limits their use for parenteral injection. As antidiarrheal drugs, they are used in combination with atropine. The atropine is added in a concentration too low to have a significant antidiarrheal effect but is presumed to further reduce the likelihood of abuse.

Loperamide is a phenylpiperidine derivative used to control diarrhea. Its potential for abuse is considered very low because of its limited access to the brain. It is therefore available without a prescription.

The usual dose with all of these antidiarrheal agents is two tablets to start and then one tablet after each diarrheal stool.

Opioids with Mixed Receptor Actions

Care should be taken not to administer any partial agonist or drug with mixed opioid receptor actions to patients receiving pure agonist drugs because of the unpredictability of both drugs' effects: reduction of analgesia or precipitation of an explosive abstinence syndrome may result.

Phenanthrenes

Nalbuphine is a strong κ -receptor *agonist* and a μ -receptor *antagonist*; it is given parenterally. At higher doses there seems to be a definite ceiling—not noted with morphine—to the respiratory depressant effect. Unfortunately, when respiratory depression does occur, it may be relatively resistant to naloxone reversal.

Buprenorphine is a potent and long-acting phenanthrene derivative that is a partial μ -receptor agonist. Its long duration of action is due to its slow dissociation from μ -receptors. This property renders its effects resistant to naloxone reversal. Its clinical applications are much like those of nalbuphine. In addition, studies continue to suggest that buprenorphine is as effective as methadone in the detoxification and maintenance of heroin abusers.

Morphinans

Butorphanol produces analgesia equivalent to nalbuphine and buprenorphine but appears to produce more sedation at equianalgesic doses. Butorphanol is considered to be predominantly a κ -agonist. However, it may also act as a partial agonist or antagonist at the μ -receptor.

Benzomorphans

Pentazocine is a κ -agonist with weak μ -antagonist or partial agonist properties. It is the oldest mixed agent available. It may be used orally or parenterally. However, because of its irritant properties, the injection of pentazocine subcutaneously is not recommended.

Dezocine is a compound structurally related to pentazocine. It has its highest affinity for μ -receptors and less interaction with κ -receptors. Although it is said to be equivalent in efficacy to morphine, its use is associated with the same problems observed with all opioids that have mixed receptor actions.

Miscellaneous

Tramadol is a central-acting analgesic whose mechanism of action is predominantly based on enhanced serotonergic neurotransmission. As such, its analgesic effectiveness can be blocked by coadministration of the serotonin (5-HT₃) receptor antagonist ondansetron. Tramadol also inhibits norepinephrine transporter function and is a weak μ -receptor agonist, since it is only partially antagonized by naloxone. The recommended dosage is 50–100 mg orally four times daily. Toxicity includes association with seizures; the drug is relatively contraindicated in patients with a history of epilepsy and for use with other drugs that lower the seizure threshold. Other side effects include nausea and dizziness, but these symptoms typically abate following several days of therapy. Surprisingly, no clinically relevant effects on respiration or the cardiovascular system have thus far been reported. Given the fact that the analgesic action of tramadol is largely independent of μ

receptor action, this agent may be useful in atypical pain such as chronic neuropathic pain.

Antitussives

As noted above, the opioid analgesics are among the most effective drugs available for the suppression of cough. This effect is often achieved at doses below those necessary to produce analgesia. The receptors involved in the antitussive effect appear to differ from those associated with the other actions of opioids. For example, the antitussive effect is also produced by stereoisomers of opioid molecules that are devoid of analgesic effects and addiction liability (see below).

The physiologic mechanism of cough is complex, and little is known about the specific mechanism of action of the opioid antitussive drugs. It is likely that both central and peripheral effects play a role.

The opioid derivatives most commonly used as antitussives are dextromethorphan, codeine, levopropoxyphene, and noscapine (levopropoxyphene and noscapine are not available in the USA). While these agents (other than codeine) are largely free of the adverse effects associated with the opioids, they should be used with caution in patients taking monoamine oxidase (MAO) inhibitors (see Table 31–5). Antitussive preparations usually also contain expectorants to thin and liquefy respiratory secretions.

Dextromethorphan is the dextrorotatory stereoisomer of a methylated derivative of levorphanol. It is purported to be free of addictive properties and produces less constipation than codeine. The usual antitussive dose is 15–30 mg three or four times daily. It is available in many over-the-counter products. Dextromethorphan has also been found to enhance the analgesic action of morphine and presumably other μ -receptor agonists.

Codeine, as noted above, has a useful antitussive action at doses lower than those required for analgesia. Thus, 15 mg is usually sufficient to relieve cough.

Levopropoxyphene is the stereoisomer of the weak opioid agonist dextropropoxyphene. It is devoid of opioid effects, although sedation has been described as a side effect. The usual antitussive dose is 50–100 mg every 4 hours.

The Opioid Antagonists

The pure opioid antagonist drugs **naloxone** (Figure 31–1), **naltrexone**, and **nalmefene** are morphine derivatives with bulkier substituents at the N₁₇ position. These agents have a relatively high affinity for μ -opioid binding sites. They have lower affinity for the other receptors but can also reverse agonists at δ and κ sites.

Pharmacokinetics

Naloxone has poor efficacy when given by the oral route and a short duration of action (1–2 hours) when given by injection. Metabolic disposition is chiefly by glucuronide conjugation like that of the agonist opioids with free hydroxyl groups. Naltrexone is well absorbed after oral administration but may undergo rapid first-pass metabolism. It has a half-life of 10 hours, and a single oral dose of 100 mg will block the effects of injected heroin for up to 48 hours. Nalmefene, the newest of these agents, is a derivative of naltrexone but is available only for intravenous administration. Like

naloxone, nalmefene is used for opioid overdose but has a longer half-life (8–10 hours).

Pharmacodynamics

When given in the absence of an agonist drug, these antagonists are almost inert at doses that produce marked antagonism of agonist effects.

When given intravenously to a morphine-treated subject, the antagonist will completely and dramatically reverse the opioid effects within 1–3 minutes. In individuals who are acutely depressed by an overdose of an opioid, the antagonist will effectively normalize respiration, level of consciousness, pupil size, bowel activity, and awareness of pain. In dependent subjects who appear normal while taking opioids, naloxone or naltrexone will almost instantaneously precipitate an abstinence syndrome, as described previously.

There is no tolerance to the antagonistic action of these agents, nor does withdrawal after chronic administration precipitate an abstinence syndrome.

Clinical Use

Naloxone is a pure antagonist and is preferred over older weak agonist-antagonist agents that had been used primarily as antagonists, eg, nalorphine and levallorphan.

The major application of naloxone is in the treatment of acute opioid overdose (see also Chapter 59: Management of the Poisoned Patient). *It is very important that the relatively short duration of action of naloxone be borne in mind, because a severely depressed patient may recover after a single dose of naloxone and appear normal, only to relapse into coma after 1–2 hours.*

The usual initial dose of naloxone is 0.1–0.4 mg intravenously for life-threatening respiratory and CNS depression. Treatment is with the same drug, 0.4–0.8 mg given intravenously, and repeated whenever necessary. In using naloxone in the severely opioid-depressed newborn, it is important to start with doses of 5–10 $\mu\text{g}/\text{kg}$ and to consider a second dose of up to a total of 25 $\mu\text{g}/\text{kg}$ if no response is noted.

Low-dose naloxone (0.04 mg) has an increasing role in the treatment of adverse effects that are commonly associated with the use of intravenous or epidural opioids. Careful titration of the naloxone dosage can often eliminate the itching, nausea, and vomiting while sparing the analgesia. Oral naloxone, and more recently developed nonabsorbable analogs of naloxone, have been shown to be efficacious in the treatment of opioid-induced ileus or constipation. The principal mechanism behind this selective therapeutic effect is believed to be local inhibition of μ receptors in the gut with minimal systemic absorption.

Because of its long duration of action, naltrexone has been proposed as a maintenance drug for addicts in treatment programs. A single dose given on alternate days blocks virtually all of the effects of a dose of heroin. It might be predicted that this approach to rehabilitation would not be popular with a large percentage of drug users unless they are motivated to become drug-free. There is evidence that naltrexone decreases craving for alcohol in chronic alcoholics, and it has been approved by the US Food and Drug Administration for this purpose (see Chapter 23: The Alcohols).

Preparations Available¹

Analgesic Opioids

Alfentanil (Alfenta)

Parenteral: 0.5 mg/mL for injection

Buprenorphine (Buprenex, others)

Oral: 2, 8 mg sublingual tablets

Parenteral: 0.3 mg/mL for injection

Butorphanol (generic, Stadol)

Parenteral: 1, 2 mg/mL for injection

Nasal (generic, Stadol NS): 10 mg/mL nasal spray

Codeine (sulfate or phosphate) (generic)

Oral: 15, 30, 60 mg tablets, 15 mg/5 mL solution

Parenteral: 30, 60 mg/mL for injection

Dezocine (Dalgan)

Parenteral: 5, 10, 15 mg/mL for injection

Fentanyl

Parenteral (generic, Sublimaze): 50 mg/mL for injection

Fentanyl Transdermal System (Duragesic): 25, 50, 75, 100 μ g/h delivery

Fentanyl Oralet: 100, 200, 300, 400 μ g oral lozenge

Fentanyl Actiq: 200, 400, 600, 800, 1200, 1600 μ g lozenge on a stick

Hydromorphone (generic, Dilaudid)

Oral: 1, 2, 3, 4, 8 mg tablets; 5 mg/mL liquid

Parenteral: 1, 2, 4, 10 mg/mL for injection

Rectal: 3 mg suppositories

Levomethadyl acetate (Orlaam)

Oral: 10 mg/mL solution. Note: Approved only for the treatment of narcotic addiction.

Levorphanol (generic, Levo-Dromoran)

Oral: 2 mg tablets

Parenteral: 2 mg/mL for injection

Meperidine (generic, Demerol)

Oral: 50, 100 mg tablets; 50 mg/5 mL syrup

Parenteral: 25, 50, 75, 100 mg per dose for injection

Methadone (generic, Dolophine)

Oral: 5, 10 mg tablets; 40 mg dispersible tablets; 1, 2, 10 mg/mL solutions

Parenteral: 10 mg/mL for injection

Morphine sulfate (generic, others)

Oral: 10, 15, 30 mg tablets; 15, 30 mg capsules; 10, 20, 100 mg/5 mL solution

Oral sustained-release tablets (MS-Contin, others): 15, 30, 60, 100, 200 mg tablets);

Oral sustained-release capsules (Kadian): 20, 50, 100 mg capsules

Parenteral: 0.5, 1, 2, 4, 5, 8, 10, 15, 25, 50 mg/mL for injection

Rectal: 5, 10, 20, 30 mg suppositories

Nalbuphine (generic, Nubain)

Parenteral: 10, 20 mg/mL for injection

Oxycodone (generic)

Oral: 5 mg tablets, capsules; 1, 20 mg/mL solutions

Oral sustained-release (OxyContin): 10, 20, 40, 80, 100 mg tablets

Oxymorphone (Numorphan)

Parenteral: 1, 1.5 mg/mL for injection

Rectal: 5 mg suppositories

Pentazocine (Talwin)

Oral: See combinations.

Parenteral: 30 mg/mL for injection

Propoxyphene (generic, Darvon Pulvules, others)

Oral: 65 mg capsules, 100 mg tablets. Note: This product is not recommended.

Remifentanil (Ultiva)

Parenteral: 3, 5, 10 mg powder for reconstitution for injection

Sufentanil (generic, Sufenta)

Parenteral: 50 µg/mL for injection

Tramadol (Ultram)

Oral: 50 mg tablets

Analgesic Combinations²

Codeine/acetaminophen (generic, Tylenol w/ Codeine, others)

Oral: 15, 30, 60 mg codeine plus 300 or 325 mg acetaminophen tablets or capsules; 12 mg codeine plus 120 mg acetaminophen tablets

Codeine/aspirin (generic, Empirin Compound, others)

Oral: 30, 60 mg codeine plus 325 mg aspirin tablets

Hydrocodone/acetaminophen (generic, Norco, Vicodin, Lortab, others)

Oral: 2.5, 5, 7.5, 10 mg hydrocodone plus 500 or 650 mg acetaminophen tablets

Hydrocodone/ibuprofen (Vicoprofen)

Oral: 7.5 mg hydrocodone plus 200 mg ibuprofen

Oxycodone/acetaminophen (generic, Percocet, Tylox, others). *Note:* High-dose acetaminophen has potential for hepatic toxicity with repeated use.

Oral: 5 mg oxycodone plus 325 or 500 mg acetaminophen tablets

Oxycodone/aspirin (generic, Percodan)

Oral: 4.9 mg oxycodone plus 325 mg aspirin

Propoxyphene/aspirin or acetaminophen (Darvon Compound-65, others). *Note:* This product is not recommended.

Oral: 65 mg propoxyphene plus 389 mg aspirin plus 32.4 mg caffeine; 50, 65, 100 mg propoxyphene plus 325 or 650 mg acetaminophen.

Opioid Antagonists

Nalmefene (Revex)

Parenteral: 0.1, 1 mg/mL for injection

Naloxone (Narcan, various)

Parenteral: 0.4, 1 mg/mL; 0.02 mg/mL (for neonatal use) for injection

Naltrexone (ReVia, Depade)

Oral: 50 mg tablets

Antitussives

Codeine (generic, others)

Oral: 15, 30, 60 mg tablets; constituent of many proprietary syrups²

Dextromethorphan (generic, Benylin DM, Delsym, others)

Oral: 2.5, 5, 7.5, 15 mg lozenges; 3.5, 5, 7.5, 10, 15 mg/5 mL syrup; 30 mg sustained-action liquid; constituent of many proprietary syrups¹

¹Antidiarrheal opioid preparations are listed in Chapter 63: Drugs Used in the Treatment of Gastrointestinal Diseases.

² Dozens of combination products are available; only a few of the most commonly prescribed ones are listed here. Codeine combination products available in several strengths are usually denoted No. 2 (15 mg codeine), No. 3 (30 mg codeine), and No. 4 (60 mg codeine). Prescribers should be aware of the possible danger of renal damage with acetaminophen, aspirin, and nonsteroidal anti-inflammatory drugs contained in these analgesic combinations.

Chapter 32. Drugs of Abuse

Katzung PHARMACOLOGY, 9e > Section V. Drugs That Act in the Central Nervous System > Chapter 32. Drugs of Abuse >

Drugs of Abuse: Introduction

The term "drug abuse" is unfortunate because it connotes social disapproval and may have different meanings to different people. One must also distinguish drug abuse from drug misuse. Abuse of a drug might be construed as any use of a drug for nonmedical purposes, usually for altering consciousness but also for bodybuilding. To misuse a drug might be to take it for the wrong indication, in the wrong dosage, or for too long a period, to mention only a few obvious examples. In the context of drug abuse, the drug itself is of less importance than the pattern of use. For example, taking 50 mg of diazepam to heighten the effect of a daily dose of methadone is an abuse

of diazepam. On the other hand, taking the same excessive daily dose of the drug but only for its anxiolytic effect is misusing diazepam.

Dependence is a biologic phenomenon often associated with "drug abuse." **Psychologic dependence** is manifested by compulsive drug-seeking behavior in which the individual uses the drug repetitively for personal satisfaction, often in the face of known risks to health. Cigarette smoking is an example. Deprivation of the agent for a short period of time typically results in a strong desire or *craving* for it. **Physiologic dependence** is present when withdrawal of the drug produces symptoms and signs that are frequently the opposite of those sought by the user. It has been suggested that the body adjusts to a new level of homeostasis during the period of drug use and reacts in opposite fashion when the new equilibrium is disturbed. Alcohol withdrawal syndrome is perhaps the best-known example, but milder degrees of withdrawal may be observed in people who drink a lot of coffee every day. Psychologic dependence almost always precedes physiologic dependence but does not inevitably lead to it. **Addiction** is usually taken to mean a state of physiologic and psychologic dependence, but the word is too imprecise for scientific usage.

Tolerance signifies a decreased response to the effects of the drug, necessitating ever larger doses to achieve the same effect. Tolerance is closely associated with the phenomenon of physiologic dependence. It is largely due to compensatory responses that mitigate the drug's pharmacodynamic action. **Metabolic tolerance** due to increased disposition of the drug after chronic use is occasionally reported. **Behavioral tolerance**, an ability to compensate for the drug's effects, is another possible mechanism of tolerance. **Functional tolerance**, which may be the most common type, is due to compensatory changes in receptors, effector enzymes, or membrane actions of the drug.

A number of experimental techniques have been devised to predict the ability of a drug to produce dependence and to assess its likelihood for abuse. Most of these techniques employ self-administration of the drug by animals. The rates of reinforcement can be altered so as to make the animal work harder for each dose of drug, providing a semiquantitative measure as well. Comparisons are made against a standard drug in the class, eg, morphine among the opioids. Withdrawal of dependent animals from drugs assesses the nature of the withdrawal syndrome and can be used to test drugs that might cross-substitute for the standard drug. Most agents with significant potential for psychologic or physiologic dependence can be readily detected by these techniques. The actual abuse liability, however, is difficult to predict, since many variables enter into the decision to abuse drugs.

Cultural Considerations

Each society accepts certain drugs as licit and condemns others as illicit. In the USA and most of Western Europe, the "national drugs" are caffeine, nicotine, and alcohol. In the Middle East, cannabis may be added to the list of licit drugs, whereas alcohol is forbidden. Among certain Native American tribes, peyote, a hallucinogen, may be used licitly for religious purposes. In the Andes of South America, cocaine is used to allay hunger and enhance the ability to perform arduous work at high altitudes. Thus, which drugs are licit or illicit or—to use other terminology—"used" or "abused" is a social judgment. A major social cost of relegating any substance to the illicit category is the criminal activity that often results, since purveyors of the substance are lured into illegal traffic by the opportunity to make large profits, while dependent users may resort to robbery, prostitution, and other types of antisocial behavior to support their habits. A major social and medical cost associated with *parenteral* abuse of drugs is the high incidence of transmission of HIV and hepatitis virus through the sharing of needles.

Current attitudes in the USA to drugs of this type are reflected in the Schedule of Controlled Drugs. This schedule is quite similar to those published by international control bodies. Such schedules affect principally ethical and law-abiding manufacturers and prescribers of the drugs and have little deterrent effect on illicit manufacturers or suppliers. Such schedules have been circumvented by the synthesis of "designer" drugs that make small modifications of the chemical structures of drugs with little or no change in their pharmacodynamic actions. Thus, schedules must constantly be revised to include these attempts to produce compounds not currently listed.

Because of the high social cost of drug abuse, many countries attempt to interdict their entry across borders. While surveys may indicate that the use of drugs such as cocaine and marijuana is increasing or decreasing, it is difficult to attribute such changes to law enforcement policies. Little progress has been made in decreasing the demand for illicit drugs. Some persons have argued that the only reasonable solution to the problem is legalization of the drugs. Such proposals are obviously highly controversial.

Any use of mind-altering drugs is based on a complicated interplay between three factors: the user, the setting in which the drug is taken, and the drug. Thus, the personality of the user and the setting may have a strong influence on what the user experiences. Nonetheless, it is usually possible to identify a pharmacologic "core" of drug effects that will be experienced by almost anyone under almost any circumstances if the dosage is adequate.

Schedule of Controlled Drugs¹

SCHEDULE I

(All nonresearch use illegal under federal law.)

Flunitrazepam (Rohypnol)

Narcotics: Heroin and many nonmarketed synthetic narcotics

Hallucinogens:

LSD

MDA, STP, DMT, DET, mescaline, peyote, bufotenine, ibogaine, psilocybin, hencyclidine (PCP; veterinary drug only)

Marijuana

Methaqualone

SCHEDULE II

(No telephone prescriptions, no refills.)²

Opioids:

Opium

Opium alkaloids and derived phenanthrene alkaloids: morphine, hydromorphone (Dilaudid), oxymorphone (Numorphan), oxycodone (dihydroxycodone, a component of Percodan, Percocet, Roxicodone, Tylox)

Designated synthetic drugs: levomethadyl (Orlaam), meperidine (Demerol), methadone, levorphanol (Levo-Dromoran), fentanyl (Sublimaze, Duragesic, Actiq), alphaprodine, alfentanil (Alfenta), sufentanil (Sufenta), remifentanil (Ultiva)

Stimulants:

Coca leaves and cocaine

Amphetamine

Amphetamine complex (Biphetamine)

Amphetamine salts (Adderall)

Dextroamphetamine (Dexedrine)

Methamphetamine (Desoxyn)

Phenmetrazine (Preludin)

Methylphenidate (Ritalin)

Above in mixtures with other controlled or uncontrolled drugs

Depressants:

Amobarbital (Amytal)

Pentobarbital (Nembutal)

Secobarbital (Seconal)

Mixtures of above (eg, Tuinal)

SCHEDULE III

(Prescription must be rewritten after 6 months or five refills.)

Opioids:

Buprenorphine (Buprenex, Subutex, Suboxone)

The following opioids in combination with one or more active nonopioid ingredients, provided the amount does not exceed that shown:

Codeine and dihydrocodeine: not to exceed 1800 mg/dL or 90 mg/tablet or other dosage unit

Dihydrocodeinone (hydrocodone in Hycodan, Vicodin, and Lortab): not to exceed 300 mg/dL or 15 mg/tablet

Opium: 500 mg/dL or 25 mg/5 mL or other dosage unit (paregoric)

Stimulants:

Benzphetamine (Didrex)

Phendimetrazine (Plegine)

Depressants:

Schedule II barbiturates in mixtures with noncontrolled drugs or in suppository dosage form

Butabarbital (Butisol)

Ketamine (Kentalar)

Thiopental (Pentothal)

Cannabinoids:

Dronabinol (Marinol)

Anabolic Steroids:

Fluoxymesterone (Halotestin)

Methyltestosterone (Android, Testred)

Nandrolone decanoate (Dec-Durabolin)

Nandrolone phenpropionate (Durabolin)

Oxandrolone (Oxandrin)

Oxymetholone (Androl-50)

Stanozolol (Winstrol)

Testolactone (Teslac)

Testosterone and its esters

SCHEDULE IV

(Prescription must be rewritten after 6 months or five refills; differs from Schedule III in penalties for illegal possession.)

Opioids:

Butorphanol (Stadol)

Difenoxin (Motofen)

Pentazocine (Talwin)

Propoxyphene (Darvon)

Stimulants:

Diethylpropion (Tenuate)

Mazindol (Sanorex)

Modafinil (Provigil)

Phentermine (Ionamin)
Pemoline (Cylert)
Sibutramine (Merida)

Depressants:

Benzodiazepines
Alprazolam (Xanax)
Chlordiazepoxide (Librium)
Clonazepam (Klonopin)
Clorazepate (Tranxene)
Diazepam (Valium)
Estazolam (ProSom)
Flurazepam (Dalmane)
Halazepam (Paxipam)
Lorazepam (Ativan)
Midazolam (Versed)
Oxazepam (Serax)
Prazepam (Centrax)
Quazepam (Doral)
Temazepam (Restoril)
Triazolam (Halcion)
Chloral hydrate
Ethchlorvynol (Placidyl)
Meprobamate (Equanil, Miltown, etc)
Mephobarbital (Mebaral)
Methohexital (Brevital)
Paraldehyde
Phenobarbital
Zaleplon (Sonata)
Zolpidem (Ambien)

SCHEDULE V

(As any other nonopioid prescription drug; may also be dispensed without prescription unless additional state regulations apply.)

Opioids:

Diphenoxylate (not more than 2.5 mg and not less than 0.025 mg of atropine per dosage unit, as in Lomotil)

The following drugs in combination with other active nonopioid ingredients and provided the amount per 100 mL or 100 g does not exceed that shown:

Codeine: 200 mg

Dihydrocodeine: 100 mg

¹See <http://www.dea.gov/pubs/scheduling.html> for additional details.

²Emergency prescriptions may be telephoned if followed within 7 days by a valid written prescription annotated to indicate it was previously placed by telephone.

Neurobiology of Abused Drugs

During the last 20 years, substantial progress has been made in elucidating the neurobiology of abused drugs and their effects not only on neurotransmitter receptors and reuptake carriers but also on the cascade of second, third, and fourth intracellular messenger systems (Nestler, 2001). Many abused drugs act through G protein-linked receptors such as the opioid, cannabinoid, and dopamine

receptors. These G proteins frequently are coupled to the cyclic adenosine monophosphate (cAMP) second messenger system, and through phosphorylation of various intracellular proteins a cascade of changes occurs in the cytoplasm and nucleus. Immediate early genes such as *c-fos* and *c-jun* are activated followed by regulation of other genes with more sustained effects on protein transcription that may lead to the observed down-regulation of receptor numbers and up-regulation of second messenger systems. These effects on DNA are also reflective of genetic risk factors for drug dependence; it is estimated that up to 50% of the risk for dependence is due to polygenic inheritance. Extensive studies are underway for alcohol, opioids, and stimulants including nicotine in order to identify specific genes associated with this risk.

For each of the classes of abused drugs a complex molecular biology has been described, including specific neuroanatomic substrates linked to different neurotransmitters during acute intoxication and during withdrawal after dependence is established. Acute reinforcing effects of abused drugs are clearly a function of specific receptor binding but are also related to the *rate of change* in synaptic levels of dopamine, a key neurotransmitter involved in reinforcement in the nucleus accumbens. The chronic effects of abused drugs include tolerance and sensitization as well as the neurobiologic substrates for withdrawal symptoms. Much has been learned about these neurobiologic substrates for withdrawal in opioid dependence, including the activation of adrenergic brain systems such as the locus ceruleus during withdrawal. The latter findings have important treatment implications, such as the use of clonidine for opioid withdrawal.

Other drug classes, such as the benzodiazepines, have specific receptors on chloride channels associated with the neurotransmitter γ -aminobutyric acid (GABA), while other abused drugs, such as phencyclidine, bind to sites on excitatory amino acid receptor-channel complexes. The functions of other receptors that bind abused drugs such as opioid and cannabinoid receptors also have been clarified with the identification of endogenous ligands for these receptors, such as β -endorphin for the μ -opioid receptor and anandamide for the cannabinoid receptor. These binding sites appear to be critical for the acute effects of these abused drugs, and substantial progress has been made in understanding the neurotransmitter basis for reinforcement of most abused drugs including recent work with the inhalant toluene (Riegel and French, 2002). The dopamine neurons connecting the ventral tegmental area to the nucleus accumbens have been considered the major reinforcement pathway for a wide range of abused drugs, but their role in reinforcement has been most clearly established for cocaine and amphetamine and less clearly for other drugs, particularly inhalants and several hallucinogens.

The neurobiologic findings in animal models have been increasingly confirmed in human studies. These human studies include pharmacologic challenges with neuroendocrine and behavioral outcomes, assessments of endogenous ligands in cerebrospinal fluid from drug-dependent patients, and neuroimaging studies, particularly neuroreceptor imaging. Available radioligands have permitted examination in humans of dopamine receptors and transporters, opioid receptors, and functional brain activity based on blood flow or glucose utilization. These receptor-neuroimaging studies have demonstrated that chronic abuse of drugs which can produce tolerance, dependence, and sensitization may have associated effects on receptor numbers (eg, dopamine D₂ receptors decrease in cocaine abusers) and on transporter numbers (eg, dopamine transporters increase in cocaine abusers). Blood flow and glucose utilization studies have shown that acute drug use is associated with substantial reductions in cerebral metabolic activity and that the rate of change is a correlate of the reinforcing effects of abused drugs.

In the following sections, we review current knowledge about the molecular neurobiology of each class of abused drugs and their clinical pharmacology.

Opioids

History

The nepenthe (Gk "free from sorrow") mentioned in the *Odyssey* probably contained opium. Opium smoking was widely practiced in China and the Near East until recently. Isolation of active opium alkaloids and the introduction of the hypodermic needle, allowing parenteral use of morphine, increased opioid use in the West. The first of several "epidemics" of opioid use in the USA followed the Civil War. About 4% of adults in the USA used opiates regularly during the postbellum period. By the 1900s, the number had dropped to about 1 in 400 people in the USA, but the problem was still considered serious enough to justify passage of the Harrison Narcotic Act just before World War I. A new epidemic of opioid use started around 1964 and has continued unabated ever since. While fear of AIDS has reduced intravenous use of heroin, recent increases in its purity have led to markedly increased intranasal use. Present estimates are that the number of opioid-dependent people in the USA has stabilized at around 750,000.

Chemistry & Pharmacology

The most commonly abused drugs in this group are heroin, morphine, oxycodone, and—among health professionals—meperidine. The chemistry and general pharmacology of these agents are presented in Chapter 31: Opioid Analgesics & Antagonists.

Tolerance to the mental effects of opioids develops with long-term use. The need for ever-increasing amounts of drugs to sustain the desired euphoriant effects—as well as to avoid the discomfort of withdrawal—has the expected consequence of strongly reinforcing dependence once it has started. The role of endogenous opioid peptides in opioid dependence is uncertain.

Clinical Aspects

Intravenous administration is routine not only because it is the most efficient route but also because it produces a bolus of high concentration of drug that reaches the brain to produce a "rush," followed by euphoria, a feeling of tranquility, and sleepiness ("the nod"). Heroin produces effects that last 3–5 hours, and several doses a day are required to forestall manifestations of withdrawal in dependent persons. Symptoms of opioid withdrawal begin 8–10 hours after the last dose. Many of these symptoms resemble those of increased activity of the autonomic nervous system. Lacrimation, rhinorrhea, yawning, and sweating appear first. Restless sleep followed by weakness, chills, gooseflesh ("cold turkey"), nausea and vomiting, muscle aches, and involuntary movements ("kicking the habit"), hyperpnea, hyperthermia, and hypertension occur in later stages of the withdrawal syndrome. The acute course of withdrawal may last 7–10 days. A secondary phase of protracted abstinence lasts for 26–30 weeks and is characterized by hypotension, bradycardia, hypothermia, mydriasis, and decreased responsiveness of the respiratory center to carbon dioxide.

Heroin users in particular tend to be polydrug users, also using alcohol, sedatives, cannabinoids, and stimulants. None of these other drugs serve as substitutes for opioids, but they have desired additive effects. One needs to be sure that the person undergoing a withdrawal reaction is not also withdrawing from alcohol or other sedatives, which might be more dangerous and more difficult to manage.

Besides the ever-present risk of fatal overdose, hepatitis B and AIDS are among the many potential complications of sharing contaminated hypodermic syringes. Bacterial infections lead to septic complications such as meningitis, osteomyelitis, and abscesses in various organs. Attempts to illicitly manufacture meperidine have resulted in the highly specific neurotoxin 1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine (MPTP), which produces parkinsonism in users (see Chapter 28: Pharmacologic Management of Parkinsonism & Other Movement Disorders).

Treatment

Treatment of acute overdoses of opioids can be lifesaving and is described in Chapters 31 and 59. In long-term treatment of opioid-dependent persons, pharmacologic and psychosocial approaches are often combined. Chronic users tend to prefer pharmacologic approaches; those with shorter histories of drug abuse are more amenable to detoxification and psychosocial interventions.

Pharmacologic treatment is most often used for detoxification. The principles of detoxification are the same for all drugs: to substitute a longer-acting, orally active, pharmacologically equivalent drug for the abused drug, stabilize the patient on that drug, and then gradually withdraw the substituted drug. **Methadone** is admirably suited for such use in opioid-dependent persons. **Clonidine**, a centrally acting sympatholytic agent, has also been used for detoxification. By reducing central sympathetic outflow, clonidine mitigates many of the signs of sympathetic overactivity. Clonidine has no narcotic action and is not addictive. Lofexidine, a clonidine analog with less hypotensive effect, is being developed for use.

While it is easy to detoxify patients, the recidivism rate (return to abuse of the agent) is high. Methadone maintenance therapy, which substitutes a long-acting orally active opioid for heroin, has been effective in some settings. A single dose can be given each day. Methadone saturates the opioid receptors and prevents the desired sudden onset of central nervous system effects normally produced by intravenous administration of additional opiates. An even longer-acting methadone analog, **L-acetylmethadol**, allows three times a week rather than daily dosing and reduced abuse potential, but its association with sudden cardiac death due to prolonged QT arrhythmias has made its use uncommon. Another candidate drug for use in this setting is buprenorphine, a partial opioid agonist, that can be given once daily or even less often at sublingual doses of 4–32 mg daily depending on the patient. The lower doses are useful for detoxification from heroin, while the higher doses are for longer maintenance treatment. Treatment in an office-based primary care setting is a potential advantage of this agent over methadone (Kosten, 2002).

Use of a narcotic antagonist is a rational alternative to the above agonist-based therapies because blocking the action of self-administered opioids should eventually extinguish the habit, but this therapy is poorly accepted by patients. Naltrexone, a long-acting orally active pure opioid antagonist, can be given three times a week at doses of 100–150 mg and a depot form for monthly administration is being developed. Because it is an antagonist, the patient must first be detoxified from opioid dependence before starting naltrexone.

Psychosocial approaches include drug-free residential communities, which use peer group pressures, emphasizing confrontation and discussion.

Barbiturates, Other Sedative-Hypnotics, & Ghb

History

Ethanol is the sedative-hypnotic with the longest history of both use and abuse; it is discussed in Chapter 23: The Alcohols. **Barbiturates** were introduced in 1903; they have been largely replaced in medical practice by newer agents, especially **benzodiazepines** in the 1960s (see Chapter 22: Sedative-Hypnotic Drugs). Short-acting members of the sedative-hypnotic group are widely abused and the most recent addition to this abused group is **gamma-hydroxybutyric acid (GHB)**.

Chemistry & Pharmacology

The chemical relationships among this class of drugs are reviewed in Chapter 22: Sedative-Hypnotic Drugs. Depending on the dose, these drugs produce sedation, hypnosis, anesthesia, coma, and death. Both barbiturates and benzodiazepines can be classified pharmacokinetically into short- and long-acting compounds; GHB is relatively short-acting. Most abuse involves short-acting drugs, eg, secobarbital or pentobarbital sodium, and not long-acting ones, eg, phenobarbital. Drugs with half-lives in the range of 8–24 hours produce a rapidly evolving, severe withdrawal syndrome; those with longer half-lives, eg, 48–96 hours, produce a withdrawal syndrome that is slower in onset and less severe but longer in duration. Drugs with half-lives longer than 96 hours usually have a built-in tapering-off action that reduces the possibility of withdrawal reactions.

Clinical Aspects

Although statistics on alcoholism are extensive, no one knows how many persons are dependent on prescription sedatives. However, physiologic dependence has been relatively rare and usually occurs following long-term treatment with doses of 40 mg/d or more of diazepam or its equivalent. These abusers often are codependent on other drugs such as opioids, alcohol, or stimulants. "Therapeutic dose dependence" at doses of 15–30 mg/d of diazepam may be characterized by weight loss, changes in perception, paresthesias, and headache.

Finally, very rapid onset benzodiazepines have been widely reported as a means of "date rape," by using a small tasteless dose of the drug to make the victim incapable of protecting herself (or himself). This produces intoxication but not dependence. The drug most commonly used in this situation has been **flunitrazepam** (Rohypnol, "roofies," not available in the USA) and more recently GHB. The amnesia-producing effects of the benzodiazepines (see Chapter 22: Sedative-Hypnotic Drugs) make the victim unable to describe the events after she or he has recovered.

As these drugs are usually taken orally and the tablets or capsules are consistent in drug content, inadvertent fatal overdoses of single agents are rare. Tolerance may develop to the sedative effect but not to the respiratory depressant effect. Thus, if these drugs are used with other respiratory depressants, eg, large amounts of alcohol or opioids, fatalities can occur.

The withdrawal syndrome from sedatives is almost identical to that from alcohol and includes anxiety, tremors, twitches, and nausea and vomiting. In the case of long-acting drugs, symptoms may not appear for 2–3 days, and initial symptoms may suggest a recrudescence of those originally treated (nervousness, anxiety). Only by the fourth or fifth day can one be sure that a withdrawal reaction is under way. Convulsions are a late manifestation when they do occur—often not until the eighth or ninth day. Following this, the syndrome subsides. Severe cases are associated with delirium, hallucinations, and other psychosis-like manifestations.

Treatment

If short-acting drugs have been abused, chlordiazepoxide or phenobarbital is substituted as the pharmacologically equivalent agent. If long-acting drugs have been used, the same drug may be continued. The patient is stabilized on whatever dose is required to cause signs and symptoms to abate, and the drug is then gradually withdrawn. The rate of decrement may be 15–25% of the daily dose early in treatment, with later decrements of 5–10%. Complete detoxification can usually be achieved in less than 2 weeks.

No specific treatment programs have been developed for prescription sedative abusers. The problem is so often complicated by abuse of other drugs that it may be more expeditious to enroll the patient in a program designed for alcoholics or opiate-dependent persons. Patients with psychiatric disorders that can be defined, especially those with depression, may be treated with drug therapy specific for the underlying disorder.

Katzung PHARMACOLOGY, 9e > Section V. Drugs That Act in the Central Nervous System > Chapter 32. Drugs of Abuse >

Stimulants

History

In this section, caffeine is discussed only briefly and the focus is on other stimulants that produce psychiatric disorders. **Caffeine** can lead to a withdrawal syndrome characterized by lethargy, irritability, and headache, but withdrawal appears to occur in less than 3% of regular coffee drinkers. Moreover, the morbidity associated with caffeine overdose, which can include disturbing effects on sleep and heart rhythm, is much less than the morbidity associated with other stimulants.

Nicotine is one of the most widely used licit drugs because it is heavily promoted and produces powerful psychologic and physical dependence. About 28% of adults in the USA still smoke cigarettes because they have become dependent on nicotine. The use of smokeless tobacco products (eg, snuff, chewing tobacco) has increased in adolescents. Deaths directly attributable to smoking account for 20% of all deaths and 30% of cancer deaths in the USA. It is estimated that about 90% of cases of chronic obstructive pulmonary disease in the USA are due to smoking. **Cocaine** is a plant product that has been used for at least 1200 years in the custom of chewing coca leaves by natives of the South American Andes. In contrast, **amphetamine** was synthesized in the late 1920s and has a large number of analogs including **methylphenidate** (Ritalin) and **methylenedioxymethamphetamine** (MDMA, "ecstasy"). A closely related natural alkaloid, **cathinone**, is found in **khat**, a plant that produces effects indistinguishable from those of the amphetamines.

Chemistry & Pharmacology

Despite their similar behavioral effects, caffeine, nicotine, cocaine, and amphetamine have very different structures and sites of action in the brain. Caffeine, a methylxanthine compound, appears to exert its central actions (and perhaps some of its peripheral ones as well) by blocking adenosine receptors. Because caffeine does not act on the dopaminergic brain structures related to reward and addiction, its abuse and dependence potential are quite small. As noted in the above section Neurobiology of Abused Drugs, dopamine is very important in the reward system of the brain; its increase probably accounts for the high dependence potential of cocaine. Cocaine binds to the dopamine reuptake transporter in the central nervous system, effectively inhibiting reuptake of dopamine as well as norepinephrine. Amphetamines probably act mainly by increasing release of catecholaminergic neurotransmitters, including dopamine, by reversal of the vesicular transporter.

A useful model of the action of these two drugs in the reward centers of the CNS is shown in Figure 32–1. Cocaine reduces reuptake of dopamine into the neuron by inhibiting the dopamine reuptake transporter. Amphetamine causes the intracellular release of dopamine within the terminal and reverses the transporter direction so that dopamine is released into the synapse by reverse transport rather than ordinary exocytosis. In addition, amphetamine inhibits intracellular MAO metabolism of dopamine. Note that both drugs result in an increase in the concentration of dopamine in the synapse.

Figure 32–1.

A model for the action of cocaine and amphetamine at a dopaminergic synapse in the central nervous system. Cocaine (right side) blocks the dopamine reuptake transporter (DAT). Amphetamine (left side) has several effects. It enters the nerve ending via reverse transport by the DAT and displaces dopamine (DA) from vesicles by altering their pH. It also inhibits dopamine metabolism by MAO in the nerve ending. The increased intraneuronal dopamine causes reversal of the DAT and dopamine floods into the synapse.

Clinical Aspects

One common pattern of amphetamine or cocaine abuse is called a "run." Repeated smoked or intravenous injections are self-administered to obtain a "rush"—an orgasm-like reaction—followed by a feeling of mental alertness and marked euphoria. When free base cocaine is smoked, entry through the lungs is almost as fast as by intravenous injection, so that effects are more accentuated

than when the drug is snorted (Figure 32–2). Because the plasma half-life of cocaine is short, effects following a single dose persist only for an hour or so and repeated dosing may occur every 30 minutes. Because tolerance develops quickly, abusers may take monumental doses compared with those used medically, eg, as anorexiant. Total daily amphetamine doses as high as 4000 mg have been reported. After several days of such spree use, subjects may enter a paranoid schizophrenia-like state. Typically, delusions that bugs are crawling under their skin develop, which leads to scratching and characteristic discrete excoriations. Finally, the spree is terminated by exhaustion from lack of sleep and lack of food, followed by a withdrawal syndrome. A typical pattern of withdrawal includes a ravenous appetite, exhaustion, and mental depression. This syndrome may last for several days after the drug is withdrawn.

Figure 32–2.

Comparison of blood concentrations achieved when cocaine is administered by different routes. Time to peak is nearly as fast by smoking as by intravenous injection. (Modified and reproduced, with permission, from Jones RT: The pharmacology of cocaine smoking in humans. In: *Research Findings on Smoking of Abused Substances*. National Institute on Drug Abuse Research Monograph 99. Chiang CN, Hawks RL [editors]. US Government Printing Office, 1990.)

Besides the paranoid psychosis associated with chronic use of amphetamines, a specific lesion associated with chronic amphetamine use is necrotizing arteritis, which may involve many small and medium-sized arteries and lead to fatal brain hemorrhage or renal failure. Overdoses of amphetamines are rarely fatal; they can usually be managed by sedating the patient with benzodiazepines.

Overdoses of cocaine are often rapidly fatal, victims dying within minutes from arrhythmias, seizures, or respiratory depression. Those who survive for 3 hours usually recover fully. Intravenous administration of diazepam, propranolol, or calcium channel-blocking drugs may be the best

treatment. The local anesthetic action of cocaine contributes to the production of seizures. The powerful vasoconstrictive action of cocaine has led to a significant number of patients with severe acute hypertensive episodes resulting in myocardial infarcts and strokes. This vasoconstrictive effect may also contribute to the multiple brain perfusion defects that have been described using single photon emission computed tomography (SPECT) blood flow imaging in cocaine abusers (Kosten, 1998). Finally, an epidemic of "cocaine babies" born to mothers who are using cocaine heavily has posed a major new challenge to health care facilities in the inner cities (Mayes, 1999). There are clear-cut deleterious effects on the pregnancy, with increased fetal morbidity and mortality as well as early childhood impairment in learning and attention.

Treatment

Subjects with residual emotional disorders, either schizophreniform psychosis or mental depression, may require treatment with antipsychotic or antidepressant drugs during weaning from stimulants. Dopamine agonists have been suggested to mitigate withdrawal from cocaine, reduce craving during abstinence, and facilitate abstinence, but neither these nor other agents have shown reliable efficacy. Depression occurs in up to 40% of stimulant-dependent patients, and antidepressants may be helpful for relapse prevention.

Nicotine dependence may respond to replacement therapy with either nicotine gum or transdermal patches, and detoxification from nicotine dependence has been described using clonidine. Bupropion, an antidepressant, also shows efficacy for smoking cessation. The nicotinic receptor blocker mecamylamine, which has good central nervous system access, has been used with limited efficacy. Overall, success rates for smoking abstinence at 1 year are about 20%, with even less success for depressed smokers.

Hallucinogens

History

Almost every society has found some bark, skin, leaf, vine, berry, fungus, or weed that contains "hallucinogenic" materials, but neither hallucinations nor psychotic states are typically induced by these drugs. The more recent "club drugs" including MDMA have also been considered to be like hallucinogens, but club drugs are better considered as related to either stimulants (MDMA) or sedatives (GHB).

Chemistry & Pharmacology

The LSD-like group of drugs includes **lysergic acid diethylamide (LSD)**, **mescaline**, **psilocybin**, and their related compounds. LSD is a synthetic agent related to the ergot alkaloids (see Chapter 16: Histamine, Serotonin, & the Ergot Alkaloids), while mescaline, a phenethylamine derivative, and psilocybin, an indol-ethylamine derivative, are found in nature. Representative structures are shown in Figure 32–3. These drugs also have chemical resemblances to three major neurotransmitters: norepinephrine, dopamine, and serotonin. LSD interacts with several serotonin (5-HT) receptor subtypes in the brain. The drug displays agonist activity at 5-HT_{1A} and 5-HT_{1C} receptors. These actions may be more relevant to LSD's hallucinogenic action than its 5-HT₂ receptor antagonism, because a number of other drugs with good antagonist effects at central 5-HT₂ receptors are not

hallucinogenic.

Figure 32–3.

Phencyclidine (PCP, "angel dust," many other names) is a synthetic phenylcyclohexylamine derivative originally used as a veterinary anesthetic. Ketamine, an analog, replaced phencyclidine as an anesthetic for use in humans (see Chapter 25: General Anesthetics). It too produces some emergent hallucinogenic effects. Since the 1970s, PCP and more recently ketamine have become widely accepted by drug abusers as desirable hallucinogenic agents. Phencyclidine may be smoked (by mixing the powder with tobacco), "snorted," taken orally, or injected intravenously.

Receptors for PCP have been identified in the brain, and PCP acts as an antagonist on the *N*-methyl-D-aspartate (NMDA) subtype of glutamate receptors. The drug is unique among hallucinogens in that animals will self-administer it.

The deliriant hallucinogens, exemplified by scopolamine (see Chapter 8: Cholinergic-Blocking Drugs) and some synthetic centrally acting cholinergic-blocking agents, are different chemically as well as pharmacologically from the LSD group. Their effects seem to be entirely explainable by blockade of central muscarinic receptors. Similar mental effects may be seen during therapeutic or deliberate overdoses of commonly used medications with antimuscarinic action, such as

anticholinergic antiparkinsonism drugs, tricyclic antidepressants, and antispasmodics. Occasional instances of abuse of these therapeutic agents have occurred.

Clinical Effects

LSD produces a series of somatic, perceptual, and psychological effects that overlap each other. Dizziness, weakness, tremors, nausea, and paresthesias are prominent somatic symptoms. Blurring of vision, distortions of perspective, organized visual illusions or "hallucinations," less discriminant hearing, and a change in sense of time are common perceptual abnormalities. Impaired memory, difficulty in thinking, poor judgment, and altered mood are prominent psychological effects. Physiologically, LSD produces signs of central stimulation and overactivity of the sympathetic nervous system, manifested by dilated pupils, increased heart rate, mild elevation of blood pressure, tremor, and alertness. Virtually identical effects are produced by mescaline and psilocybin when they are given in equivalent doses. The onset of effects is fairly rapid, but the duration varies with the dose and is usually measured in hours. Phenomena may vary considerably from one user to another owing to such factors as the personality and expectations of the user and the circumstances under which the drug is taken, but the above effects occur in almost everyone. Waxing and waning of effects is typical.

Usual doses of LSD in humans are approximately 1–2 $\mu\text{g}/\text{kg}$, making it one of the most potent pharmacologic agents known. The drug is equally effective parenterally or orally and consequently is almost always taken by mouth. Psilocybin is usually taken in doses of 250 $\mu\text{g}/\text{kg}$ and mescaline in doses of 5–6 mg/kg. Despite these differences in potency, the effects are virtually indistinguishable.

PCP and ketamine produce detachment, disorientation, distortions of body image, and loss of proprioception. Somatic symptoms and signs include numbness, nystagmus, sweating, rapid heart rate, and hypertension. Overdosage has been fatal, as contrasted with the absence of known human fatalities directly caused by drugs of the LSD group.

Scopolamine and other antimuscarinic drugs produce delirium with fluctuating levels of awareness, disorientation, marked difficulty in thinking, marked loss of memory, and bizarre delusions. Most subjects, at least under experimental conditions, find these drugs to be unpleasant and have little desire to repeat the experience.

Use of these hallucinogens has not been associated with dependence or physiologic withdrawal symptoms. This is probably because tolerance develops rapidly, so that closely spaced dosing would be necessary to cause dependence; such frequent dosing is unusual.

Treatment

Common adverse psychologic consequences of hallucinogenic drugs include panic reactions ("bad trips") and acute psychotic reactions with PCP. Treatment includes benzodiazepines for sedation and constant monitoring by a nondrugged companion for several hours. Acidification of the urine (see Chapter 59: Management of the Poisoned Patient) may hasten PCP excretion.

Overdoses of the antimuscarinic agents can be treated with infusions of physostigmine, but supportive care is usually preferred.

Marijuana

History

Use of **cannabis** has been recorded for thousands of years, and about 200–300 million people use it currently, including 30–40 million persons in the USA. Recent surveys suggest its use is starting at an earlier age (sixth to eighth grade, 11–13 years). Because of proposed medical uses, it has been legalized in several states, although federal law prohibits its distribution for any purpose. Much cannabis is now grown indoors using genetically altered strains with 10-fold higher levels of Δ^9 -**tetrahydrocannabinol (THC)** (see below).

Chemistry & Pharmacology

With the exception of THC and its analogs, no other cannabinoids have definite psychoactivity, and the content of THC varies considerably among plants. Special genetic plant lines may produce as much as 4–6% THC content.

The preferred route of administration in Western countries is by smoking. The high lipid solubility of the drug leads to extensive sequestration in the lipid compartments of the body, and metabolites may be excreted for as long as a week after a single dose.

A G protein-coupled cannabinoid receptor (CB1) is most numerous in the outflow nuclei of the basal ganglia, the substantia nigra, pars reticulata, globus pallidus, hippocampus, and brainstem. Positron emission tomographic (PET) studies have revealed increases in metabolism following THC in the same areas in which receptors are localized, suggesting that these receptors are closely involved in the clinical actions of the drug.

THC has a variety of pharmacologic effects that resemble those of amphetamines, LSD, alcohol, sedatives, atropine, and morphine. Important opioid interactions include reduction in opioid dependence in CB1 knockout mice lacking the CB1 receptor.

Clinical Effects

The expert smoker of marijuana is usually aware of a drug effect after two or three inhalations. As smoking continues, the effects increase, reaching a maximum about 20 minutes after the smoke has been finished. Most effects of the drug usually have vanished after 3 hours, by which time plasma concentrations are low. Peak effects after oral administration may be delayed until 3–4 hours after

drug ingestion but may last for 6–8 hours.

The early stage is one of being "high" and is characterized by euphoria, uncontrollable laughter, alteration of time sense, depersonalization, and sharpened vision. Later, the user becomes relaxed and experiences introspective and dream-like states if not actual sleep. Thinking or concentrating becomes difficult, though by force of will the subject can attend.

Two characteristic physiologic signs of cannabis intoxication are increased pulse rate and reddening of the conjunctiva. The latter correlates well with the presence of detectable plasma concentrations. Pupil size is not changed. The blood pressure may fall, especially in the upright position. An antiemetic effect may be present. Muscle weakness, tremors, unsteadiness, and increased deep tendon reflexes may also be noted. Virtually any psychologic test shows impairment if the doses are large enough and the test difficult enough. No distinctive biochemical changes have been found in humans.

Tolerance has been demonstrated in virtually every animal species that has been tested. It is apparent in humans only among heavy long-term users of the drug. Different degrees of tolerance develop for different effects of the drug, with tolerance for the tachycardic effect developing fairly rapidly. A mild withdrawal syndrome has been noted following chronic use at very high doses.

Three epidemiologic studies in developing countries have failed to find definite evidence of impairment among heavy users of cannabis, but field studies may lack sensitivity. Experimental studies in which subjects have smoked heavily for varying periods have shown a lower serum testosterone level in men and airway narrowing. Reports of effects on immune mechanisms, chromosomes, and cell metabolism are often contradictory. Effects on the fetus are still uncertain.

Heavy smokers of marijuana may be subject to some of the same problems of chronic bronchitis, airway obstruction, and squamous cell metaplasia as smokers of tobacco cigarettes. Angina pectoris may be aggravated by the speeding of the heart rate, orthostatic hypotension, and increased carboxyhemoglobin. Driving ability is likely to be impaired but is not easily demonstrated with usual testing. "Amotivational syndrome," in which promising young people with obvious social advantages lose interest in school and career and enter the drug culture, is a real phenomenon, but one cannot be sure whether drug use is the cause of the problem or simply a matter of personal choice. Acute panic reactions, toxic delirium, paranoid states, and frank psychoses are rare. Brain damage has not been confirmed in humans, although some suggestion of ultrastructural damage has been found in animals.

Therapeutic THC is called **dronabinol** (Marinol) and has been marketed with approval by the Food and Drug Administration to reduce nausea and vomiting in patients undergoing cancer chemotherapy and to stimulate appetite in AIDS patients. It has also been shown to reduce intraocular pressure in glaucoma. **Levonantradol**, an analog, may be useful as an analgesic.

Few abusers seek treatment, but recent studies have suggested that behavioral treatments can stop abuse and improve cognitive functioning.

Katzung PHARMACOLOGY, 9e > Section V. Drugs That Act in the Central Nervous System > Chapter 32. Drugs of Abuse >

Inhalants

Chemistry

Four types of inhalants are abused: (1) anesthetic gases; (2) industrial solvents, including a variety of hydrocarbons, such as toluene; (3) aerosol propellants, such as various fluorocarbons; and (4) organic nitrites, such as amyl or butyl nitrite. The mode of action of the inhalant anesthetics has been discussed in Chapter 25: General Anesthetics.

Clinical Aspects

Anesthetic gases such as **nitrous oxide** produce difficulty in concentrating, dreaminess, euphoria, numbness and tingling, unsteadiness, and visual and auditory disturbances. Nitrous oxide is usually taken as 35% N₂O mixed with oxygen; administration of 100% nitrous oxide may cause asphyxia and death. **Ether** and **chloroform** are readily available, and after an initial period of exhilaration, the person often loses consciousness.

Industrial solvents include **gasoline**, and various toxins such as **toluene**, **benzene**, and **trichloroethylene**. The clinical effects of industrial solvent inhalation are short, lasting only 5–15 minutes. Rags or "toques" are soaked in the solvent and the fumes inhaled. **Aerosol propellants** are usually inhaled from a plastic bag. Euphoria and a relaxed "drunk" feeling are followed by disorientation, slow passage of time, and possibly hallucinations.

Organic nitrites (amyl nitrite and isobutyl nitrite) cause dizziness, giddiness, rapid heart rate, lowered blood pressure, "speeding," and flushing of the skin. These effects last only a few minutes and can readily be repeated. The main effect of the drug on sexual performance is probably to enhance or prolong erection through the release of nitric oxide in the corpora cavernosa (see Chapter 19: Nitric Oxide, Donors, & Inhibitors).

Toxicity from chronic use of inhalants can be severe. Industrial solvents have produced liver, kidney, peripheral nerve, and possibly brain damage in animals, bone marrow suppression, and pulmonary disease. In human neuroimaging studies using magnetic resonance imaging, demyelination of white matter has been described in chronic abusers. Fluorocarbon inhalation has resulted in sudden deaths, due either to ventricular arrhythmias or to asphyxiation. Nitrites have been rather safe but might pose hazards (especially arrhythmias) for persons with preexisting cardiovascular problems. Finally, recent data have indicated that nitrate inhalants may reduce lymphocyte counts and natural killer cell activity, thereby acting as a cofactor for AIDS progression.

Katzung PHARMACOLOGY, 9e > Section V. Drugs That Act in the Central Nervous System > Chapter 32. Drugs of Abuse >

Steroids

History

Anabolic steroids were first used in competitive sports during the 1940s, and by the late 1980s, use was widespread in adolescents with distribution points in gymnasiums and physical fitness centers. However, the first urine testing for anabolic steroids did not occur until 1976 at the Olympic Games because of the fairly difficult assay methods needed for detection. These drugs are discussed in Chapter 40: The Gonadal Hormones & Inhibitors.

Clinical Use & Effects

Oral and injectable formulations of different steroids are often "stacked," ie, used simultaneously. Because detection of these different steroids is difficult and expensive, the history from the patient rather than urine toxicology is more generally useful for detecting anabolic steroid abuse. Anabolic steroids were added to Schedule III of the Controlled Substances Act in 1990.

Anabolic steroids are typically abused in a cyclic fashion, with a cycle of 4–18 weeks on steroids and 1 month to 1 year off. Abuse of other psychoactive drugs may occur in up to a third of these patients, but this is low compared with other substance abusers because of concerns about health and appearance by steroid abusers. The primary effects sought by abusers are increased muscle mass and strength, not euphoria. In the context of an adequate diet and sufficient physical activity, a significant increase in muscle mass and strength can be produced by these steroids.

Among the behavioral manifestations of heavy use are increases in aggression, changes in libido and sexual functions, and mood changes with occasional psychotic features. In studies comparing doses of 40–240 mg/d of methyltestosterone in a double-blind inpatient trial, irritability, mood swings, violent feelings, and hostility were greater during the high-dose period than at baseline. This clear ability of androgenic steroids to provoke aggression and irritability has aroused concerns about violence toward family members by abusers. In two prospective controlled trials using blinded administration, mood disturbances were reported in more than 50% of bodybuilders using anabolic steroids. Both increases and decreases in libido have been reported in studies comparing anabolic steroid abusers with nonusing athletes. Cognitive impairment, including distractibility, forgetfulness, and confusion, has also been demonstrated in controlled trials. A withdrawal syndrome has been described, with common symptoms being fatigue, depressed mood, and a craving for steroids.

Clinical findings may include hypertrophied muscles, acne, oily skin, hirsutism in females, gynecomastia in males, and needle punctures. Edema and jaundice may develop in heavy users. Common laboratory abnormalities include elevated hemoglobin and hematocrit measurements, elevated low-density lipoprotein cholesterol and depressed high-density lipoprotein cholesterol levels. Liver function test results may be elevated, and luteinizing hormone levels are usually depressed.

Treatment

Controlled trials of psychosocial treatments for anabolic steroid dependence have not been reported, and these individuals rarely present to substance abuse treatment programs. Patients may come to the attention of mental health professionals as a result of excessive aggression, sexual dysfunction, or mood disturbances. Peer counseling by former bodybuilders and group support may be of particular value for these users. Nutritional counseling and consultation with a fitness expert may also be helpful. Since gymnasiums are a frequent site for acquisition of steroids, abusers need to avoid these places until recovery is firmly established.

Section VI. Drugs Used to Treat Disease of the Blood, Inflammation, & Gout

Chapter 33. Agents Used in Anemias; Hematopoietic Growth Factors

Katzung PHARMACOLOGY, 9e > Section VI. Drugs Used to Treat Disease of the Blood, Inflammation, & Gout > Chapter 33. Agents Used in Anemias; Hematopoietic Growth Factors >

Agents Used in Anemias; Hematopoietic Growth Factors: Introduction

Hematopoiesis, the production from undifferentiated stem cells of circulating erythrocytes, platelets, and leukocytes, is a remarkable process that produces over 200 billion new cells per day in the normal person and even greater numbers of blood cells in people with conditions that cause loss or destruction of blood cells. The hematopoietic machinery resides primarily in the bone marrow in adults and requires a constant supply of three essential nutrients—**iron, vitamin B₁₂, and folic acid**—as well as the presence of **hematopoietic growth factors**, proteins that regulate the proliferation and differentiation of hematopoietic cells. Inadequate supplies of either the essential nutrients or the growth factors result in deficiency of functional blood cells. **Anemia**, a deficiency in oxygen-carrying erythrocytes, is the most common and easily treated of these conditions, but **thrombocytopenia** and **neutropenia** are not rare and in some forms are amenable to drug therapy. In this chapter, we first consider treatment of anemia due to deficiency of iron, vitamin B₁₂, or folic acid and then turn to the medical use of hematopoietic growth factors to combat anemia, thrombocytopenia, and neutropenia.

Katzung PHARMACOLOGY, 9e > Section VI. Drugs Used to Treat Disease of the Blood, Inflammation, & Gout > Chapter 33. Agents Used in Anemias; Hematopoietic Growth Factors >

Agents Used in Anemias

Iron

Basic Pharmacology

Iron deficiency is the most common cause of chronic anemia—anemia that develops over time. Like other forms of chronic anemia, iron deficiency anemia leads to pallor, fatigue, dizziness, exertional dyspnea, and other generalized symptoms of tissue ischemia. The cardiovascular adaptations to chronic anemia—tachycardia, increased cardiac output, vasodilation—can worsen the condition of patients with underlying cardiovascular disease.

Iron forms the nucleus of the iron-porphyrin heme ring, which together with globin chains forms hemoglobin. Hemoglobin reversibly binds oxygen and provides the critical mechanism for oxygen delivery from the lungs to other tissues. In the absence of adequate iron, small erythrocytes with insufficient hemoglobin are formed, giving rise to microcytic hypochromic anemia.

Pharmacokinetics

The body has an elaborate system for maintaining the supply of the iron required for hematopoiesis.

It involves specialized transport and storage proteins whose concentrations are regulated by the body's demand for hemoglobin synthesis and adequate iron stores (Table 33–1). The vast majority of the iron used to support hematopoiesis is reclaimed from catalysis of the hemoglobin in old erythrocytes. Normally, only a small amount of iron is lost from the body each day, so dietary requirements are small and easily fulfilled by the iron available in a wide variety of foods. However, in special populations with either increased iron requirements (eg, growing children, pregnant women) or increased losses of iron (eg, menstruating women), iron requirements can exceed normal dietary supplies and iron deficiency can develop.

Table 33–1. Iron Distribution in Normal Adults.^{1,2}

	Iron Content (mg)	
	Men	Women
Hemoglobin	3050	1700
Myoglobin	430	300
Enzymes	10	8
Transport (transferrin)	8	6
Storage (ferritin and other forms)	750	300
Total	4248	2314

¹Adapted, with permission, from Brown EB: Iron deficiency anemia. In: *Cecil Textbook of Medicine*, 16th ed. Wyngaarden JB, Smith LH (editors). Saunders, 1982.

²Values are based on data from various sources and assume that "normal" men weigh 80 kg and have a hemoglobin of 16 g/dL and that "normal" women weigh 55 kg and have a hemoglobin of 14 g/dL.

Absorption

Iron is normally absorbed in the duodenum and proximal jejunum, though the more distal small intestine can absorb iron if necessary. The average diet in the USA contains 10–15 mg of elemental iron daily. A normal individual without iron deficiency absorbs 5–10% of this iron, or about 0.5–1 mg daily. Iron absorption increases in response to low iron stores or increased iron requirements. Total iron absorption increases to 1–2 mg/d in normal menstruating women and may be as high as 3–4 mg/d in pregnant women. Infants and adolescents also have increased iron requirements during rapid growth periods.

Iron is available in a wide variety of foods but is especially abundant in meat. The iron in meat protein can be efficiently absorbed, since heme iron in meat hemoglobin and myoglobin can be absorbed intact without first having to be broken down into elemental iron. Iron in other foods, especially vegetables and grains, is often tightly bound to phytates or other complexing agents and may be much less available for absorption. Nonheme iron in foods and iron in inorganic iron salts and complexes must be reduced to ferrous (Fe^{2+}) iron before it can be absorbed by the intestinal mucosal cells. Such absorption is decreased by the presence of chelators or complexing agents in the intestinal lumen and is increased in the presence of hydrochloric acid and vitamin C.

Iron crosses the intestinal mucosal cell by active transport. The rate of iron uptake is regulated by mucosal cell iron stores such that more iron is transported when stores are low. Together with iron split from absorbed heme, the newly absorbed iron can be made available for immediate transport from the mucosal cell to the plasma via transferrin or can be stored in the mucosal cell as ferritin, a water-soluble complex consisting of a core crystal of ferric hydroxide covered by a shell of a specialized storage protein called apoferritin. In general, when total body iron stores are high and iron requirements by the body are low, newly absorbed iron is diverted into ferritin in the intestinal mucosal cells rather than being transported to other sites. When iron stores are low or iron requirements are high, however, newly absorbed iron is immediately transported from the mucosal cells to the bone marrow for the production of hemoglobin.

Transport

Iron is transported in the plasma bound to **transferrin**, a β -globulin that specifically binds ferric iron. The transferrin-ferric iron complex enters maturing erythroid cells by a specific receptor mechanism. Transferrin receptors—integral membrane glycoproteins present in large numbers on proliferating erythroid cells—bind the transferrin-iron complex and internalize the iron, releasing it within the cell. The transferrin and transferrin receptor are then recycled, providing an efficient mechanism for incorporating iron into hemoglobin in developing red blood cells.

Increased erythropoiesis is associated with an increase in the number of transferrin receptors on developing erythroid cells. Iron store depletion and iron deficiency anemia are associated with an increased concentration of serum transferrin.

Storage

Iron binds avidly to a protein, **apoferritin**, and forms the complex **ferritin**. Iron is stored, primarily as ferritin, in intestinal mucosal cells and in macrophages in the liver, spleen, and bone. Apoferritin synthesis is regulated by the levels of free iron. When these levels are low, apoferritin synthesis is inhibited and the balance of iron binding shifts toward transferrin. When free iron levels are high, more apoferritin is produced in an effort to safely sequester more iron and protect organs from the toxic effects of excess free iron.

Ferritin is also detectable in plasma. Since the ferritin present in plasma is in equilibrium with storage ferritin in reticuloendothelial tissues, the plasma (or serum) ferritin level can be used to estimate total body iron stores.

Elimination

There is no mechanism for excretion of iron. Small amounts are lost by exfoliation of intestinal mucosal cells into the stool, and trace amounts are excreted in bile, urine, and sweat. These losses account for no more than 1 mg of iron per day. Because the body's ability to increase excretion of iron is so limited, regulation of iron balance must be achieved by changing intestinal absorption and storage of iron, in response to the body's needs.

Clinical Pharmacology

Indications for the Use of Iron

The only clinical indication for the use of iron preparations is the treatment or prevention of iron deficiency anemia. Iron deficiency is commonly seen in populations with increased iron

requirements. These include infants, especially premature infants; children during rapid growth periods; and pregnant and lactating women. Iron deficiency also occurs frequently after gastrectomy and in patients with severe small bowel disease that results in generalized malabsorption. Iron deficiency in these gastrointestinal conditions is due to inadequate iron absorption.

The most common cause of iron deficiency in adults is blood loss. Menstruating women lose about 30 mg of iron with each menstrual period; women with heavy menstrual bleeding may lose much more. Thus, many premenopausal women have low iron stores or even iron deficiency. In men and postmenopausal women, the most common site of blood loss is the gastrointestinal tract. Patients with unexplained iron deficiency anemia should be evaluated for occult gastrointestinal bleeding.

As iron deficiency develops, storage iron decreases and then disappears; next, serum ferritin decreases; and then serum iron decreases and iron-binding capacity increases, resulting in a decrease in iron-binding (transferrin) saturation. Thereafter, anemia begins to develop. Red cell indices (mean corpuscular volume [MCV]: normal = 80–100 fL; mean corpuscular hemoglobin concentration [MCHC]: normal = 32–36 g/dL) are usually low normal when iron deficiency anemia is mild, but cells become progressively more microcytic (low MCV) and hypochromic (low MCHC) as anemia becomes more severe. By the time iron deficiency is diagnosed, serum iron is usually less than 40 $\mu\text{g/dL}$; total iron-binding capacity (TIBC) is greater than 400 $\mu\text{g/dL}$; iron-binding saturation is less than 10%; and serum ferritin is less than 10 $\mu\text{g/L}$. These laboratory measurements can be used to confirm a diagnosis of iron deficiency anemia in patients who present with signs and symptoms of microcytic anemia.

Treatment

The treatment of iron deficiency anemia consists of administration of oral or parenteral iron preparations. Oral iron corrects the anemia just as rapidly and completely as parenteral iron in most cases if iron absorption from the gastrointestinal tract is normal.

Oral Iron Therapy

A wide variety of oral iron preparations are available. Since ferrous iron is most efficiently absorbed, only ferrous salts should be used. Ferrous sulfate, ferrous gluconate, and ferrous fumarate are all effective and inexpensive and are recommended for the treatment of most patients.

Different iron salts provide different amounts of elemental iron, as shown in Table 33–2. In an iron-deficient individual, about 50–100 mg of iron can be incorporated into hemoglobin daily, and about 25% of oral iron given as ferrous salt can be absorbed. Therefore, 200–400 mg of elemental iron should be given daily to correct iron deficiency most rapidly. Patients unable to tolerate such large doses of iron can be given lower daily doses of iron, which results in slower but still complete correction of iron deficiency. Treatment with oral iron should be continued for 3–6 months. This will correct the anemia and replenish iron stores.

Table 33–2. Some Commonly Used Oral Iron Preparations.

Preparation	Tablet Size	Elemental Iron per Tablet	Usual Adult Dosage (Tablets per Day)
Ferrous sulfate, hydrated	325 mg	65 mg	3–4

Ferrous sulfate, desiccated	200 mg	65 mg	3–4
Ferrous gluconate	325 mg	36 mg	3–4
Ferrous fumarate	200 mg	66 mg	3–4
Ferrous fumarate	325 mg	106 mg	2–3

Common adverse effects of oral iron therapy include nausea, epigastric discomfort, abdominal cramps, constipation, and diarrhea. These effects are usually dose-related and can often be overcome by lowering the daily dose of iron or by taking the tablets immediately after or with meals. Some patients have less severe gastrointestinal adverse effects with one iron salt than another and benefit from changing preparations. Patients taking oral iron develop black stools; this itself has no clinical significance but may obscure the diagnosis of continued gastrointestinal blood loss.

Parenteral Iron Therapy

Parenteral therapy should be reserved for patients with documented iron deficiency unable to tolerate or absorb oral iron and patients with extensive chronic blood loss who cannot be maintained with oral iron alone. This includes patients with various postgastrectomy conditions and previous small bowel resection, inflammatory bowel disease involving the proximal small bowel, and malabsorption syndromes.

Iron dextran is a stable complex of ferric hydroxide and low-molecular-weight dextran containing 50 mg of elemental iron per milliliter of solution. **Iron-sucrose complex** and **iron sodium gluconate complex** are newer, alternative preparations. These agents can be given either by deep intramuscular injection or by intravenous infusion. Adverse effects of parenteral iron therapy include local pain and tissue staining (brown discoloration of the tissues overlying the injection site), headache, light-headedness, fever, arthralgias, nausea and vomiting, back pain, flushing, urticaria, bronchospasm, and, rarely, anaphylaxis and death.

Most adults with iron deficiency anemia require 1–2 g of replacement iron, or 20–40 mL of iron dextran. Most physicians prefer to give the entire dose in a single intravenous infusion in several hundred milliliters of normal saline over 1–2 hours. Intravenous administration eliminates the local pain and tissue staining that often occur with the intramuscular route and allows delivery of the entire dose of iron necessary to correct the iron deficiency at one time. There is no clear evidence that any of the adverse effects, including anaphylaxis, are more likely to occur with intravenous than with intramuscular administration.

Owing to the risk of a hypersensitivity reaction, a small test dose of iron dextran should always be given before full intramuscular or intravenous doses are given. Patients with a strong history of allergy and patients who have previously received parenteral iron are more likely to have hypersensitivity reactions following treatment with parenteral iron dextran.

Clinical Toxicity

Acute Iron Toxicity

Acute iron toxicity is seen almost exclusively in young children who have ingested a number of iron tablets. Although adults are able to tolerate large doses of oral iron without serious consequences, as

few as ten tablets of any of the commonly available oral iron preparations can be lethal in young children. Patients taking oral iron preparations should be instructed to store tablets in child-proof containers out of the reach of children.

Large amounts of oral iron cause necrotizing gastroenteritis, with vomiting, abdominal pain, and bloody diarrhea followed by shock, lethargy, and dyspnea. Subsequently, improvement is often noted, but this may be followed by severe metabolic acidosis, coma, and death. Urgent treatment of acute iron toxicity is necessary, especially in young children. Activated charcoal, a highly effective adsorbent for most toxins, *does not* bind iron and thus is ineffective. Whole bowel irrigation (see Chapter 59: Management of the Poisoned Patient) should be performed to flush out unabsorbed pills. **Deferoxamine**, a potent iron-chelating compound, can be given systemically to bind iron that has already been absorbed and to promote its excretion in urine and feces. Appropriate supportive therapy for gastrointestinal bleeding, metabolic acidosis, and shock must also be provided.

Chronic Iron Toxicity

Chronic iron toxicity (iron overload), also known as **hemochromatosis**, results when excess iron is deposited in the heart, liver, pancreas, and other organs. It can lead to organ failure and death. It most commonly occurs in patients with inherited hemochromatosis, a disorder characterized by excessive iron absorption, and in patients who receive many red cell transfusions over a long period of time.

Chronic iron overload in the absence of anemia is most efficiently treated by intermittent phlebotomy. One unit of blood can be removed every week or so until all of the excess iron is removed. Iron chelation therapy using parenteral deferoxamine is much less efficient as well as more complicated, expensive, and hazardous, but it can be useful for severe iron overload that cannot be managed by phlebotomy.

Vitamin B₁₂

Vitamin B₁₂ serves as a cofactor for several essential biochemical reactions in humans. Deficiency of vitamin B₁₂ leads to anemia, gastrointestinal symptoms, and neurologic abnormalities. While deficiency of vitamin B₁₂ due to an inadequate supply in the diet is unusual, deficiency of B₁₂ in adults—especially older adults—due to abnormal absorption of dietary vitamin B₁₂ is a relatively common and easily treated disorder.

Chemistry

Vitamin B₁₂ consists of a porphyrin-like ring with a central cobalt atom attached to a nucleotide. Various organic groups may be covalently bound to the cobalt atom, forming different cobalamins. Deoxyadenosylcobalamin and methylcobalamin are the active forms of the vitamin in humans. **Cyanocobalamin** and **hydroxocobalamin** (both available for therapeutic use) and other cobalamins found in food sources are converted to the above active forms. The ultimate source of vitamin B₁₂ is from microbial synthesis; the vitamin is not synthesized by animals or plants. The chief dietary source of vitamin B₁₂ is microbially derived vitamin B₁₂ in meat (especially liver), eggs, and dairy products. Vitamin B₁₂ is sometimes called **extrinsic factor** to differentiate it from **intrinsic factor**, a protein normally secreted by the stomach.

Pharmacokinetics

The average diet in the USA contains 5–30 μg of vitamin B₁₂ daily, 1–5 μg of which is usually

absorbed. The vitamin is avidly stored, primarily in the liver, with an average adult having a total vitamin B₁₂ storage pool of 3000–5000 µg. Only trace amounts of vitamin B₁₂ are normally lost in urine and stool. Since the normal daily requirements of vitamin B₁₂ are only about 2 µg, it would take about 5 years for all of the stored vitamin B₁₂ to be exhausted and for megaloblastic anemia to develop if B₁₂ absorption stopped. Vitamin B₁₂ in physiologic amounts is absorbed only after it complexes with **intrinsic factor**, a glycoprotein secreted by the parietal cells of the gastric mucosa. Intrinsic factor combines with the vitamin B₁₂ that is liberated from dietary sources in the stomach and duodenum, and the intrinsic factor-vitamin B₁₂ complex is subsequently absorbed in the distal ileum by a highly specific receptor-mediated transport system. Vitamin B₁₂ deficiency in humans most often results from malabsorption of vitamin B₁₂, due either to lack of intrinsic factor or to loss or malfunction of the specific absorptive mechanism in the distal ileum. Nutritional deficiency is rare but may be seen in strict vegetarians after many years without meat, eggs, or dairy products.

Once absorbed, vitamin B₁₂ is transported to the various cells of the body bound to a plasma glycoprotein, transcobalamin II. Excess vitamin B₁₂ is transported to the liver for storage. Significant amounts of vitamin B₁₂ are excreted in the urine only when very large amounts are given parenterally, overcoming the binding capacities of the transcobalamins (50–100 µg).

Pharmacodynamics

Two essential enzymatic reactions in humans require vitamin B₁₂ (Figure 33–1). In one, methylcobalamin serves as an intermediate in the transfer of a methyl group from *N*⁵-methyltetrahydrofolate to methionine (Figure 33–1 A; Figure 33–2, reaction 1). In the absence of vitamin B₁₂, conversion of the major dietary and storage folate, *N*⁵-methyltetrahydrofolate, to tetrahydrofolate, the precursor of folate cofactors, cannot occur. As a result, a deficiency of folate cofactors necessary for several biochemical reactions involving the transfer of one-carbon groups develops. In particular, the depletion of tetrahydrofolate prevents synthesis of adequate supplies of the deoxythymidylate (dTMP) and purines required for DNA synthesis in rapidly dividing cells as shown in Figure 33–3, reaction 2. The accumulation of folate as *N*⁵-methyltetrahydrofolate and the associated depletion of tetrahydrofolate cofactors in vitamin B₁₂ deficiency have been referred to as the "methylfolate trap." This is the biochemical step whereby vitamin B₁₂ and folic acid metabolism are linked and explains why the megaloblastic anemia of vitamin B₁₂ deficiency can be partially corrected by ingestion of relatively large amounts of folic acid. Folic acid can be reduced to dihydrofolate by the enzyme dihydrofolate reductase (Figure 33–2, reaction 3) and thus serve as a source of the tetrahydrofolate required for synthesis of the purines and dTMP that are needed for DNA synthesis.

Figure 33–1.

A. Methyl transfer

B. Isomerization of L-Methylmalonyl-CoA

Enzymatic reactions that use vitamin B12. See text for details.

Figure 33-2.

Enzymatic reactions that use folates. Section 1 shows the vitamin B₁₂-dependent reaction that allows most dietary folates to enter the tetrahydrofolate cofactor pool and becomes the "folate trap" in vitamin B₁₂ deficiency. Section 2 shows the dTMP cycle. Section 3 shows the pathway by which folate enters the tetrahydrofolate cofactor pool. Double arrows indicate pathways with more than one intermediate step.

The other enzymatic reaction that requires vitamin B₁₂ is isomerization of methylmalonyl-CoA to succinyl-CoA by the enzyme methylmalonyl-CoA mutase (Figure 33-1 B). In vitamin B₁₂ deficiency, this conversion cannot take place, and the substrate, methylmalonyl-CoA, accumulates. In the past, it was thought that abnormal accumulation of methylmalonyl-CoA causes the neurologic manifestations of vitamin B₁₂ deficiency. However, newer evidence instead implicates the disruption of the methionine synthesis pathway as the cause of neurologic problems. Whatever the biochemical explanation for neurologic damage, the important point is that administration of folic acid in the setting of vitamin B₁₂ deficiency will not prevent *neurologic* manifestations even though it will largely correct the *anemia* caused by the vitamin B₁₂ deficiency.

Clinical Pharmacology

Vitamin B₁₂ is used to treat or prevent deficiency. There is no evidence that vitamin B₁₂ injections have any benefit in persons who do not have vitamin B₁₂ deficiency. The most characteristic clinical manifestation of vitamin B₁₂ deficiency is megaloblastic anemia. The typical clinical findings in

megaloblastic anemia are macrocytic anemia (MCV usually > 120 fL), often with associated mild or moderate leukopenia or thrombocytopenia (or both), and a characteristic hypercellular bone marrow with megaloblastic maturation of erythroid and other precursor cells. Vitamin B₁₂ deficiency also causes a neurologic syndrome that usually begins with paresthesias and weakness in peripheral nerves and progresses to spasticity, ataxia, and other central nervous system dysfunctions. A characteristic pathologic feature of the neurologic syndrome is degeneration of myelin sheaths followed by disruption of axons in the dorsal and lateral horns of the spinal cord and in peripheral nerves. Correction of vitamin B₁₂ deficiency arrests the progression of neurologic disease, but it may not fully reverse neurologic symptoms that have been present for several months. Although most patients with neurologic abnormalities caused by vitamin B₁₂ deficiency have full-blown megaloblastic anemias when first seen, occasional patients have few if any hematologic abnormalities.

Once a diagnosis of megaloblastic anemia is made, it must be determined whether vitamin B₁₂ or folic acid deficiency is the cause. (Other causes of megaloblastic anemia are very rare.) This can usually be accomplished by measuring serum levels of the vitamins. The Schilling test, which measures absorption and urinary excretion of radioactively labeled vitamin B₁₂, can be used to further define the mechanism of vitamin B₁₂ malabsorption when this is found to be the cause of the megaloblastic anemia.

The most common causes of vitamin B₁₂ deficiency are pernicious anemia, partial or total gastrectomy, and diseases that affect the distal ileum, such as malabsorption syndromes, inflammatory bowel disease, or small bowel resection.

Pernicious anemia results from defective secretion of intrinsic factor by the gastric mucosal cells. Patients with pernicious anemia have gastric atrophy and fail to secrete intrinsic factor (as well as hydrochloric acid). The Schilling test shows diminished absorption of radioactively labeled vitamin B₁₂, which is corrected when hog intrinsic factor is administered with radioactive B₁₂, since the vitamin can then be normally absorbed.

Vitamin B₁₂ deficiency also occurs when the region of the distal ileum that absorbs the vitamin B₁₂-intrinsic factor complex is damaged, as when the ileum is involved with inflammatory bowel disease, or when the ileum is surgically resected. In these situations, radioactively labeled vitamin B₁₂ is not absorbed in the Schilling test, even when intrinsic factor is added. Other rare causes of vitamin B₁₂ deficiency include bacterial overgrowth of the small bowel, chronic pancreatitis, and thyroid disease. Rare cases of vitamin B₁₂ deficiency in children have been found to be secondary to congenital deficiency of intrinsic factor and congenital selective vitamin B₁₂ malabsorption due to defects of the receptor sites in the distal ileum.

Since almost all cases of vitamin B₁₂ deficiency are caused by malabsorption of the vitamin, parenteral injections of vitamin B₁₂ are required for therapy. For patients with potentially reversible diseases, the underlying disease should be treated after initial treatment with parenteral vitamin B₁₂. Most patients, however, do not have curable deficiency syndromes and require lifelong treatment with vitamin B₁₂ injections.

Vitamin B₁₂ for parenteral injection is available as cyanocobalamin or hydroxocobalamin. Hydroxocobalamin is preferred because it is more highly protein-bound and therefore remains longer in the circulation. Initial therapy should consist of 100–1000 µg of vitamin B₁₂ intramuscularly daily or every other day for 1–2 weeks to replenish body stores. Maintenance therapy consists of 100–1000 µg intramuscularly once a month for life. If neurologic abnormalities are present, maintenance therapy injections should be given every 1–2 weeks for 6 months before

switching to monthly injections. Oral vitamin B₁₂-intrinsic factor mixtures and liver extracts should not be used to treat vitamin B₁₂ deficiency; however, oral doses of 1000 µg of vitamin B₁₂ daily are usually sufficient to treat patients with pernicious anemia who refuse or cannot tolerate the injections.

Folic Acid

Reduced forms of folic acid are required for essential biochemical reactions that provide precursors for the synthesis of amino acids, purines, and DNA. Folate deficiency is not uncommon, even though the deficiency is easily corrected by administration of folic acid. The consequences of folate deficiency go beyond the problem of anemia because folate deficiency is implicated as a cause of congenital malformations in newborns and may play a role in vascular disease (see Folic Acid Supplementation: A Public Health Dilemma).

Chemistry

Folic acid (pteroylglutamic acid) is a compound composed of a heterocycle, *p*-aminobenzoic acid, and glutamic acid (Figure 33–3). Various numbers of glutamic acid moieties may be attached to the pteroyl portion of the molecule, resulting in monoglutamates, triglutamates, or polyglutamates. Folic acid can undergo reduction, catalyzed by the enzyme dihydrofolate reductase ("folate reductase"), to give dihydrofolic acid (Figure 33–2, reaction 3). Tetrahydrofolate can subsequently be transformed to folate cofactors possessing one-carbon units attached to the 5-nitrogen, to the 10-nitrogen, or to both positions (Figure 33–2). The folate cofactors are interconvertible by various enzymatic reactions and serve the important biochemical function of donating one-carbon units at various levels of oxidation. In most of these, tetrahydrofolate is regenerated and becomes available for reutilization.

Figure 33–3.

The structure and numbering of atoms of folic acid. (Reproduced, with permission, from Murray RK et al: *Harper's Biochemistry*, 24th ed. McGraw-Hill, 1996)

Pharmacokinetics

The average diet in the USA contains 500–700 µg of folates daily, 50–200 µg of which is usually

absorbed, depending on metabolic requirements (pregnant women may absorb as much as 300–400 μg of folic acid daily). Various forms of folic acid are present in a wide variety of plant and animal tissues; the richest sources are yeast, liver, kidney, and green vegetables. Normally, 5–20 mg of folates are stored in the liver and other tissues. Folates are excreted in the urine and stool and are also destroyed by catabolism, so serum levels fall within a few days when intake is diminished. Since body stores of folates are relatively low and daily requirements high, folic acid deficiency and megaloblastic anemia can develop within 1–6 months after the intake of folic acid stops, depending on the patient's nutritional status and the rate of folate utilization.

Unaltered folic acid is readily and completely absorbed in the proximal jejunum. Dietary folates, however, consist primarily of polyglutamate forms of N^5 -methyltetrahydrofolate. Before absorption, all but one of the glutamyl residues of the polyglutamates must be hydrolyzed by the enzyme α -1-glutamyl transferase ("conjugase") within the brush border of the intestinal mucosa. The monoglutamate N^5 -methyltetrahydrofolate is subsequently transported into the bloodstream by both active and passive transport and is then widely distributed throughout the body. Inside cells, N^5 -methyltetrahydrofolate is converted to tetrahydrofolate by the demethylation reaction that requires vitamin B12 (Figure 33–2, reaction 1).

Pharmacodynamics

Tetrahydrofolate cofactors participate in one-carbon transfer reactions. As described above in the section on vitamin B12, one of these essential reactions produces the dTMP needed for DNA synthesis. In this reaction, the enzyme thymidylate synthase catalyzes the transfer of the one-carbon unit of N^5,N^{10} -methylenetetrahydrofolate to deoxyuridine monophosphate (dUMP) to form dTMP (Figure 33–2, reaction 2). Unlike all of the other enzymatic reactions that utilize folate cofactors, in this reaction the cofactor is oxidized to dihydrofolate, and for each mole of dTMP produced, one mole of tetrahydrofolate is consumed. In rapidly proliferating tissues, considerable amounts of tetrahydrofolate can be consumed in this reaction, and continued DNA synthesis requires continued regeneration of tetrahydrofolate by reduction of dihydrofolate, catalyzed by the enzyme dihydrofolate reductase. The tetrahydrofolate thus produced can then reform the cofactor N^5,N^{10} -methylenetetrahydrofolate by the action of serine transhydroxymethylase and thus allow for the continued synthesis of dTMP. The combined catalytic activities of dTMP synthase, dihydrofolate reductase, and serine transhydroxymethylase are often referred to as the dTMP synthesis cycle. Enzymes in the dTMP cycle are the targets of two anticancer drugs; methotrexate inhibits dihydrofolate reductase, and a metabolite of 5-fluorouracil inhibits thymidylate synthase (see Chapter 55: Cancer Chemotherapy).

Cofactors of tetrahydrofolate participate in several other essential reactions. As described above, N^5 -methyltetrahydrofolate is required for the vitamin B12-dependent reaction that generates methionine from homocysteine (Figure 33–1 A; Figure 33–2, reaction 1). In addition, tetrahydrofolate cofactors donate one-carbon units during the de novo synthesis of essential purines. In these reactions, tetrahydrofolate is regenerated and can reenter the tetrahydrofolate cofactor pool.

Clinical Pharmacology

Folate deficiency results in a megaloblastic anemia that is microscopically indistinguishable from the anemia caused by vitamin B12 deficiency (see above). However, folate deficiency does not cause the characteristic neurologic syndrome seen in vitamin B12 deficiency. In patients with megaloblastic anemia, folate status is assessed with assays for serum folate or for red blood cell folate. Red blood cell folate levels are often of greater diagnostic value than serum levels, since serum folate levels tend to be quite labile and do not necessarily reflect tissue levels.

Folic acid deficiency, unlike vitamin B12 deficiency, is often caused by inadequate dietary intake of folates. Alcoholics and patients with liver disease develop folic acid deficiency because of poor diet and diminished hepatic storage of folates. There is also evidence that alcohol and liver disease interfere with absorption and metabolism of folates. Pregnant women and patients with hemolytic anemia have increased folate requirements and may become folic acid-deficient, especially if their diets are marginal. Evidence implicates maternal folic acid deficiency in the occurrence of fetal neural tube defects, eg, spina bifida. (See Folic Acid Supplementation: A Public Health Dilemma.) Patients with malabsorption syndromes also frequently develop folic acid deficiency. Folic acid deficiency is occasionally associated with cancer, leukemia, myeloproliferative disorders, certain chronic skin disorders, and other chronic debilitating diseases. Patients who require renal dialysis also develop folic acid deficiency, because folates are removed from the plasma each time the patient is dialyzed.

Folic acid deficiency can be caused by drugs that interfere with folate absorption or metabolism. Phenytoin, some other anticonvulsants, oral contraceptives, and isoniazid can cause folic acid deficiency by interfering with folic acid absorption. Other drugs such as methotrexate and, to a lesser extent, trimethoprim and pyrimethamine, inhibit dihydrofolate reductase and may result in a deficiency of folate cofactors and ultimately in megaloblastic anemia.

Parenteral administration of folic acid is rarely necessary, since oral folic acid is well absorbed even in patients with malabsorption syndromes. A dose of 1 mg of folic acid orally daily is sufficient to reverse megaloblastic anemia, restore normal serum folate levels, and replenish body stores of folates in almost all patients. Therapy should be continued until the underlying cause of the deficiency is removed or corrected. Therapy may be required indefinitely for patients with malabsorption or dietary inadequacy. Folic acid supplementation to prevent folic acid deficiency should be considered in high-risk patients, including pregnant women, alcoholics, and patients with hemolytic anemia, liver disease, certain skin diseases, and patients on renal dialysis.

Katzung PHARMACOLOGY, 9e > Section VI. Drugs Used to Treat Disease of the Blood, Inflammation, & Gout > Chapter 33. Agents Used in Anemias; Hematopoietic Growth Factors >

Folic Acid Supplementation: A Public Health Dilemma

By January 1998, all products made from enriched grains in the USA were required to be supplemented with folic acid. This FDA ruling was issued to reduce the incidence of congenital neural tube defects. Scientific studies show a strong correlation between maternal folic acid deficiency and the incidence of neural tube defects such as spinal bifida and anencephaly. The FDA requirement for folic acid supplementation is a public health measure aimed at the significant number of women in the USA who do not receive prenatal care and are not aware of the importance of adequate folic acid ingestion for preventing birth defects in their babies. Pregnant women have increased requirements for folic acid; at least 400 $\mu\text{g}/\text{d}$ is recommended. It is estimated that the level of folic acid fortification now required in enriched grain products provides an additional 80–100 μg of folic acid per day to the diet of women of childbearing age and 70–120 $\mu\text{g}/\text{d}$ to the diet of middle-aged and older adults.

There may be an added benefit for adults. N^5 -methyltetrahydrofolate is required for the conversion of homocysteine to methionine (Figure 33–1; Figure 33–2, reaction 1). Impaired synthesis of N^5 -methyltetrahydrofolate results in elevated serum concentrations of homocysteine. Data from several sources suggest a positive correlation between elevated serum homocysteine and occlusive vascular diseases such as ischemic heart disease and stroke. Clinical data suggest that the

folate supplementation program has improved the folate status and reduced the prevalence of hyperhomocysteinemia in a population of middle-aged and older adults who did not use vitamin supplements. It is possible, though as yet unproved, that the increased ingestion of folic acid will also reduce the risk of vascular disease in this population.

While these two potential benefits of supplemental folic acid are compelling, the decision to require folic acid in grains was—and still is—controversial. As described in the text, ingestion of folic acid can partially or totally correct the anemia caused by vitamin B₁₂ deficiency. However, folic acid supplementation *will not* prevent the potentially irreversible neurologic damage caused by vitamin B₁₂ deficiency. People with pernicious anemia and other forms of vitamin B₁₂ deficiency are usually identified because of signs and symptoms of anemia, which tend to occur before neurologic symptoms. The opponents of folic acid supplementation are concerned that increased folic acid intake in the general population will mask vitamin B₁₂ deficiency and increase the prevalence of neurologic disease in our elderly population. To put this in perspective, approximately 4000 pregnancies, including 2500 live births, in the USA each year are affected by neural tube defects. In contrast, it is estimated that over 10% of the elderly population in the USA, or several million people, are at risk of the neuropsychiatric complications of vitamin B₁₂ deficiency (Rothenberg, 1999). In acknowledgment of this controversy, the FDA kept its requirements for folic acid supplementation at a somewhat low level. They also recommend that all adults should keep their ingestion of folic acid below 1 mg/d.

Katzung PHARMACOLOGY, 9e > Section VI. Drugs Used to Treat Disease of the Blood, Inflammation, & Gout > Chapter 33. Agents Used in Anemias; Hematopoietic Growth Factors >

Hematopoietic Growth Factors

The hematopoietic growth factors are glycoprotein hormones that regulate the proliferation and differentiation of hematopoietic progenitor cells in the bone marrow. The first growth factors to be identified were called colony-stimulating factors because they could stimulate the growth of colonies of various bone marrow progenitor cells *in vitro*. In the past decade, many of these growth factors have been purified and cloned, and their effects on hematopoiesis have been extensively studied. Quantities of these growth factors sufficient for clinical use are produced by recombinant DNA technology.

Of the known hematopoietic growth factors, **erythropoietin (epoetin alfa)**, **granulocyte colony-stimulating factor (G-CSF)**, **granulocyte-macrophage colony-stimulating factor (GM-CSF)**, and **interleukin 11** are currently in clinical use. Thrombopoietin is undergoing clinical trials and will probably become available soon. Other potentially useful hematopoietic factors are still in development.

The hematopoietic growth factors have complex effects on the function of a wide variety of cell types, including nonhematologic cells. Their utility in other areas of medicine, particularly as potential anticancer and anti-inflammatory drugs, is being investigated.

Erythropoietin

Chemistry & Pharmacokinetics

Erythropoietin, a 34-39 kDA glycoprotein, was the first human hematopoietic growth factor to be isolated. It was originally purified from the urine of patients with severe anemia. Recombinant human erythropoietin (rHuEpo, epoetin alfa) is produced in a mammalian cell expression system

using recombinant DNA technology. After intravenous administration, erythropoietin has a serum half-life of 4–13 hours in patients with chronic renal failure. It is not cleared by dialysis. It is measured in international units (IU). Darbopoetin alfa is a glycosylated form of erythropoietin and differs from it functionally only in having a twofold to threefold longer half-life.

Pharmacodynamics

Erythropoietin stimulates erythroid proliferation and differentiation by interacting with specific erythropoietin receptors on red cell progenitors. It also induces release of reticulocytes from the bone marrow. Endogenous erythropoietin is produced by the kidney in response to tissue hypoxia. When anemia occurs, more erythropoietin is produced by the kidney, signaling the bone marrow to produce more red blood cells. This results in correction of the anemia provided that bone marrow response is not impaired by red cell nutritional deficiency (especially iron deficiency), primary bone marrow disorders (see below), or bone marrow suppression from drugs or chronic diseases.

Normally there is an inverse relationship between the hematocrit or hemoglobin level and the serum erythropoietin level. Nonanemic individuals have serum erythropoietin levels of less than 20 IU/L. As the hematocrit and hemoglobin levels fall and anemia becomes more severe, the serum erythropoietin level rises exponentially. Patients with moderately severe anemias usually have erythropoietin levels in the 100–500 IU/L range, and patients with severe anemias may have levels of thousands of IU/L. The most important exception to this inverse relationship is in the anemia of chronic renal failure. In patients with renal disease, erythropoietin levels are usually low because the kidneys cannot produce the growth factor. These patients are the most likely to respond to treatment with exogenous erythropoietin. In most primary bone marrow disorders (aplastic anemia, leukemias, myeloproliferative and myelodysplastic disorders, etc) and most nutritional and secondary anemias, endogenous erythropoietin levels are high, so there is less likelihood of a response to exogenous erythropoietin (but see below).

Clinical Pharmacology

The availability of erythropoietin has had a significant positive impact for patients with chronic renal failure. Erythropoietin consistently improves the hematocrit and hemoglobin level and usually eliminates the need for transfusions in these patients. An increase in reticulocyte count is usually observed in about 10 days and an increase in hematocrit and hemoglobin levels in 2–6 weeks. Most patients can maintain a hematocrit of about 35% with erythropoietin doses of 50–150 IU/kg intravenously or subcutaneously three times a week. Failure to respond to erythropoietin is most commonly due to concurrent iron deficiency, which can be corrected by giving oral iron. Folate supplementation may also be necessary in some patients.

In selected patients, erythropoietin may also be useful for the treatment of anemia due to primary bone marrow disorders and secondary anemias. This includes patients with aplastic anemia and other bone marrow failure states, myeloproliferative and myelodysplastic disorders, multiple myeloma and perhaps other chronic bone marrow malignancies, and the anemias associated with chronic inflammation, AIDS, and cancer. Patients with these disorders who have disproportionately low serum erythropoietin levels for their degree of anemia are most likely to respond to treatment with this growth factor. Patients with endogenous erythropoietin levels of less than 100 IU/L have the best chance of response, though patients with erythropoietin levels between 100 and 500 IU/L respond occasionally. These patients generally require higher erythropoietin doses (150–300 IU/kg three times a week) to achieve a response, and responses are often incomplete.

Erythropoietin has been used successfully to offset the anemia produced by zidovudine treatment in

patients with HIV infection and in the treatment of the anemia of prematurity. It can also be used to accelerate erythropoiesis after phlebotomies, when blood is being collected for autologous transfusion for elective surgery, or for treatment of iron overload (hemochromatosis).

Erythropoietin is one of the drugs banned by the International Olympic Committee. The use of erythropoietin by athletes is based on their hope that increased red blood cell concentration will increase oxygen delivery and improve performance.

Toxicity

The most common adverse effects of erythropoietin are associated with a rapid increase in hematocrit and hemoglobin and include hypertension and thrombotic complications. These difficulties can be minimized by raising the hematocrit and hemoglobin slowly and by adequately monitoring and treating hypertension. Allergic reactions have been infrequent and mild.

Myeloid Growth Factors

Chemistry & Pharmacokinetics

G-CSF and **GM-CSF**, the two myeloid growth factors currently available for clinical use, were originally purified from cultured human cell lines. Recombinant human G-CSF (**rHuG-CSF; filgrastim**) is produced in a bacterial expression system using recombinant DNA technology. It is a nonglycosylated peptide of 175 amino acids, with a molecular weight of 18 kDa. Recombinant human GM-CSF (**rHuGM-CSF; sargramostim**) is produced in a yeast expression system using recombinant DNA technology. It is a partially glycosylated peptide of 127 amino acids, with three molecular species with molecular weights of 15,500, 15,800, and 19,500. These preparations have serum half-lives of 2–7 hours after intravenous or subcutaneous administration. **Pegfilgrastim**, a covalent conjugation product of filgrastim and a form of polyethylene glycol, has a much longer serum half-life than recombinant G-CSF, and so it can be injected once per myelosuppressive chemotherapy cycle instead of daily for several days.

Pharmacodynamics

The myeloid growth factors stimulate proliferation and differentiation by interacting with specific receptors found on various myeloid progenitor cells. These receptors are members of the superfamily of receptors that transduce signals by association with cytoplasmic tyrosine kinases in the JAK/STAT pathway (see Chapter 2: Drug Receptors & Pharmacodynamics). G-CSF stimulates proliferation and differentiation of progenitors already committed to the neutrophil lineage. It also activates the phagocytic activity of mature neutrophils and prolongs their survival in the circulation. G-CSF also has a remarkable ability to mobilize hematopoietic stem cells, ie, to increase their concentration in peripheral blood. This biologic effect underlies a major advance in transplantation—the use of peripheral blood stem cells (PBSCs) instead of bone marrow stem cells for autologous and allogeneic hematopoietic stem cell transplantation (see below).

GM-CSF has broader biologic actions than G-CSF. It is a multipotential hematopoietic growth factor that stimulates proliferation and differentiation of early and late granulocytic progenitor cells as well as erythroid and megakaryocyte progenitors. Like G-CSF, GM-CSF also stimulates the function of mature neutrophils. GM-CSF acts together with interleukin-2 to stimulate T cell proliferation and appears to be a locally active factor at the site of inflammation. GM-CSF mobilizes peripheral blood stem cells, but it is significantly less efficacious than G-CSF in this

regard.

Clinical Pharmacology

Neutropenia, a common adverse effect of the cytotoxic drugs used to treat cancer, puts patients at high risk of serious infection. Unlike the treatment of anemia and thrombocytopenia, transfusion of neutropenic patients with granulocytes collected from donors is performed rarely and with limited success. The introduction of G-CSF in 1991 represented a milestone in the treatment of chemotherapy-induced neutropenia. This growth factor dramatically accelerates the rate of neutrophil recovery after dose-intensive myelosuppressive chemotherapy (Figure 33–4). It reduces the duration of neutropenia and usually raises the nadir, the lowest neutrophil count seen following a cycle of chemotherapy.

Figure 33–4.

Effects of G-CSF (color) or placebo (black line) on absolute neutrophil count (ANC) after cytotoxic chemotherapy for lung cancer. Doses of chemotherapeutic drugs were administered on days 1 and 3. G-CSF or placebo injections were started on day 4 and continued daily through day 12 or 16. The first peak in ANC reflects the recruitment of mature cells by G-CSF. The second peak reflects a marked increase in new neutrophil production by the bone marrow under stimulation by G-CSF. Treated patients in this study had fewer days of neutropenia, days of antibiotic treatment, and days of hospitalization. They also had a lower incidence of infections. (Normal ANC is $2.2\text{--}8.6 \times 10^9/\text{L}$.) (Modified and reproduced, with permission, from Crawford et al: Reduction by granulocyte colony-stimulating factor of fever and neutropenia induced by chemotherapy in patients with small-cell lung cancer. *N Engl J Med* 1991;325:164.)

While the ability of G-CSF to increase neutrophil counts after myelosuppressive chemotherapy is nearly universal, its impact upon clinical outcomes is more variable. Some clinical trials have shown that G-CSF reduces episodes of febrile neutropenia, requirements for broad-spectrum antibiotics, and days of hospitalization; however, other trials failed to find these favorable outcomes. To date, no clinical trial has shown improved survival in cancer patients treated with G-CSF. Clinical guidelines for the use of G-CSF after cytotoxic chemotherapy have been published (Ozer et al, 2001). These guidelines recommend reserving G-CSF for patients with a prior episode of febrile neutropenia after cytotoxic chemotherapy, patients receiving dose-intensive chemotherapy, patients at high risk of febrile neutropenia, and patients who are unlikely to survive an episode of febrile neutropenia. Pegfilgrastim is an alternative to G-CSF for prevention of chemotherapy-induced febrile neutropenia. Pegfilgrastim can be administered less frequently, and it may shorten the period of severe neutropenia slightly more than G-CSF.

Like G-CSF and pegfilgrastim, GM-CSF also reduces the duration of neutropenia after cytotoxic chemotherapy. It has been more difficult to show that GM-CSF reduces the incidence of febrile neutropenia, probably because GM-CSF itself can induce fever. In the treatment of chemotherapy-induced neutropenia, G-CSF, 5 $\mu\text{g}/\text{kg}/\text{d}$, or GM-CSF, 250 $\mu\text{g}/\text{m}^2/\text{d}$, is usually started within 24–72 hours after completing chemotherapy and is continued until the absolute neutrophil count is $> 10,000$ cells/ μL . Pegfilgrastim is given as a single dose instead of as daily injections.

The utility and safety of the myeloid growth factors in the postchemotherapy supportive care of patients with acute myeloid leukemia (AML) has been the subject of a number of clinical trials. Since leukemic cells arise from progenitors whose proliferation and differentiation are normally regulated by hematopoietic growth factors, including GM-CSF and G-CSF, there was concern that myeloid growth factors could stimulate leukemic cell growth and increase the rate of relapse. The results of randomized clinical trials suggest that both G-CSF and GM-CSF are safe following induction and consolidation treatment of myeloid and lymphoblastic leukemia. There has been no evidence that these growth factors reduce the rate of remission or increase relapse rate. On the contrary, the growth factors accelerate neutrophil recovery and reduce infection rates and days of hospitalization. Both G-CSF and GM-CSF have FDA approval for treatment of patients with AML.

G-CSF and GM-CSF have also been shown to be effective in treating the neutropenia associated with congenital neutropenia, cyclic neutropenia, myelodysplasia, and aplastic anemia. Many patients with these disorders respond with a prompt and sometimes dramatic increase in neutrophil count. In some cases this results in a decrease in the frequency of infections. Since G-CSF and GM-CSF do not stimulate the formation of erythrocytes or platelets, they are sometimes used in combination with other growth factors for treatment of pancytopenia.

The myeloid growth factors play an important role in autologous stem cell transplantation for patients undergoing high-dose chemotherapy. High-dose chemotherapy with autologous stem cell support is increasingly being used to treat patients with tumors that are resistant to standard doses of chemotherapeutic drugs. The high-dose regimens produce extreme myelosuppression; the myelosuppression is then counteracted by reinfusion of the patient's own hematopoietic stem cells (which are collected prior to chemotherapy). The administration of G-CSF or GM-CSF early after autologous stem cell transplantation has been shown to reduce the time to engraftment and to recovery from neutropenia in patients receiving stem cells obtained either from bone marrow or from peripheral blood. These effects are seen in patients being treated for lymphoma or for solid tumors. G-CSF and GM-CSF are also used to support patients who have received allogeneic bone marrow transplantation for treatment of hematologic malignancies or bone marrow failure states. In this setting, the growth factors speed the recovery from neutropenia without increasing the incidence of acute graft-versus-host disease.

Probably the most important role of the myeloid growth factors in transplantation is for mobilization of peripheral blood stem cells (PBSCs). Stem cells collected from peripheral blood have nearly replaced bone marrow as the hematopoietic preparation used for autologous transplantation. The cells can be collected in an outpatient setting with a procedure that avoids much of the risk and discomfort of bone marrow collection, including the need for general anesthesia. In addition, there is evidence that PBSC transplantation results in more rapid engraftment of all hematopoietic cell lineages and in reduced rates of graft failure or delayed platelet recovery. The use of PBSCs for allogeneic transplantation is also being investigated. In allogeneic transplantation, donors are treated with G-CSF in order to mobilize their PBSCs prior to leukapheresis, the procedure that separates the fraction containing stem cells from the other components in blood.

G-CSF is the cytokine most commonly used for PBSC mobilization because of its increased efficacy and reduced toxicity compared with GM-CSF. To mobilize stem cells, patients or donors are given 5–10 $\mu\text{g}/\text{kg}/\text{d}$ subcutaneously for 4 days. On the fifth day, they undergo leukapheresis. The success of PBSC transplantation depends upon transfusion of adequate numbers of stem cells. CD34, an antigen present on early progenitor cells and absent from later, committed, cells, is used as a marker for the requisite stem cells. The goal is to reinfuse at least 5×10^6 CD34 cells/kg; this number of CD34 cells usually results in prompt and durable engraftment of all cell lineages. It can take several separate leukaphereses to collect enough CD34 cells, especially from older patients and patients who have been exposed to radiotherapy or chemotherapy.

Toxicity

Although the two growth factors have similar effects on neutrophil counts, G-CSF is used more frequently because it is better tolerated. G-CSF can cause bone pain, which clears when the drug is discontinued. GM-CSF can cause more severe side effects, particularly at higher doses. These include fevers, malaise, arthralgias, myalgias, and a capillary leak syndrome characterized by peripheral edema and pleural or pericardial effusions. Allergic reactions may occur but are infrequent. Splenic rupture is a rare but serious complication of the use of G-CSF for PBSC.

Megakaryocyte Growth Factors

Chemistry & Pharmacokinetics

Interleukin-11 (IL-11) is a 65–85 kDa protein produced by fibroblasts and stromal cells in the bone marrow. **Oprelvekin**, the recombinant form of interleukin-11 approved for clinical use, is produced by expression in *E coli*. The half-life of IL-11 is 7–8 hours when the drug is injected subcutaneously.

Thrombopoietin, a 65–85 kDa glycosylated protein, is constitutively expressed by a variety of organs and cell types. Hepatocytes appear to be the major source of human thrombopoietin, and patients with cirrhosis and thrombocytopenia have low serum thrombopoietin levels. Recombinant thrombopoietin is produced by expression in human cells; the recombinant product contains two intramolecular disulfide bonds and a number of carbohydrate side chains.

Pharmacodynamics

Interleukin-11 acts through a specific cell surface cytokine receptor to stimulate the growth of multiple lymphoid and myeloid cells. It acts synergistically with other growth factors to stimulate the growth of primitive megakaryocytic progenitors and, most importantly, increases the number of peripheral platelets and neutrophils.

Acting through its own cytokine receptor, thrombopoietin also independently stimulates the growth of primitive megakaryocytic progenitors. In addition, it stimulates mature megakaryocytes and even activates mature platelets to respond to aggregation-inducing stimuli. The critical *in vivo* role of thrombopoietin has been demonstrated in genetically engineered knockout mice who lack either thrombopoietin or its receptor. These mice have marked thrombocytopenia but do not display anemia or leukopenia.

Clinical Pharmacology

Patients with thrombocytopenia have a high risk of hemorrhage. While platelet transfusion is

commonly used to treat thrombocytopenia, this procedure can cause adverse reactions in the recipient; furthermore, a significant number of patients fail to exhibit the expected increase in platelet count.

Interleukin-11 is the first growth factor to gain FDA approval for treatment of thrombocytopenia. It is approved for the secondary prevention of thrombocytopenia in patients receiving cytotoxic chemotherapy for treatment of nonmyeloid cancers. Clinical trials show that it reduces the number of platelet transfusions required by patients who experienced severe thrombocytopenia after a previous cycle of chemotherapy. Although IL-11 has broad stimulatory effects on hematopoietic cell lineages in vitro, it does not appear to have significant effects on the leukopenia or neutropenia caused by myelosuppressive chemotherapy. Interleukin-11 is given by subcutaneous injection at a dose of 50 $\mu\text{g}/\text{kg}/\text{d}$. It is started 6–24 hours after completion of chemotherapy and continued for 14–21 days or until the platelet count passes the nadir and rises to $> 50,000$ cells/ μL .

Recombinant thrombopoietin is still an investigational agent. The primary focus of current clinical trials is for the treatment of chemotherapy-induced thrombocytopenia and thrombocytopenia accompanying hematologic stem cell transplantation. Other trials are looking into the possibility of administering thrombopoietin to normal donors in order to increase the number of cells recovered by platelet apheresis. Approval of the latter application will require that thrombopoietin be shown to have an excellent short- and long-term safety profile.

Toxicity

The most common side effects of interleukin-11 are fatigue, headache, dizziness, and cardiovascular effects. The cardiovascular effects include anemia (due to hemodilution), dyspnea (due to fluid accumulation in the lungs), and transient atrial arrhythmias. Hypokalemia has also been seen in some patients. All of these adverse effects appear to be reversible. In the limited clinical trial data available thus far, recombinant thrombopoietin appears to be well tolerated.

Katzung PHARMACOLOGY, 9e > Section VI. Drugs Used to Treat Disease of the Blood, Inflammation, & Gout > Chapter 33. Agents Used in Anemias; Hematopoietic Growth Factors >

Preparations Available

Darbopoetin alfa (Aranesp)

Parenteral: 25, 40, 60, 100, 150, 200, 300, 500 $\mu\text{g}/\text{mL}$ for IV or SC injection

Deferoxamine (Desferal)

Parenteral: 500 mg vials for IM, SC, or IV injection

Epoetin alfa (erythropoietin, Epo) (Epogen, Pro-crit)

Parenteral: 2000, 3000, 4000, 10,000, 20,000 IU/mL vials for IV or SC injection

Filgrastim (G-CSF) (Neupogen)

Parenteral: 300 μg vials for IV or SC injection

Folic acid (folacin, pteroylglutamic acid) (generic)

Oral: 0.4, 0.8, 1 mg tablets

Parenteral: 5 mg/mL for injection

Iron (generic)

Oral: See Table 33–2.

Parenteral (Iron dextran) (InFeD, DexFerrum): 50 mg elemental iron/mL

Parenteral (Sodium ferric gluconate complex) (Ferlecit): 12.5 mg elemental iron/mL

Parenteral (Iron sucrose)(Venofer): 20 mg elemental iron/mL

Oprelvekin (interleukin-11) (Neumega)

Parenteral: 5 mg vials for SC injection

Pegfilgrastim (Neulasta)

Parenteral: 10 mg/mL solution in single-dose syringe

Sargramostim (GM-CSF) (Leukine)

Parenteral: 250, 500 µg vials for IV infusion

Vitamin B₁₂ (generic cyanocobalamin or hydroxo- cobalamin)

Oral (cyanocobalamin): 100, 500, 1000 µg tablets, 100, 250, 500 µg lozenges

Nasal (Nascobal): 5000 µg/mL (500 µg/spray)

Parenteral (cyanocobalamin): 100, 1000 µg/mL for IM or SC injection

Parenteral (hydroxocobalamin): 1000 µg/mL for IM injection only

Chapter 34. Drugs Used in Disorders of Coagulation

Katzung PHARMACOLOGY, 9e > Section VI. Drugs Used to Treat Disease of the Blood, Inflammation, & Gout > Chapter 34. Drugs Used in Disorders of Coagulation >

Drugs Used in Disorders of Coagulation: Introduction

Excessive bleeding and thrombosis may represent altered states of hemostasis. Impaired hemostasis results in spontaneous bleeding; stimulated hemostasis results in thrombus formation. The drugs used to arrest abnormal bleeding and to inhibit thrombosis are the subjects of this chapter.

Mechanisms of Blood Coagulation

Thrombogenesis

Hemostasis is the spontaneous arrest of bleeding from a damaged blood vessel. The normal vascular endothelial cell is not thrombogenic, and circulating blood platelets and clotting factors do not normally adhere to it to an appreciable extent. The immediate hemostatic response of a damaged vessel is **vasospasm**. Within seconds, platelets stick to the exposed collagen of the damaged endothelium (**platelet adhesion**) and to each other (**platelet aggregation**). Platelets then lose their individual membranes and form a gelatinous mass during **viscous metamorphosis**. This **platelet plug** quickly arrests bleeding but must be reinforced by fibrin for long-term effectiveness. Fibrin reinforcement results from local stimuli to blood coagulation: the exposed collagen of damaged vessels and the membranes and released contents of platelets (Figure 34–1). The local production of thrombin not only releases platelet **adenosine diphosphate (ADP)**, a powerful inducer of platelet aggregation, but also stimulates the synthesis of prostaglandins from the arachidonic acid of platelet membranes. These powerful substances are composed of two groups of eicosanoids (Chapter 18: The Eicosanoids: Prostaglandins, Thromboxanes, Leukotrienes, & Related Compounds) that have opposite effects on thrombogenesis. **Thromboxane A₂ (TXA₂)** is synthesized within platelets and induces thrombogenesis and vasoconstriction. **Prostacyclin (PGI₂)** is synthesized within vessel walls and inhibits thrombogenesis. **Serotonin (5-HT)** is also released from the platelets, stimulating further aggregation and vasoconstriction.

Figure 34–1.

Thrombus formation at the site of the damaged vascular wall (EC, endothelial cell) and the role of platelets and clotting factors. Platelet membrane receptors include the glycoprotein (GP) Ia receptor, binding to collagen (C); GP Ib receptor binding, von Willebrand factor (vWF), and GP

I**b**/IIIa, which binds fibrinogen and other macromolecules. Antiplatelet prostacyclin (PGI₂) is released from the endothelium. Aggregating substances released from the degranulating platelet include ADP, TXA₂, and 5-HT. Production of factor Xa is detailed in Figure 34–2. (Redrawn and reproduced, with permission, from Simoons ML, Decker JW: New directions in anticoagulant and antiplatelet treatment. [Editorial.] Br Heart J 1995;74:337.)

The platelet is central to normal hemostasis and to all thromboembolic disease. A **white thrombus** forms initially in high-pressure arteries by adherence of circulating platelets to areas of abnormal endothelium as described above. The growing thrombus of aggregated platelets reduces arterial flow. This localized stasis triggers fibrin formation, and a red thrombus forms around the nidus white thrombus.

A **red thrombus** can form around a white thrombus as mentioned above or de novo in low-pressure veins, initially by adherence of platelets (as in arteries) but followed promptly by the process of blood coagulation so that the bulk of the thrombus forms a long tail consisting of a fibrin network in which red cells are enmeshed. These tails become detached easily and travel as emboli to the pulmonary arteries. Such emboli often arise from a deep venous thrombosis (DVT)—a thrombus in the veins of the legs or pelvis. Although all thrombi are mixed, the platelet nidus dominates the arterial thrombus and the fibrin tail the venous thrombus. Arterial thrombi cause serious disease by producing local occlusive ischemia; venous thrombi, by giving rise to distant embolization.

Blood Coagulation

Blood coagulates by the transformation of soluble fibrinogen into insoluble fibrin. Several circulating proteins interact in a cascading series of limited proteolytic reactions. At each step, a clotting factor zymogen (eg, factor VII) undergoes limited proteolysis and becomes an active protease (eg, factor VIIa). Thus, each protease factor activates the next clotting factor until finally a solid fibrin clot is formed. Fibrinogen (factor I), the soluble precursor of fibrin, is the substrate for the enzyme thrombin (factor IIa). This protease is formed during coagulation by activation of its zymogen, prothrombin (factor II). Prothrombin is bound by calcium to a platelet phospholipid (PL) surface, where activated factor X (Xa), in the presence of factor Va, converts it into circulating thrombin. Several of the blood clotting factors are targets for drug therapy (Table 34–1).

Table 34–1. Blood Clotting Factors and Drugs That Affect Them.¹

Component or Factor	Common Synonym	Target for the Action of:
I	Fibrinogen	
II	Prothrombin	Heparin (IIa); warfarin (synthesis)
III	Tissue thromboplastin	
IV	Calcium	
V	Proaccelerin	
VII	Proconvertin	Warfarin (synthesis)
VIII	Antihemophilic factor (AHF)	
IX	Christmas factor, plasma thromboplastin	Warfarin (synthesis)

	component (PTC)	
X	Stuart-Prower factor	Heparin (Xa); warfarin (synthesis)
XI	Plasma thromboplastin antecedent (PTA)	
XII	Hageman factor	
XIII	Fibrin-stabilizing factor	
Proteins C and S		Warfarin (synthesis)
Plasminogen		Thrombolytic enzymes, aminocaproic acid

¹See Figure 34–2 and text for additional details.

The main initiator of blood coagulation is the tissue factor (TF)/factor VIIa pathway. The exposure of TF on damaged endothelium binds and activates circulating factor VII (Figure 34–2). This complex, in turn, activates factors X and IX, with the eventual generation of thrombin. Thrombin, in turn, activates upstream proteins, primarily factors V, VIII, and XI, resulting in further thrombin generation. Additionally, thrombin is a potent activator of platelets, converts fibrinogen to fibrin, and activates factor XIII, resulting in an insoluble, cross-linked fibrin molecule.

Figure 34–2.

A model of blood coagulation. With tissue factor (TF), factor VII forms an activated complex (VIIa-TF) that catalyzes the activation of factor IX to factor IXa. Activated factor XIa also

catalyzes this reaction. Tissue factor pathway inhibitor (TFPI) inhibits the catalytic action of the VIIa-TF complex. The cascade proceeds as shown, resulting ultimately in the conversion of fibrinogen to fibrin, an essential component of a functional clot. The two major anticoagulant drugs, heparin and warfarin (an oral anticoagulant), have very different actions. Heparin, acting in the blood, directly activates anticlotting factors, specifically antithrombin, which inactivates the factors enclosed in rectangles. Warfarin, acting in the liver, inhibits the synthesis of the factors enclosed in circles. Proteins C and S exert anticlotting effects by inactivating activated factors Va and VIIIa.

The TF/factor VII/factor X process is inhibited and regulated by tissue factor pathway inhibitor (TFPI). Oral anticoagulant drugs inhibit the hepatic synthesis of several clotting factors. Heparin inhibits the activity of several of these activated clotting factors by enhancing the anticoagulant activity of **antithrombin**, which inactivates the serine proteases IIa, IXa, Xa, XIa, and XIIa. The endogenous anticoagulants protein C and protein S diminish amplification in the blood clotting cascade by proteolysis of factors Va and VIIIa.

Regulation of Coagulation & Fibrinolysis

Blood coagulation and thrombus formation must be confined to the smallest possible area to achieve local hemostasis in response to bleeding from trauma or surgery without causing disseminated coagulation or impaired blood flow. Two major systems regulate and delineate these processes: **fibrin inhibition** and **fibrinolysis**.

Plasma contains protease inhibitors that rapidly inactivate the coagulation proteins as they escape from the site of vessel injury. The most important proteins of this system are α_1 -antiprotease, α_2 -macroglobulin, α_2 -antiplasmin, and antithrombin. If this system is overwhelmed, generalized intravascular clotting may occur. This process is called **disseminated intravascular coagulation (DIC)** and may follow massive tissue injury, cell lysis in malignant neoplastic disease, obstetric emergencies such as abruptio placentae, or bacterial sepsis.

The central process of fibrinolysis is conversion of inactive plasminogen to the proteolytic enzyme **plasmin**. Injured cells release activators of plasminogen. Plasmin remodels the thrombus and limits the extension of thrombosis by proteolytic digestion of fibrin.

Regulation of the fibrinolytic system is useful in therapeutics. Increased fibrinolysis is effective therapy for thrombotic disease. **Tissue plasminogen activator (t-PA)**, **urokinase**, and **streptokinase** all activate the fibrinolytic system (Figure 34–3). Conversely, decreased fibrinolysis protects clots from lysis and reduces the bleeding of hemostatic failure. **Aminocaproic acid** is a clinically useful inhibitor of fibrinolysis. Heparin and the oral anticoagulant drugs do not affect the fibrin-olytic mechanism.

Figure 34–3.

Schematic representation of the fibrin-olytic system. Plasmin is the active fibrinolytic enzyme. Several clinically useful activators are shown on the left in bold. Anistreplase is a combination of streptokinase and the proactivator plasminogen. Aminocaproic acid (right) inhibits the activation of plasminogen to plasmin and is useful in some bleeding disorders.

Basic Pharmacology of the Anticoagulant Drugs

Indirect Thrombin Inhibitors

The indirect thrombin inhibitors are so named because their antithrombotic effect is exerted by their interaction with antithrombin. **Unfractionated heparin (UFH)**, **low-molecular-weight heparin (LMWH)**, and the synthetic pentasaccharide **fondaparinux** bind to antithrombin and enhance its inactivation of factor Xa. UFH and to a lesser extent LMWH also enhance antithrombin's inactivation of thrombin (IIa).

Heparin

Chemistry & Mechanism of Action

Heparin is a heterogeneous mixture of sulfated mucopolysaccharides. It binds to endothelial cell surfaces and a variety of plasma proteins. As noted above, its biologic activity is dependent upon the plasma protease inhibitor **antithrombin**. Antithrombin inhibits clotting factor proteases, especially thrombin (IIa), IXa, and Xa, by forming equimolar stable complexes with them. In the absence of heparin, these reactions are slow; in the presence of heparin, they are accelerated 1000-fold. Only about a third of the molecules in commercial heparin preparations have an accelerating effect because the remainder lack the unique pentasaccharide sequence needed for high-affinity binding to antithrombin (Figure 34-4). The active heparin molecules bind tightly to antithrombin

and cause a conformational change in this inhibitor. The conformational change of antithrombin exposes its active site for more rapid interaction with the proteases (the activated clotting factors). Heparin catalyzes the antithrombin-protease reaction without being consumed. Once the antithrombin-protease complex is formed, heparin is released intact for renewed binding to more antithrombin.

Figure 34–4.

Subunit structure of heparin. The small polymer section shown illustrates the repeating disaccharide units typical of heparin. The sequence shows the critical pentasaccharide portion required for binding to antithrombin. In addition to those shown, other saccharides occur. Heparin is a strongly acidic molecule because of its high content of anionic sulfate and carboxylic acid groups. GlcN, glucosamine; IdUA, iduronic acid; GlcUA, glucuronic acid. The same five residues with the terminal groups shown in parentheses, constitute fondaparinux.

The antithrombin binding region of commercial unfractionated heparin consists of repeating sulfated disaccharide units composed of D-glucosamine-L-iduronic acid and D-glucosamine-D-glucuronic acid (Figure 34–4). High-molecular-weight (HMW) fractions of heparin with high affinity for antithrombin markedly inhibit blood coagulation by inhibiting all three factors, especially thrombin and factor Xa. Unfractionated heparin has a MW range of 5000–30,000. In contrast, the shorter-chain low-molecular-weight (LMW) fractions of heparin inhibit activated factor X but have less effect on thrombin (and on coagulation in general) than the HMW species. Nevertheless, numerous studies have demonstrated that LMW heparins such as **enoxaparin**, **dalteparin**, and **tinzaparin** are effective in several thromboembolic conditions. In fact, these LMW heparins—in comparison with UFH—have equal efficacy, increased bioavailability from the subcutaneous site of injection, and less frequent dosing requirements (once or twice daily is sufficient).

Because commercial heparin consists of a family of molecules of different molecular weights, the correlation between the concentration of a given heparin preparation and its effect on coagulation often is poor. Therefore, UFH is standardized by bioassay. Heparin sodium USP must contain at least 120 USP units per milligram. Heparin is generally used as the sodium salt, but calcium heparin is equally effective. Lithium heparin is used in vitro as an anticoagulant for blood samples. Commercial heparin is extracted from porcine intestinal mucosa and bovine lung. Enoxaparin is obtained from the same sources as regular heparin, but doses are specified in milligrams. Dalteparin, tinzaparin and danaparoid (an LMW heparanoid containing heparan sulfate, dermatan sulfate, and chondroitin sulfate that is no longer available in the United States), on the other hand, are specified in anti-factor Xa units.

Toxicity

The major adverse effect of heparin is bleeding. This risk can be decreased by scrupulous patient selection, careful control of dosage, and close monitoring of the activated partial thromboplastin time (aPTT) in those patients receiving unfractionated heparin. Levels for UFH may also be determined by protamine titration (therapeutic levels 0.2–0.4 unit/mL) or anti-Xa units (therapeutic levels 0.3–0.7 unit/mL). Weight-based dosing of the LMW heparins results in predictable pharmacokinetics and plasma levels in patients with normal renal function. Therefore, LMW heparin levels are not generally measured except in the setting of renal insufficiency, obesity, and pregnancy. LMW heparin levels are determined by anti-Xa units. Peak therapeutic levels are 0.5–1 unit/mL for twice daily dosing, determined 4 hours after administration, and approximately 1.5 units/mL for once daily dosing. Elderly women and patients with renal failure are more prone to hemorrhage. Heparin is of animal origin and should be used cautiously in patients with allergy. Increased loss of hair and reversible alopecia have been reported. Long-term heparin therapy is associated with osteoporosis and spontaneous fractures. Heparin accelerates the clearing of postprandial lipemia by causing the release of lipoprotein lipase from tissues, and long-term use is associated with mineralocorticoid deficiency.

Heparin causes transient thrombocytopenia in 25% or more of patients and severe thrombocytopenia in 5%. Mild platelet reduction within the first 5 days of therapy may result from heparin-induced aggregation that is postulated to be benign and transient in character. A smaller subset of patients may develop an antibody-mediated thrombocytopenia that is associated with paradoxical thrombosis. In these instances, the heparin-induced antibody is directed against the heparin-platelet factor 4 complex. These antigen-antibody complexes bind to Fc receptors on adjacent platelets, causing aggregation and thromboembolism. The following points should be considered in all patients receiving heparin: Platelet counts should be performed frequently; thrombocytopenia should be considered to be heparin-induced; any new thrombus can be the result of heparin; and thromboembolic disease thought to be heparin-induced should be treated by discontinuance of heparin and administration of an alternative drug, such as a direct thrombin inhibitor (see below). Administration of warfarin alone is contraindicated since it may exacerbate the prothrombotic state associated with heparin-induced thrombocytopenia.

Contraindications

Heparin is contraindicated in patients who are hypersensitive to the drug, are actively bleeding, or have hemophilia, significant thrombocytopenia, purpura, severe hypertension, intracranial hemorrhage, infective endocarditis, active tuberculosis, ulcerative lesions of the gastrointestinal tract, threatened abortion, visceral carcinoma, or advanced hepatic or renal disease. Heparin should be avoided in those patients who have recently had surgery of the brain, spinal cord, or eye and in patients who are undergoing lumbar puncture or regional anesthetic block. Despite the apparent lack of placental transfer, heparin should be used in pregnant women only when clearly indicated.

Administration & Dosage

The indications for the use of heparin are described in the section on clinical pharmacology. A plasma concentration of heparin of 0.2–0.4 unit/mL (by protamine titration) or 0.3–0.7 unit/mL (anti-Xa units) usually prevents pulmonary emboli in patients with established venous thrombosis. This concentration of heparin will prolong the activated partial thromboplastin time (aPTT) to 2–2.5 times that of the control value. This degree of anticoagulant effect should be maintained throughout the course of *continuous* intravenous heparin therapy. When *intermittent* heparin administration is used, the aPTT should be measured 6 hours after the administered dose to maintain prolongation of the aPTT to 2–2.5 times that of the control value.

Continuous intravenous administration of heparin is accomplished via an infusion pump. After an initial bolus injection of 80-100 units/kg, a continuous infusion of about 15-22 units/kg/h is required to maintain the aPTT at 2–2.5 times control. Patients with acute pulmonary emboli often require larger doses than these during the first few days because of binding to a variety of acute phase proteins, such as factor VIII and von Willebrand factor, and increased heparin clearance. Subcutaneous administration of heparin, as in low-dose prophylaxis, is achieved with 5000 units every 8–12 hours. Because of the danger of hematoma formation at the injection site, heparin must never be administered intramuscularly.

Prophylactic enoxaparin is given subcutaneously in a dosage of 30 mg twice daily or 40 mg once daily. Full-dose enoxaparin therapy is 1 mg/kg subcutaneously every 12 hours. This corresponds to a therapeutic anti-factor Xa level of 0.5–1 unit/mL. Selected patients may be treated with enoxaparin 1.5 mg/kg once a day, with a target anti-Xa level of 1.5 units/mL. The prophylactic dose of dalteparin is 5000 units subcutaneously once a day; therapeutic dosing is 200 units/kg once a day for venous disease or 120 units/kg every 12 hours for acute coronary syndrome. The use of LMW heparins is discouraged or contraindicated in patients with renal insufficiency or body weight greater than 150 kg.

The synthetic pentasaccharide molecule fondaparinux (Figure 34–4) avidly binds antithrombin with high specific activity, resulting in efficient inactivation of factor Xa. Fondaparinux has a long half-life of 15 hours, allowing for once-daily dosing by subcutaneous administration. A series of phase 3 studies in orthopedic patients comparing fondaparinux 2.5 mg subcutaneously daily beginning 6 hours postoperatively versus enoxaparin either 40 mg daily or 30 mg twice daily found fondaparinux to be superior in preventing development of asymptomatic deep venous thrombosis. A phase 3 study evaluating the use of fondaparinux coupled with warfarin compared with LMWH plus warfarin in the treatment of acute venous thromboembolic disease found these two treatment approaches equivalent. Increased bleeding with fondaparinux is seen in patients administered the drug sooner than 6 hours postoperatively, in those who weigh less than 50 kg, and in those with renal insufficiency.

Reversal of Heparin Action

Excessive anticoagulant action of heparin is treated by discontinuance of the drug. If bleeding occurs, administration of a specific antagonist such as protamine sulfate is indicated. Protamine is a highly basic peptide that combines with heparin as an ion pair to form a stable complex devoid of anticoagulant activity. For every 100 units of heparin remaining in the patient, administer 1 mg of protamine sulfate intravenously; the rate of infusion should not exceed 50 mg in any 10-minute period. Excess protamine must be avoided; it also has an anticoagulant effect. Neutralization of LMW heparin by protamine is incomplete. Limited experience suggests that 1 mg of protamine sulfate may be used to partially neutralize 1 mg of enoxaparin. Protamine will not reverse the activity of fondaparinux. Excess danaparoid can be removed by plasmapheresis.

Direct Thrombin Inhibitors

The direct thrombin inhibitors (DTI) are a relatively new class of agents that exert their anticoagulant effect by directly binding to the active site of thrombin, thereby inhibiting thrombin's downstream effects. The DTIs bind thrombin without additional binding proteins, such as antithrombin, and they do not bind to other plasma proteins, such as platelet factor 4. **Hirudin** and **bivalirudin** are bivalent DTIs in that they bind at both the catalytic or active site of thrombin as well as at a substrate recognition site. **Argatroban** and **melagatran** are small molecules that bind only at the thrombin active site.

Hirudin

For a number of years, surgeons have used medicinal leeches (*Hirudo medicinalis*) to prevent thrombosis in the fine vessels of reattached digits. Hirudin is a specific, irreversible thrombin inhibitor from the leech that is now available in recombinant form as **lepirudin**. Its action is independent of antithrombin, which means it can reach and inactivate fibrin-bound thrombin in thrombi. Lepirudin has little effect on platelets or the bleeding time. Like heparin, it must be administered parenterally and is monitored by the aPTT. Lepirudin is FDA-approved for use in patients with thrombosis related to heparin-induced thrombocytopenia. This drug has a short half-life, but it accumulates in renal insufficiency and no antidote exists. Up to 40% of patients on long-term infusions develop an antibody directed against the thrombin-lepirudin complex. These antigen-antibody complexes are not cleared by the kidney and may result in an enhanced anticoagulant effect.

Bivalirudin, another bivalent inhibitor of thrombin, is administered intravenously, with a rapid onset and offset of action. The drug has a short half-life with clearance that is 20% renal and the remainder metabolic. Bivalirudin inhibits platelet activation and been FDA-approved for use in percutaneous coronary angioplasty.

Argatroban is a small molecule thrombin inhibitor that is FDA approved for use in patients with heparin-induced thrombocytopenia (HIT) with or without thrombosis and coronary angioplasty in patients with HIT. It, too, has a short half-life, is given by continuous intravenous infusion, and monitoring is done by aPTT. Its clearance is not affected by renal disease but is dependent on liver function. The drug requires dose reduction in patients with liver disease. Patients on argatroban will demonstrate elevated INRs because of test interference, rendering the transition to warfarin difficult.

Melagatran is the fourth parenteral drug in this class. It and its oral prodrug, ximelagatran, are under intensive study. Attractive features of ximelagatran include predictable pharmacokinetics and bioavailability—allowing for fixed dosing and predictable anticoagulant response; no need for routine coagulation monitoring; lack of interaction with P450-interacting drugs; rapid onset and offset of action—allowing for immediate anticoagulation and thus no need for overlap with additional anticoagulant drugs. A published phase 3 trial in patients status post major orthopedic surgery found ximelagatran equivalent to warfarin in preventing postoperative DVT. Clinical trials in patients with acute DVT and chronic atrial fibrillation are on-going.

Warfarin & the Coumarin Anticoagulants

Chemistry & Pharmacokinetics

The clinical use of the coumarin anticoagulants can be traced to the discovery of an anticoagulant substance formed in spoiled sweet clover silage. It produced a deficiency of plasma prothrombin and consequent hemorrhagic disease in cattle. The toxic agent was identified as bishydroxycoumarin and synthesized as dicumarol. This drug and its congeners, most notably warfarin (Figure 34–5), are widely used as rodenticides in addition to their application as antithrombotic agents in humans. Warfarin is the most reliable member of this group, and the other coumarin anticoagulants are almost never used in the USA.

Figure 34–5.

Warfarin is generally administered as the sodium salt and has 100% bioavailability. Over 99% of racemic warfarin is bound to plasma albumin, which may contribute to its small volume of distribution (the albumin space), its long half-life in plasma (36 hours), and the lack of urinary excretion of unchanged drug. Warfarin used clinically is a racemic mixture composed of equal amounts of two enantiomorphs. The levorotatory *S*-warfarin is four times more potent than the dextrorotatory *R*-warfarin. This observation is useful in understanding the stereoselective nature of several drug interactions involving warfarin.

Mechanism of Action

Coumarin anticoagulants block the γ -carboxylation of several glutamate residues in prothrombin and factors VII, IX, and X as well as the endogenous anticoagulant proteins C and S (Figure 34–2). The blockade results in incomplete molecules that are biologically inactive in coagulation. This protein carboxylation is physiologically coupled with the oxidative deactivation of vitamin K. The anticoagulant prevents reductive metabolism of the inactive vitamin K epoxide back to its active hydroquinone form (Figure 34–6). Mutational change of the responsible enzyme, vitamin K epoxide reductase, can give rise to genetic resistance to warfarin in humans and especially in rats.

Figure 34–6.

Vitamin K cycle—metabolic interconversions of vitamin K associated with the synthesis of vitamin K-dependent clotting factors. Vitamin K₁ or K₂ is activated by reduction to the hydroquinone form (KH_2). Stepwise oxidation to vitamin K epoxide (KO) is coupled to prothrombin carboxylation by the enzyme carboxylase. The reactivation of vitamin K epoxide is the warfarin-sensitive step (warfarin). The R on the vitamin K molecule represents a 20-carbon phytanyl side chain in vitamin K₁ and a 30- to 65-carbon polyprenyl side chain in vitamin K₂.
