2. The ability to quantitatively measure pancreatic secretions
3. The ability to exclude gastric acid and pepsin

Exogenous Hormonal Stimulation

There is no standard method of hormonal stimulation. Consequently, techniques vary between centers, and each laboratory is required to establish its own range of normal values. The doses of hormones used, the mode of administration (intravenous bolus or intravenous infusion), the duration of infusion, and, in the case of a combined secretin CCK infusion, the sequence of administration may all differ. Little information exists regarding optimum doses in children, especially for synthetic secretin and CCK; in most cases, doses have been extrapolated from adult data on a weight per kilogram basis. Current sources of supply of pancreatic secretagogues are listed in Table 72-3. Synthetic preparations of secretin and CCK are preferable to animal extracts in that they are not contaminated with other gut-derived peptides and because they are less allergenic. Supply of agents approved for human use has been problematic in recent years. Combined stimulation is optimal because there is evidence that CCK or similar hormones act synergistically with secretin.[2] Other investigators have used cerulein (a decapeptide) or bombesin (a tetradecapeptide) alone or in combination with secretin because these peptides have effects on the exocrine pancreas similar to those of CCK. No published information exists regarding their use in children.

Quantification of secretions requires that precise volume data be obtained. Two approaches are used: distal occlusion of the duodenum by a balloon[3] or continuous perfusion of a nonabsorbable marker,[4] allowing correction for distal losses. Balloon occlusion techniques are less physiologic in that they may cause luminal distention and possible stimulation by this means. Similarly, gastric acid and pepsin can be excluded either by continuous nasogastric suction or by a pyloric balloon.

The technique used at The Hospital for Sick Children in Toronto and at Australian centers employs practical solutions to the above conditions and is readily adaptable. The test is a quantitative technique modified from Go and colleagues[5] and is represented diagrammatically in Figure 72-1. Subjects should be fasting, and in the case of patients on pancreatic enzyme supplements, these supplements should be discontinued at least 48 hours prior to the test to remove any suppression of the exocrine pancreas by negative-feedback inhibition. Under fluoroscopic control, a double-lumen tube is inserted into the duodenum. The tube is constructed so that one lumen opens proximally at the ampulla of Vater, and the other lumen, which has several distal ports, is positioned 5 to 12 cm distally at the ligament of Treitz. Through the proximal lumen, a nonabsorbable marker solution (gentamicin, 20 mg/mL in 5% mannitol) is infused into the duodenum at a constant rate. Pancreatic juice mixed with infused marker solution is aspirated distally by intermittent low-pressure suction and

TABLE 72-2 CRITERIA FOR THE IDEAL PANCREATIC FUNCTION TEST

Inexpensive and easily performed
Noninvasive
Specific for pancreatic disease and able to exclude patients with other digestive disorders owing to small bowel mucosal disease, inherited defects of fat transport, or cholestasis
Defines the exact level of pancreatic function in subjects with pancreatic sufficiency and in whom partial impairment of exocrine function is present but nutrient assimilation is unaffected
Repeatable, reproducible between laboratories and able to monitor exocrine function longitudinally
No interference from exogenous pancreatic supplements

is collected over four 20-minute collection periods into flasks on ice. The first period allows equilibration of marker solution with pancreatic juice and also allows residual luminal pancreatic enzymes to be washed out. During the subsequent three periods, duodenal juice mixed with marker is collected while continuously and simultaneously infusing intravenous secretin and CCK at doses known to achieve maximal pancreatic stimulation. A separate nasogastric tube facilitates aspiration of gastric juice and minimizes contamination of duodenal contents with acid and pepsin.

This technique allows both the collection and quantification of pancreatic secretions. Although the biliary tree and the duodenal mucosa contribute to fluid secretion, the vast bulk of the secretory response is generated by the action of secretin on pancreatic ductular epithelium and acini and by the effect of CCK on acini. This fact, coupled with the use of a nonabsorbable marker, allows correction for distal losses of fluid and enzyme by the assumption that once equilibration has been attained, the degree of distal loss of the marker is the same as the degree of enzyme and fluid loss.[6] A simple volume correction factor can be calculated as follows:

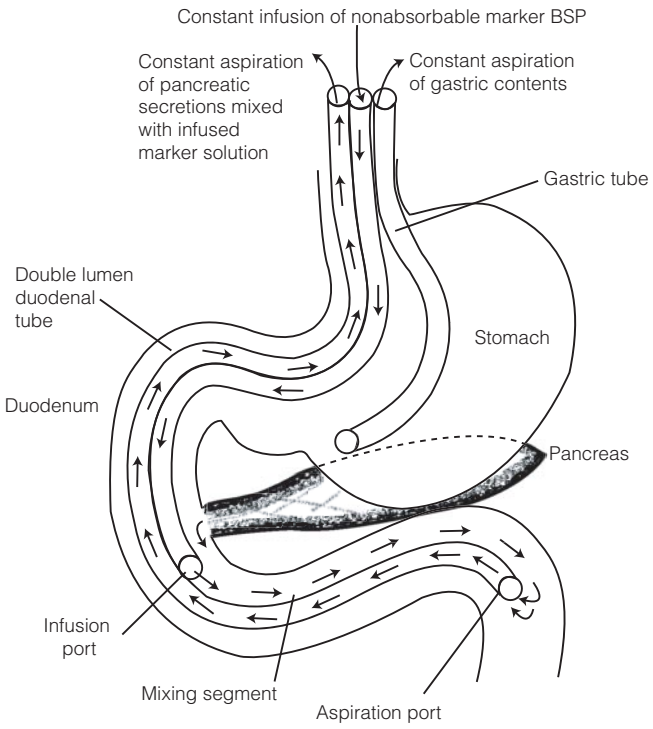

FIGURE 72-1 Scheme of the exogenous secretion/cholecystokinin pancreatic stimulation test with nonabsorbable marker perfusion. Gastric juice is removed via the nasogastric tube. Through the proximal lumen of the double-lumen intestinal tube, the nonabsorbable marker is perfused at a constant rate. Pancreatic secretions mix with the marker in the mixing segment, and the mixture is aspirated via the distal port. Pancreatic secretions are collected over a specific time period (60–80 minutes) while maximally stimulating pancreatic secretion with intravenous hormones (cholecystokinin and/or secretin). Adapted from Durie PR. Pancreatic function tests. Med Clin North Am 1988;20:3842–5.

$$\frac{\text{gentamicin in µg per period infused}}{\text{gentamicin in µg per period recovered}}$$

The determination of fluid, electrolyte, and enzymatic output can be adjusted accordingly. Trypsin, colipase, and total lipase outputs are measured routinely by titrimetric techniques, and bicarbonate output is measured by a colorimetric technique. Sodium, potassium, and chloride outputs are also measured. Other investigators have measured total protein, amylase, chymotrypsin, carboxypeptidase, elastase, cholesterol esterase, and deoxyribonuclease.

The techniques employed for enzymatic determination, especially for amylase and lipase, may differ. The substrates used for the colorimetric determination of amylase activity vary; consequently, the units used to express activity differ. In the case of lipase, results vary depending on whether a short-chain triglyceride such as glycerol tributyrate or a long-chain triglyceride such as olive oil is used as the substrate.

The invasiveness of this test tends to discourage routine clinical use, particularly in pancreatic-sufficient patients, the group in which it is most helpful. It is worthwhile reiterating that this test has helped to delineate pancreatic function in both healthy and diseased individuals. For example, the fact that colipase is the rate-controlling factor for lipolysis became apparent with the analysis of stimulated secretions from both normal individuals and patients with steatorrhea.[7] Additionally, in patients with cystic fibrosis, deficits in electrolyte secretion, particularly chloride[8] and bicarbonate secretion,[9] have been identified, which, in turn, may lead to reduced fluid secretion.[10]

Nutrient Stimulation

Nutrient stimulation of the exocrine pancreas can be undertaken by adapting the principles of the secretin-CCK stimulation test and substituting intraluminal nutrients for the intravenous secretagogues. This method is more physiologic in that the stimulus is provided both by the release of endogenous secretin and CCK directly into the splanchnic circulation and by a vagal mechanism that can be inhibited by atropine.

The most commonly used test meal has been that devised by Lundh for use in adult patients, consisting of milk powder, vegetable oil, and dextrose.[11] The total volume is 300 mL, with a final composition of 6% fat, 5% protein, and 15% carbohydrate. The Lundh meal is composed of intact nutrients. The presence of intact fat, protein, and carbohydrate renders the enzymatic determinations of lipase, protease, and amylase activity difficult. Lundh used a nonabsorbable marker to provide a reference for the absorption of nutrients, but the lack of continuous duodenal marker perfusion, coupled with the presence of salivary and gastric secretions, makes this test relatively qualitative. Although the test is more physiologic than exogenous hormonal stimulation, these practical difficulties have led other investigators to develop more quantitative methods of nutrient stimulation.

Alternative nutrients have been used. The most potent nutrient stimuli are essential amino acids, particularly phenylalanine, but methionine, valine, and tryptophan have also been shown to stimulate the pancreas.[12] Amino acids are usually given as duodenal infusions. Amino acids do not interfere with enzymatic or electrolyte determinations. For physiologic purposes, amino acid solutions should have a pH approximating that of the duodenal lumen because hydrogen ions neutralize bicarbonate, rendering assessment of secretin response difficult. A low-pH solution can also directly stimulate the pancreas through secretin release independent of the amino acid content. The volume of the infusions should be low because duodenogastric reflux of nutrients can stimulate the pancreas via gastrin release. The response of the pancreas to individual nutrients may depend in part on duodenal baroreceptors. Too low an infusion volume will result in a suboptimal stimulus.[13] With the exception of the Lundh meal, which is relatively unpalatable, nutrient stimulation has not been used clinically in children.

Other Direct Tests

A variety of alternative approaches have been used in adult patients. These include the use of radioisotopes to assess uptake, incorporation, and release of amino acids; direct ductal sampling of secretions; and other methods employing microtechniques to assess protease activity. Pancreatic synthetic capacity is measured by the ability to incorporate selenium 75 (^{75}Se)-labeled methionine.[14] In response to a CCK stimulus, ^{75}Se-labeled methionine is released into pancreatic secretions as a constitutent of enzymes and other proteins. Measurement of ^{75}Se activity serves as a guide to acinar function. ^{75}Se is a high-energy–emitting isotope, unsuitable for pediatric use. Endoscopic collections of pure pancreatic juice allow the assessment of uncontaminated samples.[15] Duodenal fluid collected at endoscopy and following intravenous infusion of secretin and CCK has been used to evaluate pancreatic function in children.[16] Unfortunately, a general anesthetic is required, and this may, in itself, suppress pancreatic function.

INDIRECT EXOCRINE PANCREATIC FUNCTION TESTS

The actions of individual pancreatic enzymes are assessed indirectly by quantifying the appearance of inappropriately increased amounts of specific nutrients in the feces (eg, fecal fat) or by measuring metabolic products in the blood, urine, or breath (eg, the bentiromide test and radiolabeled breath tests). Alternatively, the amount of enzymes such as chymotrypsin and elastase in the stool may reflect residual pancreatic function. Most of these tests cannot reliably assess the level of function in pancreatic-sufficient subjects or exclude biliary or intestinal causes of malabsorption. However, because they are relatively noninvasive and are indeed sometimes referred to as tubeless, some of the tests (such as that for fecal fat) can be used to evaluate the success of pancreatic enzyme supplementation in pancreatic-insufficient subjects.

Fecal Tests

Microscopic Examination. Microscopic examination of the stools may reveal meat fibers, neutral fat droplets, or

free fatty acid crystals, suggesting partial fat hydrolysis. Sudan III is the preferred stain for neutral fat, although the fat droplets can be seen quite easily without staining. Free fatty acid crystals are birefringent and are best visualized by a microscope with a polarizing filter. They can also be visualized by lowering the pH of the Sudan III stain.[17] If stool is obtained by rectal examination, lubricants containing oil or petroleum jelly should be avoided. Neutral fat droplets do not differentiate pancreatogenous steatorrhea from steatorrhea of intestinal or biliary origin.[18] Similarly, free fatty acid crystals do not rule out pancreatogenous malabsorption.

Attempts have been made to quantify the degree of steatorrhea by counting the number and determining the size of fat globules in a high-power field.[19] If, on cursory examination, steatorrhea is present, it is sensible to quantify fecal fat losses using balance studies. Microscopic examination of the stool should be mandatory in all cases of suspected malabsorption. However, it should not be regarded as more than a highly useful, albeit crude, screening test for malabsorption.

Steatocrit. The steatocrit, a measurement of fat malabsorption, works on the following principle: if homogenized feces are centrifuged, the lipid and liquid phases and stool residues separate, with the lipid phase on top of the liquid phase and the stool residue.[20] The lipid phase can be measured in a hematocrit tube if the tube is centrifuged at 15,000 rpm for 15 minutes. Reference values and ranges have recently been established for normal children.[21] The sensitivity of this test is markedly improved by the addition of perchloric acid to the fecal homogenate, and the acid steatocrit is determined.[22,23] This may prove to be a useful adjunct in laboratories with limited technical expertise, particularly in the third world, and may also provide a crude method for monitoring the response of patients receiving pancreatic enzyme supplements.

Pooled Stool Collections for Fat, Nitrogen, and Carbohydrate. Because of the functional reserve of the exocrine pancreas, these tests detect only pancreatic-insufficient subjects. All three nutrient classes—fat, protein, and carbohydrate—have been measured in stool to assess pancreatic function. Fecal fat analysis is the most widely used, the most informative, and the most homeostatically relevant of these tests. Pooled stool collections detect malabsorption but do not discriminate between patients with pancreatic and nonpancreatic malabsorption. Despite these limitations, fecal fat analysis is useful longitudinally, especially for assessing the efficacy of pancreatic enzyme supplements in patients with pancreatic insufficiency. Because of the odious nature of the test for both patients and laboratory technicians, it has fallen into disfavor in some circles. Alternative tests that rely on isotopic methods are more expensive, are almost as inconvenient, and still fail to differentiate the various causes of malassimilation.

The method most commonly used for the measurement of fecal fat is the titrimetric Van de Kamer method.[24] In adults, the test involves a diet containing 100 g of fat for 3 to 5 days.[25] Stools collected over 72 to 96 hours are pooled and refrigerated. The mechanics of collection can be improved by the use of a nonabsorbable marker at the start and the end of the diet. In children, the collection period is usually 3 days, although it is occasionally extended to 5 days. Because children find it difficult to adhere to a strictly regimented diet, meticulous weighing of food and careful dietary records are required to calculate the mean daily fat intake. Steatorrhea is present if more than 7% of ingested fat is excreted. Owing to the physiologic immaturity of the pancreatic and biliary secretions, infants under 6 months of age can excrete up to 15% of dietary fat.[26] The Van de Kamer method must be modified if the diet contains appreciable amounts of medium-chain triglycerides because these are not detected by the standard method. The potential for error is great because collections may be incomplete, fat intake may be inaccurately quantitated, and the occasional patient may have delayed intestinal transit. Other methods of estimating fat in feces, such as nuclear magnetic resonance spectrometry[27] and near-infrared reflectance spectroscopy,[28] may make laboratory analysis easier and less odious. The Van de Kamer method and these other methods potentially overestimate fecal fat excretion because they detect biliary lipids and complex lipids derived from intestinal cell turnover. Additionally, this test does not discriminate readily between mucosal, pancreatic, and other causes of fat absorption.

Fecal nitrogen has been used as an index of exocrine pancreatic function but does not provide further diagnostic information because it is unlikely that significant creatorrhea will occur if steatorrhea is absent. The same criticism can be made of fecal carbohydrate measurements. The most commonly used assessment of carbohydrate relies on the measurement of reducing sugars and does not assess total carbohydrate. The anthrone method, which assesses all hexose carbohydrates, has provided better quantitation of carbohydrate losses.[29] Carbohydrate measurements are likely to be elevated with small intestinal mucosal disease, and both nitrogen and carbohydrate are subject to variable colonic absorption and substrate use by fecal flora. For the above reasons, they are less accurate than neutral fat as a guide to pancreatic insufficiency.

Stool Isotopic Methods. Most of these methods are inappropriate for pediatric use because they use gamma ray–emitting isotopes. Single isotopes (iodine 131, iodine 125) bound to triglycerides are expensive, and the test necessitates a 3-day stool collection, but the need for strict dietary records is eliminated. Dual-isotope methods append markers to a nonabsorbable lipid such as glycerol triether and to a lipid subject to hydrolysis and absorption such as glycerol trioleate. This technique allows fat malabsorption to be estimated from single stool samples. Although some of the dual-labeling systems use β-emitting isotopes,[30] none of these methods has been adapted for pediatric use.

Fecal Trypsin, Chymotrypsin, Lipase, and Elastase 1. The capacity to measure both fecal trypsin and chymotrypsin has existed for 30 years. Fecal elastase 1 has been widely used only for the last decade. The initial tests

measured enzymatic activity by means of a laborious titrimetric estimation using low-molecular-weight substrates. A number of problems existed with these tests. The enzymes are subject to proteolytic degradation by both pancreatic and bacterial proteases; thus, interpretation varies with intestinal transit. Chymotrypsin was preferentially measured instead of trypsin because it is more resistant to inactivation by colonic bacteria. However, a high proportion of chymotrypsin is strongly bound to insoluble stool residue,[31] and this thwarted attempts to develop accurate and more convenient photometric methods. The early tests have been superseded by a photometric method, the BMC test developed by Boehringer Mannheim Corporation (Mannheim, Germany), which employs a detergent to solubilize chymotrypsin in stool[32] and is convenient, reproducible, and sensitive. Patients receiving pancreatic enzyme supplements should discontinue them at least 5 days prior to measurement. Fecal chymotrypsin reliably differentiates between pancreatic-insufficient and pancreatic-sufficient patients. However, it does not reliably discriminate between pancreatic-sufficient patients and normal subjects. Patients with pancreatic insufficiency can be differentiated from those with intestinal or biliary disease. This method has been validated for pediatric use by showing a good correlation between the 72-hour fecal output of chymotrypsin and the CCK-secretin–stimulated duodenal output of chymotrypsin.[33] Other observers have shown a good correlation in children between duodenal chymotrypsin output following CCK stimulation and three random stool samples collected within 72 hours of pancreatic stimulation with CCK.[34] Fecal chymotrypsin is relatively stable at 18°C for up to 72 hours and can thus be sent from peripheral centers to a reference laboratory. If random stool samples are used and a low value is obtained, repeating the test will eliminate most false-negative results.

Fecal immunoreactive lipase can be measured by using an enzyme-linked immunosorbent assay (ELISA) technique.[35,36] The test has limitations similar to those of the fecal chymotrypsin test and is both sensitive (87%) and specific (97%) in pediatric patients with cystic fibrosis.[36]

The sensitivity is reduced comparably, presumably because of the inclusion of pancreatic-sufficient subjects. The technique is absolutely specific for human pancreatic lipase, and the results are not confounded by concomitant use of pancreatic enzyme supplements. It has also been found to be useful in the first 6 months of life, when lipase secretion is traditionally held to be low owing to ontogenic immaturity of the acini.

Elastase 1 is a member of the acidic elastase family. It is a sterol-binding protein as well as an endoprotease.[37] Elastase 1 is both a human- and pancreas-specific enzyme that is stable during abnormal intestinal transport.[38] Consequently, porcine pancreatic enzyme supplements do not alter the measurement of elastase 1. Age-related increase of elastase occurs only in the first 3 months of life, probably because the ontogenic development of elastase 1 is completed in early postnatal life.[39] An ELISA has been used to assess elastase 1 as an indirect measure of pancreatic function in both children and adults. This test is both more sensitive and specific than fecal chymotrypsin in detecting pancreatic insufficiency, but it will not delineate patients who are pancreatic sufficient.[40,41] However a decline in fecal elastase concentrations precedes fat malabsorption in patients with pancreatic-sufficient cystic fibrosis who become pancreatic insufficient.[42] False-positive results may occur as a result of villous damage secondary to several conditions, including celiac disease, cow's milk protein, enteropathy, and bacterial overgrowth.[43] It is possible that these patients may have a secondary pancreatic insufficiency owing to impairment of mucosal release of pancreatic secretagogues. Diarrheal disease and short-gut syndrome may result in false-negatives owing to a dilutional effect.[44,45] This problem can be overcome by lyophilization of stool samples, which removes stool water content as a confounding variable.[46] False-negatives are occasionally seen in pancreatic-sufficient patients with Shwachman-Diamond syndrome.[45] Despite these limitations, the stability of this enzyme allows storage at room temperature for at least a week, which facilitates mailing of fecal samples, and the absolute specificity of this test makes it one of the most attractive "tubeless" pancreatic function tests.[37,40] The use of this test is becoming more prevalent in pediatric practice.

Breath Tests

Radiolabeled and Stable Isotope Breath Tests. The technique and principles of breath testing are described in Chapter 73, "Breath Analysis." Ingested lipids are predominantly hydrolyzed by pancreatic lipases in the small intestine, absorbed as free fatty acids and monoglycerides, and transported to the liver, where oxidative metabolism liberates carbon dioxide (CO_2). The radiolabeled breath tests take advantage of this fact by substituting either carbon 14 (^{14}C) or 13 (^{13}C) for carbon 12 in a triglyceride molecule. The three triglycerides of different carbon chain lengths that have been commonly used are trioctanoin, tripalmitate, and triolein. All three substrates labeled with ^{14}C are sensitive in detecting fat malabsorption.[47] Triolein is more specific than either trioctanoin or tripalmitate for fat malabsorption; however, it does not differentiate between pancreatic and nonpancreatic causes of fat malabsorption. Normal release of CO_2 from triolein and tripalmitate requires adequate lipolysis, bile salt solubilization, and an adequate mucosal surface and transport capability. The release of CO_2 from trioctanoin is limited by lipolysis alone and can distinguish pancreatic insufficiency from bile salt deficiency and mucosal defects. Using these substrates in combination with one another (eg, testing with triolein and repeating the test with trioctanoin) improves specificity but not sensitivity. Other confounding variables are the action of lingual and gastric lipases on the substrate, varying individual lipid pool sizes, and the variable respiratory excretion of CO_2 in chronic respiratory disease. ^{14}C labeling mandates that these tests not be used in children.

The specificity of these tests may be improved by repeating them after administering pancreatic enzyme supplements. The same compounds have been labeled with ^{13}C, a stable isotope that is measurable by mass spec-

troscopy, and similar results have been obtained in children.[48] These tests have also recently been adapted to assess gastric emptying in children. Recently, ^{14}C cholesteryl octanoate, which is hydrolyzed by the pancreatic-specific cholesterol esterase, has been used as a substrate.[49] Studies suggest that hydrolysis by cholesterol esterase is the rate-limiting step.[50] The test is adaptable to ^{13}C labeling, allowing its use in children.[50] A synthetic mixed triglyceride (1,3-distearyl 2[^{13}C] octanolyl glycerol) has also been used as a substrate.[51] Excretion of ^{13}C-labeled CO_2 ($^{13}CO_2$) is slower than that seen with cholesteryl octanoate. Stearyl hydrolysis by pancreatic lipase is the rate-limiting step.

Release of CO_2 from ^{13}C-labeled starch has been assessed in adults.[52] This test works on the principle that hydrolysis of starch by pancreatic isoamylase is the rate-limiting step in carbohydrate metabolism. Test specificity is improved by also measuring CO_2 release after ^{13}C-labeled glucose. The ratio of $^{13}CO_2$ excretion after starch ingestion to $^{13}CO_2$ excretion after glucose ingestion corrects for differences in oxidative metabolism. Even after correction, the test is relatively insensitive and will only detect pancreatic-insufficient subjects.

Release of CO^2 from ^{13}C-labeled egg white has been assessed in adults with pancreatic disease. This test is a crude test of proteolytic activity and could be adapted to pediatric subjects.[53]

Because stable isotopes and mass spectroscopy are expensive, these breath tests have not found a niche for routine pediatric use. However, benchtop devices for measuring ^{13}C have become more affordable, making these tests more accessible.

Hydrogen Breath Test. This test measures breath hydrogen excretion following starch ingestion. Starch is normally cleaved enzymatically into oligosaccharides by pancreatic isoamylase prior to further cleavage by brush border disaccharidases. When amylase secretion is impaired, undigested starch is digested by colonic bacteria, generating hydrogen, which is absorbed and excreted in the breath. A two-stage test with concomitant ingestion of oral pancreatic enzymes results in reduced breath hydrogen. This test is extremely nonspecific; false-positive results may occur in blind loop syndromes and also when small intestinal transit time is reduced. False-negative results may occur when the colon is colonized with non–hydrogen-producing bacteria and in subjects who have recently received antibiotics. Currently, there are no pediatric data.

Urinary/Plasma Markers

Bentiromide Test. Bentiromide is a nonabsorbable synthetic peptide (*N*-benzoyl-L-tyrosyl-*p*-aminobenzoic acid) that is specifically cleaved by pancreatic chymotrypsin in the upper small intestine. This results in the release of *p*-aminobenzoic acid (PABA), which serves as a marker and which is rapidly absorbed, conjugated in the liver, and excreted in the urine. Colorimetric assay can measure PABA in both blood and urine, and the detection and quantification of PABA form the basis of the test. Falsely abnormal results have been demonstrated in subjects with bowel, liver, or renal disease owing to defects in the absorption, conjugation, or excretion of PABA. Additionally, both intestinal bacteria and the intestinal brush border may demonstrate chymotrypsin-like activity, reducing specificity. Ingestion of a number of drugs such as sulfonamides, diuretics, acetaminophen, and chloramphenicol and foods such as prunes and cranberries may result in elevated aromatic amines that may interfere with laboratory determinations of PABA.[54] Recently, high-pressure liquid chromatography techniques have been developed to sensitively detect PABA and its metabolites, and these techniques may prove to be superior to colorimetric assay because they eliminate interference from drug and dietary amines.[55]

The bentiromide test was introduced in 1972, and initial reports relied on a one-stage test with a urinary collection.[56] The method involved collections over varying time periods and varying doses of substrate. Consequently, reports of test specificity and sensitivity varied widely. In North America, the recommended method for adults entails the patient receiving a 500 mg dose of bentiromide (170 mg of PABA), ingesting sufficient fluid to maintain an adequate diuresis, and collecting urine for a period of 6 hours.[57] The urinary recovery of PABA is expressed as a percentage of the orally ingested PABA. Less than 50% PABA excretion purportedly reflects pancreatic insufficiency. To correct for potential defects of absorption, hepatic conjugation, or excretion, a two-stage test has been suggested with an equivalent dose of free PABA administered subsequently and the urine collected for an identical time period.[58] This allows the urinary recovery of PABA after bentiromide to be corrected for the urinary recovery of equimolar free PABA. The results are expressed as a PABA excretion index (PEI):

$$\text{PEI} = \frac{\text{PABA recovered after bentiromide (\%)}}{\text{PABA recovered after free PABA (\%)}}$$

This maneuver improves sensitivity and specificity, but the test is cumbersome and time-consuming. Additionally, timed urine collections make the test awkward to perform in infants. In adults, this drawback has been circumvented by the simultaneous administration of ^{14}C-free PABA[59] or a free structural analog of PABA, *p*-aminosalicylic acid (PAS).[60] The ^{14}C-PABA method is impractical for pediatric use. A ^{13}C-PABA method that could be adapted for use in children has been described.[61] The PAS method has been used in the pediatric age group and has improved the sensitivity of the test.[62]

The initial pediatric experience with the bentiromide test concentrated on timed urine collections.[63] However, the specificity and sensitivity of the test have been improved with the development of methods to measure plasma PABA,[55] and the need for dual collections and urinary collections has been eliminated. The recommended pediatric dose of bentiromide (15 mg/kg) has been used in older children and is based on extrapolation from adult data. For the first 3 hours following ingestion of the dose, plasma PABA concentrations rise, and optimal discrimination between normal adolescent controls and patients with pancreatic

insufficiency is obtained at the 90- and 120-minute points.[64] Reliable detection was not obtained in patients with cystic fibrosis and pancreatic sufficiency (between 5 and 10% of normal pancreatic chymotrypsin output as measured by the secretin-CCK test). In patients with Shwachman-Diamond syndrome, none of whom had malabsorption, the plasma test failed to detect pancreatic dysfunction in those patients with an enzyme output as low as 1% of normal. Bentiromide (15 mg/kg) is not useful for assessment in infants if clear fluids are given with the dose. Test sensitivity is improved by using a liquid meal and by increasing the dose to 30 mg/kg.[65] The bentiromide test may discriminate between pancreatic steatorrhea and steatorrhea from other causes and could potentially provide a method of monitoring the effect of pancreatic enzyme supplementation.

4-(*N*-Acetyl-L-tyrosyl) aminobenzoic acid has been used in adults and children[66,67] and has reportedly allowed better differentiation between controls and patients with chronic pancreatitis in comparison with the standard bentiromide test.[66] A modified Lundh meal was used in the pediatric study, and extremely good separation was obtained between normal controls and patients with cystic fibrosis.[67] However, no information exists on its usefulness in subjects who have pancreatic sufficiency but reduced functional reserve.

Fluorescein Dilaurate (Pancreolauryl) Test. This test is based on a principle similar to that of the bentiromide test. Orally administered fluorescein dilaurate is hydrolyzed by pancreatic cholesterol esterase, liberating lauric acid and free water-soluble fluorescein. Fluorescein is readily absorbed in the small intestine, partially conjugated in the liver, and excreted in the urine, predominantly as fluorescein diglucuronide. Fluorescein is nontoxic and can be easily measured in both serum and urine by spectrophotometric or fluorometric techniques.

The commercial version of this test in adult patients involves the ingestion of 0.5 mmol of fluorescein dilaurate with a standard meal. To enhance diuresis, 1 L of unsweetened tea is consumed between the third and fifth hour of the test. All urine is collected over a 10-hour period. To correct for individual differences in intestinal absorption, conjugation, and urinary excretion, the test is repeated using equimolar free fluorescein after an interval of at least 24 hours. The results are expressed as a ratio of the fluorescein detected on the test and the control days. A ratio of greater than 30% is considered normal, a ratio of between 20 and 30% is equivocal, and a ratio of less than 20% is abnormal.[54] Equivocal results should be repeated. The dose can be modified for pediatric purposes.[68] Caution should be used in interpreting this test in diabetic patients in whom glucose interferes owing to the formation of fluorescein glucuronide.[69]

The serum test is more convenient because it is less time-consuming and because the need for urine collection is eliminated. Peak serum levels occur at approximately 210 minutes after absorption, and the best cutoff point for discriminating between pancreatic exocrine-insufficient patients and controls appears to be between 240 and 300 minutes.[70] Concomitant administration of mannitol, which is transported in a similar fashion to free fluorescein, permits completion of the test in 1 day. The results are expressed as a fluorescein-to-mannitol ratio and are equivalent to those of the more cumbersome 2-day test. This method has been used successfully in pediatric subjects.[71] This test has some advantages over the bentiromide test but is not capable of detecting subtle impairment of function in pancreatic-sufficient subjects. Analysis is easier, and there is less interference by exogenous compounds, although it is recommended that niacin and sulfasalazine be avoided prior to the test.[68] False-positive results can occur in patients with biliary tract and mucosal disorders. Cholesterol esterase is pancreatic specific, and the test is therefore not subject to the influence of brush border enzymes. However, bacterial overgrowth can influence the results because some bacteria (in particular, streptococci) are able to hydrolyze fluorescein dilaurate.[68]

Oral Tolerance Tests

Oral fat-loading tests may provide useful information in patients from whom a reliable stool sample cannot be obtained. Serum triglycerides and chylomicron levels are measured at 2, 3, and 5 hours following the ingestion of a meal consisting of 50 g of fat, containing equal amounts of butter and margarine, emulsified in 70 mL of water. Serum triglycerides usually peak at 3 hours after ingestion. An abnormal result consists of a serum triglyceride rise of less than 1.13 mmol/L, or less than 100% above the fasting level, and/or the appearance of less than 7% chylomicrons.[72] This test does not differentiate among patients with pancreatic disease, intestinal mucosal defects, and bile salt deficiency.

Attempts have been made to improve test specificity by using radiolabeled lipids. Initial tests in adults employed triolein labeled with iodine 131 (^{131}I). Subsequently, a dual-label lipid system was evaluated using a tritium (^{3}H)-labeled free fatty acid (oleic acid) and a ^{14}C-labeled triglyceride (triolein). The substrates are administered simultaneously, and the serum ^{3}H-to-^{14}C ratio is calculated.[72] Patients with pancreatic insufficiency have a higher ratio than normal patients or patients with mucosal disease. However, this test does not exclude patients with defects of bile salt delivery or synthesis. Labeling with radioisotopes precludes using this test in children.

Dual-Label Schilling Test

Patients with exocrine pancreatic insufficiency often have an abnormal Schilling test. Pancreatic enzymes are responsible for the cleavage of intrinsic factor from the R protein–intrinsic factor complex secreted by the gastric parietal cells. This step is required for intrinsic factor–cyanocobalamin binding to occur before ileal absorption. A dual-label Schilling test using this principle has been developed.[73] Cobalt 57 (^{57}Co) cobalamin–intrinsic factor complex is administered with cobalt 58 (^{58}Co) cobalamin–hog R protein complex. Free human intrinsic factor and a cobalamin analog are administered to prevent endogenous human R protein from stripping ^{57}Co cobalamin from intrinsic factor. The excretion of ^{58}Co and ^{57}Co is measured in the urine and expressed as a ratio. A low ratio is said to denote

severe pancreatic insufficiency. Because transfer of cobalamin from R protein to intrinsic factor is pH dependent, this test is capable of detecting pancreatic-sufficient patients with impaired pancreatic bicarbonate secretion.[74] Unfortunately, this test is not suitable for pediatric use owing to the radiation dose.

Urinary Lactulose. Lactulose is a poorly absorbed and nonmetabolized disaccharide. Increased small intestinal permeability to lactulose, reflected by increased urinary lactulose excretion as measured by thin-layer chromatography, has been demonstrated in patients with pancreatic insufficiency owing to cystic fibrosis and Shwachman-Diamond syndrome.[75] Less pronounced increases in lactulose excretion were also seen in pancreatic-sufficient patients. The mechanisms responsible for this finding are unknown, but the test could prove to be a useful screening test for pancreatic exocrine insufficiency. Unfortunately, it does not exclude mucosal defects such as celiac disease. Lactulose excretion could also vary with intestinal transit; this could be a problem in cystic fibrosis, where increased intestinal transit time has been noted. Although intestinal transit should be factored into this test, altered intestinal transit has been shown to be a major contributor to increased urinary lactulose excretion.[76]

BLOOD TESTS

All pancreatic enzymes are detectable in small quantities (ng/mL) in the sera of normal individuals. Some enzymes, such as lipase and amylase, are released as active enzymes, whereas others, such as trypsin, are released as the zymogen or proenzyme trypsinogen. Excessive quantities of circulated pancreatic enzymes are seen in the following three circumstances:

1. *Acute pancreatitis*. Enzymes and proenzymes may be released directly into the circulation as a consequence of inflammation.
2. *Ductal obstruction*. Obstruction of pancreatic enzymatic outflow may result in elevated levels of pancreatic enzymes in sera in the absence of inflammation. The mechanism responsible is thought to be regurgitant release of enzymes from the acini or ducts.
3. *Impaired renal function*. Pancreatic enzymes are cleared from the circulation by the kidneys. Impaired renal function may result in significant elevations of pancreatic enzymes in the absence of pancreatic disease.

Theoretically, in the absence of inflammation, ductal obstruction, or impaired renal function, the serum level of a particular enzyme should reflect the amount of functioning acinar tissue, and this consideration forms the rationale for enzyme determination in sera. However, until recently, two considerations have prevented this goal from being attained. The first is a lack of test specificity. Biochemical determinations of enzymes in sera (total amylase, in particular) have been used for many years as a crude screening test for acute pancreatitis. The major limitation of enzymatic techniques has been the lack of substrate specificity. For example, the traditional starch and iodine method does not distinguish between salivary and pancreatic isoamylases. Similarly, trypsin substrates are subject to degradation by other circulating serine proteases. Immunoassay techniques have been developed that sensitively detect and measure specific pancreatic enzymes and that should circumvent these problems. Because techniques vary, it is vital that each laboratory establish its own normative data.

The second constraint on serum enzyme determination is the variable maturation (ontogeny) of pancreatic enzymes. Concentration of serum enzymes varies with age, especially in early infancy. In most instances, serum enzyme levels increase with age and reflect the ongoing maturation of the exocrine pancreas and consequent pancreatic parenchymal enzyme levels. For example, at birth, the pancreas synthesizes and secretes very little amylase and continues to produce very little during the first year of life. In contrast, trypsin(ogen) production is relatively mature, and comparatively larger amounts of trypsin are secreted.[77] Serum trypsinogen levels change relatively little during childhood, whereas serum amylase levels increase markedly. The different rates of maturation of pancreatic enzymes lead to varying degrees of usefulness of serum enzyme determinations for diagnosing pancreatic disease or for determining function. An appreciation of the dynamics of enzyme maturation helps in the interpretation of serum enzyme data. These considerations are best addressed by detailed examination of the various tests.

Serum Amylase

Total amylase measurements are extremely nonspecific because the enzymatic determination does not distinguish between salivary and pancreatic isoenzymes. Refinement of amylase measurement has concentrated on distinguishing between pancreatic and salivary isoamylase. Biochemical methods include column chromatography, electrophoresis, isoelectric focusing, salivary isoenzyme inhibitors derived from wheat, and differential thermolability. In addition, highly specific monoclonal antibodies to the pancreatic isoenzyme have been raised, permitting the development of immunoassay techniques. The pancreatic isoenzyme peak on isoelectric focusing or electrophoresis appears to correlate with the level of function in older patients with cystic fibrosis and Shwachman-Diamond syndrome.[78] However, in patients with slight or moderate reduction of function, values are within the normal range. This test is therefore of little use in pancreatic-sufficient individuals. In addition, levels of pancreatic isoenzyme are low in both normal neonates and neonates with cystic fibrosis, and the levels rise throughout childhood.[79] This finding limits the interpretability of the test in younger patients.

Serum Lipase

The enzymatic measurement of serum lipase relies on a titrimetric or turbidometric method in which lipase hydrolyzes a triglyceride substrate, producing free fatty acids and glycerol. These methods are not conducive to the assessment of large sample numbers. A sensitive ELISA is available commercially and allows rapid determination of

lipase in sera from multiple patients. Cross-sectional evaluation of the usefulness of serum lipase as a measure of pancreatic exocrine function was undertaken in a population with cystic fibrosis and was compared with normal controls. The results were validated by fecal fat evaluation and/or a secretin-CCK stimulation test in younger patients (less than 5 years of age) and in older patients (greater than 5 years of age) with cystic fibrosis.[80,81] The patterns seen in each group are distinctive. In all cystic fibrosis patients, serum lipase is much higher than control values during the first year of life. In pancreatic-insufficient patients, the levels decline after the first year of life, gradually reaching a nadir of 25% of control values after 5 years of age. In pancreatic-sufficient subjects, levels also decline during early childhood, but after 5 years of age, they remain elevated approximately threefold above control levels. There is a wide scatter, however, and some pancreatic-sufficient patients have levels within the normal range. The elevated serum lipase in the first year of life has encouraged the adaptation of serum lipase as a screening test for cystic fibrosis. However, the test has not attained the same popularity as cationic trypsinogen. It is less sensitive, with a detection rate of 76% in the first year of life as opposed to a 90% detection rate with cationic trypsinogen. After 5 years of age, the test is reasonably sensitive and specific for the detection of pancreatic insufficiency (95% and 85%, respectively) but remains relatively imprecise for the detection of pancreatic-sufficient subjects. There is no information about the usefulness of serum lipase in delineating pancreatic insufficiency in other pancreatic diseases of childhood.

Serum Immunoreactive Trypsin(ogen)

Two forms of trypsin(ogen) (cationic and anionic trypsinogen) exist and are detectable in sera. Specific radioimmunoassays, particularly for the cationic form, have permitted the population screening of pediatric groups at risk for pancreatic disease. An ELISA method using a monoclonal antibody specific for the zymogen (proenzyme) trypsinogen is quicker, easier to perform, and less labor intensive.[82] Neonatal screening for cystic fibrosis by measuring immunoreactive trypsinogen in dried blood spots is now routine in some parts of the world.[83,84]

Serum immunoreactive trypsinogen levels have been evaluated both cross-sectionally and longitudinally in pediatric patients with cystic fibrosis[85] and also in children with exocrine pancreatic functional impairment attributable to other causes.[86] The findings have been validated in comparison with those in normal controls. In cystic fibrosis, two patterns emerge. In all individuals with cystic fibrosis, the serum immunoreactive trypsinogen level is grossly elevated during the first year of life.[87] In pancreatic-insufficient patients, a rapid decline is noted during the second year of life, with levels becoming subnormal by 6 years of age.[87] In pancreatic-sufficient patients with cystic fibrosis, no consistent pattern of decline is seen; indeed, many older patients continue to have elevated serum levels.[80] However, there is a wide scatter, and the test is of little value for predicting the degree of functional impairment in this group. The control group provides a reasonably narrow normal range, with individual values being unrelated to age. Serum immunoreactive trypsinogen measurement in cystic fibrosis is useful in two circumstances. In infants less than 1 year of age, the test is a sensitive diagnostic screening test; the detection rate is 90%. In patients over 7 years of age, depressed serum levels are highly predictive of pancreatic insufficiency. In 199 patients with cystic fibrosis over 7 years of age who had pancreatic insufficiency, only 9 had normal values and 3 had elevated values, resulting in a predictive rate of 94%.[85] Although this test does not distinguish pancreatic-sufficient subjects from normal individuals, it is a sensitive, relatively noninvasive method of screening for pancreatic insufficiency in older subjects. Below 7 years of age, a fecal fat determination is recommended.

In patients with other pancreatic diseases of childhood, this test has proved useful in distinguishing pancreatic steatorrhea from nonpancreatic steatorrhea. At The Hospital for Sick Children, this test provided absolute separation of 10 children with pancreatic steatorrhea from 22 children with other causes of steatorrhea (Figure 72-2).

The other causes of pancreatic steatorrhea included Shwachman-Diamond syndrome, insulin-dependent diabetes mellitus, idiopathic pancreatic insufficiency, and celiac disease with primary pancreatic insufficiency.

Serum Pancreatic Polypeptide

Pancreatic polypeptide, a 36–amino acid straight-chain peptide, is predominantly confined to the pancreatic islets of Langerhans and is also located between acinar cells. Pancreatic polypeptide is an inhibitor of pancreatic enzyme secretion and is released into the circulation in response to various stimuli, particularly protein meals and CCK.

A radioimmunoassay technique has been used to assess fasting pancreatic polypeptide levels or to assess serial responses of plasma pancreatic polypeptide evoked by CCK infusions or in response to various nutrients.[88,89] In adult patients with chronic pancreatitis, fasting plasma pancreatic polypeptide levels are low. Additionally, in response to CCK octapeptide, patients with chronic pancreatitis display either no rise in pancreatic polypeptide or a greatly limited rise compared with both normal controls and patients with other causes of steatorrhea. Thus, the test is capable of differentiating between patients with pancreatic steatorrhea and those with nonpancreatic steatorrhea. However, the test fails to discriminate between pancreatic-sufficient and pancreatic-insufficient subjects with chronic pancreatitis and, as such, gives no indication of actual pancreatic function.[89] This test has not been used in pediatric practice.

Amino Acids

Plasma amino acid levels decrease if the exocrine pancreas is stimulated. The amino acids are incorporated into enzymatic protein within minutes of hormonal stimulation. Both CCK and cerulein stimulation coupled with secretin result in a decrease of plasma amino acid levels in humans.[90,91] The magnitude of this decrease at 45 minutes after stimulation appears to be directly related to

pancreatic function and can differentiate patients who are pancreatic sufficient with decreased functional reserve as measured by stimulated chymotrypsin output.[91] Serine, valine, isoleucine, and histidine reduction may discriminate mild impairment of function better than total plasma amino acid reduction. More recently, others have not been able to replicate these results by using CCK alone.[92] This test is time-consuming and expensive and has not been used in pediatric practice.

FUTURE DIRECTIONS

Fecal elastase is the only new widely used pancreatic function test to be developed in the last 15 years. It is becoming increasingly unlikely that new stool urine and breath tests more specific and sensitive than current tests will be developed. Functional imaging techniques using new imaging technology have been developed and trialed in adult patients. These tests, which both image the pancreas and allow an estimate of function, may be adaptable in the future to pediatric patients.

The first of these tests to be reported uses magnetic resonance cholangiopancreatography after secretin stimulation.[93] This technique, which employs a negative bowel contrast agent, was evaluated in 34 adult patients who had undergone prior pancreatoduodenectomy. The caliber of the main pancreatic duct can be graded on a scale of 1 to 3, reflecting secretion. More recently, the technique has been further refined to calculate water secretion rates by correcting for signal intensity.[94] These gradings correlate well with clinical symptoms but do not correlate well with a urine bentiromide test. The poor correlation with the bentiromide test, the necessity for the patient to cooperate and stay still, and the expense of the technique suggest that it will not be adaptable for pediatric use.

More recently, biliary excretion has been assessed by secretin stimulation after injection of sodium bicarbonate ($NaH^{11}CO_3$) in adult patients.[95] This test, which is adaptable to pancreatic function, requires a cyclotron (to generate carbon 11) and a positron emission tomography scanner. Patients need to stay still for 10 minutes. Most pediatric units do not have access to this technology. Carbon 11 is radioactive but has a short half-life, which may allow the adaptation of this test to selected older pediatric patients.

SUMMARY, CONCLUSION, AND RECOMMENDATIONS

Clinical use of pancreatic function tests depends on three major variables: (1) the indications for pancreatic function testing, (2) how the test satisfies the criteria for ideal pancreatic function in the clinical circumstance in which it is being used, and (3) the age of the patient. If useful clinical information can be obtained that subverts the need for a pancreatic function test, this information should be obtained. For example, if a mucosal cause of malabsorption is suspected, it is sensible to perform an intestinal biopsy as the primary investigation. Similarly, if biliary disease is suspected, there are usually good clinical signs that will point in this direction, and pancreatic function testing is usually inappropriate.

Invasive tests are now used much less frequently in pediatric practice. The major use of the direct pancreatic function tests in pediatric practice was to delineate pancreatic-insufficient from pancreatic-sufficient cystic fibrosis and also to establish a diagnosis of cystic fibrosis in those cystic fibrosis patients in whom sweat tests and clinical signs were equivocal. Genetic testing and, to a lesser extent, nasal potential difference have rendered this indication partially obsolete. If we know a patient's genotype, we can, with a degree of certainty, predict whether they have cystic fibrosis and whether they either have or will develop pancreatic sufficiency.[96] The genetic diagnosis of other disorders, coupled with an awareness of the clinic constellation, also means that direct pancreatic function testing is seldom required. Genetic diagnosis is possible for lipase,[97] colipase,[98] trypsinogen,[99] and enterokinase[100] deficiency; Pearson bone marrow pancreas syndrome[101]; some forms of pancreatic aplasia[102]; and Shwachman syndrome.[103] It should soon be possible for Johanson-Blizzard syndrome. In these circumstances, the diagnosis should be sought, and the presence of malabsorption should be sought either by microscopy for fecal fat or a 3-day fecal fat collection in an older child or by fecal elastase 1 determination in a younger child.

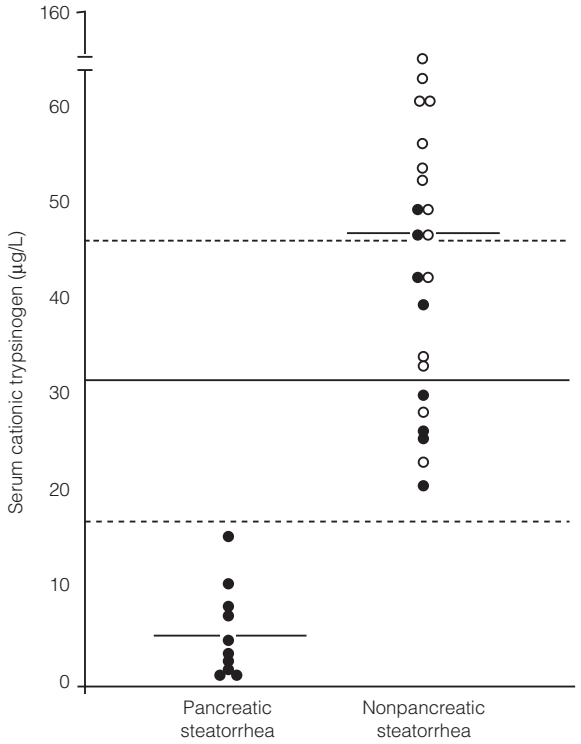

FIGURE 72-2 Serum cationic trypsinogen values in patients with pancreatic and nonpancreatic steatorrhea. The solid and interrupted horizontal lines indicate mean normal cationic trypsinogen of ±2 SD, respectively (31.4 ± 14.8 g/L). *Closed circles* = patients who underwent a pancreatic stimulation test. *Open circles* = patients with nonpancreatic steatorrhea who did not have a pancreatic stimulation test. Reproduced with permission from Moore DJ et al.[86]

TABLE 72-4 RECOMMENDED PANCREATIC FUNCTION TEST: CLINICAL INDICATIONS

Determination of pancreatogenous malabsorption
Fecal elastase 1
^{13}C octanoin breath test
^{13}C cholesterol octanoate
^{13}C mixed synthetic triglyceride
Serum fluorescein dilaurate/mannitol collection
Serum bentiromide/PAS collection or ^{13}C label
Direct pancreatic stimulation—CCK
Direct pancreatic stimulation—CCK + secretion
Natural history of disease
Fecal elastase
Serum cationic trypsinogen
Acid steatocrit
Fecal fat 3 or 5 d (near-infrared reflectance spectroscopy or magnetic resonance spectrometry analysis)
^{13}C octanoin breath test
^{13}C cholesterol octanoate
^{13}C mixed synthetic triglyceride
Serum fluorescein dilaurate/mannitol
Serum bentiromide/PAS collection
Direct pancreatic stimulation
Effectiveness of pancreatic enzyme supplements
Acid steatocrit
3- to 5-d fecal fat
^{13}C octanoin and other breath tests
Serum fluorescein dilaurate/mannitol collection
Serum bentiromide/PAS collection or ^{13}C PABA

CCK = cholecystokinin; PABA = *p*-aminobenzoic acid; PAS = *p*-aminosalicylic acid.

TABLE 72-5 RECOMMENDED PANCREATIC TESTS BY AGE GROUP

Age < 1 yr
Fecal elastase
Serum cationic trypsinogen
^{13}C-labeled breath tests
Age > 1 yr–toilet training
Fecal elastase
^{13}C-labeled breath tests
Acid steatocrit
Direct pancreatic function tests
Toilet training to 7 yr of age
Fecal elastase
^{13}C-labeled breath tests
Acid steatocrit
3- to 5-d fecal fat
Fluorescein dilaurate test bentiromide + PAS or ^{13}C PABA modification
Direct pancreatic function tests
Seven yr of age and older
Fecal elastase
^{3}C-labeled breath tests
Acid steatocrit
3- to 5-d fecal fat
Fluorescein dilaurate
Serum bentiromide/PAS collection or ^{13}C PABA
Direct pancreatic function test
Lundh meal
Teenagers
All the above tests and MRCP with secretin

MRCP = magnetic resonance cholangiopancreatography; PABA = *p*-aminobenzoic acid; PAS = *p*-aminosalicylic acid.

The other major consideration for pancreatic function testing is to assess the efficacy of enzyme supplements, and in these circumstances, the more dynamic tests that rely on proteolysis or lipolysis, such as the bentiromide tests, the pancreolauryl tests, and breath-stable isotope-labeled tests, are more appropriate.

The most appropriate tests for the clinical indications are listed in Table 72-4, and the most appropriate tests for the various pediatric age groups are listed in Table 72-5. The principle employed in listing these tests is the axiom *primum non nocere*. The tests are listed pragmatically, with the easiest and most applicable test listed first and the most difficult, invasive, and expensive test last.

CHAPTER 73

BREATH ANALYSIS

Geoffrey P. Davidson, MBBS, MD, FRACP
Ross N. Butler, PhD

The analysis of components of the breath to assess gastrointestinal function has undergone a resurgence in recent years. Dynamic function testing using expired breath to better understand both physiology and pathology depends on the measurement of freely diffusible gases that are either produced endogenously or in response to an orally administered substrate. In the former case, the gas is produced as either a bacterial metabolite or in response to cellular damage following oxidant stress or inflammation. The gas detected can then indicate the presence or absence of an infection or an inflammatory process and the intactness of digestive processes such as fat absorption or gut motility (Figure 73-1).

This chapter discusses the current status of breath testing, which is rapidly evolving; thus, many of the tests discussed are not yet in routine clinical practice.

HISTORY

The noninvasive nature of breath tests makes them particularly useful for application in pediatric settings; nonetheless, no clinical applications were to be realized for almost 40 years after alveolar carbon dioxide (CO_2) was first measured.[1] The two major gases in expired air for understanding and investigating gastrointestinal function are hydrogen (H_2) and CO_2. However, other gases, such as methane (CH_4), ethane, pentane, and mercaptans, are also likely to be important indicators of disease and gastrointestinal malfunction in the future. The principles of measuring labeled CO_2 using radioactive substrates tagged with carbon (^{14}C) were introduced in the 1960s.[2] In the early 1970s, use of nonradioactive breath tests, led by H_2 assessment,[3] ushered in a new era for diagnosis, particularly in childhood for the assessment of lactose and other carbohydrate intolerances. For breath tests using expired CO_2 as the end point, several technological advances and observations have redefined the potential scope of clinical use. The first was the observation that an individual at rest produces a roughly constant amount of CO_2 output per unit time.[4] This allowed interval breath sampling for estimating labeled CO_2 in expired breath as a paradigm for the determination of absorption and subsequent metabolism of a test substrate. The second was the availability of a wide variety of substrates labeled with the radioactive isotope of carbon, ^{14}C. The third more recent development has been the introduction of user-friendly mass spectrometers (isotope ratio mass spectrometry) for the detection of the stable isotope of carbon, ^{13}C, in expired air. For H_2 breath testing, the important demonstration of a direct relationship between expired H_2 and H_2 produced by the microflora in the large bowel formed the basis of this test for diagnosis of sugar intolerances.[5]

ANALYTIC TECHNIQUES

The variety of techniques for measurement of particular gases primarily rely on gas chromatography to separate the gases as a first step prior to detection by selected detectors (eg, thermal conductivity, mass spectrometry). This is not the case for detection of radioactively labeled ^{14}C, in which the CO_2 is trapped using an alkaline liquid scintillation fluid for adsorption of the CO_2 to a solid substrate, and the disintegrations per minute are subsequently assessed using a scintillation counter or similar device. The implications of using the radioactive ^{14}C versus the stable isotope (^{13}C) are discussed below. For mea-

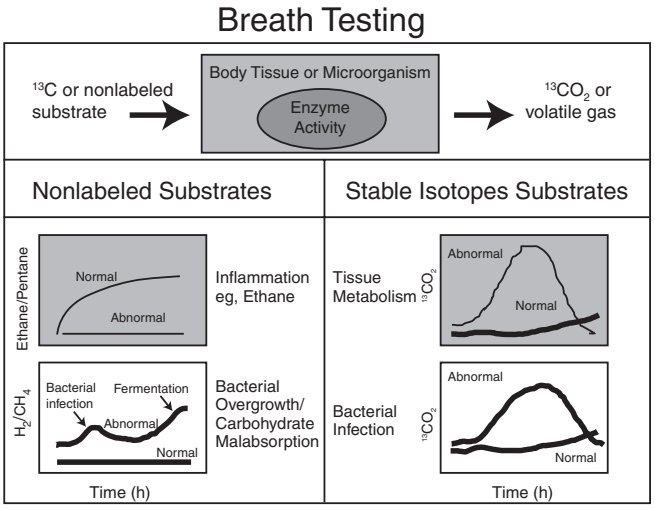

FIGURE 73-1 Principles of $^{13}CO_2$ breath tests, nonlabeled substrate breath tests, and volatile gas breath tests. Theoretic curves are presented for presence or absence of various gases where nonlabeled substrates or no substrates (eg, ethane) are used. Where ^{13}C substrates are used, the curves presented are $^{13}CO_2$ expiration. Ideal excretion curves are illustrated for tissue tests, inflammation, bacterial overgrowth, and fermentation.

surement of H_2, CH_4, and other hydrocarbons (eg, ethane and pentane), gas chromatography followed by flame ionization detection, thermal conductivity, or solid-state sensing devices is commonly used.

BREATH SAMPLING AND COLLECTION TECHNIQUES

Although interval sampling methods are less precise than closed continuous collection techniques, they are certainly adequate for patient management and clinical research. Most clinical applications only need the concentration of the specific gas at particular time points from which an estimate of output over time can be made (usually expressed as an area under the curve generated) and not the absolute quantity excreted. In pediatric populations, well-tolerated collection systems have been developed that can be used in infants and toddlers who cannot actively cooperate. The most successful method for this is the nasal prong, which is held at the nostril by the patient or collector.[6] As the patient expires, the collector aspirates 2 to 4 mL during the latter period of expiration until a sample sufficient for analysis has been obtained. Correction for contamination with ambient air using either O_2 or CO_2 is mandatory when collecting expired gases using this technique.[7,8] For older children and adults, samples can be collected by simply blowing through a straw into an evacuated glass tube or a suitable gas-tight bag (eg, Mylar, Teflon).

SAFETY ISSUES

Depending on the substrate, a wide variety of breath tests are unquestionably safe. For breath tests that do not involve the ingestion of an isotopically labeled substrate, the major probes used to date have been sugars, both natural and synthetic. Of the synthetic sugars, the disaccharide lactulose (constituent sugars galactose and fructose), generally derived from lactose, is the most studied carbohydrate probe. This sugar is a laxative and therefore requires some care in the dose used. This has been well characterized in more than 20 years of use as a diagnostic tool. Routinely, a dose of less than 10 g is administered to children.

For isotopic studies, the situation is different, particularly in women of childbearing age and children in whom the use of a radioactive substrate is contraindicated. This is both on environmental grounds and to protect the patient from unnecessary exposure to radiation no matter how small the actual measured and the biologically active dose. Thus, ^{13}C substrates should be used for breath testing. The instruments required for measurement of $^{13}CO_2$ are now much more user-friendly and are becoming more widely available. Indeed, more stable isotopes are also now on the market, and the use of naturally enriched substrates is likely to open up many more possibilities for studies in nutrition[9] and in the clinical setting (lactose).[10]

SAMPLE STORAGE

In many cases, sample storage is not required; however, where collection is carried out remotely from the analytic unit, then evacuated glass tubes that have not been irradiated (because this releases gases into the evacuated glass tubes from the rubber seals) can be employed. Indeed, these collection tubes are used in most isotope ratio mass spectrometers and thus afford a standardized system for collection of H_2, CH_4, and ^{13}C-labeled CO_2. Other hydrocarbons may also be stored and collected in these containers provided that special attention is paid to the type of seal used (eg, silicon or silicon plus Teflon seals may be necessary for storing samples other than H_2 and CH_4).

H_2, CH_4, and $^{13}CO_2$ can be collected and stored at room temperature for at least 30 days[6] and, in our experience in the latter case, for 6 months or longer.

NONLABELED COMPONENTS OF BREATH

The clinical applications of nonlabeled components of breath H_2 testing are outlined in Table 73-1. This does not include tests such as breath CH_4, which is still being evaluated. The use of breath H_2 test for carbohydrate malabsorption was the first clinical application of breath testing and is still the only one used continually in clinical practice. Most of the information on the efficacy of breath H_2 testing relates to lactose malabsorption owing to its high prevalence in most parts of the world. Other components of the breath, such as methane, ethane, and pentane, have been studied but have not yet been validated for use in routine clinical practice.

HYDROGEN BREATH TEST

The criterion for H_2 breath test positivity is a sustained rise in H_2 of greater than 10 ppm above baseline, which is usually seen 60 to 120 minutes after sugar ingestion.[7,11] Others have suggested a rise of 20 ppm, but this may lead to decreased sensitivity.[3]

TABLE 73-1 CLINICAL APPLICATIONS OF NONLABELED COMPONENTS OF BREATH

CLINICAL QUESTION	SUBSTRATE	DOSE	INTERVAL/DURATION	REFERENCE
Lactose malabsorption	Lactose	2 g/kg; maximum 20 g in 20% solution	Every 30 min for 3 h	7, 11
Sucrose malabsorption	Sucrose	2 g/kg; maximum 20 g in 20% solution	Every 30 min for 3 h	6, 27–29
Glucose malabsorption	Glucose	1 g/kg; maximum 20 g in 20% solution	Every 30 min for 4 h	41
Fructose malabsorption	Fructose	0.3–0.5 g/kg; maximum 20 g in 20% solution	Every 30 min for 3 h	33
Bacterial overgrowth	Glucose	20 g	Every 20 min for first hour	51, 46, 47
	Lactulose	6.68 g (10 mL Duphalac)	then every 30 min for 2 h	

In some cases, the baseline H_2 is high (> 10 ppm) but drops to lower levels within the first 30 minutes. In this situation, the 30-minute sample is considered as the baseline. A persistently elevated fasting H_2 may indicate either inadequate fasting or a high nonabsorbable carbohydrate diet in the previous 24 hours.[12] The possibility of gastrointestinal stasis and bacterial overgrowth also needs to be considered, as discussed below.[13]

A false-negative result may be obtained because of factors affecting H_2 production, which requires a colonic bacterial flora capable of fermenting carbohydrate. Failure to detect H_2 occurs in 2 to 40% of subjects.[3,7,14,15] The prevalence of true nonhydrogen detection in breath may, however, be quite low and dependent on the time of collection, as shown by Strocchi and colleagues, who collected for up to 8 hours.[12] Antibiotics may also suppress H_2 production, which may last for several months, although, again, this may be questioned.[12] In a recent study of patients with bacterial overgrowth, H_2 production was significantly decreased after 1 week of antibiotic therapy.[16] Rapid ventilation can also reduce H_2 in expired air,[17] whereas cigarette smoking can produce a falsely elevated H_2.[18] To avoid a false-negative result, any subject on recent antibiotic therapy and all negative results should have a lactulose breath test to confirm H_2 detection.

CARBOHYDRATE MALABSORPTION

Lactose

The principal clinical use of the breath H_2 test is for the diagnosis of lactose malabsorption, and it has been clearly shown to be the most accurate indirect test of lactase deficiency[19] and is used widely in pediatric practice.[20,21] Because it assesses the function of the small intestine as a whole, it is also more reliable than the rather invasive small intestinal biopsy,[22] which is probably required only to prove a congenital absence of lactase.

The importance of testing for carbohydrate malabsorption rather than relying on clinical symptoms (abdominal pain, distention, and diarrhea) is highlighted by studies showing that patients with these symptoms were unaware that they were due to lactose ingestion,[23] and, alternatively, those who believed themselves to be severely intolerant were shown to be breath test negative.[24] The use of clinical symptoms as the basis to invoke dietary change is thus unreliable and may contribute to unnecessary parental anxiety and the possibility of dietary insufficiency.[25,26] It is, therefore, best clinical practice to prove the diagnosis of lactase deficiency before embarking on dietary change.

Sucrose

Both primary and secondary sucrase deficiency can be diagnosed using breath H_2 testing.[6,27–29] In primary sucrose malabsorption (congenital sucrase-isomaltase deficiency), the diagnosis can be suspected with clinical improvement following removal of sucrose from the diet but needs to be proven by showing sucrase deficiency in an intestinal mucosal biopsy sample. In a recent study of children with cystic fibrosis and abnormal bowel function, breath testing showed a high prevalence of secondary sucrose malabsorption.[29]

Monosaccharides

Fructose malabsorption has been demonstrated in children with diarrhea and abdominal pain using the breath H_2 test.[30,31] Both children and adults may physiologically malabsorb fructose owing to a limited absorptive capacity.[31–33] Fructose absorption can be facilitated by equimolar doses of glucose and especially L-alanine, although the mechanism remains unclear.[34] Without the underlying knowledge of the rate-limiting step in fructose absorption, it is difficult to apply a standardized breath H_2 test to investigate for possible fructose malabsorption.[33,35]

Sorbitol, which is present naturally in fruits and juices and is also used as a sweetener in low-joule products, has a similar structure to fructose and has also been shown to be malabsorbed in children.[36] Like fructose, sorbitol is commonly malabsorbed in healthy individuals; therefore, a breath H_2 test cannot be used to simply demonstrate abnormality.[37] Although the demonstration of fructose or sorbitol malabsorption, even in patients with abdominal symptoms, cannot of itself be considered pathologic,[38,39] there may be a subgroup of patients with functional bowel symptoms who can be identified and improved by a fructose-sorbitol–free diet.[40] Breath testing with fructose and sorbitol may help identify those patients.

Glucose malabsorption as an isolated event is extremely rare and probably occurs only in association with severe mucosal injury except in the case of congenital glucose-galactose malabsorption. Douwes and colleagues were able to use the breath H_2 test to confirm this diagnosis in a breastfed infant with severe diarrhea.[41]

Bacterial Overgrowth

Its noninvasive nature and lack of a radioactive label prompted the use of the H_2 breath test for diagnosis of bacterial overgrowth. Lactulose was used as the initial substrate because it is fermented rapidly, appearing in the breath within 8 minutes of bacterial contact. The first study in adults showed an early peak within 30 minutes of lactulose administration followed by a later peak when the rest of the lactulose bolus reached the colon.[42] Several subsequent studies in children confirmed the double peak as a diagnostic feature.[15,43] These children presented with symptoms of chronic diarrhea and abdominal pain, and bacterial overgrowth was unsuspected.[43] Lactulose was given in a dose of 6.68 g (10 mL) in 100 mL of water, and samples were collected every 20 minutes for the first 60 minutes and at 30-minute intervals for the next 2 hours. The finding in this study and others of an elevated fasting breath H_2 may be a useful indicator of small bowel bacterial overgrowth, but it is not specific, and the diagnosis needs to be confirmed with an oral glucose or lactulose challenge.[43–45] The combination of an elevated fasting breath H_2 concentration and increased breath H_2 excretion after a sugar load has been reported to have a 100% specificity for small bowel bacterial overgrowth.[44]

Most recently, Pimentel and colleagues have shown evidence of small bowel bacterial overgrowth in patients with irritable bowel syndrome using lactulose as the substrate.[45]

Glucose has also been shown to be an effective substrate for the diagnosis of bacterial overgrowth in both adults[46] and children.[47] In the latter study, glucose was given in a dose of 1 g/kg, and samples were collected at 20, 40, 60, and 90 minutes after ingestion. Recently, glucose has been used as the substrate to diagnose small bowel strictures and secondary bacterial overgrowth in Crohn disease.[48]

As with other breath H_2 tests, the major limitation is the possibility of non-H_2 detection, which is quite variable, occurring in 5 to 42% of patients.[7,14] The sensitivities of both lactulose (68%) and glucose (52%) breath H_2 tests to detect bacterial overgrowth have also been shown to be low when compared to jejunal culture in one study.[46] Despite these potential shortcomings, the noninvasive nature of the test, the ease of performance, the ability to repeat the test following therapy, and the lack of a suitable alternative make this approach worthwhile until more accurate tests become available.

Methane

Methane is produced in the left colon by reduction of H_2 and CO_2. Thus, delivery of an increased carbohydrate load to the colon may provide extra substrate for H_2 and CO_2 production in intolerant individuals, thus increasing the substrate for methanogenic bacteria and hence an increase in breath CH_4. Some studies have suggested that low or absent H_2 production following lactulose ingestion is related to H_2 consumption by methanogenic bacteria.[49] At present, it is unclear whether CH_4 measurement can usefully contribute to routine studies of carbohydrate malabsorption, particularly lactose. It has been shown that the prevalence of CH_4 production in lactose absorbers and malabsorbers was identical, and the same proportion of subjects were lactose malabsorbers regardless of methane status.[50] It has also been reported that the percentage of children with lactose intolerance who produce CH_4 is similar to that of normal children.[51] Most recently, Myo-Khin and colleagues showed breath CH_4 to be ineffective as a test for lactose malabsorption.[52]

Although the role of CH_4 as a useful tool in assessing large bowel bacterial metabolism is unclear, an interesting recent report showed that CH_4 production during a lactulose breath test was positive in 100% of constipation-predominant irritable bowel syndrome patients compared with diarrheal conditions such as ulcerative colitis and Crohn disease.[53]

Ethane/Pentane

The alkanes ethane and pentane are the major volatile hydrocarbons resulting from in vivo peroxidation of unsaturated fatty acids, especially those in lipid bilayers of cell membranes, and can be measured in breath. Ethane may be the better marker of lipid peroxidation because it passes through the liver intact, whereas pentane undergoes extensive hepatic oxidation. Both of these gases have been used to study the conditions that could affect lipid peroxidation in intact animals and humans. Vitamin E status in children has been studied noninvasively using both ethane[54] and pentane[55] as markers. More recently, an adult study has shown a reduction in oxidative stress in Crohn disease following vitamin E and C supplementation using ethane and pentane as breath markers.[56]

Excessive lipid peroxidation is probably an important pathogenic factor in inflammatory bowel disease that can now be assessed noninvasively by breath measurement.[57] Both breath ethane[58] and pentane[59] have also been shown to correlate with disease activity in ulcerative colitis.

Stable Isotope Breath Tests

The majority of stable isotope breath tests depend on the measurement of changes in labeled breath CO_2 concentration. CO_2 can be labeled radioactively with ^{14}C or ^{13}C, which is the nonradioactive stable isotope of carbon. The latter is the preferred isotope in children and women of childbearing age. ^{13}C is a naturally occurring isotope consisting of approximately 1.1% of total carbon. It is not radioactive and can be detected by a number of techniques (isotope ratio mass spectrometry, infrared spectroscopy, laser resonance spectroscopy), of which isotope ratio mass spectrometry is the traditional method used for breath tests because it has a high accuracy for a low level of enrichment (0.001–0.01 atom %). To enable suitable precision, stability, and comparable data, the ^{13}C abundance is always measured against a universal reference standard, which is carbon from Pee Dee Belemnite limestone.

The substrates most commonly used for CO_2 breath tests include carbohydrate, starch, fatty acids, bile acids, amino acids, and urea. The only test currently used widely in clinical practice is the ^{13}C urea breath test (UBT) for the diagnosis of *Helicobacter pylori* infection. Other potential clinical applications include evaluation of mucosal function, bacterial overgrowth, gastrointestinal motility, carbohydrate absorption, bile acid absorption, lipid absorption and pancreatic lipase activity, hepatic function, and protein absorption (Table 73-2). This review only discusses the ^{13}C breath tests because they are safe and suitable for use in children, unlike the radioactively labeled isotopes.

^{13}C Urea Breath Test

H. pylori is a gastric infection acquired in childhood that has been shown to be the major cause of gastritis in humans. The mode of acquisition and the evolution of the infection and disease associations must be studied in childhood and therefore require a safe, reliable, noninvasive diagnostic test. The ^{13}C UBT meets these requirements because it has been demonstrated to have a sensitivity of 100% and a specificity from 90 to 98%.[60]

The principle of the test relies on the presence of *H. pylori* infection in the gastric mucosa, a urease-producing organism that splits the orally administered ^{13}C-labeled urea into ammonia and labeled bicarbonate. The bicarbonate is absorbed, and labeled CO_2 is excreted in expired breath. Expired breath samples can be collected either using a nasal prong or by blowing through a straw into an evacuated glass tube. Analysis of the ^{13}C content of breath

TABLE 73-2 STABLE ISOTOPE BREATH TESTS IN CURRENT USE

FUNCTIONAL TEST	SUBSTRATE	REFERENCES
Motility		
Gastric emptying	^{13}C-octanoate	80–83
Orocecal transit	^{13}C–lactose ureide	86
Digestion and absorption		
Lipase	^{13}C–mixed triglyceride	69, 72, 76, 77

Small intestinal bacterial overgrowth	^{13}C-xylose	94

*Only test currently widely accepted in clinical practice.

can be carried out using isotope ratio mass spectrometry. Other techniques, such as laser or infrared spectroscopy, may prove to be cheaper but have the disadvantage of requiring larger breath samples.[61]

The test can be performed after a 2-hour fast, and no test meal is required.[61] The oral dose of urea varies between 50 and 100 mg ^{13}C urea and can be administered dissolved in 10 mL of glucose polymer solution or citric acid solution. Citric acid is preferred to orange juice because the latter reduces the diagnostic accuracy of the tests.[62] Citric acid may also reduce contamination of the test by oral flora. Samples are collected before and 30 minutes after ingestion of the substrate. The ratio of ^{13}C to ^{12}C in the two samples is measured, with a positive test being above a cutoff value of 3.5%.

One of the most important advantages of the ^{13}C UBT, apart from its safety, is that it samples the whole stomach and is thus not prone to sampling error, as are biopsy-based tests. More experience is now being acquired with the use of this test in younger children[63] and children in developing countries.[64] It is suitable for epidemiologic studies, in any clinical condition in which endoscopy is not required and for assessing the efficacy of eradication therapy. It is also possible that the level of $^{13}CO_2$ in expired breath using the ^{13}C UBT may be a predictor of *H. pylori* bacterial load and the severity of gastritis.[65]

Pancreatic Function and Fat Malabsorption

^{13}C-labeled substrates offer a safe, noninvasive, attractive alternative to 3-day fecal fat collections because they provide a simple test that can be performed in a single day with minimal discomfort to the child.

The tests use lipids labeled with ^{13}C in the carboxyl moiety using either triolein,[66] hiolein,[67] or mixed triglyceride (MTG).[68–70] Recovery of labeled CO_2 in breath in amounts within a range established in healthy individuals is assumed to indicate normal fat digestion and absorption and, as such, an indirect measure of lipolysis within the small intestine.

A number of factors can theoretically affect the absorption or metabolism of labeled triglycerides and hence cause discordant or false results. These include gastric emptying, lung disorders reducing CO_2 excretion, disorders affecting fat metabolism, or oxidations such as obesity, hyperlypidemia, hepatic disease, thyroid disease, and small bowel transit time.

The MTG breath test molecule contains both long- and medium-chain fatty acids with stearic acid in the 1 and 3 position forming free fatty acids after lipase hydrolysis and ^{13}C octanoic acid at the 2 position forming the monoglyceride. MTG has advantages over other triglycerides such as trioctanoin and triolein because the rate-limiting step in its digestion is hydrolysis of the two stearyl groups by pancreatic lipase. Octanoic acid is rapidly absorbed and oxidized by the liver and in adults has been shown to correlate closely with pancreatic lipase activity. Normal values for this test have been obtained in children[69] and adults.[71] It may be used to compare the level of fat digestion of patients with pancreatic disease with healthy controls[71] and optimize the use of pancreatic enzyme replacement therapy in children with steatorrhea or poor growth.[72] The ^{13}C hiolein breath test, on the other hand, will assess pancreatic steatorrhea but does not reflect pancreatic function, and its primary clinical value would be in diagnosing pancreatic steatorrhea and monitoring efficacy of pancreatic enzyme replacement therapy.[68] This probably also applies to the ^{13}C triolein breath test. The ^{13}C cholesteryl-octanoate breath test has also been used to study pancreatic insufficiency, which, as in the MTG breath test, uses octanoic acid, in this case released by pancreatic cholesterol esterase activity.[73] Its specificity and sensitivity for pancreatic insufficiency are similar to those of other tube-

less pancreatic function tests. Unlike the other breath tests, it can be shortened to 3 hours.

The ^{13}C starch breath test has also been used in children to assess starch digestion in cystic fibrosis.[74] Corn provides a naturally enriched ^{13}C labeled starch and is thus cheaply and readily available. The study showed evidence of impaired starch digestion[74] but is not a suitable test for pancreatic function in clinical practice because of limited specificity and sensitivity.[75]

The above breath tests, particularly the ^{13}C MTG, represent a simple, safe, noninvasive, and repeatable method to study fat digestion and monitor pancreatic enzyme replacement therapy in children.[68,69,72] There is a need for studies aimed at standardizing the test parameters, which include the dose of isotope, type of meal, collection periods, exercise, and the length of fasting required.[76] Another unresolved issue is the significant discrepancy between the dose of isotope given and the percentage recovered, which can be as high as 80%.[77]

Carbohydrate Absorption

Unlike the H_2 breath test, which measures carbohydrate malabsorption, ^{13}C-labeled carbohydrates can measure carbohydrate absorption, providing a noninvasive analysis of enzyme or transport activity. Naturally enriched ^{13}C lactose has been the most widely used, with studies in both adults and children.[10,78,79] The test has also been used in combination with the H_2 breath test and was found to be more sensitive than the H_2 breath test alone.[79]

Fructose absorption has also been studied using combined breath H_2 and breath $^{13}CO_2$ using ^{13}C-labeled fructose.[35] Unfortunately, $^{13}CO_2$ in breath reflects both the absorbed fructose fraction and also the fraction formed as a result of colonic fermentation of unabsorbed fructose, and because of the inability to separate these over time, the test is of limited value in studies of fructose absorption. Thus, the H_2 breath test, although it only reflects malabsorption, may provide a more reproducible method for studying intestinal fructose transport.[35] The ^{13}C breath tests to study carbohydrate absorption are simple to use in clinical practice but are only in their infancy at present. They do, however, have the potential to provide the information needed to allow breath tests to stand alone as routine diagnostic tools.[78]

MOTILITY

Gastric Emptying

The understanding of both normal and aberrant gastrointestinal motility has been hampered by the invasiveness and lack of portability of scintigraphic techniques. Impaired gastric emptying causes significant morbidity in the pediatric population, with different presentations in various age groups. For example, determining the optimum time to institute enteral feeding in premature infants and in children and adolescents dyspepsia may involve altered gastric emptying.[80] Methods to study gastric emptying used in adults are not readily applicable to pediatrics. The results of noninvasive techniques such as applied potential tomography and ultrasonography are difficult to quantify. Breath testing to probe gut motility using ^{13}C-labeled substrates is now being increasingly applied to infants and children to measure gastric emptying.

Ghoos and colleagues pioneered the use of ^{13}C octanoic acid in adults and children,[81] and this has now been used in neonates[80] and premature infants.[82] Gastric emptying of liquids initially received more attention largely because it is easier to assess than gastric emptying of solids.[83] However, studies on the development of reproducible techniques for estimating emptying of solids have now increased.[84] Specific aspects of the methodology, including the test meal and sampling techniques, require standardization for different age groups. Research on gastric emptying in cystic fibrosis and other diseases is progressing but is not yet completely standardized for routine clinical use outside specialist centers.[77]

Small Intestinal Transit Time

Although administration of lactulose and measurement of breath H_2 has been widely used to obtain an estimate of small intestinal transit time, because it is a laxative, at the doses administered, the probe accelerates transit time.[85] The stable isotope probe lactose ^{13}C ureide, at a dose lacking the osmotic properties of lactulose, is likely to be more applicable in the future in a clinical setting.[86]

The use of naturally enriched substrates is also likely to become important for nutritional studies in children in which the ability to follow the transit of functional foods such as labeled starch[87] and nonstarch polysaccharides[88] will enable us to understand both normal and pathologic dynamics of handling and assimilation of different components of a meal. Furthermore, the development of naturally derived substrates with sufficient enrichment for detection may also provide a more affordable array of useful substrates for a variety of different breath tests.[87]

Bacterial Overgrowth

The efficacy of breath tests to detect small intestinal bacterial overgrowth is, at present, controversial. The ^{14}C-labeled bile acid breath test was originally designed to demonstrate bacterial overgrowth in the jejunum and ileum but also measures ileal function[89]; its efficacy as a marker of small intestinal bacterial overgrowth has been questioned,[90] and it is largely not used. However, significant differences between young and old individuals with respect to bile acid metabolism have been shown using this test. Whether a ^{13}C-labeled bile acid breath test can also be used to assess either bacterial overgrowth or ileal dysfunction has also been questioned.[91] The most acceptable labeled breath test is the use of xylose.[92,93] This has also been performed with ^{13}C xylose, and results are promising, but more studies need to be done.[94]

Combination breath tests have been suggested where, for example, ^{13}C xylose is combined with lactulose and the measurement of $^{13}CO_2$ and products of bacterial fermentation is assessed simultaneously. This potentially enhances the precision and accuracy of a test for bacterial overgrowth. Application of stable isotope breath tests has been limited in pediatrics.[94]

LIVER FUNCTION

A number of different stable isotope probes of liver function have been assessed experimentally in children (and adults), but none has yet been adopted in routine clinical practice. These tests assess liver function by determining the integrity of different metabolic pathways.[95] However, before application to clinical practice, tests need to be validated for normality, specific liver function, and variability.[96] The challenge now is to identify substrates that can be used to measure liver function validly and to compare these in prospective studies with conventional liver function tests.

PROTEIN ABSORPTION

Labeled amino acids have been used for some time to study protein metabolism in vivo in animals and humans. These studies mainly involved the measurement of protein synthesis and breakdown. Only recently have stable isotope labeled proteins become available for the study of protein digestion and absorption following a meal. Milk[97] and egg proteins[98] have been labelled with L-(1-^{13}C) leucine. Simultaneous measurement of ^{13}C enrichment of breath and enrichment of plasma in L-(1-^{13}C) leucine after ingestion of a ^{13}C-labeled egg white protein meal in healthy volunteers and patients with pancreatic insufficiency has confirmed that assimilation kinetics are accurately reflected by the breath test.[99] Although this test can be considered as showing promise for the evaluation and follow-up of patients with pancreatic insufficiency and studies of protein absorption in other disease states, more work is required. This relates particularly to an appropriately labeled test meal and establishing the sensitivity and specificity of the test and the effects of other parameters, such as gastric emptying.

SUMMARY

Because of their simplicity in application, particularly in the pediatric age group, breath tests provide the ideal noninvasive investigative modality for gastrointestinal function in health and disease. It is apparent that they are significantly underused in routine practice despite the amount of information supporting their veracity. This has been recently highlighted in a review of all English language abstracts from 1966 to March 2001, suggesting that breath tests are valuable tools and are generally underused, particularly in the pediatric setting.[100]

CHAPTER 74

IMAGING

1. *Plain Radiographs and Contrast Studies*

Ghislaine Sayer, MRCP, DMRD, FRCR
Helen Carty, FRCR, FRCPI, FRCP, FRCPCH, FFRRCSI(Hon)

Radiologic investigations are frequently required in the diagnosis of pediatric gastrointestinal disease. Close cooperation between clinicians and radiologists is essential in selecting and interpreting those tests, which will contribute meaningful information to the diagnostic process. To avoid unnecessary repeat examinations, all of the patient's previous imaging should be available for review. The motto should be do it once, properly. To comply with radiation exposure regulations, each medical exposure should be justified. The referring clinician is obliged to provide sufficient and accurate clinical information.[1]

All radiologic modalities (including plain films, fluoroscopy, ultrasonography, computed tomography [CT], magnetic resonance imaging [MRI], and radioisotope studies) have applications in pediatric gastroenterology. This chapter outlines the use of plain radiographs and contrast studies of the gastrointestinal tract.

Although not strictly a gastroenterologic investigation, a plain chest radiograph is an important part of the initial assessment of an ill child. It should be remembered that erect chest radiography is not possible in very young children; therefore, the absence of free subdiaphragmatic air on the chest film cannot always rule out a perforation.

Children with chest infections do not expectorate but swallow sputum, subsequently presenting with vomiting. Abdominal pain, mimicking appendicitis, may be the clinical presentation of basal lung consolidation (Figure 74.1-1).

ABDOMINAL RADIOGRAPH

INDICATIONS

An abdominal radiograph is a useful starting point in the investigation of acute abdominal pain,[2] although it may be unhelpful in up to half of such cases.[3] It is essential in suspected intestinal obstruction or perforation. Ingestion of foreign bodies does not necessitate an abdominal radiograph unless the object is sharp or potentially dangerous (eg, batteries, which may leak),[4,5] although a chest film is important to exclude aspiration (Figure 74.1-2).

The plain film is particularly useful in neonates with obstruction, in whom the distribution of bowel gas is a

FIGURE 74.1-1 Abdominal radiograph of a child presenting with abdominal pain. There is right lower lobe consolidation.

FIGURE 74.1-2 Foreign body ingestion: this patient had swallowed a battery.

clue to the level of obstruction, for example, differentiating esophageal from distal atresia. Associated findings such as the bubbly appearance of gas in meconium ileus, calcification following antenatal perforation, or gas in the bladder in a high anorectal malformation may give further clues as to the cause of the obstruction.[6] In modern practice, ultrasonography is often used in addition to the plain film and can be particularly useful in the diagnosis of intussusception, hypertrophic pyloric stenosis, and appendicitis.

The role of the plain film in chronic abdominal pain is less certain. Its main use here is to exclude pathology such as calcification in the renal tracts or biliary tree. It is diagnostically helpful when such calcification is found. Other features that may be suspected on the plain abdominal film are malrotation (easily missed on ultrasonography), impacted foreign bodies in a Meckel diverticulum, foreign bodies in the colon from compulsive pica, bezoars, and, rarely, duplication cysts seen as a mass or air-fluid levels in a focal area of ileal dysgenesis, which is sometimes called a giant Meckel diverticulum.[7]

Technique

A supine film is adequate in the majority of cases. The lung bases and hernial orifices must be included on the film.[2,3] The radiation dose can be reduced by the use of computed radiography,[8] the addition of extra filtration,[9] and not using antiscatter grids.[10] Specialized pediatric departments consistently record lower doses than do general hospitals,[10] not least because of familiarity with the unique challenges involved in gaining the cooperation of children and their parents: getting it right the first time avoids repeat films and unnecessary additional radiation.

Gonad shielding should not be used in girls because it may obscure important signs within the pelvis.[2] Indeed, studies have shown that lead shields are seldom appropriately placed to protect the ovaries in any case.[11,12]

In adult practice, erect films of the abdomen are sometimes performed to identify free intraperitoneal air and to look for fluid levels in intestinal obstruction. The incidence of intestinal perforation after the neonatal period is extremely low in children. Free air in the neonate is usually of large volume and easy to see on a supine film. Intestinal obstruction, after the neonatal period, usually occurs only with intussusception, postoperative adhesive obstruction, inguinal hernias, and sepsis. In most instances, the diagnosis is clinically obvious—hence the relatively limited value of a routine additional erect or decubitus film. If the diagnosis of intestinal perforation is in doubt, a lateral decubitus film (or, in neonates, a horizontal beam "shoot-through" with the patient supine) should clearly delineate free intraperitoneal gas, which will "float" above dependent fluid levels in the peritoneal space.

Interpretation

All abdominal radiographs should be reviewed in a systematic fashion. The following approach will ensure that nothing is missed:

1. Check the name, date, and left and right markers.
2. Identify the liver and stomach bubble to exclude situs inversus.
3. Check bowel gas distribution: masses or fluid collections will displace the bowel from its normal position. Identify, if possible, the cecum in the right iliac fossa (Figure 74.1-3).
4. Look for any gas that does not lie within the stomach or bowel; triangles, arcs, or straight lines of gas usually denote a perforation. The falciform ligament may be seen near the midline, outlined, or either side with free gas (Figures 74.1-4 and 74.1-5). Mottled or patchy areas of gas may lie within an abscess. Retroperitoneal air is notoriously difficult to see on a plain film but may be seen outlining the kidneys (Figures 74.1-6 and 74.1-7).
5. If distended bowel loops are present, identify the level to which they extend and the presence of any distal gas. In general, the jejunum has a feathery pattern owing to the plenitude of mucosal folds, whereas the ileum is more featureless. Haustral folds are present in the colon. An important caveat in neonates is that the colon has poorly developed haustral folds and can be mistaken for small bowel.[13] Owing to the absence of a pelvic cavity in an infant, the sigmoid colon may lie on the right side of the abdomen or even abut the liver. Assess the thickness of the bowel wall and the separation of bowel loops.
6. Identify both renal outlines, the liver and the spleen. Are there any unexplained masses? Renal outlines are

FIGURE 74.1-3 Malrotation: abnormal distribution of bowel gas with the small bowel lying to the right of the midline and the cecum clearly in the left iliac fossa.

poorly seen in children owing to the paucity of perirenal fat, but, as a rule of thumb, the kidneys should each measure about three and a half vertebral bodies in length. Liver size is poorly assessed on abdominal radiography. A Riedel lobe is a normal variant that may extend to the right iliac fossa. Spleen size may be reliably assessed; if the tip of the spleen is seen below the ribs, it is likely to be enlarged (Figure 74.1-8).

7. Look for any calcifications and decide on their location: renal tract, a mass lesion, lymph nodes?
8. Check the corners of the film (ie, lung bases and hernial orifices). Abdominal pain may be referred from above the diaphragm, and strangulated hernias are a common cause of bowel obstruction.
9. Examine the bones: vertebral anomalies are a clue to congenital anomalies such as tracheoesophageal fistulae and renal and anorectal malformations (Figure 74.1-9). Check sites of tubes and lines (see below).
10. Identify the properitoneal fat lines, which are normally convex medially beyond infant age. Distention of these, particularly if coupled with separation from bowel

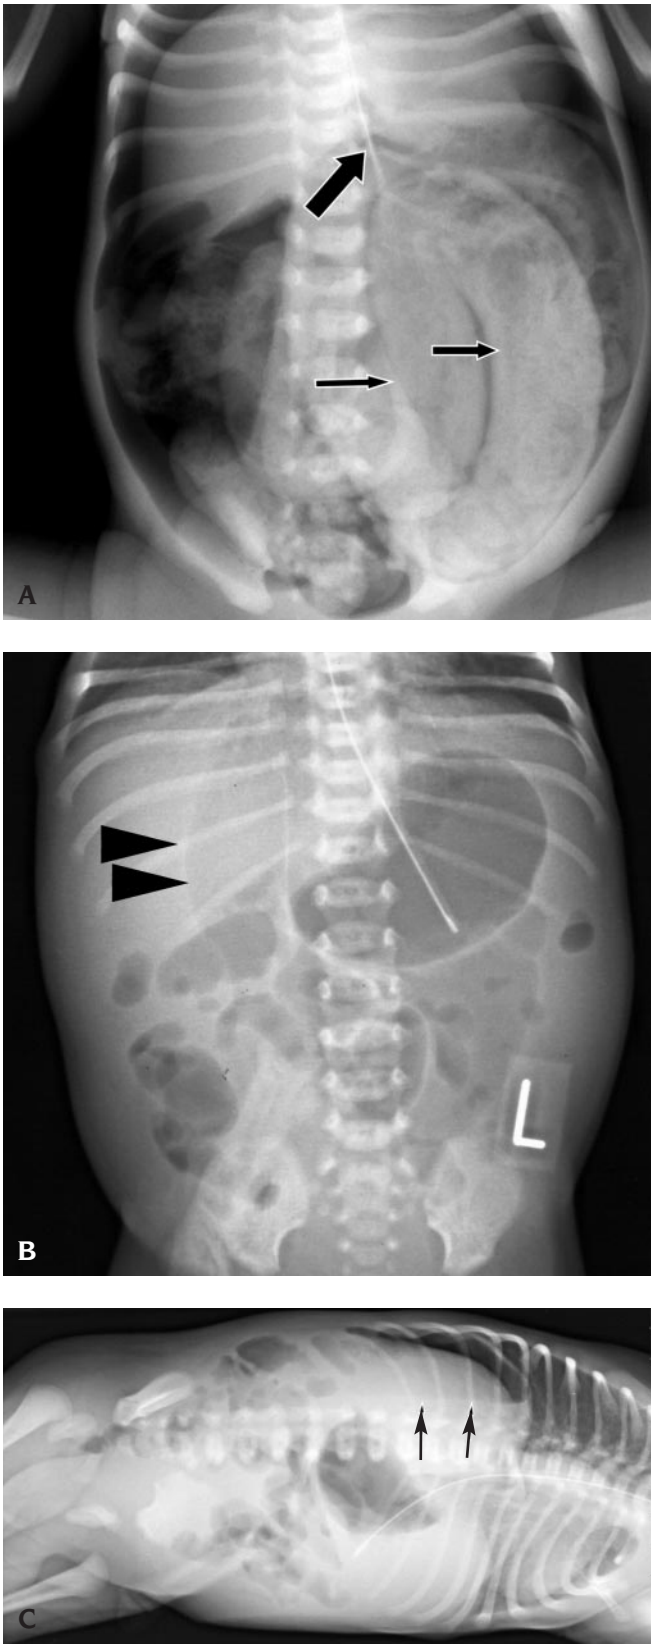

FIGURE 74.1-4 *A*, Perforation in a neonate with meconium ileus. Gas outlines the liver and the falciform ligament (*large arrow*) and distends the flanks (so-called "football sign"). Loops of bowel filled with granular-looking meconium are seen (*small arrows*). *B*, A more subtle example of perforation: an abnormal gas lucency lies centrally in the abdomen (*arrows*). Again, the falciform ligament is clearly seen. *C*, Decubitus film of the baby in *B*. A horizontal air-fluid level is now visible (*arrows*).

FIGURE 74.1-5 Perforation: crescents of air are seen beneath both hemidiaphragms.

loops, may indicate ascites (although this is much more easily identified on ultrasonography). Look for the psoas outline, which is rendered visible by a fat plane. This may become obscured in intra-abdominal sepsis, which is classically described with perforated appendix. However, the psoas outline may be obscured in normal children owing to rotation of the film.

The following conditions have characteristic appearances and may be diagnosed on plain films:

Congenital Obstruction. The level of obstruction can usually be deduced from the plain film. Esophageal atresia could be expected to produce a gasless abdomen, but in practice, there is often a large amount of bowel gas present owing to a tracheoesophageal fistula distal to the esophageal atresia (Figure 74.1-10). Duodenal atresia produces the "double bubble" sign, with air in the distended stomach and proximal duodenum (Figure 74.1-11). Jejunal obstruction produces several dilated loops of small bowel in the left upper quadrant (Figure 74.1-12). The more distal the obstruction, the more loops of distended bowel are seen. Distal small bowel obstruction may be difficult to distinguish from large bowel obstruction.[14]

Anorectal Anomalies. The diagnosis of anorectal anomalies is clinical. However, a plain abdominal film is required to assess the sacrum for associated anomalies. A prone lateral "shoot-through" of the rectum will help to delineate the level of the anorectal atresia, but meticulous technique is essential. The baby should be laid prone with its bottom elevated for 30 minutes prior to the film being taken to allow air to rise to the most distal portion of the rectum. A radiopaque marker should be placed on the skin at the anal dimple. Rarely, there is air in the bladder owing to a colovesical fistula.

Acquired Bowel Obstruction. The plain film in acquired obstruction typically shows dilated loops of

FIGURE 74.1-11 "Double bubble" sign in duodenal atresia.

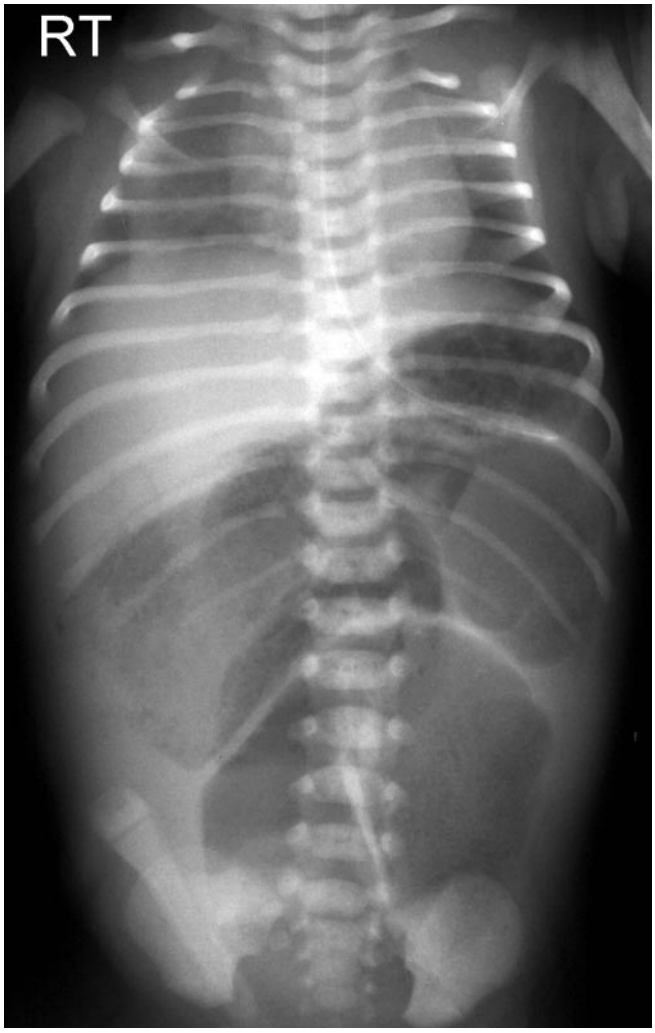

FIGURE 74.1-12 Jejunal atresia.

bowel proximal to the obstruction (Figure 74.1-13). If the obstruction is of recent onset, there may still be gas in the bowel distal to the obstruction. Multiple fluid levels within dilated loops form a "ladder" pattern.[2] In high-level obstruction, or when the bowel is very full of fluid, such as in closed-loop obstruction, air-fluid levels may not be present. Nasogastric suction may also alter the pattern of fluid levels.

Ileus. In paralytic ileus, there is an absence of peristalsis rather than mechanical obstruction. Therefore, both small and large bowel are dilated (Figure 74.1-14). The individual loops tend to be less distended than in mechanical obstruction, and fluid levels are longer.[2] Gas is seen as far as the rectum. Confusion may arise, however, in cases of prolonged mechanical obstruction, when ileus may ensue. Since sepsis is a common cause of ileus in children, ultrasonography is supplementary to identify any intra-abdominal or pelvic collections.

Intra-abdominal Abscess. Large abscesses will be visible on the plain radiograph as mass lesions with displacement of bowel loops. There is often gas within the abscess; depending on its location, this may be a subtle finding, such as in a subphrenic collection, in which the gas overlies the dome of the liver, and may form a gas-fluid level. A localized ileus may cause a few loops of distended bowel adjacent to the abscess.

FIGURE 74.1-13 Small bowel obstruction. Note absence of gas in the rectum.

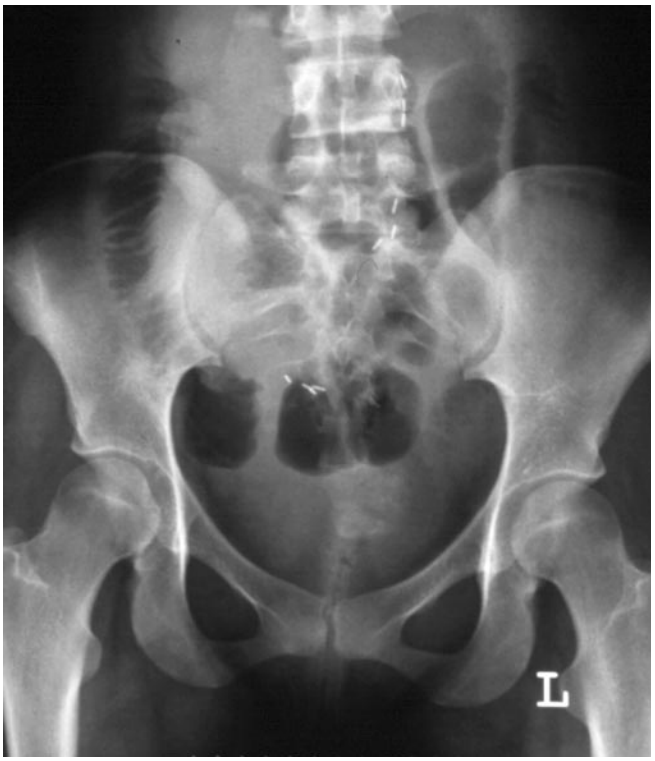

FIGURE 74.1-14 Postoperative ileus. Note the surgical clips and several loops of dilated small bowel.

Necrotizing Enterocolitis. The abdominal radiograph in the neonate with necrotizing enterocolitis will display nonspecific signs such as widespread dilatation of bowel loops and separation of loops. The radiologic hallmark, however, is intramural gas. This may be present at any level from the esophagus to the rectum and may be linear or bubbly in appearance (Figure 74.1-15). Portal venous gas may be present and is no longer regarded as an ominous prognostic sign.[13,15] It must be differentiated from air in the biliary tree, which tends to be more centrally located (around the porta hepatis) and displays a branching pattern. Portal venous gas occasionally may be introduced via an umbilical vein catheter.

Bowel Wall Thickening. Edematous, inflamed bowel wall appears thickened, and loops lie slightly separated from one another. "Thumbprinting" occurs with ischemia and may also be due to hemorrhage into the bowel wall, such as occurs in hemolytic uremic syndrome, Henoch-Schönlein purpura, or thrombocytopenia (Figure 74.1-16). Toxic megacolon, when the transverse colon is unduly dilated and inflamed, is rare in children.

Hernias. Gas within the scrotal sac in boys (or below the inguinal ligament in girls) indicates a hernia; however, in strangulated hernias, the gas may be absent, but there will be asymmetry of the scrotal shadow (Figure 74.1-17). Umbilical hernias may cause unusual gas shadows on plain films owing to air interposed between the hernial sac and the anterior abdominal wall (Figure 74.1-18).

Foreign Bodies. Incidental foreign bodies are frequently seen in children, particularly in the colon. Most will pass without incident. Swallowed dental amalgam

FIGURE 74.1-15 Necrotizing enterocolitis resulting in linear gas lucencies within the thickened bowel wall (*arrow*).

FIGURE 74.1-16 "Thumbprinting" of the colonic mucosa in a patient with Hirschsprung disease and necrotizing enterocolitis.

FIGURE 74.1-17 Small bowel obstruction owing to an inguinal hernia. There is gas in the scrotum (*arrow*).

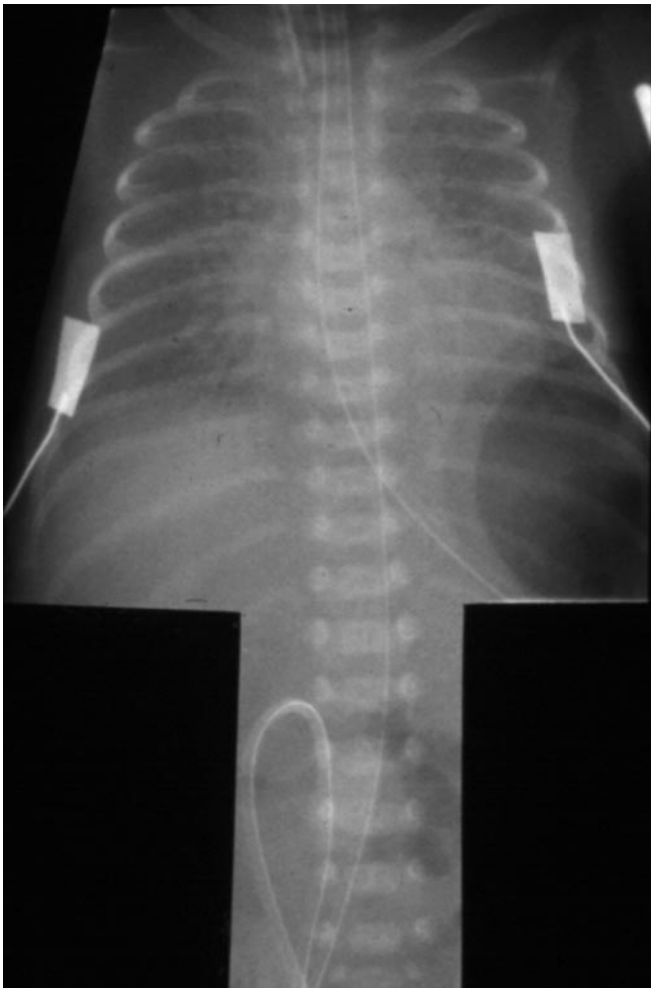

FIGURE 74.1-19 The umbilical vein catheter has been placed too high; its tip lies in a neck vein. Note endotracheal tube and nasogastric tube in a satisfactory position.

results in a characteristic pattern of small flakes distributed throughout the colon.

Tubes and Lines. The tip of a nasogastric tube should lie in the body of the stomach.

An umbilical vein catheter should lie in the right atrium[16]; a lateral film may be required to confirm this because malposition in the left atrium is associated with an increased incidence of intracardiac thrombus formation.[17] An umbilical artery catheter should lie between T6 and T10 (or L3–L5 if the low position is used) (Figures 74.1-19 and 74.1-20).[16] The positions of lines will vary in neonates with congenital diaphragmatic hernias and may give clues as to the contents of the hernia.[18] Ventriculoperitoneal shunts should terminate within the peritoneal cavity but may migrate upward as the child grows. If there is doubt as to the position of the line tip, a lateral film may be useful. If the tip is projected below the costal margin on the frontal radiograph, a lateral radiograph may show it to be superficial to the liver, where it may pass in and out of the peritoneal cavity, creating a valve effect, resulting in intermittent hydrocephalus.

Calcification. It is important to determine exactly where calcification on an abdominal radiograph is and to decide on its cause. Adrenal calcification commonly follows neonatal adrenal hemorrhage and is seen on either side of the vertebral column, at the top of the renal outlines. Antenatal intestinal perforation results in calcified meconium in the peritoneal cavity. Calcification within a mass lesion should always raise suspicion: neuroblastomas commonly calcify, and calcification is seen rarely in Wilms tumor, hepatoblastoma, and liver hemangioma (Figure 74.1-21).[19] In older children with cystic fibrosis, pancreatic calcification may be seen extending across the midline at the L1 level. Previous tuberculous infection may cause calcification in mesenteric lymph nodes, liver, and spleen; treatment of lymphoma with radiotherapy may also result in lymph node calcification. Fecoliths are common incidental findings, but their presence should be reported because elective appendectomy is indicated.[2] Renal calcification should be differentiated into parenchymal versus pelvic: medullary sponge kidney, renal papillary necrosis, and hyperparathyroidism are among the causes of the former, whereas calcification within the lumen of the renal pelvis, ureters, or bladder is likely to represent a true "stone." A transplant kidney may calcify owing to chronic rejection. In older children, phleboliths within the pelvic veins are easily mistaken for ureteric stones. In general, phleboliths are rounded with a slightly lucent center, whereas urinary tract calculi tend to be more angular in shape. An intravenous urogram, possibly including an oblique film of the bladder area, may be required to show whether a calcific focus lies along the path of the ureter.

Appendicitis. A child with unequivocal clinical signs of appendicitis does not require imaging. However, in cases in which the diagnosis is in doubt, radiologic input may be

FIGURE 74.1-20 The umbilical artery catheter has been placed too low.

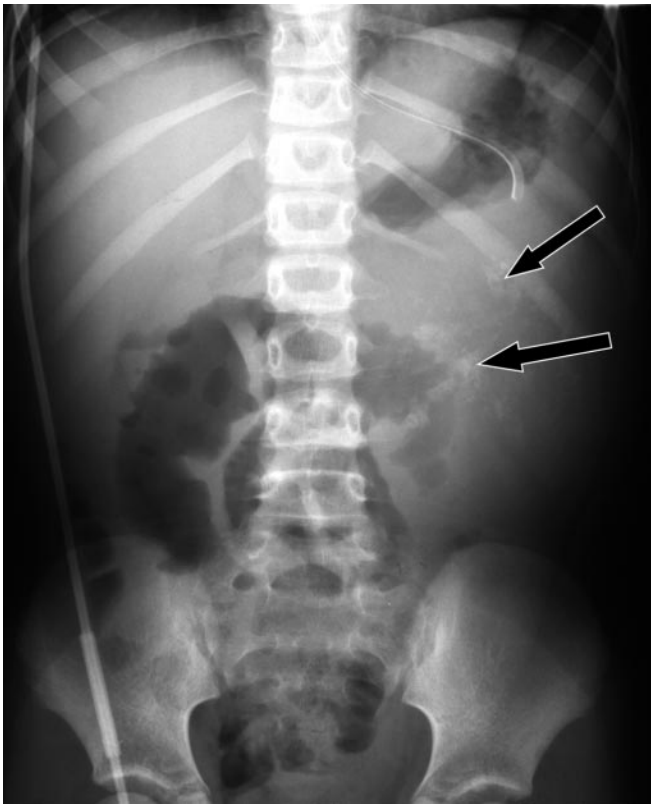

FIGURE 74.1-21 Left-sided abdominal mass containing calcification (*arrows*). This was a neuroblastoma.

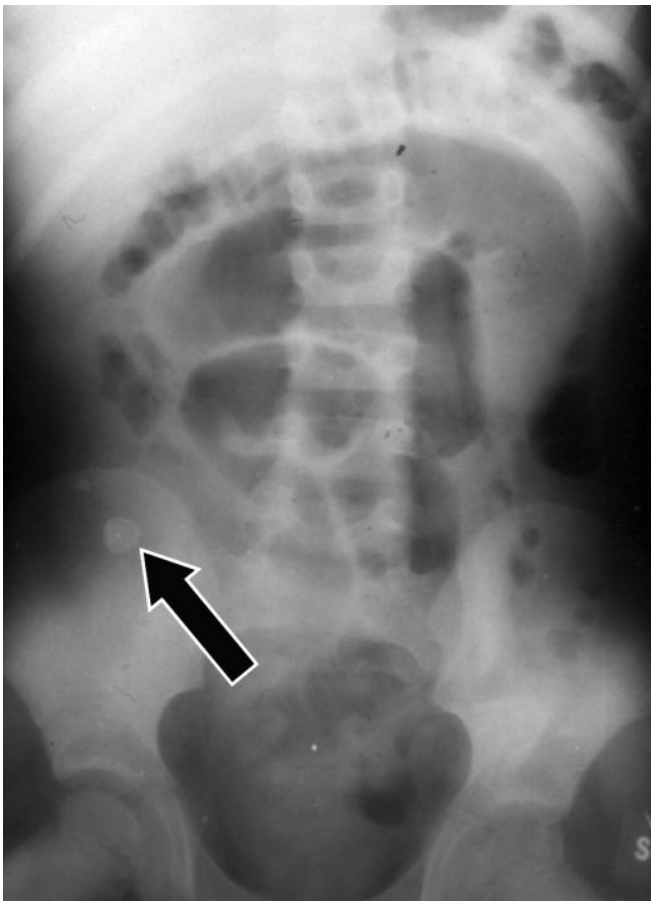

FIGURE 74.1-22 Appendicitis: there is a fecolith in the right iliac fossa (*arrow*).

valuable. The plain abdominal film is frequently normal in appendicitis. In about 10% of cases, a calcified fecolith in the right iliac fossa will confirm the diagnosis (Figure 74.1-22).[2] If the appendix is retrocecal, the fecolith may lie more superiorly and may even mimic a gallstone. Other plain film findings that have been described in appendicitis include a mass in the right iliac fossa with displacement of bowel loops and possibly containing gas (Figure 74.1-23), a localized ileus or even complete small bowel obstruction, and blurring of the peritoneal fat lines. In modern practice, ultrasonography is the first-line investigation in suspected appendicitis[20] and has the considerable advantage of not using ionizing radiation. There is also increasing evidence that CT in selected cases can significantly reduce the rate of negative appendectomies (Figure 74.1-24).[21,22]

Typhlitis. This severe form of colitis is seen in neutropenic and immunocompromised children. The name strictly refers to cecal inflammation, but the whole colon may be involved. Plain film signs include bowel wall edema

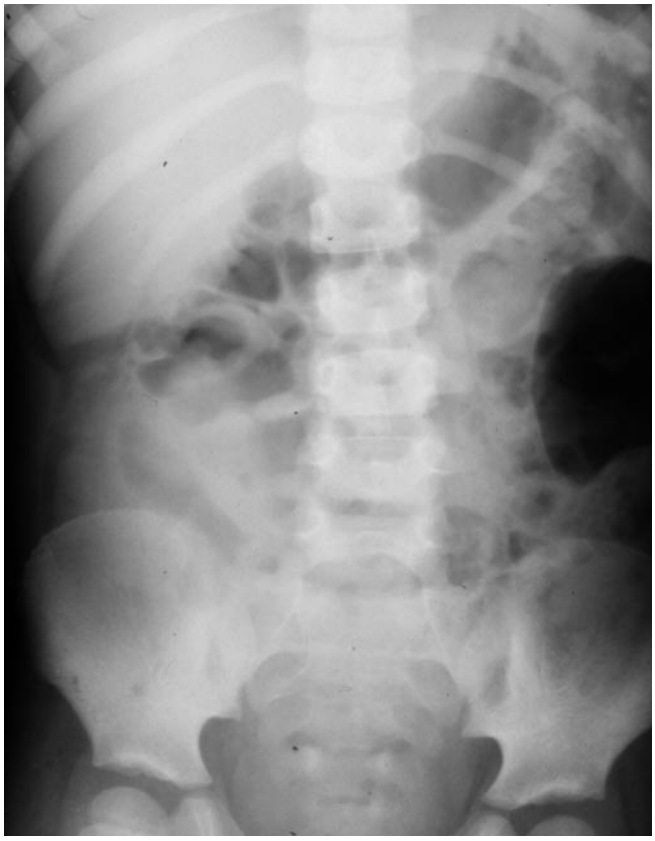

FIGURE 74.1-23 Appendicitis: a rounded soft tissue density in the right iliac fossa displaces bowel loops.

and "thumbprinting"; in severe cases, intramural gas may be present. Secondary dilatation of the small bowel may occur.[2] As with appendicitis, ultrasonography and CT are playing an increasingly important role in the diagnosis of typhlitis. It is particularly important to distinguish this condition from appendicitis because surgical intervention is not required in typhlitis unless complications (such as perforation) occur.[23,24]

Intussusception. The plain film may be entirely normal in cases of intussusception. The typical finding of a soft tissue mass indenting the colon (usually seen in the transverse colon) is seen in only about 25% of patients (Figure 74.1-25).[2,25] Less specific findings include the absence of gas in the right upper quadrant (with failure to identify the cecum and the typical hepatic flexure gas pattern) and a vague right-sided mass. Varying degrees of small bowel obstruction may be present, depending on the time elapsed since the onset of symptoms. Ultrasonography is sensitive in the diagnosis of intussusception and should be performed before proceeding to a contrast study and attempts at reduction.[26]

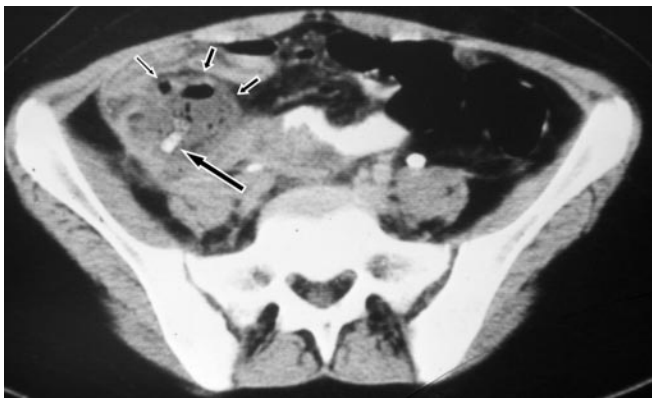

FIGURE 74.1-24 Computed tomographic scan of appendicitis: there is a fecolith (*large arrow*) and a rounded fluid collection (*small arrows*) containing flecks of gas.

Pitfalls for the Unwary. While assessing a pediatric abdominal radiograph, the clinician should be aware of several "oddities" that may masquerade as pathology. Films taken on the intensive care unit often include various tubes and equipment, which, in fact, lie outside the patient. The access hatch of an incubator may cause a mysterious circular lucency in the center of the film. Similarly, the umbilical cord, particularly if there is no clamp, may simulate a mass. The same effect can be produced by the penis seen end on. The tip of the normal coccyx may be misinterpreted as abnormal calcification within the pelvis. When assessing suspected intestinal obstruction, it is important to remember that air seen in the rectum may have been introduced by digital rectal examination and therefore cannot be relied on as a sign of patency of the distal bowel.

FIGURE 74.1-25 Intussusception.

CONTRAST STUDIES

Indications

Contrast studies of the gastrointestinal tract, when tailored specifically to the clinical indications, can provide the clinician with anatomic detail and functional information about motility and gastric emptying. The spectrum of disease in children differs from that in adults; ulcers and tumors are rare, and congenital anomalies, such as malrotation, are more frequent. Thus, the emphasis is on anatomy and function rather than mucosal detail, making a fluoroscopic contrast study a potentially more useful diagnostic tool than endoscopy in many cases. Contrast studies are well tolerated by the vast majority of children, whereas endoscopy requires sedation or a general anesthetic. However, contrast studies of the esophagus, stomach and duodenum, and colon have largely been replaced by endoscopy in specialist pediatric units. Contrast studies of the small bowel now make up a larger proportion of the work in a pediatric radiology department, although ultrasonography and CT are often complementary investigations in the diagnosis of small bowel lesions (Table 74.1-1 and Figure 74.1-26).

As well as the conventional techniques listed above, there is frequently the need for specific investigations in specific circumstances: "loopograms" or sinograms, which are intended to answer a particular clinical question, most often in surgical patients (Figure 74.1-27). It cannot be overemphasized that communication between the clinician and the radiologist is of the utmost importance to ensure that the appropriate test is performed. In some cases, CT may be used in conjunction with fluoroscopy, for example, giving more detail about the track of a sinus or fistula in three dimensions.

Contrast studies have been used in the past for the investigation of the gallbladder and biliary tract in children. Ultrasonography is extremely reliable in the diagnosis of biliary tract dilatation, choledochal cysts, and gallstones. More recently, MRI has advanced to the point where magnetic resonance cholangiopancreatography (MRCP) can provide high-resolution images of the biliary tree, gallbladder, and pancreatic duct, obviating the need for invasive procedures such as percutaneous transhepatic cholangiography or endoscopic retrograde cholangiopancreatography. MRCP has proved useful in the investigation of acute pancreatitis, primary sclerosing cholangitis, choledochal cyst, and congenital anomalies, such as pancreas divisum.[27–30] New techniques are continually being explored in this exciting field, and in the near future, virtual endoscopy of the pancreatic and biliary ducts using data from MRCP studies is likely to become routinely available.[31]

Choice of Contrast

Barium sulfate is the traditional gastrointestinal contrast medium of choice. It is cheap and readily available, and its high density provides excellent contrast and definition. It is not absorbed by the gut and can, therefore, be used anywhere in the bowel. It remains the contrast medium of choice for small bowel studies and for double-contrast enemas on the rare occasions that these are done. However, if any of the following contraindications exist, a water-soluble contrast medium (see below) should be used:

- Suspected perforation (barium excites an aggressive inflammatory response if allowed to escape into the mediastinum or peritoneum).
- Possibility of aspiration, for example, in neurologically impaired children (although aspirated barium is usually well tolerated, serious respiratory impairment can occur).
- Because barium is contraindicated, water-soluble media are now the contrast of choice for neonates.
- Barium may become inspissated in defunctioned bowel (eg, loopograms postsurgical resection), and there is a risk of impaction in Hirschprung disease and cystic fibrosis.

Gastrografin should not be used in the upper gastrointestinal tract because it is very hyperosmolar and can precipitate pulmonary edema if aspirated. It is used for

TABLE 74.1-1 GASTROINTESTINAL CONTRAST STUDIES PERFORMED IN CHILDREN AND SOME OF THEIR INDICATIONS

Speech study/phonetics
Identification of palatal movement and choanal closure
Pre- and postsurgical repair of cleft palate
Speech problems with nasal escape
Nasal reflux of food
Swallowing study
Oropharyngeal incoordination, mainly in children with neurologic impairment
Contrast swallow
Vascular rings and other extrinsic masses affecting swallowing
Tracheoesophageal fistula (including follow-up postsurgical repair) (see Figure 74.1-26)
Gastroesophageal reflux
Foreign body ingestion
Strictures
Upper gastrointestinal study
Usually follows contrast swallow
Demonstrates anatomy (eg, duodenojejunal flexure) and motility
Pyloric stenosis (now largely replaced by ultrasonography)
Gastrostomy study
Contrast instilled via gastrostomy tube
Assesses gastric emptying and reflux
Small bowel studies
Assesses the bowel, which is not within reach of endoscopy
Performed as follow-through or enteroclysis (see below)
Crohn disease
Small bowel strictures (traumatic/postsurgical)
Dysmotility
Barium enema
Now rarely performed
A limited study may be performed in severe constipation to exclude Hirschsprung disease
Defecating proctography
To assess pelvic floor dysfunction in obstructed defecation
Fistulography/sinography
Identification of tracks
Water-soluble contrast enema
Performed in neonates
To identify cause of intestinal obstruction, eg, Hirschsprung disease, meconium ileus, meconium plug, intussusception

FIGURE 74.1-26 Contrast swallow in a patient with H-type tracheoesophageal fistula. Contrast is seen outlining the trachea and bronchial tree.

therapeutic enemas in meconium ileus, where it draws fluid into the bowel lumen to aid disimpaction of the sticky meconium. However, it may cause dehydration by drawing excessive amounts of water into the bowel,[6] particularly in a vulnerable neonate, and great care should be taken to ensure adequate fluid replacement. The radiologist must inform the clinician that Gastrografin has been used.

The iso-osmolar contrast agents are more expensive than Gastrografin but are safe if aspirated and have no effect on the peritoneum or mediastinum. Perhaps surprisingly, there is no evidence that iso-osmolar agents are any less effective in the treatment of meconium ileus than hyperosmolar media.[6]

Double-contrast studies of the gastrointestinal tract are performed in adult practice and provide excellent mucosal detail. The technique uses a thin coating of barium to define the mucosa, combined with distention of the viscus with air. With the advent of endoscopy, double-contrast studies are now rarely required in children.

Air is now the medium of choice for intussusception reduction.[32,33] It is introduced into the colon at pressures of up to 120 mm of mercury. Perforation is a rare complication, but if it occurs, a large pneumoperitoneum will result, with respiratory compromise. Accordingly, a large trochar should be available for immediate decompression of the peritoneum.[2]

TECHNIQUE

General Considerations. A pediatric "barium" list presents a unique challenge. Flexibility and ingenuity are essential so that each study is specifically tailored to the patient and the clinical problem.

Steps should always be taken to minimize the radiation dose to children undergoing fluoroscopic examinations. Digital fluoroscopy delivers a lower dose than older cine-film systems, and the dose can be reduced further by using pulsed screening.[34,35] A last-image-hold ("frame grab") facility allows images to be recorded without a static exposure being made. Grids should not be used routinely.

Video recordings should be made of all gastrointestinal contrast studies. This allows dynamic processes such as swallowing, gastroesophageal reflux, or gastric transit to be viewed in real time, or frame by frame. If an uncooperative child has allowed only an incomplete study to be performed, the video footage will often contain sufficient information even if no static images have been recorded, thus obviating the need for a repeat study.

Specific Techniques. *Speech and Swallowing Studies.* Speech and swallowing difficulties frequently coexist in neurologically impaired children. A multidisciplinary approach is essential in their management, and videofluoroscopy swallowing studies should be carried out with the speech therapist. Videofluoroscopy swallowing studies provide more detailed and objective evidence of swallowing dysfunction than traditional bedside evaluation.[36] The aim is to assess the phases of swallowing and to ensure that there is complete glottic closure without aspiration. Specific observable problems include poor tongue movements, delayed swallow reflex, reduced laryngeal elevation, and silent aspiration.[37] Aspiration is more likely to occur with thin fluids; therefore, swallowing of thicker consistencies should be assessed first, using, for example, bread or bis-

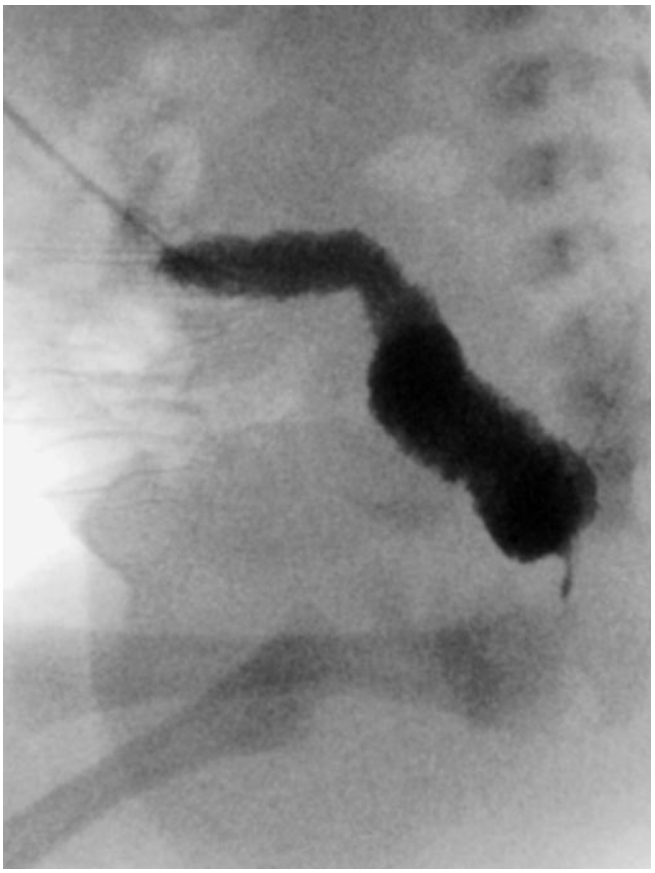

FIGURE 74.1-27 "Loopogram." Contrast has been introduced via the defunctioning stoma to demonstrate the level of the anorectal atresia.

cuits dipped in barium or yogurt mixed with barium for infants who cannot yet manage solids. Appropriate commercial thickening agents are available. The result of these studies can be of vital importance in the future management of the child, for example, determining the safest position for feeding, which will help prevent long-term aspiration and malnutrition.[38,39]

Upper Gastrointestinal Studies. Infants whose last feed has been withheld are usually quite willing to drink unflavored barium or (amazingly!) Omnipaque from a bottle. For older children, barium can be flavored to make a relatively pleasant milkshake-style drink; Omnipaque is effectively disguised in orange juice. To assess swallowing of solids, marshmallows can be soaked in barium.

Contrast swallows have historically been performed mainly for the detection of gastroesophageal reflux. However, the sensitivity of radiologic studies for reflux has been reported to be as low as 52%[40]; therefore, a negative study is of little diagnostic value. Barium swallows continue to be useful in the diagnosis of structural causes of dysphagia, such as vascular rings, strictures following caustic ingestion, long-standing reflux disease, or postsurgical repair of tracheoesophageal fistulae, as well as functional disorders such as achalasia and globus hystericus. Views should always be taken in the supine oblique position to fully distend the lower esophagus. A careful history is important: establish exactly what provokes the child's symptoms and try to reproduce these conditions as closely as possible during the study.

In children with feeding gastrostomies, the parent or caregiver should be asked to replicate the child's usual feeding process, using contrast mixed with food. Again, the conditions that produce symptoms should be reproduced; for example, if the patient habitually vomits after 200 mL of food have been given, a study using only a small volume of contrast will not be helpful.

The radiologist should take the opportunity during all upper gastrointestinal studies in children to observe the passage of contrast around the duodenal loop to the duodenojejunal flexure. An image of the correctly sited flexure (to the left of the spinal column, at the level of L1) will rule out 98% of cases of malrotation (Figure 74.1-28). In some centers, a contrast enema (rather than an upper gastrointestinal study) is the investigation of choice to rule out malrotation; however, in 16% of children with malrotation, the cecum is normally sited in the right iliac fossa. Furthermore, the cecum may be displaced from the right iliac fossa in 15% of normal children.[6] In cases of strong clinical suspicion of malrotation, where the duodenal position appears normal or equivocal, it is logical to proceed to an enema study to evaluate the cecal position.

All radiologic studies for malrotation are limited by the fact that only the bowel is imaged, not the mesenteric fixation, which is what actually determines the malrotation. It is also well recognized that the normal duodenum may be markedly mobile, especially in neonates, and this may lead to further confusion.[41]

Small Bowel Follow-through. Most would agree that the initial investigation of the small bowel should be by follow-through, with enteroclysis (see below) being reserved for selected difficult cases in which a follow-through study has failed to make a diagnosis.[42] In the follow-through technique, the child drinks about 500 mL of dilute barium after a 6-hour fast. An immediate supine film is taken, followed by prone films (the prone position separates bowel loops) at intervals until the ileocecal junction has been visualized. The films should be carefully examined as they are done, and fluoroscopy should be performed to clarify any doubtful areas, for example, to confirm fixation or separation of bowel loops. The terminal ileum should always be screened to ensure that underfilling is not misinterpreted as a stricture. If the colon is loaded with feces, the passage of barium will be slowed; this may often be overcome by giving the child a meal once contrast has reached the ileum.

Enteroclysis. Enteroclysis (or small bowel enema) involves introduction of contrast directly into the proximal jejunum via a long, wide-bore oro- or nasojejunal tube. A bolus of dilute barium is used, followed by water or methylcellulose for a double-contrast effect, and is monitored with fluoroscopy throughout the small bowel. The technique is more sensitive than follow-through studies, particularly for the demonstration of polyps, but is often poorly tolerated by children. Intubation may be difficult, and if the tube is too proximal, barium will reflux into the stomach and result in vomiting.

Peroral Pneumocolon. This technique is supplementary to a small bowel follow-through study. Once barium has reached the terminal ileum, air is insufflated per rectum to distend the colon and terminal ileum. This gives good mucosal detail of the terminal ileum but is relatively more invasive.

Characteristic Appearances of Selected Conditions on Contrast Studies. The reader is referred to the individual chapters for a more complete discussion of these conditions.

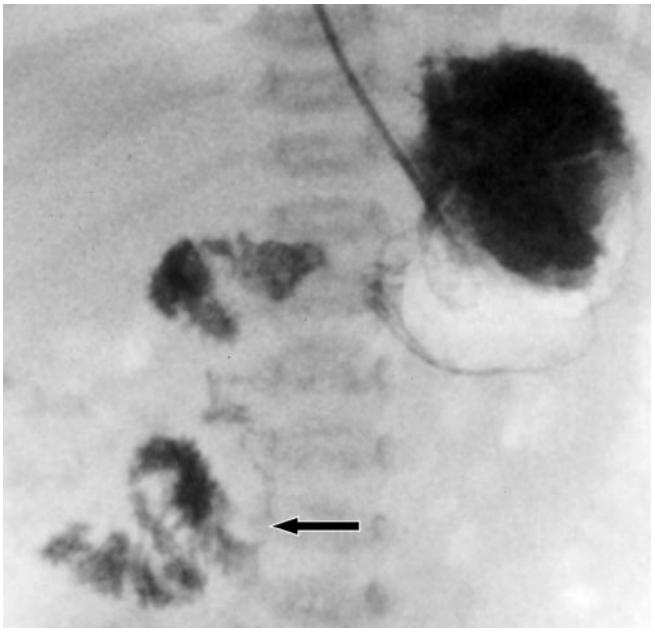

FIGURE 74.1-28 Malrotation: upper gastrointestinal contrast study showing abnormal position of the duodenojejunal flexure, which lies to the right of the midline (*arrow*).

Vascular Rings. The lateral view of the esophagus during a contrast swallow can predict the type of vascular anomaly in most cases. The plain chest radiograph will provide additional information about the aortic arch and tracheal position. In modern practice, the definitive diagnosis is usually made by MRI.

There are four patterns of esophageal and/or tracheal compression on the contrast swallow; these correspond to four major vascular anomalies. A double aortic arch causes posterior esophageal compression together with anterior tracheal compression. (A similar pattern occurs with a right-sided arch in combination with a left ductus arteriosus and aberrant left subclavian artery.) Compression of the trachea by a prominent innominate artery causes an anterior impression on the trachea but a normal esophagus. Aberrant right subclavian artery (the most common anomaly of the aortic arch) results in a posterior impression on the esophagus with a normal trachea. Finally, a posterior impression on the trachea, coupled with anterior compression of the esophagus, is caused by an aberrant left pulmonary artery, arising from the right pulmonary artery and passing between the trachea and esophagus.[14,43]

Achalasia. Videofluoroscopy in achalasia shows abnormal motility and failure of relaxation of the lower esophageal sphincter. The esophagus becomes dilated in long-standing cases and may be filled with food debris. The narrowed lower esophageal sphincter has a characteristic "rat-tail" appearance.[14]

Hiatal Hernia and Gastroesophageal Reflux. If the gastroesophageal junction lies above the diaphragm, a hiatal hernia is present. The significance of hiatal hernia in reflux disease has yet to be established.[44] A small amount of reflux is a normal finding in children. A clinical history of repeated vomiting, failure to thrive, and recurrent chest infections (owing to aspiration) are clues that significant reflux is present. If the gastroesophageal junction is widened and the esophagus appears "baggy," significant reflux is likely to be present. Any contrast refluxing above the gastroesophageal junction should be noted, as well as the level to which it ascends and the frequency of episodes during the study.[2] Failure to demonstrate reflux on videofluoroscopy does not exclude the diagnosis (see under "Technique" above). In chronic reflux disease, an esophageal stricture may develop, which is usually smooth and tapering in appearance.

Duodenal Obstruction. Complete duodenal atresia is usually diagnosed on the plain film, which typically shows the "double bubble" sign. Partial duodenal obstruction may be due to congenital webs, annular pancreas, Ladd bands, or a preduodenal portal vein. A web may appear as a linear filling defect within the duodenum, and the dilated, barium-filled distal duodenum with a convex end has been described as a "wind sock." Other causes of partial duodenal obstruction are difficult to distinguish from webs on barium studies (Figures 74.1-29 and 74.1-30). Cross-sectional imaging will be helpful in demonstrating pancreatic and portal vein anomalies.[14] However, pragmatically, this is not done in neonates because these children require surgery.

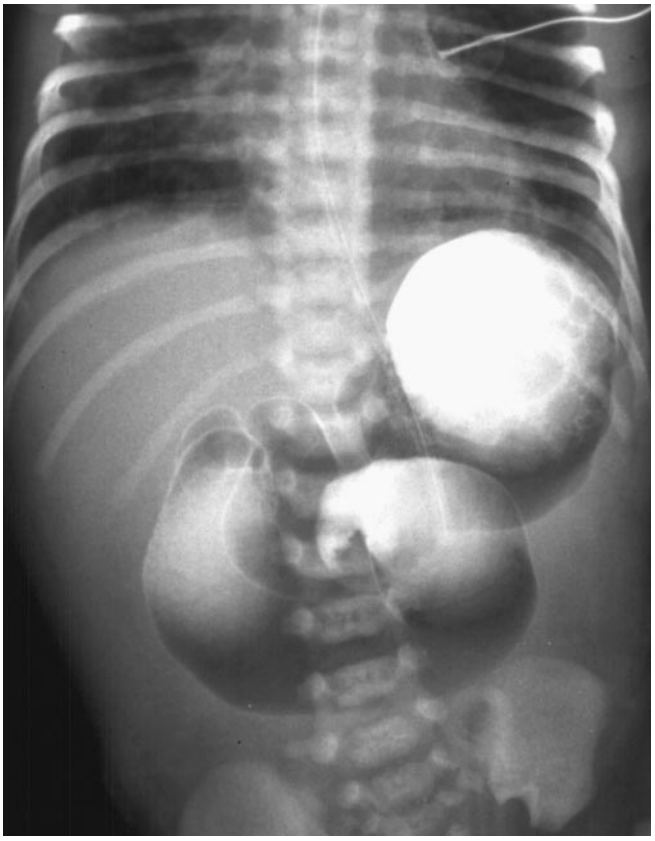

FIGURE 74.1-29 Contrast study demonstrating duodenal atresia.

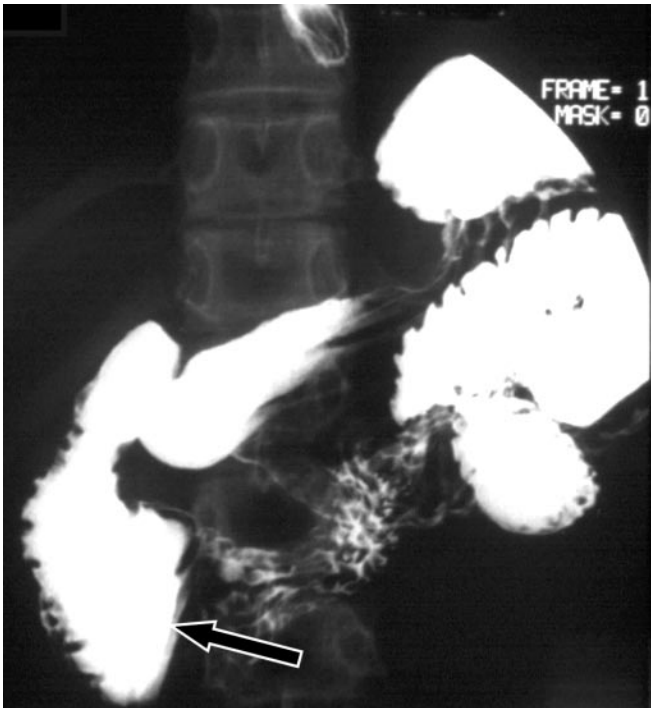

FIGURE 74.1-30 Partial duodenal obstruction, owing in this case to compression by the superior mesenteric artery. There is dilatation of the duodenum proximal to the obstruction (*arrow*).

Malrotation and Volvulus. As discussed under "Technique" above, contrast studies are not infallible in the diagnosis of malrotation. The major life-threatening complication of malrotation is volvulus of the small bowel around the superior mesenteric artery. If this is present, the contrast study may demonstrate a corkscrew or "twisted ribbon" appearance of the duodenum and jejunum, with thickened mucosal folds owing to edema of the bowel wall. Classically, the contrast terminates in a "bird's beak" at the point of obstruction; however, the obstruction may be rounded and appear to be similar to duodenal atresia.[14]

Malabsorption. Malabsorption attributable to any cause characteristically results in nonspecific changes in the small bowel contrast study: fragmentation of the barium column, flocculation of barium, and mild dilatation of the small bowel. Celiac disease is classically described as causing a featureless, smooth jejunum with an increase in mucosal folds in the ileum (so-called "jejunization" of the ileum) (Figure 74.1-31). Transient intussusceptions may be seen during the small bowel study.[2,45] There is an increased risk of small bowel lymphoma, so any mass should be treated with suspicion.

Crohn Disease. Crohn disease may affect any part of the gastrointestinal tract. In the small bowel, the terminal ileum is the most commonly affected region; however, up to 20% of children with small bowel Crohn disease will have a normal terminal ileum on imaging.[14,46] More typically, there is a segment of narrowed, rigid bowel with mucosal nodularity or "cobblestoning" and deep ulcers (Figure 74.1-32). If the stricture is tight, the proximal portion of bowel may be dilated. Several sections of bowel may be affected, with the intervening areas appearing normal ("skip lesions"). Fistulae may occur between adjacent loops of small bowel or between small bowel and colon or even stomach. In long-standing disease, eccentric scarring occurs, resulting in "pseudosacculations" on the antimesenteric border of the bowel. CT and ultrasonography have an important supplementary role in delineating thickened bowel loops and inflammatory masses.[47] In difficult cases, an isotope-labeled white cell scan may be required to identify an intra-abdominal site of inflammation.[2]

Crohn disease of the colon can be demonstrated on a double-contrast barium enema; however, these are rarely performed in modern pediatric practice because endoscopy is the mainstay of diagnosis for inflammatory diseases of the colon. The colon is usually asymmetrically involved (in contrast to ulcerative colitis), with predominantly the right colon being affected and less commonly the rectum.[14] In early Crohn colitis, there may be discrete aphthae (ulcers with a smooth raised edge); these later coalesce to form

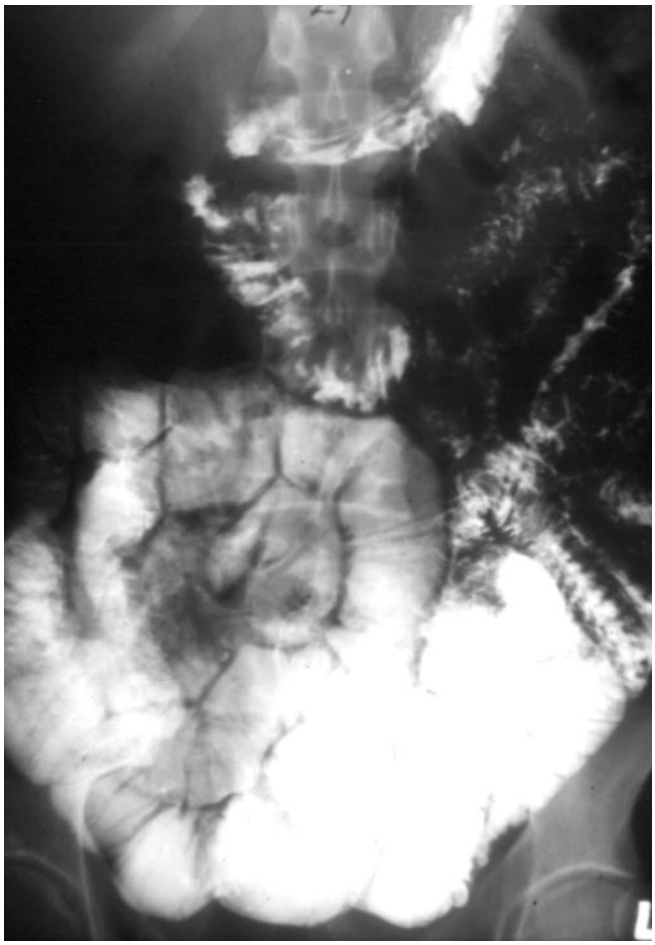

FIGURE 74.1-31 Small bowel meal in celiac disease. The jejunum is mildly dilated, smooth, and relatively featureless.

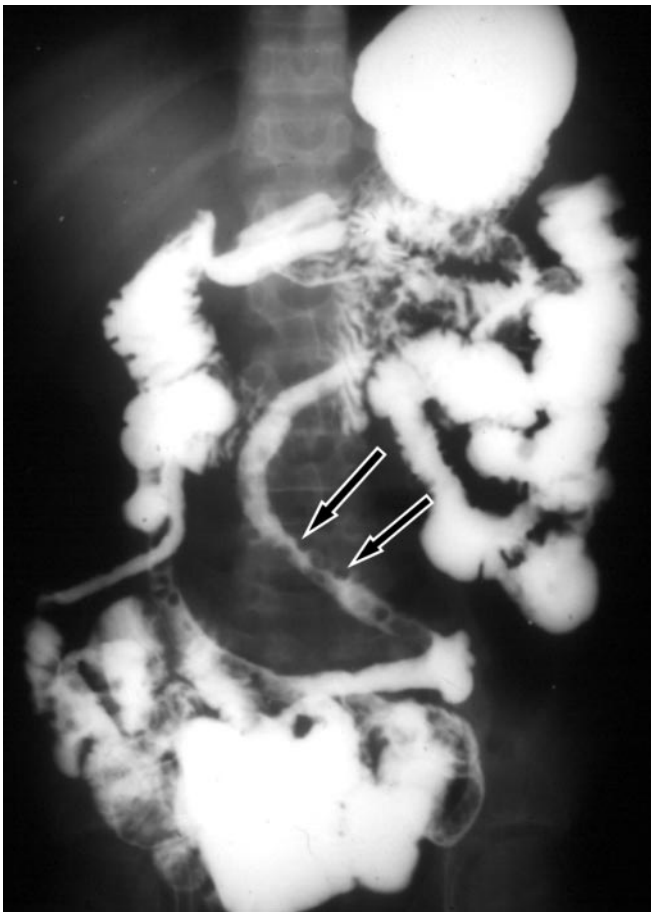

FIGURE 74.1-32 Crohn disease. There are several long strictures of the small bowel with "cobblestoning" and "rose-thorn" ulcers (*arrows*).

linear ulceration and may penetrate the bowel wall to form sinuses or fistulae. As in the small bowel, skip lesions are characteristic, and pseudosacculations may occur.

Intussusception. Intussusception may be ileoileal, ileocolic, or ileoileocolic (in which an ileoileal intussusception then invaginates into the colon). In all of these cases, the intussusceptum will be seen as a filling defect indenting the column of contrast or air (Figure 74.1-33). Following successful reduction, a residual filling defect is often seen in the cecum: this is the edematous ileocecal valve.[2,14]

Meconium Ileus. A contrast enema in meconium ileus will show a microcolon, and contrast refluxing into the terminal ileum will outline inspissated meconium (Figure 74.1-34). The colon is also of very small caliber in distal ileal atresia but tends to be of near-normal caliber in proximal ileal or jejunal atresia owing to a larger quantity of small intestinal secretions reaching the colon in fetal life.[14,48] However, in practice, the colon is seldom examined radiologically.

Meconium Plug. In meconium plug syndrome, there is functional immaturity of the colon. A contrast enema will demonstrate the meconium in a normal-caliber colon. A caliber change at or proximal to the splenic flexure, with the descending colon being narrowed, is known as small left colon syndrome but is a variant of meconium plug syndrome. A therapeutic enema with water-soluble contrast medium will aid the passage of meconium.[14]

FIGURE 74.1-33 Contrast enema in intussusception. The intussusceptum shows as a filling defect (*arrows*).

FIGURE 74.1-34 Contrast enema in meconium ileus. Note meconium within the terminal ileum.

Hirschsprung Disease. The characteristic indicator of Hirschsprung disease is a transitional zone between the proximal, dilated (normal) bowel and the distal, small-caliber aganglionic segment (Figure 74.1-35). Irregular

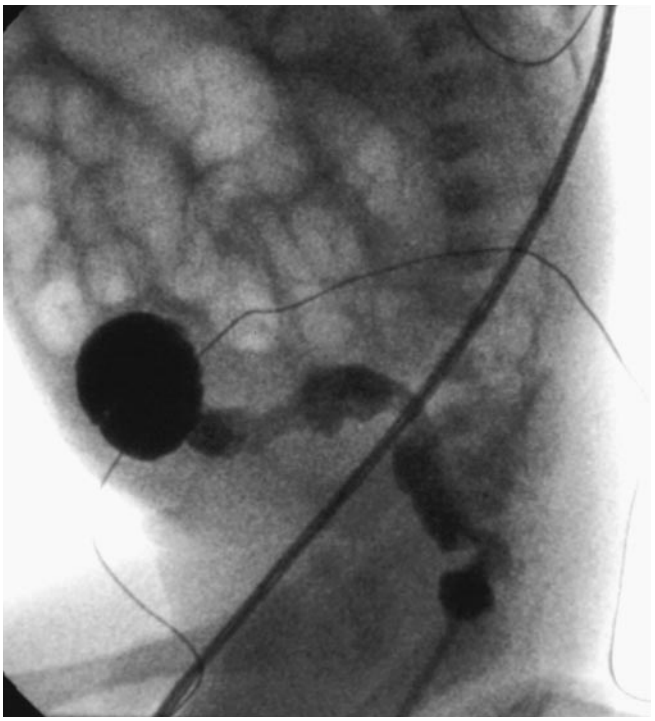

FIGURE 74.1-35 Contrast enema in Hirschsprung disease showing sharp caliber change at the transitional zone.

"sawtooth" contractions in the aganglionic segment may be seen.[14] A rectum that is narrower in caliber than the sigmoid colon is also highly suggestive of the diagnosis, although the value of this sign is debatable.[49] In rare cases of total colonic aganglionosis, there will be no transitional zone.

Ulcerative Colitis. As with Crohn colitis, endoscopy has largely replaced double-contrast barium enema in the diagnosis of ulcerative colitis in children. Barium studies show diffusely granular mucosa in early colitis. Unlike Crohn disease, involvement of the colon is continuous, usually extending proximally from the rectum. As the disease progresses, there is haustral thickening owing to edema, and deepening ulcers result in islands of normal mucosa appearing as "pseudopolyps." In long-standing cases, the colon may appear shortened and tubular—the "lead pipe" colon. Reflux ileitis may result in a patulous terminal ileum.[50]

Polyps. Polyps appear as sessile or pedunculated filling defects on barium studies. The appearances of the polyps in the various polyposis syndromes are nonspecific, but their distribution in the gastrointestinal tract, together with the associated clinical features, may suggest the diagnosis.[51] However, fiberoptic endoscopy is now the preferred diagnostic technique.

2. Cross-Sectional Imaging: Ultrasonography, Computed Tomography, Magnetic Resonance Imaging

Karen Norton, MD
Keith J. Benkov, MD

The subspecialty of pediatric gastroenterology began almost 30 years ago, coinciding with revolutionary technological advances being made in the field of diagnostic imaging. Concurrent with the introduction of ultrasonography (US) in the early 1970s, gastrointestinal endoscopy was introduced. Rapidly following the introduction of US, computed tomography (CT) and then magnetic resonance imaging (MRI) were developed. These advances in imaging, which allow complex images to be stored, manipulated, and retrieved in microseconds, have now become routine radiology procedures rather than what might have been envisioned in science fiction stories 30 years ago. The detail of anatomic information gathered by these radiology examinations often approaches what is depicted at direct surgical exploration or pathology. Pediatric-sized endoscopes have made direct visualization and intervention possible even in very small children. It is now implausible to envision practicing the subspecialty of pediatric gastroenterology without these remarkable complementary technologies.

To successfully practice pediatric gastroenterology requires more than casual familiarity with cross-sectional imaging modalities. Although the clinical gastroenterologist is usually not required to perform or independently interpret these studies, an understanding of the indications, strengths, and limitations of particular investigative studies is extremely useful. In a rapidly evolving field, it is sometimes difficult to know the true benefit of a new technique until years later, when it has been fully applied and compared with other techniques. Especially important is to know when to use these often expensive technologies, which may involve exposure to ionizing radiation, the injection of potentially nephrotoxic contrast agents, and the risks of conscious sedation or general anesthesia. In this regard, there is no substitute for a good history and physical examination, and there is probably no more important a colleague than a trusted pediatric radiologist to help direct the imaging evaluation.

ULTRASONOGRAPHY

In children, US is often the initial choice of radiologic investigation because it does not require ionizing radiation, is not painful, requires little or no preparation, and is a relatively inexpensive examination. In children, especially younger infants, it is ideal because the general lack of internal body fat facilitates imaging. In certain settings, US is superior to other modalities, especially for delineation of cystic lesions. Generally, no sedation is needed, and even with young infants and children, little or no restraint is required.[1]

Technically, US uses sound above the audible range of frequencies of 20 kHz or 20,000 cycles per second. In practice, diagnostic US uses a much higher frequency, from 1 to 20 MHz (a million cycles per second). These sound waves are emitted from a transducer that contains crystals with piezoelectric properties. When the crystals are subjected to an electric current, they emit sound waves at a particular frequency depending on the size of the crystals and the current. Once the sound is emitted, it is directed through the body and is either reflected, refracted, scattered, or absorbed, depending on the properties of the tissues that are encountered, producing the equivalent of a reflected echo. This reflected echo, when returned to the transducer crystal, causes a vibration that generates an interpretable electric pulse. The returning sound beam will have a different speed and intensity from the original, which is referred to as attenuation, which depends on the properties of the encountered tissues.[2] "Real-time" images can be generated if rapid sound emissions are done at a rate of at least 15 image frames per second.[3]

US can also be used to determine blood flow moving through vessels and structures, based on the "Doppler shift principle." Sound reflecting off a moving target will change in frequency, proportional to the speed of the moving target. The returning echo can be detected as audible sound or as a traceable wave pattern depending on velocity. The use of color allows determination of direction of flow, conventionally with red indicating flow toward the transducer and blue indicating flow away from the transducer. Some investigators are using contrast agents such as stabilized intravascular microbubbles to accentuate detection of blood flow, but these techniques are not widely used in clinical practice.[4]

US has limitations that should be addressed and understood. US cannot penetrate air-containing structures well, as in bowel or lungs. Structures underlying bowel gas may

be completely obscured. US has little ability to penetrate bone, other calcified structures, and metal, such as sutures or plates.[5] The images are obtained in small sectors or wedges of information, and depth of penetration is limited, especially in older and larger patients. The spatial relationships and resolution are not as great as in CT or MRI, which sometimes leads nonradiologists to not fully understand or trust and therefore not fully appreciate the anatomic information offered by US.[3]

COMPUTED TOMOGRAPHY

Similar to routine radiographic studies, CT uses electromagnetic radiation to obtain images. A well-collimated beam is passed through the subject and, depending on the characteristics of the tissues and spaces, the x-ray will be subject to differing attenuation, making it possible to reconstruct an image via complex computer programs to create a cross-sectional image. Sophisticated hardware and software advances have enabled finely detailed images to be displayed by a grayscale, with a spectrum from air, seen as black, to water, seen as gray, to bone, seen as white. With use of the newer spiral and helical technology, the image is generated quickly and accurately as the table moves while the scan is being done. Now with the advent of multislice CT, the images can be acquired so quickly that CT "fluoroscopy" to assist biopsies and catheter insertions are possible. Vascular studies can be obtained from a single rapid injection in a matter of seconds. Traditionally, CT images are obtained in the axial plane, but images can be reconstructed in any plane desired at modern workstations after processing.[6]

Before ordering a CT scan, the clinician should be aware of several issues related to the risks versus the benefits of the modality. CT does involve exposure to radiation, raising important safety concerns that should be carefully considered, especially in children. Recent evidence postulating an increased cancer risk in adulthood in children exposed to diagnostic CT[7] has led to a complete revamping of the CT protocols used in pediatric studies to minimize dosage while still delivering high-quality images. Newer multislice CT scanners are now capable of better imaging with less radiation exposure than older machines and are preferable. Motion degrades the images, usually making some form of sedation or even anesthesia necessary in younger children. Intravenous injection of iodinated contrast is useful in most body cases, requiring adequate venous access. Although relatively safe, these agents can be nephrotoxic, and occasional allergic and anaphylactoid reactions are reported. Adequate ingestion of oral contrast, which is difficult to obtain in children who require sedation, increases the accuracy of the study. Young children and sedated subjects cannot maintain rectal contrast. The lack of internal body fat in children often makes interpretation of CT of the abdomen and pelvis challenging. CT is a more expensive test than US. The greatest advantage of CT is the high-resolution images it produces, including the ability to evaluate air-containing structures such as bowel that are relatively deep to the surface and may not be readily palpable or accessible to US.[8]

MAGNETIC RESONANCE IMAGING

This technique is based on the interaction between atomic nuclei of various tissues and radio waves that are directed through the body in a strong magnetic field. How the mobile nuclei are modified is labeled magnetic relaxation times (T_1 and T_2), which can be measured as a change in the electromagnetic field. The hydrogen atom is used for imaging purposes because it is the most abundant nucleus with a strong magnetic signal. A superconductor-type magnet generates the electromagnetic field by use of large coils reduced to near absolute zero to offer no resistance. In the presence of the strong magnetic field, the randomly oriented protons are aligned in the longitudinal axis. When subjected to a radio frequency in a perpendicular transverse axis, the protons are disrupted in their alignment. Once the pulse is discontinued, they will precess until they resume their alignment in the magnetized field, which can be detected as a voltage.[9] The rate of return to the magnetized state is the T_1 relaxation time and the rate of decay of the transverse signal is the T_2 parameter.[10]

Variations can be added to the magnetic field or the radio waves to highlight various features of the scan. The detail afforded by MRI allows precise characterization in different planes. With the injection of materials with distinct spectroscopic qualities, detailed images can be obtained. The most commonly used agent, gadolinium chelate, is useful in evaluation of solid organs, and enhancement characteristics often aid in differential diagnosis. With rapid injection of gadolinium, blood flow through various vessels can be highlighted, producing an angiography-like study.[11]

No ionizing radiation is involved in MRI, and there are no known biologic side effects from this imaging modality, making it excellent for pediatric applications. Images are, however, very affected by movement, often requiring conscious sedation or anesthesia, and, at times, extended breath-holding is needed to optimize certain acquisitions, something many young children cannot do. Even persistalsis from bowel can produce artifacts. Recent advances have reduced the acquisition times for MRI substantially, making MRI a more practical modality in pediatric settings.[12] Finally, MRI examinations are relatively expensive and sometimes less readily available than CT.

NORMAL APPEARANCE AND ANATOMY AS SEEN WITH CROSS-SECTIONAL IMAGING

Some baseline findings need to be appreciated before looking for abnormalities on any of these imaging modalities. Each modality has some advantages when compared with the other modalities, and they are very often complementary.

LIVER

Normal hepatic parenchyma appears homogeneous on US, with relative increased echogenicity compared with the renal cortex and echogenicity similar to that of the spleen. The vessels of the liver are determined by their point of origin and course.[13] Color Doppler US easily separates

vessels, which have slightly echogenic walls, from the biliary tree. On nonenhanced CT, normal liver parenchyma is slightly higher in attenuation than the spleen, with contrasting hypodense vessels. With contrast, the parenchyma enhances uniformly, with vessels that become hyperdense compared with the parenchyma. On MRI, the hepatic parenchyma varies with imaging sequences, with T_1-weighted images showing a higher signal intensity than the spleen and the reverse being true with T_2-weighted images.[14]

On previous classification schemata, the liver was broken down by anatomic lobar divisions; however, a more useful subdivision for the surgeon is based on the vessels that supply the various segments.[15] The right and left hepatic ducts are seen on all cross-sectional imaging studies, anterior to the portal vein bifurcation. The extrahepatic ducts should not measure more than 4 to 7 mm in diameter. In fact, the range within the pediatric population is substantially smaller, with normal ducts usually less than 4 mm.[16] The common bile duct is important to identify and can be seen at the level of the pancreas on MRI or CT. With US or magnetic resonance cholangiopancreatography (MRCP), the entire course of the common duct can be determined, although it is technically often difficult with US owing to overlying bowel gas. The gallbladder is generally pear shaped at the inferior border of the liver and in its normal state is thin walled and enhances after intravenous contrast on CT. On MRI, bile has the same signal as water but may have a higher intensity if it is concentrated in the gallbladder.[17] On heavily T_2-weighted images, the entire biliary tree can be imaged without the use of any contrast agents, producing MRCP of striking detail (Figure 74.2-1).

Spleen

The normal spleen on US shows a homogeneous echogenicity, similar to that of the liver, and lies adjacent to the left hemidiaphragm and stomach. The hilum is generally directed medially, and both the splenic vein and artery are easily seen on US. CT will also show homogeneous density with attenuation equal to or slightly lower than that of the liver. Rapid injection of contrast will show heteregeneous uptake initially as a manifestation of variable flow patterns.[18] On MRI, T_1-weighted images show signals of lower intensity than the liver, and T_2-weighted images will show brighter intensity. Intravenous gadolinium causes a similar enhancement pattern of the spleen, as seen on CT scan.

Pancreas

In children, the entire pancreas is usually not well defined on US because it lies obliquely or transversely in the retroperitoneum and is often obscured in parts by gas in the bowel. The normal pancreas is of uniform, cross-hatched echo-texture and of an echogenicity similar to that of the liver, but it can also be normal and hyperechoic or hypoechoic, especially in children. The normal pancreatic duct, if visualized, is a 2 mm or less tubular structure that runs through the pancreatic body and tail. The common bile duct, as well as either one or two gastroduodenal arteries[19] within the head of the pancreas, can be seen. On CT, the pancreas is better defined, with borders well highlighted when the adjacent bowel is opacified with oral contrast and blood vessels are highlighted by intravenous contrast, especially if there is retroperitoneal fat. The splenic vein and superior mesenteric vein can be seen posterior to the body. The lateral aspect of the head is nestled by the second and third portions of the duodenum, with the third and fourth portions of the duodenum extending inferior to the pancreas. The attenuation of the pancreas on CT is less than that of the liver.[20] On MRI, the pancreas can also be well displayed; however, thin-section CT is usually easier to obtain and requires shorter study times to produce high-resolution images.

Gastrointestinal Tract

The gastrointestinal tract is a hollow tube that is either fluid or air filled, and the gas pattern on plain film often dictates the imaging plan. On US, the mucosa of the bowel will appear as an echogenic interface with the echolucent muscularis. Bowel wall thickening can be appreciated, especially if the bowel is fluid filled. Although, more traditionally, the bowel is studied by upper gastrointestinal (UGI) and small bowel follow-through (SBFT) or by barium enema (BE), the bowel can be well studied by CT after the administration of oral and sometimes intravenous contrast. On CT, bowel wall thickening may be appreciated, and inflamed mucosa will enhance after the administration of intravenous contrast. The lumen can be delineated by oral contrast, but mucosal details are better

FIGURE 74.2-1 Normal coronal magnetic resonance cholangiopancreatogram reveals a normal extrahepatic bile duct (*arrow*).

defined by UGI, SBFT, or BE. Inflammatory changes in the mesentery and associated lymphadenopathy are well displayed. MRI is less useful at present for evaluating the bowel, but newer MRI techniques are being investigated to help better define the bowel.

Congenital Hepatobiliary Anomalies

Anatomic anomalies of the hepatic lobar structure do exist but generally are not of great clinical significance and can be evaluated by CT, US, or MRI. Atresia of a specific lobe of the liver is usually associated with hypertrophy of the remaining lobes and can be an isolated finding or may be associated with other anomalies.[21] Venous anomalies most frequently involve variations in the branching of the portal vein, with the only real clinical significance reserved for the technical aspects that arise during liver transplant. Color Doppler US is probably the best modality for demonstrating most of these vascular variations.[22] Congenital absence of the portal vein, which can also be documented by color Doppler US, is rare and is associated with a multitude of clinical associations, including cardiac defects, extrahepatic biliary atresia, and polysplenia.[23]

Also included under congenital vascular anomalies are vascular malformations, which consist mostly of hemangiomas and, less frequently, arteriovenous malformations. Both can present with high-output heart failure in the newborn period. Infantile hemangiotheliomas and cavernous hemangiomas are both mesenchymal tumors that demonstrate a considerable amount of variability of endothelial proliferation—hence their potential for both growth and involution.[24] Hemangioendotheliomas are the more common vascular liver tumors in infants, almost always presenting before 6 months of age with hepatomegaly and sometimes heart failure, massive bleeding, and uncontrollable coagulopathy. Hemangioendotheliomas can occur as solitary lesions or as multiple hepatic lesions, and probably half are associated with cutaneous hemangiomas.[25–27] Hemangioendotheliomas (Figure 74.2-2) on US are predominantly hypoechoic, whereas cavernous hemangiomas are hyperechoic, with a very high-velocity flow that can be demonstrated by color flow Doppler US.[28] On unenhanced CT scan, hemangioendotheliomas will show calcification in 40%. After the intravenous injection of contrast, both hemangioendotheliomas and hemangiomas classically show peripheral enhancement and delayed enhancement of the central areas (Figure 74.2-3).[29] Infarction can create considerable variations in enhancement patterns. Small lesions demonstrate homogeneous low signal intensity on T_1-weighted MRI, but larger lesions can be more heterogeneous (Figure 74.2-4). A T_2-weighted MRI will show high signal intensity of small lesions and more heterogeneity of large lesions (Figures 74.2-5 and 74.2-6).[30]

Anomalies of gallbladder position and number are more common than total agenesis, hypoplasia, duplication, and left-sided position. Although US is still the modality of choice to screen for biliary anomalies,[31] radionuclide scans and MRI can also be useful.

Choledochal cysts can be diagnosed at any age and are classified by location and shape. The most common are fusiform dilatation of the common duct (type I), but other variants, such as saccular diverticulum, choledochoceles that extend into the wall of the duodenum, and multiple cystic dilatations, as in Caroli disease (Figure 74.2-7), occur.[32] US is the study of choice for suspected cases (Figures 74.2-8 and 74.2-9), with MRCP used for confirmation and pre-preoperative definition, replacing percutaneous transhepatic cholangiography and endoscopic retrograde cholangiography (Figure 74.2-10).[33] The presentation of choledochal cysts during the neonatal period can be confused with biliary atresia, in which a cystic remnant of the atretic biliary system can remain. Choledochal cysts in later childhood can present with significant obstruction, and other causes of biliary dilatation, such as stone, stricture, or tumor, need to be excluded.[34]

US is often the preliminary study done when biliary

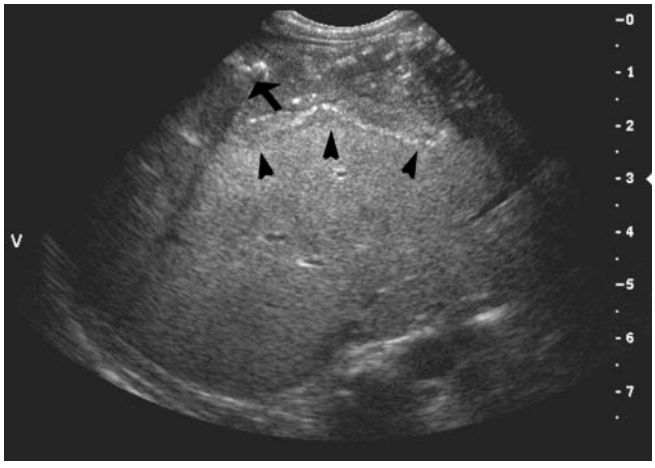

FIGURE 74.2-2 Transverse sonogram of the liver of a newborn infant with a hemangioendothelioma reveals a well-defined hypoechogenic mass with echogenic borders (*arrowheads*). Several echogenic foci with associated shadowing within the mass represent areas of calcification (*arrow*).

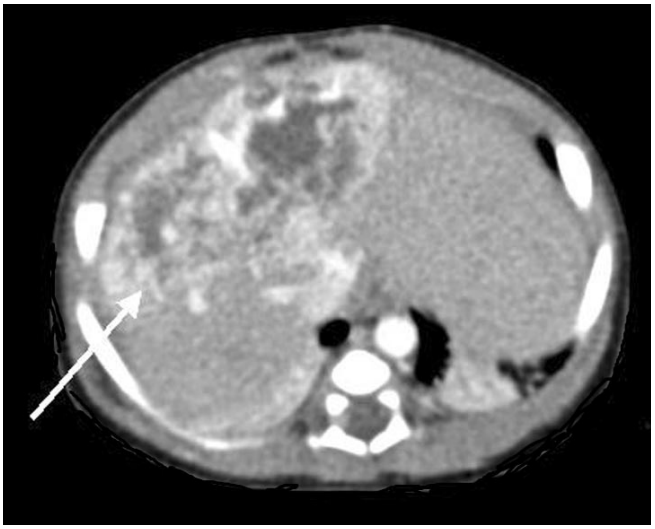

FIGURE 74.2-3 Contrast-enhanced axial computed tomographic scan of an infant with hemangioendothelioma reveals a large mass in the liver with peripheral enhancement (*arrow*).

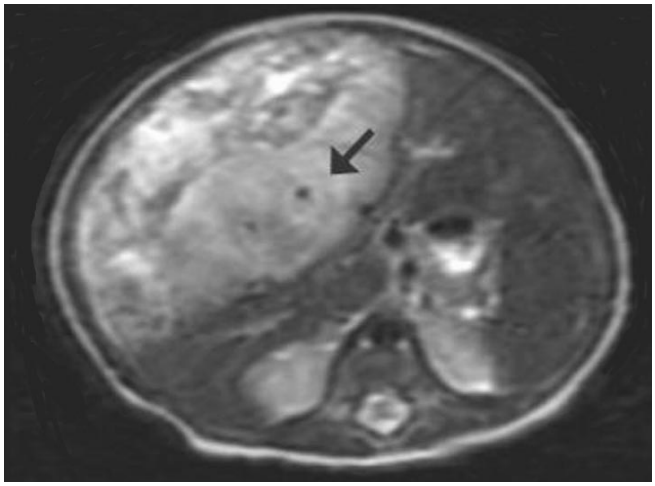

FIGURE 74.2-4 T_2-weighted magnetic resonance image of the infant in Figure 74.2-2 reveals the large, well-defined mass to have variable signal characteristics. Calcification appears as a signal void (*arrow*).

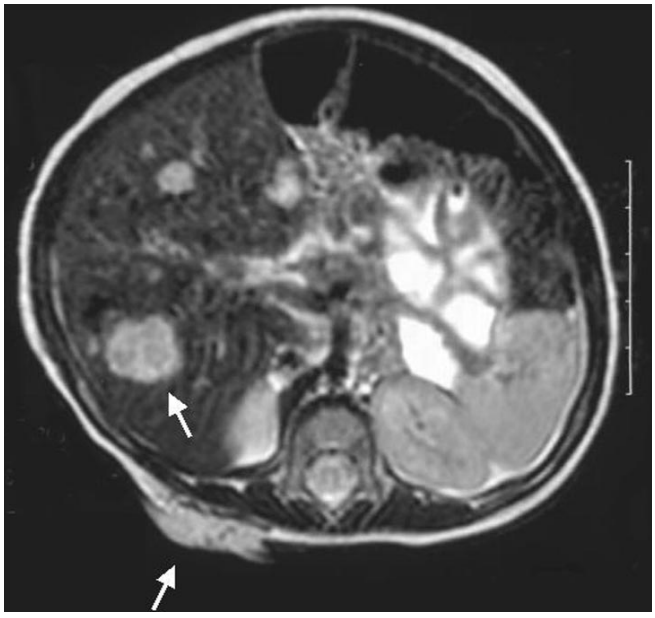

FIGURE 74.2-6 Axial T_2-weighted magnetic resonance image reveals that the lesions are of bright signal intensity (*arrows*).

FIGURE 74.2-8 Transverse sonogram of the liver in an infant with a choledochal cyst reveals significant intrahepatic biliary dilatation, seen anterior to the portal vein (PV).

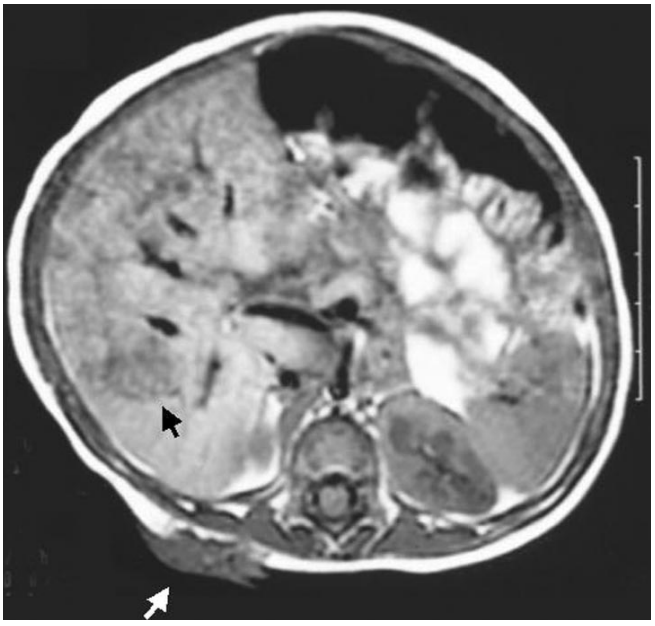

FIGURE 74.2-5 Axial T_1-weighted image of the liver of an infant with disseminated hemangiomas reveals multiple soft tissue masses in the liver (one indicated by a *black arrow*) and a soft tissue mass that arises from the posterior back (*white arrow*).

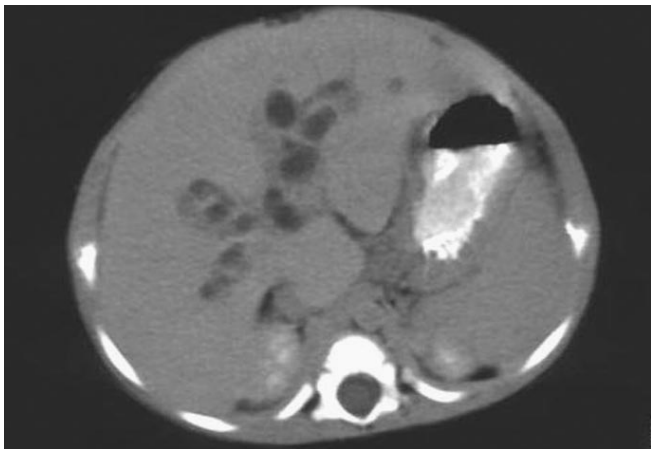

FIGURE 74.2-7 Axial contrast-enhanced computed tomographic scan of the abdomen shows multiple cystic branching structures within the liver in this patient with Caroli disease.

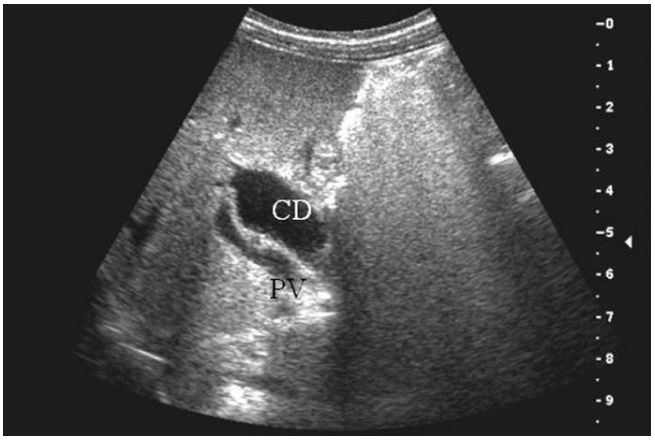

FIGURE 74.2-9 Sagittal sonogram of an infant with cholestasis reveals enlargement of the common duct (CD), consistent with a choledochal abnormality. PV = portal vein.

atresia is suspected; however, the absence of a normal-size gallbladder and failure to delineate the extrahepatic duct on US is suggestive but not conclusive. Documentation of the triangular cord, a periportal band of fibrotic tissue, both on US[35] and more recently on CT,[36] has been shown to correlate well with the documentation of biliary atresia at the time of surgical exploration. There was initial enthusiasm for MRCP for evaluating infants with cholestasis, but MRI is no more sensitive or specific than other modalities, including radionucleotide scanning, with a 75% positive predictive rate and roughly a 90% negative predictive rate[37] for biliary atresia. MRCP (Figure 74.2-11) does have the advantages of not requiring pretreatment and not using ionizing radiation,[38] and it has been shown to be extremely helpful in supporting the diagnosis of biliary atresia in late-presenters, in whom the morbidity and mortality of exploratory laparotomy are especially increased.[37]

Congenital Splenic Anomalies

The shape and position of the spleen can be quite variable and are not of clinical significance. Splenic clefts are common, as is persistent fetal lobulation, and both can occasionally be confused with lacerations.[39] US is generally adequate for most examinations, but CT will yield better images. The orientation of the hilum can be variable, and laxity of the ligamentous attachment can result in a mobile spleen. Occasionally, a "wandering spleen" can be confused for a neoplasm or can result in torsion.[40] Accessory spleens or splenules (Figure 74.2-12) occur in 10% or more of healthy individuals and are typically near the splenic hilum.[39] These are usually at least 2 cm in diameter to be visualized by radionucleotide scanning. Although not clinically significant, accessory spleens can hypertrophy after splenectomy or in patients with splenomegaly (Figure 74.2-13). Primary asplenia is not common and with polysplenia falls into the category of situs anomalies or heterotaxy syndromes (Figure 74.2-14), half of which are associated with cardiac and renal malformations and many with immunodeficiency. Because of the complexity and variability of the heterotaxy syndromes, US, followed by MRI, CT, and sometimes red blood cell–tagged radionuclide scanning, is helpful for full delineation.[41] True congenital splenic cysts are extremely rare, and those less than 5 cm can be managed conservatively.[42]

Pancreas

Most congenital anomalies of the pancreas involve anatomic variations of the ductal system. Numerous series have reported the inadequacies of US and CT and the need for endoscopic retrograde cholangiopancreatography (ERCP) to delineate ductal anatomy. Most recently, MRCP has proved useful in defining pancreatic duct anatomy.[43] Pancreas divisum (Figure 74.2-15) is a common anomaly that arguably may predispose the patient to pancreatitis.[44] Hypoplasia and agenesis of the pancreas have been reported but are extremely rare. Isolated congenital cysts and cystic disease of the pancreas are associated with polycystic disease of the kidneys and liver,[45] as well as the rare case of von Hippel-Lindau disease (Figures 74.2-16 and 74.2-17). Annular pancreas, which typically presents in the newborn period with bilious vomiting, is generally not diagnosed by cross-sectional imaging but rather by UGI series. Variations of annular pancreas have been reported in adults and can be imaged by MRI.

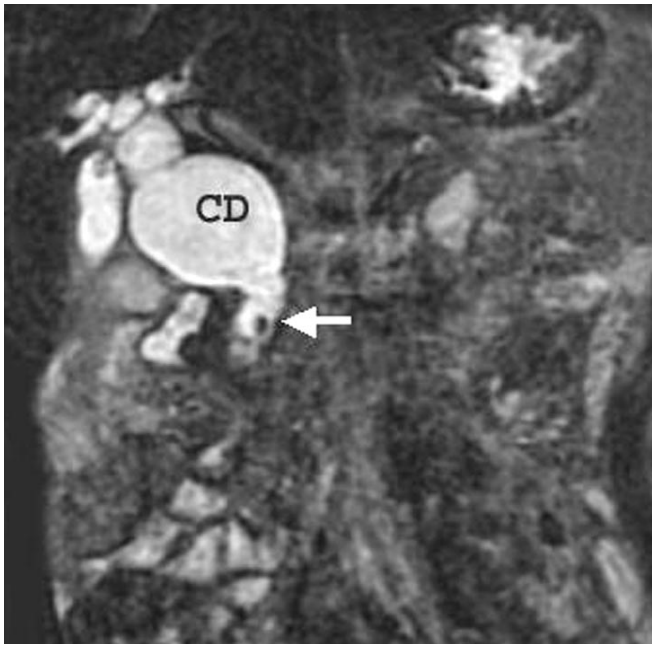

FIGURE 74.2-10 Coronal magnetic resonance cholangiopancreatogram of an infant with jaundice reveals marked enlargement of the extraheptic bile duct consistent with a type I choledochal cyst. A signal void in the distal end was caused by a stone (*arrow*). CD = common duct.

FIGURE 74.2-11 Coronal magnetic resonance cholangiopancreatography failed to reveal the extrahepatic biliary system in this infant evaluated for cholestasis. A chord of tissue was present in the anticipated location (*arrow*). Biliary atresia was confirmed at laparotomy.

FIGURE 74.2-12 Axial contrast-enhanced computed tomographic scan of the abdomen reveals a small, well-defined mass (*arrow*) in the splenic hilum, of identical attenuation to normal spleen.

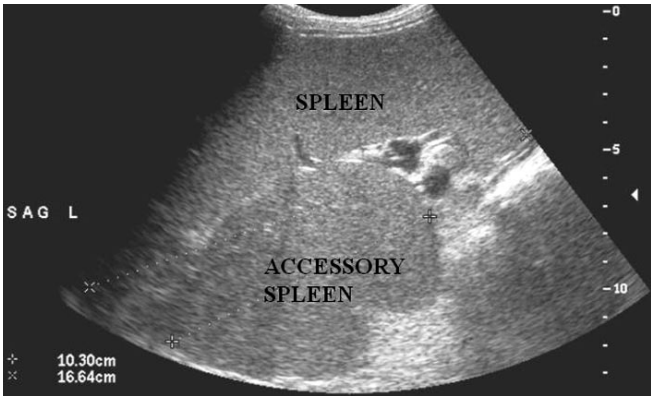

FIGURE 74.2-13 Sagittal sonogram of the left upper quadrant of a patient with Jeune syndrome, a rare cause of hepatic fibrosis, reveals an enlarged spleen. A large mass of identical echogenicity in the splenic hilum is consistent with an accessory spleen.

FIGURE 74.2-14 Axial contrast-enhanced computed tomographic scan of the abdomen reveals several small spleens (s) on the right, inferior to the liver (L) in this patient with heterotaxy syndrome.

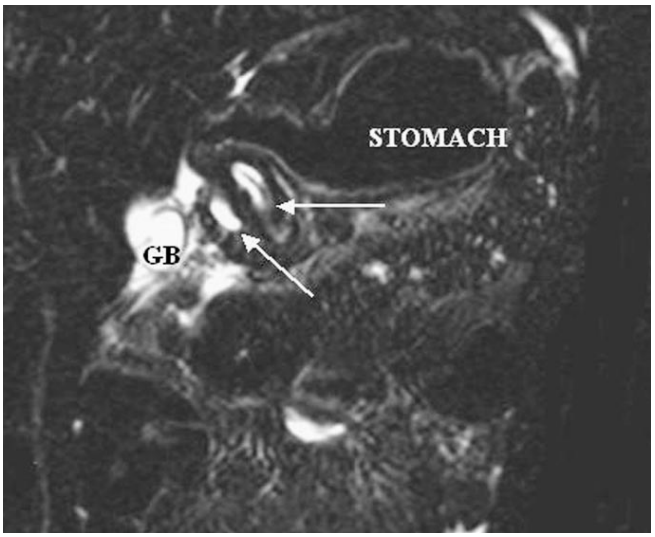

FIGURE 74.2-15 Coronal magnetic resonance cholangiopancreatography was performed in this 5-year-old female with recurrent pancreatitis. A dual drainage (*arrows*) system was seen in the head of the pancreas consistent with pancreas divisum. GB = gallbladder.

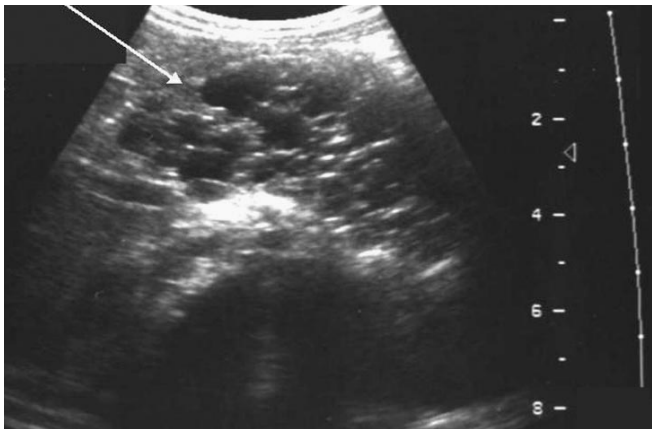

FIGURE 74.2-16 Transverse sonogram of a 7-month-old male with a palpable mass reveals that the pancreas is replaced by multiple cysts (*arrow*).

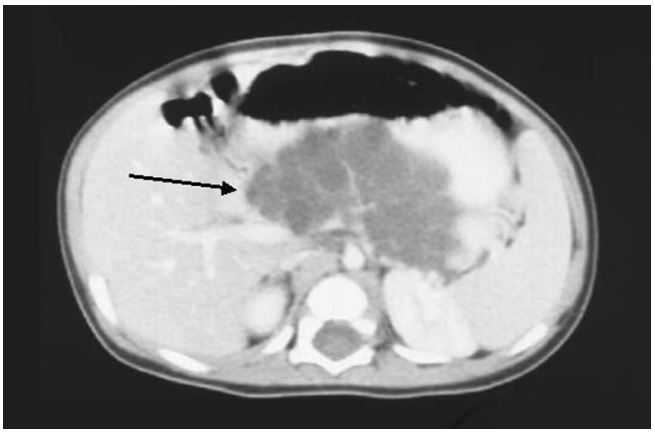

FIGURE 74.2-17 Follow-up contrast-enhanced axial computed tomographic scan of a 7-month-old boy confirms that the pancreas is replaced by multiple cysts (*arrow*) and no other cysts were present in other intra-abdominal organs. A diagnosis of von Hippple-Lindau disease was subsequently made.

Gastrointestinal Tract

Numerous congenital malformations of the esophagus and the remaining gastrointestinal tract exist, including esophageal duplication cysts, which may be detected on CT (Figure 74.2-18).[46] Vascular rings and impinging vessels, traditionally suggested by UGI series and confirmed by angiography, can now be well demonstrated by either CT or MRI (Figure 74.2-19).[47] Although antral webs and pyloric atresia can occasionally be seen on US as an intraluminal diaphragm of linear echo density within a fluid-filled cavity,[48] UGI or endoscopy remains the mainstay of diagnosis. High obstructions of the gastrointestinal tract, such as duodenal atresia, are readily suggested by a fluid-filled "double bubble" on prenatal US but are typically confirmed in the newborn period by UGI and not cross-sectional imaging. Low obstruction in the neonatal period may be caused by intrauterine perforation, resulting in meconium peritonitis, which calcifies and is evident on plain film. In this clinical situation, US is extremely useful in distinguishing active peritonitis and surgical emergency from a healed perforation by the detection of intra-abdominal fluid. Absence of fluid suggests recannalization and resolution in utero, allowing these infants to be fed and clinically monitored. Encysted collections of meconium will show a heterogeneous appearance on US.[49] Duplication and intestinal cysts, unless detected on prenatal US, generally present later in childhood. Duplication cysts most commonly occur in the distal ileum and esophagus, usually do not communicate with the intestinal lumen, and may or may not cause obstruction. US can be useful to define these fluid-filled lesions when intra-abdominal, and the presence of a double-walled sign helps distinguish gastrointestinal cysts from single-walled simple mesenteric cysts (Figure 74.2-20).[50] MRCP is helpful in distinguishing gastric duplication cysts from cysts of biliary origin (Figure 74.2-21).

Although hypertrophic pyloric stenosis does not usually present at birth but typically after the first month of

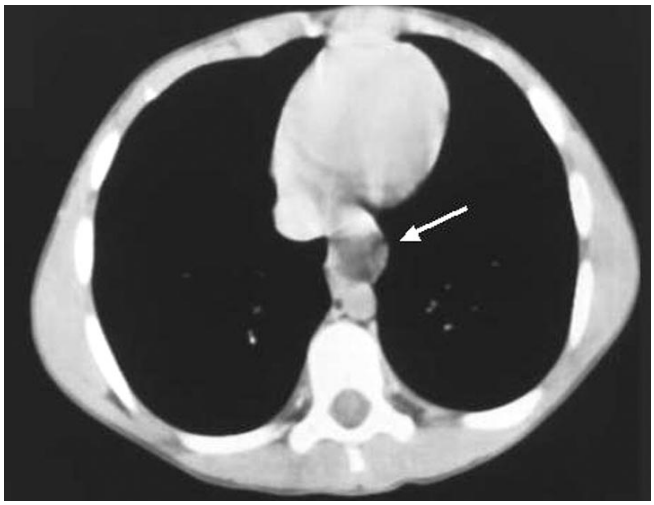

FIGURE 74.2-18 Axial computed tomographic scan of the lower chest of a 5-year-old boy with a history of dysphasia reveals a cystic mass adjacent to the esophagus (*arrow*), consistent with a duplication.

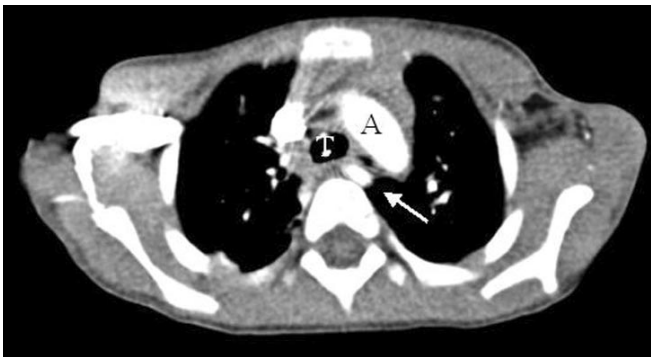

FIGURE 74.2-19 Contrast-enhanced multislice computed tomographic angiography demonstrating an aberrant subclavian artery.

FIGURE 74.2-20 Sonogram of the right lower quadrant was performed on a newborn infant because of an abnormal prenatal sonogram. The presence of a cystic mass (*arrow*) was confirmed. The double wall suggests that it arises from the bowel as opposed to a simple cyst of another origin, such as the ovary or mesentery.

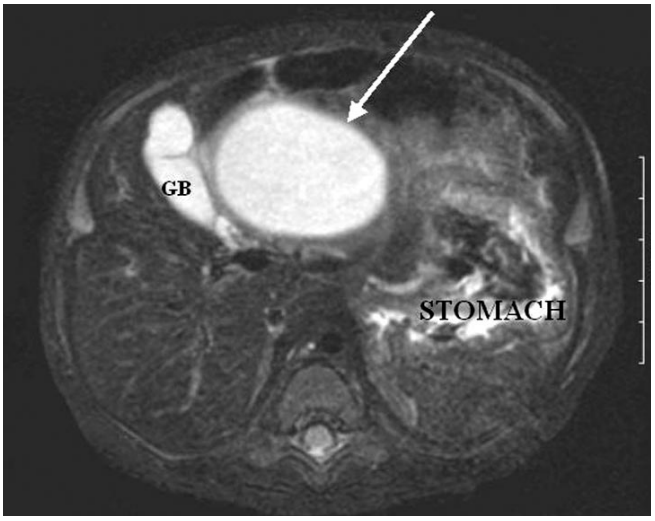

FIGURE 74.2-21 Axial magnetic resonance cholangiopancreatogram of a 4-month-old girl with a history of vomiting and cystic mass seen on ultrasonography demonstrates that the mass (*arrow*) arises in close proximity to the lesser curvature of the stomach and appeared separate from the gallbladder (GB), biliary system, and liver. A gastric duplication cyst was successfully resected.

life, it can be classified under congenital lesions of the stomach. The condition results from hypertrophy of the circular muscle of the pylorus, causing both thickening and elongating. The typical finding on physical examination is the palpated "olive" of hypertrophied muscle. When this cannot be felt, US is the study of choice to demonstrate the increased thickness and the increased length of the pyloric muscle (Figure 74.2-22).[51]

CROSS-SECTIONAL IMAGING IN ABDOMINAL TRAUMA

In pediatric settings, there is much less experience with penetrating injuries than with blunt trauma. With the increasing tendency toward conservative, nonoperative management of abdominal trauma, precise imaging of the abdomen is of the utmost importance. The liver is still the most frequently injured organ; however, in 20% of cases, multiple organs are involved. In general, contrast-enhanced CT is the recommended modality for diagnosing traumatic injury, with US reserved for serial follow-up examinations.[52] The use of imaging is both to detect specific injuries such as lacerations and subcapsular hematomas and to search for peritoneal fluid that might indicate impending clinical compromise.

Parenchymal disruption to the liver can vary from small lacerations to extensive fractures with significant extravasation of blood. Lacerations can be simple or complex and on CT (Figure 74.2-23) appear hypodense in either a linear, round, or stellate shape. Subscapular hematomas (Figure 74.2-24) vary in density according to the amount of blood loss and hematocrit, and tears in the capsule will allow blood to fill the peritoneal spaces. Traumatic injuries to the spleen (Figure 74.2-25) are very

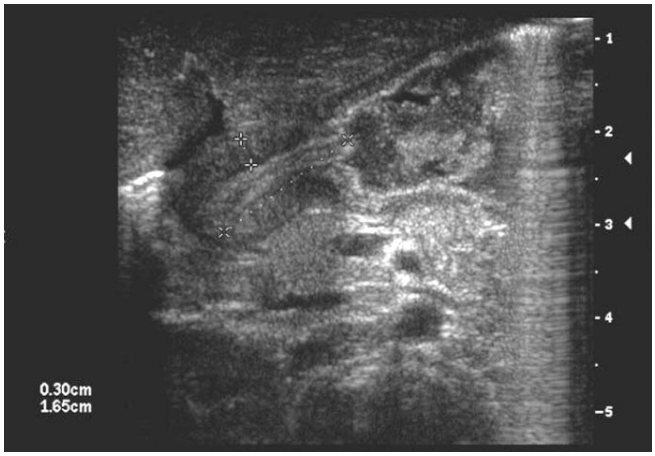

FIGURE 74.2-22 Hypertrophic pyloric stenosis. Transverse sonogram of the abdomen in an infant with nonbilious vomiting reveals both elongation of the pyloric channel (x) and thickening of the muscle (+), consistent with the diagnosis of hypertrophic pyloric stenosis.

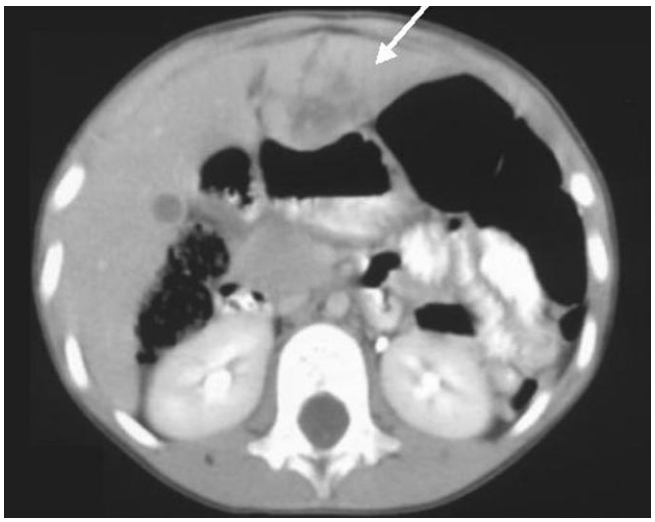

FIGURE 74.2-23 Axial contrast-enhanced computed tomographic scan of the abdomen was performed in this 11-year-old boy after a fall. Laceration of the left lobe of the liver is evident (*arrow*).

FIGURE 74.2-24 Contrast-enhanced computed tomographic scan of the liver of a 10 year old after a sledding accident reveals a large subcapsular hematoma peripheral to a lacerated liver (*arrow*).

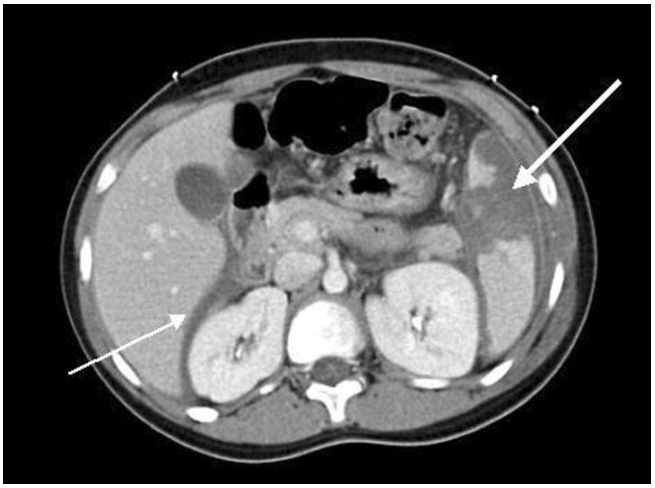

FIGURE 74.2-25 Contrast-enhanced axial computed tomographic scan performed after a motor vehicle accident on this 11-year-old boy reveals a fractured spleen (*thick arrow*) and free ascites, presumably blood, in Morrison pouch (*thin arrow*).

similar in CT appearance and are easily missed on initial US because acute injuries may appear isoechoic. US should be reserved for serial examinations of known injuries (Figure 74.2-26).

Much debate has surrounded the management of patients with blunt abdominal trauma. Most clinicians agree that in clinical settings in which surgical intervention is not necessary, there is little need for follow-up CT scans.[53] US is usually adequate for following the evolution from poorly defined and iso- or hyperechoic to less echogenic and smaller because liquefaction and organization occur over time.[54] Complications, such as the formation of cysts, bile lakes, infarctions, and calcifications, can also be determined by US[55] but are best defined by CT with contrast.

Contrast-enhanced multidetector CT angiography[56] has largely replaced angiography in the screening for arterial vascular injury, and interventional angiography with embolization has reduced the need for surgery in a significant number of cases.[57] Contrast-enhanced multidetector CT can be very useful in determining active hemorrhage but is inadequate in diagnosing disruption of the bile ducts, whereas radionucleotide scanning is useful in diagnosing suspected bile leaks.[58]

CT is the modality of choice for detecting trauma to the pancreas, which can be manifested by enlargement, edema, or complete transection (Figure 74.2-27), as well as pseudocyst formation. US is useful to follow pseudocysts, but pancreatic duct injury is best seen on MRCP.[59]

Hollow viscus gastrointestinal tract, namely the stomach and small and large intestine, is also subject to blunt trauma. CT is able to detect bowel and mesenteric injuries in greater than 90% of cases but cannot necessarily differentiate the need for surgical intervention.[60] Free air from perforation is readily identified on CT. Bowel wall hematomas are sometimes more readily seen on UGI and SBFT, and water-soluble studies should be obtained if clinically suspect.[61] Focused abdominal US for trauma has been advocated, but the high false-negative rate supports the use of CT for all significant injuries.[62]

TUMORS

Approximately 5% of all intra-abdominal masses, benign and malignant, occur in the liver, and of all pediatric malignancies, almost 2% are primary hepatic.[15] US is the preferred initial examination for lesions that are either purely cystic or typical for benign hemangiomata, seen as small, well-defined, echogenic masses. Serial US is recommended to follow these benign findings. Contrast-enhanced CT and MRI both provide further definition of all other liver masses. CT-guided biopsies may be used for diagnosis.[62,63]

Malignant Hepatic Tumors

Hepatoblastoma is the most common primary malignancy of the gastrointestinal tract in children and is the third most common abdominal malignancy after Wilms tumor and neuroblastoma.[15] Hepatoblastoma usually presents at a median of 1 year of age as a painless, solitary lesion, but it may be multifocal. Serum α-fetoprotein is elevated in 90% of patients, and metastasis occurs in up to 20%. Plain films will show calcifications in up to 55%. On US, there is usually a large, well-outlined, predominantly echogenic mass. CT will show any calcifications present in the mass well, and with intravenous contrast, there will be heterogeneous enhancement, usually related to hemorrhage and/or necrosis within the tumor. MRI also reveals a solid mass that typically enhances irregularly after the administration of gadolinium (Figures 74.2-28 and 74.2-29). Calcifications are not well seen on MRI but rather appear as signal voids.[64]

Hepatocellular carcinoma (HCC) (Figure 74.2-30) is more common in older children and is typically associated with some progressive, preexisting liver disease, such as chronic hepatitis, tyrosinemia, or glycogen storage disease. HCC is more often multifocal and infiltrative. In the setting of end-stage liver disease, it can be difficult to distinguish from diseased parenchyma on all imaging modalities. Small lesions are typically hyperechoic on US, whereas larger lesions are generally mixed. Color Doppler US is useful to demonstrate low-resistance tumor flow, as

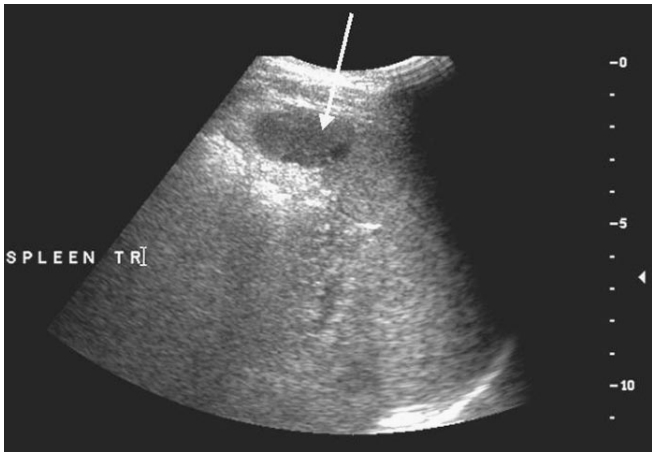

FIGURE 74.2-26 Transverse ultrasonography was used to follow the fractured spleen serially. Six months after the initial trauma, a hypoechoic area was still visualized (*arrow*) consistent with an organizing hematoma.

FIGURE 74.2-27 Contrast-enhanced axial computed tomographic scan of a 10-year-old boy who was struck by an automobile reveals a complete transection of the pancreas (*arrow*).

well as thrombosis of the adjacent veins by tumor extension if present.[65,66] Nonenhanced CT will show poorly defined masses, but after the intravenous administration of contrast, HCC usually demonstrates intense enhancement secondary to its hypervascular nature. Calcifications are unusual.[67] HCC is typically of low signal intensity on T_1-weighted MRI and hyperintense on T_2-weighted imaging. Gadolinium-enhanced imaging demonstrates a hypervascular tumor, similar to a contrast-enhanced CT scan.[68,69]

Fibrolamellar carcinoma is a very rare hepatic neoplasm but is often discussed in the differential diagnosis of HCC, despite very different features and presentation. In contrast to HCC, patients with fibrolamellar carcinoma are usually symptomatic, have normal serum α-fetoprotein, do not have predisposing liver disease, and carry a much poorer prognosis.[70] The tumors are usually solitary and lobulated, with a distinguishing central fibrous scar that is typically hyperechoic on US and at times calcified. On nonenhanced CT, the lesion, and especially the central scar, is well demarcated and of low attenuation relative to the surrounding normal liver. With the administration of intravenous contrast, the entire tumor, but not the central scar, will enhance. On MRI, the lesion will appear of low signal intensity on T_1-weighted images and of high signal intensity on T_2-weighted images, with failure of the central scar to enhance after the injection of gadolinium (Figure 74.2-31).[71] The presence of a central scar, although help-

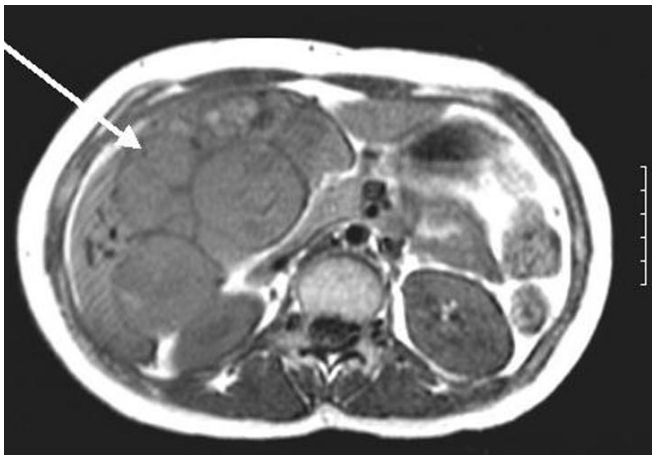

FIGURE 74.2-28 Axial T_1-weighted magnetic resonance image of an 11-year-old girl with a firm liver reveals a multilobulated solid mass within the liver (*arrow*), which was subsequently proven to be a hepatoblastoma.

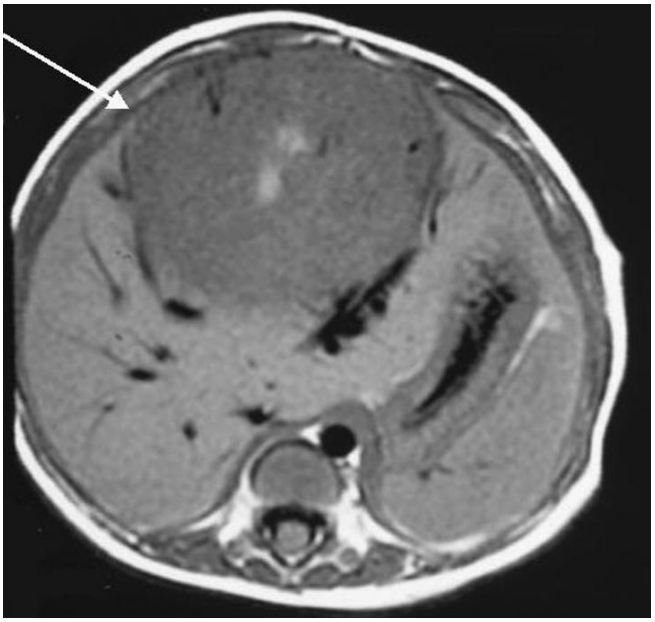

FIGURE 74.2-29 T_1-weighted axial magnetic resonance image of the abdomen of an infant reveals a large, well-defined mass (*arrow*) with a central area of high signal, which was proven to represent a hepatoblastoma with central hemorrhage.

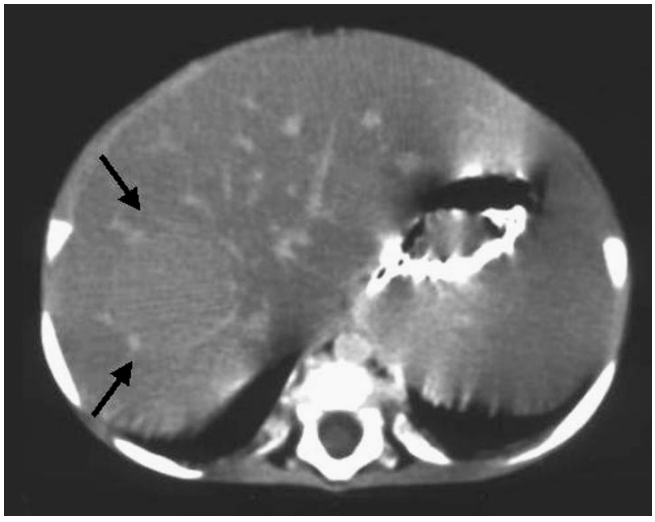

FIGURE 74.2-30 Axial contrast-enhanced computed tomographic scan of the abdomen of a 12-year-old girl who was hepatitis B positive reveals a well-defined mass in the posterior right lobe (*arrows*). Biopsy revealed hepatocellular carcinoma.

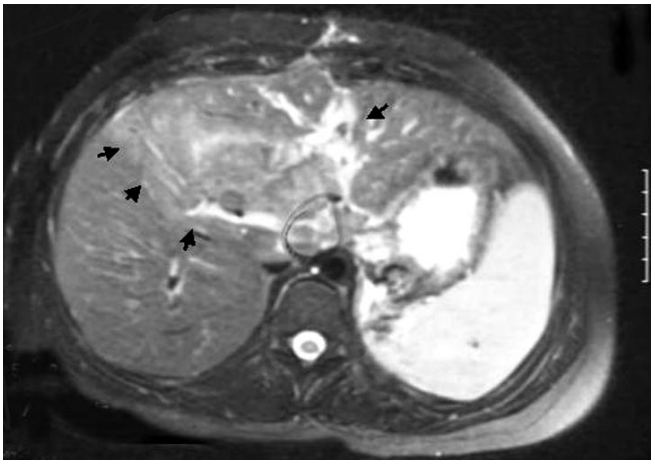

FIGURE 74.2-31 Axial T_2-weighted magnetic resonance image of a 16-year-old girl with a firm liver mass reveals a poorly defined mass (*arrows*) with a large central scar of increased signal after the administration of gadolinium. The patient underwent a computed tomography–guided biopsy that confirmed fibrolamellar carcinoma. Enhancement of the central scar is more typical for focal nodular hyperplasia.

ful, is not diagnostic because it can also be seen in focal nodular hyperplasia (FNH) and giant hemangiomas.

The fourth most common pediatric hepatic tumor is the undifferentiated embryonal sarcoma, which may be difficult to differentiate from a mesenchymal hamartoma. Unlike the latter, embryonal sarcoma often presents with symptoms of pain or mass. On US, it is usually solitary and echogenic, with small anechoic areas that probably represent cystic necrosis.[72] Nonenhanced CT shows a well-demarcated, low-attenuation mass. On contrast-enhanced CT, septations become evident. The lesion tends to be of low signal intensity on both T_1- and T_2-weighted MRIs, with enhancement of the tumor contrasting with low signal of the septa[73] after gadolinium administration.

As in adults, tumors of the biliary tree are much less common than hepatic tumors, and the prognosis is much worse. Embryonal rhabdomyosarcoma is probably the only one in this category that is seen at all in children, and it usually presents with jaundice. US will show biliary obstruction as well as an inhomogeneous echogenic mass, typically in the porta hepatis. CT shows a low-attenuation mass with some enhancement with contrast, and MRCP will show irregular, berry-like filling defects within the biliary system.[74]

Secondary malignant tumors of the liver occur, most commonly from neuroblastoma, Wilms tumor, lymphoma (Figure 74.2-32), and leukemia. All can be diffuse or focal. Immunosuppressed patients can develop post-transplant lymphoproliferative disease (PTLD) with various lesions that range from polyclonal B-cell hyperplasia to malignant lymphoma. Hepatic metastases from other tumors occur rather late in the disease process and carry a poor prognosis. The value of US in detecting lesions depends on the primary tumor and the pattern of metastasis, and even the presence of hepatomegaly is not useful.[75] CT with contrast can be more useful but may require dual-phase arterial and venous scanning for full evaluation. MRI with and without gadolinium is also sensitive for detection of focal liver lesions.

Benign Hepatic Tumors

FNH is an uncommon epithelial lesion in childhood, more often seen in middle-aged women. In children, it is usually an incidental finding, as a solitary lesion of less than 5 cm in size, without internal hemorrhage or necrosis. The distinguishing feature is a central fibrous scar, which is vascular and extends outward into fibrous septa. On US, FNH is a well-demarcated, either iso- or hyperechoic lesion, with a central scar demonstrated in 20% of cases. Associated calcifications are rare enough to suggest another pathology.[76] On nonenhanced CT, the lesion appears as a hypo- or isodense lesion that enhances after the administration of contrast but becomes isodense on delayed scans. The central scar in FNH will enhance in 70% of cases, helping to distinguish FNH from fibrolamellar carcinoma, in which the scar typically does not enhance. On T_1-weighted MRIs, FNH appears as a lesion of decreased or isointensity, and on T_2-weighted images, the signal intensity increases. After the administration of gadolinium, over 80% of cases will show enhancement of the central scar,[48] again distinguishing FNH from fibrolamellar carcinoma (Figures 74.2-33 and 74.2-34).

Hepatocellular adenoma is a rare epithelial tumor with an increasing incidence secondary to oral contraceptive and androgen use. Hepatocellular adenomas are also reported in association with glycogen storage disease type Ia and diabetes. In 80% of cases, hepatocellular adenoma is a solitary, well-circumscribed, and encapsulated mass. The US appearance can be variable, depending on the presence of lipid or internal hemorrhage.[77] On nonenhanced CT, the lesions are generally of decreased attenuation, with 50% containing calcifications (Figure 74.2-35). After the injection of intravenous contrast, feeding vessels may be identified.[78] The lesions have a variable appearance on MRI. Gadolinium is useful to identify feeding vessels.[79] Serial US

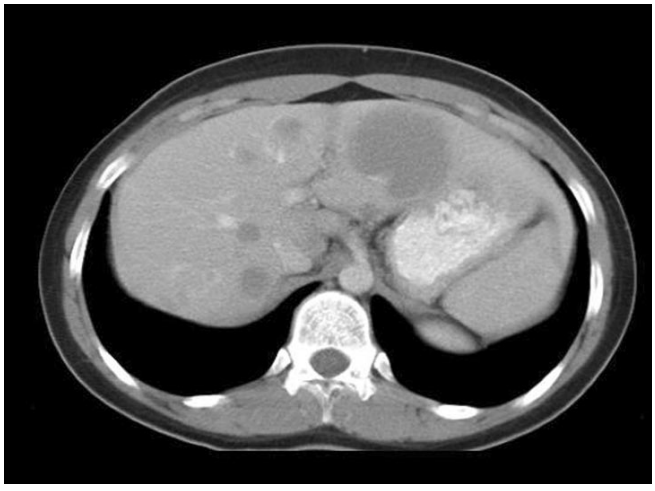

FIGURE 74.2-32 Axial contrast-enhanced computed tomographic scan of the abdomen of an 18-year-old female patient with night sweats reveals multiple low-attenuation masses within the liver. Bone marrow biopsy was consistent with B-cell lymphoma.

FIGURE 74.2-33 Axial magnetic resonance image of a 14-year-old asymptomatic girl followed for a liver mass discovered incidentally during renal ultrasonography shows a well-defined low signal lesion (*arrow*) with a central scar. Differential diagnosis was fibrolamellar carcinoma versus focal nodular hyperplasia.

examinations, in conjunction with monitoring the serum α-fetoprotein level, are recommended to screen for malignant degeneration, seen as sudden growth, necrosis, or a change to a heterogeneous appearance.[80]

Mesenchymal hamartomas, like most hamartomas, should probably be considered as developmental anomalies rather than true neoplasms. They contain gelatinous serous fluid in cystic spaces, intermixed with biliary ductal and connective tissue. On US, mesenchymal hamartomas are predominantly cystic, with multiple echogenic septa (Figure 74.2-36). Their appearance is similar on CT scan (Figure 74.2-37) and MRI (Figure 74.2-38).[81] Occasionally, mesenchymal hamartomas present as purely cystic lesions (Figure 74.2-39). Serial US examinations aid in distinguishing simple liver cysts (Figures 74.2-40 and 74.2-41) from cystic hamartoma; the latter tend to grow and change in appearance, and may develop more solid components with time.[82]

Related and more common entities are mesenchymal tumors, which include hemangiomas, hemangioendotheliomas, and lipomas. The first two have been discussed in part above. Cavernous hemangiomas are more commonly seen in adults than in children. Lipomas, benign masses of mature adipose tissue, are rarely seen in children.

Splenic Tumors

Splenic tumors are in general rare and can be divided between cystic lesions and solid neoplasia. Cysts are classified as true cysts, pseudocysts, and parasitic cysts. True cysts (Figures 74.2-42 and 74.2-43) have an epithelial lin-

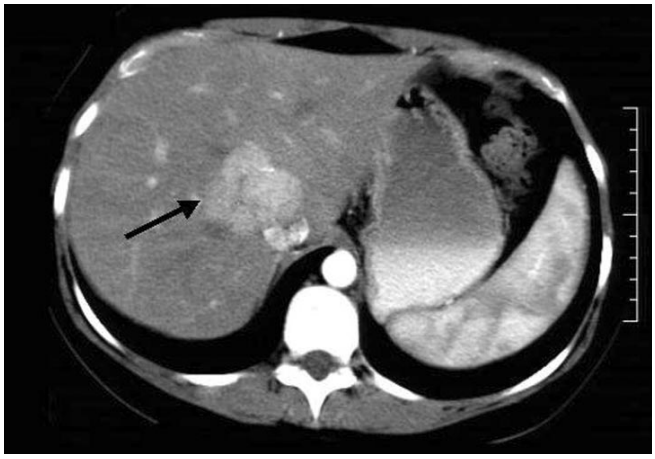

FIGURE 74.2-34 After the intravenous administration of gadolinium, there is intense enhancement of the mass (*arrow*) but not the central scar, a finding suggestive of fibrolamellar carcinoma rather than focal nodular hyperplasia. α-Fetoprotein remained normal, and the mass has remained stable in size for 5 years, findings more suggestive of focal nodular hyperplasia.

FIGURE 74.2-36 Sonogram of the liver of a newborn with an enlarged liver reveals a complex cyst within the liver, containing multiple septations. It was resected, and histopathology revealed a cystic hamartoma.

FIGURE 74.2-35 Non–contrast-enhanced computed tomographic scan of a 10-year-old girl with type IV glycogen storage disease reveals a large low-attenuation mass within the liver. A central calcification (*arrow*) was present. It was resected, and the diagnosis of giant adenoma was made.

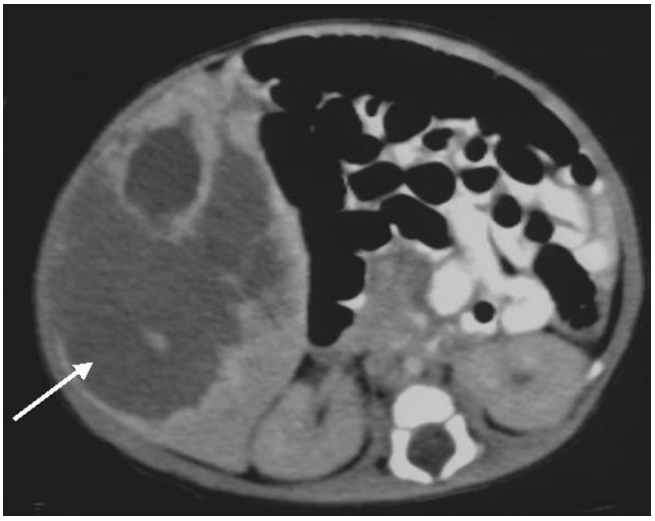

FIGURE 74.2-37 Contrast-enhanced computed tomographic scan of the liver demonstrates that a large portion of the liver has been replaced by cystic and solid tumor. Peripheral enhancement was seen. The patient underwent a three-quadrant resection for this hamartoma. The arrow demonstrates the cystic hamartoma within normal liver parenchyma.

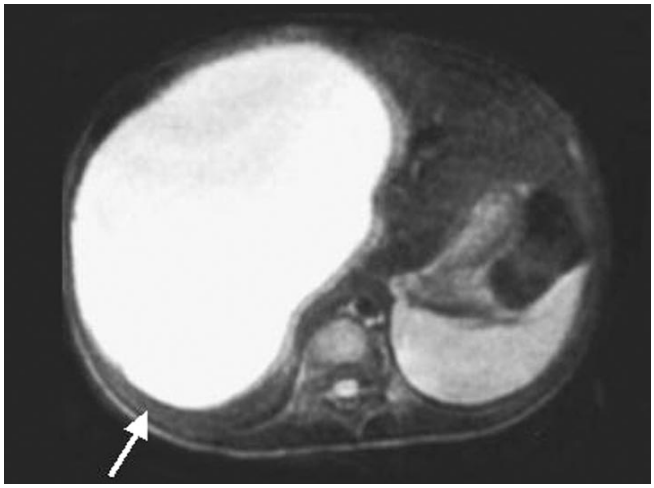

FIGURE 74.2-38 T_2-weighted axial magnetic resonance image of the abdomen of this infant with an enlarged liver reveals a large cystic mass (*arrow*). It was unroofed, but pathology was consistent with a cystic hamartoma rather than a simple liver cyst. It regrew with more solid components, and the patient underwent a successful wide resection of this tumor.

FIGURE 74.2-39 Axial contrast-enhanced computed tomographic scan of the abdomen of a 5 year old with right upper quadrant pain reveals a multilobulated cystic mass within the liver, which was subsequently proven to be a mesenchymal hamartoma.

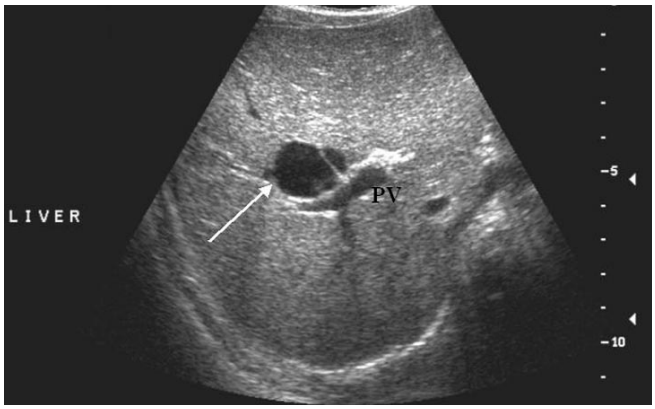

FIGURE 74.2-40 Transverse sonogram of the liver of an 8-month-old girl shows a multilobulated cyst within the liver above the portal vein (PV).

FIGURE 74.2-41 Follow-up coronal magnetic resonance cholangiopancreatogram confirms that the cysts (long *arrow*) are within the liver and separate from the biliary system. The normal extrahepatic duct is demarcated by the *short arrow*. A portion of the gallbladder (GB) is also seen.

ing and are sometimes termed congenital epidermoids (Figure 74.2-44). They may contain brightly reflective echoes within them from floating crystals. Pseudocysts, which contain no epithelial lining, are believed to be secondary to infection, trauma, or infarction and cannot be distinguished from true cysts radiologically. Some neoplasms, such as lymphangioma, hemangioma, and hamartoma, may appear largely cystic on US. Septations and rim calcifications may be present.[83] Hemorrhage or protein content can increase the attenuation on CT. MRI will also demonstrate true solid lesions (Figure 74.2-45).

Splenic involvement by lymphoma and leukemia presents in several ways. On US, homogeneous enlargement with normal echogenicity, solitary or multifocal hypoechoic lesions, or diffuse infiltration with heterogeneous echogenicity can be seen. CT and MRI demonstrate similar findings, although MRI may be less useful because lymphomatous tissue can have signal intensity similar to that of normal splenic tissue.[55]

Pancreatic Tumors

Pancreatic tumors are a very small percentage of pediatric intra-abdominal tumors and usually present with either a mass, abdominal distention, or a variety of endocrine abnormalities. Atypically, they present with the more usual adult presentation of bowel obstruction, weight loss, or jaundice.[84] These tumors can be classified into nonfunc-

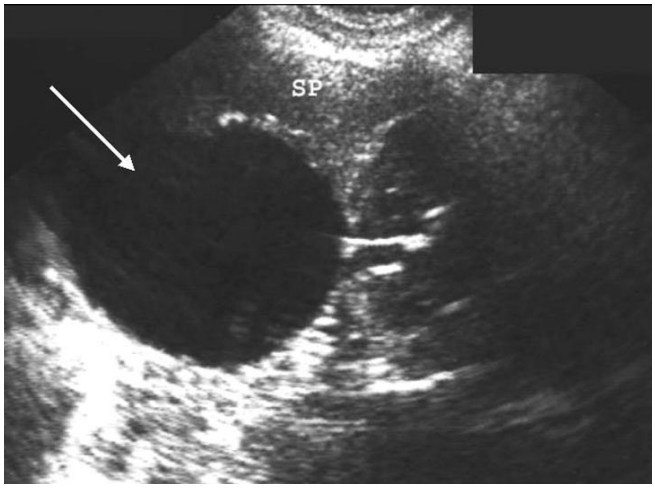

FIGURE 74.2-42 Sagittal sonogram of the left upper quadrant reveals a simple cyst (*arrow*) arising from the spleen (SP).

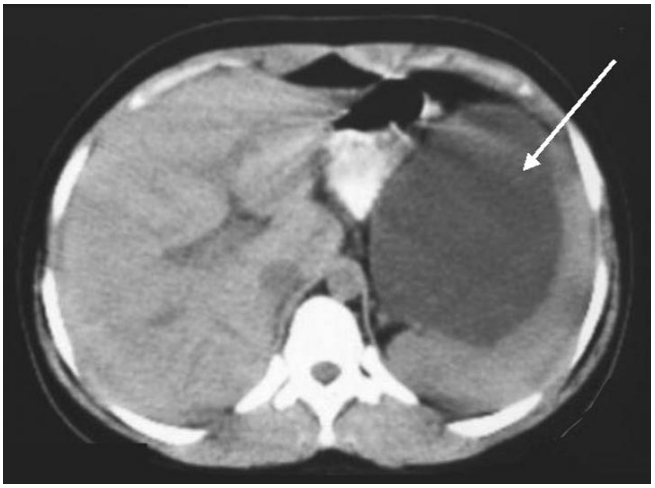

FIGURE 74.2-43 Non–contrast enhanced computed tomographic scan demonstrates a large cyst arising from the spleen (*arrow*).

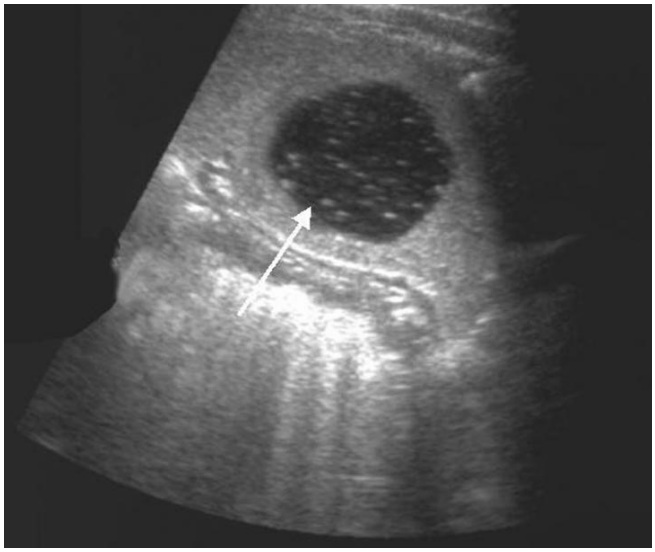

FIGURE 74.2-44 Sagittal sonogram of the spleen reveals a central cyst with particular echoes dispersed throughout. This is a typical appearance for an epidermoid cyst (*arrow*).

FIGURE 74.2-45 Axial T_2-weighted magnetic resonance image of the abdomen reveals a solid mass with a central scar arising from the spleen, which was subsequently proven to be a hamartoma (*arrow*).

tioning and functioning tumors, as well as malignant or benign tumors.[85] Pancreatoblastomas usually occur before 8 years of age as large, well-defined masses, with both cystic and solid components arising from the body or tail. Although pancreatoblastomas can be seen on US, CT is better at fully defining these tumors and demonstrating any associated calcifications.[86] Solid and papillary epithelial neoplasm is a rare, low-grade malignancy that typically occurs in young adult women, but a third of cases are described in adolescents. These tumors typically have cystic areas, as well as areas of hemorrhage and calcification, producing a very heterogeneous appearance on imaging studies (Figure 74.2-46).[87] Acute lymphocytic leukeumia is a rare cause of diffuse pancreatic infiltration and enlargement (Figure 74.2-47).[88] Thin-section contrast-enhanced CT is the best modality to image the pancreas because it is unaffected by overlying bowel gas, which can obscure the pancreas on US. Functioning pancreatic tumors, including insulinoma, gastrinoma, and VIPoma, are notoriously difficult to image, especially because these lesions may be very small. Gadolinium-enhanced MRI, which can depict subtle changes in tissue planes, may be of benefit in the detection of small tumors.[89]

Gastrointestinal Tumors

Primary malignancies such as adenocarcinoma, lymphoma, and sarcoma are rarely reported in childhood. Cross-sectional imaging is most useful for staging to determine the extent of tumor and the presence of metastatic disease. In general, intra-abdominal lymph nodes in excess of 1 cm should raise suspicion.[90] Primary lymphoma is rare, occurring most commonly in the ileocecal region, followed by gastric origin.[91] Polyps can sometimes be detected on US as incidental findings. The use of compression US in unprepared patients can be useful. Juvenile polyps may appear almost cystic on US but vascular on color flow

Doppler US.[92] Desmoid tumors, encountered in association with familial polyposis, are not malignant but can be quite aggressive (Figure 74.2-48).[93] PTLD can present in the immunosuppressed patient as nonspecific hepatosplenomegaly or focal masses within the bowel wall, organs, or lymph nodes. US and CT combined will detect up to three-quarters of cases of PTLD (Figure 74.2-49).[94]

INFECTIOUS PROCESSES

The most common infectious processes that affect the liver are abscesses and hepatitis. Fungal, bacterial, or other infectious abscesses are more commonly seen in immunocompromised children, those with human immunodeficiency virus (HIV), chronic granulomatous disease, or leukemia or on immunosuppression therapy following organ transplant or for treatment of diseases such as inflammatory bowel disease (IBD). US is an excellent initial study and a useful guide for diagnostic biopsy. Fungal abscesses are usually small and multiple and appear on US as "target" lesions, with a central echogenic focus surrounded by a hypochoic rim. On contrast-enhanced CT, the central area enhances within the low-attenuation lesions.[95] Bacterial abscesses tend to be singular, round, and located in the periphery. A hypoechoic halo may be seen on US.[96] Similarly on CT and MRI, pyogenic abscesses are well-defined, low-density lesions that demonstrate peripheral enhancement after contrast administration.[97] Staphylococcal abscesses can also present as target lesions. Amebic or hydatid abscesses can be difficult to diffentiate from pyogenic abscesses.[98] Echinococcosis is endemic in certain parts of the world, and two-thirds of cases will involve only the liver. US, CT, or MRI will show either single or a few very large cysts,

FIGURE 74.2-46 Contrast-enhanced axial computed tomographic scan of the abdomen of a 13-year-old girl with abdominal pain reveals a solid tumor in the head of the pancreas (*arrow*). The patient underwent a modified Whipple procedure for what proved to be a cystadenoma.

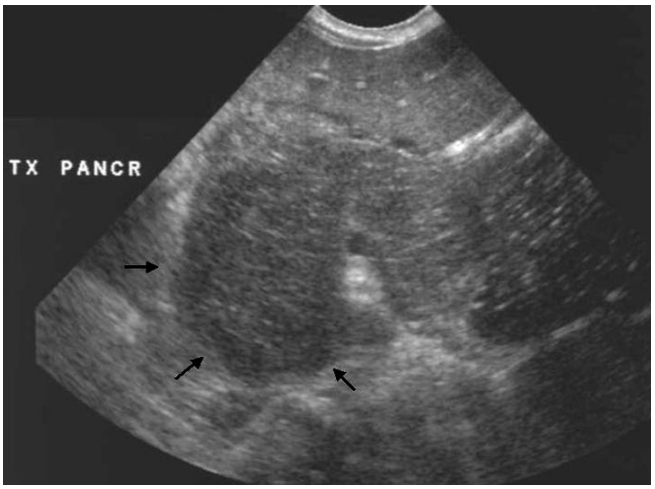

FIGURE 74.2-47 Transverse sonogram of a 3-week-old female infant showed marked enlargement of the pancreas. The echotexture appears decreased. The patient was diagnosed with acute lymphocytic leukemia. *Arrows* indicate the leukemic infiltration.

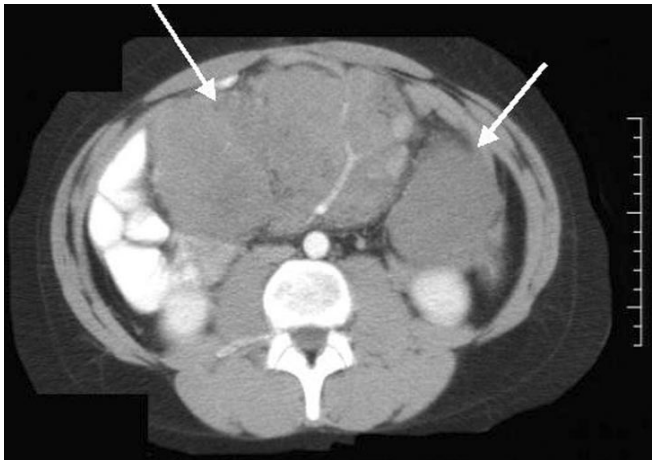

FIGURE 74.2-48 Axial contrast-enhanced computed tomographic scan of the lower abdomen of a 14-year-old boy who underwent a total colectomy for familial polyposis demonstrates bulky soft tissue masses (*arrows*). The patient was diagnosed with Gardner syndrome and desmoid tumors.

FIGURE 74.2-49 Axial contrast-enhanced computed tomographic scan of the pelvis of a 6-year-old female heart recipient on immunosuppression shows a large soft tissue mass encasing loops of bowel (*arrow*). Biopsy confirmed the diagnosis of monoclonal lymphoproliferative disease.

sometimes with calcifications (Figure 74.2-50). Perforation into the biliary tree has been reported.[99]

In general, most children with acute hepatitis have a normal US examination, although diffuse hepatomegaly may be present and echogenicity may be either increased or decreased.[31] Thickening of the gallbladder wall is sometimes seen in acute hepatitis as well as a contraction of the total volume of the gallbladder.[100] In certain settings, as with ingestion of a fatty meal, paradoxical dilatation of the gallbladder can also be seen on US.[101] CT and MRI will show similar nonspecific changes. Assorted neonatal infections, including cytomegalovirus, toxoplasmosis, and coxsackievirus, have been associated with parenchymal liver calcifications. Interestingly, infections in older children rarely result in calcifications.[102]

Splenic abscesses appear hypoechoic on US, with low attenuation on CT and with high fluid content on MRI. Peripheral enhancement after contrast administration is seen on CT and MRI. Fungal abscess may be very small, multiple, and occasionally calcified and is seen better on CT scan.[103,104] The spleen is subject to opportunistic infections, including *Pneumocystis* and *Mycobacterium*, especially in immunocompromised patients.[105]

Primary pancreatic abscesses do not occur, but there can be secondary infection of pseudocysts, usually occurring 4 to 6 weeks after acute pancreatitis and appearing as well-circumscribed complex cysts on imaging studies. This occurrence usually requires surgical débridement.[106]

Intra-abdominal abscesses occur with some frequency in children and are usually secondary to ruptured appendicitis. They can also be secondary to trauma and Crohn disease.[107] US has limited usefulness in searching for intra-abdominal abscess, and contrast-enhanced CT of the abdomen and pelvis with both oral and rectal contrast is the modality of choice.

Various bacterial enteritides, including *Campylobacter jejuni* and *Yersinia enterocolitica*, can also cause thickening and inflammation of the bowel wall, especially in the ileum, and may be associated with mesenteric adenitis, making them difficult to distinguish from Crohn disease.[108]

ACQUIRED CONDITIONS

Liver

Parenchymal disease from various processes, including metabolic diseases, drug and environmental toxicities, and congenital hepatic fibrosis, does not offer specific imaging findings. Some of these processes cause fatty infiltration, fibrosis, and even cirrhosis, all of which have further imaging findings, albeit nonspecific. Fatty infiltration with enlargement of the organ is a common finding in early liver disease, seen on US as diffuse increased echogenicity (Figure 74.2-51). On CT, the liver with fatty infiltration has lower attenuation to the spleen rather than the normally expected similar or increased attenuation (Figure 74.2-52). As liver parenchyma is destroyed and the organ becomes fibrotic, there is a commensurate decrease in size and a heterogeneous increase in echogenicity on US.

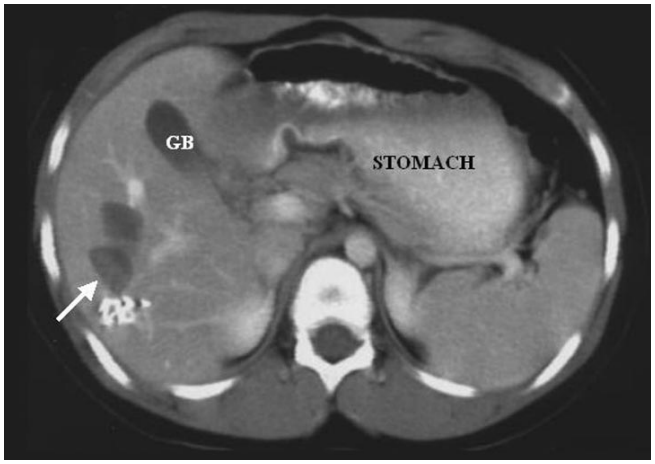

FIGURE 74.2-50 Contrast-enhanced computed tomographic scan of a 14-year-old boy reveals recurrent cystic masses (*arrow*) arising anterior to multiple clips, status postresection of ecchinococcal cysts.

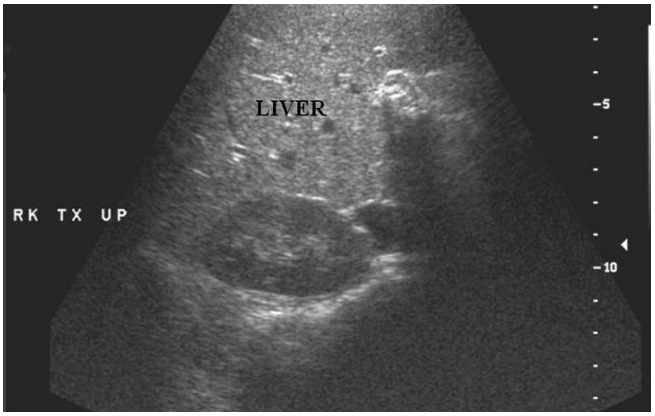

FIGURE 74.2-51 Transverse sonogram of the right upper quadrant shows the liver to be of increased echogenicity compared with the right kidney, suggesting fatty infiltration. Normally, the liver is of decreased attenuation compared with the kidney.

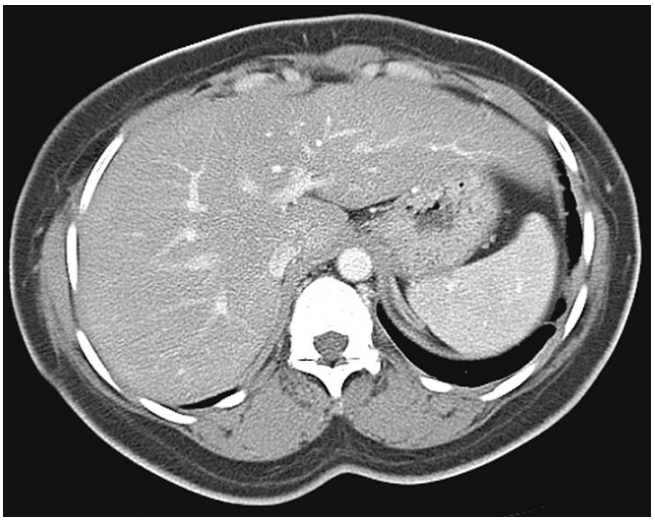

FIGURE 74.2-52 Axial contrast-enhanced computed tomographic scan of the abdomen of an 18 year old with cystic fibrosis reveals that the liver has lower attenuation to the spleen rather than the normally expected similar or increased attenuation, a finding suggestive of fatty infiltration. The spleen is mildly enlarged.

US, CT, or MRI can also demonstrate changes associated with chronic liver disease and cirrhosis. Such findings include macronodular contours, regenerating relative enlargement of the caudate and left lobes,[109] and sclerotic nodules (Figure 74.2-53), as well as the development of portal hypertension, with splenomegaly, varices (Figure 74.2-54), and ascites. Recannalization of the umbilical vein, hypertrophy of the hepatic artery signal, and biphasic and eventual reversal of flow in the portal vein are demonstrated by color Doppler US. Enlarged coronary veins and retroperitoneal varices can be seen with portal vein thrombosis and cavernous transformation. CT and MRI can show collaterals and clots extending into vessels.[110] Increased attenuation of parenchyma can be seen with iron deposition, with glycogen storage disease, and after the administration of cisplatinum for chemotherapy.[111] MRI may be more sensitive than CT for detecting early deposition. Because deposition can be preceded by the accumulation of fat, the liver may initially appear of decreased attenuation on CT.[112] Budd-Chiari syndrome is a relatively rare disorder caused by the acute or chronic obstruction of the hepatic veins, usually by membranous obstruction. It may also be caused by hypercoagulability associated with hematologic and systemic disease. The presentation of Budd-Chiari syndrome is similar to other liver diseases, with right upper quadrant pain, tender hepatomegaly, and possibly ascites. Astute clinical suspicion and proper imaging are essential for diagnosis. Angiography had been the principal diagnostic modality; however, noninvasive duplex Doppler US is now preferred to show the venous anomalies, with a sensitivity that approaches angiography.[113] Contrast-enhanced CT and MRI do not demonstrate venous obstruction as well but do detect the associated parenchymal disease, the relative preservation of the caudate lobe, and large regenerative nodules (Figures 74.2-55 and 74.2-56). [114]

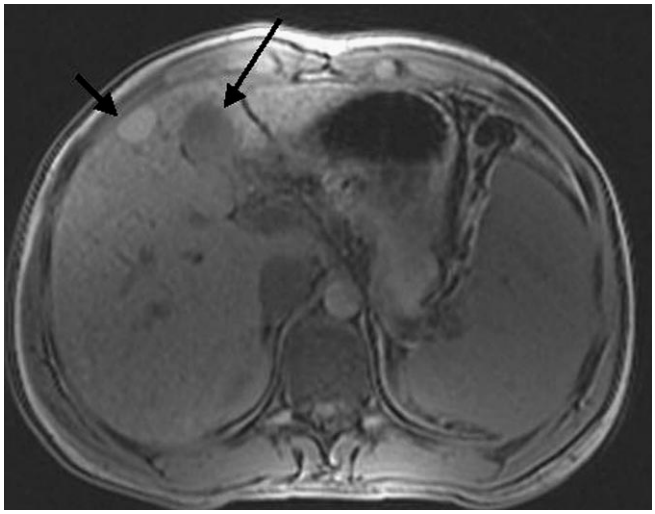

FIGURE 74.2-53 Spoiled gradiant axial magnetic resonance image of the liver in an 18-year-old male patient with chronic active hepatitis B demonstrates multiple nodules within the liver. Most were of low signal characteristic and did not enhance after gadolinium, similar to the nodule demarcated by the *thin arrow*. These were presumed to represent siderotic type nodules. One lesion was of bright signal on multiple sequences but also did not enhance (*short arrow*) and was thought to represent a regenerating nodule. All nodules remained stable over a 3-year follow-up.

Liver Transplant

The most significant and dramatic acquired condition of the liver is transplant. Accurate imaging is crucial for both pre- and post-transplant evaluations. Potential recipients are typically followed by serial US examinations to document progression of disease, the development of portal hypertension, and the patency of vessels essential for graft anastomosis. Congenital anomalies that might complicate the surgical procedure, such as a preduodenal portal vein, are documented. CT and MRI are reserved for

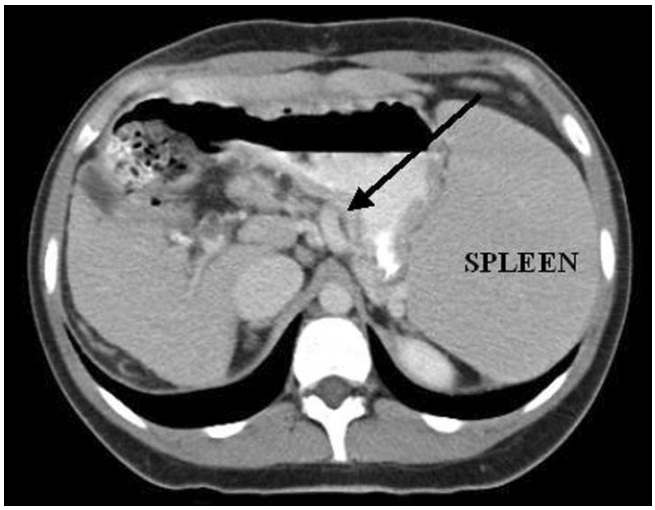

FIGURE 74.2-54 Axial contrast-enhanced computed tomographic scan of the abdomen of a 16-year-old female patient with autoimmune hepatitis reveals splenomegaly, varices (*arrow*), and the inferior portion of a small liver. Clinically, the patient had portal hypertension.

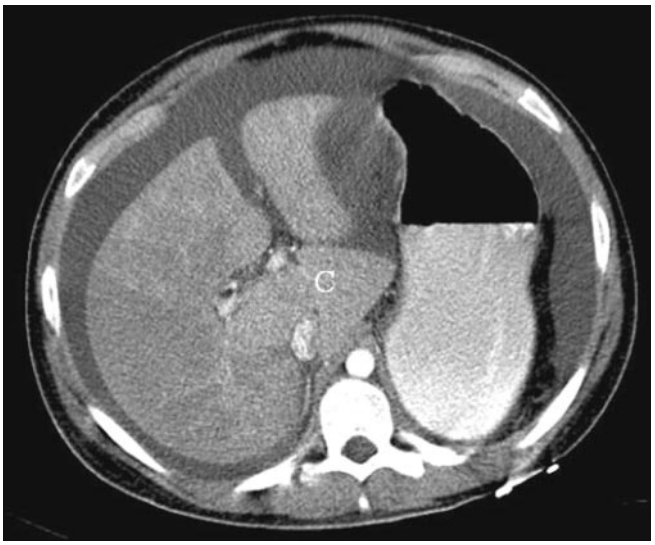

FIGURE 74.2-55 Budd-Chiari syndrome. Axial computed tomographic scan after the intravenous administration of contrast reveals heterogeneous enhancement of the liver, except for the caudate lobe (c), which appears preserved.

excluding the possibility of malignancy[115] and establishing accurate liver volume for surgical planning. MRCP, in conjunction with liver biopsy, is particularly important in excluding large duct primary sclerosing cholangitis as the cause of liver failure because this diagnosis requires that a Roux-en-Y portoenterostomy be performed rather than a duct-to-duct anastomosis.

Serial US examinations are crucial in the postoperative period to access for patency of the newly anastomosed vessels. Vascular complications of stenosis or occlusion, if diagnosed promptly and corrected in the immediate postoperative period, can significantly improve graft success and decrease the incidence of biliary compromise. Bile duct dilatation can be related to vascular compromise or anastomotic stricture. Dilatation or beading of the biliary system on a chronic basis may also be related to prolonged cold-ischemia at the time of transplant. Biliary dilatation will be seen on US or CT if moderate to severe[116] and on MRCP even if mild (Figure 74.2-57). Small focal areas of infarction are not uncommon in the immediate postoperative period and can be detected on US as hypoechoic, peripheral, wedge-shaped areas of decreased perfusion but may be more evident on CT scan, where they appear to be of decreased attenuation.[117] US-guided biopsies and interventional percutaneous transhepatic drainage of bilomas or abscesses[118] play an important role in the postsurgical management. Contrast-enhanced CT of the abdomen and pelvis remains the mainstay of evaluating for post-transplant abscess, collections, and PTLD.

Biliary Disease

The most common form of acquired biliary disease is cholelithiasis, and although the incidence is not as common as in adults, it does occur with some frequency in children, especially in the setting of sickle cell disease, hereditary spherocytosis, and related hematologic diseases (Figure 74.2-58). In children, both gallstones and sludge can be well seen on US (Figure 74.2-59), although the clinical significance of each is different. Sludge is more often associated with prior parenteral nutrition or antibi-

FIGURE 74.2-56 Delayed axial computed tomographic scan after the intravenous administration of contrast reveals filling defects in the liver corresponding to thrombosed hepatic veins (*short arrow*) in this 16-year-old patient with Budd-Chiari syndrome. The *long arrow* demonstrates ascitic fluid surrounding the liver.

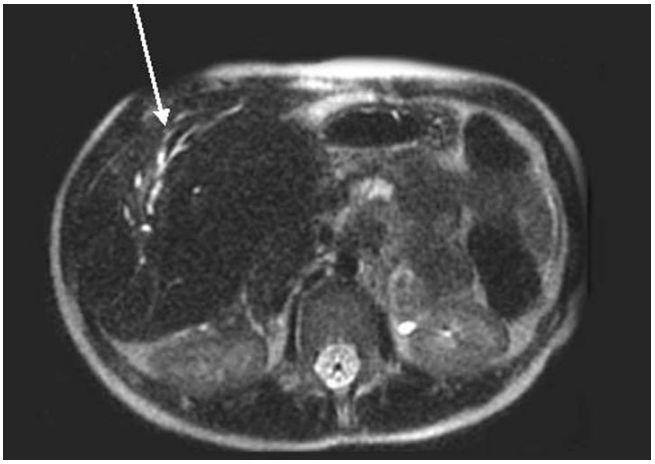

FIGURE 74.2-57 Axial magnetic resonance cholangiopancreatography performed on a 6-year-old girl with rising liver enzymes 5 years following a segmented liver transplant reveals mild intrahepatic biliary dilatation and beading (*arrow*).

FIGURE 74.2-58 Acute cholecystitis. Sagittal sonogram of the gallbladder reveals a thick wall and a scant amount of pericholecystic fluid (*arrow*).

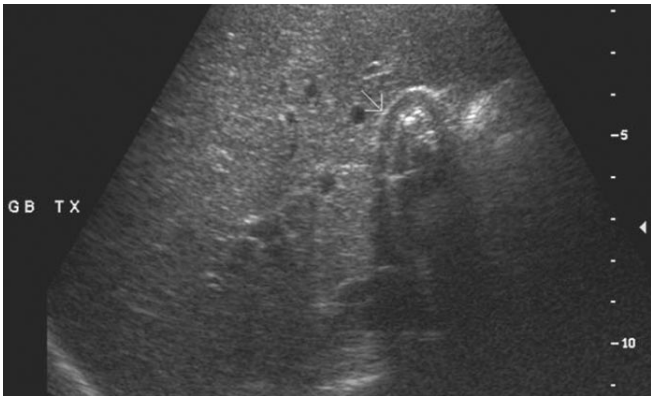

FIGURE 74.2-59 Transverse sonogram of the liver of a 16-year-old female patient with right upper quadrant pain reveals a thick-walled, contracted gallbladder (*arrow*) filled with shadowing stones. The patient was treated for acute cholecystitis.

otics and can appear and resolve in a matter of days. Most stones are related to hemolytic processes and, unlike in adults, do not necessarily require surgery.[119] Common duct stones are rare in children (Figure 74.2-60). Acalculous cholecystitis may show thickening of the gallbladder wall on US, although hypoalbuminemia and infections may cause similar findings.[32]

Primary sclerosing cholangitis, a chronic inflammatory process affecting the extrahepatic and/or medium to large bile ducts, is seen in children and has features suggesting an autoimmune pathogenesis. It is associated with IBD, histiocytosis, and, less commonly, lymphoma and infections related to immunodeficiencies.[120] MRCP is as sensitive as ERCP in demonstrating large duct primary sclerosing cholangitis in children by demonstrating beading of the ducts (Figure 74.2-61).[121]

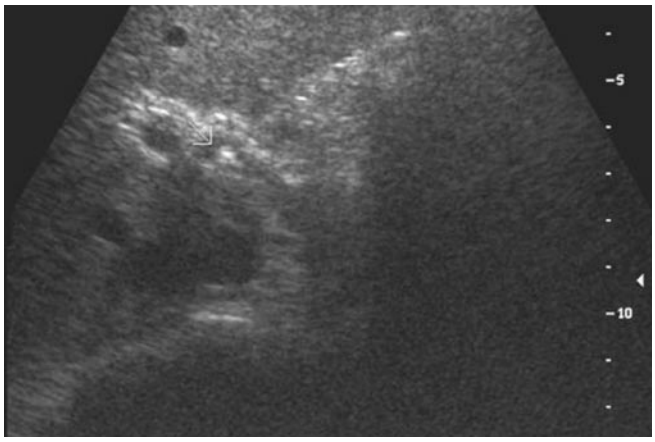

FIGURE 74.2-60 Sagittal sonogram of the porta hepatis reveals an echogenic focus within the common duct (*arrow*), consistent with a stone.

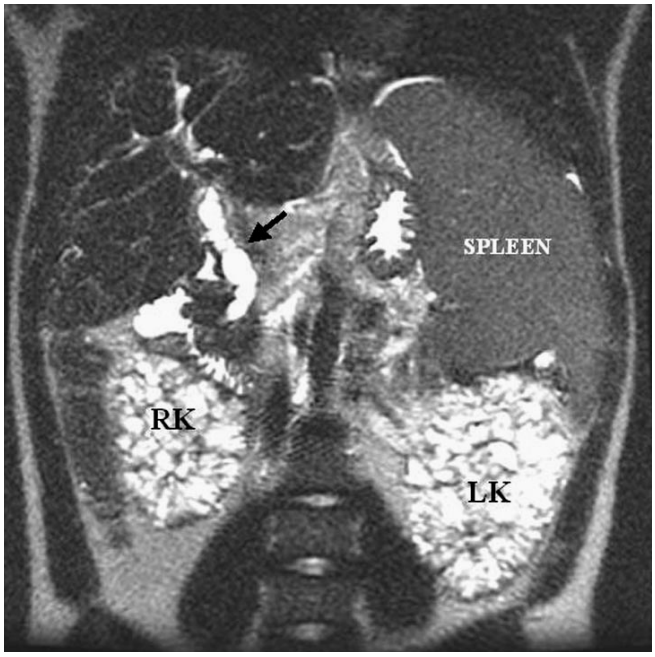

FIGURE 74.2-61 Coronal magnetic resonance cholangiopancreatogram of an 8-year-old boy with autosomal dominant polycystic kidney disease reveals dilatation and beading of the extrahepatic bile duct (*arrow*), as well as milder intrahepatic biliary beading, suggesting the appearance of primary sclerosing cholangitis. Note the multicystic enlarged kidneys and splenomegaly.

Spleen

The spleen is not usually the primary organ of disease processes, but it is frequently secondarily enlarged by neoplasia, infection, venous engorgement from portal hypertension, or infiltrative disease as in storage diseases. Gaucher disease is associated with some of the largest documented spleens (Figure 74.2-62). On all modalities, the parenchyma is usually uniform. Complicating splenomegaly, infarction appears as hypoperfused, wedge-shaped, round, or irregular areas on US and as low-attenuation areas on contrast-enhanced CT unless superimposed hemorrhage causes an increase in attenuation. When followed serially, infarcts tend to contract and progressively liquefy, and may calcify. In sickle cell disease, multiple, recurrent infarctions result in eventual destruction of the entire spleen.[122]

Pancreas

Of the identifiable causes of pancreatitis, trauma is the most common in childhood, and abuse should always be excluded. Nontraumatic pancreatitis may be caused by viral infection, hypercholesterolemia, and obstruction. Obstruction as an etiology is much less common in children than in adults. It may appear as focal or diffuse enlargement, which is sometimes difficult to define because there is great variability in the size of the normal pancreas. US is an excellent modality for the initial study; however, owing to obscuring bowel gas, demonstration of the entire pancreas can present challenges. Associated findings of acute pancreatitis include ductal enlargement, either decreased or increased echogenicity of the entire gland, or heterogeneous echogenicity within the same gland. Peripancreatic fluid can be detected loculated

FIGURE 74.2-62 Axial non–contrast-enhanced computed tomographic scan of the abdomen of a 16-year-old female patient with Gaucher disease demonstrates marked splenomegaly with multiple peripheral low-attenuation areas consistent with infarcts (*arrow*). A thin calcified rim is present. Free ascites (A) is also present.

adjacent to the pancreas or free in the peritoneal space as ascites and pleural effusions (Figure 74.2-63). Phlegmons, fistulae, infarctions, and pseudocysts[123] can complicate pancreatitis. CT with contrast has been used to evaluate pancreatic morphology, detect pancreatic necrosis, and depict retroperitoneal complications, resulting in a CT staging severity index that has proven to be a reliable indicator of prognosis (Figure 74.2-64).[124] In children with recurrent episodes of idiopathic acute pancreatitis, MRCP allows visualization of the pancreatic duct anatomy, including side branches, ductal narrowing, endoluminal filling defects, irregular ductal contour, cavities, and pancreas divisum, thus increasing the ability to diagnose risk factors associated with chronic pancreatitis (Figure 74.2-65).[125]

Chronic pancreatitis, relatively rare in childhood, shows ductal dilatation, irregularity, calcification, pseudocyst formation, and, ultimately, a smaller gland. In cystic fibrosis, pancreatic atrophy and fatty infiltration may be dramatic (Figure 74.2-66).[126] Diffuse enlargement or focal alteration of the gland is seen in fibrosing pancreatitis and may result in biliary obstruction.[127]

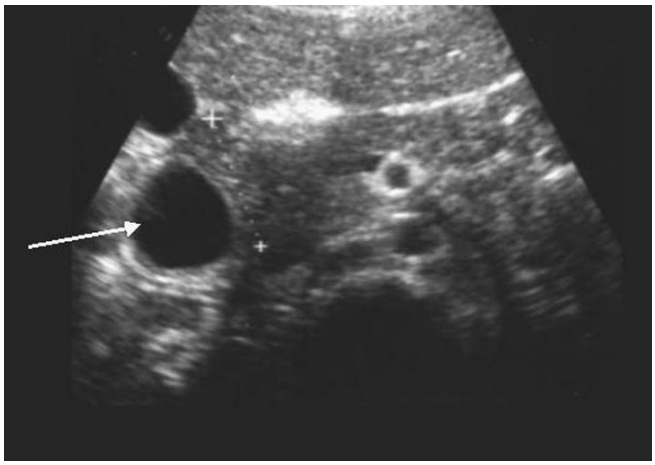

FIGURE 74.2-63 Transverse sonogram of the abdomen reveals an enlarged head of the pancreas with a central pseudocyst (*arrow*).

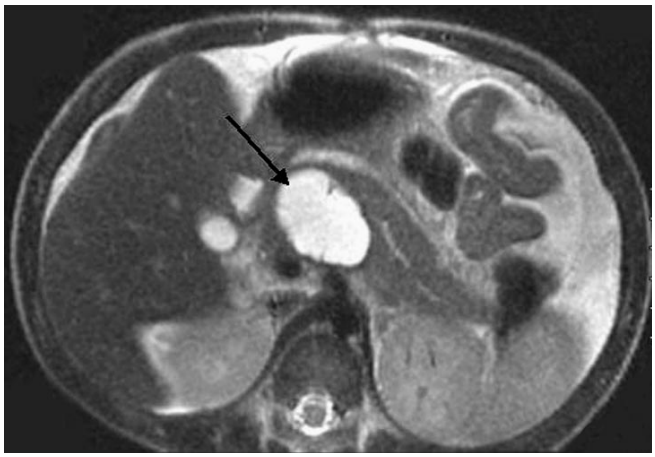

FIGURE 74.2-65 Axial magnetic resonance cholangiopancreatogram of a 5-year-old boy with a history of abuse demonstrates a large pseudocyst in the pancreas (*arrow*).

Gastrointestinal Tract

Cross-sectional imaging of the gastrointestinal tract has dramatically altered the standard of care in gastrointestinal disorders over the past several decades. Various imaging studies are routinely ordered for diagnosing entities such as appendicitis, intussusception, IBD, and even bowel obstruction, although plain films and contrast studies, coupled with clinical judgment, still play a very large role in the diagnosis and management of these disorders.

Up to 20% of small bowel obstruction will not be evident on plain films,[128] but it is unclear whether these undetected cases can be managed conservatively or indeed need surgical management. Contrast studies are at times not useful owing to delayed transit time and dilution of contrast. US examination of small bowel obstruction will demonstrate either hyperactive or hypoactive, atonic and dilated, fluid-filled bowel, but the same findings can be seen in gastroenteritis.[129] US may suggest malrotation based on demonstrating the superior mesenteric vein to the left of the superior mesenteric artery.[130] CT can reveal

FIGURE 74.2-64 Axial contrast-enhanced computed tomographic scan of a 12-year-old boy with familial hypercholesterolemia and pancreatitis reveals an enlarged head of the pancreas and a central pseudocyst (*arrow*).

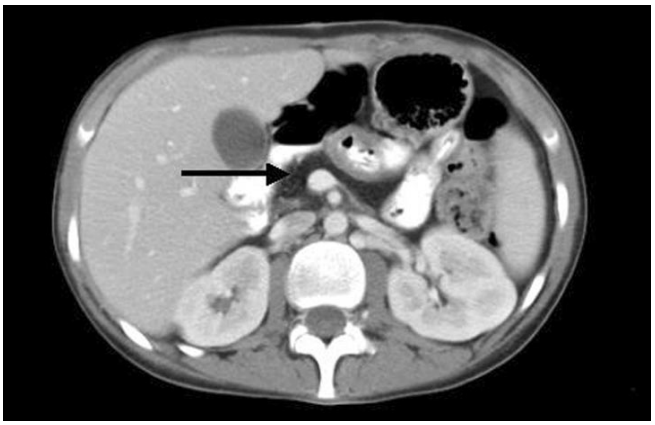

FIGURE 74.2-66 Axial contrast-enhanced computed tomographic scan of an 18-year-old female patient with cystic fibrosis reveals complete fatty replacement of the pancreas (*arrow*). The patient clinically had insulin-dependent diabetes.

high-grade obstruction with dilated loops of bowel and closed-loop strangulating obstruction, and some authors advocate CT as the investigative modality of choice. Specific causes of small bowel obstruction can be seen on cross-sectional imaging studies, although traditional SBFT remains helpful.[128]

Causes of obstruction include congenital duplication and mesenteric cysts. If the cyst contains gastric mucosa, it can ulcerate, bleed, or even perforate.[129] Another cause of intestinal obstruction is Meckel diverticulum, which can contain gastric mucosa and therefore can be detected by radionucleotide scan. Occasionally, the diverticulum can be imaged by US or CT[131] as the lead point for an intussusception, with a blind-ended, thick-walled bowel segment projecting beyond the apex of the intussusceptum.[132]

Appendicitis

The diagnosis of appendicitis,[133] once a clinical one with a large margin of error, has been considerably changed by advances in cross-sectional imaging. The US finding of an appendix greater than 6 mm in diameter, with a blind-ending lumen that is noncompressible and hyperemic, became the hallmark of acute appendicitis, with up to a 90% sensitivity and 95% specificity.[134] The presence of a appendicolith and periappendiceal fluid supports the diagnosis,[135] although documentation of an appendicolith may be associated with normal appendices in up to 14% of surgically explored cases.[136] US is useful to exclude ovarian pathology in female patients and can demonstrate abscess formation suggesting perforation. Unfortunately, as in physical examination, US is limited by overlying bowel gas and the fact that many appendices are not in a typical location. The inability to demonstrate an inflamed appendix does not exclude acute appendicitis on US. Because the technique uses graded compression, US is uncomfortable and can be difficult to perform in uncooperative children. Furthermore, US of the appendix is highly operator dependent.

Because of these limitations, CT of the abdomen and pelvis has largely replaced US for the diagnosis of acute appendicitis. Various techniques are advocated, including contrast- and noncontrast-enhanced techniques. Some radiologists prefer oral, rectal, and intravenous contrast, whereas others perform the examination with only rectal contrast. Despite these differences in technique, the objective is to visualize the enlarged and inflamed appendix (Figure 74.2-67) and an appendicolith if present (Figure 74.2-68) and to identify any associated findings of pericecal fluid and inflammation. CT is also used extensively to document suspected complications such as abscess formation both pre- and postoperatively (Figure 74.2-69). With the widespread use of US and CT, the negative appendectomy rate has dropped from 15 to 4%, whereas the rate of perforation has decreased from 35 to 16% in one reporting institution.[137]

Intussusception

The most common cause of intestinal obstruction from 6 months to 6 years of age is intussusception, which most commonly occurs before age 2 years, with a peak incidence between 3 and 9 months. Of the intussusceptions that

FIGURE 74.2-67 Axial contrast-enhanced computed tomographic scan with oral and rectal contrast reveals a fluid-filled, swollen appendix in the right lower quandrant (*arrow*). The inflammed appendix wall is enhancing.

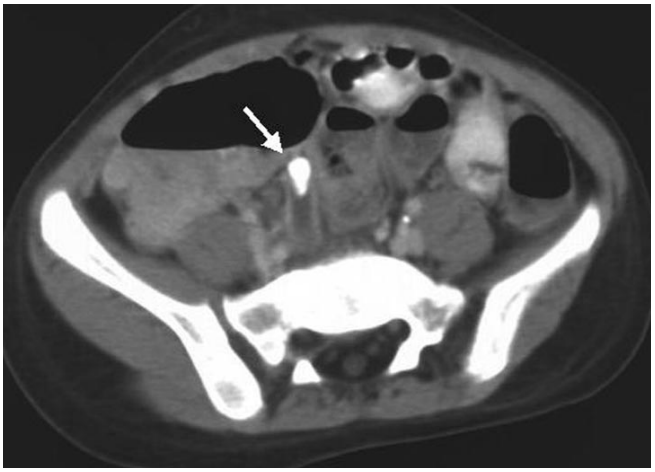

FIGURE 74.2-68 Axial computed tomographic scan of the pelvis reveals a thick tubular structure in the right lower quandrant consistent with a swollen appendix. A calcified appendicolith (*arrow*) is present.

FIGURE 74.2-69 Axial contrast-enhanced computed tomographic scan of the pelvis reveals a fluid collection with a thin enhancing rim in the right lower quandrant (*arrow*) adjacent to thick-walled bowel. At surgery, a perforated appendix with a periappendiceal abscess was found.

occur in the typical age group, 90% are ileocolic and probably only 5% have a lead point, whereas the occurrence under the age of 6 months and over 3 years of age can be located in other segments of the bowel and may have a lead point.[138] Not all children will have the typical clinical presentation of episodic cramps, currant jelly stools, and abdominal pain, making it most important to maintain a high clinical suspicion and have sensitive imaging techniques to confirm. Findings of intussusception may be evident on plain film radiographs, but in 25% of cases, the bowel pattern is normal. Enema, using either barium or air, is the gold standard, both for diagnosis and treatment.

US is a reliable study for diagnosing intussusception, although it may not reach the high sensitivity and 100% negative predictive values that have been reported.[139] The characteristic finding is an intra-abdominal mass that demonstrates a hypoechoic ring of bowel wall mucosa surrounding an echogenic center of trapped mesenteric fat and vessels, the "doughnut sign" (Figure 74.2-70).[140] Multiple concentric circles may be seen when there are multiple layers of both intussusceptum and intussuscipiens. In the plane longitudinal to the mass, there are alternating hypoechogenic and echogenic layers, the "sandwich" or "pseudokidney" sign.[141] Thickening of the echolucent rim greater than 8 mm and fluid within the intussusceptum, especially if there is a dilated apex, have been suggested as indications of significant ischemia and irreducibility by enema reduction.[142] Free intraperitoneal fluid and bowel thickness did not alter outcome of reduction in another large series; however, the presence of small bowel obstruction on plain film reduced the success rate from 90 to 65%.[143]

FIGURE 74.2-70 Sonogram of the abdomen in a 2 year old with crampy abdominal pain reveals a soft tissue mass in the right upper quadrant. The alternating echogenic and hypoechoic layers are typical for an intussusception.

Clinical peritonitis is a contraindication to hydrostatic or air reduction. An intussusception present for greater than 48 hours or one in an infant less than 6 months with bowel obstruction on plain films has a high likelihood of perforation.[144] Lead points have included most polyps, Meckel diverticulum, duplication cysts, and submucosal bleeds associated with Henoch-Schönlein purpura. Although the vast majority of intussusceptions are reduced under conventional fluoroscopic guidance, recent attempts at air reduction under US guidance have been met with some success.[145]

INFLAMMATORY CONDITIONS

Various inflammatory processes demonstrate bowel wall thickening on cross-sectional imaging. Although this is usually caused by an infectious process and is accompanied by mesenteric adenitis, IBD can cause similar findings. Using bowel wall thickness as a criterion for diagnosing IBD on US and comparing it with colonoscopic findings as the gold standard, US showed a sensitivity of 88% and a specificity of 93%.[146] In addition, CT can demonstrate transmesenteric disease associated with Crohn disease, such as creeping apposition of fat, mesenteric lymphadenopathy, and fistula formation helping to distinguish Crohn disease from ulcerative colitis (Figures 74.2-71 and 74.2-72). Intravenous contrast will enhance the margins of inflamed bowel wall or an inflammatory mass (Figure 74.2-73), whereas oral or rectal contrast will identify lumen. Another study, which looked at a combined group of IBD, infectious colitis, pseudomembranous colitis, Henoch-Schönlein purpura, and hemolytic syndrome, could not differentiate one condition from another.[147] Bowel thickening without transmesenteric disease is, however, more typical of colitis from causes other than Crohn disease (Figure 74.2-74).[148] Currently, MRI is less effective in demonstrating bowel pathology.[149]

In necrotizing enterocolitis, US has been demonstrated to be sensitive in detecting bowel wall thickening, pneumatosis intestinalis, portal venous gas, and perforation causing inflammatory mass[150]; however, serial plain films

FIGURE 74.2-71 Contrast-enhanced computed tomographic scan of the pelvis in this 15-year-old male patient with Crohn colitis reveals contrast extending into a perirectal fistula (*arrow*).

FIGURE 74.2-72 Axial contrast-enhanced computed tomographic scan of the abdomen in an adolescent female with Crohn disease reveals an abscess arising from the wall of the transverse colon (*arrow*).

FIGURE 74.2-73 Axial contrast-enhanced computed tomographic scan of the pelvis reveals a collection with an enhancing rim abutting the psoas muscle (*long arrow*) in this adolescent male with Crohn disease and right lower quadrant pain. Note the thick-walled bowel adjacent to the abscess (*short arrow*).

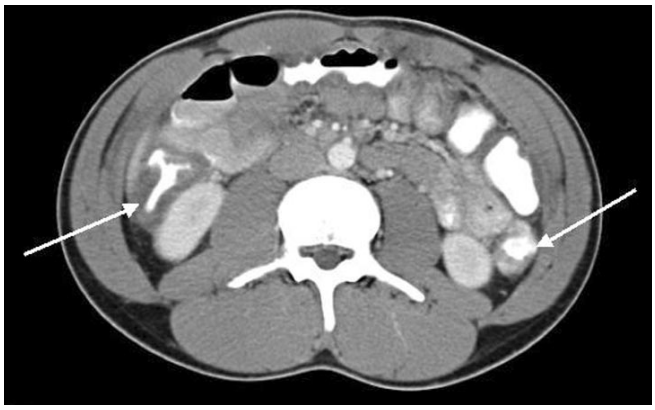

FIGURE 74.2-74 Contrast-enhanced computed tomographic scan of the lower abdomen reveals a thick-walled ascending colon (*up arrow*) and a descending colon (*down arrow*) in this teenager with known colitis.

remain the mainstay of diagnosis. In an investigative study, MRI showed good correlation with operative findings in a small group of premature infants determined to have necrotizing enterocolitis.[151] However, in view of the technical and practical considerations, cross-sectional imaging probably does not have a great deal to contribute to the care of these critically ill infants.

CONCLUSION

Imaging technology has markedly altered the traditional workup of gastrointestinal disorders. Ongoing advances in US, CT, and MRI have revolutionized the approach to many common diseases and greatly increased the accuracy of diagnosis. The risks of radiation exposure, contrast toxicity, and sedation should always be considerations, especially when a pediatric patient is concerned. As with any modality, an understanding of the risks, benefits, and limitations of a procedure is needed to effectively use these sophisticated technologies.

3. Interventional Gastrointestinal Radiology

Peter G. Chait, MBBCh(Rand)(D), SA, FRCPR(Eng)

Pediatric interventional radiology[1,2] has expanded in the last 5 to 10 years as a direct result of the improvement in cross-sectional imaging, including ultrasonography, computed tomography (CT), and magnetic resonance imaging (MRI), as well as rapid biotechnologic advancement in the development of catheter materials, balloons, wires, stents, filters, retrieval devices, and embolic and sclerosing agents.[3,4] The development of this subspecialty has been facilitated by the emergence of pediatric radiologists specifically trained in interventional procedures. To perform these procedures, a fully equipped, dedicated interventional facility must be established. This facility would include anesthetic equipment and monitoring for sedation, color Doppler ultrasonography with a variety of high-resolution interventional probes, a CT scanner, and, finally, a C-arm interventional fluoroscopic table with digital subtraction.

INTERVENTIONAL RADIOLOGY SERVICE

To provide a highly successful service that achieves excellence in patient care, a team approach is stressed.[3,5] Dedicated professionals should include a pediatric interventional radiologist; a fellow or resident in training; pediatric radiology nurses with training in patient assessment, sedation, and postsedation recovery; and technologists trained in angiography, interventional procedures, CT, and ultrasonography. It is important for the team members to liaise with referring physicians, other radiologists, the parent, and the patient to provide the best care possible.[5] The development of the interventional radiology service provides both inpatient and outpatient care and establishes interventional radiology as an important primary service.[4,6]

The following overview is based largely on the experience at The Hospital for Sick Children, Toronto, during the past 4 years. In this period, there has been significant growth and development of interventional procedures, with approximately 1,500 interventional procedures being performed per year. Gastrointestinal (GI) and biliary procedures represent almost half of these procedures. Gastrostomy tube (G tube) placement, follow-up studies, and G-tube changes represent the largest single technique performed at our hospital.

PREPROCEDURE PLANNING

Careful assessment of all patients prior to performing procedures is an essential prerequisite. This includes discussion with the referring physician with respect to the indications and specifics of the procedure required; assessment of the patient; and review of previous imaging studies and laboratory findings, including prothrombin time, partial thromboplastin time, platelets, and hemoglobin, the patient's medical history, drug allergies, and response to previous sedation. Where necessary, further imaging or laboratory studies are ordered and other services are consulted, particularly with regard to patient safety and the suitability of the procedure.[7,8] If sedation or anesthesia is required, intravenous access is placed prior to the procedure. According to the guidelines of the American Society of Pediatrics, presedation or anesthetic orders should include no solid food for 6 hours prior to the procedure, but clear fluids up to 2 hours are permissible.[9] We strictly enforce these guidelines and delay the procedure if necessary. At least 1 hour prior to the procedure, Emla cream (Astra, Mississauga, ON), a topical anesthetic, is applied to the area where percutaneous entry is to be performed. This significantly decreases the pain experienced when local anesthetic is administered.

SEDATION AND ANALGESIA

During the past year, 45% of procedures were performed with a local anesthetic alone, 50% with a local anesthetic plus sedation, and 5% with a general anesthetic. The need for a general anesthetic is determined by the status of the patient, the nature of the procedure, and, in some cases, the needs of the physician.

Patients are categorized according to the American Society of Anesthesiologists' classification[10]:

I. Normal healthy patient
II. Patient with mild systemic disease
III. Patient with severe systemic disease that limits activity but is not incapacitating
IV. Patient with incapacitating systemic disease that is a constant threat to life
V. Moribund patient not expected to survive 24 hours with or without intervention

Class I and II patients are candidates for conscious deep sedation. Patients in class III or IV require special considerations; they generally require general anesthesia but should be dealt with on an individual basis. Patients who have airway anomalies or who have experienced airway complications during past anesthesia or sedation should be thoroughly assessed prior to the administration of any sedative or anesthetic agent. In neonates with oropharyngeal or airway problems, the procedures may be performed with a local anesthetic alone. In older, cooperative children, a local anesthetic alone or combined with

sedation may be all that is needed. General anesthetic is also indicated for (1) lengthy procedures, (2) complete patient cooperation, (3) an area of interest close to vital structures, and (4) procedures requiring a high degree of technical expertise and accuracy.

Numerous drugs are available for sedation and pain control.[11–19] Individuals ordering and administering the drugs and those monitoring the patient should be comfortable with the drugs in use; their effective use is best accomplished by using a carefully described protocol. We use a combination of drugs for sedation and pain control (Table 74.3-1).

We do not use intramuscular sedation. If sedation is required, intravenous access is essential, whereas the response to intramuscular injection is variable. The pain experienced during the introduction of 1% lidocaine into subcutaneous tissues is thought to be due to its low pH. Premixing the lidocaine with bicarbonate prior to injection increases the pH and appears to effectively reduce the pain.[20] It is also helpful to inject the lidocaine with a 27- or 30-gauge needle at a slow rate. Patients are monitored with pulse oximetry, blood pressure, and electrocardiography (ECG) throughout the procedure and following the procedure until they are fully responsive.[21] Postprocedure vital signs are recorded every 5 minutes until the patient awakes and then every 15 minutes. The patient is discharged from the radiology department when cardiovascular and airway stability is ensured and the patient is alert and can talk, sit unattended, and ambulate with assistance.

PATIENT PREPARATION

It is important to predetermine the best position for the patient undergoing the procedure, whether it be supine, oblique, decubitus, or prone. The position of the head of the patient, the ultrasound machine, the intravenous (IV) pole, the anesthetist (if present), and the radiologist should all be predetermined prior to placing the patient on the table. The position of the patient's arms, monitors, and ECG wires is optimized for the procedure and for patient comfort, which is always a high priority. For smaller patients, a restraining device (Figure 74.3-1) is useful to reduce the need for sedation and improve patient control. The body temperature of the neonate or small child is maintained by either increasing the room temperature, placing the child on heating blankets, covering the child with blankets or plastic wrap, using radiant heat from a baby warmer, or blowing hot air over the infant. Most gastrointestinal procedures accessed percutaneously require antibiotic coverage. For upper gastrointestinal procedures, a first-generation cephalosporin (cefazolin 20–30 mg/kg) is used as a single dose prior to the procedure.[22] For small bowel and colorectal procedures, we use cefoxitin (25 mg/kg) and for biliary procedures cefazolin (20 mg/kg).

IMAGING GUIDING SYSTEMS

Interventional procedures may be performed under fluoroscopic, ultrasonographic, or CT guidance or a combination of these modalities. The relative merits of the various guidance systems are listed in Table 74.3-2. Pediatric patients are ideally suited to ultrasonography guidance because of the small size of the patient and the decreased subcutaneous and intraperitoneal fat.[23,24] Furthermore, ultrasonography uses no ionizing radiation, is portable, and provides a real-time image. It is not suitable for structures that are poorly visualized or obscured by overlying bone or air-filled structures. Therefore, structures that can be clearly visualized, such as abdominal solid organs and masses, are ideally suited for ultrasonography guidance. Fluoroscopy is generally used for guidance in areas in which there are differences in x-ray density, such as needle placement into a gas-filled stomach. When ultrasonography guidance is used to place a needle in the correct position, fluoroscopy is often used to allow further intervention, whether this is wire placement, stent deployment, or merely injection of contrast. CT is infrequently used in the pediatric setting. It is indicated primarily when lesions are small or not well visualized by ultrasonography or fluoroscopy.[25] The prime disadvantage of this modality is that it is not portable and fails to provide real-time images. Furthermore, it is time-consuming and therefore expensive and exposes the patient to significant radiation. It is, however, often used in the diagnostic evaluation to exclude other pathologies and to define anatomy and structural relationships, thereby allowing planning of a procedure. After prior imaging and laboratory studies have been adequately reviewed, the optimal guidance method is chosen to provide the safest, easiest, and least invasive approach. Intervening structures such as bowel loops, fluid-filled bladder, vessels, and other sterile spaces, particularly the pleura and the peritoneal cavity, are avoided to reduce complications.

CONTRAST MEDIA

Water-soluble contrast media are used for all interventional procedures performed under fluoroscopy or those requiring fluoroscopic guidance after ultrasonography or CT placement of a needle. High osmolar contrast media are hypertonic ionic triodinated fully substituted benzene derivatives with osmolalities of 1,200 to 2,000 mOsm/L (four to seven times the osmolality of blood). Low osmolar

TABLE 74.3-1 DRUGS AND DOSAGES FOR SEDATION AND PAIN CONTROL

0–5 KG	5–20 KG	> 20 KG

IV = intravenous.

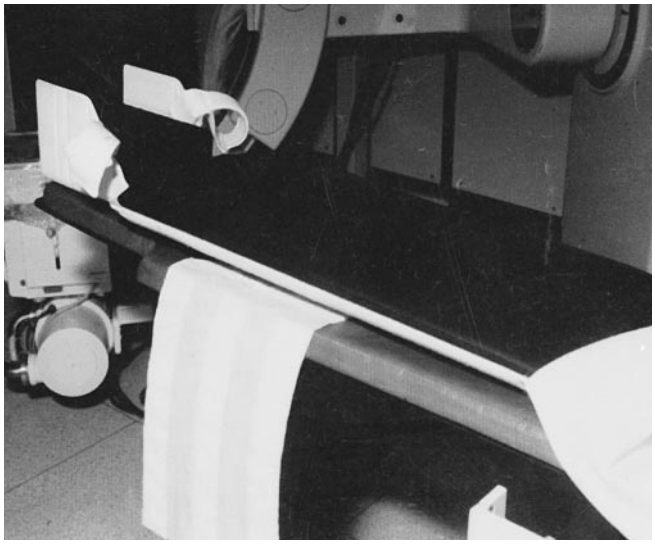

FIGURE 74.3-1 General Electric restraining device designed primarily for computed tomography.

contrast media (LOCM) are significantly more expensive, with significantly less osmolar composition,[7] with an osmolality of approximately 470 mOsm/L. Numerous studies have documented a reduction in overall adverse reactions with the use of LOCM in childhood.[8–12] LOCM also offer a reduction in side effects, especially nausea and vomiting. All water-soluble contrast media are absorbed from the GI tract and other tissues. The high osmolar agents cause significant pain if introduced into the subcutaneous tissue, may cause tissue necrosis,[26] and, obviously, produce an increased risk of pulmonary edema if aspirated. Because of these considerations, low-osmolar, nonionic contrast media are uniformly used for procedures in our institution. Barium sulfate and other varieties of barium suspensions are rarely used, and they are contraindicated if there is any risk of peritoneal spill,[27] extravasation into tissues, or aspiration.[28] Barium is used to do G- or gastrojejunostomy (GJ) tube checks to confirm positions provided that there is no risk of intraperitoneal spillage.[29]

SPECIFIC PROCEDURES

Percutaneous Gastrostomy and Gastroenterostomy

Percutaneous G tube and GJ tube are by far the most common procedures performed in our diagnostic imaging department. Before 1980, the only approach to G-tube placement was surgical.[30] In 1980, Gauderer and colleagues described G-tube placement by a percutaneous endoscopic gastrostomy (PEG) technique.[31] Most pediatric institutions now use this technique.[32–36] A radiologically guided retrograde technique was described a few years later,[37–44] followed by a radiologically guided antegrade technique similar to the PEG1 (Table 74.3-3[45–58]). More recently, laparoscopically performed gastrostomy has been described as a safe alternative to open surgical gastrostomy in patients who cannot undergo percutaneous gastrostomy.[59–64] All approaches to nonsurgical G-tube placement have proved to be cost-effective, with reduced morbidity and mortality.[32,65–67]

There has been a concomitant increase in the number and variety of replacement tubes (Figure 74.3-2) and types of enteral feeding formulas. This has allowed provision for nutrition support on an ambulatory basis using pump-regulated overnight enteral feeding. Currently, the Home Feeding Program at The Hospital for Sick Children, Toronto, monitors approximately 200 patients on overnight enteral feeds compared with only 8 to 10 patients on home total parenteral nutrition. Almost all G tubes are placed in diagnostic imaging; approximately 120 new G tubes are inserted annually. This large patient group requires specialized care, which is best approached by a medical team including interventional radiologists, nutritionists, gastroenterologists, dietitians, and trained enterostomy nursing staff.[68]

Informed consent is obtained either from the patient (if over 16 years and able to give consent) or from the parent or

TABLE 74.3-2 RELATIVE MERITS OF DIFFERENT IMAGING GUIDING SYSTEMS

ADVANTAGES		
FLUOROSCOPY	**ULTRASONOGRAPHY**	**COMPUTED TOMOGRAPHY**
Availability	Rapid localization	Small lesions shown
Rapid localization	Flexible imaging	Needle tip easily seen
Needle tip easy to identify	Flexible patient positioning	Precise anatomic relationship revealed
Diaphragm easily seen	No radiation	Precise target sampling
Modality of choice for further imaging and intervention after needle placement	Ideal for superficial structures or solid organs or masses	No interference because of overlying bowel or gas images, easy to comprehend in three dimensions
Real time	Portable

TABLE 74.3-3 RELATIVE MERITS OF ANTEGRADE AND RETROGRADE GASTROSTOMY TECHNIQUES

ADVANTAGES	
ANTEGRADE	**RETROGRADE**
Stable catheter	Seldom needs general anesthetic—can be performed on unstable patient with airway instability with local anesthetic alone[45] Catheters are smaller and less bulky Can be performed in patient with esophageal strictures or atresia No risk to upper airway or esophagus Change, removal, or manipulation of catheter is easily performed on an outpatient basis Versatile
DISADVANTAGES	
ANTEGRADE	**RETROGRADE**
May go through other loops of bowel (colon)[46] Potential esophageal damage[47] Not possible if esophageal stricture or atresia Pulls down bacteria and infection from the mouth, pharynx, and esophagus[47,48] Difficult to remove (may need repeat gastroscopy)[47–51] Requires nasogastric and orogastric tubes for radiologic placement[49,52–54] If catheter is cut, it may cause obstruction[55,56] Catheters are bulky[57,58]	Easier to dislodge Catheter smaller

guardian. The various risks of the procedure are explained, including gastric leak with associated cellulitis or peritonitis, which is the most significant complication. Other complications include the risk of hemorrhage and some discomfort and pain after the procedure.[69] Six hours before the procedure, a nasogastric tube is inserted and barium is administered so that the colon will be outlined. Prior to the procedure, antibiotics (cefazolin 30 mg/kg) and an analgesia (rectal acetaminophen 15 mg/kg) are administered and Emla cream is applied to the left upper quadrant to reduce the discomfort during introduction of a local anesthetic. The position of the lower edge of the liver and spleen is marked using ultrasonography (Figure 74.3-3). The patient is assessed to determine the need for sedation, a general anesthetic, or a local anesthetic alone. The choice of drugs and the doses used are outlined in the previous section on sedation.

Procedure

The patient is placed on a C-arm fluoroscopic table (Figure 74.3-4).[44] Fluoroscopy is used to identify the contrast-filled colon (Figure 74.3-5). If this is not adequately filled with contrast, a dilute barium single-contrast enema is performed. The patient is given IV glucagon (0.2–0.5 mg). Stomach contents are aspirated via the nasogastric tube. Air is then injected into the stomach under direct vision, and the chosen site for placement of the G tube (lateral to the left rectus muscle and below the costal margin) is marked with a metallic object. Safe access at this site is ascertained prior to skin cleansing and introduction of a local anesthetic. The C-arm table is tilted as necessary to ensure a safe route into the stomach. The stomach is then deflated. Using standard sterile technique, with operating room gowns and gloves, the anterior abdominal wall is prepared and draped.

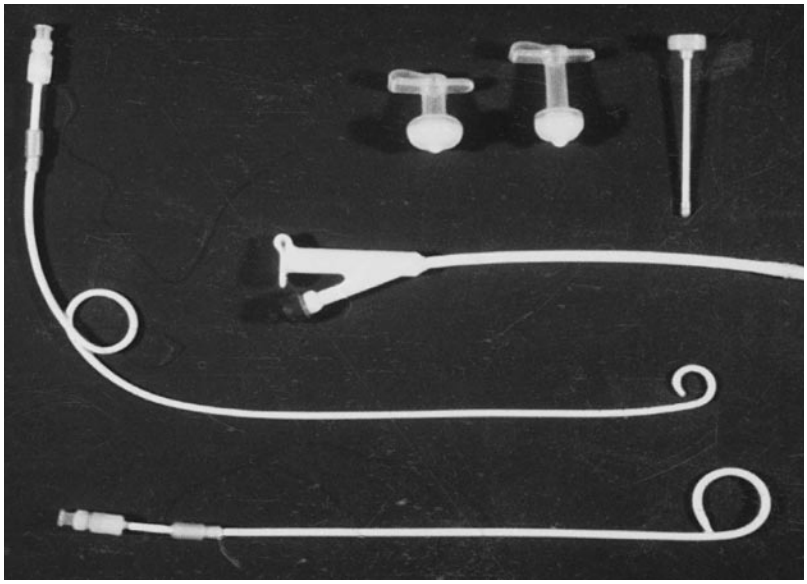

FIGURE 74.3-2 A variety of feeding tubes. *A*, Cope loop gastrostomy tube. *B*, Chait gastrojejunostomy tube. *C*, Balloon gastrostomy tube. *D*, Bard low-profile button gastrostomy tube.

FIGURE 74.3-3 Ultrasonography is used to mark the lower limits of the liver and spleen on a patient prior to gastrostomy placement.

The chosen site for puncture is then infiltrated with 1% lidocaine (maximum dose of 0.5 cc/kg) using a 27-gauge needle. A spinal needle is used if the depth to the stomach is of significant distance. An incision is made with a number 11 scalpel blade to approximately equal the size of the catheter that is to be introduced. Usually, an 8.5 French catheter is used in the neonate; in infants and slightly older children, a 10 French catheter is used, whereas in children over 5 years of age, a 12 French catheter is introduced. The stomach is then reinflated with air, and the distended stomach is punctured percutaneously with a 19-gauge single-wall puncture needle (Cook, Bloomington, IN) using rapid entry. Contrast is then injected to confirm the position, and the retention suture, which is loaded within the access needle, is deposited in the stomach using an 0.25-inch guidewire (Figure 74.3-6).[70–72] The needle is then removed, and the retention suture is pulled up to maintain the stomach against the anterior abdominal wall. A second puncture is then performed with a 19-gauge Seldinger-type needle (Inrad, Kentwood, MI), through which a 0.35-inch straight guidewire (Cook; 70 cm) is introduced. A Coons dilator (Cook) is then used to dilate the tract (Figure 74.3-7).

Dilatation is assisted by using muco jelly on the tip of the dilator and by viewing the dilatation under fluoroscopy to reduce the risk of the retention suture breaking. The dilator is then removed, and the G tube (15 cm Dawson Mueller Mac-Loc, Cook) of chosen size is introduced. The locking loop is tied, and the loop is pulled up to the anterior abdominal wall. The position is checked with contrast to confirm placement and to check for leaks (Figure 74.3-8). If indicated, a GJ catheter can be placed as a primary procedure.[73] In this situation, once access has been obtained with the Seldinger needle, a 5 French dilator is then introduced, followed by a 5 French directional catheter (JB-1, Cook). A Benston wire (0.035 inch) is then introduced through the directional catheter, and the catheter and wire are manipulated into the pylorus and down the duodenum into the proximal jejunum. Once the wire is in position, the catheter is removed and the tract is dilated to the required size. An 8.5 or 10 French GJ catheter (Chait, GJ tube, Cook) (see Figure 74.3-7) is then introduced with a stiffener (Figure 74.3-9). The position of the GJ tube is confirmed prior to returning the patient to the ward.

Postprocedure Orders

Patients fast for 12 hours after the procedure. IV fluids are given to maintain hydration and to replace fluids lost via GI drainage. Nasogastric and G tubes are left to gravity drainage. Antibiotics are continued if there was any difficulty with the procedure or if there is an increased risk of infection. However, in 99% of cases, a single dose of antibiotics given at the time of the procedure is all that is needed. Analgesia in the form of morphine (0.05 mg/kg IV for the first 24 hours) and then acetaminophen (15 mg/kg) is given.

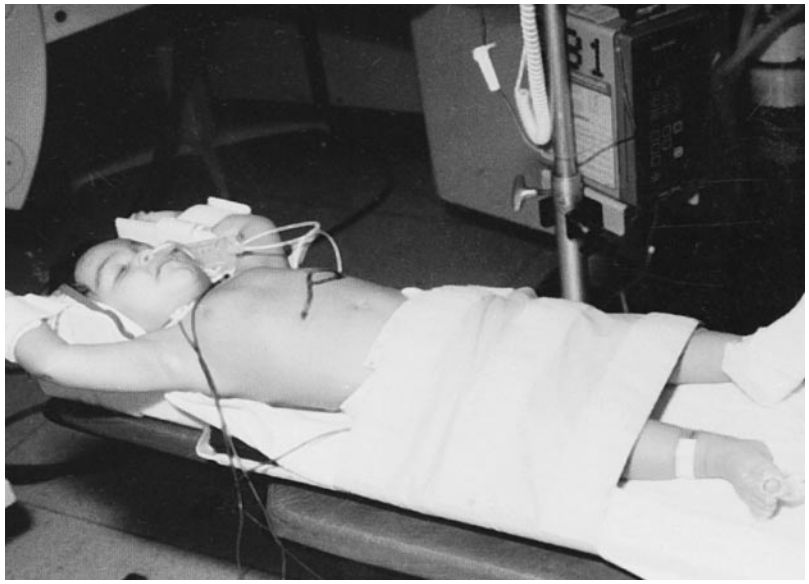

FIGURE 74.3-4 Patient is placed in the restraining device on the C-arm fluoroscopic table with a nasogastric tube, electrocardiograph, and pulse oximetry in position, as well as peripheral intravenous access in the left foot. The position of the liver has been outlined with ultrasonography and the site for gastrostomy placement outlined.

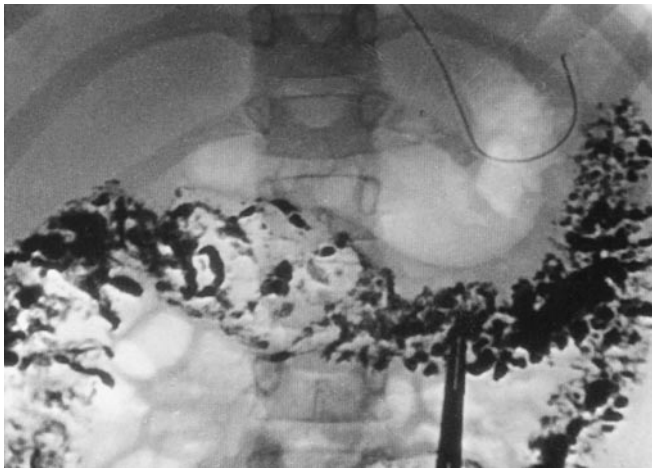

FIGURE 74.3-5 Contrast-filled transverse colon is seen in a patient with a nasogastric tube in position. The side position of a gastrostomy tube is marked with forceps, and the stomach is undistended.

At 12 hours, tube feeding is begun if the patient is clinically well and bowel sounds are present. Initially, clear fluids (Pedialyte) are given either intermittently or continuously, followed by half-strength feed and, finally, full-strength feed. Patients are usually kept in hospital for 72 hours and then discharged. Patients are assessed at 6 weeks, at which time long-term nutritional needs are assessed. At this stage, the Cope loop catheter is exchanged for a balloon type G catheter (see Figure 74.3-2) (MICC, Milpitas, CA). The balloon catheter permits the parent to replace it at home without the need to return to the hospital. Second, the size of the catheter can be increased over the ensuing 3 months to allow placement of a button G tube.

Some patients require gastric drainage and GJ feeding. This can be achieved by placing two catheters, one as a GJ tube and the other as a draining G tube. Alternatively, a balloon type G catheter containing a central jejunostomy feeding catheter can be placed, thereby allowing for feeding and gastric drainage through the same G tube site (MICC).

The indications for this procedure are to maintain the nutritional support of patients who are unable to maintain adequate nutrition by mouth or are unable to tolerate nasogastric tubes or for gastric decompression.[74–78] The vast majority of patients have neurologic deficits,[79] have swallowing disorders, or suffer from malignancies. We also use the G tube for gastric decompression in patients with small bowel obstruction or GI dysmotility.

Results and Follow-Up Studies

Our interventional service has placed an average of 160 new G and 25 primary GJ tubes per year since 1995. There were no major complications of bowel perforation or catheter placement through another loop of bowel. In one patient, the catheter was malpositioned, and peritonitis developed, requiring laparotomy. Initially, a small number of patients developed local cellulitis, but routine use of antibiotics before the procedure has almost completely eliminated this complication.[55]

Two types of low-profile silicon button type G catheters are available. These are not placed before 3 months.[80,81] In most cases, the procedure is performed without difficulty by the enterostomy nurse in the outpatient clinic, but if there is any difficulty or if the patient requires sedation, it is performed in the radiology department. The indwelling G tube is removed, and a wire is left in position in the stomach. Lidocaine jelly is applied to the G tube site. Dilatation of the tract is performed if necessary. The more popular Bard button catheter (see Figure 74.3-2) is placed in boiling water, and then with the stiffener in place, the button is introduced into the stomach under fluoroscopic control using the wire in the tract as a guide. Dilatation of the tract may be needed because this is an 18 French catheter. The position is then confirmed radiologically. The other balloon low-profile catheter (MICC) is used usually in smaller children when dilatation is thought to be a problem. This catheter has the advantage of being small (14 French) and can be placed over a wire because it has a central opening. This catheter is best used as a replacement catheter rather than as a primary catheter because it is not

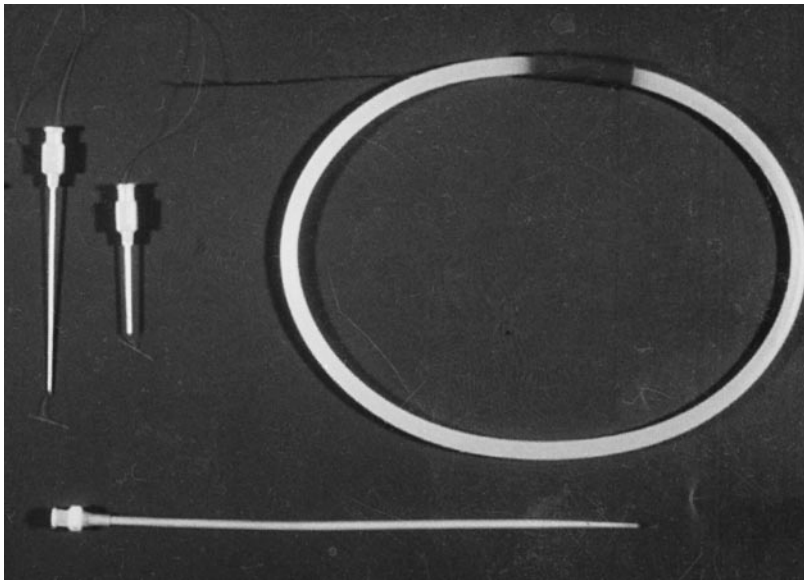

FIGURE 74.3-6 Retention suture is seen with the 19-gauge needle and wire introducer, as well as a Coons fascial dilator.

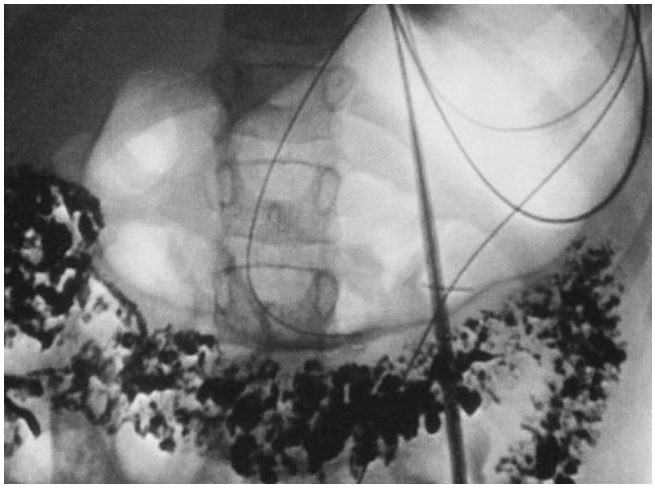

FIGURE 74.3-7 After a second puncture with a Seldinger needle, the tract was dilated with a Coons fascial dilator under fluoroscopic control.

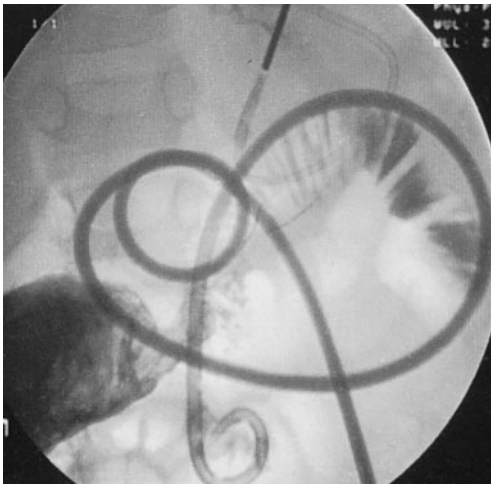

FIGURE 74.3-9 Example of the gastrojejunostomy catheter with the proximal loop in the stomach and the distal catheter in the proximal jejunum with a distal tight pigtail.

very well tapered. The MICC balloon catheter is not as durable as the Bard button catheter because it is more prone to rupture or leakage of the balloon. It is used in selected cases or because of parent preference.

In the small number of patients with proximal small bowel dysmotility, a gastrojejunal feeding tube and a gastric drainage tube are needed; in this situation, we favor the placement of two catheters at separate sites (Figure 74.3-10).

Percutaneous Cecostomy

Percutaneous cecostomy, commonly used in adults for decompression,[82–85] is less frequently performed in children. A surgically described technique of performing reversed appendicocecostomy for performing antegrade enemas has been described.[83] On occasion, a cecostomy is required in patients with severe intestinal pseudo-obstruction or in those with spina bifida and meningomyelocele who have severe constipation or fecal incontinence. The cecostomy permits introduction of a catheter to allow for direct enemas to the large bowel or to allow decompression. The percutaneous procedures can be performed under sedation. Before the procedure, the patient is kept on oral fluids for 2 days. Then, prior to the procedure, a balanced electrolyte lavage solution is infused via a nasogastric tube at a rate of 25 mL/kg/h until rectal effluent is clear of solid fecal material. Antibiotics are given prior to the procedure. A large Foley catheter is introduced into the rectum, and air is introduced to fill the cecum. The technique is similar to that described for placement of a G tube using a transperitoneal or retroperitoneal approach (Figure 74.3-11).[83] There has been a single report of abdominal wall cellulitis secondary to percutaneous cecostomy.[86]

Placement of Nasoduodenal Tubes

Catheters used primarily for duodenal manometry or pancreatic function tests are placed nasojejunally, but if a G tube is present, a gastrojejunal approach is feasible. The latter approach is less invasive and easier. Initially, a direc-

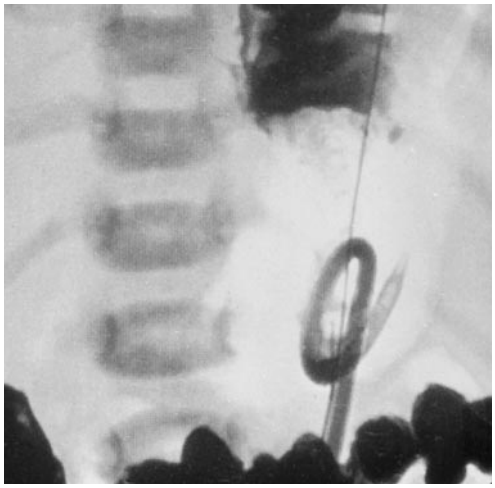

FIGURE 74.3-8 Cope loop gastrostomy tube is tightened and pulled up against the anterior abdominal wall and its position confirmed with contrast.

FIGURE 74.3-10 Gastrostomy and gastrojejunostomy tubes shown in a patient with separate entrance site, with the gastrostomy tube used for gastric aspiration and drainage and the gastrojejunostomy tube for feeding.

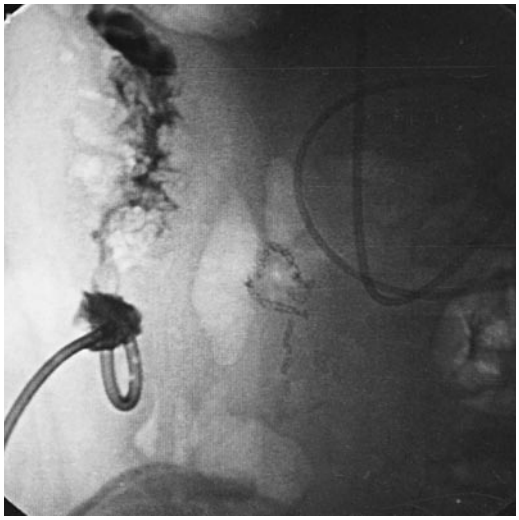

FIGURE 74.3-11 Cecostomy showing a catheter in the right iliac fossa with contrast filling the cecum.

tional catheter and wire are used to get into the proximal jejunum. The manometry catheter has multiple ports and a very small central lumen requiring an 0.018- or 0.025-inch wire over which the catheter is introduced.

Dilatation Procedures

Esophageal Dilatation. Traditionally, esophageal strictures are dilated blindly following the introduction of bougie dilators through the mouth. However, the introduction of balloon catheters for angioplasty has resulted in the development of catheters for dilatation of esophageal strictures.[87] Larger balloons have also been developed for use in the GI tract. Balloon dilatation appears to carry a reduced risk of complications in comparison with traditional bougie dilatation, particularly when used with fluoroscopic guidance. Over a 3-year period, we have done 70 esophageal dilatations in 30 patients carrying a variety of diagnoses, including achalasia,[88] strictures owing to caustic ingestion or radiation,[89] and gastroesophageal reflux. The choice of catheter size depends on the patient and the diameter of the esophagus above and below the stricture. In patients with achalasia, balloons of 25, 30, and 35 mm are routinely used, and a variety of balloon diameters from 4 mm up are used for other cases.

The procedure is performed under sedation or, if indicated, under general anesthetic. Local anesthetic is sprayed into the back of the throat. A nasogastric tube is placed to aspirate any residual gastric contents and to introduce contrast. A bite block is used to keep the teeth apart, and a directional catheter (JB-1) stabilized by a Benston 0.035-inch wire is directed down the esophagus. This procedure can be done through either the transoral or nasal approach. Occasionally, oblique or lateral fluoroscopy is required to direct the wire into the correct position. The length and diameter of the stricture and its relationship to the rest of the esophagus are assessed with contrast. The wire and catheter are placed through the stricture with little risk of damage or perforation. The correct-sized balloon catheter is introduced over the wire. Dilatations are performed by inflating the balloon for 30 seconds, and then, after deflation, the procedure is repeated three times at each level (Figure 74.3-12). Contrast is then injected to assess for any leaks, and the proximal esophagus is aspirated during withdrawal of the nasogastric tube. After the procedure, the patient is kept with nothing per mouth for 24 hours and is monitored for any complications. Occasionally, combined radiologic and endoscopic procedures are performed, and,

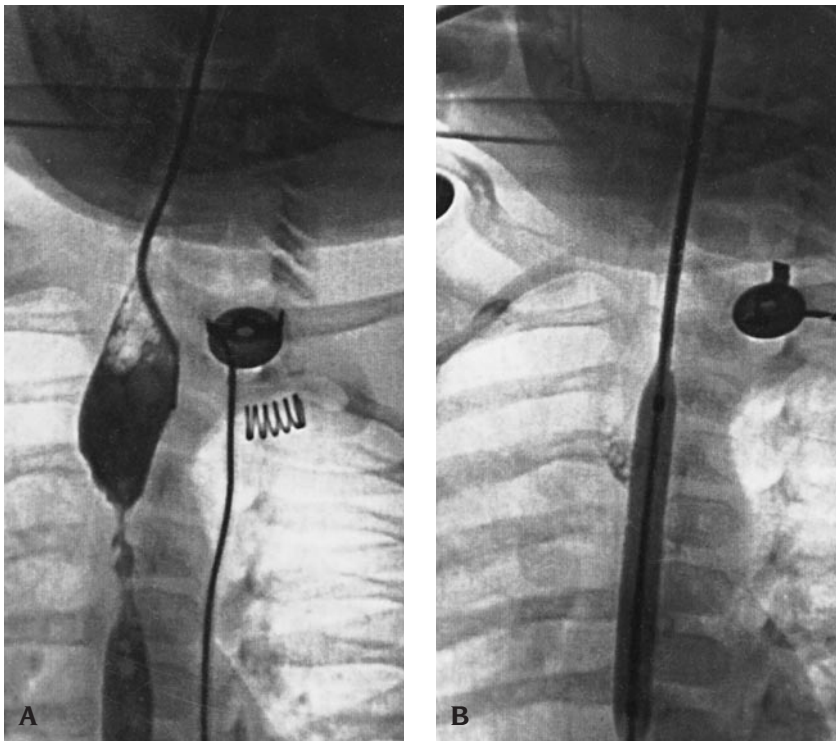

FIGURE 74.3-12 *A*, Esophageal stricture post tracheoesophageal fistula. *B*, Stricture dilatation using a balloon.

if indicated, a corticosteroid is injected directly into the wall of the esophagus to reduce the risk of scarring and inflammation. Repeat dilatation is performed as necessary. In patients with a G tube, esophageal strictures can be dilated via the G-tube site instead of the more traditional oral or nasal approach. Treatment of the underlying cause of the stricture must also be considered, which might include antireflux surgery for reflux esophagitis or chemotherapy or radiotherapy for malignant strictures. Recently, expandable metallic stents have been used for esophageal strictures, particularly in strictures caused by malignancies. We have not had any experience with this technique.

Using the aforementioned approach, no patients have developed mediastinitis or an esophageal leak.[90] However, we have treated several patients who experienced complications from bougie dilatation who required percutaneous drainage of abscesses and leaks.

Dilatation of Other Intestinal Strictures. Occasionally, prepyloric strictures develop following the ingestion of corrosive materials. These patients are usually treated with gastroenterostomy. However, in those patients deemed unsuitable for operative treatment, dilatation may be considered. This technique, which requires the use of a balloon catheter, is very similar to that used for esophageal dilatation. The correct size of the balloon may be difficult to determine because the pylorus is a dynamic channel. Similarly, the technique for the dilatation of the esophageal strictures may be applied to anastomotic strictures elsewhere in the intestinal tract provided that they are accessible.

Colonic strictures may be treated by balloon dilatation via the rectal approach or, if present, through a colostomy (Figure 74.3-13).[91,92] Owing to the higher risk of infection, antibiotic coverage is required. These procedures are not commonly performed in the pediatric setting.

Percutaneous Biopsy of Abdominal Masses

Percutaneous biopsy of abdominal masses is a commonly performed procedure using ultrasonography or CT guidance.[24,93–96] Increased availability and use of image-guided biopsy is a direct result of the development of various cross-sectional imaging modalities, including fluoroscopy, ultrasonography, CT, and MRI.[97,98] As well, thin-walled fine-gauge needles possessing a variety of tips have been developed, which allows for obtaining larger tissue specimens. At the same time, great advances in the histopathologic methods for identifying and grading tumor material determine the need for larger tissue specimens.[99–101] A high proportion of intra-abdominal tumors in the pediatric population are sarcomas, and aspiration biopsies or small-core biopsies fail to provide sufficient tissue for diagnosis. Furthermore, in patients with known primary malignancies, fine-needle biopsies are ideal for confirmation of malignancy, to document metastases, or to identify recurrent tumors.

Prior review of the patient's imaging studies is required, which, together with consultation with responsible physicians, surgeons, and pathologists, will predetermine the probable identity of the tumor, the amount of tissue required, and the potential risks and benefits of using a percutaneous approach. Patient preparation is similar to that with other interventional procedures, and choice of sedation versus a general anesthetic is made on an individual basis. The primary contraindications to percutaneous biopsy include a significant, uncorrectible coagulopathy and/or lack of a safe pathway for needle placement and guidance. The most accessible lesion is identified if they are multiple, and a skin entrance site is chosen. If it is a large lesion, the periphery of the lesion is biopsied preferentially to avoid the risk of biopsying a central necrotic area. Most intra-abdominal biopsies are performed under

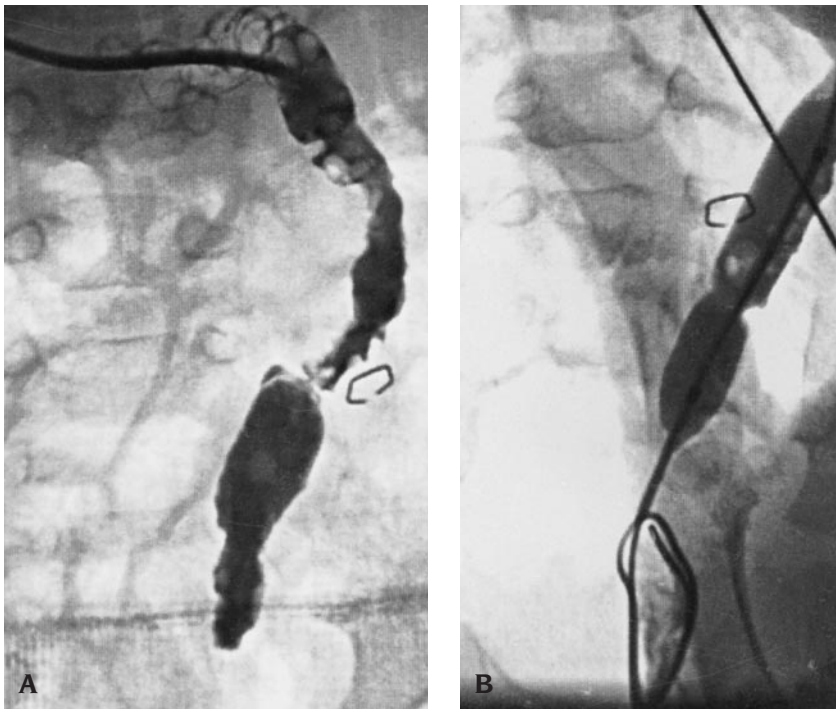

FIGURE 74.3-13 *A*, Colonic strictures following necrotizing enterocolitis. *B,* Stricture dilated via the colostomy with a 10 mm balloon.

ultrasonography guidance (Figure 74.3-14). CT is seldom used because it is time-consuming and expensive and requires patient cooperation or a general anesthetic. Ultrasonography is ideal for biopsies of solid organs such as the liver, accessible solid lesions arising from the pancreas or spleen, or other intra-abdominal masses. The chosen puncture site is marked prior to the procedure using a permanent marker. The patient is positioned for the procedure to allow optimum access. The overlying skin is then prepared and draped using sterile technique. After lidocaine is introduced in the subcutaneous tissues, a small nick is made in the skin with a scalpel blade.

A variety of needles are available for percutaneous biopsies. They differ in gauge, length, and mechanism of obtaining tissue. They can be categorized into aspiration or cutting mechanisms and automated or manual devices.

The Chiba and Turner needles are both aspiration biopsy needles (20–23 gauge). The Chiba needle has a beveled edge of 25° and the Turner needle of 45°. Aspiration needles can be used for obtaining cytologic and bacteriologic material. Occasionally, histologic material may be obtained, especially with the Turner needle, owing to the acutely beveled edge.

Cutting needles, categorized as end-cutting and side-cutting types, are designed to increase the probability of obtaining histologic material. The end-cutting needles either have an end-cutting bevel or a serrated edge, which allows for optimal cutting and retention of core material. The side-cutting needles include the Truecut, the automated, reusable Biopty (Bard, Murray Hill, NJ) (Figure 74.3-15), and minopty guns (Meditech, Westwood, MA) (Figure 74.3-16). The Autovac needle (Angiomed, Karlsruhe, Germany), an end-cutting needle, is automated to allow a variety of depths of tissues to be biopsied, ranging from 1 to 4 cm (see Figure 74.3-16). This needle, which permits the operator to guide the needle with ultrasonography, is ideally suited for most abdominal core biopsies. In general, fine needles (20–23 gauge) should be used when there is a risk of entering vital structures such as blood vessels or bowel loops.[102] Larger needles may be selected for percutaneous biopsy in certain situations in which there is no intervening vital structure, when a retroperitoneal or a posterior extraperitoneal approach is used, or when round cell tumors are suspected.

FIGURE 74.3-15 Bard resterilizable Biopty gun with disposable needles in (14, 16, and 18 gauge) and a 2.3 cm throw.

Percutaneous Liver Biopsy. Blind percutaneous biopsy of the liver has been performed for a number of years, with a high success rate. However, biopsies of focal hepatic lesions are best performed with image guidance using either ultrasonography or CT. It is possible to biopsy a lesion as small as a few millimeters in size under ultrasonography control (Figure 74.3-17). We routinely use an 18-gauge Surecut (TSK Laboratory, Tochigi, Japan) needle for biopsy of diffuse parenchymal lesions and a Surecut, Autovac (Angiomed), or Biopty gun for the biopsy of focal lesions.[103–105]

In patients with coagulopathies, transcutaneous biopsy of liver lesions can be performed coaxially with removal of the biopsy needle and then introduction of Gelfoam or coils to reduce the risk of bleeding.[106–108]

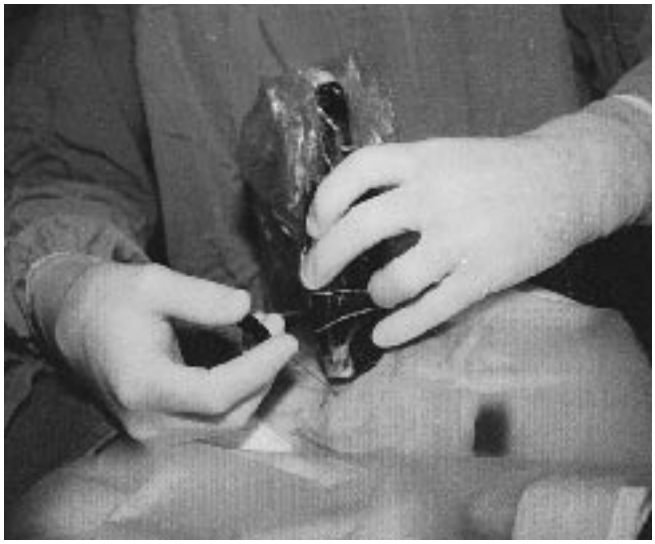

FIGURE 74.3-14 Ultrasonography guidance is shown using an ultrasound probe with a sterile cover and freehand guidance.

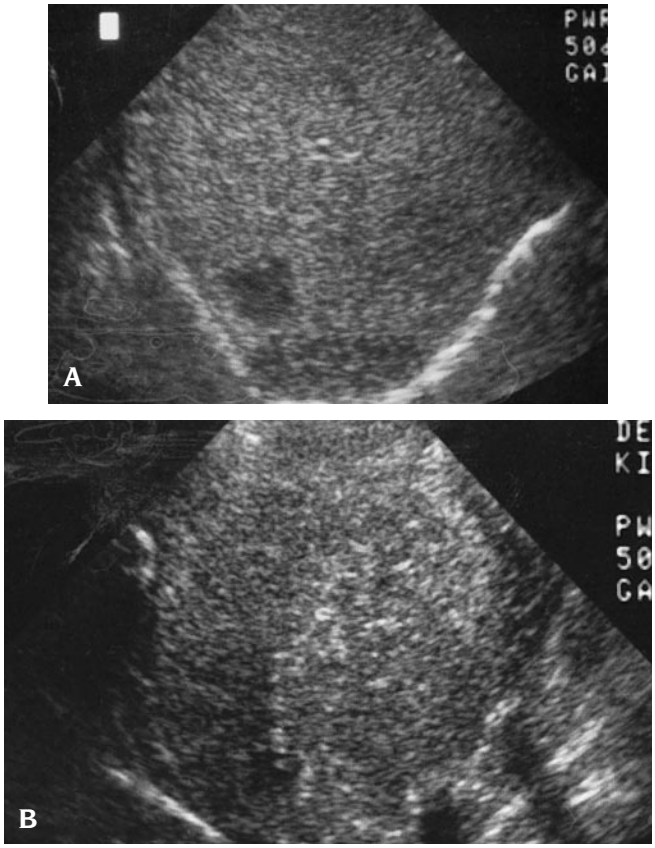

FIGURE 74.3-17 *A*, Deep 5 mm lesion is seen in the posterior aspect of the right lobe of the liver on ultrasonography. *B*, Biopsy under ultrasonography guidance is performed successfully with the needle seen traversing the lesion.

Transjugular Liver Biopsy. Transjugular biopsy is reserved for patients with severe coagulopathies that are uncorrectable.[109–111] This procedure is usually performed under a general anesthetic with the patient in the supine Trendelenberg position. The right internal jugular vein is accessed percutaneously, and a wire and sheath are introduced. Selective catheterization of the right hepatic vein is performed. Wedge pressures and free hepatic and inferior vena cava pressures are taken. A wedge of hepatic and free hepatic venogram is performed. The biopsy is performed with a Colapinto (Cook)-type biopsy needle with the tip of the needle directed posteriorly and a sheath placed within the right hepatic vein (Figure 74.3-18). The biopsy technique involves rapid puncture with aspiration. Saline is injected to release the core of liver tissues. Postprocedure venograms are performed to exclude perforation of the liver capsule (Figure 74.3-19). Transvenous biopsies can also be performed from a femoral approach using a claw-type biopsy forceps through a sheath and catheter.

Transcatheter biopsy of hepatic lesions is not commonly required in the pediatric setting because primary hilar lesions are rare. These are performed using a brush biopsy technique or by introducing a needle through the biliary drainage catheter, and biopsies are made at the site of the mass.[112] Fluoroscopy can also be used to guide a biopsy needle to a presumed tumor site shown with percutaneous transhepatic cholangiography (PTC) or as an area of stricture or mass.

Pancreatic Biopsy. Primary pancreatic tumors are relatively rare in pediatric patients. The principles for obtaining a biopsy are similar to those for other solid masses. The decision to perform a percutaneous biopsy depends on the extent of the primary lesion, the presence of secondary pathology, and the surgical alternatives. Direct visualization with ultrasonography or CT[111] is usually required to allow accurate placement of needles for small pancreatic lesions.[106,113,114]

Lymph Node Biopsy. Percutaneous biopsy of intra-abdominal lymph nodes can be accomplished with fluoroscopic guidance following opacification by lymphangiography. In the case of suspected lymphoma, percutaneous lymph node biopsy can be performed using ultrasonography or CT guidance. The results obtained from percutaneous lymph node biopsy are generally not as rewarding as those of biopsies of other organs.

Splenic Biopsy. Splenic aspiration and biopsy under ultrasonography or CT guidance are usually indicated for the histologic diagnosis of the etiology of diffuse splenomegaly[115] or focal masses. Fine-needle biopsy may be sufficient for the confirmation of known tumors or identifying an organism, but core biopsy with either 20- or 18-gauge needles provides a much better yield. In our experience in those patients with normal clotting, there is little risk of intraperitoneal hemorrhage, even with the larger needles.

Percutaneous Aspiration and Drainage

Percutaneous drainage of abdominal abscesses has proved to be one of the most successful and gratifying of all interventional procedures. In a relatively short time, it has achieved a remarkable degree of acceptance within the surgical community.[116] Intra-abdominal abscesses can now be

FIGURE 74.3-18 Subtracted image with a sheath seen in the right hepatic vein in the position ready for placement of the Colapinto biopsy needle.

FIGURE 74.3-19 Postprocedure venogram is performed to exclude extravasation of contrast and perforation.

aspirated and drained percutaneously, with a "cure" rate approaching 85%.[117–121] A variety of other intra-abdominal fluid collections can be safely aspirated and drained percutaneously, including hematomas, seromas, lymphoceles, bilomas, pancreatic pseudocysts, and loculated ascites. In general, the technique is similar for all fluid collections. This involves guided introduction of a needle and aspiration of the material. If drainage is required, the needle is exchanged over a wire with a catheter. Contraindications to aspiration and drainage include the absence of a safe access route, which would include the transgression of major organs such as liver, spleen, or kidney; the presence of overlying blood vessels and nerves; or sterile spaces such as the peritoneum or pleura. The presence of coagulation abnormalities is a relative contraindication.

The procedure is performed under sterile conditions. The skin is prepared and draped, and 1% lidocaine is introduced. The technique usually involves placement of a 22-gauge Chiba needle into the collection under ultrasonography guidance. The collection is aspirated, and if drainage is required, a 0.018-inch wire is exchanged using a Neff introducer system (Cook) for a 0.035-inch wire. The tract is dilated, and a catheter is introduced. An 8.5 or 10 French all-purpose drainage catheter (Meditech) is usually sufficient for most fluid collections. A larger-caliber catheter such as a Sump drain or a Thalquick (Cook) abscess drainage catheter is used if necessary. The abscess or fluid collection is drained using a closed system drainage bag (Medics, Hilliard, OH) either by gravity drainage or suction using a Hemovac (Zimmer, Dover, OH). For large or superficial lesions, a trocar technique can be used with direct introduction of an all-purpose drain (Meditech), which is supplied with a sharp inner stylet.

Monitoring Drainage Procedures. Regular saline irrigation is used to help clear the cavity of pus or particulate debris. Antibiotics are continued postprocedure until the signs and symptoms of infection have resolved. The volume of drainage is reviewed daily, and if there is a sudden drop in volume, a block in the catheter should be suspected. If the volume increases dramatically, this might represent development of a fistula or leak. A sinogram, using dilute water-soluble contrast medium, should be performed 1 to 2 days after the initial drainage. This will define the extent of the abscess and its communication with other structures. Ultrasonography or CT should be repeated 3 to 4 days after the procedure and again immediately before the catheter is removed. Percutaneous drainage may not be successful because of a persistent fistula, necrotic material within the collection, viscous pus, multiloculated (or multiple) abscesses, or a large abscess cavity. To improve the success of drainage and to minimize complications, bowel loops should be avoided and sterile spaces should not be contaminated. Catheter manipulation should be minimized to reduce the spread of infection. Tissue trauma should also be kept to a minimum to reduce complications, and a large catheter should be used if the collection is viscous or contains cellular debris.

Abscesses. *Hepatic Abscess.* Primary hepatic abscesses are relatively uncommon in pediatrics. Pyogenic abscesses are most commonly seen in children with chronic granulomatous disease or those immunocompromised owing to treatment.[122] They are also seen as a complication of appendicitis with portal vein thrombophlebitis.

Amebic liver abscesses are seen in Southeast Asia, Africa, and South America and are typically single and loculated in the posterosuperior or anteroinferior aspect of the right lobe of the liver. These can be complicated by rupture intra-abdominally or even into the pleural space. Depending on the size of the abscess, they can be treated either by antibiotics (metronidazole) or by percutaneous drainage (Figure 74.3-20).

In the immunocompromised patient, microabscesses of fungal origin are often present. These are usually too small to require drainage but may be aspirated to make the diagnosis.[123]

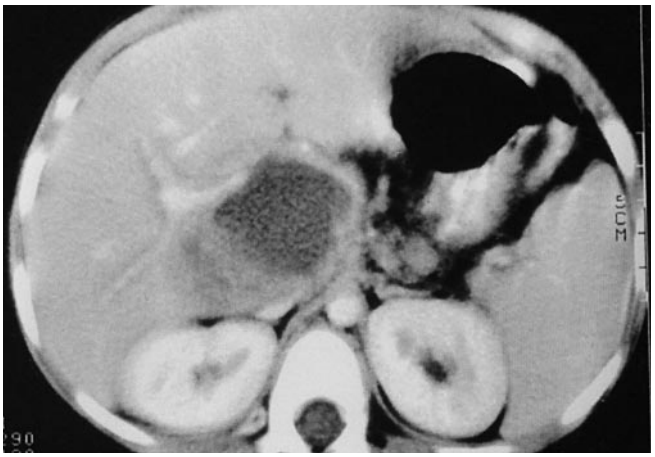

FIGURE 74.3-20 A hypodense collection is seen in the caudate lobe of the liver, which is well seen on computed tomography and is best drained under ultrasonography and fluoroscopic guidance.

Subphrenic Abscess. Subphrenic abscesses arise postoperatively or occur quite commonly in childhood following a ruptured appendix. Subphrenic abscesses are frequently difficult to access, and a transhepatic or intercostal route may be necessary (Figure 74.3-21). A combination of CT and ultrasonography guidance may be required.[124,125]

Splenic Abscesses. Splenic abscesses can be aspirated or drained successfully under ultrasonography control.[126] Most cases can be treated effectively with repeated aspiration or catheter drainage with a relatively low rate of complication (13%) (Figure 74.3-22).[127] Splenectomy should be performed only in splenic abscesses that are not accessible percutaneously and in those cases with percutaneous drainage failure.[127]

Pelvic Abscess. Pelvic abscesses are often deep and obscured by overlying bowel, vessels, urinary bladder, and bony pelvis (Figure 74.3-23). If they are superficial and easily visualized under ultrasonography or CT guidance, transabdominal access for drainage can be performed. If the lesions are deep and anterior to the rectum, a transrectal approach can be used.[128] The patient is placed in the decubitus position. Ultrasonography is performed transabdominally to identify the abscess and to place the needle (Figure 74.3-24). Guidance can also be obtained with a transrectal ultrasound probe.[129–131] An enema tip catheter is introduced into the rectum, and a trocar needle is advanced to the tip of the catheter. Under ultrasonography control, the needle and stylet are advanced through the anterior rectum into the abscess. This is followed by placement of a wire, dilatation, and catheter placement. We have performed this procedure in 30 patients and have shown that we can achieve a significant reduction in the time of recovery when compared with the traditional transabdominal or surgical approach (Figure 74.3-25). These deep abscesses can also be drained under CT guidance via the paracoccygeal route.[132]

FIGURE 74.3-22 A posterior hypodense lesion seen in the spleen, which was aspirated successfully under ultrasonography guidance.

FIGURE 74.3-21 *A*, Subphrenic abscesses on computed tomography just below the right hemidiaphragm posterior to the liver. *B*, Lateral view of fluoroscopy seen with a needle entering the abscess. Guidance was performed under ultrasonography and further wire and catheter placement was performed under fluoroscopy.

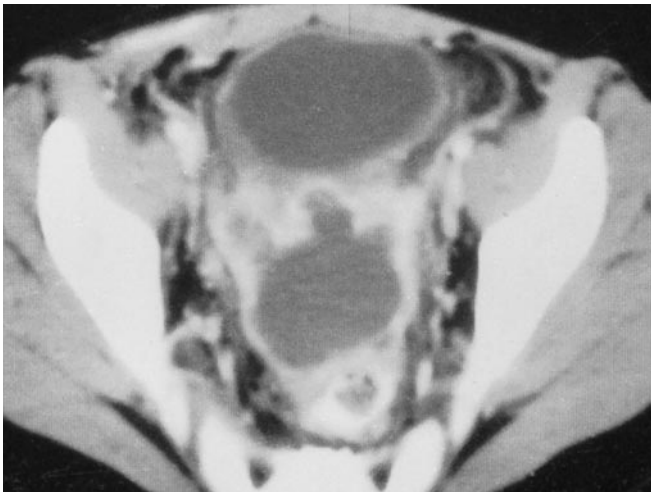

FIGURE 74.3-23 Deep pelvic abscess seen posterior to the bladder (*arrow*) with enhancing rim and the rectum seen posteriorly.

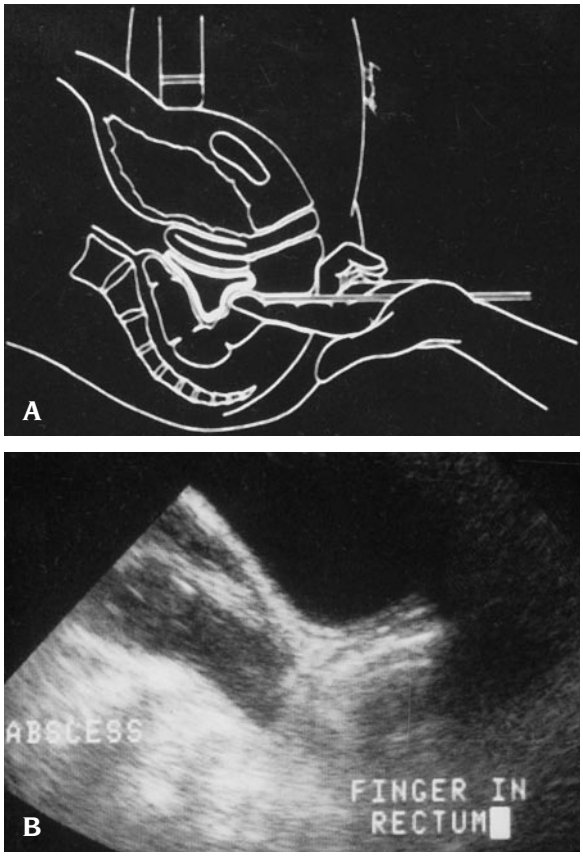

FIGURE 74.3-24 *A*, Diagram of transabdominal ultrasonography with rectal placement of the index finger with a trocar needle anterior to the index finger seen through the distended urinary bladder. *B*, Ultrasonographic view of the same patient with the finger seen in the rectum. The abscess posterior to the bladder is seen in the longitudinal section.

Interloop Abscess. Because of the position and the overlying bowel loops, these abscesses are difficult to access. It is best to assess interloop abscesses with CT to determine the precise location. Aspiration can be performed under CT or ultrasonography guidance, transgressing bowel with a 22-gauge Chiba needle.[133]

Pancreatic Pseudocyst. Pseudocysts develop following acute pancreatitis, which in the pediatric age group can be due to multiple etiologies.[134] They present as low-density collections on CT and hypoechoic masses on ultrasonography (Figure 74.3-26). Most pseudocysts resolve spontaneously over a period of weeks or months. If the patient is asymptomatic, a pseudocyst can be drained percutaneously or preferably transgastrically. Under ultrasonography guidance, the position of the pseudocyst is marked on the skin of the patient. The stomach is then inflated using a nasogastric tube, and a trocar needle (18 gauge) is introduced through the anterior and posterior stomach walls into the pseudocyst behind. After the pseudocyst has been drained, the needle is replaced with a wire, the tract is dilated, and a Cope loop catheter is introduced into the pseudocyst. The pseudocyst is left to drain for 4 to 6 weeks. A cystogram may be performed to assess communication with the pancreatic duct. Once the catheter is removed, residual drainage will continue through the fistulous tract into the stomach (Figure 74.3-27).

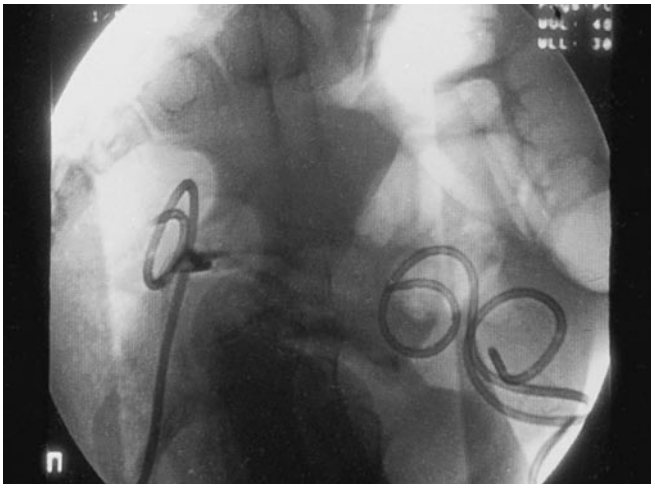

FIGURE 74.3-25 Lateral radiograph of a patient who has a transrectal drain in position and two transpercutaneous drains seen anteriorly for the treatment of a ruptured appendix.

Pancreatic Abscesses. Abscesses related to pancreatitis can be treated percutaneously if a safe access route is available. Percutaneous aspiration of these lesions can also be performed for diagnostic purposes. Phlegmonous pancreatitis does not respond to simple drainage and is not suited to simple percutaneous drainage because of the nature of the tissues (Figure 74.3-28).

Biliary Intervention

PTC, percutaneous transhepatic transcholecystic cholangiography (PTTC), percutaneous biliary drainage, dilatation of biliary strictures, and stone removal are established interventional techniques in the diagnosis and management of biliary tract disease.[135–140] Owing to the advent of liver transplant, there has been an increase in the need for

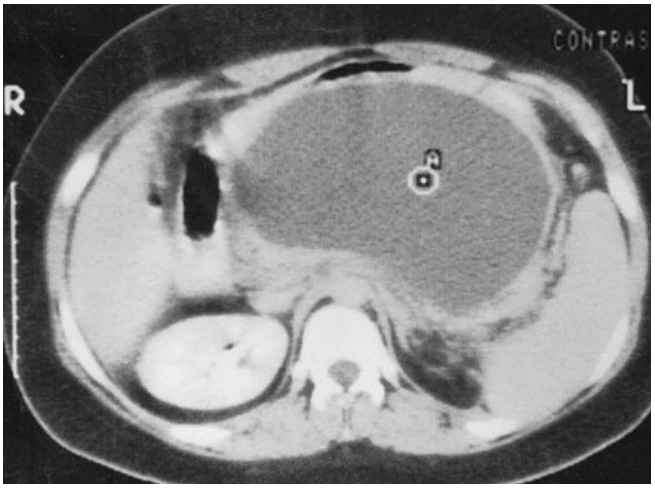

FIGURE 74.3-26 A computed tomographic scan of an abdomen showing a large, relatively hypodense collection in the midabdomen posterior to the stomach consistent with a large pseudocyst.

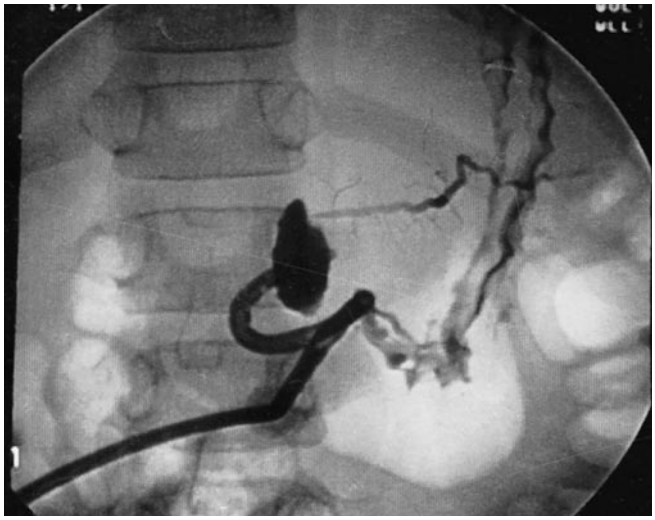

FIGURE 74.3-27 Transgastric drainage of a pseudocyst had been performed, with 6 weeks of drainage. A contrast study through the tube demonstrates filling of the small remaining cyst and the distal part of the pancreatic duct. Some contrast is draining into the stomach.

these procedures in the pediatric population.[141–143] Endoscopic retrograde cholangiographic procedures are indicated in those patients with intact common bile ducts and where access is possible.[144]

Percutaneous Transhepatic Cholangiography

The primary indications for PTC or PTTC include the differentiation of medically treatable from surgically treatable causes of cholestasis, demonstration of intrahepatic calculi, or extrahepatic choledocholithiasis. In addition, cholangiographic investigations are invaluable to diagnose a congenital abnormality such as biliary atresia or choledochal cyst and inflammatory conditions such as sclerosing or ascending cholangitis. They can also be used to evaluate surgical conditions such as biliary-enteric anastomoses and to assess if intrahepatic abscesses communicate with the biliary radical. Contraindications include uncorrectable bleeding disorders or a previous life-threatening reaction to iodinated contrast material. Vascular hepatic tumors and vascular malformations, as well as ascites, are relative contraindications.

General anesthesia is used for most children because the procedure requires significant patient control, especially in those with small biliary radicals. If there is a strong suggestion of cholangitis, triple antibiotics (ampicillin, gentamicin, and metronidazole) are started 6 hours before the procedure. If there is no obvious cholangitis, a single IV dose of cefazolin (30 mg/kg) is given prior to the procedure.

Cholangiograms are performed with a 22-gauge Chiba needle with ultrasonography guidance.[145] We make use of a hiliter needle (Inrad), which is better seen on ultrasonography. All procedures are performed under ultrasonography guidance (Figure 74.3-29). After prior imaging investigation has been reviewed, a choice is made between a right hepatic, left hepatic, or transcholecystic approach. The right hepatic approach at the midaxillary line is most commonly used (Figure 74.3-30). Fluoroscopy of the upper abdomen is performed to identify the position of the chest cavity. The right-sided approach has the disadvantages of transgressing pleura, increased pain owing to the intercostal approach, and the possibility of intervening bowel. The left-sided approach is more vertical and may allow easier access to the common bile duct via the common hepatic duct. This is a safer approach because the pleura is not being transgressed.

Transcholecystic studies are performed in patients who do not have dilated bile ducts or if repeated attempts at transhepatic cholangiography have been unsuccessful. This procedure is also performed using a 22-gauge needle under ultrasonography guidance, with a transhepatic route (Figure 74.3-31). Once the gallbladder is penetrated, a specimen is obtained, and dilute contrast is injected. After completion of the procedure, it is important to drain the gallbladder completely to reduce the risk of bowel peritonitis. In my own experience, the success rate with trans-

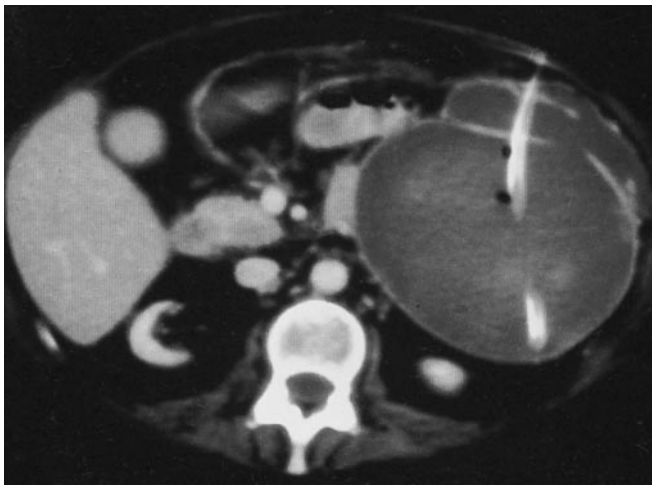

FIGURE 74.3-28 A complicated pancreatic pseudocyst with hemorrhage and infection. Percutaneous drainage was attempted but was unsuccessful owing to the thickness of the materials.

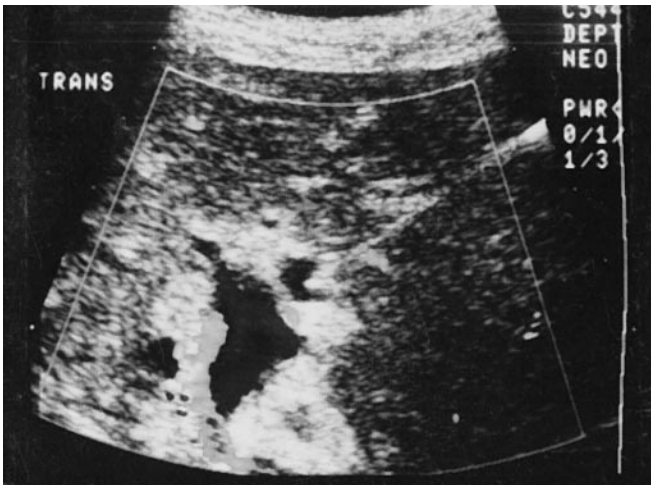

FIGURE 74.3-29 Ultrasonography guidance is used to place a 22-gauge Chiba needle into mildly dilated bile duct seen close to the portal vein and hepatic artery.

FIGURE 74.3-30 Right hepatic approach into transplanted reduced left hepatic lobe. A relatively normal-sized duct is seen with a focal biliary stricture just distal to the puncture site (*arrow*).

hepatic cholangiography in the patient with undilated intrahepatic ducts is approximately 70%, whereas the success rate of transcholecystic cholangiography approaches 100%. Our experience with 30 PTTCs has been very successful, with only one complication in our first patient, who developed a bile leak. In this case, the procedure was not performed under a general anesthetic.

Biliary Drainage

The decision to perform biliary drainage depends on the nature of the pathology. Indications include malignant obstruction with associated cholangitis, pruritus with liver dysfunction, biliary stricture owing to previous surgery, or sclerosing cholangitis. Drainage is also performed in patients with bile leaks, which is a relatively frequent postoperative complication following hepatic transplant.[146–148]

After cholangiography has been performed, it is important to carefully select the correct duct to drain. The duct should be entered peripherally, thus reducing the risk of damage to major vessels and increasing the purchase (ie, the length of catheter within the ductal system). The puncture site should be chosen so that there is a minimum of curvature, thus allowing for the forces during dilatation to be directed inferiorly. A 22-gauge Chiba needle is introduced into the selected duct, either under fluoroscopic guidance with a C-arm unit or with ultrasonography. Bile is aspirated, and a 0.018 Mandril (Cook) wire is introduced. The stricture is usually transgressed using selective wires and dilators. If there is evidence of cholangitis, manipulation should be kept to a minimum and drainage achieved as soon as possible. Further manipulation can occur once infection has resolved.

The ultimate goal of biliary drainage is to place a 10 French or larger catheter in position. We use a Cope loop catheter and hole punch to fashion the catheter according to the patient's size. After the stricture has been dilated or the obstruction has been transgressed, the tube should be allowed to drain externally until the bile is clear. Subsequent daily irrigations can be done with the catheter closed (Figure 74.3-32).

Biliary Dilatation

Dilatation of a biliary stricture is usually performed with a balloon catheter (Figure 74.3-33).[149] The size of the dilatation should be gauged from the size of the normal duct proximal and distal to the obstruction. The dilatation is performed, and a catheter with multiple side holes is inserted. Occasionally, an internal stent may be used. The polyethylene type of internal stent should be considered only in patients with a short life expectancy or irreversible hepatic dysfunction.[150] We have made use of a wall-expandable stainless steel stent in a patient who developed an anastomotic stricture after hepatic transplant. The patient has remained symptom free, with no evidence of obstruction for a period of 18 months (Figure 74.3-34).[151]

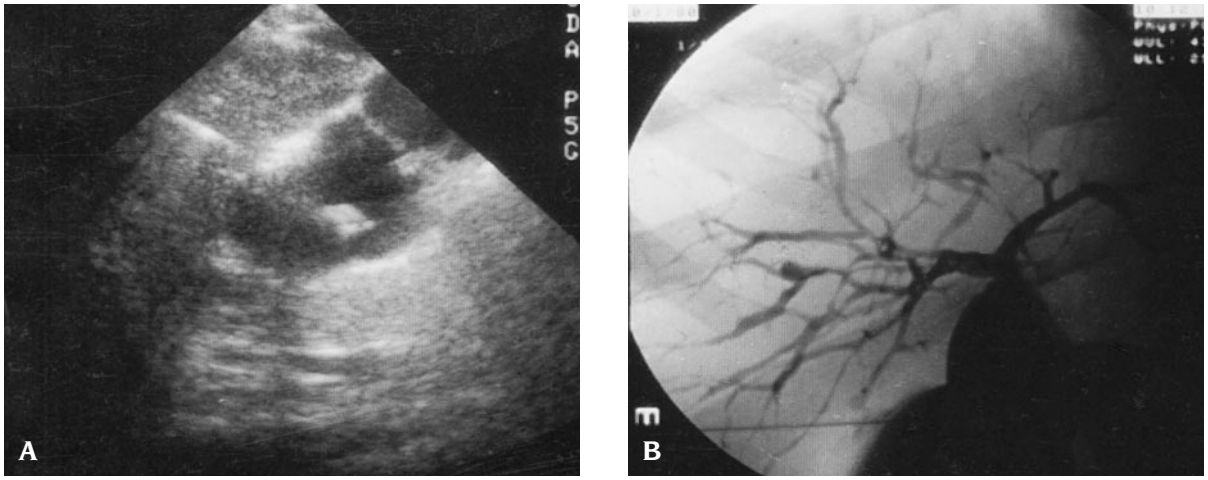

FIGURE 74.3-31 *A*, Sonogram of transhepatic placement of a Chiba needle into the gallbladder for the performance of a cholecystic cholangiogram. *B*, Contrast is injected through the catheter, and this demonstrates filling of the intrahepatic radicals, which demonstrate the features of sclerosing cholangitis with bleeding and irregularity of the bile ducts.

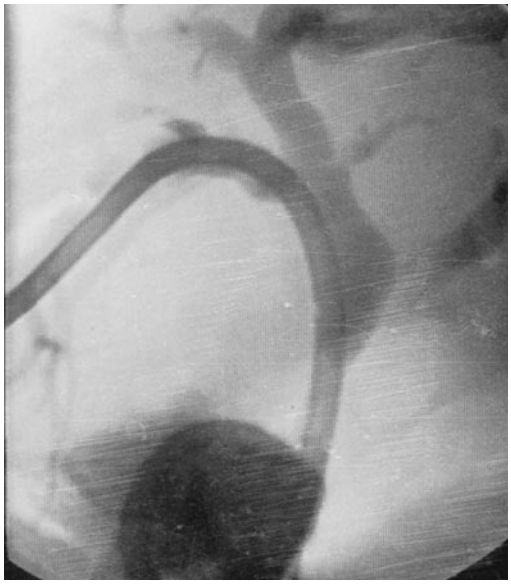

FIGURE 74.3-32 Internal and external biliary drainage has been performed in a patient with a focal stricture at the site of the choledochal jejunostomy anastomosis.

FIGURE 74.3-34 An internal metallic wall stent has been placed in a patient with a persistent choledochal jejunostomy stricture that was not responsive to repeated biliary dilatation.

T-Tube Cholangiography and Biliary Intervention

T-tube cholangiography is performed in patients who have a T tube following surgical removal of the gallbladder or in patients who have had a total liver transplant with a bile duct anastomosis. Retained stones or debris can be removed via the tract. The tube is usually left in place for 6 weeks to form a fistulous tract. The T tube is then removed over a wire, a catheter is introduced, and the calculi or debris is removed with a basket. This is best performed using a steerable Burhenne (Cook)-type catheter.

Biliary debris or calculi can be removed percutaneously. After the correct duct has been accessed, a sheath is introduced followed by a basket, which is then used to grab or crush the calculi prior to removal (Figure 74.3-35).[152] Debris can be removed in a similar manner.

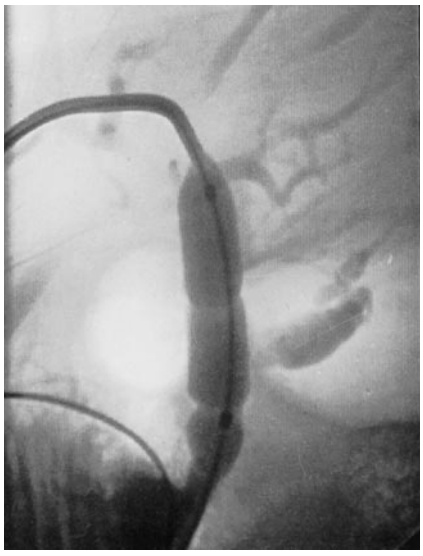

FIGURE 74.3-33 Dilatation of a choledochal jejunostomy stricture with a balloon dilator, with areas of narrowing seen in the balloon.

Transhepatic Portal Venous Intervention

The portal venous system can be accessed percutaneously quite easily using ultrasonography guidance. The technique is similar to that used for biliary cannulation using a 22-gauge Chiba needle followed by a 0.018 wire and then an exchange system. This allows for measurement of pressures, embolization of bleeding varices, and dilatation of portal venous anastomotic strictures. It can also be used to embolize portal venous to hepatic venous malformations. Dilatation of portal venous strictures after hepatic transplant can also be achieved (Figure 74.3-36).

Transjugular Intrahepatic Portosystemic Shunts

Transjugular intrahepatic portosystemic shunting (TIPSS) is a recently developed procedure for the treatment of GI bleeding from varices owing to portal hypertension. It involves the creation of a parenchymal tract from the hepatic to portal vein, which is given support by the insertion of a metallic stent.[153–155]

TIPSS is described as a safe, effective, short-term procedure for the reduction of portal pressure. The short-term success rate is reported to be over 90%. The long-term outlook for the procedure will ultimately depend on the treatment and prevention of intimal hyperplasia within the shunt and draining veins.

The procedure is highly effective in lowering portal pressure and controlling acute variceal bleeding. However, its long-term effectiveness in preventing recurrent bleeding and as a treatment for ascites has not been clearly established when compared with conventional therapy. In addition, acute and chronic complications of the procedure are not insubstantial.

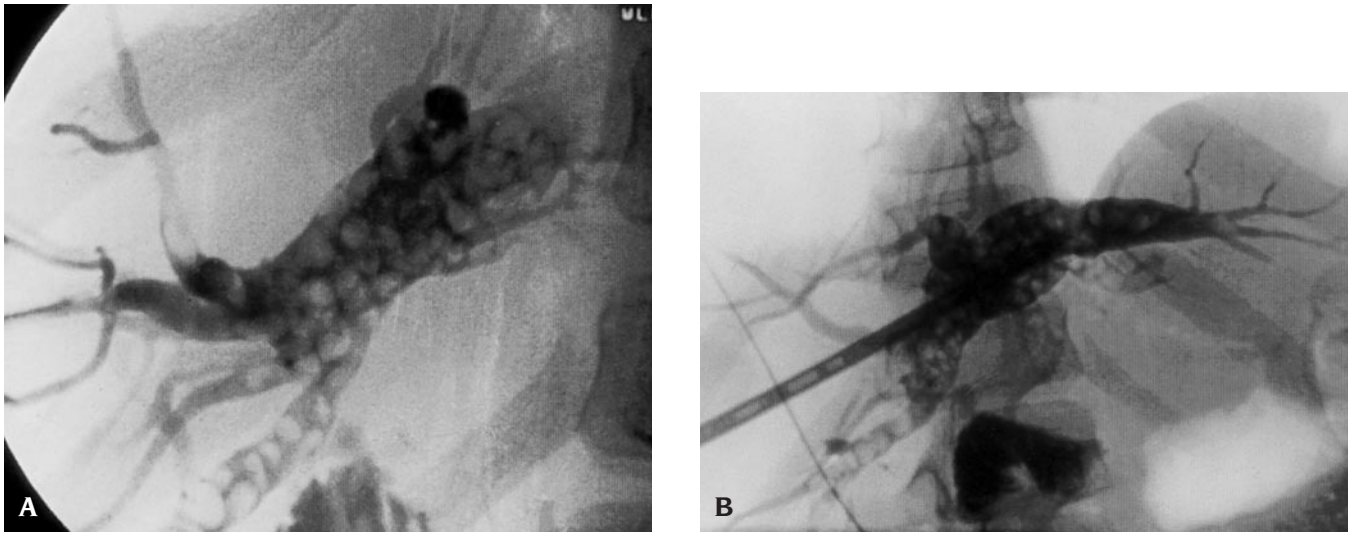

FIGURE 74.3-35 *A*, Cholangiogram demonstrating the biliary system of a patient with numerous calculi. *B*, Calculi were removed with the placement of a sheath and basket. This required repeated removal of calculi.

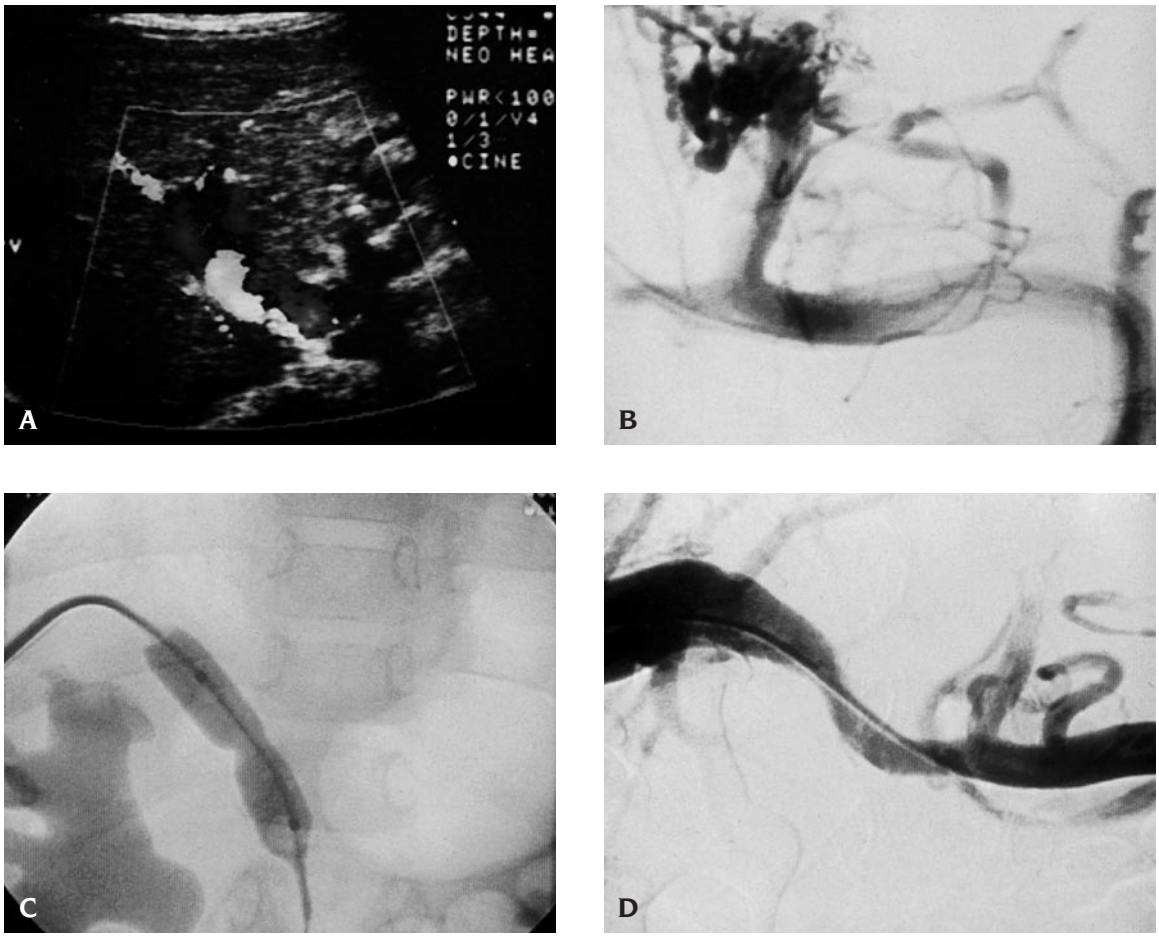

FIGURE 74.3-36 *A*, Ultrasonography of the portal venous system showed turbulence, and color Doppler ultrasonography showed changes consistent with a portal venous stricture. *B*, Transhepatic placement of a catheter in the portal venous system demonstrated gastric varices and prominence of the cardinal veins and esophageal varices. Portal hypertension was due to a portal venous anastomotic stricture. *C*, Balloon dilatation of the portal-venous stricture. *D*, Postdilatation venogram demonstrated resolution of the portal hypertension and pressure differential and antegrade flow into the liver.

The two main indications are (1) acute variceal bleeding uncontrolled by medical treatment, including sclerotherapy, and (2) recurrent variceal bleeding in patients who are refractory or intolerant to conventional management.[156] TIPSS is preferable to surgical shunting in Child's class C patients for both indications and in patients with refractory bleeding awaiting liver transplant.

Unproven indications are initial therapy of acute variceal hemorrhage, prophylactic therapy to prevent recurrent variceal hemorrhage, refractory ascites, and Budd-Chiari syndrome and to reduce intraoperative morbidity during liver transplant surgery. Contraindications include heart failure, polycystic liver disease, infection, severe hepatic encephalopathy, and fulminant liver failure.

Minor procedural complications occur in 10% of cases. Severe, life-threatening complications occur 1 to 2% of the time and include hemoperitoneum, hemobilia, acute hepatic ischemia, and pulmonary edema. Chronic complications include portal vein thrombosis, hemolysis, shunt stenosis, and hepatic encephalopathy. The latter may occur in 15 to 30% of cases and is associated with prior history of hepatic encephalopathy, severe liver disease, an older age group, large shunt diameters, and low final portosystemic gradient. Most respond to medical therapy, although the occasional shunt has to be occluded.[156]

The procedure is approached via puncture of the right internal jugular vein. A wire is then introduced, and the right hepatic vein is selectively catheterized. The catheter is wedged, and pressures are recorded. A wedged hepatic venogram may demonstrate the portal vein. The catheter is replaced by a sheath, and a Colapinto transjugular biopsy needle is introduced into the sheath and into the hepatic vein. The needle is directed anteromedially 2 to 3 cm into the parenchyma. Gentle aspiration is applied as the needle is slowly withdrawn, and when blood appears, contrast is injected to confirm entry into the portal vein or a branch. A wire is then introduced into the portal vein. The parenchymal tract is dilated with an 8 mm angioplasty balloon. The balloon is deflated, and the transjugular catheter and 9 French sheath are advanced into the portal vein. The transjugular catheter and balloon are removed, and a wall stent catheter, with a balloon attached, is introduced over the wire across from the hepatic vein to the portal vein. The balloon is inflated to distend the stent. Portal venous pressures are recorded, and venography is performed. This usually demonstrates the shunt and shows hepatopedal flow to the inferior vena cava with collapse of the varices. Rarely, the varices persist despite a well-functioning shunt, in which case, embolization is performed. If the shunt is felt to be open but the pressure remains above 12 mm Hg, the stent is dilated up to 10 mm.

Problems with accessing the portal vein do occur. In these circumstances, use of ultrasonography or the placement of a wire into the portal vein under ultrasonography control may help to direct the portal venous transjugular puncture. Some pain may be experienced during the procedure; for this reason, the procedure is best performed under a general anesthetic. If the stent is not long enough or does not cover the entire length of the parenchymal tract, an additional stent can be deployed to complete the shunt; parallel shunts may be used in patients with persistent portal hypertension. Doppler ultrasonography is used to monitor shunt patency approximately every 3 months, and venography is performed twice yearly. If shunt stenosis or occlusion is suspected, the patient is restudied. Stenosis is treated by angioplasty first and, in some cases, by additional stent placement. Thrombus within the shunt can be easily pushed into the portal vein using a soft occlusion balloon catheter. The clot presumably passes into the reopened varices and occludes them.[157–159]

4. *Radionuclide Diagnosis*

David Casson, BA, MBBS, MRCPI
Helen J. Williams, MB, ChB, MRCP, FRCR

GENERAL ASPECTS OF PEDIATRIC NUCLEAR MEDICINE

Nuclear medicine is the branch of medicine and imaging that uses radionuclides (radioisotopes) for diagnostic and therapeutic purposes. The radioisotope is bound to a compound to form a radiopharmaceutical that is often organ specific. Images are produced by mapping the distribution of radioactivity of the administered radiopharmaceutical in the body using radioactivity detectors. The most commonly used detector is the gamma camera. In most studies, planar images are produced, but by moving the gamma camera around the patient, a three-dimensional data set is obtained and can be reconstructed and viewed in different planes, a technique known as single photon emission computed tomography (SPECT). This technique is used routinely in certain areas of nuclear medicine (eg, cardiac and brain imaging). In gastrointestinal radionuclide imaging, SPECT may be used to detect small amounts of isotope uptake or excreted isotope not visible on planar scans, perhaps owing to overlying structures.

Nuclear medicine studies provide information about organ function, and although they give some anatomic information, this is often limited, as is their ability to differentiate between pathologies, which ultimately have the same effect on organ function. There are few situations in pediatric gastroenterology in which nuclear medicine should be used as a first-line investigation, but the role of nuclear medicine in gastrointestinal diagnosis is often to provide the answer to a specific question, and the results must be interpreted in the context of other investigations.

The underlying principles of nuclear medicine are parallel in both adult and pediatric practice. However, certain aspects of pediatric nuclear medicine are unique. Indications for some investigations in pediatrics are different because of the different spectrum of pathology in children compared with adults (Table 74.4-1), and there is frequently a requirement for modification of technique.

In all cases, obtaining a high-quality diagnostic nuclear medicine study is dependent on the cooperation of the child, parent, or other caregiver and staff in the nuclear medicine department. In nuclear medicine departments dealing primarily with adult patients, it is essential that staff carrying out procedures on children are familiar with handling and communicating with children and understand their special needs. A full explanation of the procedure to both the child and parent or carer is mandatory and will often allay any fears and misconceptions early. Many departments supply information leaflets with the appointment letter or on arrival in the department, which can answer a number of frequently asked questions. The patient and their parent should be aware of what the investigation entails, including the anticipated length of time that they will need to be in the hospital. This is often several hours for a nuclear medicine study, and advice should be given to bring toys or books to keep a young child amused. The unpleasant aspects of the study, such as the intravenous injection of isotope, should also be fully explained. This is usually acceptable to both child and parent when a local anesthetic cream is applied to the skin before the injection, rendering it a relatively painless procedure. When venipuncture is required, it must be done by trained staff, skilled in obtaining intravenous access in children to minimize discomfort and stress to the child.[1]

During the nuclear medicine study, parents should be allowed to remain with the child at all times. Immobiliza-

TABLE 74.4-1 CURRENT INDICATIONS FOR RADIONUCLIDE IMAGING IN PEDIATRIC GASTROENTEROLOGY

^{99m}Tc SULFUR COLLOID OR PHYTATE COLLOIDS
Assessment of esophageal dysmotility and gastric emptying
Evaluation of gastroesophageal reflux
Investigation of suspected pulmonary aspiration
^{99m}Tc IDA COMPOUNDS
Investigation of neonatal jaundice
Confirmation of biliary origin of choledochal cysts
Assessment of hepatobiliary function in acquired liver disease
Postoperative and post-trauma assessment of bile duct integrity
Heat-denatured red blood cells
Detection of functioning splenic tissue (heterotopic or ectopic)
Labeled white cell scans
Diagnosis of inflammatory bowel disease, detection of active disease
^{99m}Tc HUMAN SERUM ALBUMIN
Diagnosis of protein-losing enteropathy
^{99m}Tc-LABELED RED BLOOD CELLS AND ^{99m}Tc PERTECHNETATE
Investigation of gastrointestinal bleeding
Labeled somatostatin analogues
Detection of somatostatin receptor positive tumors
Labeled bile acid analogues
Diagnosis of bile acid malabsorption in cases of unexplained chronic diarrhea

IDA = iminodiacetic acid; ^{99m}Tc = technetium 99m.

tion is an essential requirement for obtaining high-quality images, and this can be a particular challenge, given the length of time taken to obtain views for some nuclear medicine studies. For neonates and children up to the age of 2 years, it is usually sufficient to hold the child in place or use sandbags and padding to aid immobilization. Sleep deprivation prior to the procedure and feeding the child while lying on the gamma camera table may also be useful. In many departments, music and television are used to help prevent the child from becoming bored and restless. Provided that the procedure is carried out in a calm environment and the child is accompanied and kept amused throughout, sedation is seldom required. During the scan, whenever possible, the gamma camera should be positioned underneath the child on the table because positioning the camera above children tends to frighten them. It is also customary to obtain the most important images first.[2,3]

Most pediatric nuclear medicine studies use the isotope technetium 99m (^{99m}Tc), which emits gamma rays and has a half-life of 6 hours. ^{99m}Tc can be bound to several substances, which are taken up by specific organs. The dose of the radiopharmaceutical should be scaled down according to the child's body surface area or weight (Table 74.4-2). Age is not used because of the wide variation in body surface area and weight, which would result in a variation in dose that may not necessarily be appropriate. There is also a minimum dose of radiopharmaceutical for each examination, below which the injected activity is too low to obtain adequate images no matter how small the child (Table 74.4-3). Absorbed radiation doses from gastrointestinal radionuclide examinations are usually lower than from radiographic procedures such as fluoroscopy or computed tomography (CT) of the abdomen. After the injection, where possible, patients should be encouraged to void frequently for those examinations in which the radiopharmaceutical is excreted by the kidneys so as to reduce the radiation burden to the pelvic organs.

TABLE 74.4-2 FRACTION OF ADULT ADMINISTERED ACTIVITY FOR CHILDREN BASED ON BODY WEIGHT*

KG	FRACTION OF ADULT-ADMINISTERED ACTIVITY	KG	FRACTION OF ADULT-ADMINISTERED ACTIVITY
3	0.1	30	0.62
4	0.14	32	0.65
6	0.19	34	0.68
8	0.23	36	0.71
10	0.27	38	0.73
12	0.32	40	0.76
14	0.36	42	0.78
16	0.40	44	0.80

28	0.58	60–62	1.00

*Recommended by the Pediatric Task Group of the European Association of Nuclear Medicine.[90]

TABLE 74.4-3 MINIMUM AMOUNTS OF ADMINISTERED ACTIVITIES FOR CHILDREN FOR GASTROINTESTINAL SCINTIGRAPHY*

RADIOPHARMACEUTICAL	MINIMUM ADMINISTERED ACTIVITY FOR CHILDREN (MBq)
^{99m}Tc colloid (liver and spleen)	15
^{99m}Tc colloid (gastric reflux)	10
^{99m}Tc spleen (denatured RBCs)	20
^{99m}Tc HIDA (biliary)	20
^{99m}Tc HMPAO (WBC)	40
^{99m}Tc pertechnetate (Meckel diverticulum)	20
^{99m}Tc RBCs (blood pool)	80

HIDA = hepatobiliary iminodiacetic acid; HMPAO = hexamethylpropyleneamine oxime; RBCs = red blood cells; ^{99m}Tc = technetium 99m.
*Recommended by the Pediatric Task Group of the European Association of Nuclear Medicine.[90]

SCINTIGRAPHIC ASSESSMENT OF GASTROESOPHAGEAL DYSFUNCTION AND REFLUX

Many techniques are used for the diagnosis of esophageal disorders, gastroesophageal reflux, and gastric emptying in children. These include pH studies, barium radiology, manometry, ultrasonography, impedance studies, endoscopy with biopsy, and scintigraphy. Each of these techniques has its own merits and limitations, and each may be informative about different aspects of esophagogastric physiology and pathophysiology. There is little recent published work comparing these methodologies and their relative contributions.

In this field, the main symptoms of relevance to pediatric practice are related to gastroesophageal reflux. Esophageal dysfunction and delay in gastric emptying are thought to contribute to reflux, as well as representing disease entities in their own right. The assessment of each is difficult for several reasons. There is no consensus as to what represents the reference or "gold standard." Additionally, the presence of gastroesophageal reflux in itself does not necessarily equate with a disease state. Thus, a distinction should be made between gastroesophageal reflux and gastroesophageal reflux disease. This is further complicated in pediatric practice by marked clinical and physiologic differences between age groups and between those children who seem to have reflux disease as an isolated problem and those in whom it is associated with another disorder, such as cerebral palsy or chronic lung disease. Because gastroesophageal reflux is mostly intermittent, methods of investigation must be longitudinal. Such limitations must be borne in mind when considering the role of scintigraphy.

Oral ^{99m}Tc sulfur colloid or phytate colloids are used in gastroesophageal scintigraphy because they are not absorbed from the gastrointestinal tract. Also, if aspirated, they remain localized, are readily detectable, and are eventually cleared without sequel.[4] The labeled colloid is mixed with the feed to be administered, residual activity is cleared from the mouth and esophagus with an unlabeled liquid or feed, and the patient is imaged for 1 hour. Ideally, milk

should be used because this does not enhance gastric emptying. Dynamic images are taken at regular intervals (eg, every 10 seconds with the child lying comfortably on the scanning table). The stomach activity is masked by the use of lead shields to maximize esophageal visualization. Both images and time-activity curves are recorded. This enables the identification of the frequency of reflux episodes together with their proximal extent (Figure 74.4-1).

Using this method, the results obtained can be considered to represent only the postprandial situation. This

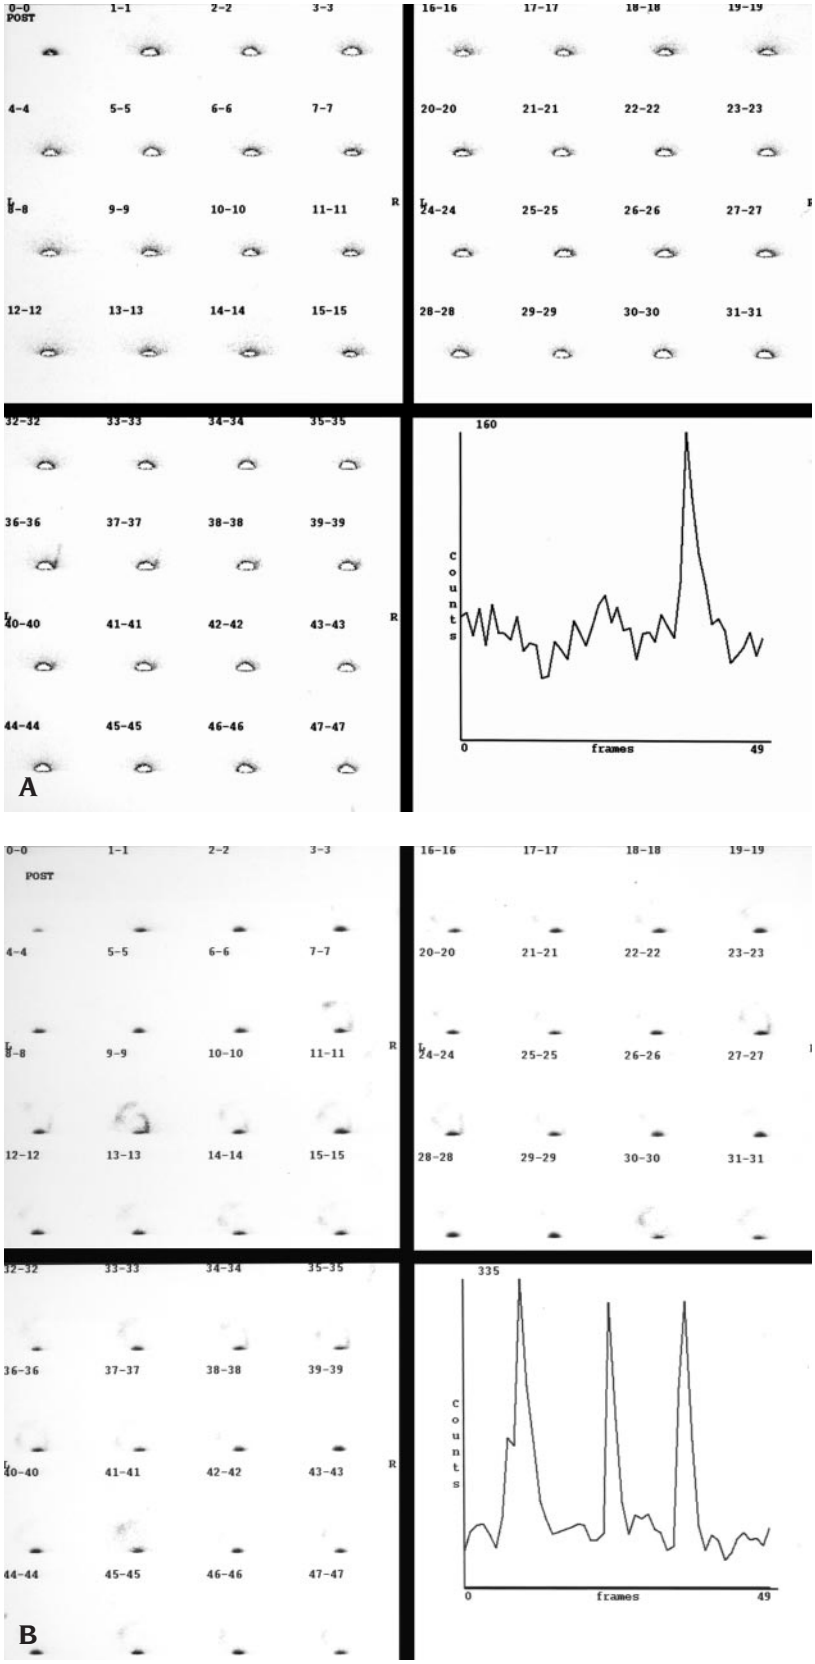

FIGURE 74.4-1 Gastroesophageal reflux studies using labeled sulfur colloid mixed with milk feed. Episodes of gastroesophageal reflux are indicated by the peaks on the activity curves. These represent individual reflux episodes, one in *A* and three in *B*. The proximal extent of the reflux is assessed from the accompanying images.

offers certain advantages over pH studies because gastric acidity may be neutralized by food, especially milk, in the immediate postprandial period, making pH studies unreliable.[5,6] Although scintigraphy is unable to delineate anatomic features, such as hiatus hernia, the radiation exposure is considerably less than that with barium studies. In addition, it has the advantage of allowing longer periods of observation to detect reflux. Piepsz and colleagues performed gastroesophageal scintigraphy in 35 children of varying ages who were felt clinically to have gastroesophageal reflux.[7] Compared with barium studies and findings on endoscopy with esophageal histology, gastroesophageal scintigraphy is more likely to detect reflux episodes than barium studies. However, there was no consistent correlation of scintigraphic results with findings at endoscopy. A second study compared several different methodologies in the diagnosis of 30 infants and children with symptoms of gastroesophageal reflux.[8] Gastroesophageal scintigraphy was positive in only 17 (56.6%) patients. The authors suggest that barium studies and scintigraphy are complementary evaluations and that a combination of the two increases sensitivity.

Images of the thorax taken 1 and 4 hours after the reflux study occasionally detect pulmonary aspiration, but this method of detecting aspiration is generally unreliable.[9] A salivagram has been developed in which a small amount of labeled colloid is placed on the tongue and is allowed to mix with saliva. Subsequent images of the tracheobronchial tree collected up to an hour afterward may indicate aspiration of saliva.[10] However, the accuracy of this method has not been assessed, and it is specific for aspiration of saliva as opposed to refluxate.

SCINTIGRAPHIC ASSESSMENT OF GASTRIC EMPTYING

The concept of abnormal gastric emptying as a disease entity and its possible relationship to gastroesophageal reflux disease has not been well validated. It has been suggested that delayed gastric emptying predisposes infants to reflux and to aspiration,[11] but this point was not confirmed in other studies.[12] Much of the uncertainty is due to the number of variables that can affect gastric emptying, such as age, feed type, and the lack of standardized normal values. Therefore, although scintigraphic assessment of gastric emptying in association with the assessment of reflux is feasible, its value must be considered questionable.

Gastric emptying studies may be useful in selected patients, for example, when considering gastrostomy placement or evaluation of patients with dumping syndrome. The patient's usual volume of milk or food is labeled with ^{99m}Tc sulfur colloid and is administered either orally or by nasogastric or gastric tube. Patients are imaged supine for 1 hour. If gastric emptying is roughly 50% at 1 hour, the study can be terminated. If there is delayed emptying at 1 hour, the patient is allowed to sit upright or walk around before delayed images are acquired at 90 minutes and 2 hours. If emptying is graphically displayed, then certain patterns may be recognized. These include plateau phase seen in pylorospasm or antral web, increasing gastric counts owing to overlapping duodenum, and a rapid fall in activity seen in dumping syndrome.[13]

SCINTIGRAPHIC ASSESSMENT OF THE ESOPHAGUS

Scintigraphy can be used to assess esophageal motility and transit time. It is a dynamic method and so allows appropriate physiologic analysis. The technique can be performed only in cooperative children. A labeled colloid is used, as in the assessment of reflux, and is delivered as small oral boluses, which can be observed individually and summated to allow activity in any particular segment. Generalized dysmotility can be distinguished from focal areas of abnormality, such as a stricture.[14] As with many scintigraphic techniques, this approach has not been well validated compared with other methods, and its place in the routine investigation of children is not established. Esophageal scintigraphy may be considered in children with persistent symptoms of dysphagia in whom contrast studies are normal.

HEPATOBILIARY SCINTIGRAPHY

Hepatobiliary scintigraphy is used to assess hepatocyte function and the excretion of bile into the small intestine. There are many uses of hepatobiliary scintigraphy, but in pediatric practice, the most frequent one is to help determine the etiology of jaundice in the neonatal period.

The radiopharmaceuticals employed in hepatobiliary scintigraphy are those of the ^{99m}Tc-labeled iminodiacetic acid (IDA) group. The agent is given intravenously and is then transported to the liver bound to albumin, where it is taken up by the hepatocytes via an active process. Excretion into the bile ducts is by a combination of active and passive transport mechanisms. The kidneys excrete a proportion of the agent, but with increasing hepatocellular dysfunction, a higher percentage is renally excreted.[15] ^{99m}Tc diisopropryl-IDA (DISIDA) is the radiopharmaceutical most frequently used in hepatobiliary scintigraphy. In the normal patient, ^{99m}Tc DISIDA has a hepatic extraction of 88% and urinary excretion of 11%. ^{99m}Tc trimethylbromo-IDA (TBIDA; mebrofenin) has a hepatic extraction of 98% and urinary excretion of 1.5% and is currently the best agent for use in patients with high bilirubin levels because it has a higher resistance to displacement by bilirubin, which is also carried in the blood bound to albumin.[16] ^{99m}Tc TBIDA has a greater than 70% hepatic extraction with bilirubin levels over 20 mg/dL, whereas ^{99m}Tc DISIDA has a lower hepatic extraction at 36% with bilirubin levels of 10 mg/dL.[15]

INVESTIGATION OF NEONATAL JAUNDICE

Hyperbilirubinemia is common in the neonatal period and in the majority of cases is due to benign physiologic jaundice. Prolonged neonatal jaundice is defined as jaundice lasting more than 14 to 21 days. The immediate priority in prolonged neonatal jaundice is to differentiate between

pathologic neonatal cholestasis (conjugated hyperbilirubinemia) and unconjugated hyperbilirubinemia, which is usually benign. More than 15% conjugated hyperbilirubinemia is considered to be significant rather than the absolute bilirubin level.[17] Cholestasis can be due to multiple intrahepatic causes such as infection, metabolic or genetic conditions, or extrahepatic abnormalities causing mechanical obstruction to bile flow. Early recognition of extrahepatic causes is vital because early surgical intervention in extrahepatic biliary atresia (EHBA) is associated with a better outcome.[18,19] In EHBA, all or part of the extrahepatic bile ducts are obliterated, leading to complete biliary obstruction. In approximately 5% of cases, the gallbladder or parts of the common bile duct are patent. Treatment is by the formation of a Kasai portoenterostomy in which the atretic extrahepatic biliary tissue is removed and a Roux-en-Y jejunal loop is anastomosed to the hepatic hilum to try to establish biliary drainage into the intestine. The likelihood of this surgery being successful is reduced after 60 days of age[20]; therefore, early diagnosis of EHBA is vital.

The complete workup of an infant with cholestasis will include laboratory tests of liver function, serologic tests for infection, metabolic screening tests, and imaging investigations, which are all correlated with clinical information. Ultrasonography is the primary imaging modality used to visualize the hepatobiliary anatomy and exclude congenital abnormalities of the liver and biliary system and other abdominal organs. Congenital bile duct dilatation, or choledochal cyst, is the disorder most commonly diagnosed by ultrasonography. Gallstones or sludge in the biliary system may be detected, sometimes in association with proximal biliary dilatation. Biliary dilatation is not a feature of EHBA. Ultrasonography is unable to diagnose EHBA, although many series report certain ultrasound findings that increase or decrease the likelihood of EHBA. These include the "triangular cord sign," which is a triangular- or tubular-shaped echogenic structure seen ultrasonographically in the vicinity of the portal vein at the porta hepatis and is said to represent the fibrous cone of atretic extrahepatic biliary tissue in patients with EHBA.[21] Although this is a helpful sign, it is not considered to be a reliable method of detecting or diagnosing EHBA.[22] A small or absent gallbladder in a fasting infant is suggestive of EHBA. Visualization of a normal-sized gallbladder makes the diagnosis of EHBA less likely, but appearances of the gallbladder at ultrasonography cannot be accurately relied on.[23]

The role of hepatobiliary scintigraphy in the investigation of neonatal cholestasis is primarily to exclude EHBA, but it cannot differentiate between other forms of cholestasis. Hepatobiliary scintigraphy demonstrates the ability of the hepatocytes to take up isotope, as a measure of hepatocyte function, and demonstrates patency of the biliary tree by the visualization of excretion of isotope into the gut. In neonates being investigated to differentiate between intrahepatic and extrahepatic causes of cholestasis, premedication with phenobarbital at a dose of 5 mg/kg/d orally is used for at least 3 days to induce hepatocyte microsomal enzymes, thereby increasing bilirubin conjugation and excretion. This approach increases the specificity of the test in distinguishing EHBA from other causes of neonatal cholestasis by ensuring the best possible excretion of hepatobiliary agents. If the test is performed urgently without premedication, it may have to be repeated following phenobarbital premedication if excretion of isotope into the bowel is not seen. Patients should be fasted for 3 to 4 hours prior to the study. Following injection of a radiopharmaceutical, dynamic imaging is performed for the first 5 minutes to visualize the distribution of tracer in the blood pool and to assess hepatic uptake. The gamma camera is placed anteriorly over the abdomen and positioned to include the heart, liver, and bowel. Thereafter, static images are acquired at intervals up to 1 hour after the injection. A suggested regimen is to obtain static images at 5, 10, 15, 30, and 45 minutes and 1 hour. If there is no excretion into the bowel at 1 hour, then further imaging is performed at later intervals, for example, at 3 to 4 hours until activity is seen in the bowel. If bowel activity remains undetectable, imaging at 24 hours is undertaken with anterior and lateral images to detect activity in the bowel or rectum. If the gallbladder has been visualized but fails to empty significantly during the first 60 minutes, an additional series of images should be taken following a normal feed to stimulate gallbladder contraction. Cholecystokinin can also be used to stimulate gallbladder emptying.[24]

Images can be interpreted to assess the following parameters: blood flow and extraction of isotope by the liver, time of excretion and visualization of the biliary tree, time of visualization of isotope in the duodenum, parenchymal clearance of isotope, gallbladder contractility, duodenogastric reflux, delayed images of bowel or rectal activity, and position of the small bowel. However, there are two main phases: hepatic extraction (uptake) and excretion of isotope into the bowel. In normal neonates, hepatic extraction of isotope is prompt, with a uniform distribution. Maximum hepatic accumulation is usually seen within 5 minutes. The gallbladder may be visualized as early as 10 minutes into the study but is not always seen. Bowel activity is usually observed by 30 to 40 minutes. The hepatic, cystic, and common bile ducts are not normally visualized in the neonatal period but become more obvious after 12 months of age. Over the age of 8 years and in adulthood, the left hepatic bile ducts become prominent on hepatobiliary scintigraphy (Figure 74.4-2).[25] The hepatic extraction function (HEF) is defined by the extraction of isotope by the liver and reflects hepatocyte function. It can be assessed visually and quantitatively by analysis of the initial hepatic uptake phase of the study. The normal pediatric HEF is over 92%.[26] Hepatic half clearance times ($t_{1/2}$) are defined as hepatic parenchymal clearance divided by excretion and can be quantitatively assessed. The hepatic $t_{1/2}$ is normally less than 37 minutes.[25] However, there is a large overlap in the neonatal period, and determination of the hepatic $t_{1/2}$ has not been found helpful in differentiating between EHBA and other forms of cholestasis.

Typically, patients with EHBA presenting in the first 2 months of life show prompt hepatic extraction with a normal HEF (over 92%), nonvisualization of the gallbladder, prolonged retention of isotope in the liver, and absent

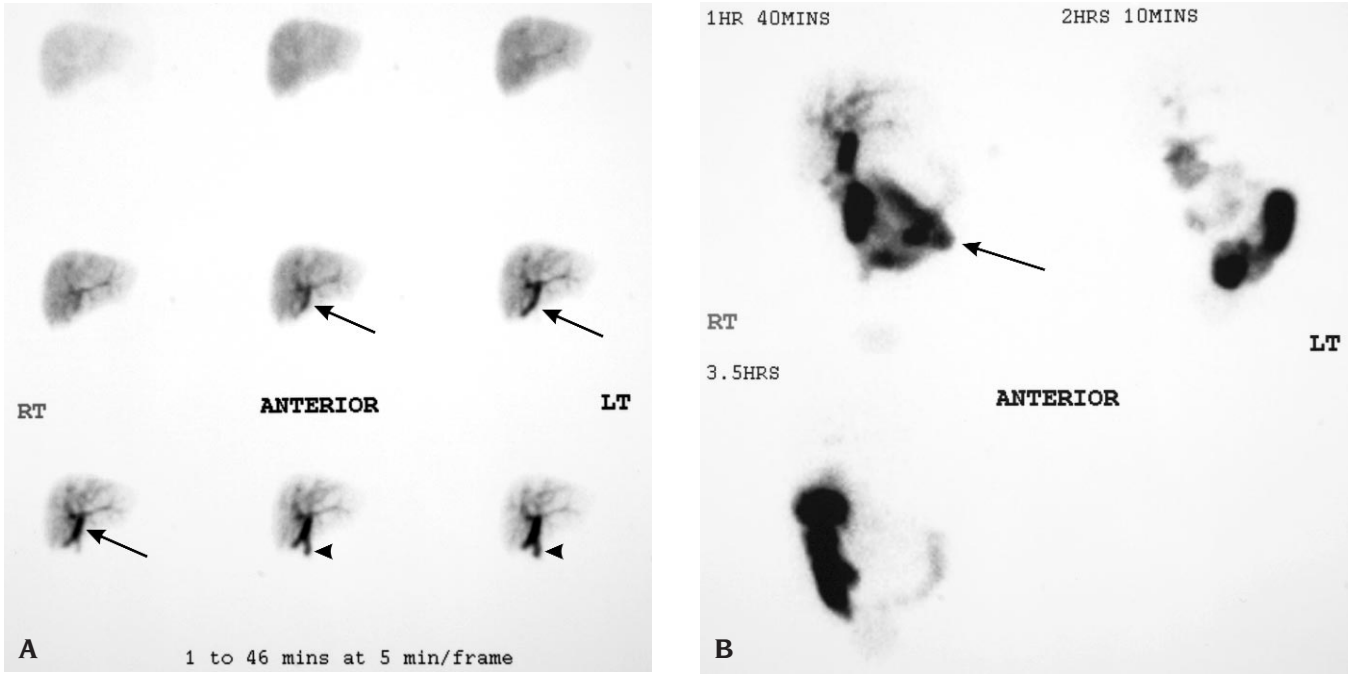

FIGURE 74.4-2 Normal hepatobiliary scintigraphy in a 9-year-old child. *A*, Initial images taken over the first hour of the study demonstrate normal uptake of isotope with good visualization of the intrahepatic bile ducts. The second and third rows of three images also demonstrate gallbladder filling (*arrows*) and the common bile duct (*arrowheads*). *B*, By 1 hour and 40 minutes, isotope has been excreted into the bowel (*arrow*). Subsequent images demonstrate gallbladder emptying and increased isotope excretion into the bowel.

excretion into the bowel even at 24 hours. Patients presenting after 3 months of age usually have compromised hepatocyte function and show reduced hepatic extraction, with reduced HEF and no biliary excretion. With this picture, differentiation from severe neonatal hepatitis or cholestasis may prove difficult. There are reports of patients with EHBA in whom excretion of isotope into the bowel was seen on scintigraphy in the early neonatal period, but repeat studies showed no excretion.[27] This may be due to progressive obliteration of the extrahepatic ducts continuing after birth. Therefore, it is appropriate to carefully monitor infants who show good extraction of isotope but only minimal excretion into the bowel.

Three patterns of hepatobiliary scintigraphic findings are described in neonatal hepatitis.[28] There may be normal hepatic extraction with visualization of isotope in the bowel, which excludes biliary atresia. Reduced hepatic extraction with absent excretion indicates severe parenchymal liver damage but would be inconsistent with EHBA in the first 3 months of life. Normal or near-normal hepatic uptake with no excretion is consistent with EHBA, but this pattern has been described in cases of severe neonatal hepatitis, cystic fibrosis (CF), α_1-antitrypsin deficiency, and syndromes with paucity of intrahepatic bile ducts.

In patients with neonatal hepatitis, the HEF is generally reduced, reflecting reduced hepatocyte function. There is persistent blood pool activity with delayed clearance because of reduced hepatocyte extraction. If there is severe hepatocyte dysfunction, there is reduced or absent excretion into the bowel and concurrent increased renal excretion of isotope (Figure 74.4-3). Any excretion of isotope into the bowel excludes EHBA.

The single most informative investigation in neonatal cholestasis is a liver biopsy. In experienced hands, liver biopsy has over 90% diagnostic accuracy, but it must be performed in a specialist pediatric center because it is not without risk, and the histopathology must be interpreted in the context of clinical information and other laboratory investigations.[29] The diagnosis of EHBA is ultimately confirmed at laparotomy and intraoperative cholangiography.

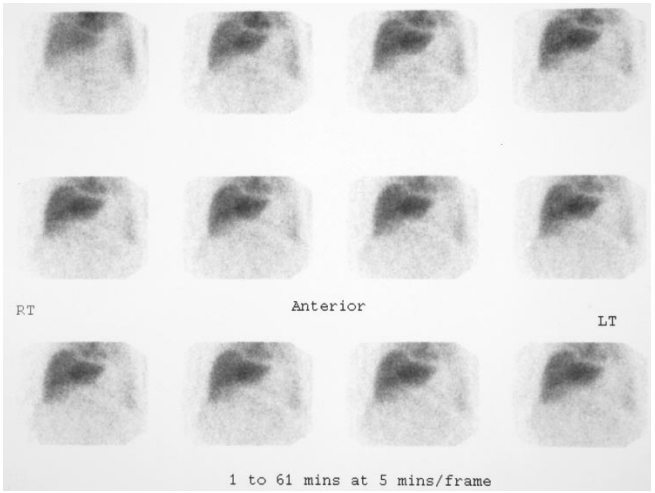

FIGURE 74.4-3 Hepatobiliary scintigraphy demonstrating generalized poor hepatic uptake of isotope, with persistent high background activity. The gallbladder is not visualized, and there is no excretion of isotope into the bowel. These findings reflect severe hepatocyte dysfunction in a patient with neonatal hepatitis, but extrahepatic biliary atresia cannot be excluded on the basis of this scan.

Spontaneous rupture of the common bile duct usually occurs in the first 1 to 2 weeks of life, and the cause is unknown. Infants present with jaundice and abdominal distention owing to ascites, which is bile stained on aspiration. Hepatobiliary ultrasonography may be normal in these children but often demonstrates a pseudocyst at the porta hepatis, usually without biliary dilatation. Occasionally, sludge or stones are seen in the common bile duct distal to the site of perforation, which is at the junction of the cystic duct and common bile duct. Hepatobiliary scintigraphy may show a photopenic area owing to the pseudocyst or extravasation of isotope into the peritoneal cavity. Intraoperative cholangiography confirms the diagnosis at the time of surgery.[25]

USE OF HEPATOBILIARY SCINTIGRAPHY BEYOND THE NEONATAL PERIOD

Patients with congenital bile duct dilatation (choledochal cyst) may present with cholestatic jaundice and acholic stools in the first few months of life. Most cases of choledochal cyst present under the age of 10 years, with 30% under 1 year of age. Presentation can even be delayed into adulthood, although this is uncommon. The diagnosis is usually made with ultrasonography at all ages. Following ultrasound examination, ^{99m}Tc IDA scintigraphy can be used to confirm the biliary origin of the cyst if thought clinically necessary. There is a known association of choledochal cysts with EHBA. Scintigraphy may help to determine the type of cystic dilatation and whether the cystic structure communicates with the biliary system. The scintigraphic appearance will depend partly on the degree of biliary obstruction caused by the cyst because extremely large cysts may obstruct biliary flow completely. There may be normal hepatic extraction and excretion of isotope, or, alternatively, isotope may accumulate in dilated ducts or cysts. A photopenic defect may be seen in the region of the porta hepatis depending on the size of the cyst. Complete obstruction with negligible biliary flow and nonfilling of the mass may occur. Rarely, activity is seen in the peritoneal cavity after cyst rupture. Like the gallbladder, choledochal cysts may contract after a fatty meal or cholecystokinin. Caroli disease (type 5 choledochal cyst) may present in infancy and shows an irregular pattern of cystic dilatation, with accumulation of isotope in the intrahepatic bile ducts on delayed images.[25] Although these findings are well described, with the advent of high-resolution ultrasonography and magnetic resonance cholangiography, radionuclides are currently seldom used in these clinical situations.

Patients with increased bile viscosity are at risk of developing bile plugs (inspissated bile syndrome), which can cause biliary obstruction. These include patients with CF, patients on total parenteral nutrition, and following extensive ileal resection. Appearances on ^{99m}Tc IDA scintigraphy are variable because there may be secondary liver damage, but there is typically good hepatic extraction of isotope and poor excretion into the gut. Occasionally, absent excretion is found in the neonatal period or in infancy, and the study is unable to exclude EHBA.[30] In Alagille syndrome, which is characterized by a paucity of interlobular bile ducts in association with certain phenotypic features and congenital cardiac and vertebral abnormalities, patients develop cholestasis, and ^{99m}Tc IDA scintigraphy demonstrates good extraction of isotope by the liver with marked retention of isotope in the hepatic parenchyma and usually minimal excretion into the gut. Occasionally, absent excretion is shown, and EHBA cannot be excluded.

HEPATOBILIARY SCINTIGRAPHY IN CF

^{99m}Tc IDA scintigraphy may be incorporated in the assessment and follow-up of patients who develop CF-related liver disease and is complementary to ultrasonography. Deficiency of the CF transmembrane regulator in the bile duct epithelial cells of these patients causes increased viscosity of bile that becomes inspissated, leading to plugging of intrahepatic bile ducts. Impairment of both intra- and extrahepatic biliary drainage contributes to the development of liver disease in these patients, with the development of fatty liver, chronic cholestasis, and, eventually, cirrhosis. Peak onset is during adolescence. ^{99m}Tc IDA scintigraphy allows assessment of hepatic extraction, clearance of isotope from the hepatic parenchyma, and biliary drainage and may have a role in monitoring disease progression and the success of treatment.[31]

POSTOPERATIVE AND POST-TRAUMATIC HEPATOBILIARY SCINTIGRAPHY

Postoperative evaluation of biliary drainage using ^{99m}Tc IDA scintigraphy is useful in patients who have undergone portoenterostomy (Kasai procedure) and also following liver transplant. The main indications for performing scintigraphy are to assess hepatic perfusion, parenchymal function, detect bile leaks, and assess transit of radiopharmaceutical from the liver into the intestine.[32]

In cases of liver trauma, CT scanning is the best method of assessing liver injury acutely. ^{99m}Tc TBIDA scintigraphy is useful in the early detection of bile duct injuries and biliary leaks.[33] The technique demonstrates active leakage of isotope into the peritoneal cavity or focal abnormal areas of activity owing to bile collections (Figure 74.4-4).

RADIONUCLIDE IMAGING OF THE LIVER AND SPLEEN

Radionuclide imaging of the liver and spleen can be performed using ^{99m}Tc sulfur colloid by virtue of the reticuloendothelial activity of these organs. This technique was used to provide structural information and to evaluate focal or diffuse disorders affecting the liver or spleen, but it has now been superseded by ultrasonography, CT, and magnetic resonance imaging (MRI), which provide excellent anatomic information and better resolution. Injected ^{99m}Tc sulfur colloid particles are phagocytosed by the reticuloendothelial cells of the liver, spleen, and bone marrow. The bone marrow of normal patients is not visualized owing to greater concentration of reticuloendothelial activity in the

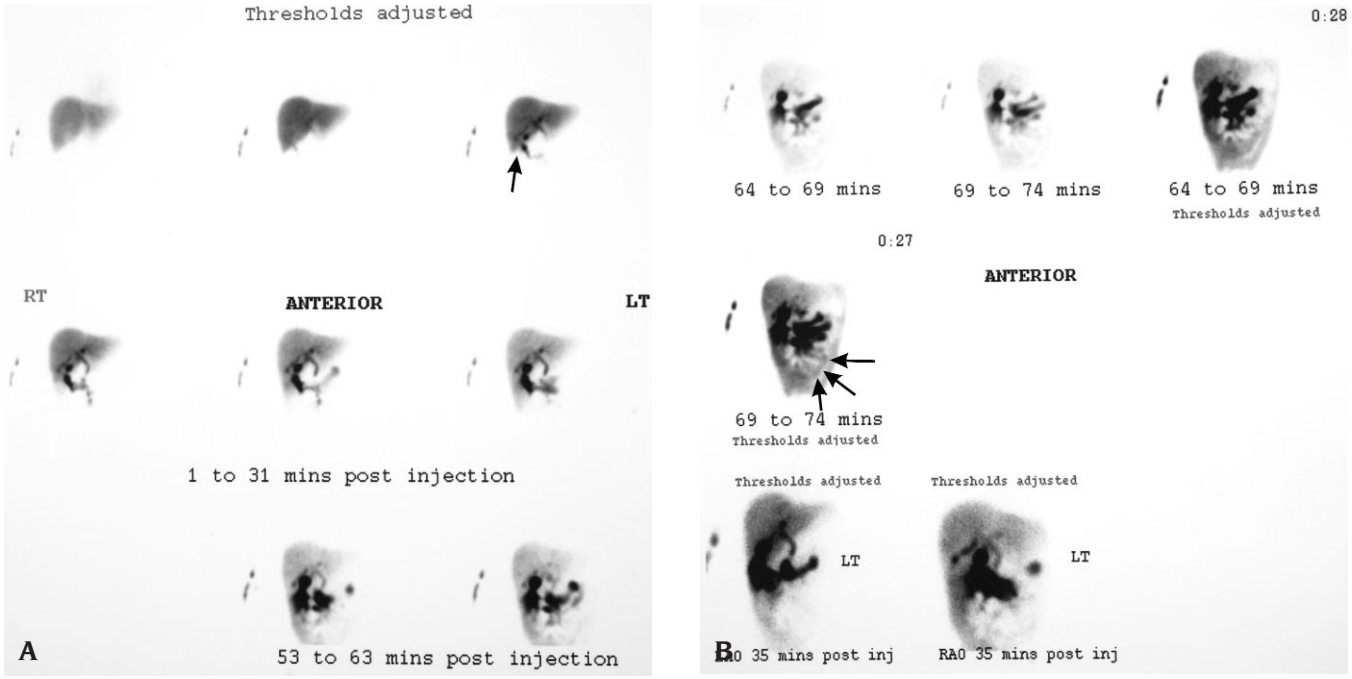

FIGURE 74.4-4 An 8-year-old boy who sustained liver lacerations in a road traffic accident. *A*, Hepatobiliary scintigraphy demonstrates normal hepatic uptake of isotope with visualization of main intrahepatic ducts. Focal collections of isotope around the porta hepatis on the far right image of the top row (*arrow*), and subsequent images are due to focal bile collections as a result of biliary leakage. There is excretion of isotope into the bowel but on images taken at 53 to 63 minutes (*bottom row*) and subsequently (*B*), peritoneal reflections are outlined by free isotope within the peritoneal cavity (*arrows*). This is better demonstrated following adjustment of the gamma camera parameters (threshold adjustment). Biliary leakage was confirmed at surgery.

liver and spleen. ^{99m}Tc sulfur colloid particles are cleared rapidly from the bloodstream following intravenous injection (typical $t_{1/2}$ of less than 3 minutes). Rapid sequence (dynamic) imaging is performed to show blood flow to the organs. There is earlier and more rapid uptake in the spleen and kidneys because the majority of the hepatic blood flow is via the portal vein. Static views are then obtained in multiple projections to visualize the organs and separate overlapping structures. SPECT images may improve resolution.

Imaging of primary and secondary hepatic tumors is now primarily with CT and MRI, and radionuclide imaging is not indicated. When performed, these studies show increased blood flow to the tumor on dynamic imaging, with photopenic defects on delayed static imaging using ^{99m}Tc sulfur colloid or ^{99m}Tc IDA compounds.[13] Vascular lesions, such as hepatic hemangiomas or hemangioendotheliomas, can be differentiated from hypervascular tumors because although both demonstrate increased perfusion during dynamic imaging using ^{99m}Tc sulfur colloid, there is prolonged retention of activity in the vascular spaces of hepatic vascular lesions (which does not occur in tumors). Both vascular lesions and tumors show photopenic defects on delayed static images owing to the absence of reticuloendothelial cells. The use of ^{99m}Tc-labeled red blood cells (RBCs) has been advocated in the case of suspected hepatic vascular lesions because of the overlap in scintigraphic findings with hypervascular tumors. However, three-phase CT and MRI have been shown to have greater sensitivity and accuracy and have therefore replaced scintigraphy in the evaluation of such lesions.

Hepatic infection, either diffuse hepatitis or focal infection with abscess formation, may show hepatomegaly with heterogeneous distribution of isotope. However, radionuclide imaging is not used routinely or as the primary method of imaging in these conditions. ^{99m}Tc sulfur colloid has been used as a screening or monitoring tool in patients with diffuse liver disease such as cirrhosis, α_1-antitrypsin deficiency, CF, storage diseases, or congenital hepatic fibrosis. In these disorders, the primary findings are diminished or heterogeneous uptake by the liver, with relatively increased uptake in the spleen and bone marrow in the setting of progressive disease. Hepatomegaly or reduction in liver size will depend on the stage of the disease.[32] In hepatic venous occlusion (Budd-Chiari syndrome), there is typically caudate lobe hypertrophy with increased uptake of ^{99m}Tc sulfur colloid and reduced uptake in the remainder of the liver, although other patterns are described.[34] Again, ultrasonography, CT, and MRI have replaced radionuclide imaging in screening for veno-occlusive disorders.

RADIONUCLIDE IMAGING OF THE SPLEEN

The spleen alone can be anatomically and physiologically imaged using ^{99m}Tc-labeled heat-denatured RBCs. The main indication for performing splenic scintigraphy is to identify functioning splenic tissue in patients with visceral heterotaxy syndromes and disorders that affect splenic function, such as sickle cell disease. Demonstration of splenic tissue on ultrasonography or cross-sectional imaging does not indicate splenic function, and this is particu-

larly true for patients with visceral heterotaxy or abnormalities of isomerism associated with congenital cardiac disease. Functional asplenia may be suspected from the detection of Howell-Jolly bodies in the circulating blood. It is important to identify patients with asplenia or functional asplenia because they are susceptible to overwhelming bacterial sepsis and require vaccination and antibiotic prophylaxis. However, when functional asplenia is suspected, the necessary precautions against sepsis are usually instituted, without risk and without resorting to splenic scintigraphy for confirmation.

Splenic scintigraphy may be employed in the detection of abnormally sited splenic tissue, which can be implanted in the chest, abdomen, or pelvis following trauma to the native spleen (splenosis). The extrasplenic tissue accumulates ^{99m}Tc-labeled RBCs in the same manner as the spleen, and this finding is useful in identifying apparently abnormally sited masses, which are, in fact, implanted splenic tissue. A further related use of splenic scintigraphy is in the identification of accessory spleens or splenunculi. These are considered to be a normal variant, but their identification is important in patients undergoing splenectomy for hematologic reasons.

Heat-denatured RBCs are injected intravenously and are avidly sequestered by the normal spleen, thereby demonstrating splenic function in addition to showing the position and size of the organ. This is accompanied by only faint uptake in the liver. If no functioning splenic tissue is present, there will be hepatic uptake owing to its reticuloendothelial activity and some excretion of free pertechnetate by the kidneys.

Between 3 and 8 mL of blood are taken from the patient depending on chronologic age and body weight. Under sterile conditions, the cells are labeled with ^{99m}Tc pertechnetate and then heated in a water bath at 49.5°C for 12 to 15 minutes.[32] The ^{99m}Tc-labeled RBCs are then reinjected intravenously, and static scans are performed in a number of planes after at least 30 minutes. SPECT scanning can be performed to improve localization, particularly if only small volumes of splenic tissue are present.

LEUKOCYTE SCINTIGRAPHY IN INFLAMMATORY BOWEL DISEASE

Leukocyte scintigraphy is a well-established technique that has a role in the detection of inflammation and sepsis. Its initial use in the investigation of inflammatory bowel diseases (IBDs) was reported in 1981.[35,36] Since that time, the place of labeled white cell scans (WCSs) has not been well defined in existing guidelines for the investigation of IBD, and use seems to reflect preferences in personal practice.[37] The technique has been evaluated as part of the routine investigation of suspected IBD, as a method for assessing both disease location and disease activity, and as a tool for following disease progression.

White cell scanning offers several advantages over other techniques commonly used to investigate IBD. The technique is noninvasive, does not require any patient preparation, and is well tolerated. It also allows whole-bowel examination with low radiation exposure,[38] and patients prefer WCSs to barium follow-through studies or enteroclysis.[39] These features suggest that white cell scanning is a technique that could be applied more frequently than either barium imaging or endoscopy and, more specifically, that it might be a more appropriate technique for children.

As the migration of leukocytes into tissues is a direct manifestation of a pathophysiologic process, it has been suggested that WCSs represent a direct measure of disease activity. Assessment of mucosal inflammation is otherwise possible only for areas of bowel that can be directly visualized and biopsied.

Several different indices of scintigraphic activity have been published. Broadly, these encompass visual grading systems requiring comparison of bowel activity with that of bone marrow, liver, or spleen[40,41] and computer-based methods with or without background subtraction.[42] Visual assessment has been demonstrated to have a high degree of interobserver variability.[43] Currently, there is no apparent consensus between studies as to how various areas of the bowel should be divided for an assessment of disease activity. Commonly, segmental analysis is reported according to uptake in the small bowel; ileum; cecum; right, transverse, and left colon; sigmoid colon; and rectum. A lack of universally accepted measures likely contributes to the variability of reported results and the lack of a generally agreed on role for use of WCSs in the assessment of disease activity in IBD.

There are two main isotopes used in leukocyte imaging. White cells may be labeled with ^{111}indium (^{111}In) oxime or ^{99m}Tc hexamethylpropyleneamine oxime (^{99m}Tc HMPAO). ^{111}In is cyclotron produced, whereas ^{99m}Tc is generator produced and is therefore more readily available. ^{111}In also gives a relatively higher bone marrow dose to children compared with adults owing to the greater proportion of red marrow in children.[44] HMPAO has the advantage of having a longer shelf life of 5.5 months and is more specific for granulocytes in a mixed cell population. ^{99m}Tc HMPAO also generates a superior image quality. Therefore, this compound has become the most widely used radioisotope in current practice.[45,46] Using ^{111}In or ^{99m}Tc HMPAO, the labeling process is relatively simple, but the leukocytes must first be separated from whole blood using sedimentation, centrifugation, and washing. The leukocyte pellet is then resuspended in sterile saline. When using ^{99m}Tc HMPAO, the preparation is simply added to the leukocyte suspension and is gently mixed. Following a short period of incubation at room temperature, washing, and resuspension in a small quantity of plasma, the labeled leukocytes are ready for reinjection. The labeling yield is usually about 50%.[47]

After injection, the labeled granulocytes migrate into the inflamed area. Using ^{99m}Tc, the most reliable images are generated soon after injection of labeled cells, generally at 30 to 60 minutes, although delayed scans, at 2 to 4 hours, may also be helpful (Figure 74.4-5).[48] Careful interpretation of the images is important because activity occurring in the bowel on later images can represent normal "physiologic" bowel activity. The process underlying this is uncertain, although there is some suggestion that it may represent cells being shed into the bowel lumen.

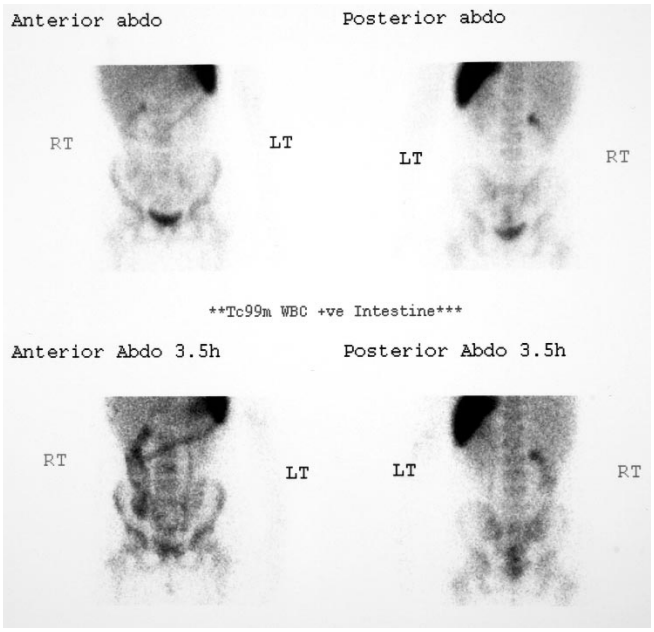

FIGURE 74.4-5 Labeled white cell scan demonstrating increased uptake in the cecum, ascending colon, and transverse colon in a 12-year-old boy with Crohn disease.

WCSs have obvious limitations. They cannot define anatomic features such as stricture, fistula, or prestenotic dilatation, although they may assist in distinguishing an inflammatory from a noninflammatory stricture. In interpretation of the images, potential causes of a false-positive WCS also must be considered. These include the presence of gastrointestinal bleeding, stoma sites, wounds, hematomas, deep vein thrombosis, and ischemic and infective bowel disease.[49] Other causes of bowel inflammation, such as infection or chronic granulomatous disease, may also generate positive studies.[50] Interpretation of anatomic distribution may be limited by bone, liver, spleen, and renal uptake, which can impair accurate assessment of small bowel involvement, and by urinary excretion because isotope within the bladder can affect assessment of uptake by rectal mucosa.

Several studies in children have compared the results of WCSs with histologic analysis of mucosal biopsies taken at colonoscopy. Such studies allow an assessment of the accuracy of the technique compared with the accepted diagnostic gold standard. A prospective investigation of 39 cases demonstrated that white cell scanning was able to diagnose IBD with a sensitivity of 90% and a specificity of 75% compared with colonic histology.[51] A similar prospective study compared scintigraphy in 137 children in whom colonoscopy and biopsy were also performed within 30 days and reported a sensitivity of 90%, a specificity of 97%, a positive predictive value of 97%, and a negative predictive value of 93% for WCSs.[39] However, endoscopic findings and histology remain the cornerstones for the diagnosis of pediatric IBD. It is not envisaged that these techniques would be replaced by scintigraphy.

Studies comparing WCSs and barium radiology demonstrate that scintigraphy has a higher accuracy for identifying IBD.[51,52] This suggests that the role of barium studies needs re-evaluation, particularly in screening for IBD. However, studies report less enthusiastic results for the scintigraphic diagnosis of IBD.[53,54] Reported differences in reliability likely reflect several factors, including different patient populations and differences in the severity of disease activity.

Bowel scintigraphy examines the whole of the bowel during one procedure. However, disease location is not always accurate when assessed by WCSs. Charron and colleagues assessed the accuracy of scintigraphy compared with endoscopy and biopsy for identifying colonic or ileal disease and found that scintigraphic location of disease activity limited to the colon yielded sensitivity and a positive predictive value of 97% and 97%, respectively.[55] For locating disease activity to the ileum, scintigraphy was less sensitive and specific. Inflammation within the terminal ileum is frequently difficult to distinguish from lymphoid nodular hyperplasia seen in up to 24% of barium studies when investigating IBD.[56] Furthermore, direct endoscopic visualization of the terminal ileum is not always possible for technical reasons. Studies in patients being investigated for IBD or for nonspecific gastrointestinal symptoms and other unrelated medical reasons have not reported terminal ileal uptake in any children without a final diagnosis of IBD, even in the presence of lymphoid nodular hyperplasia.[54,55]

Very few studies comment on the ability of scintigraphy to distinguish Crohn disease from ulcerative colitis on the appearance of activity within the colon. With continuous colonic activity, a distinction between Crohn disease and ulcerative colitis is not possible. Demonstration of discontinuous activity does not indicate Crohn disease with absolute certainty because discontinuous uptake has also been found in patients with ulcerative colitis, perhaps related to the attenuation of already minimal disease activity.[53,57] In this respect, WCSs are not sufficiently accurate and cannot be considered an alternative to endoscopic evaluation.

The accuracy of scintigraphy in the evaluation of small bowel disease is uncertain. Activity in overlying liver, spleen, transverse colon, and skeletal structures makes WCSs less sensitive in detecting upper gastrointestinal disease, and localization of proximal small bowel disease is poor. Reduced sensitivity of WCSs may also be related to the absence of active disease, with only the sequel of previous inflammation evident on barium studies.[58] The timing of scans is also important to avoid errors of interpretation owing to the normal hepatobiliary excretion of ^{99m}Tc.[59] Scintigraphy cannot be as informative as barium radiology in the definition of anatomic detail such as stricture formation. However, WCSs may provide information, allowing a distinction to be made between an inflammatory and a fixed stricture.

Currently, the role of scintigraphy in the routine investigation and monitoring of IBD is not well established. However, an understanding of the principles underlying these investigations and knowledge of the advantages and disadvantages of the technique allow the practitioner to decide whether scintigraphy could contribute to the optimal management of individual patients. Demonstration of florid disease activity, for example, would reinforce a decision to use more aggressive medical and surgical treatment.[60]

WCSs might have a role in the detection of postoperative disease activity, thus avoiding invasive tests in such patients. However, there are only limited reports in the pediatric literature, many of which are anecdotal. In a study of adults, Biancone and colleagues reported using leukocyte scintigraphy for the early detection of postoperative recurrence in Crohn disease.[61] Anastomosis-related activity was controlled for by comparison with patients who had undergone ileocecal resection for cecal carcinoma, and the findings were compared with those noted at endoscopy. There was good correlation between the endoscopic and the 30-minute scintigraphy scores at both 6 and 12 months postoperatively, suggesting that white cell scanning may prove to be a sensitive technique for this purpose.

The relatively noninvasive nature of leukocyte scintigraphy recommends its use for the screening of IBD. As with other indications for these investigations, there is uncertainty about its exact role and the advantages it has over endoscopy, biopsy, and barium radiology. Several studies in adults have looked at the role of WCSs in the screening of patients with suspected irritable bowel syndrome. Some authors express concerns over the high rates of false-positive results.[62] Shah and colleagues evaluated the accuracy of WCSs in screening children with suspected IBD and found false-positive scans in patients with postenteritis syndrome, infectious colitis, and anorexia nervosa, but there were no false-negative WCSs.[49] In clinical practice, if the clinical suspicion of IBD is high, it is likely that even with a negative WCS, further investigation should be recommended. Concerns over the possible inadequacies of WCSs in identifying small bowel disease also mitigate against the use of WCSs as a screening tool.

Leukocyte scintigraphy has also been used for identifying bowel inflammation associated with other disease entities. Hoare and colleagues reported a positive scan in a child with colitis owing to chronic granulomatous disease.[50] WCSs have been used following bone marrow transplant and cord cell infusion as treatment for chronic granulomatous disease to assess whether there is recurrence of colonic inflammation, without recourse to more invasive diagnostic tests.

Overall, it appears that there is currently no generally accepted role for leukocyte scintigraphy in pediatric IBDs. Nevertheless, WCSs are of value in certain situations, and the clinician should be aware of their potential. Wider use may well lead to a better understanding of their place in the diagnostic armamentarium.

ROLE OF SCINTIGRAPHY IN PROTEIN-LOSING ENTEROPATHY

Protein-losing enteropathy (PLE) is defined as a condition in which excess protein loss into the gastrointestinal lumen is severe enough to produce hypoproteinemia. PLE can occur in conditions such as ulcerative colitis, Ménétrier disease, celiac disease, and intestinal lymphangiectasia.[63] Most proteins lost into the bowel undergo proteolysis and are thus unreliable as a generalized measurement of PLE. α_1-Antitrypsin is resistant to intestinal proteolysis and thus its fecal level is indicative of the degree of loss of serum protein into the gastrointestinal tract.[64] Although this test provides a quantitative measure of intestinal protein losses, it does not allow localization of the site where this loss is occurring. Studies with ^{99m}Tc-labeled human serum albumin suggest that it is stable in the gut and that it is impermeable to normal bowel, making it an appropriate nucleotide for scintigraphic detection of PLE.[65] After intravenous injection of freshly prepared ^{99m}Tc human serum albumin, serial images of the abdomen are obtained from 10 minutes up to 24 hours after injection. A ^{99m}Tc human serum albumin scan is considered positive for PLE if there is visible tracer exudation in the gut (Figure 74.4-6).

Lan and colleagues presented two cases of PLE in children in which the loss was localized to the stomach in one child with transient Ménétrier disease and the small bowel in another child with primary oxalosis.[66] The diagnosis was confirmed in both cases by elevated 72-hour fecal α_1-antitrypsin levels. Halaby and colleagues reported a retrospective review of ^{99m}Tc human serum albumin scans in 18 children.[67] Scans were positive in 12 children, of whom 10 had primary intestinal lymphangiectasia, 1 had active *Salmonella* enterocolitis, and 1 had giardiasis. Scans were normal in the remaining 6 children, of whom 5 were subsequently demonstrated to have a primary intestinal lymphangiectasia. The authors noted that serum indices of PLE were less decreased than in those with positive scans, suggesting that a lower rate of protein loss might explain the false-negative scans. Chiu and colleagues stressed the importance of obtaining images up to 24 hours following the administration of the labeled albumin.[63] In summary, labeled albumin scintigraphy may be a useful tool in establishing a PLE. However, owing to concerns about accuracy, it is most appropriately used in association with other investigations.

NUCLEAR MEDICINE IN THE INVESTIGATION OF GASTROINTESTINAL TRACT BLEEDING

The causes of gastrointestinal bleeding in children are numerous, and radiology has a role in detecting the origin of the blood loss, defining associated pathology, and, in certain cases, intervening to control hemorrhage. There are two main techniques in nuclear medicine used to localize the site of gastrointestinal bleeding. Administration of ^{99m}Tc sulfur colloid or radiolabeled RBCs during active bleeding can localize the source of hemorrhage. It is said that RBC scans have detection rates higher than angiography at lower rates of blood loss—even as little as 0.1 mL per minute.[68] RBC and sulfur colloid scans have the advantage of being less invasive than angiography. The second technique, the so-called Meckel scan, involves administration of radiolabeled pertechnetate, which localizes in gastric mucosa and can identify ectopic sites of gastric mucosa as the source of blood loss. This type of scan is more frequently used when bleeding is intermittent and more occult.

GASTROINTESTINAL BLEEDING SCANS

There is an important difference between the two agents used to perform gastrointestinal bleeding studies. ^{99m}Tc sulfur colloid is a non–blood pool agent, which is cleared rapidly from the blood following injection. ^{99m}Tc-labeled RBCs are a blood pool agent that circulate in the blood for hours. When ^{99m}Tc sulfur colloid is injected intravenously, the particles circulate through the mesenteric vascular supply before being cleared by the liver and reticuloendothelial system. Any site of bleeding, vascular leak, or tear will allow the ^{99m}Tc sulfur colloid particles to extravasate, and this is detected using the gamma camera as a site of focal accumulation of isotope. Very small amounts of hemorrhage can be detected, but the patient must be actively bleeding between the time of injection and clearance of tracer, a window of approximately 15 to 20 minutes. For this reason, there is a high incidence of false-negative scans.[69] Bleeding near the liver or spleen may be obscured by activity in these organs, with a false-negative test result.

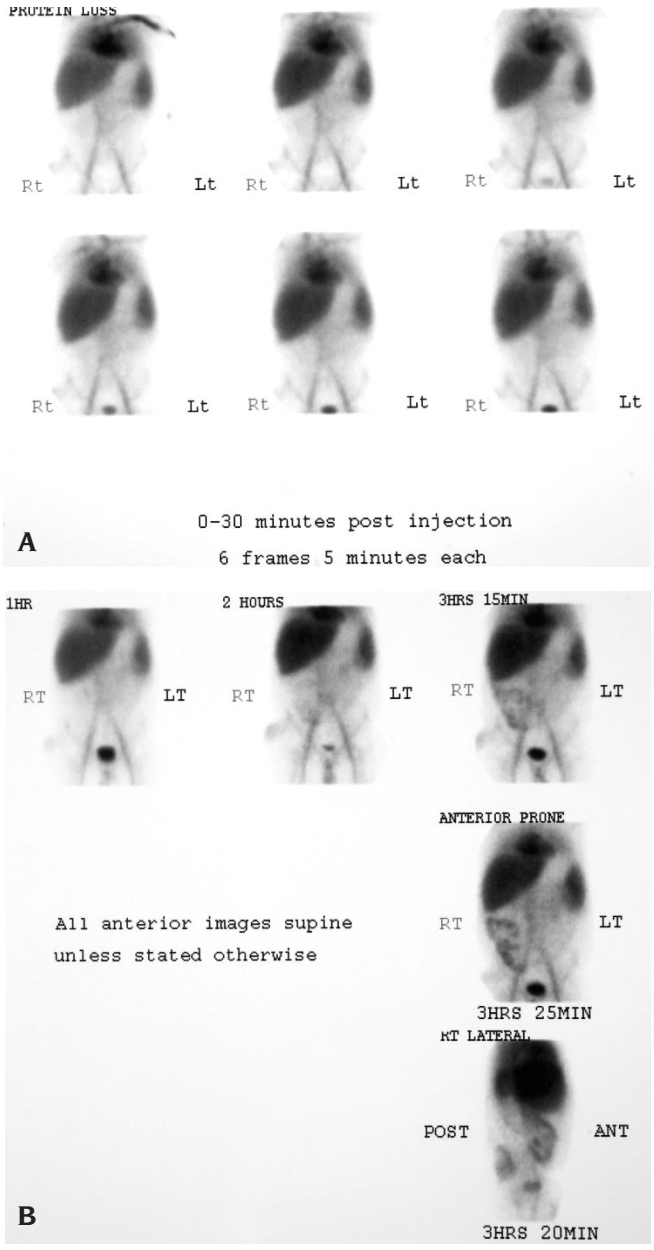

FIGURE 74.4-6 Protein-losing enteropathy. *A* demonstrates normal isotope uptake in the liver and spleen, normal activity in the vascular system, and renal excretion of isotope with activity in the bladder. *B*, By 2 hours, activity is seen within the gut in the right side of the abdomen and becomes more prominent on later images. This is due to loss of labeled albumin into the gut lumen.

The use of ^{99m}Tc-labeled RBCs is the preferred method for investigating acute gastrointestinal bleeding in children using radioisotope. It is more suitable for patients who are bleeding slowly or intermittently. However, this method requires more preparation time for labeling the RBCs and careful handling of the patient's blood. The labeling process can occur in vivo or in vitro. With in vivo labeling, an initial intravenous injection of nonradioactive stannous (tin) ion is given, followed 10 to 20 minutes later by an injection of ^{99m}Tc pertechnetate. The RBCs react first with the stannous ion and then the pertechnetate. Pertechnetate is reduced by the intracellular stannous ion, forming a complex with intracellular hemoglobin. Images can be acquired for several hours after the injection. However, high background activity reduces the sensitivity of in vivo labeled RBCs. Therefore, an in vitro labeling method is more commonly employed with a sample of approximately 5 mL blood taken into a syringe containing acid citrate dextrose to which stannous chloride is added.[70] The blood is then re-injected, and the patient is imaged immediately to demonstrate initial blood flow, followed by imaging for up to 2 hours. A normal ^{99m}Tc RBC study (both in vivo or in vitro labeled RBCs) will demonstrate tracer within the blood pools of the aorta, inferior vena cava, iliac vessels, and portal, renal, and mesenteric vessels. Tracer activity also persists in the kidneys and penis. Free pertechnetate can be seen in the kidneys, ureters, and urinary bladder. These are normal scintigraphic features and, most importantly, do not change over time. Sites of active bleeding are seen as focal, increasing accumulation of tracer that does move over time owing to gut peristalsis. Peristaltic movement may lead to erroneous impression of the exact site of bleeding. Computerized acquisition with dynamic cinescintigraphic display of sequential images is reported to improve the localization of bleeding sites.[71]

MECKEL SCAN

A Meckel diverticulum is a remnant of the omphalomesenteric (vitelline) duct, which is normally obliterated between the fifth and ninth week of gestation. It is present in approximately 2% of the population on the antimesenteric border of the small intestine, approximately 2 feet proximal to the ileocecal valve. Approximately half of Meckel diverticula contain ectopic mucosa, 80% of which contain gastric mucosa and therefore may become symptomatic owing to mucosal ulceration and intestinal bleeding. Ectopic pancreatic mucosa is present in approximately 5%, and this can occur concomitantly with gastric mucosa.[72]

^{99m}Tc pertechnetate is used to evaluate patients with lower gastrointestinal bleeding and abdominal pain and in whom a Meckel diverticulum is suspected. ^{99m}Tc pertech-

netate is taken up by the gastric mucin-producing cells and is then secreted into the gut lumen. Excretion of ^{99m}Tc pertechnetate is not dependent on the presence of parietal (acid producing) cells. It therefore detects the presence of gastric mucosa contained within a Meckel diverticulum rather than the diverticulum itself. In large case series, the test has a surgically proven sensitivity up to 85% and specificities as high as 95% for the detection of ectopic gastric mucosa.[73,74]

Ectopic gastric mucosa is visible as a focal area of isotope uptake simultaneous with uptake in eutopic gastric mucosa, usually within 10 minutes of injection of ^{99m}Tc pertechnetate (Figure 74.4-7). The intensity of the tracer accumulation may be less than that within the stomach, depending on the amount of mucosa present within the diverticulum and its secretory activity. Meckel diverticula are typically located in the right lower quadrant but may be found in different quadrants of the abdomen and can even move during the examination (Figure 74.4-8).[75] Normal excretion of ^{99m}Tc pertechnetate in the kidneys, ureters, and bladder should not be confused with pathology. Hydronephrosis, hydroureter, a pelvic kidney, and communicating urachal cysts can be mistaken for a Meckel diverticulum.[76] The bladder should be included on the abdominal images and postvoid images should be taken to ensure that a focal area of uptake is not obscured by activity within a full bladder.

Drugs that increase uptake or decrease the secretory activity of gastric mucosa can enhance the detection of a Meckel diverticulum. Pentagastrin given subcutaneously prior to the injection of ^{99m}Tc pertechnetate stimulates gastric mucosal uptake, whereas histamine$_2$-receptor antagonists inhibit the secretion of ^{99m}Tc pertechnetate from the mucin cells into the gut lumen. Glucagon acts to decrease gut peristalsis, thereby increasing retention of isotope within a diverticulum. In some institutions, pharmacologic enhancement is reserved for patients with a negative scan and a persisting high index of clinical suspicion.[13]

False-negative scans do occur and may be due to a number of factors, including suboptimal examination technique, impaired blood supply to the bowel, or insufficient mass of gastric tissue in the Meckel diverticulum to take up isotope. Continued bleeding or excessive secretions may cause washout of the isotope, leading to a false-negative test result. Repeat scanning, up to three times, is justified in patients with lower intestinal tract bleeding that is highly suspicious for originating from ectopic gastric mucosa and an initial negative ^{99m}Tc pertechnetate scan.[77] The use of SPECT has been advocated to increase the diagnostic accuracy of Meckel scans, particularly if the scan result is equivocal or if there is a strong clinical suspicion together with a negative Meckel scan.[78] Barium and contrast can interfere with visualization on scintigraphic examination. Therefore, Meckel scans or ^{99m}Tc RBC studies should be performed before barium studies or angiography. If both Meckel scan and ^{99m}Tc RBC imaging are to be performed, then Meckel scan should be performed first because stannous-containing agents affect the distribution of ^{99m}Tc pertechnetate within the body.[79]

False-positive scans may be seen with intestinal duplications that contain gastric mucosa. The presence of ectopic mucosa predisposes the patient to peptic ulceration, bleeding, and, occasionally, perforation as observed with Meckel diverticula. If a communication between the

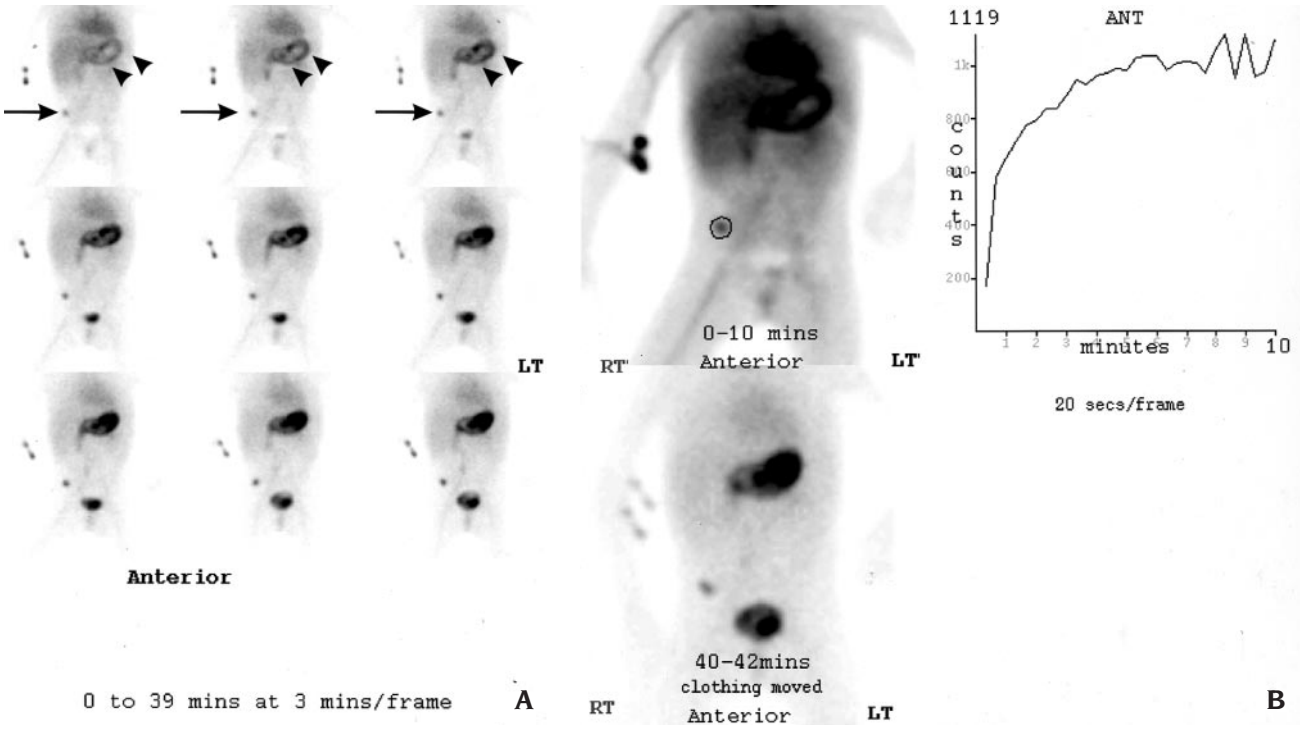

FIGURE 74.4-7 Positive Meckel scan. Uptake in the ectopic gastric mucosa of the Meckel diverticulum situated in the right lower quadrant (*arrow*) is simultaneous with uptake in gastric mucosa of the stomach (*arrowheads*). By drawing a region of interest around the ectopic gastric mucosa and plotting the count rate, maximum uptake is seen at approximately 5 minutes (*B*).

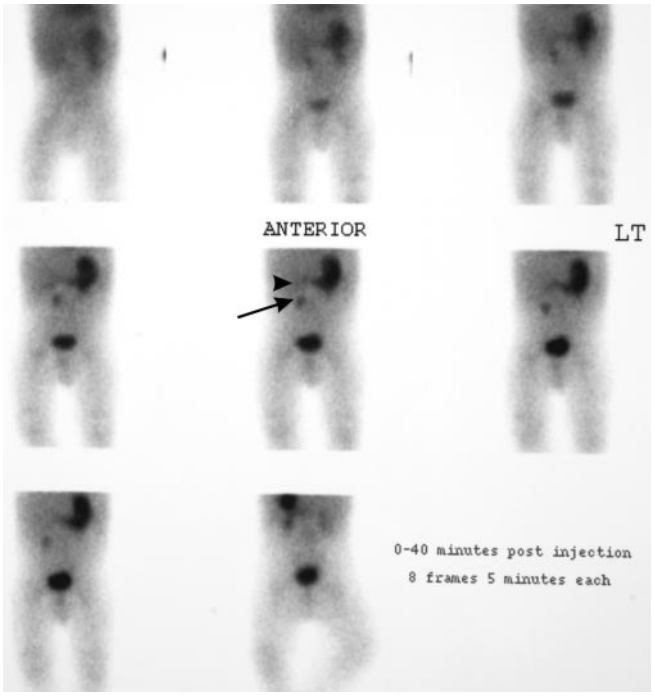

FIGURE 74.4-8 Positive Meckel scan. The Meckel diverticulum in this patient is located in the right upper quadrant (*arrow*), inferior to secreted activity in the first part of the duodenum (*arrowhead*).

cyst and the bowel exists, then bleeding will be intraluminal. If there is no communication, blood can accumulate within the cyst, and the patients present with a painful, rapidly enlarging abdominal mass.[72] Barrett esophagus, peptic ulcers, IBD, intussusception, vascular malformations, and neoplasms can also cause false-positive scans owing to the nonspecific accumulation of isotope.[13,72]

SOMATOSTATIN RECEPTOR SCINTIGRAPHY

Although neuroendocrine tumors affecting the gastrointestinal tract are uncommon in children, the gastrinoma (Zollinger-Ellison) syndrome and the VIPoma (Verner-Morrison) syndrome are well described (see Chapter 47, "Secretory Tumors Affecting the Gut"). These neuroendocrine tumors predominantly overexpress the somatostatin receptor SSTR2, which has a high affinity for synthetic analogues of somatostatin, such as octreotide.[80] This property has been exploited to allow accurate localization of the tumors. Radiolabeled peptides, such as ^{111}In pentreotide, bind to the SSTR expressed on the tumor, thereby allowing identification and localization.[81] Compared with other imaging techniques, including ultrasonography, CT, MRI, and angiography, somatostatin receptor scintigraphy is the most sensitive.[82,83] The ability of scintigraphy to image the whole body allows identification of both primary lesions and sites of metastatic spread. The technique has been further developed to allow tumor localization at surgery by use of a probe that detects preoperatively injected labeled octreotide.[84] Consideration has also been given to using receptor expression to target radiotherapy.

SCINTIGRAPHY IN BILE ACID MALABSORPTION

Bile acids are reabsorbed by an active transport mechanism in the terminal ileum as part of the enterohepatic circulation. Bile acid malabsorption is described as a rare cause of chronic diarrhea in infants owing to the effect of the bile acids on the colonic ability to reabsorb sodium.[85] Malabsorption of bile acids can also arise as a result of ileal resection (eg, in Crohn disease) and has been observed in association with cholecystectomy, chronic pancreatitis, celiac disease, and diabetes mellitus.[86] ^{75}Selenium (Se)-labeled homocholic acid conjugated with taurine (^{75}SeHCAT) can be used to measure bile acid losses from the gut. Tauroselcholic acid does not occur naturally but is an analogue of the naturally occurring bile acid conjugate taurocholic acid. ^{75}SeHCAT is administered intravenously and, through hepatobiliary excretion, becomes mixed with the endogenous bile acid pool. Malabsorption is assessed either by regular fecal collections or by assessing the 7-day retention, which is measured as a whole-body gamma camera count. The effective dose for this study in adults is 0.3 mSv, but there are no equivalent pediatric data. For comparison, the effective dose of a posteroanterior chest radiograph is 0.02 mSv and for a CT scan of the abdomen, 10 mSv. The average effective dose from natural background radiation per year is 3 mSv.[87]

In adults, normal retention at 7 days is over 10%.[88] Unfortunately, no lower limit has been determined for use in pediatric practice. However, this has not prevented its use in the diagnosis of primary bile acid malabsorption as a cause of protracted diarrhea in infants.[89] In this report, two sisters with chronic diarrhea are described in whom the ^{75}SeHCAT retention over 7 days was less than 0.1%. Subsequent investigations confirmed the absence of the bile acid transporter in the apical membrane of ileal enterocytes. Thus, although experience is still quite limited in children, the use of ^{75} SeHCAT can be justified in the investigation of children with unexplained chronic diarrhea and impaired growth.

CHAPTER 75

1. Fluid and Dietary Therapy of Diarrhea

Dilip Mahalanabis, MBBS, FRCP
John D. Snyder, MD

Because diarrheal diseases have long been a major cause of morbidity and mortality,[1] the development of oral rehydration therapy (ORT) solutions has been hailed as one of the most important medical advances of the twentieth century.[2] This therapy is a rare but important example of the reverse transfer of technology from developing countries to developed countries. The initial trials of ORT were carried out primarily in less developed populations, where its effectiveness was established in children and adults with acute diarrhea from many etiologies.[3–6] The impact of ORT was established early in its development when it was used with dramatic effect during a cholera epidemic in West Bengal refugee camps in 1971.[7] ORT has been estimated to save about 1 million lives each year in the developing world.[8]

Although many of the basic science studies that provided the foundation of ORT were carried out in industrialized countries, these countries were slow to use ORT despite its successful use in the developing world.[9,10] The low rate of use of ORT occurred despite the endorsement of organizations including the American Academy of Pediatrics (AAP), the US Centers for Disease Control and Prevention (CDC), and the European Society for Pediatrics, Gastroenterology, Hepatology, and Nutrition.[11–13]

Optimal oral therapy has continued to evolve and now includes appropriate feeding during and after diarrhea in addition to the use of fluid and electrolyte solutions.[1,8] The emphasis on early feeding has helped to address the problem of malnutrition, which is often a major accompanying problem of diarrheal illness in developing countries.

This chapter discusses the continuing evolution of oral therapy, with special emphasis on dietary management of diarrhea. The principles of care established in developing countries now provide the basis for treatment in all parts of the world.

PHYSIOLOGIC BASIS OF ORAL THERAPY

To understand the concepts involved in effective oral therapy, it is helpful to review the physiology of intestinal fluid movement. Each day, about 9 L of fluid are processed by the adult intestine.[8,10] These fluids dilute food and are essential to the digestive process.

Reabsorption of that large volume of fluid occurs through the villous cells of the small intestine and the epithelial cells of the colon. The main driving force for water absorption is the osmotic response to the absorption of electrolytes and solutes, especially sodium and glucose. The bulk of sodium and water absorption from the small intestine results from coupled transport, in which the absorption of sodium molecules is linked to glucose or other small organic molecules such as amino acids, short-chain polypeptides, bile acids, or water-soluble vitamins by a variety of sodium-solute cotransporters expressed in the enterocyte apical membrane.[8] Sodium uptake in the small intestine can also occur passively down a concentration gradient created by active pumping of the ion out of the enterocyte by several ion-coupled mechanisms, facilitated by sodium/potassium-exchanging adenosine triphosphatase.[14] In addition to coupled transport, sodium transport occurs by solvent drag through the paracellular pathway.[14,15]

Diarrhea results when these secretion or reabsorption mechanisms are disrupted, causing dehydration by depletion of intravascular fluid and electrolytes. Diarrhea-causing organisms can increase the chloride-secreting activity of the crypt cells (toxigenic), can disrupt the absorption of sodium by villous cells (invasion or adherence), or can affect both mechanisms (see Chapter 2, "Microbial Interactions with Gut Epithelium"). Coupled transport of sodium and glucose or other organic solutes is not affected in toxigenic diarrhea and is at least partially competent in other types of diarrhea, such as that caused by *Rotavirus*.[8] The key physiologic foundation for successful ORT is a functioning sodium-glucose transporter.[2]

In 1964, Phillips was the first to show that glucose-linked sodium absorption is retained during severe diarrhea owing to cholera.[3] The initial success of ORT for adult cholera patients was soon tested under controlled conditions in the treatment of children with cholera, *Rotavirus*,

enterotoxigenic *Escherichia coli*, and other etiologic agents.[6,16–18] ORT emerged as a powerful therapeutic tool to correct dehydration resulting from acute diarrhea in all but the most severe cases and in all ages, irrespective of etiologic agents.[1,8] In severe cases, such as *Rotavirus* enteritis in infants, insufficient glucose-sodium absorptive capacity may be present to support ORT, perhaps because the infection involves all or most of the small intestine.

In addition to sodium and glucose, ORT also contains potassium, chloride, bicarbonate or citrate, and water (Table 75.1-1). Clinical balance studies have provided guidelines for the optimal concentration of the five components of ORT solutions and resulted in the formulation recommended by the World Health Organization/United Nations International Children's Emergency Fund (WHO/UNICEF) for over 30 years (see Table 75.1-1).[8] Maximal cotransport occurs when the molar ratio of glucose to sodium approaches 1.[8,10] Potassium is required because diarrheal dehydration can cause substantial loss of the ion, especially in infants and small children.[10] Chloride losses also occur during diarrhea, and the ion is required to balance the positive sodium and potassium ions. Varying degrees of base-deficit acidosis occur in diarrheal dehydration, and base replacement can speed the therapeutic response.[10] These other ions follow passively the coupled transport of sodium and glucose.

In North America, several commercial sugar-electrolyte solutions similar to the WHO/UNICEF formulation are widely available (see Table 75.1-1). They differ primarily in having slightly higher glucose and lower sodium concentrations than the WHO/UNICEF solution and are supplied in the more costly reconstituted form. In controlled trials in the United States, sugar-electrolyte solutions with sodium concentrations of 45 to 75 µmol/L have proven to be effective in the treatment of well-nourished children with mild to severe dehydration.[18–21] However, such solutions with sodium concentrations < 75 µmol/L are not suitable for use in adults and older children with cholera and similar secretory diarrheas.[10,11]

CONTINUING EVOLUTION OF ORAL THERAPY FOR DIARRHEA

Since 1971, WHO has recommended a single formulation of oral rehydration salts (ORS) to treat dehydration from diarrhea of any cause, including cholera, in all age groups.[1,8] Although ORS has been immensely successful,[1,8] it has not been used as widely as anticipated, primarily because it has no effect on shortening the duration or volume of diarrhea[9]; in fact, stool volume may increase on ORS. To help address this important limitation, a variety of strategies have been tried to add antidiarrheal properties to oral therapy.

Polymers and Added Solutes

Efforts to replace glucose with more effective cotransport molecules have included trials of amino acids, including glycine, glycyl-glycine, alanine, and glutamine.[22] These solutions have performed no better than ORS, especially in noncholera diarrhea, and have some important limitations, including the limited availability and high cost of amino acids and peptides, the development of metabolic abnormalities, and instability during storage.[22] The use of glucose polymers, including maltodextrins, permits the inclusion of additional cotransport molecules without incurring an osmotic penalty.[23] However, the reduced-osmolarity maltodextrin solutions resulted in no appreciable improvement over ORS.[22]

Cereal-Based Oral Therapy

A more effective approach to improving absorption of solutes and water proved to be the use of cereal-based solutions that use the complex carbohydrates and simple proteins of cereals as cotransport molecules.[23] Many of the studies of cereal-based therapy have used cooked rice and salts added in concentrations identical to the standard ORS.[24–26] Other cereals that have been used effectively include wheat, corn, sorghum, and millet.[26,27] A meta-analysis of randomized clinical trials of cereal-based ORT, especially rice-based ORT, has demonstrated that this form of ORT is superior to glucose ORT in adults and children with cholera and other high-purging diarrheas.[28] These solutions produced a mean reduction in stool output in the first 24 hours of therapy of ~ 30 to 40%. For children with acute noncholera diarrhea, the reduction in stool output was ~ 18%.[28] Despite these impressive results, cereal-based ORT has not been widely used, probably for a combination of reasons. One important constraint relates to the ease of preparation. Most studies of cereal-based ORT used cooked cereals, which require time and fuel to prepare, making these solutions less attractive than the easy-to-prepare packets of ORS. However, commercially prepackaged cereal-based ORT

TABLE 75.1-1 COMPOSITION OF GLUCOSE ELECTROLYTE SOLUTIONS

	CONCENTRATION (mmol/L)				
SOLUTION	CHO	NA	K	BASE	OSMOLALITY
KaoLectrolyte (Pharmacia/Pfizer, New York, NY, USA)	112	48	28	20	240
Pediatric Electrolyte (PharmaScience, Montreal, QC, Canada)	140	45	20	30	250
Pedialyte (Ross, Columbus, OH, USA)	140	45	20	30	250
Infalyte (Mead Johnson Evansville, ID, USA)	70	50	25	30	200
Rehydralyte (Ross Columbus, OH, USA)	140	75	20	30	301
Cera-lyte (Cera Products, Jessup, MD, USA)	80	70	20	30	235
Reduced osmolar ORS (WHO/UNICEF)	75	75	20	30	245
Previously recommended WHO/UNICEF ORS	111	90	20	30	310

CHO = carbohydrate; ORS = oral rehydration solution.

solutions that dissolve easily in water are now available (see Table 75.1-1). Perhaps more importantly, the use of these solutions was affected by the nearly simultaneous introduction of early appropriate feeding along with ORS. The interest in feeding as an integral part of oral therapy arose from the same potential advantages of enhanced solute uptake from easily digested foods that stimulated the development of cereal-based ORT and is discussed below.

Hypo-osmolar Solutions

The renewed interest in oral hypo-osmolar solutions for the treatment of diarrhea stems from perfusion studies that demonstrate a significant inverse correlation between ORT osmolality and water absorption in animals and humans.[29] Recent studies in children have demonstrated that hypo-osmolar ORT formulations can result in lower stool output (~ 20%), less vomiting (~ 30%), and less need for intravenous therapy for failures of ORT (~ 33%) compared with standard ORS.[30–34] A meta-analysis of 15 randomized controlled studies has helped to confirm the superiority of the reduced-osmolarity ORS over the standard WHO/UNICEF ORS.[35] However, concern exists for the development of hyponatremia when the reduced-osmolarity ORS is used in patients with high purging rates such as those caused by cholera because of the reduced sodium concentration. In the clinical trials, asymptomatic hyponatremia was reported in some patients, and WHO/UNICEF recommends that careful monitoring of electrolytes be done for patients with high purging rates who receive the new reduced-osmolarity solution.[36] Because of less need for intravenous therapy, decreased vomiting, and lower stool output, WHO/UNICEF now recommends the use of the reduced-osmolarity solution (see Table 75.1-1) as the single ORS for use in persons with diarrhea.[36]

Early Appropriate Feeding

Theoretical Considerations. The inclusion of early appropriate feeding along with ORT required the overturning of the common practice, used in many countries and cultures, of withholding feedings during diarrhea.[37] The rationale for withholding food during diarrhea was based primarily on the concern for malabsorption, which can occur because of an altered intestinal mucosa, decreased brush border enzymes, and a more rapid intestinal transit time.[38] The theoretical risk of increased macromolecular uptake across the damaged mucosa leading to intestinal allergy has been postulated but has never been shown to be of practical importance in diarrhea.[39] In contrast, the several important potential benefits of early feeding became a strong stimulus to study its safety and efficacy. These benefits include the chance to provide nutritional therapy to malnourished patients with diarrhea, especially in developing countries.[37,38] In addition, nutrient uptake plays an important role in intestinal repair.[40]

Nutrient Absorption during Diarrhea. Although some element of malabsorption is often associated with diarrhea, it is rarely complete, and substantial amounts of nutrients can be absorbed.[37,38,41,42] This is especially true for the digestion and absorption of complex carbohydrates in staple foods because the luminal concentrations of amylases and pancreatic enzymes appear to be largely unaffected during diarrhea.[37,38] Balance studies of nutrient absorption of staple foods have demonstrated that as much as 90% of complex carbohydrates, 70% of protein, and 60% of fat can be absorbed during acute diarrheal episodes.[41–43] Factors that influence the success of feeding include the age of the child, the etiology of the diarrhea, the severity of the stooling, and the composition of the diet.

Impact of Feeding on Diarrhea. Feeding is usually well tolerated in acute infectious diarrhea and can have a direct beneficial effect on diarrhea when combined with ORT.[38] Controlled clinical trials have shown that appropriate early feeding combined with ORT can reduce stool output[44–49] and the duration of diarrhea[46,48–53] compared with ORT or intravenous therapy alone.

Effective Feeding Regimens. Cereal-based staple-food diets have been among the most effective diets studied, but if cereals or legumes provide the sole source of protein, an amino acid profile deficient in essential amino acids is likely to result.[54] Also, a greater proportion of protein may be required in cereal- or legume-based diets because of their digestibility.[54] A solution to this problem is to include milk, a more complete protein source, along with cereals to improve the amino acid profile and digestibility. Ideally, milk can provide these essential amino acids, but because brush border lactase levels are often reduced during diarrhea, milk has often been avoided or diluted because of concerns about possible lactose intolerance.[37] The amount of lactose that can be tolerated by children with diarrhea is still a subject of controversy, but several principles have become clear.[54] Breastfed infants, who receive a higher concentration of lactose than children receiving cow's milk or cow's milk formula, can be fed safely through diarrhea.[37,38] Full-strength animal milk or animal milk formula is usually well tolerated by children who have mild, self-limited diarrhea, which is very common in the United States.[50] A meta-analysis on the use of lactose in children with acute diarrhea found that most children can safely tolerate full-strength animal milk, especially when combined with staple foods.[55] These mixed diets are better tolerated than milk alone[43] and are thought to be successful in part because of the smaller total lactose load and because solid foods help delay gastric emptying and thus slow transit time.[56]

Banana, Rice, Applesauce, and Toast Diet. This diet, commonly referred to as the BRAT diet, has long been used in North America to begin refeeding children who have had diarrhea. However, this diet is no longer recommended because it is low in energy density, protein, and fat and because the banana and applesauce may add an excessive load of sugars to the gut.[11] In addition, diets high in simple sugars (including sweet tea, juices, and soft drinks) (Table 75.1-2)[57] or fats should be avoided.[12] Optimal diets should provide a nutritionally acceptable balance of carbohydrate, protein, and fat.

TABLE 75.1-2 COMPOSITION OF REPRESENTATIVE CLEAR LIQUIDS NOT APPROPRIATE FOR ORAL REHYDRATION THERAPY*

LIQUID	CHO, mmol/L	Na, mmol/L	K, mol/L	BASE, mmol/L	OSMOLALITY, mmol/L
Cola	700 (F, G)	2	0	13	750
Apple juice	690 (F, G, S)	3	32	0	730
Chicken broth	0	250	8	0	500
Sports beverage	255 (S, G)	20	3	3	330

*Adapted from Snyder JD.[69]
CHO = carbohydrate; F = fructose; G = glucose; K = potassium; Na = sodium; S = sucrose.

Soy Formulas. Many practitioners in North America have switched their pediatric patients with diarrhea to soy formulas because of concerns for malabsorption of lactose in cow's milk and cow's milk formulas. However, data from controlled clinical trials demonstrate no benefit in soy formulas compared with cow's milk, especially when used with staple-food diets.[55] In addition, recent studies show that soy formulas were not as well tolerated in children with acute diarrhea as mixed staple-food diets[47] or soy formula with fiber.[58]

MANAGEMENT GUIDELINES

ORT can be administered to infants with a cup and spoon, a cup alone, or a feeding bottle. For weak small babies, a dropper or a syringe can be used to put small volumes of solution into the mouth. A nasogastric tube can be used to administer the ORT in babies or children who cannot drink because of fatigue or drowsiness but who are not in shock. In the vomiting child, small volumes, often 5 mL at a time, can be given frequently, as often as every few minutes (see below).

Early appropriate feeding, which has become an integral component of oral therapy, is the component that has the potential for the greatest impact on stool volume and duration.[11] Successful feeding trials have been carried out using breast milk, dilute or full-strength animal milk or animal milk formulas, dilute and full-strength lactose-free formulas, and mixed diets of staple foods with milk.[44–56] Recent studies indicate that diets of naturally occurring, culturally acceptable, inexpensive foods can be effective in diarrhea.[54] The implications of these findings are enormous from a health policy standpoint because they provide hope that the important ingredients of successful feeding therapy are already present, even in developing countries.

The specific recommendations for treatment depend on the severity of the diarrhea (Table 75.1-3).

No Dehydration

Intake of ORT is often low, in part because of the potentially salty taste of ORT.[9,11] Fortunately, if the stool output remains modest, ORT may not be required. If no dehydration develops, which is the case for the great majority of diarrhea patients in the United States, continued age-appropriate feeding is the only therapy required. Controlled clinical trials have demonstrated a number of foods that can be used safely and effectively in most children with diarrhea (Table 75.1-4). Unweaned infants should receive breast milk or continue to receive the regular formula. The formula does not require dilution if the diarrhea remains mild. If a diluted formula is used, the concentration should be increased rapidly if the diarrhea does not worsen. Weaned infants and children should have their regular nutritionally balanced diet continued, emphasizing complex carbohydrates (such as rice, wheat, and potatoes), meats (especially chicken), and the child's regular milk or formula. Diets high in simple sugars and fats should be avoided.[11,12]

Mild, Moderate, or Severe Dehydration

After dehydration is corrected, appropriate feeding is begun, using the guidelines above (see Table 75.1-3). Children with severe dehydration, which is a shock or a shock-like condition,[11,12] should be treated as an emergency. A large-bore catheter should be used for the infusion of Ringer lactate, normal saline, or similar solution, and boluses of 20 to 40 mL/kg should be administered until signs of shock resolve. Fluid and electrolyte resuscitation may require more than one intravenous site, and alternate access sites (including venous cutdown, femoral vein, or interosseous locations) may be needed.[11,12] As the patient's level of consciousness improves, ORT can be instituted. The hydration status must be frequently reassessed to monitor the effectiveness of the therapy. When rehydration is complete, feeding is continued as directed above.

TABLE 75.1-3 EFFECTIVE FOODS FOR USE DURING DIARRHEA

FOOD	OUTCOME
Breast milk[44] + ORT	↓ Stool volume compared with ORT alone
Cow's milk + staples[43] + ORT	No difference compared with ORT alone
Rice-based diet[26,28,42] + ORT	↓ Stool volume and duration compared with ORT alone
Wheat-based diet[27] + ORT	↓ Stool volume and duration compared with ORT alone
Wheat-pea diet[45] + ORT	↓ Stool volume and duration compared with ORT alone
Potato diet[43] + ORT	↓ Stool volume and duration compared with ORT alone
Chicken[51] + ORT	↓ Stool volume and duration compared with ORT alone
Egg[53] + ORT	↓ Stool volume and duration compared with ORT alone

ORT = oral rehydration therapy.

TABLE 75.1-4 MANAGEMENT OF ACUTE DIARRHEA

TREATMENT	MILD DIARRHEA, NO DEHYDRATION	MILD DEHYDRATION (< 5%)	MODERATE DEHYDRATION (5–9%)	SEVERE DEHYDRATION (> 10%)
ORT	Rehydration: may not be required	Rehydration: 50 mL/kg over 4 h	Rehydration: 100 mL/kg over 4 h	Rehydration: IV therapy with solution like normal saline or Ringer lactate, 20–40 mL/kg/h until rehydrated; then may begin ORT
	Continuing losses: if required: 10 mL/kg/each stool	Continuing losses: 10 mL/kg for each stool and estimated emesis volume	Continuing losses: same as for mild dehydration	
Early appropriate feeding	Continue age-appropriate diet (see Table 75.1-3)	Begin age-appropriate diet when dehydration corrected	Begin age-appropriate diet when dehydration corrected	Begin age-appropriate diet when dehydration corrected and patient stabilized

Adapted from American Academy of Pediatrics, Subcommittee on Acute Gastroenteritis.[11]
ORT = oral rehydration therapy.

Special Considerations

Vomiting. Vomiting, commonly associated with acute diarrhea, can make ORT more challenging, but almost all children with vomiting can be treated successfully with ORT.[11,12] When small volumes (eg, 5 mL) are given frequently (eg, every 1 to 2 minutes), an effective volume of ORT can be administered to a vomiting child.[11,12] Although this technique is labor intensive, as much as 150 to 300 mL/h of fluid can be administered.

Correction of fluid and electrolyte deficits by balanced-electrolyte ORT can help speed recovery from vomiting.[11,12] As vomiting decreases, ORT can be given in larger volumes, and when rehydration is complete, feeding can begin.

Nasogastric tubes can sometimes be of benefit in administering ORT to vomiting children. Continuous infusion of ORT can result in improved absorption of fluid and electrolytes and may permit more aggressive therapy in a child with poor intravenous access. Nasogastric infusion cannot be considered in children who are comatose or who have ileus or evidence of intestinal obstruction.

Zinc Supplementation. Several recent studies have identified zinc supplementation to have a significant impact on the duration and severity of acute and persistent diarrhea in children in nonindustrialized countries.[59–61] The mechanisms for this effect are not yet known but may include the effect of zinc on the absorption of water and electrolytes, improvement of intestinal function and enzyme activities, or enhanced immunocompetence.[62]

Hypernatremia. A long-standing concern, especially in developed countries, is the perceived risk of hypernatremia from ORT, especially with a relatively high sodium concentration in rehydration solutions.[8,10,11] However, a large body of data has clearly shown that oral rehydration solutions are an effective treatment for hypernatremia, given normal renal function.[63,64] These studies demonstrate that ORT can result in better outcomes than the best results reported with intravenous therapy.

Refusal to Take ORT. Refusal of pediatric patients to take ORT is a common complaint of practitioners in North America,[11] but children who are dehydrated rarely refuse ORT because they usually crave salt and water. The problem is usually found in children who have little or no dehydration. Most children do not require ORT if their diarrhea is mild, if they remain stable, and if they show no evidence of dehydration.[11]

Methods for increasing ORT intake include the use of flavored ORT, which does not alter the composition of fluid and electrolytes but which improves taste.[11] These flavored solutions are now the most popular forms of ORT sold in North America. Another effective way to increase intake is to freeze the ORT solution in an ice-pop form.

Management at Home. The principles for the effective household treatment of diarrhea, which have been developed primarily from extensive experience in developing countries, are the same for all settings.[9,11,12] As mentioned above, the most essential principles are the use of ORT to replace fluid and electrolyte losses and the continuation of appropriate feeding as soon as dehydration has been corrected. This is true both for developing and developed countries, but greater educational efforts are needed in all settings to help parents and caretakers provide effective therapy and to recognize the development of serious conditions.[65] The need for better education is underscored by the fact that approximately 10% of preventable infant deaths in the United States are caused by improper recognition and inappropriate treatment of acute diarrhea.[66]

Severe Malnutrition and ORT. Diarrhea is a serious and often fatal event in children with severe malnutrition. Although treatment and prevention of dehydration are essential, care must also focus on careful management of malnutrition and on treatment of other infections. Dehydration owing to acute diarrhea in children with severe protein-energy malnutrition (eg, marasmus, kwashiorkor) can be managed with ORT as described above.[1,12] In children with kwashiorkor, ORT must be closely supervised

because of the increased risk of edema and congestive heart failure, especially with intravenous therapy.

Use of Antibiotics or Nonspecific Antidiarrheal Agents. The message that neither antibiotics nor nonspecific antidiarrheal agents are indicated for most diarrheal episodes also requires emphasis.[11,12,67] However, antibiotics are indicated for a few specific infections, including cholera *Shigella* with systemic spread, *Clostridium difficile*, *Salmonella* in children < 3 months old, *Giardia*, and *Entamoeba histolytica*.[68]

Drugs that alter intestinal motility, secretion, adsorption of fluid and toxins, or intestinal microflora have little or no data to support their use in children.[11,12,68] The AAP, CDC, and WHO all recommend that such drugs not be used to treat acute diarrhea.[11,12,68]

Low Use Rates for ORT. Low use rates continue to be an important problem in both the developing and the developed world. Despite its unquestioned success in saving lives, only about 40% of diarrheal episodes are treated with ORT in the developing world,[67] and the estimates for use in North America are far lower.[9,65,69] The efforts to improve the antidiarrheal properties of ORT may have an important impact on use. In the United States, the cost of ORT is often 20 to 50 times higher than the $0.10 to $0.15 per-packet cost for ORS in the developing world, limiting its use in the most disadvantaged portions of the population, who are at the greatest risk for morbidity and mortality from diarrhea.[66] In countries without state-sponsored health care, many third-party payers do not reimburse clinicians and hospitals for oral fluid therapy despite its proven ability to reduce unnecessary medical visits and hospitalization.[65]

Persistent Diarrhea. Persistent diarrhea, defined operationally as episodes that continue for 14 days or longer, is responsible for a large proportion of deaths in young children with diarrhea.[70–73] General treatment guidelines include the use of appropriate fluids to prevent or treat dehydration, a nutritionally effective diet that does not worsen the diarrhea, and supplementary vitamins, minerals, and antimicrobial agents to treat concurrent infections such as pneumonia, sepsis, and urinary tract infections.

A spectrum of illness exists for persistent diarrhea, but a common pattern is for affected children to pass several liquid stools in a day, without much dehydration. Growth failure and adverse nutritional consequences may result. In other cases, children may have severe and persistent watery diarrhea with dehydration. When more severe diarrhea is present, the principles of ORT are the same as for acute diarrhea except for the few children who will exhibit evidence of temporary glucose malabsorption. These children may require intravenous fluids until their glucose malabsorption resolves.

The feeding principles described earlier also apply to children with persistent diarrhea. A multicenter study that evaluated a diet algorithm for the treatment of persistent diarrhea in young children in developing countries provided several practical guidelines.[73] In this study, the initial diet used locally available staple foods (rice or corn), milk or yogurt (< 4 g lactose/150 kcal), vegetable oil, and sugar. The children who did not improve were given a lactose- and sucrose-free cereal-based diet. Most of the children had resolution of or improvement in their diarrhea while on these nutritional therapies even though this was a population of very compromised children, including many who had extraintestinal infections. Influenced by this study, the current guidelines on nutritional therapy for persistent diarrhea include (1) breastfeeding whenever possible, (2) animal milk (limited to 50 mL/kg/d) mixed with cereal for non-breastfed children, (3) a daily intake of at least 110 calories/kg, and (4) supplemental vitamins and minerals.[73]

2. *Feeding Difficulties*

Thomas M. Foy, MD
Danita I. Czyzewski, PhD

Although primary nutrient deficiencies are now rare in developed countries,[1] feeding difficulties are a continuing challenge for those who care for infants and children. It is estimated that up to 54% of infants and toddlers have problematic feeding behavior and that in 25% of children, feeding problems prompt parents to seek professional advice.[2,3] Feeding difficulties may persist and in 1 to 2% of infants will lead to retarded growth.[4–6] A survey of children with cerebral palsy found that in the first 12 months of life, 38% had problems with swallowing, 57% had problems with sucking, and more than 90% had significant oral-motor dysfunction.[7]

Disorders of the gastrointestinal tract will interfere with adequate intake of nutrients and may compromise the nutritional status of the infant at several levels. Poor intake owing to anorexia, fatigue, or dysphagia may add to the dilemma of increased losses from vomiting or malabsorption. The goals of nutritional therapy are to restore the patient to normal nutritional status, to enhance recovery from the underlying disease process, and, ultimately, to attain nutritionally adequate and developmentally appropriate feedings. This chapter examines the basis of feeding disorders in infants and children and current approaches to their evaluation and treatment.

NORMAL DEVELOPMENT AND MECHANICS

Feeding problems represent a deviation from normal feeding skill development and mechanics.[8–10] Maturation of deglutition, which begins in utero and is completed by 3 years of age, depends on integration of oral-motor, fine-motor, gross-motor, sensory, and behavioral skills. An outline of feeding development in normal infants is seen in Table 75.2-1. Whereas sucking movements can be seen at 15 to 18 weeks gestation, adequate coordination of suck, swallow, and breathing to permit significant nutrient intake is not present until 34 to 35 weeks gestation. Reflex behaviors present at term may disappear later in infancy (rooting, phasic bite) or may persist (gag, swallow).[11]

For the infant, successful feeding depends on coordination of suck, swallow, and breathing. Sucking itself has a developmental progression, with the earliest tongue movements described as "suckling" and characterized by an in-out horizonmental movement. "Sucking" appears later in infancy, indicates an up-down tongue movement with firm lip approximation, and is used in a general sense in this discussion. Swallowing, or deglutition, occurs in at least three phases, as shown in Figure 75.2-1.[11,12] The oral phase includes bolus formation of solid food or liquid by the

TABLE 75.2-1 NORMAL FEEDING DEVELOPMENT

AGE	REFLEXES	ORAL-MOTOR SKILLS	SELF-FEEDING
15–18 wk gestation		Sucking movement	
34–35 wk gestation		Adequate suck-swallow coordination	
Term	Rooting, gag, phasic bite	Jaw and tongue move up and down; air swallowing common	
3–4 mo	Phasic bite disappearing	Tongue protrudes in anticipation of feeding	Visual recognition of bottle/nipple
5–6 mo	Rooting diminishes	Munching begins, smacks lips together, strained foods begin	Puts hands on bottle, begins finger-feeding
7 mo	Mature gag		May insert spoon in mouth
9 mo		Lip closure, lateral tongue movement	
12 mo		Rotary chewing, controlled, sustained bite	Finger-feeds independently, brings spoon to mouth
18 mo		Swallows without food loss, tongue elevates intermittently or consistently	Cup drinking with two hands, spoon-feeds messily
24 months		Lips contain food/saliva within mouth, tongue transfers food one side to other side	Fills spoon with finger or spoon to mouth without inversion

tongue, with the soft palate lowering to prevent food from entering the pharynx and initiating a swallow. The pharyngeal phase is both voluntary and involuntary and begins as a swallow is initiated. As food enters the pharynx, the soft palate elevates to protect the nasopharynx and the larynx elevates and closes to protect the airway. The final or esophageal phase begins with relaxation of the upper esophageal sphincter (cricopharyngeus muscle) and carries the bolus to the stomach under involuntary control. The return of the upper esophageal sphincter to its tonically contracted state prevents laryngeal penetration or aspiration of esophageal contents or reflux of the bolus back into the pharynx.

ETIOLOGY

Infants with feeding problems are usually referred for evaluation when inadequate intake has led to growth faltering or eventually failure to thrive, or perhaps less frequently when a caregiver perceives significant difficulty in feeding the infant even if weight has not dropped off. The feeding problem may be the primary cause of poor growth, secondary to other disease processes, or both. Understanding which patients are at risk for feeding disorders will promote early intervention.[13]

Table 75.2-2 presents selected etiologies for feeding difficulties. Appetite will be altered if the timing or volume of feedings is inappropriate, an example being the "grazing" behavior of toddlers.[14] A common iatrogenic alteration of appetite occurs with the use of supplemental tube feedings. Although these may be necessary for adequate weight gain, they eventually interfere with normal hunger-satiety cycles. Anorexia is common in disorders of the urea cycle and organic acid metabolism, whereas a major cause of weight loss in Crohn disease is decreased intake owing to poor appetite.[15,16]

A child's diet can lead to feeding difficulties, and food allergy is one cause of vomiting or irritability associated with feeds.[17] Age-appropriate foods are essential to acquiring normal feeding behaviors.[18]

Dysphagia specifically refers to difficulty with swallowing and implies an organic basis.[19] Illingworth distinguished between anatomic, neuromuscular, and inflammatory factors for dysphagia.[20] Anatomic lesions range from the cleft lip and palate that present at birth to the more subtle anomalies such as submucous cleft palate or vascular ring. The neurologic immaturity of the premature infant results in predictable feeding concerns based on the gestational age and general medical conditions.[21] Other neuromuscular disorders may affect coordination of suck and swallow or esophageal peristalsis (pseudo-obstruction, repaired tracheoesophageal fistula).[22] Although not specifically related to difficulty in producing a swallow, as with neuromuscular and anatomic causes, the term dysphagia is also applied when the act of eating or swallowing produces pain or other discomfort. Acute inflammatory disorders are usually infectious, and chronic conditions are likely acid related (peptic esophagitis). A review of 600 infants with gastroesophageal reflux found that 4% had severe feeding resistance sufficient to warrant tube feedings, and this feeding resistance was often the initial or only symptom.[23] Dysphagia may be the first complaint in older children with gastroesophageal reflux disease (GERD).[24]

Systemic conditions, such as cardiovascular or pulmonary disease, may require extra work of breathing and stress the feeding infant. Such illnesses place greater caloric demand on the patient while also interfering with intake.[25–27]

Successful feeding results from appropriate infant responses to food and nurturing caregivers in a dynamic interaction. Not surprisingly, many infant feeding problems involve primarily nonorganic or behavioral factors.[13] These nonorganic feeding problems have been categorized or described by several authors. One categorization is tripartite: young infants (2–8 months) with an attachment disorder owing to poor parent–infant interaction, the older infant or toddler (6–36 months) with "infantile anorexia" and struggles around autonomy, and the less affected "picky eater" who is not yet malnourished.[28] Others describe early nonorganic failure to thrive as "failure to

imbibe" in young infants with poor intake and no apparent problems with mother–infant interactions.[29–31]

When the introduction of feedings is delayed beyond a sensitive or critical period, later acquisition of feeding skills may be difficult.[32] Medical or surgical disorders early in life may necessitate the use of nasogastric or gastrostomy feedings or parenteral nutrition to maintain adequate nutrition. If supplemental feeding is required on a short-term basis, growth is maintained, and generally the infant quickly resumes normal feeding behavior. However, if long-term tube feeding or intravenous alimentation is required, especially if the infant has had little previous positive experience with normal feeding, the child is at risk for the development of an aversion to oral feedings. Intrusive oral procedures such as nasogastric tube placement, endotracheal intubation, and oropharyngeal suctioning have been associated with aversion to oral feedings.[33] The long-term pairing of eating and pain, as occurs in GERD, may establish a negative feeding experience and a "conditioned dysphagia."[23,34,35] Older children who experience an episode of choking have developed an acute food refusal, described as a post-traumatic eating disorder.[36]

Even in the case in which medical conditions impact nutrition, the parental reaction to feeding can play a pivotal role. Parents may be faced with innumerable negative feeding interactions because of the need to focus on the child's nutrient intake. These experiences can change feeding from a satisfying parent–child interaction to a grim, anxiety-producing chore. Further, infants with early medical problems may be perceived as "vulnerable" by their parents, who consequently may have difficulty setting age-appropriate limits, in this case around eating.[3,37] Therefore, even after an organic disorder is resolved, the feeding interaction remains stressed.

Multiple etiologies are often present in the child being evaluated for poor feeding. In 50 infants with feeding disorders, Budd and colleagues found that 64% had problems with both organic and nonorganic symptoms, contributing to their insufficient food intake.[38] Burklow and colleagues reviewed 103 children with complex feeding problems, identifying 80% with a significant behavioral component and 85% with multiple conditions leading to the feeding disorder.[39] Careful study of infants with a diagnosis of nonorganic failure to thrive has revealed that subtle oral-motor dysfunction may be responsible for inadequate feeding skills, contributing to their poor weight gain.[40,41] In children with multiple risk factors, these problems may coexist or evolve separately in time, with the nonorganic component remaining after the organic problem is resolved.

EVALUATION

The presence of feeding difficulties may be first noted by the infant's caregiver, primary care physician, early intervention specialist, or other health care personnel. The type and severity of the feeding problem will usually lead to the involvement of several allied professionals (Figure 75.2-2). Often an interdisciplinary team approach facilitates an efficient evaluation.[14,42]

The first step in evaluating feeding difficulties is a complete history and physical examination. The prenatal history, gestational age, birth weight, and neonatal course may suggest particular risk factors. The answers to questions regarding general psychomotor developmental progress will inform an understanding of feeding progress and why it might be delayed. The review of systems can identify those infants with chronic lung disease, cardiac malformations, or neurologic conditions that are likely to affect feeding (see Table 75.2-2). Symptoms of GERD should be sought because feeding resistance may be one of the early manifestations.[23] The nutritionist has a major role in obtaining the diet history, which will include the type, amount, and nutritional value of what is offered to the infant or child, as well as what is actually ingested. A 24-hour diet recall or a more formal 3-day diet record assists in calculating fluid, calorie,

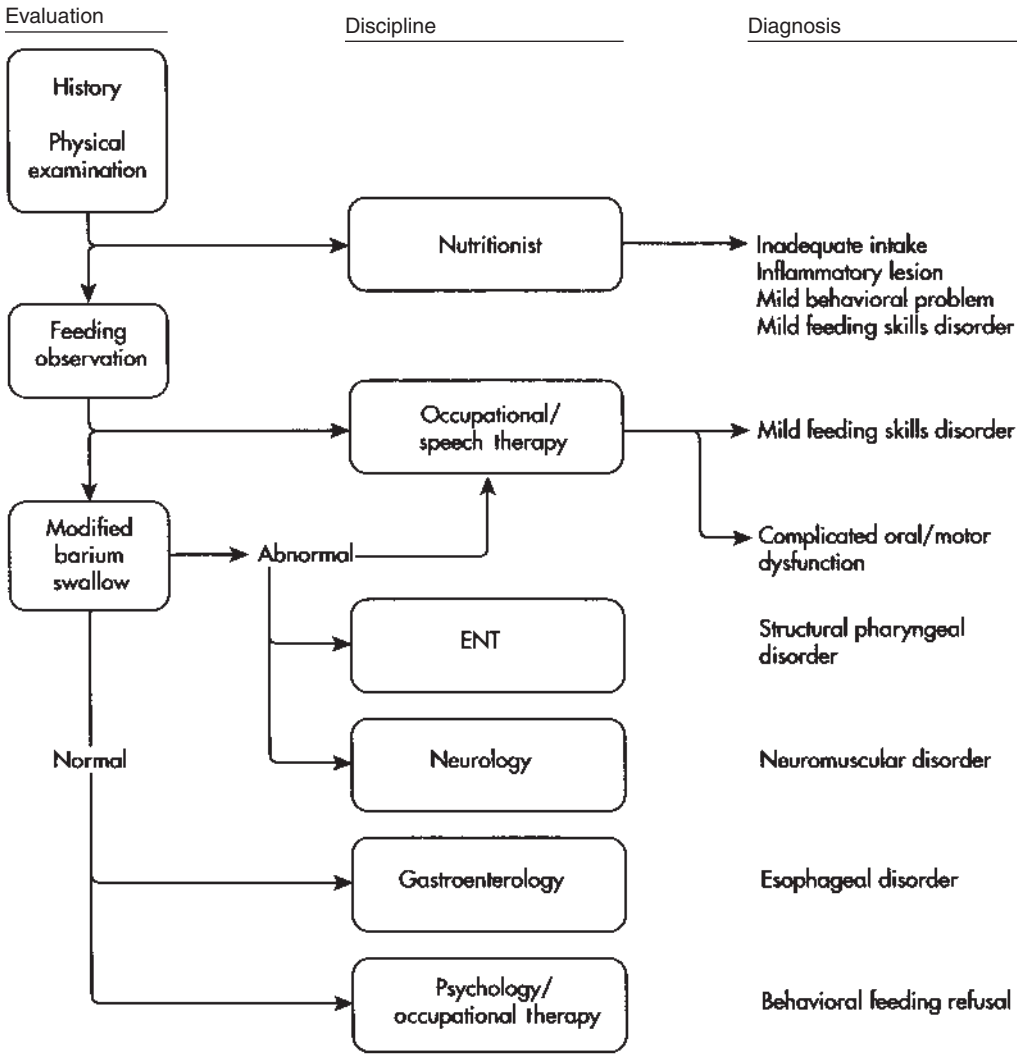

FIGURE 75.2-2 Steps in the evaluation of feeding difficulties. ENT = otorhinolaryngology.

mineral, and vitamin intake. This information, together with a review of feeding methods, will often suggest inadequate calorie intake or developmentally inappropriate food choices indicative of a feeding skill disorder.

Physical examination begins with careful anthropometric measurement, which can be plotted on the appropriate growth charts.[43] Progressive movement away from previous growth percentiles may indicate inadequate intake and the need for further investigation. Weight-for-length ratio is a sensitive measure of acute malnutrition.[44]

Oral examination should evaluate lip closure, tongue position and movement, and palatal movement. Nonnutritive sucking can be evaluated by allowing the infant to suck on the examiner's gloved finger. Infants with oral-motor problems may have poor coordination of suck, swallow, and breathing; poor mouth closure; decreased tongue movement; decreased jaw stability; or sustained or prolonged jaw closure. Oral hypersensitivity with increased gag reflex is common after mechanical ventilation or tube feeding.[45] Further neurologic examination may reveal cranial nerve deficits associated with dysphagia, as well as problems with posture, head and neck control, muscle tone, and persistence of primitive reflexes.[46]

The feeding observation is the central element of the clinical evaluation. The occupational therapist or speech-language pathologist can assist in assessing nutritive sucking and feeding by the primary caregiver, which may detect subtle disorders of feeding skills.[40,47] A prospective study of neonates found that those with disorganized or dysfunctional sucking patterns were more likely to have feeding problems at 6 and 12 months of age.[48] When observing parent–child interactions around feeding, the clinician should notice how the food is presented, which foods an infant prefers, and the parental responses to good and inappropriate feeding behaviors.

Several imaging methods are available to evaluate more complex oral-motor dysfunction. The primary technique is the modified barium swallow, also referred to as a videofluoroscopic swallow study.[49] It requires involvement of a feeding specialist (occupational therapist or speech-language pathologist) and radiologist. Unlike standard upper gastrointestinal barium contrast radiographs, in this study, the infant is placed in a standard feeding position and presented with a variety of textures (see Chapter 23, "Disorders of Deglutition"). This study is the best method of evaluating the pharyngeal phase of swallowing. Clini-

cally inapparent difficulties with suck and swallow, nasopharyngeal reflux, ineffective pharyngeal closure, and aspiration can be seen and taped for later review. Aspiration is often subclinical. It is present in up to 40% of adults without previously identified aspiration undergoing modified barium swallow.[50] Knowledge of aspiration risk and the ability to handle food of different consistencies will assist in developing a safe feeding program.

Ultrasonography is ideal for evaluating the oral preparatory phase of swallow.[51,52] The infant and feeder can be studied in a more physiologic state, with repeated observations of swallow possible. No contrast material is needed, and there is no radiation exposure. Ultrasound study of the pharyngeal phase is difficult owing to air-filled spaces, and aspiration will not be detected.

Flexible endoscopic evaluation of swallowing is another technique that allows for evaluation of swallowing, particularly the pharyngeal phase.[53] After topical anesthesia of nasal tissues, a nasopharyngoscope is passed transnasally for observation of the anatomy and function of the palate, pharynx, and larynx. Next, swallowing function is evaluated with administration of food. The ability to handle liquids and risk of aspiration can be directly assessed. The study can be repeated as often as necessary because there is no preparation needed and no radiation exposure.[54]

Manometry is used to assess the esophageal phase of swallowing. It will detect abnormalities of upper esophageal sphincter relaxation or esophageal peristalsis but may be impractical during early infancy or childhood.

For the infant with behavioral refusal to feed, the presence of a psychologist on the treatment team can be crucial to understanding the development of the problem and the best way to approach the family. Behavioral assessment includes a thorough feeding history, including details of both the infant's feeding and the parental responses, intake history over several days to demonstrate the pattern of feedings, and feeding observation live or on videotape.[55]

TREATMENT

Treatment of feeding problems, which are often complex, should emanate from the interdisciplinary assessment. Generally, not all aspects of the plan are begun simultaneously. Medical conditions causing pain or discomfort during eating should be resolved. Initial attention should be directed to providing sufficient intake for maintenance and catch-up growth. As nutritional status improves, the occupational therapist, speech therapist, and psychologist can help develop a program to establish normal feeding skills and parent–child interactions.

Whenever possible, oral feeding should be maintained even if alternative feeding is also used. This preserves the sensory function of taste and smell and the neuromotor skills of suck and swallow. Oral feeding promotes speech development and provides what should be a pleasurable social experience for the infant. Sucking appears to increase the concentration of lingual lipase, which, together with breast milk lipase, is important for digestion of lipid in the neonatal period.[56,57] Salivary amylase, along with small intestinal glucoamylase, is primarily responsible for starch digestion in early infancy because pancreatic amylase activity is low until 4 months of age.[58] Swallowing initiates primary peristalsis in the esophagus, enhancing esophageal acid clearance.

If nutritional support beyond oral supplementation is required, the route for provision of supplements can be chosen and therapy initiated (Figure 75.2-3). No advantage is achieved in delaying nutritional therapy in children with feeding problems because malnutrition is the primary cause of growth retardation and altered body composition in chronic illness.[59] Details of enteral and parenteral feeding are described in Chapter 75.4, "Nutrition Support."

Nutrient administration is based on patient needs and limitations. Nasogastric or orogastric tubes are easy to place, with feedings given on an intermittent (bolus) or continuous basis. Bolus feeds are more physiologic in preserving hunger-satiety cycles and allow greater mobility for the patient and family. Continuous feedings may be preferable when there is delayed gastric emptying or decreased gut absorptive capacity.[60,61]

Although gastric feeding is preferable, transpyloric tube placement is indicated when there is a high risk of aspiration.[62,63] The type of gastric tube used should be based on the length of time the tube is required. Polyvinylchloride tubes are relatively easy to pass but must be changed every 3 to 4 days. For many clinical situations, a flexible silicone

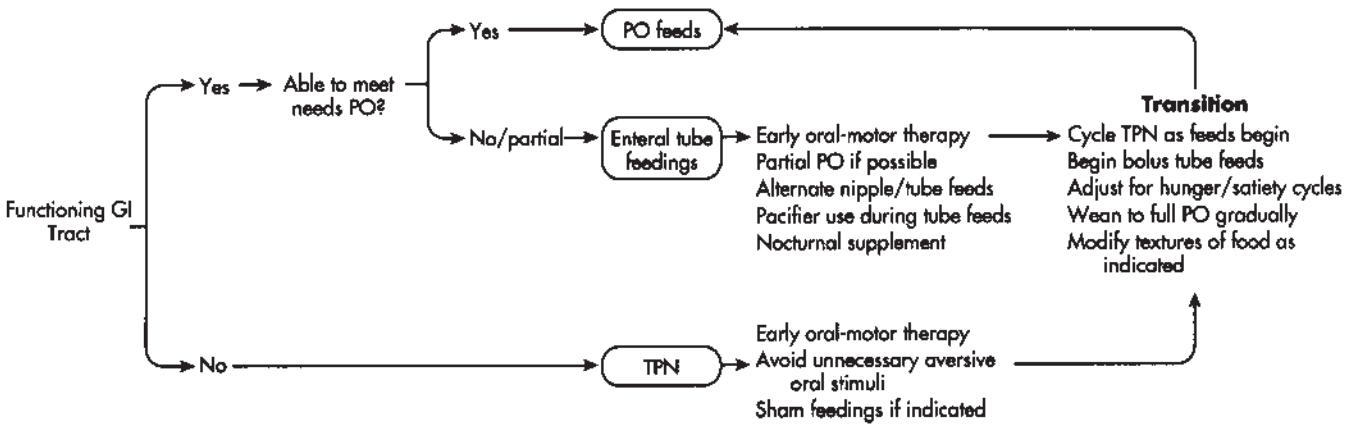

FIGURE 75.2-3 Treatment of feeding difficulties. GI = gastrointestinal; PO = per os; TPN = total parenteral nutrition.

elastic tube is more comfortable for the patient. These tubes produce less sensation when the child swallows, interfere less with feeding, and can remain in place for up to several weeks.[64] Fewer tube changes decrease noxious oral-facial stimuli for the child, which may help reduce the likelihood of future negative feeding behaviors.

Nocturnal feedings have been shown to provide excellent nutritional support while not interfering with daytime activities.[65–68] Percutaneous endoscopic gastrostomy and use of low-profile gastrostomy buttons facilitate the care of patients on long-term enteral support.[69] Families have often had significant distress regarding feedings by the time a gastrostomy is placed and need support and understanding when the decision is finally made.[70]

Various approaches to advancing feedings are available.[62,71] Tolerance can be assessed by gastric residuals and the absence of vomiting, diarrhea, or abdominal pain. Infants with chronic diarrhea and malnutrition can be successfully managed with enteral therapy, but the volume of the infusion should be increased gradually.[72] Attention to adequate water intake will prevent problems of dehydration owing to formulas with a high renal solute load.[73]

Gastrostomy tube feedings should not be considered an obstacle to overcoming feeding problems. A review of 100 infants fed by nasogastric tube indicated that earlier placement of a gastrostomy tube for the poor feeders was associated with improved success in transition to oral feeding.[74] In a study of 19 patients with severe feeding refusal, those gastrostomy-fed infants took slightly longer than the nasogastric tube–fed infants to achieve oral feeding, but use of gastrostomy feedings did not adversely affect eventual transition to oral feeds.[75]

Careful attention to appropriate techniques for the provision of proper diets can be of great benefit to children with major feeding difficulties. Two examples of such clinical problems are discussed below. Other dietary issues encountered in a range of gastrointestinal disorders are discussed in Chapter 75.5, "Special Dietary Therapy."

Oral-Facial Anomalies

The newborn with cleft lip or palate has an immediate feeding problem. With a minor cleft lip or palate, the feeding problem is usually related to the inability to generate adequate negative pressure for suction. Apart from its nutritional advantages, breastfeeding may best facilitate intake because the soft tissue of the breast can help seal the cleft during feedings. When there is cleft lip and palate, the breastfed infant may be unable to generate sufficient negative pressure to hold the nipple and areola in place for compression, and the bottle-fed infant may not develop efficient suction on a nipple. Breastfeeding may be assisted with use of the Supplemental Nursing System (Medela, Inc., McHenry, IL); feeding devices for bottle-fed cleft lip and palate infants should deliver an adequate volume of milk into the mouth while allowing time for the infant to swallow (Table 75.2-3).[76,77]

Oral feeding of the infant with cleft lip or palate may be facilitated by upright positioning, small frequent feedings, careful burping, and applying pressure to the infant's cheek and beneath the jaw to assist lip closure and sucking.[78] Nonoral feedings become necessary if significant risk of aspiration is present or if the infant fails to thrive because of either inadequate volume intake or prolonged feeding sessions. When micrognathia and glossoptosis occur with cleft palate (the Robin sequence), respiratory distress may preclude oral feeding. These infants have feeding difficulties caused by inadequate suction, swallowing difficulties, and compromised breathing owing to airway obstruction by the tongue.[79] Some infants will require surgical tongue-lip adhesion, use of a nasopharyngeal airway, or even tracheostomy.[80,81] These operative procedures are reserved for patients with the inability to maintain a stable airway using conversative measures. The incidence of failure to thrive was reduced when the families of infants with Robin sequence received assistance from a feeding-support nurse and supervised airway management.[82]

Cerebral Palsy

Cerebral palsy is a chronic, nonprogressive disorder of the nervous system, with an estimated incidence of 1 in 500 infants.[83] Cerebral palsy is a disorder of movement and posture, and most patients demonstrate spasticity of the extremities. Swallowing difficulties result from supranuclear bulbar palsies, and more severely affected children may have language and intellectual deficits and seizures. In a large survey of families with children with neurologic impairment, prolonged feeding times of 3 or more hours per day were common.[84] Early on, affected infants may have decreased sucking reflex and weak or uncoordinated sucking behavior; later, they can have tonic bite, tongue thrust or lip retraction, and lip pursing.[85,86]

Before oral feeds are begun, non-nutritive sucking can be encouraged at the breast (emptied by pumping) or with a pacifier. Non-nutritive sucking during gavage feeds has been shown to help the maturation of the sucking reflex in premature infants and may improve integration of oral and pharyngeal reflexes in the infant with an immature nervous system.[87]

Treatment techniques are available to enhance oral feeding at the breast and with bottle-feeding.[77,86,88] For the older

TABLE 75.2-3 SPECIAL NIPPLES AND FEEDING DEVICES

NIPPLE/DEVICE	CHARACTERISTICS
Supplemental Nursing System	For breastfeeding infants; allows control of volume of milk from reservoir
Ross red premature nipple	Soft, durable
Mead-Johnson cleft palate feeder	Squeeze bottle helps with control of milk delivery; cross-cut nipple
Haberman feeder	Easy to use, with nipple the feeder can compress to help express milk
Any broad-based nipple	May conform to a cleft lip and help attain suction
Feeding obturator (prosthesis)	To stabilize wide cleft

Adapted from Case-Smith J and Humphry R.[86]

infant, the texture of foods can be adjusted, and with thicker liquids passing more slowly from mouth to throat, they often will be better tolerated. The use of a spoon requires that the infant open the mouth wide enough so that lateral tongue movements are adequate to remove the food and that jaw control is adequate. Spoons are designed with narrow, shallow bowls and are made of durable, plastic material; they may have specialized handles to help with the grasp. Cups are available with cut-out rims (to allow easier lifting), covers to decrease spillage, and wide bases to prevent tipping. The feeder can use techniques to provide external jaw and cheek support and to stabilize head position. Adaptive equipment is available to improve postural alignment during feedings. The feeder may hold an infant in the lap or use a foam-filled Tumble-Forms (Sammons Preston Rolyan, Bolingbrook, IL) seat. The older infant or toddler with fair sitting stability can use the Rifton chair (Rifton Equipment, Chester, NY) or other adaptive seating device for upright positioning with foot rests, arm supports, and pelvic strapping.[86] As noted above, some children with an inability to meet nutritional needs orally will require a feeding gastrostomy. The safety of oral feedings and risk of aspiration can be evaluated with videofluoroscopy of swallowing. Early attention to treatment of feeding disorders in these patients can result in significantly improved nutritional status.[89,90]

Behavioral Approaches to Feeding

Principles of learning are used to understand the development of feeding disorders and to design treatment programs for children with feeding problems when there is no apparent organic disease or when correction of an organic disorder or oral-motor deficit does not result in normal feeding.[14,91–99] Respondent learning or classic conditioning posits that the occurrence of some behaviors is increased or decreased based on their association with normal physiologic reactions, in this case hunger or pain. Specifically, eating may have been associated with pain in the development of the disorder. Further, in children with feeding disorders, the positive association between hunger, eating, and satiety is inconsistent. Often interventions for feeding disorders manipulate hunger to prompt eating behaviors. The rationale is that children are more likely to emit eating behaviors (show interest in food, accept food put into their mouth, put food into the mouth, swallow food) when they are hungry.

Hunger may be manipulated in several ways.[91] For the child fed by the mouth, the timing of meals should be regulated, and between-meal eating and drinking should be minimized or eliminated so that the child is hungry at mealtime. The length of meals is also regulated, so that meals last only 20 to 30 minutes, regardless of the amount of food ingested. After 20 to 30 minutes, it is assumed that rising blood sugar from the food that has been consumed leads to diminished sensation of hunger. From the respondent learning perspective, keeping meals short continues to reinforce the association of hunger-eating-satiety.

For children who are tube-fed, the timing and amount of the feeding should be regulated to maximize hunger. Bolus, rather than continuous, feeding and daytime, rather than nighttime, feeding will more closely mimic meals and thus move the child toward normal eating patterns. Tube feeding after, rather than before, an oral feeding session is generally recommended. Modestly decreasing the calories received by tube will, in many patients, increase appetite and better motivate the child to eat by mouth.

One caveat is necessary with respect to the manipulation of hunger. Although a modest amount of calorie restriction is typically helpful to encouraging eating behavior, severe calorie restriction is not. Many naive interveners, both lay and professional, have found that the statement "He'll eat when he gets hungry enough" is not true for those feeding disorders usually seen in a tertiary care center.

Operant learning principles posit that behaviors are increased or decreased based on the responses to the behaviors. Operant techniques are used to increase desired behaviors and decrease undesirable behaviors.[92] In the treatment of feeding problems, the most commonly used and effective operant treatment technique is differential attention.[93–98] During the meal, the child receives positive reinforcement or attention for specific behaviors related to feeding and no attention for inappropriate or off-task behaviors. Positive attention is often social interaction and praise from the caregiver, but depending on the child, it can be music or access to a preferred food. Inappropriate and off-task behaviors include tantrums, not approaching the food, and playing with the food. The target behaviors (behaviors to be increased) are changed as the treatment progresses. For example, the child may initially be reinforced for allowing food to be put in his mouth, then for swallowing the food, then for self-feeding, and, finally, for self-feeding a sufficient quantity in a specified time. Depending on the child's feeding problem, physical quidance of appropriate feeding behaviors may be used along with differential attention.[100–105] The physical guidance is decreased and then stopped as the child progresses through the program.

Extinction is the operant principle that suggests that a behavior will eventually cease if it is never reinforced. Extinction-based techniques have been used in the treatment of severe feeding refusal. Most typically, these are children who, for medical reasons and from a very early age, have not been fed by mouth and/or have experienced very aversive oral procedures, such as intubation. When faced with oral feeding these children produce strong rejecting behaviors such as screaming, spitting food, and physically resisting placement of food in the mouth. When the caregiver stops the feeding in response to these rejecting behaviors, the child's behaviors have been reinforced (by escaping the negative situation). Extinction techniques dictate that feeding should not stop in response to rejecting behaviors. Thus, spoonfuls of food (sometimes very little food) are put into the child's mouth repeatedly despite the child's protest. Eventually, when the child's protest behavior does not stop the feeding (ie, the protest behavior is not reinforced), the protest behavior stops. Although these extinction techniques have been successful in cases of severe feeding refusal,[75,105–109] they must be carefully planned and executed in an inpatient setting.

The role of parents in carrying out behavioral treatment programs for feeding must be fully appreciated and sup-

ported.[14] As discussed earlier in this chapter, parental anxiety about nutrition is an important factor in the development and maintenance of many feeding problems. For parents to decrease unhelpful behavior that is motivated by their own anxiety, their concerns and anxiety must by addressed specifically. The entire treatment team should know and agree on the treatment plan for the child's nutritional and behavioral feeding problem, and this consensus plan should be presented to the family. Most parents need help to understand that the multiple components of their child's feeding problem cannot all be addressed at once. They need to understand that the team has a plan to resolve all of the concerns in time and that the child's physical health will not be in danger during this process. Parental lack of understanding of this process can severely impede the progress of treatment. For example, parents will not follow guidelines to stop meals after 30 minutes and may give in to inappropriate feeding rituals if they fear that the child's nutritional status will be irretrievably harmed.

For the child with mild to moderate feeding problems, most parents can be taught behavioral treatment techniques. The behavioral feeding plan needs to be carried out consistently, that is, at every meal, to change the child's negative feeding behaviors. Thus, training the parent to carry out the treatment at each meal is far superior to an "expert feeder" who treats the child weekly or even several times per week. Parents will need to understand the behavioral principles and the importance of consistency in applying these techniques and that the target behaviors will more closely approximate normal eating as the child progresses. For children with very severe feeding refusal, especially if extinction procedures are used, inpatient treatment with alternative feeders may be most appropriate. In these cases, parents must initially understand and support the treatment and then must be taught to carry out the procedures themselves as feeding is transferred to the more normal parent–child interaction and home environment.

TRANSITION TO ORAL FEEDS

When medical or surgical disorders necessitate nonoral feedings or parenteral nutrition, planning for transition to oral feedings should begin early. Oral-motor skills should be assessed and swallowing ability documented. Oral feedings, even in small amounts, should continue, if at all possible, to maintain oral-motor skills. Total parenteral nutrition can be cycled while enteral feedings are advanced, even in the young infant.[110] Sham feedings for children with esophageal atresia and esophagostomies facilitate the return to normal feedings.[111] Other useful techniques include non-nutritive sucking during tube feeding of premature infants and giving nipple feeds during the daytime, with the balance of the feeding volume delivered by tube at night.[112] Attention to eating-related behaviors, the feeding environment, and hunger-satiety cycles will help normalize feedings.[113] Ongoing communication between the family and involved professionals will enhance the transition to normal eating behavior.

3. Nutritional Assessment and Requirements

Christopher Duggan, MD, MPH

Children with gastrointestinal diseases are uniquely susceptible to many forms of malnutrition (Table 75.3-1), including acute and chronic protein-energy malnutrition,[1,2] micronutrient deficiencies,[3,4] and hypoalbuminemic malnutrition.[5] Patients who are force-fed (either enterally or parenterally) are even liable to overnutrition or obesity.[6] Although nutritional management of children with gastrointestinal disease is often considered a secondary therapeutic goal behind primary medical or surgical care, there is an increasing appreciation that nutritional therapy can and should be the prime focus. Gastrointestinal diseases for which nutritional management assumes primary importance include inflammatory bowel disease, cow's milk protein and other allergic enteropathies, celiac disease, short-bowel syndrome (and any condition in which parenteral nutrition is employed), and a wide variety of metabolic diseases of the liver. Further, many studies have shown that malnourished patients are more prone to both infectious and noninfectious complications of their disease or therapy[7] and require longer lengths of stay in hospital and more resources.[8,9] It is therefore essential that pediatric practitioners understand the principles of nutritional assessment, as well as the scientific basis of nutritional requirements, for effective medical and nutritional care of their patients.

TABLE 75.3-1 SUSCEPTIBILITY OF THE PEDIATRIC GASTROINTESTINAL PATIENT TO MALNUTRITION

DECREASED INTAKE/ANOREXIA
Primary anorexia nervosa
Secondary anorexia owing to chronic disease, inflammation, infection, micronutrient deficiencies, abdominal pain
Dysphagia
MALABSORPTION/MALDIGESTION
Mucosal, hepatobiliary, or pancreatic disease
Drug–nutrient interactions
Short-gut syndrome
Congenital transport defects
ALTERED NUTRIENT REQUIREMENTS
Fever, stress, malabsorption, recovery from malnutrition, prematurity
Immobility, decreased energy expenditure, hypothyroidism
Congenital metabolic defects or conditions requiring pharmacologic doses of some nutrients and/or dietary avoidance of others
DEPENDENCE ON CARETAKERS FOR NUTRIENT INTAKE
Parenteral/enteral nutrition is "force-feeding"
Neglect/maltreatment

NUTRITIONAL ASSESSMENT TECHNIQUES

The medical history, physical examination, and selective laboratory testing form the basis of nutritional assessment. Increasingly sophisticated biologic methodologies are also available for nutritional assessment,[10] especially in the area of body composition analysis. This chapter reviews those aspects of nutritional assessment that are most germane to the care of children with gastrointestinal diseases.

History

A detailed medical history is essential to the nutritional evaluation of a patient. In addition to recording the type and onset of gastrointestinal symptoms, the physician should document the following:

- Current symptoms and their effect on nutrient intake, absorption, and retention
- Past history, including neonatal history, duration of breastfeeding versus formula-feeding, past growth data, gastrointestinal surgery
- Chronic illnesses with known risk factors for malnutrition
- Developmental status, with special attention to milestones of swallowing function
- Known or perceived food allergies
- Medications, with special attention to those with known drug–nutrient interactions (eg, sulfasalazine and folate, corticosteroids and calcium)
- Family history, parental heights, and sibling growth patterns
- Social history, food preferences/beliefs, and food availability

A careful history, in conjunction with a physical examination, is an effective method to diagnose and evaluate patients with idiopathic growth failure,[11] but in patients with chronic gastrointestinal diseases, more detailed assessment techniques are often indicated.

Dietary Intake Methods

Techniques of dietary assessment range from the straightforward recall of recent intake to the detailed and methodical measuring and weighing of all intake during a 7- to 14-day period.[12] Semiquantitative food frequency questionnaires have been developed and validated in adults[13] and, more recently, in children.[14] From a population perspective, food

disappearance and agricultural data may be used, but, of course, they offer no insight into individual nutrient intake. A comprehensive discussion of dietary assessment techniques is provided elsewhere.[15]

In the clinical setting, a 24-hour dietary recall, which is the most rapid dietary intake method, sheds light on family eating patterns and food availability; it can be easily incorporated into the general history and physical examination. Problems of recall bias and under- or overreporting of intake[16] limit the validity of this technique.

A prospective food diary, in which a patient measures and writes down all intake for 3 to 5 days, is probably the most reliable and valid clinical tool. Proper interpretation of these diet records requires consultation with a qualified dietitian. The nutritional composition of these foods is determined by using one of the common nutritional databases, often with the use of proprietary software.[17] An average daily intake of energy, macronutrients, and micronutrients can then be calculated and compared with published reference data. Prospective diet records should generally be performed while the patient is feeling well, free of the effects of acute illness, and should include at least one weekend day in school-age children.

Physical Examination and Anthropometric Data

The examination of all patients with growth failure should be thorough (Table 75.3-2). Careful inspection and palpation of tissues such as hair, skin, oral mucosa, and subcutaneous fat and muscle stores are particularly important in the physical examination. Formal measures of arm anthropometrics are possible, but encircling the patient's upper arm with the examiner's hand can provide informal assessment of arm muscle and fat stores.

Basic anthropometric data include body weight and height (or length in those children less than age 2 years). When compared with age- and sex-appropriate standards, these data can provide objective measures of nutritional status. The weight of infants should be recorded to the nearest gram with the child wearing no clothes or a diaper. In older children, shoes and heavy clothing should not be worn, and the scale should be accurate to the nearest 0.1 kg. Length should be measured on a length board with a tape measure attached and a moveable foot board. Children older than age 2 years should be measured with a stadiometer while standing erect. The average of three readings should be obtained for accurate height/length measurements and should be recorded to the nearest 0.1 cm.

TABLE 75.3-2 CLINICAL SIGNS ASSOCIATED WITH NUTRITIONAL DEFICIENCIES.

ORGAN	CLINICAL SIGN(S)	NUTRIENT DEFICIENCY
Hair	Thin, sparse, easily pluckable	Protein energy, zinc
Face	Diffuse pigmentation	Protein energy
	Moon face	Protein
	Nasolabial seborrhea	Riboflavin, niacin, or pyridoxine
Eyes	Pale conjunctivae	Iron, folate, or vitamin B_{12}
	Bitôt spots, conjunctival or corneal xerosis, or keratomalacia	Vitamin A
	Angular palpebritis	Riboflavin or niacin
Lips	Angular stomatitis or cheilosis	Riboflavin, niacin, iron, or pyridoxine
Mouth	Ageusia, dysgeusia	Zinc
Tongue	Magenta tongue	Riboflavin
	Atrophic filiform papillae	Folate, niacin, riboflavin, iron, or vitamin B_{12}
	Glossitis	Niacin, folate, riboflavin, iron, vitamin B_{12}, pyridoxine, tryptophan
Teeth	Caries	Fluoride
Gums	Swollen, bleeding	Vitamin C
Glands	Thyromegaly	Iodine
	Parotid enlargement	Protein energy
Skin	Xerosis, follicular keratosis	Vitamin A or essential fatty acids
	Perifolliculosis with blood or pigment	Vitamin C
	Petechiae, ecchymoses	Vitamin C or K
	Pellagrous dermatosis	Niacin, tryptophan
	Scrotal or vulval dermatosis	Riboflavin
Nails	Koilonychia	Iron
Subcutaneous tissues	Edema	Protein, thiamine
	Decreased subcutaneous fat	Protein energy
Musculoskeletal system	Muscle wasting	Protein energy
	Craniotabes, frontal bossing, rachitic rosary, epiphyseal enlargement	Vitamin D
	Epiphyseal enlargement, subperiosteal hemorrhage	Vitamin C
Hepatobiliary system	Hepatomegaly	Protein energy
Nervous system	Psychomotor changes, confusion, irritability	Protein
	Sensory loss, motor weakness, calf tenderness	Thiamine
	Loss of vibratory sense, decreased deep tendon reflexes	Vitamin B_{12} or E
Cardiovascular system	Cardiomegaly, tachycardia	Thiamine

Adapted from Suskind R andVarma R.[96]

Detailed methodologies are given elsewhere[18,19]; recent studies have confirmed that body length is often poorly measured in practice.[20]

Raw data are then plotted on reference curves for age and sex, and the corresponding percentile is determined. The 2000 release of updated growth curves was a welcome advance in the field of pediatric nutrition assessment. The previously used curves were criticized for the homogeneous genetic, geographic, and socioeconomic background of the participants less than age 2 years.[21] In addition, these infants were generally fed infant formulas, whereas breastfed infants show significantly different patterns of weight and length gain.[22,23]

The major differences between the 2000 US Centers for Disease Control and Prevention (CDC) growth charts and the 1977 National Center for Health Statistics (NCHS) charts were (1) inclusion of breastfed infants proportional to their distribution in the US population during the past 30 years; (2) wider representation of a cross-section of children living in the United States between 1971 and 1994 (versus primarily white, middle-class infants); (3) expansion to include up to 20 years of age; (4) body mass index (BMI) percentile curves for 2 to 20 years; and (5) using one data source to decrease the disjunction between recumbent length and stature when changing from the infant (0–36 months) to the older child growth chart.[24] The NCHS has prepared curves for the visual display of the data that are widely available in general pediatric texts, wards, and clinics.

Although deficits in weight for age were originally proposed as criteria for malnutrition by Gomez in the 1950s, the currently accepted standard for anthropometric screening is the criteria of Waterlow (Table 75.3-3).[25] These criteria recognize that children who are underweight may be either short and well proportioned (so-called "stunted") or truly underweight for their height (so-called "wasted"). Wasted children have an acute deficit of body mass that is more amenable to immediate nutritional therapy, whereas stunted children are more chronically undernourished. Acutely wasted patients suffer a variety of functional deficits (eg, decreased muscle strength, impaired immune function, and decreased organ mass, among others); the physiologic impairment of stunting is less obvious and is controversial.[26] Aggressive feeding in either case can actually lead to accumulation of excess body fat.

TABLE 75.3-3 WATERLOW CRITERIA FOR CATEGORIZING TYPE AND CHRONICITY OF MALNUTRITION

	ACUTE MALNUTRITION (WEIGHT FOR HEIGHT; % OF MEDIAN)	CHRONIC MALNUTRITION (HEIGHT FOR AGE) (% OF MEDIAN)
Normal	> 90	> 95
Mild	80–90	90–95
Moderate	70–80	85–90
Severe	< 70	< 85

Adapted from Waterlow J.[25]
Deficits of weight for height are termed "wasting" and those of height for age are called "stunting."

The statistical analysis of groups of patients, especially those whose anthropometric data place them at less than the 5th or greater than the 95th percentile, has been improved by the use of standard deviation scores (also termed z-scores).[27] By definition, a z-score of +2 represents a value 2 SD above the mean, +3 is 3 SD above the mean, etc. The calculation of a z-score is as follows:

$$\text{z-score} = \frac{(\text{actual value} - \text{median value for age and sex})}{\text{standard deviation of value for age and sex}}$$

Because the mean weight and standard deviation of boys aged 12 months are 10.1 kg and 1.0, respectively, a boy weighing 7 kg at this age has a z-score of $(7 - 10.1)/1.0 = -3.1$. His weight is therefore more than 3 SD below the mean. Z-scores can be calculated for patients with the use of software distributed free of charge by the CDC (<http://www.cdc.gov/epo/epi/epiinfo.htm>).

An increasingly used anthropometric index is the BMI.[28,29] The value, calculated by dividing weight in kilograms by height in meters squared, was shown by Quetelet in the nineteenth century to be a good measure of body mass but only minimally correlated with height, and therefore was a good candidate variable to measure body fatness. As the incidence of obesity has reached epidemic proportions in the United States and other industrialized countries,[30] assessment of BMI has been recommended as a valid and reliable screening tool for obesity. Children with BMIs greater than the 85th percentile for age and sex are termed overweight, and those with BMIs greater than the 95th percentile are obese. Reference values for BMIs are available, and the new growth curves include a visual display of BMI reference curves instead of weight-for-height curves of preadolescents. Because of the dramatic increase in obesity in childhood, the more recent survey data (Third National Health and Nutrition Examination Survey [NHANES III]) were not included in the weight-for-age and BMI-for-age curves for children age 6 years and older.

More sensitive than attained weight and height in diagnosing malnutrition are weight gain and growth velocity data. Serial growth data are very helpful in establishing a patient's previous growth pattern and interpreting its change with medical or nutritional interventions. For example, a substantial number of children with Crohn disease demonstrate a reduction in height velocity in the months preceding their diagnosis,[1] suggesting that malnutrition can be a presenting feature of this disease. Graphs are available for displaying height velocity data. Table 75.3-4 provides data on average rates of weight and height gain for a US sample of healthy children.[31] Determining an infant's or toddler's growth velocity between outpatient visits or in response to a nutritional intervention can help confirm or refute subjective clinical impressions of improved well-being.

Body Composition Methodologies

Perhaps the most significant limitation of the anthropometric techniques summarized above is their inability to precisely measure body composition, namely the amount of body weight that is either fat mass or fat-free mass

TABLE 75.3-4 MEAN INCREMENTS IN WEIGHT AND LENGTH FOR HEALTH US CHILDREN

	WEIGHT (g/d)		LENGTH (mm/d)	
AGE (MO)	BOYS	GIRLS	BOYS	GIRLS
Up to 3	31	26	1.07	0.99
1–4	27	24	1.00	0.95
2–5	21	20	0.84	0.80
3–6	18	17	0.69	0.67
4-7	16	15	0.62	0.60
5–8	14	14	0.56	0.56
6–9	13	13	0.52	0.52
7–10	12	12	0.48	0.48
8–11	11	11	0.45	0.46
9–12	11	11	0.43	0.44
10–13	10	10	0.41	0.42
11–14	10	9	0.39	0.40
12–15	9	9	0.37	0.38
13–16	9	9	0.36	0.37
14–17	8	8	0.35	0.36
15–18	8	8	0.33	0.34
16–19	8	8	0.32	0.33
17–20	8	8	0.31	0.32
18–21	7	8	0.30	0.32
19–21	7	7	0.30	0.31
20–23	7	7	0.29	0.30
21–24	7	7	0.28	0.29

Adapted from Guo SM et al.[31]

(FFM). The accepted standard test for body composition is hydrodensitometry (so-called underwater weighing). This technique relies on the principle that body composition can be known from measurements of body density, using assumptions about the average density of fat mass (0.9 g/cm^3) and FFM (1.1 g/cm^3). Weighing the subject in air and then while underwater allows calculations of body density. Obviously, this method is not feasible for infants and young children. Among the available clinical techniques for children are skinfold measurements, bioelectrical impedance analysis (BIA), and dual-energy x-ray absorptiometry (DXA).

Skinfold measurements, which offer the advantage of directly measuring body fat, have been widely used in clinical and epidemiologic studies. They are commonly obtained at four sites: the triceps, biceps, subscapular, and suprailiac. In addition to comparing individual skinfold measurements with published data for age and sex, some investigators have proposed the arithmetic sum of four skinfold measurements as a valid measure of body fatness.[32,33] Triceps skinfold measurement can be used in conjunction with mid–upper arm circumference measures to estimate measures of fat and lean body mass via nomograms[34] or equations:

$$\text{MAMA} = \frac{(\text{MUAC} - \pi * \text{TSF})^2}{4 * \pi}$$

where MAMA = midarm muscle area (cm^2), MUAC = mid–upper arm circumference (cm), TSF = triceps skinfold (cm), and π = 3.1416. This equation assumes that the midarm muscle is circular, that the triceps skinfold gives a good measure of the total rim of midarm fat, and that bone area is negligible. Because these are all questionable assumptions, others have made modifications in the equation, using either computed tomography[35] or magnetic resonance imaging[36] as gold standards.

Skinfold measurements are prone to significant inter- and intraobserver variation. As a measure of total body fat, they do not measure intra-abdominal fat, and it is therefore not surprising to note the relatively low correlation between skinfold measures and total body fat. Skinfold thickness, as a measure of peripheral versus truncal obesity, may be helpful in the evaluation of some patients. The optimal use of skinfold measurements continues to be debated.[37]

BIA is a noninvasive, nonradioactive measure of body composition analysis. The technique relies on the principle that FFM, being composed of water and ions, conducts an electrical charge better than fat mass.[38] Lean body mass therefore has a lower resistance to current. Reactance, a measure of cell membrane capacitance, is also measured by BIA and, together with resistance, can be used to measure total body water, both intra- and extracellular. Using assumptions about the water content of FFM, FFM is calculated. In patients with human immunodeficiency virus (HIV) infection, BIA has been widely used as a measure of fat and FFM.[39,40] BIA has also been performed in children and compared with anthropometric measures of body fat,[41,42] as well as deuterium dilution[43] and underwater weighing.[44] Because the total body water content of infants and young children is not stable, there are inherent difficulties with using BIA in this age group. Nonetheless, this technique holds promise as a bedside measure of lean body mass. More recent validation of BIA has been performed using larger datasets and a multicomponent body composition model.[45]

The primary role of DXA scanning is to measure bone mineral content, bone mineral density, and total body bone mineral content. Some instruments also measure total body bone mineral content, nonbone lean tissue, and fat, thereby providing body composition information using a three-compartment model. A number of studies have compared measurements of fat mass with DXA versus results obtained from hydrodensitometry,[46] and the correlation between the methods has generally been high. Unlike hydrodensitometry, DXA also measures the composition of particular body parts, thereby allowing one to compare visceral and subcutaneous adiposity. Adults with inflammatory bowel disease have been reported to have lower fat mass and altered ratios of intracellular water to FFM than age-matched healthy controls.[47] DXA scanning has also been used to document the high prevalence of osteopenia in children with inflammatory bowel disease[48] and cerebral palsy.[49] The ultimate applicability of DXA scanning to human body composition is still evolving.[50,51]

Laboratory Assessment of Nutritional Status

Laboratory tests are useful in confirming the assessment made initially by history and physical examination, as well as in diagnosing subclinical nutritional deficiencies. As with any assessment technique, knowledge of the normal

range of parameters and confidence in the reliability and validity of the technique used are crucial.

General Laboratory Measures

A complete blood count with differential is perhaps the most useful and least expensive laboratory measure of nutritional status. Lymphopenia is a well-known feature of protein-energy malnutrition owing to a reduction in circulating T lymphocytes. Total lymphocyte count (TLC) can be calculated as follows:

$$\text{TLC (cells/mm}^3\text{)} = \text{white blood cell count} \times \text{percentage of lymphocytes}$$

With mild malnutrition, TLC is < 1,500/mm^3; with moderate malnutrition, TLC is 800 to 1,200/mm^3; and with severe malnutrition, TLC is < 800/mm^3. TLC is both a nonspecific and an insensitive measure of nutritional status, however.

Another common functional test of immunocompetence and, therefore, adequate nutritional status is delayed-type hypersensitivity testing. Cutaneous anergy, a delayed or absent response to intradermal injection of antigens, is a consistent finding in moderate to severe malnutrition and has been associated with an increased risk of complications of surgery. Anergy is also a nonspecific measure of nutritional status; other factors, such as the use of immunosuppressive agents, radiotherapy, and critical illness, may be associated with anergy as well.

Nitrogen (N) balance is one of the oldest and best-known methods of assessing nutritional status,[52] having been described as early as the 1830s. It has generally been used as a technique to measure the adequacy of dietary protein. Because negative N balance will ensue if an essential amino acid is ingested in inadequate amounts, the method has also been used to define requirements for specific amino acids and to define which amino acids are essential or nonessential.[53] The N balance technique has also been used to evaluate the response of amino acid supplements to the diet and to determine how exercise or other interventions impact on protein metabolism. Children and adults who are actively gaining lean body mass should be in positive N balance, whereas healthy adults may be said to be in nitrogen equilibrium if N loss is within 5% of N intake.

The concept of the N balance technique is straightforward: N intake is compared to N output to calculate net N balance. The difficulties of the test reside in the full and complete collection of all intake and output. These efforts require cooperative subjects and intensive monitoring. In addition, a stabilization phase of several days to weeks is needed to truly measure the effect of diet on N balance owing to the body's adaptation to the altered intake. Thus, a full N balance is best considered a research tool.

Clinical application of a N balance technique, measuring urine urea N only, has been proposed as an easy method to estimate protein nutriture and the adequacy of nutritional support in hospitalized patients.[54] Urea is the main excretory product of N metabolism, and approximately 85% of the body's N is lost in the urine, the majority via urine urea N. Other sources of N loss include fecal losses, integumental losses (eg, desquamating skin, sweat, hair and nail growth), and miscellaneous losses (eg, saliva, vomitus, blood drawing and menstrual losses, etc). Some of these losses can be high in patients with wounds, burn injuries, or exudative gastrointestinal disease such as ulcerative colitis. Healthy adults excrete 7 to 10 g of urinary urea N per day. Because most proteins contain 16% N, dietary protein intake is customarily divided by a factor of 6.25 to estimate N intake. The equation for calculating N balance is therefore:

$$\begin{aligned}\text{N balance} &= \text{N intake} - \text{N output}\\ &= (\text{24-hour dietary protein intake in g}/6.25)\\ &\quad - \text{24-hour UUN} - \text{factor}\end{aligned}$$

where UUN = urine urea nitrogen (in grams) and factor = allowance made for uncollected N loss in stool, skin, and miscellaneous sources. In adults, this factor is 2 to 4 g/d, and in children, an estimate of 10 mg/kg/d may be used.

Negative N balance can result from inadequate energy intake, inadequate protein intake, or catabolic stress and lean body mass breakdown. Positive N balance implies adequate energy and/or protein intake and, generally, an anabolic state. Nonetheless, the conceptual and methodologic problems in N balance studies should be recognized. The mere demonstration of positive N balance does not disclose information about N distribution throughout the body or about accumulation of lean body mass. Moreover, a positive N balance can occur despite the presence of other important nutrient deficiencies (eg, some micronutrients).

Visceral Protein Levels

The blood concentrations of visceral proteins synthesized by the liver are often used to assess nutritional status because decreased levels presumably reflect a reduced supply of amino acid precursors and/or decreased hepatic (and other visceral) mass. The blood levels of these proteins, however, depend on their rates of synthesis, degradation, and escape from the circulatory system. Stable isotopes have been used to measure the rate of visceral protein synthesis, which is generally of greatest interest.[55,56]

Serum proteins are also affected by infectious or catabolic processes (Table 75.3-5). The concentrations of positive acute-phase proteins are increased in infectious or

TABLE 75.3-5 SERUM PROTEINS AND ACUTE ILLNESS

POSITIVE ACUTE-PHASE PROTEINS	NEGATIVE ACUTE-PHASE PROTEINS
C-reactive protein	Albumin
Fibrinogen	Prealbumin
Ferritin	Retinol binding protein
Ceruloplasmin	Transferrin
α_1-Antitrypsin	
α_1-Glycoprotein	

The blood concentrations of positive acute-phase proteins increase with fever, infection, or other catabolic stresses, whereas those of the negative acute-phase proteins generally decline.

other catabolic illnesses, whereas negative acute-phase proteins are decreased in these circumstances.

Albumin is the most abundant serum protein, making up nearly 5 of the 10 g/dL of total protein in the serum. It is the least expensive and easiest protein to measure and therefore is the most commonly used biochemical marker to assess protein status. Because more than half of body albumin is extravascular (primarily in skin and muscle), maintenance of normal serum levels can occur from mobilization of these stores despite prolonged energy or protein inadequacy. Combined with its long half-life of 20 days, these factors make serum albumin a relatively insensitive marker of nutritional status or a marker to follow nutritional interventions. Nonetheless, hypoalbuminemia is quite common among hospitalized pediatric patients[57] and is a surprisingly good predictor of mortality in hospitalized adults. Healthy adults with low normal concentrations of serum albumin have an increased risk of death than do those with higher levels,[58] although this may be a reflection of acute-phase protein shifts in visceral protein synthesis.[59]

Hypoalbuminemia is not necessarily diagnostic of malnutrition; it can occur in situations of decreased synthesis (eg, liver disease, age over 70 years, malignancy), increased losses (eg, nephrosis, protein-losing enteropathy, burn injuries), or redistribution between intra- and extravascular spaces (eg, acute catabolic stress with capillary leak syndrome). Fluid overload can also dilute albumin concentrations, and bed rest can decrease levels 0.5 g/dL.

Prealbumin is another visceral protein, named because of its proximity to albumin on an electrophoretic strip. It functions as a transport molecule for thyroxine—hence its alternative name, transthyretin. Prealbumin circulates in plasma in a 1:1 ratio with retinol binding protein (RBP). Its short half-life (2 days) and high ratio of essential to nonessential amino acids make it a good measure of visceral protein status, more sensitive than albumin as a measure of nutritional recovery. Studies have shown prealbumin to correlate well with N balance,[60,61] and it is likely the best available serum marker of nutritional status. Like albumin, concentrations fall with an acute-phase protein response or liver disease. Levels increase with renal failure.

Like prealbumin, RBP has a small body pool and a rapid response to protein-energy depletion and repletion. Its half-life is 12 hours. Because RBP is metabolized in the kidneys, levels will be artificially high in renal failure. RBP concentrations are lowered in vitamin A deficiency and, as with albumin and prealbumin, with infectious or other catabolic stresses.

Transferrin is another serum protein sometimes used to assess visceral protein status. It is synthesized primarily in the liver and has a half-life of 8 days. Transferrin concentrations are decreased in all situations that depress serum albumin (see above), as well as with steroid therapy, iron overload, and anemia of chronic disease. Increased concentrations are seen in pregnancy, oral contraceptive use, and iron deficiency anemia.

Other serum proteins of possible use in assessing nutritional status include insulin-like growth factor I (IGF-I), which is the mediator for the anabolic effects of growth hormone. Although IGF-I levels vary with liver and kidney disease, the levels seem to correlate with N balance reasonably well. Fibronectin, a plasma protein with a half-life of 15 hours, has also been used as a marker for nutritional repletion in some studies.

Indirect Calorimetry and Energy Requirements

When considering energy requirements in the pediatric patient, it is helpful to review the components of total energy expenditure (TEE):

$$TEE = BMR + SDA + E_{activity} + E_{growth} + E_{losses}$$

where BMR = basal metabolic rate (the amount of energy required by the body at rest and while fasted), SDA = the specific dynamic action of food or thermic effect of food (the energy produced as heat during digestion and metabolism of food), $E_{activity}$ = energy required for physical activity, E_{growth} = energy needed for somatic growth, and E_{losses} = obligatory energy lost in urine and stool owing to inefficiencies of absorption and metabolism.

BMR is the largest component of TEE, and several equations have been published to calculate BMR from readily available anthropometric data, age and sex. The oldest and best known of these are the Harris Benedict equations for adults (Table 75.3-6). In children, it has been reported that the correlation between measured and predicted BMR is highest for the equations of Schofield (Table 75.3-7).[62,63]

The technique of indirect calorimetry to measure a patient's resting energy expenditure (REE) has recently shed much light on the subject of the energy requirements in health and disease. As the name implies (*calor* is the Latin word for heat), indirect calorimetry is the determination of heat production of a biochemical reaction by measuring uptake of oxygen and liberation of carbon dioxide. With direct calorimetry, the heat produced by the body at rest is measured. Oxygen consumption and carbon dioxide production measured by the calorimeter are entered into the Weir equation to calculate REE:

$$REE = (3.94 \times VO_2) + (1.06 \times VCO_2) - (2.17 \times UUN)$$

where UUN = urinary urea N excretion (g), used as a correction factor for protein oxidation, VO_2 = oxygen consumption (mL/min), and VCO_2 = carbon dioxide production (mL/min).

Note that although REE measurements are usually taken to approximate BMR, REE actually includes BMR, as well as nonshivering thermogenesis and stress hyper-

TABLE 75.3-6 HARRIS BENEDICT EQUATIONS FOR CALCULATING BMR IN ADULTS

Males:
BMR = 66 + (13.7 × weight [kg]) + (5 × height [cm]) – (6.9 × age [yr])

Females:
BMR = 665 + (9.6 × weight [kg]) + (1.8 × height [cm]) – (4.7 × age [yr])

BMR = basal metabolic rate.

TABLE 75.3-7 SCHOFIELD EQUATIONS FOR CALCULATING BASAL METABOLIC RATE IN CHILDREN

GROUP (AGE IN YR)	EQUATION
Males	
0–3	REE = 0.167W + 151.74H – 617.6
3–10	REE = 19.59W + 13.03H + 414.9
10–18	REE = 16.25W + 13.72H + 515.5
> 18	REE = 15.057W + 1.004H + 705.8
Females	
0–3	REE = 16.252W + 10.232H – 413.5
3–10	REE = 16.969W + 1.618H + 371.2
10–18	REE = 8.365W + 4.65H + 200
> 18	REE = 13.623W + 23.8H + 98.2

Adapted from Schofield W.[63]
REE = kcal/day, W = weight (kg), and H = height (cm).

metabolism. The difference between REE and BMR is estimated to be 10% or less.

The utility of indirect calorimetry in assessing energy needs has been evaluated by many investigators in adult[64] and pediatric patients[62,65]; these and other studies have generally confirmed that predictive equations have limited validity in hospitalized or sick patients. Among children with neurodevelopmental delay, studies of REE have shown that their basal energy needs are significantly lower than those predicted by a variety of methods.[6,66] These data have serious implications for a patient population often fed by gastrostomy tube and may explain their tendency to become overweight. A recent study of energy expenditure in children undergoing stem cell transplant has also suggested that these patients are not as hypermetabolic as previously thought.[67] Another study of patients with inflammatory bowel disease reported an increased REE in Crohn disease patients as opposed to healthy controls and those with ulcerative colitis.[68] More studies will be needed to determine whether patients with inflammatory bowel disease truly have an increased energy expenditure and, if so, whether this contributes to their undernutrition.

Indirect calorimetry can also help determine whether a patient is being overfed. The ratio of VCO_2 to VO_2 is termed the respiratory quotient (RQ), which is used to estimate substrate oxidation. For example, in the case of pure glucose oxidation, one mole of carbohydrate reacts with 6 moles of oxygen to create 6 moles each of water and carbon dioxide:

$$C_6H_{12}O_6 + 6\ O_2 \rightarrow 6\ CO_2 + 6\ H_2O$$

The RQ would then be 6/6 = 1.0. When long-chain fat such as palmitic acid is oxidized,

$$CH_3(CH_2CH_2)_7COOH + 23\ O_2 \rightarrow 16\ CO_2 + 16\ H_2O$$

The RQ = 16/23 = 0.695. Thus, the RQ in a fasted state is normally 0.70 to 1.00, and the RQ in this range usually represents a mixed substrate oxidation. The lower RQ noted for lipid oxidation has been used as a rationale for feeding patients with advanced lung disease a diet higher in fat than in glucose to avoid an increased carbon dioxide load to excrete, although this strategy remains controversial.[69] When excess energy is provided and lipogenesis results,

$$9\ C_6H_{12}0_6 + 8\ O_2 \rightarrow 2\ CH_3(CH_2CH_2)_7COOH + 22\ CO_2 + 22\ H_2O$$

The resulting RQ = 22/8 = 2.75. Therefore, the finding of an RQ significantly greater than 1.0 is consistent with energy intake in excess of energy requirements. Other reasons would include hyperventilation (wherein CO_2 is excreted at high rates) or failure to achieve a steady state in gas measurement.

Stable Isotopes and Energy Requirements

The advent in the 1950s of using doubly labeled water (two stable isotopes of water: ^2H_2O and $H_2{}^{18}O$) to measure TEE was a breakthrough in nutritional science. For the first time, TEE in free-living individuals could be validly and reliably measured, and the technique was applied widely in the 1980s and continues to be an important tool for determining energy requirements and validating epidemiologic questionnaires.[70] The method relies on the fact that ^2H_2O is excreted solely in body water, but $H_2{}^{18}O$ is excreted via water losses but also via the carbonic anhydrase system, so that measuring the differential decay rates of the two isotopes provides a measure of CO_2 production from which TEE can be calculated.

The advantages of this technique include the fact that it is noninvasive and safe, requires only serial urine collection, and provides data over a 7- to 14-day period. It has been widely used in pediatric studies.[71–73]

An alternative isotopic approach is the use of labeled bicarbonate (eg, $NaH^{13}CO_3$), which measures energy expenditure in an analogous fashion to doubly labeled water but over a shorter time frame. Studies in neonates and other pediatric subjects have confirmed the validity of this technique,[74] and it is generally less costly than doubly labeled water.

NUTRITIONAL REQUIREMENTS

Definitions of Essential and Nonessential Nutrients

Perhaps the most revolutionary concept in modern nutritional science has been the change in our appreciation of what makes a nutrient "essential."[75] As noted above, the classic experiments of Rose and colleagues defined an essential amino acid as one that is required in the diet of healthy human adults to maintain N equilibrium. Largely using this definition, the 20 amino acids were defined as either essential or nonessential. Indeed, the first half of the twentieth century was marked by a tremendous outpouring of scientific knowledge in the field of nutrition, with the essential nature of most vitamins (Table 75.3-8) and minerals (Table 75.3-9) being determined.

However, the practical and theoretical limitations of balance experiments, as well as their inapplicability to sick or pediatric patients, have been noted. A variety of techniques have therefore been applied to augment how nutrients have come to be defined as essential and what the precise

TABLE 75.3-8 VITAMINS: FUNCTION, DEFICIENCY STATES, AND LABORATORY ASSESSMENT TECHNIQUES

VITAMIN	FUNCTION	CLINICAL DEFICIENCY STATE	LABORATORY ASSESSMENT
Vitamin A (retinol [β-carotene is dietary precursor])	Retinal in rhodopsin and iodopsin Carbohydrate transfer to glycoprotein Maintains epithelial integrity Required for cell proliferation	Night blindness Xerophthalmia Bitot spots Keratomalacia	Plasma retinol (HPLC) Plasma retinol binding protein Relative dose response Dark adaptation test Liver biopsy concentration
Vitamin D (cholecalciferol D_3 [endogenous], ergocalciferol D_2 [synthetic])	Regulates calcium and phosphate Gut absorption, excretion by kidney, and bone resorption	Rickets/osteomalacia Dental caries Hypocalcemia/hypophosphatemia Increased alkaline phosphatase Phosphaturia, aminoaciduria	Plasma 25-hydroxyvitamin D (HPLC) Serum alkaline phosphatase, calcium, and phosphate Radiography Bone densitometry
Vitamin E (α-tocopherol)	Cell membrane antioxidant	Anemia/hemolysis	Plasma tocopherol (HPLC) (corrected for total or LDL cholesterol)
	Inhibits polyunsaturated fatty acid oxidation	Neurologic deficit (ocular palsy, wide-based gait, decreased DTRs) Altered prostaglandin synthesis	Hydrogen peroxide hemolysis
Vitamin K (phylloquinone, menadione [synthetic])	Carboxylation of clotting factors Affects bone formation	Coagulopathy/prolonged PT Abnormal bone matrix synthesis	PT (prolonged) Plasma phylloquinone Clotting factor levels Proteins induced by vitamin K absence or antagonists II
Vitamin B_1 (thiamine)	Oxidative phosphorylation Pentose phosphate shunt Aldehyde transferase Triosephosphate isomerase	Beriberi ("wet" or "dry") Cardiac failure/neuropathy Korsakoff syndrome Wernicke encephalopathy Lactic acidosis	Red cell transketolase activity Whole blood level (HPLC) Urine thiamine-to-creatinine ratio
Vitamin B_2 (riboflavin)	Oxidation/reduction reactions	Seborrheic dermatitis/cheilosis/glossitis Decreased fatty acid oxidation Altered vitamin B_6 activation to coenzyme Decreased tryptophan to niacin conversion	Red cell glutathione reductase activity Red cell flavine adenine dinucleotide Urine riboflavin-to-creatinine ratio
Vitamin B_6 (pyridoxine)	Aminotransferase reactions	Dermatitis/cheilosis/glossitis Microcytic anemia/weight loss Decreased serum transaminases Peripheral neuritis/irritability/convulsions	Red cell aminotransferase activity Plasma pyridoxal phosphate (HPLC) Tryptophan loading test Urine 4-pyridoxic acid
	Irritability/convulsions Decreased tryptophan to niacin conversion		
Vitamin B_{12} (cyanocobalamin)	Methyl group donor Sulfur amino acid conversion Branched-chain amino acid catabolism	Megaloblastic anemia Hypersegmented neutrophils Demyelination/posterior spinal column changes Methylmalonicacidemia Hyperhomocysteinemia	Plasma level (RIA or microbiologic) Schilling test Plasma homocysteine Deoxyuridine suppression test
Vitamin C (ascorbate)	Reducing agent (regenerates vitamin E) Cofactor for hydroxylators Noradrenaline/carnitine synthesis? Cholesterol synthesis? Leukocyte function	Scurvy Perifollicular/petechial hemorrhages Hematologic abnormalities Poor wound healing Impaired collagen synthesis Psychological disturbances	Plasma level (enzyme assay/HPLC) Leukocyte concentration (longer term) Whole blood concentration Urine concentration
Folic acid	Methyl group donor DNA/RNA synthesis Amino acid metabolism	Megaloblastic anemia, neutropenia Altered amino acid metabolism Impaired growth Diarrhea	Plasma level (RIA/microbiologic) Red cell level
Biotin	Coenzyme for carboxylases, decarboxylases, and transcarboxylases	Multiple carboxylase deficiency Organic acidemia/acidosis Dermatitis/alopecia CNS: seizures/ataxia/depression	Plasma (microbiologic assay) Plasma lactate Urine organic acids Lymphocyte carboxylase

(*continues*)

TABLE 75.3-8 Continued

VITAMIN	FUNCTION	CLINICAL DEFICIENCY STATE	LABORATORY ASSESSMENT
Niacin	Dehydrogenase activity	Pellagra: diarrhea/dermatitis/dementia Glossitis/stomatitis/vaginitis Impaired absorption of fat, carbohydrate, and vitamin B_{12} Achlorhydria	Urine ratio of metabolites (*N*-methylnicotinamide: 2-pyridone) Tryptophan load Red cell NAD or NAD:NADP ratio
Pantothenic acid	Pyruvate dehydrogenase cofactor Carrier of acyl groups Acetylation of alcohol/amines	Postural hypotension Anorexia and vomiting Reduced acetylation Neuromuscular defects/hyperreflexia	Urine excretion Whole blood level (RIA/microbiologic)

Adapted from Loughrey C and Duggan C.[97]
CNS = central nervous system; DNA = deoxyribonucleic acid; DTR = deep tendon reflex; HPLC = high-performance liquid chromatography; LDL = low-density lipoprotein; NAD = nicotinamide adenine dinucleotide; NADP = nicotinamide adenine dinucleotide phosphate; PT = prothrombin time; RIA = radioimmunoassay; RNA = ribonucleic acid.

requirements are in health and disease. In addition to balance studies, investigators have used the "factorial approach" to estimate requirements. This method, which was pioneered in estimating protein requirements in children,[76] is a theoretical approach that relies on the following factors: the body content of a nutrient needed for normal body growth; the amount lost in skin, urine, and other secretions; and the efficiency of gastrointestinal absorption.

Another approach to define optimal nutrient intakes, especially well suited for infants, has been the "analogy to breast milk" approach. This approach starts with the assumption that the types and amounts of nutrients commonly found in human breast milk are reasonable starting points in estimating human nutrient requirements. Although for many nutrients, and perhaps more significantly non-nutrients, this concept has considerable merit, the very low vitamin D content of human milk points out the limitations of this approach alone.[77]

Among the more recent and attractive options are studies in which the metabolic pathways of nutrients are measured using stable isotopes.[78] These experiments employ nonradioactive probes to quantify rates of nutrient synthesis, absorption, excretion, and flux into the bloodstream and have allowed better and more precise estimates of nutrient requirements. Important examples of this work include the use of $^{2}H_2{}^{18}O$ (so-called doubly labeled water) to measure TEE[79]; ^{13}C-leucine to measure oxidation rates of a large number of amino acids[80]; ^{67}Zn, ^{68}Zn, and ^{70}Zn for studies of zinc nutriture[81,82]; ^{44}Ca, ^{46}Ca, and other calcium isotopes for the assessment of calcium absorption[83]; and many others.

Well-conducted clinical trials of nutrient supplementation have also been used to more fully define nutrient requirements, especially in a variety of disease states. The finding of an improved clinical or metabolic outcome with supplementation of a nutrient normally considered nonessential has led to the introduction of the term "conditionally essential." Conditionally essential nutrients have been defined as those nutrients that normally are synthesized endogenously by the body but whose synthetic rates may be inadequate to meet needs in times of disease, stress, or developmental stages. Examples of nutrients thought to be conditionally essential include several amino acids (cysteine,[84] taurine, and glutamine[85]), inositol, nucleotides,[86] and others.[75] Other nutrients well known to be essential but increasingly appreciated in optimizing health include folate (which prevents neural tube defects[87] and lowers plasma homocysteine levels[88]), vitamin A (which reduces mortality rates in communities at risk of deficiency[89]), and zinc (which reduces rates of diarrheal diseases and respiratory infections[90,91]).

Finally, the use of nutrients and other biologic substances in high, perhaps pharmacologic, doses has spawned the terms "nutritional pharmacology" or "nutraceuticals" to describe their use.[92] Among nutrients used in this fashion are precursors of nutrients (eg, organic phosphates, dipeptides), probiotics (eg, lactobacilli), prebiotics (eg, fructose oligosaccharides), and various growth factors (eg, growth hormone, IGF, epidermal growth factor).

New Definitions

In concert with the increasing appreciation of essential and conditionally essential nutrients has been a change in how nutrient requirements are set. Previous levels of requirements had largely been derived from the observations of the metabolic derangements and/or clinical signs of deficiency states that would ensue when otherwise healthy subjects consumed a diet with inadequate amounts of the nutrient in question. Indeed, the genesis of the Food and Nutrition Board in the 1940s was in part due to the finding of a high frequency of malnutrition among draftees for the US armed forces,[93] and vitamin and mineral enrichment of wheat flour soon followed. With the growing realization of the importance of diet in influencing long-term health outcomes as well, published nutrient requirements have been rethought and redesigned. In the 1990s, nutrition scientists in the United States and Canada embarked on a thorough revision of the Recommended Dietary Allowances (RDAs; United States) and Recommended Nutrient Intakes (Canada) and published new definitions more suitable to optimizing health. These efforts were spearheaded by the Institute of Medicine of the National Academy of Science, a private, nongovernmental organization chartered by the US federal government to provide advice on scientific matters.

TABLE 75.3-9 MINERALS AND TRACE ELEMENTS: FUNCTION, DEFICIENCY STATES, AND LABORATORY ASSESSMENT TECHNIQUES

MINERAL/ TRACE ELEMENT	FUNCTION	CLINICAL DEFICIENCY STATE	LABORATORY ASSESSMENT
Calcium	Bone structure	Bone demineralization	Plasma total calcium
	Cell metabolic regulator	Tetany/seizures	Plasma free calcium in altered protein binding (eg, hypoalbuminemia, acidosis)
	Nerve excitation threshold	Cardiac arrhythmias	Radiographs
			CT and photon densitometry
Chromium	Glucose tolerance factor	Glucose intolerance	Plasma chromium
	Metabolism of nucleic acids	Neuropathy/encephalopathy	Glucose tolerance
	? Iodine/thyroid function	Altered nitrogen metabolism	
		Increased free fatty acids	
Copper	Cofactor for several enzymes including superoxide dismutase, tyrosinase, ferrochelatase, cytochrome *c* oxidase	Hypochromic anemia, neutropenia	Plasma copper
		Skin depigmentation	Plasma ceruloplasmin (ferrochelatase)
		Dyslipidemia	
		CNS problems	Liver biopsy concentration
			Superoxide dismutase activity
Iodide	Component of thyroid hormones	Goiter	Thyroid hormones, TSH
		Cretinism	Urinary iodide-to-creatinine ratio
Iron	Heme synthesis	Hypochromic microcytic anemia	Plasma iron and ferritin
	Component of cytochromes	Altered oxidative phosphorylation	Total iron-binding capacity
			Hemoglobin/hematocrit, red cell indices
		Diminished concentrative ability	RBC zinc protoporphyrin-to-heme ratio
		Decreased exercise tolerance	Bone marrow aspirate stain
Magnesium	Cofactor for hexokinase and phosphokinase	Cardiac dysrhythmias	Plasma total or free magnesium
		Neuromuscular excitability	Magnesium loading test
	Alters ribosomal aggregation in protein synthesis	Decreased PTH level/activity	
		Hypocalcemia/hypokalemia	
	Increases nerve excitation threshold	Convulsions	
Manganese	Mucopolysaccharide synthesis	Dermatitis	Plasma level
	Cholesterol synthesis	Decreased clotting factors	Whole blood level
	Cartilage/bone formation	Decreased nail/hair growth	Mitochondrial superoxide dismutase
	Pyruvate carboxylase cofactor	?Hair color change	
	Superoxide dismutase cofactor		
Phosphorus	Bone structure	Tissue hypoxia	Serum/plasma levels
	Cell membrane structure	Respiratory failure (ventilatory dependence)	Alkaline phosphatase activity
	Energy use		Radiography
	Glycogen deposition	Hemolytic anemia	Densitometry
	Acid-base balance: buffering	Rickets	Renal tubular excretion threshold
	Oxygen release (2,3-DPG)	CNS abnormalities	
Selenium	Glutathione peroxidase constituent	Myositis	Plasma concentration
	Thyroid hormone metabolism	Cardiomyopathy	Glutathione peroxidase acitivity
		Nail bed changes	Nail/hair selenium
		Macrocytic anemia?	
Zinc	Cofactor for > 70 enzymes	Skin lesions/poor wound healing	Plasma concentration
	Immune function	Immune dysfunction (especially T cell)	Alkaline phosphatase activity
	Cell replication	Anorexia/dysgeusia	Urinary excretion
	Vision	Growth failure/nitrogen wasting	Leukocyte concentration
		Hypogonadism/delayed puberty	
		Diarrhea	

Adapted from Loughrey C and Duggan C.[97]
CNS = central nervous system; CT = computed tomography; DPG = 2,3-diphosphoglycerate; PTH = parathyroid hormone; RBC = red blood cell; TSH = thyroid-stimulating hormone.

The mere prevention of a deficiency state is no longer the gold standard in setting nutrient requirement levels; instead, a broader concept of nutrition health has been taken. Nutritional requirements are those levels of intakes that are most consistent with optimal physiologic functioning and well-being at all life stages. Examples include using bone mineral accretion data in setting dietary calcium intake levels and dental caries protection data in setting reference intakes of fluoride.[94] Table 75.3-10 outlines the definitions now used to describe nutrient requirements since the publication of these new standards in 1994. Figure 75.3-1 shows the relationship between the three Dietary Reference Intakes (DRIs) and the risks of dietary inadequacy and adverse effects at various levels of dietary intake.

TABLE 75.3-10 DEFINITIONS OF NUTRITIONAL REQUIREMENTS TO SET STANDARDS OF INTAKE (FNB/IOM/NAS)

TERM	ABBREVIATION	YEAR INTRODUCED	DEFINITION/USE
Old			
Recommended Dietary Allowances	RDAs	1943	Average daily dietary intake value sufficient to meet the requirement of nearly all (97–98%) healthy individuals in a group; more recently, the term has been calculated as EAR plus 2 SD of the EAR (see below)
New			
Dietary Reference Intakes	DRIs	1994	Umbrella term including RDA, EAR, AI, and UL (see below)
Estimated Average Requirement	EAR	1994	Nutrient intake value that is estimated to meet the requirement of half the individuals in a group
Adequate Intake	AI	1994	Used when no EAR is available and therefore no RDA can be calculated; nutrient intake value based on observed or experimentally determined approximations of nutrient intakes by a group or groups of healthy people
Tolerable Upper Intake Level	UI	1994	Highest level of a daily nutrient intake that is likely to pose no risks of adverse health effects to almost all individuals in the general population

FNB/IOM/NAS = Food and Nutrition Board of the Institute of Medicine/National Academy of Sciences.

Of the new DRIs, RDAs are still the most appropriate measure to use when reviewing an individual's dietary intake (because, by definition, dietary intake at or above the RDA is likely to be adequate for healthy persons). Conversely, because an individual's specific requirement for each nutrient cannot be easily determined, the fact that his/her intake does not meet the RDA is not a sufficient cause to conclude that the diet is deficient. Dietary intake patterns in healthy individuals follow a distribution curve showing a range of intake levels associated with normal health. The risks of dietary inadequacy increase significantly as intake falls to less than 2 SD below the Estimated Average Requirement (EAR). In contrast to the RDAs, Adequate Intakes (AIs) and EARs are better suited to evaluating dietary patterns of groups of subjects rather than individuals alone.

Tables 75.3-11 through 75.3-14 present the most recently published data from the Food and Nutrition Board for a variety of micronutrients, protein, and energy. In cases for which no EAR has been set, the AI is used instead.

Concurrent with the new terminology proposed by the Food and Nutrition Board, new definitions from the US Food and Drug Administration (FDA) used for food labeling have been published (Table 75.3-15). The similarity between these sets of abbreviations may lead to some confusion, but their functions are distinct. The DRIs of the Food and Nutrition Board are published as proposed reference dietary intakes for healthy US and Canadian persons by a nongovernmental institute. In contrast, the Daily Reference Values (DRVs) and Reference Daily Intakes (RDIs) are published by the FDA and are designed to help consumers use food information to plan a healthy diet. Using an estimated energy intake of 2,000 or 2,500 calories per day, the DRVs express nutrient content as a proportion of generally recommended guidelines for a healthy diet (eg, less than 30% of calories as fat, less than 10% of calories as saturated fat, 11.5 g of fiber per 1,000 calories, etc). A second role of these new terms is to allow objective assessment and regulation of foods marketed as "low fat" or "high fiber." For example,

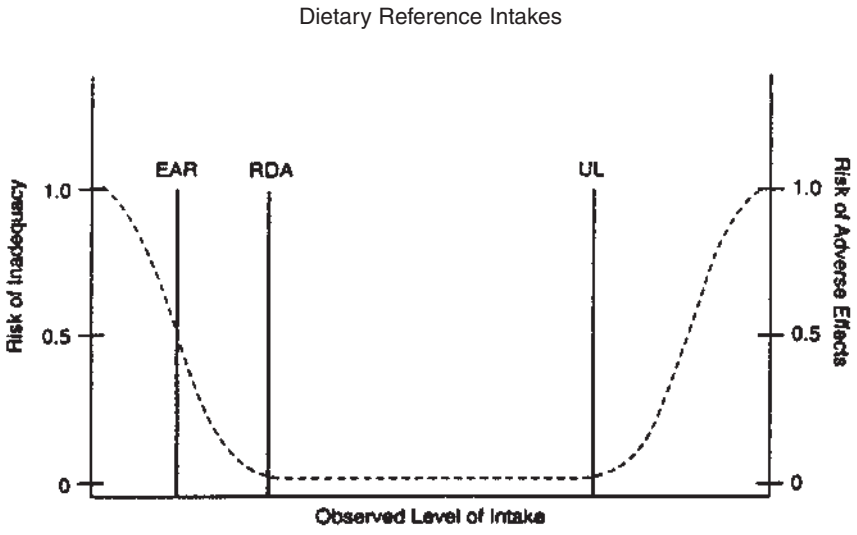

FIGURE 75.3-1 The relationship between Estimated Average Requirement (EAR), Recommended Dietary Allowance (RDA), and Tolerable Upper Intake Level (UL). The risk of inadequate intake is 50% at the EAR, 2 to 3% at the RDA, and close to 0% at the UL. Risks of adverse effects are close to 0% at the UL but increase with increasing intake. Reproduced with permission from Standing Committee on the Scientific Evaluation of Dietary Reference Intakes, Food and Nutrition Board, Institute of Medicine.[94]

TABLE 75.3-11 CRITERIA AND DIETARY REFERENCE INTAKE VALUES FOR PROTEIN BY LIFE STAGE GROUP

LIFE STAGE GROUP	CRITERION	AI OR RDA FOR REFERENCE INDIVIDUAL (g/d)		EAR (g/kg/d)		RDA (g/kg/d)		AI (g/kg/d)
		MALES	FEMALES	MALES	FEMALES	MALES	FEMALES	
0–6 mo	Average consumption of protein from human milk	9.1 (AI)	9.1 (AI)					1.52
7–12 mo	Nitrogen equilibrium + protein deposition	13.5	13.5	1.1	1.1	1.5	1.5	
1–3 yr	Nitrogen equilibrium + protein deposition	13	13	0.88	0.88	1.10	1.10	
4–8 yr	Nitrogen equilibrium + protein deposition	19	19	0.76	0.76	0.95	0.95	
9–13 yr	Nitrogen equilibrium + protein deposition	34	34	0.76	0.76	0.95	0.95	
14–18 yr	Nitrogen equilibrium + protein deposition	52	46	0.73	0.71	0.85	0.85	
>18 yr	Nitrogen equilibrium	56	46	0.66	0.66	0.80	0.80	

Adapted from Standing Committee on the Scientific Evaluation of Dietary Reference Intakes, Food and Nutrition Board, Institute of Medicine.[98]
EAR = Estimated Average Requirement: the intake that meets the estimated nutrient needs of half of the individuals in a group.
RDA = Recommended Dietary Allowance: the intake that meets the nutrient need of almost all (97–98%) of individuals in a group.
AI = Adequate Intake: the observed average or experimentally determined intake by a defined population or subgroup that appears to sustain a defined nutritional status, such as growth rate, normal circulating nutrient values, or other functional indicators of health. The AI is used if sufficient scientific evidence is not available to derive an EAR. For healthy infants receiving human milk, the AI is the mean intake. The AI is not equivalent to an RDA.

TABLE 75.3-12 CRITERIA AND DIETARY REFERENCE INTAKE VALUES FOR ENERGY BY ACTIVE INDIVIDUALS BY LIFE STAGE GROUP (FOR HEALTHY MODERATELY ACTIVE AMERICANS AND CANADIANS)

LIFE STAGE GROUP	CRITERION	ACTIVE PAL EER (kcal/d)	
		MALE	FEMALE
0–6 mo	Average consumption of protein from human milk	570	520 (3 mo)
7–12 mo	Nitrogen equilibrium + protein deposition	743	676 (9 mo)
1–2 yr	Nitrogen equilibrium + protein deposition	1,046	992 (24 mo)
3–8 yr	Nitrogen equilibrium + protein deposition	1,742	1,642 (6 yr)
9–13 yr	Nitrogen equilibrium + protein deposition	2,279	2,071 (11 yr)
14–18 yr	Nitrogen equilibrium + protein deposition	3,152	2,368 (16 yr)
> 18 yr	Nitrogen equilibrium	3,067*	2,403* (19 yr)
Pregnancy			
14–18 yr	Adolescent female EER plus change in TEE plus pregnancy energy deposition		
	1st trimester		2,368 (16 yr)
	2nd trimester		2,708 (16 yr)
	3rd trimester		2,820 (16 yr)
19–50 yr	Adult female EER plus change in TEE plus pregnancy energy deposition		
	1st trimester		2,403† (19 yr)
	2nd trimester		2,743† (19 yr)
	3rd trimester		2,855† (19 yr)
Lactation			
14–18 yr	Adolescent female EER plus milk energy output minus weight loss		
	1st 6 mo		2,698 (16 yr)
	2nd 6 mo		2,768 (16 yr)
19–50 yr	Adult female EER plus milk energy output minus weight loss		
	1st 6 mo		2,733‡ (19 yr)
	2nd 6 mo		2,803‡ (19 yr)

Adapted from Standing Committee on the Scientific Evaluation of Dietary Reference Intakes, Food and Nutrition Board, Institute of Medicine.[98]
EER = estimated energy requirement; PAL = physical activity level; TEE = total energy expenditure. The intake that meets the average energy expenditure of individuals at the reference height, weight, and age.
*Subtract 10 kcal/d for males and 7 kcal/d for females for each year of age above 19 years.
†The Estimated Average Requirement (EAR) and Recommended Dietary Allowance (RDA) for pregnancy are only for the second half of pregnancy. For the first half of pregnancy, the protein requirements are the same as those of the nonpregnant woman.
‡In addition to the EAR and RDA of the nonlactating adolescent or woman.

Adapted from Standing Committee on the Scientific Evaluation of Dietary Reference Intakes, Food and Nutrition Board, Institute of Medicine.[94,99–101]

This table (taken from the Dietary Reference Intake reports (see <www.nap.edu>) presents Recommended Dietary Allowances (RDAs) in bold type and Adequate Intakes (AIs) in ordinary type followed by an asterisk. RDAs and AIs may both be used as goals for individual intake. RDAs are set to meet the needs of almost all (97–98%) individuals in a group. For healthy breastfed infants, the AI is the mean intake. The AI for other life stage and gender groups is believed to cover the needs of all individuals in the group, but lack of data or uncertainty in the data prevents specifying with confidence the percentage of individuals covered by this intake.

†As retinol activity equivalents (RAEs). 1 RAE = 1 mg retinol, 12 mg β-carotene, 24 mg α-carotene, or 24 mg β-cryptoxanthin. The RAE for dietary provitamin A carotenoids is twofold greater than retinol equivalent (RE), whereas the RAE for preformed vitamin A is the same as RE.

‡Cholecalciferol. 1 mg cholecalciferol = 40 IU vitamin D.

§In the absence of adequate exposure to sunlight.

||As α-tocopherol. α-Tocopherol includes RRR-α-tocopherol, the only form of α-tocopherol that occurs naturally in foods, and the 2R-stereoisomeric forms of α-tocopherol (RRR-, RSR-, RRS-, and RRS-α-tocopherol) that occur in fortified foods and supplements. It does not include the 2S-stereoisomeric forms of α-tocopherol (SRR-, SSR, SRS-, and SSS-α-tocopherol), also found in fortified foods and supplements.

#As niacin equivalents (NE). 1 mg of niacin = 60 mg of tryptophan; 0–6 mo = preformed niacin (not NE).

**As dietary folate equivalents (DFE). 1 DFE = 1 mg food folate = 0.6 mg of folic acid from fortified food or as a supplement consumed with food = 0.5 mg of a supplement taken on an empty stomach.

††Although AIs have been set for choline, there are few data to assess whether a dietary supply of choline is needed at all stages of the life cycle, and it may be that the choline requirement can be met by endogenous synthesis at some of these stages.

‡‡Because 10 to 30% of older people may malabsorb food-bound vitamin B_{12}, it is advisable for those older than 50 years to meet their RDA mainly by consuming foods fortified with vitamin B_{12} or a supplement containing vitamin B_{12}.

§§In view of evidence linking folate intake with neural tube defects in the fetus, it is recommended that all women capable of becoming pregnant consume 400 mg from supplements or fortified foods in addition to intake of food folate from a varied diet.

This table presents Recommended Dietary Allowances (RDAs) in bold type and Adequate Intakes (AIs) in ordinary type followed by an asterisk. RDAs and AIs may both be used as goals for individual intake. RDAs are set to meet the needs of almost all (97–98%) individuals in a group. For healthy breastfed infants, the AI is the mean intake. The AI for other life stage and gender groups is believed to cover the needs of all individuals in the group, but lack of data or uncertainty in the data prevents specifying with confidence the percentage of individuals covered by this intake.

Adapted from Dietary Reference Intakes for calcium, phosphorous, magnesium, vitamin D, and fluoride (1997); Dietary Reference Intakes for thiamine, riboflavin, niacin, vitamin B_6, folate, vitamin B_{12}, pantothenic acid, biotin, and choline (1998); Dietary Reference Intakes for vitamin C, vitamin E, selenium, and carotenoids (2000); and Dietary Reference Intakes for vitamin A, vitamin K, arsenic, boron, chromium, copper, iodine, iron, manganese, molybdenum, nickel, silicon, vanadium, and zinc (2001). These reports may be accessed at <www.nap.edu>.

TABLE 75.3-15 DEFINITIONS OF NUTRITIONAL REQUIREMENT USED FOR FOOD LABELING (FDA)

TERM	ABBREVIATION	YEAR INTRODUCED	DEFINITION/USE
Old			
US Recommended Daily Allowances	USRDAs	1973	Reference values for vitamins, minerals, and protein used in food labeling; based on RDAs (see Table 75.3-10)
New			
Reference Daily Intakes	RDIs	1994	Replaces the term "USRDAs"; values are generally comparable to them
Daily Reference Values	DRVs	1994	Dietary references applying to fat, saturated fat, cholesterol, carbohydrate, protein, fiber, sodium, and potassium; a 2,000- or 2,500-calorie reference diet is assumed

FDA = US Food and Drug Administration.

foods labeled as "high fiber" must contain at least 20% of the DRV for fiber per serving.

CONCLUSION

The precise nutrient needs of healthy persons is still a matter of intense scientific inquiry and debate, so it is not surprising that those of children with gastrointestinal disease are not well known. Despite the uncertainties of the field, clinicians must still use appropriate tools to accurately assess the dietary intake, anthropometric status, and biochemical profile of their patients. Significant malnutrition with functional and biochemical deficits can exist in patients with gastrointestinal disease even in the absence of overt symptoms or signs of active disease.[95] Advances in the technology of body composition analysis hold promise to further evaluate strategies to preserve and augment lean body mass. A heightened awareness of the susceptibility of the pediatric gastrointestinal patient to malnutrition and constant efforts to improve nutritional status are of paramount importance in patient care.

4A. *Parenteral* Nutrition

Susan S. Baker, MD, PhD
Robert D. Baker, MD, PhD

In 1968, Dudrick and colleagues reported that exclusive intravenous feeding via a central vein could support the long-term survival and growth of puppies.[1] This breakthrough in technology was quickly applied to adult humans[2] and then children.[3] Subsequently, parenteral nutrition (PN) solutions have been widely used. However, knowledge to support this technology dates to the 1600s, when the circulation of blood was discovered and the first infusion of a liquid, wine, was accomplished.[4] Approximately 200 years later, the practice of starving ill patients began to change. In the twentieth century, safe infusates of fats, carbohydrates, and proteins were synthesized, production processes for the manufacture of components arose, and nutritional scientists began to develop an understanding of nutritional requirements. Knowledge of the requirements for micronutrients and metabolic changes associated with infection, injury, or surgery permitted the tailoring of infusions for specific situations. The identification of nutrients that may be essential under specific situations, the compatibility of PN solutions with medications, and the use of pharmacologic substances to promote growth and healing, scavenge oxidants, and prevent or ameliorate metabolic changes associated with inflammation have permitted the treatment of patients who cannot fully support their nutritional requirements through their gastrointestinal (GI) tract. The design of backpacks, subcutaneously accessible central lines, and cycled nutrient delivery permits patients, especially children, to receive nutrition support while they attend school and engage in other age-appropriate activities. For patients who are critically ill or are not candidates for a small bowel transplant, PN can be lifesaving. Still, the technique is not free of complications. It was initially assumed that these complications could be overcome with further fine-tuning. Subsequent experience has shown this to be only partially true. For instance, there have been vast improvements in line technology that resulted in a decrease in line-related complications.[5] Amino acid solutions have been improved, and special solutions for special conditions have been developed.[6,7] The problem of fat administration and essential fatty acid deficiency (EFAD) has been largely solved.[8] Some complications have proven difficult to resolve, bone disease and cholestasis being among these. Because of evidence for the benefits of enteral feeds[9,10] and the serious complications associated with PN,[11–14] parenterally administered nutrition should be reserved only for specific indications when enteral nutrition is not possible or adequate. Table 75.4A-1 lists situations in which the GI tract is nonfunctional or partially functional. Figure 75.4A-1 is an algorithm for initiation of pediatric PN. PN can be partial, used as an adjunct when enteral nutrition cannot meet all nutrient needs, or total, supplying all nutritional needs. Total PN must supply all of the nutrients needed by an individual in amounts necessary to replete malnourished states, prevent muscle breakdown during metabolic stress, and support normal growth and development over the long term.

INDICATIONS FOR PN IN THE PEDIATRIC PATIENT

There are few absolute indications for PN. In some circumstances, such as prematurely born infants, severe malnutrition that is refractory to enteral feedings, pseudo-obstruction, short small bowel, and children who undergo surgery of the GI tract and are not able to be fed, PN is beneficial. In the premature infant, especially the very low birth weight infant, the GI tract may not be capable of processing the amount of nutrients needed for the infant to survive and grow. Over the past three decades, the use of PN in the pediatric population has shifted. In a recent review of 30 years experience with PN in a single institution for pediatric patients, the number of parenterally fed patients did not change; however, the

TABLE 75.4A-1 GASTROINTESTINAL FUNCTION

PARTIALLY FUNCTIONAL OR INADEQUATE FUNCTION
Cannot meet nutrient requirements after maximizing enteral support
Burns
Multiorgan failure
Malabsorption
Short bowel, intractable diarrhea, villous atrophy, dysmotility syndromes
Risk of aspiration when small bowel feeds are not possible
Malnutrition with hypoproteinemia
NONFUNCTIONAL
Paralytic ileus
Intractable vomiting when small bowel feedings are not possible
Small bowel ischemia
Necrotizing enterocolitis
Severe acute pancreatitis
Gastrointestinal surgery
Gastroschisis, omphalocele, multiple intestinal atresias, etc. until enteral route is accessible
Severe inflammatory bowel disease with possible impending surgery

Adapted from Baker SS.[123]

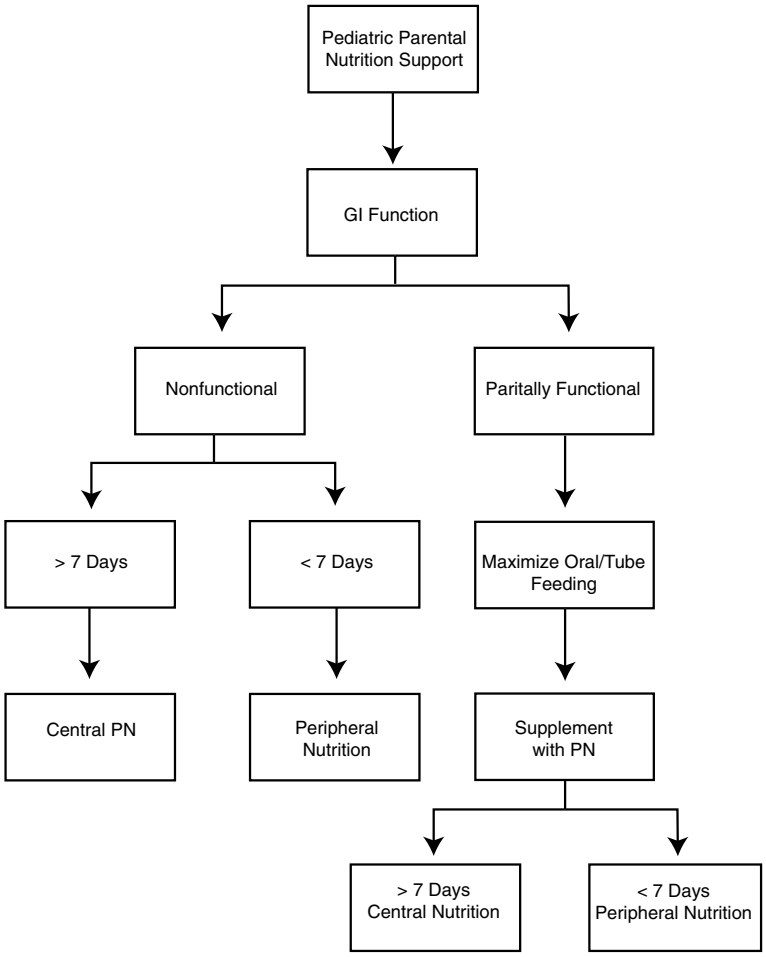

FIGURE 75.4A-1 Algorithm for initiating pediatric parenteral nutrition (PN) support. Adapted from Baker SS.[123] GI = gastrointestinal.

number of premature babies fed parenterally increased significantly, whereas the number of all other patients receiving PN decreased.[15] Severe malnutrition is associated with poor GI function, which is likely multifactorial in origin. Malnutrition causes atrophy of the GI tract in animals.[16] This phenomenon has not been demonstrated in humans, but "functional" atrophy is said to occur. Edema of the intestinal wall, radiographically visualized as separated loops of bowel, may impede nutrient absorption, as occurs in intestinal lymphangiectasia.[17] If of sufficient severity, pseudo-obstruction may require PN. However, intestinal pseudo-obstruction is a rare disease, and some cases of presumed pseudo-obstruction were shown to be Munchausen syndrome by proxy.[18] There is little evidence that nutrition support by itself is beneficial in pediatric oncologic disease. However, children in good nutritional status are better able to tolerate antitumor therapy. For a variety of reasons, children with cancer do not or cannot voluntarily consume adequate nutrition. Assisted enteral feeding in such cases should be considered before PN. PN, either pre- or postsurgery, has not been definitively demonstrated to be beneficial.[19] When surgery involves the GI tract and the child will not be able to be fed, PN is required.

SOLUTION COMPOSITION

The essential nutrients are water, protein, carbohydrate, fat, minerals, trace elements, and vitamins. In general, PN should not be used to correct acute fluid or electrolyte abnormalities. Parenteral solutions are compounded once a day. Over- or underestimates of electrolyte requirements that result in the need to change solutions more frequently than once every 24 hours could result in the patient receiving no nutrition support during part of the day and waste of an expensive therapeutic agent. PN solutions can be used to replace nutritional deficits over the long term. For example, PN solutions can be used to replete muscle mass, providing the extra protein, minerals, electrolytes, and calories that this process requires in addition to the needs for normal growth.

Fluid requirements for infants and children are based on seminal studies performed by Darrow.[20] The objective of fluid therapy is to provide water to meet the requirements for physiologic processes, including insensible and urinary losses. These requirements are based on healthy infants and children and do not take into account the increased losses that may occur with diarrhea, vomiting, fistula, burns, and fever; decreased losses that might occur with the use of mist tents; or altered patient states, as occurs with heart failure or renal disease. Fluid requirements roughly parallel energy metabolism and do not parallel body mass.[21] Although there are several methods to estimate fluid requirements (Table 75.4A-2), the most commonly used is that of Holliday, volume/weight.[21]

During fetal life, there is a gradual decrease in total-body water and extracellular fluid.[22] In the first trimester,

TABLE 75.4A-2 FLUID REQUIREMENTS PER DAY IN PEDIATRIC PATIENTS AS DETERMINED BY VARIOUS METHODS

METHOD	BODY WEIGHT (KG)	AMOUNT/D
Volume/weight	0–10	100 mL/kg
	10–20	1,000 + 50 mL/kg over 10 kg
	> 20	1,500 + 20 mL/kg over 20 kg
Volume/surface area	1–70	1,500–1,700 mL/m^2
Volume/kcal	0–70	100 mL/100 kcal metabolized

body water accounts for 95% of body weight. Body water decreases to 80% by 32 weeks and 78% at term. This shift is interrupted when an infant is born prematurely. Care must be taken to provide adequate water for the increased insensible skin losses yet permit the normal diuresis that occurs after birth. Too much water is associated with an increased incidence of patent ductus arteriosus, bronchopulmonary dysplasia, intraventricular hemorrhage, and necrotizing enterocolitis.[23] Anderson recommends 60 to 140 mL/kg/d for the first day of life, the higher amount for infants nursed under a radiant warmer or dry incubator and the lower amount for infants nursed in a humidified incubator or under a radiant warmer with a plastic blanket.[24] As the infant matures, the fluid requirement increases to 120 to 150 mL/kg/d to allow for increases in renal solute load, stool water output, and infant growth.[25]

Electrolytes are critically important in PN for the short term but also long term because normal muscle accretion cannot occur in the presence of insufficient electrolytes and minerals.[25] Essentially, all electrolyte loss occurs via the urine unless there is an ongoing source of additional losses such as diarrhea, fistula, or stoma. Table 75.4A-3 lists parenteral electrolyte requirements. When GI fluid losses occur, electrolytes and fluids must be replaced. Table 75.4A-4 lists the approximate electrolyte content of GI fluids.

PROTEIN

Proteins are essential for all metabolic functions in the body and serve as the main structural element of the body, as biochemical catalysts, and as regulators of gene expression. Proteins are complex, and their function is influenced by the availability of energy and nutrients such as minerals, vitamins, and trace elements. The average content of nitrogen in dietary protein is 16% by weight, and nitrogen metabolism is often considered synonymous with protein metabolism. Proteins consist of amino acids that have been categorized as essential, or indispensable, and nonessential, or dispensable. The nine essential amino acids—histidine, isoleucine, leucine, lysine, methionine, phenylalanine, threonine, tryptophan, and valine—are those that cannot be synthesized from precursors and hence must be provided. However, as more information on protein and intermediary metabolism becomes available, the definition of essential becomes blurred. Laidlaw and Kopple propose adding a third category of amino acid, conditionally indispensable.[26] Conditionally indispensable amino acids are those amino acids that are synthesized from other amino acids or their synthesis is limited under special physiologic conditions.[26–28] These amino acids can be especially important in the neonate, for whom it is likely that alanine, aspartate, glutamate, serine, and perhaps asparagine are conditionally indispensable.[29]

Unlike energy and other nutrients, the body has little in the way of protein that can be mobilized during times of insufficient intake. In a 70 kg adult, the "reservoir" of labile protein is estimated at about 1% of total-body protein. More than half of the body protein is present as skeletal muscle, skin, and blood. The liver and kidney are metabolically active tissues that contain about 10% of total-body protein. Brain, heart, lung, and bone account for about 15% of whole-body protein. The distribution of protein among these organs varies with age because the newborn has proportionately more brain and visceral tissue and less muscle. Thus, when exogenous protein is inadequate, functional body proteins are used. The body can adapt to a wide range of protein intakes; however, patho-

TABLE 75.4A-3 PARENTERAL ELECTROLYTE AND MINERAL REQUIREMENTS

NUTRIENT	PRETERM INFANTS*	TERM INFANT*	CHILDREN > 1 YR
Sodium (mEq/kg/d)	3	3	3
Potassium (mEq/kg/d)	2	2	2
Chloride (mEq/kg/d)	5	5	5
Calcium† (mg/kg/d)	80–100‡	60–90	24–60
Phosphorus† (mg/kg/d)	43–62	48–68	18–45
Magnesium† (mg/kg/d)	3–6	6–10.5	2.4–6.0

*Preterm infants have the same requirements as term infants.[24,65] For preterm infants, electrolytes are generally not administered on the first day of life.

†Adapted from Greene HL et al.[65] American Society for Parenteral and Enteral Nutrition (ASPEN) based its recommendations[39] on the National Academy of Science Dietary Reference Intake.[178]—210 mg/d for infants 0 to 6 months, 270 mg/d for ages 6 months to 1 year, 500 mg/d for ages 1 to 3 years, 800 mg/d for ages 4 to 8 years, and 1,300 mg/d for ages 9 to 18 years—but notes that these levels may be difficult to achieve because administration is often limited by its solubility. ASPEN clinical guidelines make no recommendations for phosphorus or magnesium.

*Decreases in volume occur with time after resection. Also dependent on length of small bowel removed.

logic conditions such as infection or trauma can cause substantial protein loss as the demand for either amino acids increases or as amino acid carbon skeletons are used to meet energy demands. If these extra needs are not met, a serious depletion of body protein mass occurs. Skeletal muscle is the largest single contributor to protein loss.

Protein requirements are based on the assumptions that adequate energy is provided so that the carbon skeletons of amino acids are not needed as an energy source and the protein quality is high. Table 75.4A-5 lists estimates of protein requirements by age. Protein quality is determined by digestibility (not a factor in PN) and the indispensable amino acid composition of the protein. If the content of a single indispensable amino acid is less than the requirement, that amino acid limits the use of other amino acids, preventing normal rates of protein synthesis even when the total nitrogen is adequate. Proposed amino acid requirements of the nine indispensable amino acids for infants (based on the amino acid composition of human milk), children, and adults have been reviewed.[30] Data exist, however, to suggest that histidine is conditionally essential for infants to 6 months of age[31] and cysteine is conditionally essential in low birth weight infants.[32] Table 75.4A-6 lists examples of the amino acid composition of some PN solutions.

The most reliable method to assess the adequacy of dietary protein is nitrogen balance, the difference between nitrogen intake and the amount excreted in urine, feces, skin, and sweat. This measurement is not practical clinically, especially for children. There is no reliable clinical measure of protein nutritional status. In infants and children, failure to gain weight or length can be used to assess the overall nutritional adequacy of a diet, and failure to gain length occurs with borderline inadequate protein intake.[33] Other anthropometrics are less sensitive. The most commonly used clinical tools to assess protein status are albumin and prealbumin.

Most individuals can tolerate a wide range of protein intakes. Foman reviewed adverse outcomes with increased protein intakes in healthy formula- and breastfed infants.[34] Diets high in protein were associated with an increase in renal solute load, a potential safety concern for water balance in the infant. Transient tyrosinemia as a consequence of delay in maturation of *p*-hydroxyphenylpyruvic acid oxidase can occur. The elevated levels can last as long as 6 weeks, raising a concern for long-term sequelae.

High-protein diets can alter the serum amino acid profile. The significance of this in infants and children who are already ill and may have an abnormal profile secondary to

TABLE 75.4A-5 ESTIMATES OF PROTEIN REQUIREMENTS BY AGE

the primary disease is not known. In an assessment of the tolerable upper limits in healthy populations for individual amino acids recently published by the National Academy of Sciences, no adverse effects were noted for branched-chain amino acids prescribed for PN.[30] The report cautions, however, that the studies may not have carefully monitored for adverse outcomes. Similarly, there are few, if any, reports of adverse effects of glutamine in the doses generally prescribed in PN solutions.

Specialized amino acid solutions have been proposed for a variety of clinical situations, including trauma, liver failure, metabolic stress, and to improve immune function. Branched chain–enriched preparations, glutamine-enhanced solutions, and a solution specially designed for infants are most commonly used.

The term "immunonutrition" refers to the use of specific nutrients, arginine, glutamine, nucleotides, and ω-3 fatty acids, alone or in combination to influence nutritional, immunologic, and inflammatory parameters in laboratory and clinical studies. The use of immunonutrition was systematically reviewed.[35] The primary outcomes of interest were mortality and the number of patients with new infectious complications. In the 22 articles that met the inclusion criteria, the reviewers found no consistently used standard definition of what constitutes immunonutriton. Pneumonia, intra-abdominal abscess, sepsis, line sepsis, wound infection, and urinary tract infections were identified as primary adverse outcomes. Secondary outcomes included length of hospital and intensive care unit stays and duration of mechanical ventilation. From this review, the authors concluded that immunonutrition may decrease infectious complication rates, but the treatment effect varies depending on the patient population, the intervention, and the quality of the study. In surgical patients, immunonutrition was associated with a reduction in infectious complication rates and shorter length of hospital stay without adverse effects on mortality. In critically ill patients, immunonutrition was not associated with any apparent clinical benefit and may be harmful in some subgroups of patients. Thus, immunonutrition is not recommended for all critically ill patients.

The use of glutamine was systematically reviewed.[36] Fourteen randomized trials compared the use of glutamine supplementation in surgical and critically ill patients. The review concluded that in surgical patients, glutamine supplementation (doses > 0.20 g/kg/d) may be associated with a reduction in infectious complication rates and shorter hospital stay. In critically ill patients, glutamine supplementation may be associated with a reduction in complication and mortality rates. The authors caution, however, that further separate studies of the surgical and critically ill groups need to be performed and powered large enough to detect clinically important differences using parenterally delivered glutamine. There was no evidence of harm with glutamine supplementation.

Protein-energy malnutrition is common in patients with liver disease. As the disease progresses and encephalopathy ensues, branched chain–enriched PN solutions may offer benefits.[37] However, rigorous clinical studies are not available to support the use of branched chain–enriched PN solutions in all patients with liver disease.[38] Branched chain–enriched amino acid solutions can offer benefit for patients who have hepatic encephalopathy, and these solutions are recommended for such patients.[39–41]

Two amino acid solutions are specifically designed for infants less than 1 year of age. Use of these solutions results in plasma amino acid concentrations that approximate the profile seen in breastfed infants. The differences between these two solutions and others is that they contain taurine, glutamate, and aspartate; reduced amounts of methionine, glycine, and alanine; and increased arginine and leucine. Although there are differences between the two solutions, both have shown benefits in term and preterm infants.[42–44] There appears to be no difference in occurrence or magnitude of cholestasis between children who receive either of the two solutions.[45] Use of these solutions is recommended for infants less than 1 year of age. In addition to the differing amino acid compositions, these solutions are more acidic and permit the solubilization of a higher concentration of calcium and phosphorus than the amino acid mixtures prepared for adults.

CARBOHYDRATES

Glucose is the major energy source in PN because it is safe, economic, and readily available. Other sugars—fructose, sorbitol, glycerol, and xylitol—have been suggested as useful energy sources for specific conditions such as diabetes or post-trauma but are not readily available or used. Glucose in PN solutions is in the monohydrous form containing 3.4 kcal/g and is available commercially in concentrations of 2.5 to 70%. The glucose concentration of PN solutions that can be safely administered is limited by osmolality. Concentrations higher than about 12.5% sclerose peripheral veins, increasing the incidence of phlebitis and shortening the time that a vein could be used for infusion. Glucose solutions higher than 12.5% must be administered in a central vein. Glucose is calculated to provide 60 to 75% of nonprotein calories. Estimated energy requirements are provided in Table 75.4A-7.

Initiation of glucose infusion should occur in an incremental fashion to prevent hyperosmolarity and hyperinsulinemia (Table 75.4A-8). The glucose infusion rate (GIR) can be calculated using the following equation:

$$\text{GIR} = \frac{\text{g/kg/d dextrose} \times 1{,}000}{1{,}440 \text{ min/d}}$$

A GIR of 12 to 14 mg/kg/min is tolerated in a healthy child, and infants can be safely given a GIR of 8 to 12 mg/kg/min. In adult patients, there is no apparent correlation between glucose clearance and the rate of oxidation of glucose.[46] Increases in the rate of glucose infusion from 4 to 7 mg/kg/min are associated with an increase in the rate of glucose oxidation. At higher rates, fat is synthesized without a further increase in oxidation. High glucose loads (ie, those containing more than 25% glucose and delivered at > 26 mg/kg/min) may not be beneficial to infants and may contribute to hepatosteatosis.

TABLE 75.4A-7 ESTIMATES OF PARENTERAL ENERGY REQUIREMENTS

AGE (YR)	ENERGY (KCAL/KG/D)	CARBOHYDRATE (MG/KG/MIN)*
Premature infant	80–120	10–18

*Estimate based on 60–75% of nonprotein calories as glucose.

The American Academy of Pediatrics recommends that insulin not be routinely added to PN solutions because responses to the addition of this hormone by infants are unpredictable.[47] For persistently hyperglycemic infants, insulin may improve tolerance to glucose.[48] However, a limited number of studies assess the clinical outcomes of infants treated with insulin.[49–51] Concerns about the use of insulin in the neonate include the possibility that suppression of muscle proteolysis may be undesirable, the composition of the resultant weight gain is not clearly understood, serum glucose is driven to tissues other than brain, and the possibility that glucose is converted to fat rather than being oxidized.[47]

Glucose intolerance can develop in critically ill patients, such as those who have experienced trauma, burns, sepsis, or cancer. For these patients, the GIR is limited to 5 to 7 mg/kg/min.[52] Infusion of excess glucose causes hyperglycemia, glucosuria, dehydration, and the conversion of glucose to fat. When hyperglycemia occurs, the GIR can be decreased or insulin can be added to the therapy. Exogenous insulin enhances the movement of substrate from the periphery to the liver and increases fat synthesis and storage. This can lead to hepatosteatosis; hence, insulin is not commonly used in critically ill patients outside the neonatal age group.

Complications associated with glucose infusion are listed in Table 75.4A-9.

INTRAVENOUS FAT ADMINISTRATION

Lipids are administered to virtually all patients who receive PN. Initially, intravenous fats were given to patients who had no oral intake to overcome EFAD; however, because intravenous lipids are the most calorically dense component of PN, intravenous fats are considered an important source of calories, especially for patients who are fluid restricted. Thus, intravenous lipids have at least two roles: avoiding or treating EFAD and as a source of energy.

There are a number of reasons to choose fat-predominant PN solutions over glucose-predominant ones. Glucose results in a higher specific dynamic action and thus higher resting energy expenditures and higher metabolic rates. Glucose-predominant PN can result in a respiratory quotient (RQ) of greater than 1.0, indicating the use of energy for lipogenesis. Finally, glucose metabolism results in an increased carbon dioxide elimination by the lungs when compared with fat metabolism. This fact can be of importance to mechanically ventilated patients and those with marginal lung function. In general, the ratio of calories derived from glucose to the calories derived from fats in the range of 3:1 or 2:1 minimizes carbon dioxide stress.[53,54]

Fats are bioactive precursors of prostaglandins, leukotrienes, and other mediators of inflammation and metabolism. They are also an essential part of neural tissue and cell membranes. These facts are especially important for the child who is growing, laying down tissue and gaining cells. Thus, intravenous lipids act as more than a source of calories, and in the future, intravenous fats will be used in a more specialized and directed way.[55,56]

Intravenous fats consist of three components: an aqueous phase, a lipid phase, and an emulsifier. The lipid phase supplies the majority of the calories and the essential fatty acids. Glycerin is present in the aqueous phrase

TABLE 75.4A-8 GLUCOSE CONCENTRATION IN PARENTERAL SOLUTIONS

	PREMATURE INFANT (< 1,000 G OR 28 WK GESTATION)	INFANT	CHILD (1–10 YR)	ADOLESCENT (11–18 YR)
Begin infusion	5–7.5% or glucose concentration in current IV solution	5–7.5% or glucose concentration in current IV solution	10% or percent higher than concentration in current IV solution	10% or percent higher than concentration in current IV solution

TABLE 75.4A-9 COMMONLY REPORTED COMPLICATIONS OF GLUCOSE

COMPLICATION	USUAL CAUSE	PREVENTION OR TREATMENT
Phelibitis	High osmolarity	Limit glucose concentration to 12.5% for peripheral administration
Refeeding syndrome	Rapid refeeding of a malnourished patient	Refeed slowly; monitor serum phosphorus, potassium, calcium, and magnesium
Hepatosteatosis	All nonprotein calories provided as carbohydrate or excessive calories	Provide 30% of calories as lipid
Cholestasis	Infant fed exclusively by PN	Enteral feeding
Carbon dioxide retention	High GIR in a patient with respiratory failure	Decrease GIR
Hypoglycemia	Abrupt discontinuation of PN or decrease in GIR	Taper PN
Hyperglycemia	High GIR, stress, burns, sepsis, incorrect glucose concentration	Decrease GIR, add insulin

Adapted from Lee PC and Werlin SL.[182]
GIR = glucose infusion rate; PN = parenteral nutrition.

and raises the tonicity as well as incidentally supplying calories. The emulsifier is usually egg phospholipid. Soybean oil, safflower oil, and mixtures of the two have been used as sources of lipid. The caloric density of 10% lipid emulsions is 1.1 kcal/mL, 20% emulsion is 2.0 kcal/mL, and 30% emulsion is 3.0 kcal/mL (available for three-in-one solutions only).

Preventing EFAD is one of the two major reasons for administering intravenous fats. The essential fats for humans are linoleic ($C_{18:2\ \omega\text{-}6}$) and linolenic ($C_{18:3\ \omega\text{-}3}$). EFAD has been described in children and adults who have no exogenous source of fats for 3 weeks or more. In the preterm infant, EFAD is seen after only 1 week without essential fatty acids. Symptoms of EFAD include scaly skin rash, sparse hair, susceptibility to infection, failure to thrive, hypotonia, increased red cell fragility, and electroencephalographic and electrocardiographic changes. In EFAD, the ratio of trienoic to tetraenoic acids increases to greater than 0.2.[57] In older children and adults, EFAD can be prevented by supplying 0.5 to 1.0 g/kg/d as intravenous lipid, and for premature infants, 0.6 to 0.8 g/kg/d prevents EFAD.

For the most part, fats supplied intravenously as a lipid emulsion are handled in the circulation in much the same fashion as very-low-density lipoprotein (VLDL) particles. Lipoprotein lipase, present in the capillary endothelium, reduces the triglycerides at the core of the particle, whereas the polar lipids, at the surface of the VLDL, are removed to form nascent high-density lipoprotein (HDL). Lecithin-cholesterol acyltransferase (LCAT), released into the circulation from the liver, converts the nascent HDL into mature HDL.[58] These two enzymes, lipoprotein lipase at the endothelial surface and LCAT in circulation, seem to be key in clearing the infused lipid from the circulation.

Lipids can be cleared by other mechanisms, such as endothelial cell endocytosis via cell-surface heparin sulfate proteoglycans in a receptor-independent manner.[59]

The amount of lipid that can be given safely by the intravenous route is limited by the rate of clearance of lipids from circulation. Two to three grams/kg/d of lipid can be safely administered to premature infants, term babies, and older children. Serum triglycerides must be monitored to ensure that the clearing mechanism has not been overwhelmed. It has been suggested that heparin might enhance clearance. In a randomized trial of two heparin doses, the drug caused an increase in circulating free fatty acids, presumably because of release of the lipoprotein lipase into circulation. There was no increase in lipid use.[60] It was concluded that heparin was of no benefit for fat metabolism. Administering intravenous lipid over 20 hours while allowing 4 hours for lipid clearing has been proposed as another method of facilitating lipid clearing. Evidence does not support this practice.[61]

Lipid emulsions used for parenteral administration contain phytosterols. These are plant-derived isoflavones that possess estrogenic properties. Their importance, either beneficial or detrimental, as part of PN is not known. Phytoestrogens, present in soy-based formulas, have been suggested as a cause of decreased bone mineral content in premature infants. Whether these compounds figure in PN-associated bone disease is unknown. No consistent effect of soy feeding on menarche and telarche has been found.[62,63] The importance of phytosterols in infused lipid emulsions as feminizing compounds has not been studied. To date, there is no proof that phytosterols play a role in PN-associated cholestasis, although this relationship has been suggested.[64]

MINERALS AND TRACE ELEMENTS

In the context of pediatric PN solutions, calcium, phosphorus, and magnesium are usually termed "minerals." Trace elements are those minerals found in the body in small amounts and include iron, zinc, copper, selenium, chromium, manganese, molybdenum iodine, fluoride, strontium, lithium, nickel, boron, vanadium, and arsenic. The discussion of trace elements will include those present in PN trace element solutions (zinc, copper, manganese, and chromium), as well as iodine, selenium, and iron. Deficiency of iodine, selenium, and iron has been described in children receiving long-term PN. These minerals are not included in trace element solutions, but they are frequently added in the solutions of children receiving

long-term PN. Table 75.4A-3 provides estimates of PN mineral requirements, and Table 75.4A-10 lists PN requirements for trace elements.

In 1988, the American Society for Clinical Nutrition (ASCN) published recommendations for parenteral trace elements for the pediatric age range.[65] These recommendations are based on calculations using the factorial method. As this committee recognized, trace element requirements of children receiving PN are inadequately studied. When the ASCN recommendations were critically assessed, some of the recommendations were found to be inaccurate. For instance, Mouser and colleagues found that children receiving the ASCN recommended amount of chromium had 10 times the serum concentration of children consuming a normal diet.[66]

Calcium, Phosphorus, and Magnesium

The minerals calcium, phosphorus, and magnesium are vital to intermediary metabolism serving in energy transfer. Calcium and phosphorus also serve a structural function, and calcium is a regulator for a variety of intracellular processes. Calcium and phosphorus are presumed to be actively transported across the placenta against a concentration gradient.[67] Between the time a fetus weighs 1,000 g and 4,400 g at term, whole-body calcium content increases by 86%, phosphorus by 82%, and magnesium by 78%.[68] Many chronic diseases that require PN support are associated with calcium depletion. Approximately 99% of total-body calcium is found in bone, whereas 85% of phosphorus is in bone, and 50 to 60% of magnesium is in bone. Bone acts as a reservoir for calcium, phosphorus, and magnesium, so serum levels often do not reflect total-body content. This makes it difficult to identify deficiency states. Less than 1% of the total-body calcium, phosphorus, and magnesium is in the circulation. Because serum calcium is tightly controlled at the expense of bone, calcium deficiency is a chronic problem of bone loss. Calcium circulates in three forms: 45% is in the biologically active ionized form, 45% is bound to protein, mainly albumin, and 10% is complexed to phosphate, lactate, and citrate.[69] Measurement of ionized calcium, because it is the active form, better reflects calcium homeostasis than does measuring total serum calcium. Fifty percent of phosphorus exists in circulation as free ions, 10% is protein bound, and 40% is complexed to calcium, magnesium, and sodium as salts. Phosphorus deficiency can be a serious acute problem when malnourished patients are refed and sufficient phosphorus is not provided.[70] Magnesium is mainly an intracellular anion, so serum magnesium levels may not accurately reflect total-body magnesium status.

The parenteral requirements for calcium and phosphorus can be tremendous, especially in small prematurely born infants and in children with a chronic disease. Peak bone mass is attained in late adolescence and is determined by nutritional factors, genetics, mechanical factors, and the environment.[71] PN should supply adequate minerals to attain optimal peak bone mass. Metabolic bone disease is common in premature infants and in children receiving long-term PN.[72,73] The hypocalcemia associated with metabolic bone disease results from not supplying adequate calcium and from urinary calcium losses. Because at varying concentrations, calcium and phosphorus will complex with each other in PN solutions and form a precipitate, there are limitations to the amounts of calcium and phosphorus that can be supplied in PN solutions.[74] These limitations caused nutritionists to seek creative ways of providing the minerals, such as alternating intravenous solutions of high cal-

The nutrients not addressed by the AMA panel consensus levels from diverse literature as discussed by Solomons N[186] have been listed.

The table is adapted from Solomons NW and Ruz M.[187]

*For full-term infants 0–3 months.

†For infants 3–12 months.

‡Depends on gender; extra is needed in females to compensate for menstrual losses.

cium concentration with those of high phosphorus content. These strategies have no proven benefit. Amino acid solutions designed for children under 1 year have added cysteine. Cysteine lowers the pH enough to permit the addition of calcium and phosphorus in amounts that may meet daily requirements.[75] In premature infants, it may not be possible to deliver these minerals in quantities that simulate intrauterine mineral accretion, but severe bone disease can be reduced. Because the amount of calcium that can be delivered is limited, maneuvers that decrease urinary calcium losses have been explored. Factors that promote hypercalciuria are increased calcium intake,[76] decreased phosphate intake,[76] increased amino acid infusion,[77] metabolic acidosis,[78] and cycling PN infusions.[79]

Children on long-term PN do not experience bone pain or fractures because the metabolic disease associated with PN is mostly subclinical.[80] Aluminum present as a contaminant in PN solutions and in additives can lead to decreased bone mineralization.[81] Parenteral amino acid solutions prepared from casein hydrolysates were contaminated with aluminum. Aluminum contamination is associated with osteopenia, growth arrest, fractures, and pain.[82–84] Since the discontinuation of these solutions, metabolic bone disease has become less of an issue. However, osteopenia remains a problem for children.[85,86] A study of children who had bowel resections of varying length, necessitating PN support for 1 to 67 months, showed appropriate bone mineralization for their weight and height after the PN solutions were discontinued.[87] The bone mineralization was less than that of children of the same age. Although this observation is encouraging, the findings must be viewed with caution because more than half of the children had relatively small amounts of bowel removed and required PN for less than 8 months.

Refeeding syndrome frequently accompanies the nutritional rehabilitation of malnourished individuals. The refeeding syndrome is a set of metabolic and functional complications that occurs as a result of intracellular shifts of elements. During rapid nutritional rehabilitation, profound hypophosphatemia, hypomagnesemia, and hypokalemia can precipitate acute respiratory and circulatory collapse. Neurologic manifestations of the refeeding syndrome include weakness, lethargy, paralysis, and confusion. Deaths have been documented.[88] Phosphorus, magnesium, and potassium must be carefully monitored in malnourished patients. Aggressive supplementation and correction of low values prevent the adverse outcomes of refeeding syndrome.

Zinc

Zinc is essential for growth. It is involved in chromosome replication and regulation of the translation of genetic information, provides structure for "zinc finger" proteins, stabilizes ribosomes and membranes, and is a component of a number of enzymes.[89] Zinc deficiency in humans impairs cell-mediated immunity.[90] Signs of zinc deficiency include dermatitis, alopecia, diarrhea, and immune deficiency. Severe PN-associated zinc deficiency mimics acrodermatitis enteropathica.[91] With zinc deficiency, relatively more fat accrues than lean tissue.[92] Zinc status is difficult to monitor. Stress, infections, and trauma all alter circulating zinc levels. Merely administering PN diminishes plasma zinc by about 30%.[92] Despite these shortcomings, serum zinc is commonly used to monitor zinc nutriture. Zinc is lost from the body through urine, sweat, and stool. Zinc status should be assessed and corrected if necessary in the face of extra loss, as in the case of diarrhea or high ostomy output. The composition of the tissue acquired during nutritional rehabilitation may be affected by zinc status. Acute zinc toxicity has resulted in pancreatitis.[93] Chronic toxicity has not been described in pediatric patients receiving PN.

Copper

Copper is important in many enzyme systems, especially those that involve oxygen, hydrogen peroxide, and superoxide. It is necessary for the formation of melanin, catecholamine synthesis, and crosslinking of elastin and collage.[94] Copper circulates bound to ceruloplasmin, which may have antioxidant properties of its own. Copper deficiency has been described in long-term PN patients frequently.[95,96] Premature infants are at special risk of becoming copper deficient because copper accumulates in the fetus during the third trimester. Signs of copper deficiency include hypochromic, microcystic anemia, depigmentation of skin and hair, hypothermia, and hypotonia.

Manganese

Manganese has two known functions: as cofactor for the enzyme pyruvate carboxylase and as part of the mitochondrial enzyme superoxide dismutase. Manganese deficiency in long-term PN has not been described; however, toxicity has been described. High levels of manganese have been implicated as a causative factor in the cholestatic effect of PN and also in basal ganglia damage resulting in Parkinson disease in adults on long-term PN.[97] Fell and colleagues have monitored basal ganglia damage associated with manganese accumulation in children on long-term PN using magnetic resonance imaging. This group also followed the cholestatic effects of manganese in children. This study supports a causative role for manganese in both of these complications of PN.[98]

Chromium

The metabolic role of chromium is poorly understood. Proof that chromium plays a part in a "glucose tolerance factor," thought to activate insulin, is lacking. Two cases of chromium deficiency have been described in adults receiving PN. The symptoms of the described cases include glucose intolerance, hyperosmolarity, dehydration, and glucosuria. Symptoms responded poorly to insulin, but insulin responsiveness was restored with administration of chromium.[99] Chromium deficiency in children receiving PN has not been described; however, chromium excess has been reported.[100] Chromium toxicity results in skin irritation and carcinogenesis in animals.[101] The trivalent chromic ions present in PN solutions are not highly toxic, so excessive chromium from PN is not likely to be harmful.

Iodine

Iodine is essential, and its deficiency has been described in children.[102] However, iodine deficiency had not been described in children receiving PN until recently. Ibrahim and colleagues studied a group of extremely premature infants on PN who were in negative iodine balance.[103] Because the absorption of iodine is good, the parenteral dose should be similar to the enteral recommendation. One microgram/kg/d administered parenterally is recommended for the very low birth weight infant, whereas the enteral recommendation is 30 µg/kg/day.[104,105] Iodine is a minor contaminating component of many PN solutions and is present in antiseptics used to cleanse the skin at the catheter insertion site. PN patients receive measurable iodine from both of these sources.[106] No toxicity has been found in subjects receiving 20 times the Recommended Dietary Allowance for iodine. Any pediatric patient receiving long-term PN requires supplemental iodine.

Selenium

Selenium is bound at the catalytic site of glutathione peroxidase, an enzyme that catalyzes the reduction of H_2O_2 to H_2O. Selenium is also at the active site of type 1 and 3 iodothyronine deiodinase, which is important in the synthesis and degradation of triiodothyronine.[107] However, one study did not show a correlation between selenium supplementation and thyroid function in very low birth weight infants receiving long-term PN.[108] Selenium deficiency has been reported in children receiving PN.[109–111] The ASCN guidelines list the parenteral selenium requirements at 2.0 µg/kg/d for preterm and term infants as well as children.[65] Selenium toxicity is described.[112]

Cholestasis

Because copper and manganese are excreted in the bile, patients with cholestasis who require PN are at risk of developing increased levels of manganese and copper. Therefore, the blood levels of these micronutrients should be carefully monitored and the content of manganese and copper in the PN solutions adjusted as indicated. Similarly, selenium, chromium, and molybdenum should be monitored and the PN content of these minerals adjusted as needed in children with renal disease.

Iron

Iron deficiency is the most common cause of anemia in children.[113] However, anemia is a manifestation of the severe end of the iron deficiency spectrum because iron is used for erythropoiesis at the expense of other tissues, including brain. Iron deficiency adversely affects behavior and neurodevelopment.[114] Iron deficiency is common among children receiving long-term PN. It occurs as a result of the underlying condition necessitating PN rather than as a result of the PN itself. Long-term PN without iron supplementation results in iron deficiency and iron deficiency anemia. Causes of anemia other than iron deficiency may be present and should be searched for before assuming that anemia is due to iron deficiency. These include the anemia of chronic disease, zinc deficiency, vitamin E deficiency, and hemolysis. Chronic blood loss from stool, urine, or vomitus can lead to iron deficiency. These losses should be corrected when possible. A number of tests are useful in assessing iron nutriture: ferritin, free erythrocyte protoporphyrin, zinc protoporphyrin, transferrin saturation, transferrin receptors, and hemoglobin and hematocrit. Hemoglobin and hematocrit are readily accessible but represent severe, end-stage iron deficiency. Ferritin is an early marker of iron deficiency, reflecting liver stores of iron; however, ferritin is also an acute-phase reactant, making interpretation of this test problematic. Changes in protoporphyrin levels reflect early alteration of erythropoiesis. In the context of a child receiving PN, a combination of these tests is recommended.[115]

Prematurely born infants are at particular risk for deficiency because iron is transferred to the fetus via the placenta during the last trimester. Iron precipitates as iron phosphate from lipid emulsions and three-in-one solutions. Iron dextrans are compatible with PN solutions that do not contain lipid.[116]

See Table 75.4A-10 for recommended daily amounts of iron for parenteral administration. Iron can be given either intravenously or intramuscularly as iron dextran.[117] Inorganic salts of iron are used in PN solution in Europe.[118] Some report increased infection rates in children receiving iron supplementation.[119] Other reports have not found this association.[120] Iron homeostasis is regulated at the level of GI absorption. Parenterally administered iron bypasses this control mechanism, making iron overload possible. Iron administration should be reduced or eliminated if overload is present.[121]

VITAMINS

Vitamins are essential nutrients and must be provided by the PN solution, with the possible exception of vitamin D, to avoid deficiency. For the purposes of PN, both water-soluble and fat-soluble vitamins are available in a single solution. Several parenteral vitamin preparations are available for children and adults. Table 75.4A-11 lists some of the preparations, the US Food and Drug Administration (FDA) requirements for adult vitamin solutions (there is no FDA guideline for pediatric multivitamins), and the recommendations of the Committee on Clinical Practice Issues of the ASCN. These recommendations are based on the requirements for stable patients. Adjustments may need to be made for patients who have specific vitamin deficiencies or organ dysfunction, require ventilatory support, or are catabolic. Carnitine is likely a conditionally essential nutrient in the neonate and should be provided after deficiency has been confirmed.[39] To avoid potential toxicity, vitamin preparations designed for preterm infants should not be formulated with propylene glycol or polysorbate.[65]

CENTRAL VERSUS PERIPHERAL ADMINISTRATION OF PN

Central administration of PN solution is required in the infant and the premature infant to deliver meaningful nutrition support.[122] In the older child, peripheral administration can be maintained for a few days, but central

access is necessary for long-term (greater than 1 week) administration of PN. Because PN is not recommended for a duration less than a week,[123] peripheral PN should be thought of as a bridge until a central line can be placed. Although it is possible to provide peripheral PN over a long period of time in children and adolescents, it requires multiple intravenous site changes, risks local complications, and is inconvenient for both the patient and the caregivers. Therefore, central intravenous access for PN should be sought. The technique of peripherally accessed central catheterization (PICC line) for establishing central lines is relatively easily accomplished.[124]

INTRAVENOUS CATHETERS

There are three categories of PN central lines: (1) tunneled lines such as the Broviac or Hickman lines, (2) subcutaneous port lines such as the Medi-port or Hide-a-Port, and (3) PICC lines. No one type of catheter is clearly superior to the others in all situations.[125] PICC lines are easily placed and removed but are associated with the highest incidence of malposition, inadvertent removal, thrombophlebitis, and mechanical obstruction.[126,127] Subcutaneous ports are associated with the least number of infections[128,129] and have a smaller risk of intraluminal thrombosis when compared with the tunneled catheters.[130] Ports are the most difficult to place and require repeated percutaneous access.

In general, reducing the number of lumens reduces the risk.[131] Double-lumen PICC lines are often too large to be of use in young children. Subcutaneous reservoir devices are available with double lumens and divided ports but may be too large to be practical, especially in the small child. It is possible to place a second separate central line if additional access is required.

Catheters should be placed into the superior vena cava or right atrium. The superior vena cava can be reached via the internal jugular vein, the subclavian vein, and peripheral veins. Use of the femoral vein is discouraged. Femoral lines are associated with higher rates of venous thrombosis and catheter-related sepsis.[132] With subclavian access, there is a greater risk of pneumothorax when compared with internal jugular access.[133] Internal jugular insertion is associated with higher rates of hematoma formation, arterial injury, and catheter-related infections.[134] In a large series, radiologic insertion technique was superior to surgical insertion. The radiologic insertion led to fewer infections (1.9 vs 4.0 per 1,000 catheter days), fewer pneumothoraces, and fewer complications overall.[135] Maintaining central venous access long term can be challenging. When all conventional sites have been exhausted, thoracotomy with cannulation of the azygos vein or direct right atrial cannulation[136] has been used. More recently, use of a transhepatic approach for establishing central access for PN has been described.[137]

COMPLICATIONS

Complications associated with PN fall into three general categories: mechanical, metabolic, and infectious. Mechan-

ical complications include misplaced lines and lines that move, fall out, are pulled out, break, kink, or become occluded. Table 75.4A-12 lists some examples of the specific injuries that can occur with mechanical misadventures. Some mechanical complications represent significant life-threatening events, and their occurrence is evident almost immediately or within a short period of time. Others, such as development of a thrombus, occur over a longer time and are heralded by the progressive difficulty in aspirating blood through the catheter. Children experience higher catheter occlusion rates than adults: 10% of children receiving home PN support,[87] 13 to 16% of oncology patients,[138,139] 31% of infants,[140] and 41% of patients with cystic fibrosis.[141] Catheters can be occluded by a thrombus, a kink in the line, too tight sutures, deposition of drugs, mineral precipitation, and lipid deposition within the lumen of the line or abutment of the catheter tip against the vessel wall. Mechanical maneuvers should be attempted as soon as a line is identified as occluded to restore the patency of the line. These maneuvers are not often successful and can be associated with dislodgment of a thrombus and pulmonary embolization, line rupture, or malposition of the catheter.

Thrombosis in central catheters is relatively common. Clot may form as a fibrin sheath at the catheter tip, or a thrombus may form on the outside wall of the catheter and/or on the wall of the vessel adjacent to the catheter. The fibrin sheath is a consistent finding on all indwelling catheters regardless of the type of material, but the amount of sheath varies with the thrombogenicity of catheter material.[142] Mural thrombi occur within 48 hours of catheter insertion. Many strategies have been attempted to prevent the development of catheter-related thrombosis, including the administration of salicylates, dextran, and heparin. Catheters have also been coated with salicylates, heparin, and antibiotics. Some advocate the routine addition of heparin to infused solutions (500–2000 U/L) because this may decrease thrombotic complications with long-term catheter use.[143] But saline flushes are equally efficacious in maintaining catheter patency.[144] Although heparin has been used for many years, some caution is necessary. Heparin can cause a transient fall in platelet count 1 to 3 days after initiation of treatment. In most patients, this is of no clinical significance; the platelet levels return to normal within a few days of the discontinuation of heparin. In some patients, heparin-induced thrombocytopenia, a life- and limb-threatening complication of heparin therapy, can occur. Heparin-induced thrombocytopenia is likely an immune-mediated syndrome that can be precipitated even by minute quantities of heparin given to flush catheters.[145,146] To restore line patency to a fibrin-occluded catheter, streptokinase, urokinase, and tissue plasminogen activator have been used successfully. Currently, recombinant tissue plasminogen activator is the agent of choice to restore patency of thrombin-occluded catheters.[147] Treatment of thrombotic occlusions with tissue plasminogen activator has resulted in removing the obstruction in over 90% of catheters treated[148] and has a low complication rate compared with treatment with either streptokinase or urokinase. Catheter occlusions by some drugs and minerals may be resolved with the instillation of 0.2 to 1.0 mL of 0.1N HCl for 30 minutes to 1 hour.[149–151] More than one instillation may be required. For other drugs, an alkaline solution may be necessary. In clinical situations that do not respond to usual treatment, the possibility of fragmentation or disconnection of part of the indwelling catheter with embolization should be considered.[152] Figure 75.4A-2 is an algorithm for the diagnosis and treatment of catheter occlusion in adult patients with short small bowel syndrome.

Infections related to the catheter can occur systemically or locally at the insertion site. A number of maneuvers have been demonstrated to reduce the risk of infection. These include (1) cleansing the skin prior to insertion with chlorhexidine,[153] (2) avoiding catheter insertion in a febrile child, (3) radiologic insertion by an expert team,[135] and (4) using full-barrier precautions during insertion.[154] Prophylactic antibiotics at the time of insertion do not decrease the risk of infection, and antibiotic ointment at the insertion site should be avoided because it results in the acquisition of resistant organisms and does not decrease the risk of infection.[155] Catheters impregnated with antimicrobial materials such as chlorhexidine, silver sulfadiazine, minocycline, and rifampin are associated with a lower incidence of line infection, but their higher cost may limit their use.[153,156] Certainly, these special catheters do not obviate the need to use all other techniques to reduce infections. Systemic infections occur in 10 to 60% of patients, often require removal of the catheter to clear,[138,157–159] and can be complicated by urinary tract infection, osteomyelitis, and abscess formation. Infections can be caused by bacteria such as those that occur on the skin, populate the GI tract, or have no identifiable source or fungi, the most common of which is *Candida*. The most important route of catheter-related contamination is thought to be migration of organisms from the skin along the subcutaneous tract into the vein. Another important source of infection is catheter hub contamination during tubing manipulations. One study noted that the infectious agent was often found on the skin of nurses who changed the PN fluid bag.[160] Some have hypothesized that a GI tract injured by inflammation, ischemia, surgical manipulation, or malnutrition may be more permeable to infectious organisms.[139,161] If a child with a central line develops a significant fever (38°C), whether or not there is another source of infection, central and peripheral cultures should be obtained, and the child should be treated with intravenous antibiotics covering both gram-positive cocci and gram-negative bacteria. If a source of fever other than the catheter is identified, such as an ear infection or a urinary tract infection, neither the catheter nor the other site can be assumed to be the source of the fever; therefore, antibiotic coverage should include coverage for organisms associated with catheter infections and possible non–catheter-related sources. Catheter-related infections can be eradicated with appropriate antibiotics; however, tunnel-related infections are more difficult to eliminate.[128,162] Catheter removal is usually curative if antibiotic coverage is extended 48 hours after the catheter is

TABLE 75.4A-12 COMPLICATIONS ASSOCIATED WITH PARENTERAL NUTRITION

COMPLICATION	CAUSE	INTERVENTION
Catheter related		
Cardiac arrhythmia	Catheter tip in heart	Remove catheter
Air embolus	Inadvertent injection of air; accidental uncoupling of infusion system	Place patient on left side and lower the head of the bed; this may keep air within apex of the right ventricle until it is absorbed
Thrombosis of central vein	Uncoupling of infusion system; catheter induced	Anticoagulation therapy; remove catheter if unsuccessful (see figure75.4-2)
Catheter occlusion	Hypotension; failure to maintain line patency; formation of fibrin sheath outside the catheter; lipid or mineral precipitates	Anticoagulation therapy (see Figure 75.4A-2)
Perforation and/or infusion leak	More common with polyvinyl polyethylene catheters	Check device connection sites; replace faulty devices, tubing, catheter
Infusion system obstruction	Catheter kinking, clot; bacterial filter airlock; clamping of line	Attempt mechanical manipulation
Phlebitis	Peripheral administration of hypertonic solution (osmolarity ≥ 900 mOsm/kg); line infiltration	Change peripheral line site
Infectious		
Sepsis	Improper aseptic technique; catheter insertion; catheter care; mixing of parenteral solutions	Blood cultures; antimicrobial medication (see Figure 75.4A-3)
Local infection	Improper aseptic technique	Local and/or systemic antimicrobial medications (see Figure 75.4A-3)
Metabolic		
Osmotic diuresis	Hyperglycemia; increased glucose in urine	Reduce infusion rate or decrease dextrose concentration; give insulin
Hyperammonemia	Hepatic dysfunction; excess free ammonia; insufficient arginine; excessive amino acid infusion	Reduce protein concentration; increase nonprotein calorie-to-nitrogen ratio
Azotemia or elevated blood urea nitrogen	Dehydration; calorie-nitrogen imbalance; renal dysfunction	Correct dehydration; increase nonprotein calorie-to-nitrogen ratio or reduce amino acid concentration; give insulin if hyperglycemia is present
Hyperglycemia	Excessive infusion rate or concentration of glucose; concurrent steroid therapy; possible sepsis; insulin insufficiency	Reduce rate or concentration of dextrose; rule out sepsis; give insulin
Hypoglycemia	Abrupt interruption of infusion of a high glucose concentration	Start dextrose infusion; monitor for seizures
Metabolic acidosis	Renal or gastrointestinal losses; infusion of hydrogen ion; inadequate amount of base-producing substance in solutions to neutralize acid products of amino acid degradation; excessive protein and/or calories; acute postinjury phase with increased metabolic rate	Increase acetate in solutions; decrease chloride in solutions with hypochloremic acidosis; provide maintenance calories and protein
Metabolic alkalosis	Base introduction or nasogastric drainage	Provide additional fluid and NaCl, KCl, or NH_4Cl
Fluid overload	Cardiac or renal insufficiency or excessive infusion rate	Decrease fluid; can increase the nutrient concentration of nutrient solutions
Respiratory acidosis	Increased calorie load with high fraction of calories as dextrose	Decrease total caloric intake; decrease fraction of calories from dextrose and increase fraction of calories from lipid
Cholestasis	Idiopathic; lack of enteral feeding	Provide some enteral nutrition, even if only 1–2 mL/h
Hypophosphatemia	Inadequate phosphate; refeeding syndrome; increased losses (diarrhea); high dextrose concentration infusion may increase phosphorus needs	Increase phosphate in solution; monitor solution for compatibility; monitor serum levels
Hyperphosphatemia	Renal insufficiency	Decrease phosphorus in nutrient solution but do not omit; check for other phosphorus source
Hypocalcemia	Refeeding syndrome; inadequate calcium in solution	Increase calcium in solution; monitor compatibility; monitor serum levels
Hypomagnesemia	Inadequate magnesium in solution; refeeding syndrome; gastrointestinal or renal losses	Increase magnesium in solution; monitor solution compatibility; monitor serum levels
Hypokalemia	Gastrointestinal or renal losses; refeeding syndrome; inadequate potassium in solution; high dextrose infusion; hypomagnesemia	Increase potassium in solution; may require 4 mEq K/kg/d; monitor serum levels
Hyponatremia	Gastrointestinal or renal losses; inadequate sodium in solution; excessive fluid intake	Increase sodium in solution; decrease fluid volume; check all sources of intake; monitor intake and output, serum sodium and urine-specific gravity
Essential fatty acid deficiency	Fat-free solutions	Provide at least 2–4% of calories as fat (0.5–1.0 g/kg/d)
Hypertriglyceridemia	Lipid infusion dose too high; acute inflammatory state	Increase duration of infusion; decrease total g/kg/d lipid infused
Rash	Possible allergy	Discontinue lipid administration or change lipid preparation
Trace element deficiency	Inadequate or incomplete trace element supplementation; gastrointestinal losses (zinc)	Routine trace element supplementation, monitor nutritional trace element status
Vitamin disorders	Inadequate intake; excess needs	Monitor serum levels; provide additional vitamins

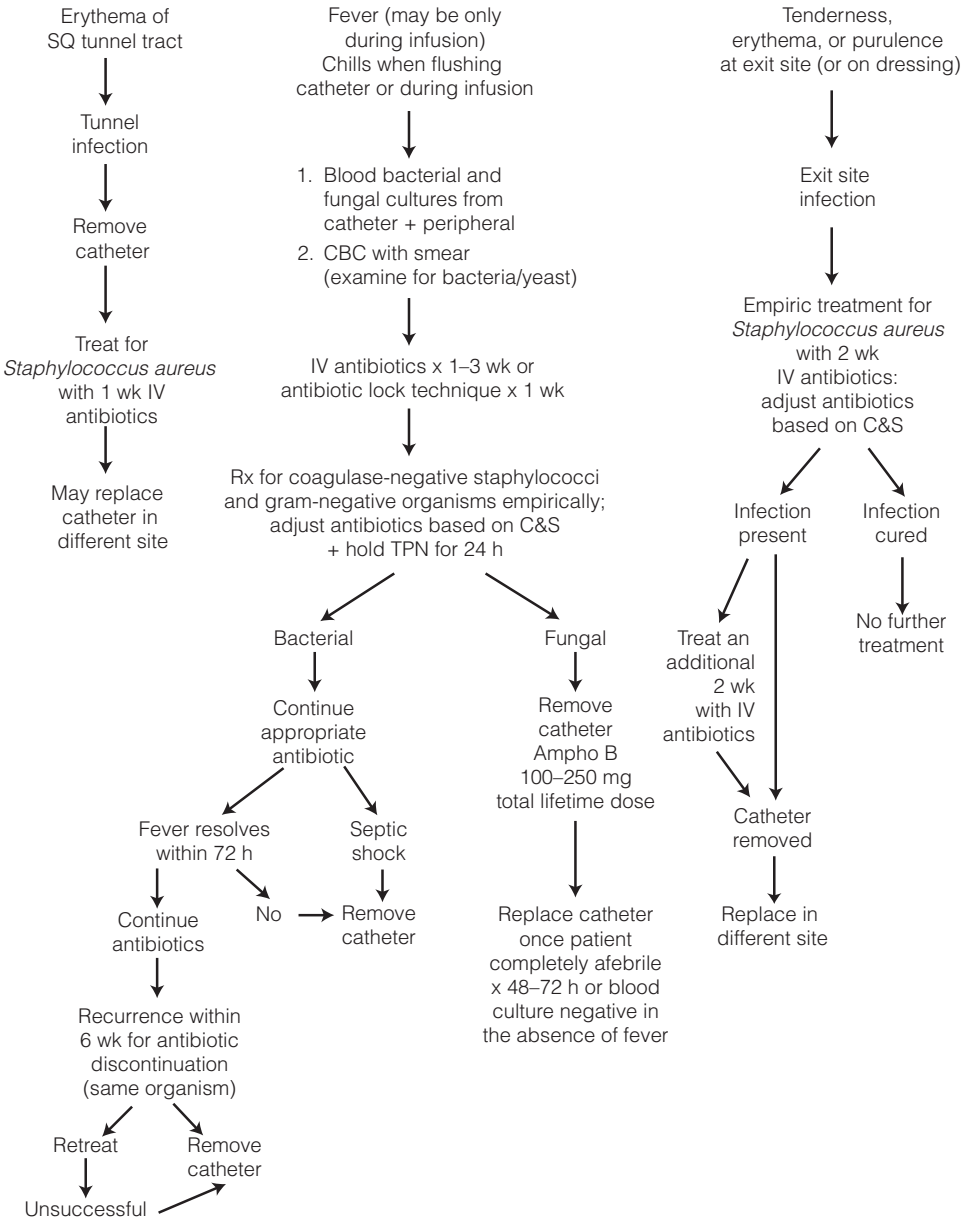

FIGURE 75.4A-2 Algorithm for the diagnosis and treatment of catheter occlusion. Reproduced with permission from the American Gastroenterological Association.[188] Ampho B = amphotericin B; C&S = culture and sensitivity; CBC = complete blood count; IV = intravenous; SQ = subcutaneous; TPN = total parenteral nutrition.

taken out. The catheter should be removed in the face of clinical deterioration, continued bacteremia, and suspected cardiac sepsis or after failing two courses of intravenous antibiotics. Figure 75.4A-3 is an algorithm for the diagnosis and treatment of catheter-related infection in adults with short small bowel syndrome.

The most common metabolic complications associated with PN are over- or underhydration. Too much fluid is sometimes administered when all fluid sources (other intravenous lines, enteral feedings, oral feedings, water flushes) are not considered. Underhydration can develop when inadequate fluids from all routes are provided, during extended periods of hyperglycemia, and when conditions arise that increase fluid requirements (ie, fever, increased renal solute load, ostomy losses, diarrhea). Other metabolic complications include hypoglycemia, electrolyte imbalances, inadequate growth, substrate intolerance, hypersensitivity reactions, and specific nutrient deficiencies. Hypoglycemia can occur if PN is abruptly stopped. Cholestasis associated with PN support is a major problem. The etiology is unknown. Medications such as phenobarbital and ursodiol have been used with limited success. Factors associated with cholestasis include lack of enteral feeding; excessive carbohydrate, fat, and/or calories; inappropriate quality and quantity of amino acids; and deficient trace elements.[163] The only effective treatment is discontinuation of PN.

INITIATION

There is no standard pediatric patient. An individualized plan for initiation, advancement, and maintenance goals should be formulated before starting PN. The plan is based on estimates of requirements and should account for increased or decreased needs of each patient. Before starting PN, baseline laboratory values should be measured and electrolyte and mineral abnormalities corrected. The steps in devising a PN plan are as follows: (1) Determine fluid volume and rate. This determination is based on the fluid requirement and ability of

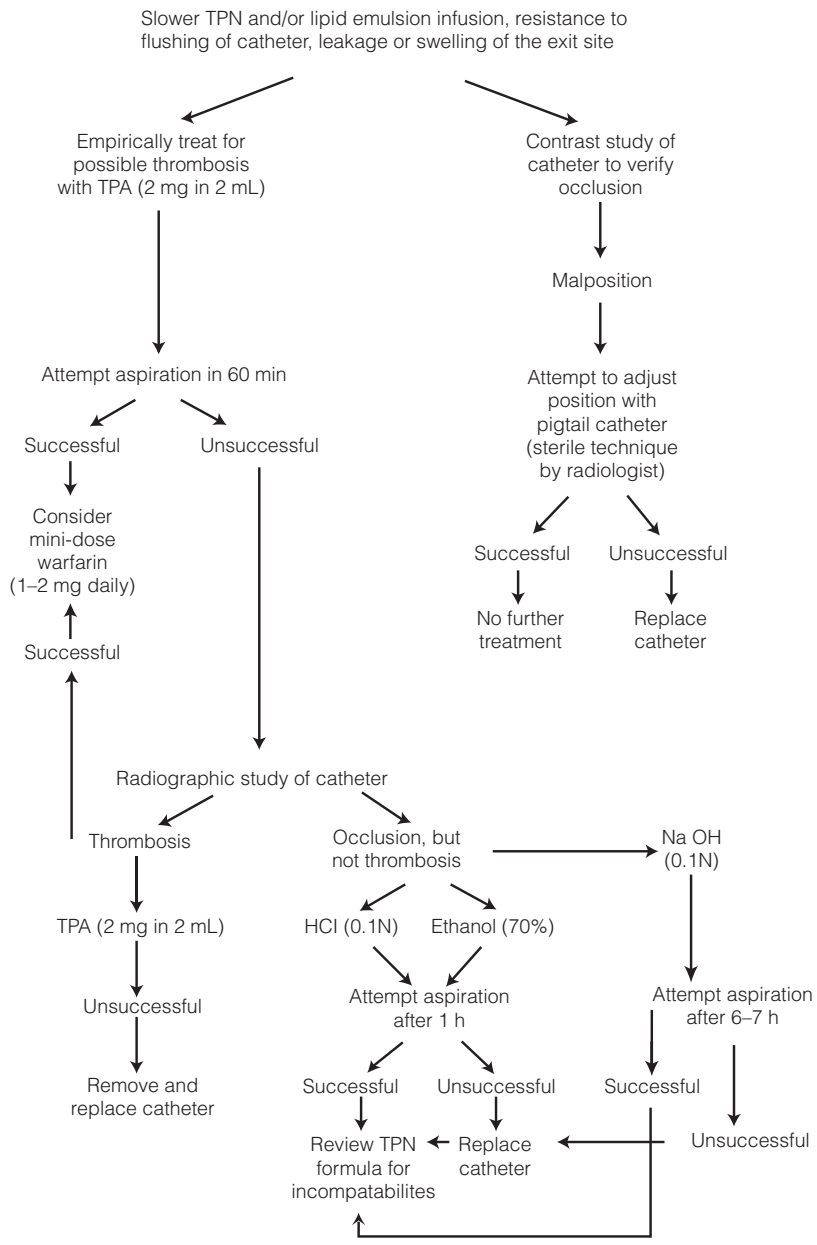

FIGURE 75.4A-3 Algorithm for the diagnosis and treatment of catheter-related infection. Reproduced with permission from the American Gastroenterological Association.[188] HCl = hydrochloric acid; Na OH = sodium hydroxide; TPA = tissue plasminogen activator; TPN = total parenteral nutrition.

the patient to tolerate a fluid load. (2) Calculate the amount of dextrose to be used initially, during advancement, and for maintenance. (3) Determine the amount of protein to be given at initiation, during advancement, and at maintenance. (4) Determine the dose of lipid, again taking into account the three phases, initiation, advancement, and maintenance. (5) Determine the amounts of micronutrients, electrolytes, minerals, trace elements, and vitamins. Vitamins and mineral and trace elements come as prepackaged units. Special consideration of acid-base balance is necessary. Increasing the amount of acetate while decreasing the chloride can shift the balance toward base.[164] Suggested ranges for macronutrient provision in pediatric PN solutions are given in Table 75.4A-13. The distribution of calories derived from macronutrients is quite flexible and depends on the clinical setting: from 7 to 20% of calories in the PN solution can be derived from protein, carbohydrate can account for 20 to 60% of calories, and lipid can range from 20 to 50%.

MONITORING

During initiation, while advancing, and at maintenance rates, patients need to be monitored for complications and to ensure that the goals of the PN are being achieved. A suggested list of laboratory determinations and a schedule for monitoring are provided in Table 75.4A-14. The PN plan as outlined in the previous section should be continually assessed and revised based on the results of monitoring and the changing clinical status of the patient.

DISCONTINUATION AND CYCLING

Sudden discontinuation of high glucose infusion has resulted in hypoglycemia, especially in children under 3 years of age.[165,166] Blood glucose levels should be monitored following cessation of high glucose infusions. PN should be tapered by decreasing to half the rate for 1 hour and to one-fourth the

TABLE 75.4A-13 SUGGESTED PEDIATRIC PARENTERAL SUBSTRATE PROVISION

	NUTRIENT	AMOUNT
INITIATION	Carbohydrate	10% dextrose (6–8 mg/kg/min)
Amino acids	50–100% of goal	
Lipid		0.5–1.0 g/kg/d
ADVANCEMENT	Carbohydrate	5% dextrose per day (2–4 mg/kg/min)
Amino acid	100% of goal	
Lipid		0.5–1.0 g/kg/d
USUAL UPPER LIMIT	Carbohydrate	8–18 mg/kg/min
Peripheral	12.5% dextrose	
Central	25–35% dextrose	
Amino acid		3.0 g/kg/d

original rate for another hour before complete discontinuation. A similar strategy for tapering the PN and monitoring blood sugars should be followed when cycling PN.

There are physiologic and psychological advantages to cycling PN administration, that is, infusing the PN solution in less than 24 hours. For the older child, time without the infusion apparatus allows freedom for greater activity, more social interaction, and school attendance. Continuous PN infusion leads to continuously high serum insulin levels. This hyperinsulinemia causes hepatic lipid deposition and increased hepatic lipogenesis. EFAD may occur because insulin inhibits the release of free fatty acids from adipose tissue. These physiologic effects of continuous PN are reversed by cycling.[167] However, as discussed, cycling increases urinary calcium losses.

CRITICAL CARE

Changes in energy requirements in critically ill or injured children can be quite large, proportionately larger than the changes seen in adults. Especially during early childhood, the energy requirements for growth account for a significant proportion of total requirements. During growth, nutrients need to be supplied in amounts that accommodate tissue accretion, but during the catabolic response to illness or injury, somatic growth is not possible. At times when children are catabolic, overfeeding results from including a share for growth when calculating requirements. The dangers of overfeeding during critical illness are well recognized.[168] It remains a challenge to supply the correct nutrients for each phase of the acute response, allowing for changes in metabolic rate and for growth when it occurs while avoiding overfeeding.

The acute-phase response is proportional to the magnitude and duration of the injury. The response can be divided into three phases: the immediate response lasts minutes to hours and is characterized by autonomic stimulation, resulting in tachycardia, fever, and hypoglycemia. The second, or "ebb phase," is heralded by a sharp decrease in metabolic rate. Insulin levels and body temperature fall, whereas catecholamines, glucose, lactate, and free fatty acids increase. Cardiac output decreases. The second phase lasts from one to several days. The third phase is termed the "flow phase" and is characterized by hypermetabolism. The flow phase can be further subdivided into an early flow phase characterized by hypermetabolism and a negative nitrogen balance. During the late flow phase, hypermetabolism persists, but anabolic repair of tissues and resumption of growth are signaled by a positive nitrogen balance.[169]

Nutritional assessment of a critically ill child includes measuring the constitutive protein pool, the acute-phase protein pool, nitrogen balance, and energy expenditure. All of these measurements can be easily accomplished in the pediatric intensive care unit setting. Prealbumin is a measure of the short-term status of constitutive proteins. C-reactive protein measures acute-phase reactants. These two tests, prealbumin and C-reactive protein, are inversely related and, when measured daily during an acute illness or injury, track the progression of the response. Levels of serum C-reactive protein less than 2 mg/dL are associated with a resumption of anabolic metabolism.[170] Prealbumin begins to rise once an anabolic state is achieved. There are a number of equations for calculating energy expenditure.[171] However, all of these equations are estimates and, especially in infants, can be inaccurate.[172] Indirect calorimetry, using a metabolic cart, measures oxygen consumption and carbon dioxide production. Resting energy expenditure (REE) can be calculated using the Weir equation:

Complete formula:
$$REE = [3.9(VO_2) + (VCO_2)]1.44 - 2.17(UN)$$

Abbreviated formula:
$$REE = [3.9(VO_2) + (VCO_2)]1.44$$

where REE is resting energy expenditure (kcal/d), VO_2 is oxygen consumption (mL/min), VCO_2 is carbon dioxide production (mL/min), and UN is urinary nitrogen (g/d). The RQ can be calculated from the measurements obtained by indirect calorimetry:

$$RQ = VCO_2 / VO_2$$

The RQ is dependent on the substrate being used. Thus, when only fat is being oxidized, the RQ = 0.71. When only carbohydrates are oxidized, the RQ = 1.00. A mixed substrate yields an RQ of about 0.85. Some caution with regard to interpreting RQ; it does not reflect substrate oxidation during hyperventilation, metabolic alkalosis, or for about 6 to 8 hours after general anesthesia.[173]

A number of studies in adults suggest that in nutritional support of a critically ill patient, the enteral route is

TABLE 75.4A-14 SUGGESTED MONITORING PARAMETERS AND SCHEDULE DURING PARENTERAL NUTRITION IN PEDIATRICS

	SUGGESTED FREQUENCY	
PARAMETER	**INITIAL/HOSPITALIZED**	**FOLLOW-UP/HOME**
GROWTH		
Weight	Daily	Daily to monthly
Height/length	Weekly	Weekly to monthly
Head circumference	Weekly	Weekly to monthly
Body composition	Monthly	Monthly to annually
METABOLIC/SERUM*		
Electrolytes	Daily to weekly	Weekly to monthly
BUN/creatinine	Weekly	Monthly
Ca, PO_4, Mg	Twice weekly	Weekly to monthly
Acid-base status	Until stable	Weekly to monthly
Albumin/prealbumin	Weekly	Weekly to monthly

Adminsitration system	6 to 12 times/d	6 to 12 times/d
Catheter site/dressing	6 to 12 times/d	6 to 12 times/d

Adapted from Davis AM.[191]
BUN = blood urea nitrogen; PT = prothrombin time; PTT = partial thromboplastin time.
Frequency depends on clinical conditions.
*For metabolically unstable patients, may need to check more frequently.
†Vital signs include respiratory rate, heart rate, temperature, and blood pressure.

preferred over PN.[174–176] In severe injury, enteral nutrition results in a greater and earlier visceral protein response.[177]

The aims of PN support in the critically ill child are to minimize the effects of catabolism and hypermetabolism that are part of the acute-phase response, to return the patient to positive nitrogen balance quickly, and, finally, to support growth when it resumes. In striving to achieve these aims, caution must be exercised to avoid both under- and overfeeding.

CONCLUSION

PN has saved lives and continues to do so. However, its use is fraught with complications: it is difficult to administer and requires knowledgeable personnel with technical expertise to design complete nutritional fluids, administer them, and monitor for complications. There are limited indications for PN. Its use has declined as medical personnel have become more proficient in the use of enteral feedings, and evidence-based medicine that focuses on outcomes has shown that benefit is limited to defined groups of patients.

4B. *Enteral* Nutrition

Ana Abad-Sinden, MS, RD, CNSD
James Sutphen, MD, PhD

Pediatric patients unable to tolerate adequate oral feedings may be nutritionally managed with enteral nutrition (EN). Commonly used EN routes include nasogastric (NG) tube, gastrostomy, nasojejunal (NJ) tube, and jejunostomy. The nutritional goal for pediatric patients with chronic illness should be the provision of nutrients appropriate to the patients' metabolic and physiologic limitations and capable of promoting continued growth and development. Although both enteral and parenteral nutrition can provide nutritional support to pediatric patients unable or unwilling to take in adequate oral feedings, EN support is generally considered the preferred modality for critically and chronically ill pediatric patients because they are more physiologic and economic and are easier and safer to administer than parenteral nutrition. Absence of a central venous catheter decreases infection and thrombotic complications. Delivery of nutrients to the intestine minimizes gut atrophy and decreases the risk for bacterial translocation. EN reduces the risk for infectious complications compared with parenteral nutrition.[1] Furthermore, EN allows for better physiologic control of electrolyte levels through endocrine modulation of intestinal absorption and serves as effective prophylaxis against stress-induced gastropathy and gastrointestinal (GI) hemorrhage. EN also offers more complete nutrient provision, including glutamine, nucleotides, trace elements, short-chain fatty acids, and fiber. EN avoids the hepatic complications associated with parenteral nutrition. In addition, EN provides trophic stimulation to the gut by promoting pancreatic and biliary secretions as well as endocrine, paracrine, and neural factors, which promote the physiologic and immunologic integrity of the GI tract.[2–4] Timely initiation of EN is also important, with the greatest metabolic benefits resulting from initiating early EN within less than 72 hours of injury or admission.[4]

Initial attempts at EN should be via the oral route. If the oral route is not emphasized during infancy, the suck reflex may be lost. Because it may take 8 to 9 months for the child to develop sufficiently for use of a cup, oral aversion and language delay may occur during this time interval. Some common indications for initiating EN include oral-motor or esophageal dysfunction owing to prematurity, morphologic abnormalities of the head or neck, or neurologic disease. Excessive respiratory demands from cardiorespiratory disease may compromise coordination of respiration and swallowing.[5] Although nasoenteric feedings are effective in the short-term support of these patients, long-term nutritional support often requires the placement of a feeding gastrostomy. This may be particularly important in the infant who develops oral aversion owing to the prolonged noxious stimulus of a NG tube and to minimize the risks associated with prolonged NG feedings, including sinusitis and otitis media.

This discussion reviews the pathophysiologic mechanisms and nutritional aspects of various pediatric disorders that have been successfully managed with EN. Formula selection and modification as well as enteral feeding techniques and equipment are presented. The administration and monitoring of pediatric EN techniques and the management of common complications are also discussed.

INDICATIONS FOR ENTERAL FEEDINGS: MANAGEMENT OF NUTRITION-RELATED DISORDERS

Table 75.4B-1 lists common conditions under which EN may be warranted in pediatric patients.

Preterm Infants

Feeding methods for preterm infants should be individualized to gestational age, birth weight, and medical status.[6] Preterm infants present a unique nutritional challenge owing to their GI and immunologic immaturity; increased requirements for specific nutrients such as protein, fat, sodium, calcium, and phosphorus; limited renal function; and predisposition to specific metabolic and clinical com-

TABLE 75.4B-1 CONDITIONS UNDER WHICH ENTERAL NUTRITION MAY BE WARRANTED

Preterm infants
Cardiorespiratory disease
Bronchopulmonary dysplasia
Congenital heart disease
Cystic fibrosis
Gastrointestinal disease and dysfunction
Biliary atresia
Inflammatory bowel disease
Gastroesophageal reflux disease
Pancreatitis
Protacted diarrhea of infancy
Short-gut syndrome
Critical illness and postoperative malnutrition
Burn injury
Cancer
HIV/AIDS malnutrition
Trauma/head injury
Renal disease
Neurologic disease and/or impairment

plications such as hypoglycemia, periodic dysmotility, and necrotizing enterocolitis.[6–8] As the coordination of sucking and swallowing appears at approximately 34 weeks gestation, intragastric or jejunal feedings are often used before this time, or beyond, in infants unable to tolerate adequate oral feedings. A number of studies in preterm infants suggest that minimal EN or trophic feedings, defined as the provision of low-volume feedings (10–24 cc/kg/d over 5–14 days) and administered within the first week of life, enhance intestinal adaptation to extrauterine conditions.[8–10] These feedings promote maturation of the mucosal lining, decrease cholestatic jaundice, aid maturation of intestinal motility, and allow earlier progression to full enteral feedings.[9–11] Intermittent bolus feedings may better promote gastrocolic reflexes, gallbladder emptying, and GI hormone release in preterm infants, thus promoting the trophic response,[12,13] and increase accommodation of the stomach to volume loads. Continuous feedings are reserved for neonates with short-gut syndrome, severe gastroesophageal reflux (GER) disease, or persistent feeding intolerance. Transpyloric feedings may promote less GER and overcome gastric dysmotility; however, they are technically more difficult and bypass the gastric phase of fat absorption promoted by lingual lipase and may therefore decrease total fat absorption.[6] This may be a particular concern when bile salt deficiency from prematurity or short-bowel syndrome exists. Early initiation of fat digestion in the stomach may partially offset the effect of bile salt deficiency by earlier formation of mixed micelles.

Cardiorespiratory Illness

Infants and children with cardiorespiratory disorders often require EN support during acute exacerbations of their primary disease, for nutritional rehabilitation of chronic secondary malnutrition, or for promotion of growth prior to surgical procedures. The etiology of growth failure and delayed neurointellectual development in patients with bronchopulmonary dysplasia (BPD) is related to the combined effects of prolonged hypoxia, elevated metabolic rates, inefficient suck and swallow mechanisms, poor appetite, prolonged periods of caloric and nutrient deficits, recurrent emesis, and GI dysmotility.[12–14] Potassium, sodium, and chloride supplementation of the formula is often required in conjunction with diuretic therapy. Increasing formula caloric and nutrient density through either formula concentration or the addition of carbohydrate and fat may be used to achieve caloric densities of 30 to 33 kcal per ounce (1.0 to 1.3 kcal per mL). Excess reliance on carbohydrate in infants who are fluid restricted, however, may result in CO_2 retention and suboptimal protein, vitamin, and mineral delivery if the base formula is excessively diluted.[15] Children with cystic fibrosis (CF) present additional challenges owing to maldigestion.[16] Although behavior modification techniques to improve intake and provision of appetizing high-calorie supplements should be instituted as routine components of medical nutrition therapy for children with CF, EN using semielemental or intact nutrient formulas supplemented with pancreatic enzymes is often necessary for patients who have failed owing to noncompliance.[16,17] Pancreatic enzyme replacement is usually dosed based on lipase units per gram of long-chain triglycerides (mean of 1,800 lipase units). NG feedings have resulted in increased caloric intake and significant weight gain for patients with CF, but long-term effectiveness is hampered by noncompliance.[15] Nocturnal gastrostomy feedings provided over 8 to 10 hours for long-term management may be superior for selected patients.[16]

Infants with congenital heart disease are also at significant nutritional risk generally owing to inadequate calorie intake.[5] Growth failure results from poor nutritional intake, increased respiratory rates, and elevated energy expenditure. It may be exacerbated by tissue hypoxia, suboptimal nutrient absorption, delayed gastric emptying, or more generalized GI dysmotility.[18,19] Owing to their elevated nutritional needs and limited fluid tolerance, these infants often require high–caloric density formulas achieved through formula concentration to a maximum of 24 to 27 kcal per ounce, depending on GI tolerance. Concentration beyond 27 kcal per ounce may not allow enough free water for excretion of the renal osmotic load. Additional calories can be provided through the addition of carbohydrate or fat. Infants with congenital heart disease often benefit from the use of nocturnal continuous feeds while combined with oral intake ad libitum during the day. Alternatively, provision of oral feedings intermittently with NG supplementation of the remainder of the required intake volume may also facilitate provision of the nutritional goals.[5,20,21] Ultimately, effective EN can promote significant catch-up growth and facilitate surgical correction of cardiac defects.

Gastrointestinal Disease

Pediatric patients with acute and chronic GI disease and dysfunction, such as inflammatory bowel disease, short-bowel syndrome, and pancreatitis, often benefit from EN regimens. The etiology of growth failure in children with Crohn disease is multifactorial but often related to inadequate nutrient intake. Semielemental and elemental diets administered orally and nasogastrically have been clinically demonstrated to induce remission in selected patients and produce a significant improvement in nutritional status.[22,23] Clinical remission is more likely in Crohn disease of the small bowel than of the colon.[23] Elemental, semielemental, and polymeric diets have been shown to produce similar clinical results.[24,25] Supplementation of an oral polymeric formula with transforming growth factor-β_2, a polypeptide normally found in human and cow's milk, resulted in clinical remission of 79% in 29 children with intestinal Crohn disease, as well as mucosal healing and a reduction in proinflammatory mediators.[26] For simple weight gain, however, emphasis on high-calorie appetizing food is the gold standard before implementation of less palatable enteral supplements.

The nutritional management of the infant or child with short-bowel syndrome involves the initial use of total parenteral nutrition with a gradually increasing amount of EN. The period of transition to complete EN may take

weeks to years depending on the location and length of intestinal resection, associated dysmotility, presence of the ileocecal valve, and extent of colon preservation. Parenteral nutrition, however, must be continued until it is clinically evident that positive fluid and nutrient balance and weight gain can be maintained on EN alone.[27] Water and sodium may be considered the first limiting nutrients in short-bowel syndrome. Often stool sodium losses or negative water balance or both obscure weight gain. Important considerations for provision of adequate EN include the method of administration, volume, osmolality, and nutrient quality (polymeric versus elemental). Polymeric formulas with intact protein, long-chain fats, and complex carbohydrates may be less tolerated in the initial stages of the enteral feeding progression than glucose and glucose polymers, medium-chain triglycerides (MCTs), and hydrolyzed protein and dipeptides, which require less digestion, are less allergenic, and are more easily tolerated.[27,28] Long-term parenteral nutrition in these infants is associated with cholestatic liver disease, a significant cause of death in children with short-gut syndrome. To prevent liver disease, cyclic parenteral nutrition with provision of a 4- to 6-hour "window" in infants has been shown to reduce the incidence of cholestasis.[29] In older children and adolescents, provision of cyclic parenteral nutrition over 10 to 12 hours with continuous or intermittent enteral feedings, as tolerated, while promoting oral intake during the day can usually be managed in the home setting.[30] Furthermore, treatment of small bowel bacterial overgrowth, provision of supplemental ursodeoxycholic acid, and prevention of sepsis are also adjunctive therapies to decrease the risk of cholestatic liver disease. Prevention of oral aversion involves careful attention to persistent use of oral feedings and avoidance of noxious stimuli to the oral area. Proactive involvement of speech pathology experts during enteral feeding of infants is extremely helpful.

Several other GI diseases impacting nutritional intake and status can be successfully managed with EN. Infants with biliary atresia frequently experience reduced intake associated with liver disease and infection.[31] Following surgical procedures or liver transplant, nutritional support of these infants with continuous NG feedings using a semielemental formula rich in MCTs can promote energy and nitrogen balance.[31,32] Once the postoperative infant or child is clinically stable, transition to an intact nutrient formula or to an oral diet should be made.[33] Careful monitoring of fat-soluble vitamin levels and supplementation with water-soluble varieties using multiple doses during the day may help in the prevention of fat-soluble vitamin deficiency. Infants with GER disease who have failed conventional therapy with acid inhibition, thickened feeds, and upright positioning and have subsequently experienced growth failure have been shown to benefit from continuous NG feedings with improved intake, reduction or cessation of vomiting, and catch-up growth.[34] Children with acute and chronic pancreatitis may be nutritionally managed with NJ feedings of a standard pediatric or, if needed, semielemental formula administered beyond the ligament of Treitz. Clinical studies in adult patients with pancreatitis have demonstrated improved clinical outcomes with fewer infectious complications, decreased incidence of hyperglycemia, and decreased incidence of multiorgan failure and mortality in enterally fed patients compared with those on parenteral nutrition.[35,36]

Critical Illness and Postoperative Malnutrition

EN for the critically ill or postoperative pediatric patient has improved in recent years owing to improvements in EN products, equipment, and techniques.[3] Early EN within 48 hours of injury or surgery reduces sepsis and enhances GI immune function through maintenance of the gut mucosal barrier and enteric lymphoid tissue. Early postoperative EN helps prevent mucosal damage and bacterial translocation, results in decreased sepsis, and blunts the hypermetabolic response in some critically ill patients.[2,4] Clinical studies have demonstrated that GI function can be adequately maintained with improved nitrogen balance and nutritional status in the postsurgical trauma patient.[37,38]

Critically ill patients in hypermetabolic states, such as those with cancer or human immunodeficiency virus/acquired immune deficiency syndrome (HIV/AIDS), may also benefit from EN support. Cancer patients at high nutritional risk who have minimal GI symptoms and adequate platelet counts may be enterally fed via nocturnal or 24-hour feedings depending on the extent of oral intake.[39] Various studies have demonstrated the effectiveness and safety of gastrostomy tube feedings in malnourished children with cancer.[40,41] Pediatric HIV patients with protein-calorie malnutrition who are unable to meet their elevated energy requirements with oral intake alone may also benefit from enteral NG feedings with pediatric or other high–caloric density formulas. Nocturnal enteral feeding is the preferred method of EN in this patient population because it allows the child to eat during the day.[42] Gastrostomy tube feedings for the provision of supplemental nutrition have resulted in improvement in weight gain and reduced morbidity and mortality in pediatric HIV patients.[43]

Renal Disease

Chronic renal failure in infants and children commonly results in growth failure and developmental delay, particularly in those patients with congenital renal disease early in life.[44] The etiology of growth failure in these children is thought to be related to protein-calorie deficiency, renal osteodystrophy, chronic metabolic acidosis, and endocrine dysfunction.[45] Despite aggressive medical management and use of specialized formulas of high caloric density, poor growth and development may persist. Early nutritional intervention and dialysis can result in improved growth and development.[44,45] Nocturnal NG feedings over a period of 8 to 12 hours in patients with renal insufficiency have resulted in catch-up growth.[45]

Neurologic Disease and/or Impairment

The specific nutritional requirements and feeding approach for neurologically impaired children are highly variable and depend on the degree of impairment, oral-

motor function, mobility, and muscular tone. Children with Down syndrome, Prader-Willi syndrome, or myelomeningocele have decreased energy needs, growth rates, and motor activity compared with healthy children.[46] Children with cerebral palsy, however, are generally underweight for height and may have increased energy needs, particularly if they are severely spastic or have choreoathetoid movements. Those patients who are severely affected often require high–caloric density enteral feedings and are often managed via continuous nocturnal gastrostomy feedings and intermittent bolus feedings during the day when oral intake is inadequate.[46] Important considerations for provision of EN to these patients include method of feeding, risk of aspiration, formula caloric density, osmolality and fiber content, fluid intake, and effect of enteral feeding therapy on current and future oral-motor function and intake.[47] Often daytime bolus feedings are preferred by caregivers because they are more easily given and avoid the risk of nighttime aspiration from continuous feedings. The goal of nutritional support for these children should not necessarily be persistent weight gain because increased weight may further compromise muscular ability and complicate the caregiver's ability to move the child. These children are also often at risk for constipation, which can compromise formula tolerance.

NUTRITIONAL NEEDS OF THE ENTERALLY FED CHILD

Preterm Infant

Caloric requirements to support a daily weight gain of 15 g/kg are estimated at 105 to 130 kcal/kg in the appropriate for gestational age preterm infant. Higher energy needs are required depending on the infant's thermal environment, cardiorespiratory status, presence of intrauterine growth retardation, and metabolic stress.[48,49] Infants who are small for gestational age or those with BPD may have caloric requirements of between 130 and 150 kcal/kg.[15] Intake of formulas with whey-to-casein ratios similar to those of breast milk results in metabolic indices and plasma amino acid profiles closer to those of breastfed infants.[50] Because of their GI immaturity, preterm infants demonstrate improved nutrient absorption when fed a mixture of MCT and long-chain unsaturated fatty acids and a mixture of lactose and glucose polymers as their fat and carbohydrate sources, respectively. Owing to the high accretion rates for calcium, phosphorus, and trace elements during the final trimester of gestation, preterm infants have elevated requirements for these nutrients.[8,49]

Infants and Children

The nutritional requirements of infants and children are outlined elsewhere in the literarure.[48,49,51] It must be emphasized that these recommended allowances are intended for healthy active children and represent the average intake of nutrients that would maintain good health for an extended period.[51] As previously discussed, tube-fed children often have illnesses that result in malnutrition and inactivity and thus require adjusted allowances for energy and other nutrients. The specialized nutritional requirements of nutrition-related illnesses have been reviewed extensively in the literature.[5,12–16,28,32,39,42,44,46,49]

EN support of critically ill pediatric patients requires careful attention to prevent overfeeding of calories with exacerbation of the underlying clinical status. Energy and protein requirements in the critically ill child are significantly different from those of healthy children. Although basal metabolic needs may be elevated owing to the stress response and its associated elevation of counterregulatory hormones and cytokines, inhibition of growth and reduced physical activity may result in an overall decrease in energy requirements.[52] Studies in critically ill pediatric patients have underscored the importance of not using the published Dietary Reference Intakes for estimating energy requirements but rather using the child's basic energy expenditure multiplied by a factor correlated to the underlying disease or injury process.[53] Overfeeding cannot reverse the catabolic process until the acute metabolic stress response resolves; furthermore, overfeeding of calories may result in iatrogenic hepatic and respiratory disease and decreased survival.[54]

In the child with failure to thrive, particular attention should be given to the estimation of the energy and protein for achievement of catch-up growth, which occurs when the cause of growth impairment is removed and requires the provision of calories and protein in excess of normal needs.[55] It is best to allow the child's appetite to be the determinant of intake whenever possible because overfeeding during the initial stages of rehabilitation may be associated with edema and refeeding syndrome in the severely malnourished child.[56] Estimated catch-up growth requirements can be calculated from the following equation[55]:

$$\frac{\text{kcal}}{\text{kg}} = \frac{\text{RDA kcal/kg for weight age} \times \text{ideal body weight (kg)}}{\text{actual weight (kg)}}$$

Weight age is the age at which the present weight is at the 50th percentile, ideal weight is at the 50th percentile for age or ideal weight for height, and RDA means Recommended Dietary Allowance.

Fluid requirements can be calculated by estimating normal water requirements adjusted for specific disease-related factors; special consideration must be given to monitoring the fluid balance of children receiving high-calorie, high-protein formulas; those who have short-bowel syndrome or severe neurologic impairment; or those with emesis, diarrhea, fever, or polyuria.[2,57] The provision of extra water to prevent slow dehydration or "tube feeding syndrome" is especially important for neurologically devastated or immature children who cannot communicate their thirst to the care provider.

INFANT AND PEDIATRIC FORMULA SELECTION FOR ENTERAL FEEDINGS

Selection of an optimal infant enteral formula depends on a number of factors, including diagnosis, associated nutritional problems and requirements, and GI function.

Important formula factors include osmolality, renal solute load, caloric density, viscosity, and composition. Figure 75.4B-1 presents an algorithm that identifies appropriate infant and pediatric formulas based on indication for use. Table 75.4B-2 lists and describes the nutrient sources of a variety of infant and pediatric formulas.

Preterm Infant Formulas

Specialized formulas have been developed that are uniquely suited to the physiologic needs of the preterm infant. Physiologic factors in the preterm infant that call for alterations in their nutritional management include limited oral-motor function, lactase deficiency, limited bile salt pool, decreased energy and nutrient stores, limited gastric volume, decreased intestinal motility, and limited renal function.[7,8]

There are several differences in nutrient content between preterm and term infant formulas. Preterm formulas provide a combination of both lactose and glucose polymers versus lactose alone in standard formulas, thus decreasing osmolality and improving digestibility and calcium absorption.[50,58] Preterm formulas use a fat blend containing both long-chain triglycerides, very-long-chain triglycerides such as docosahexaenoic acid (DHA) and arachidonic acid (ARA), and MCTs, which promote improved weight gain and fat, nitrogen, and calcium absorption.[59,60] Documented improvement in weight gain, linear growth, and central nervous system development in preterm infants fed DHA- and ARA-supplemented formula[61,62] has been observed and subsequently resulted in the addition of very-long-chain triglycerides to preterm and term infant formulas. An elevated protein content and 60:40 whey-to-casein formulation promote plasma amino acid profiles closer to those of the breastfed infant.[50,63] Increased amounts of sodium, calcium, and phosphorus compensate for the increased urinary sodium losses seen in the preterm infant and promote bone mineralization closer to intrauterine rates.[50] The concentration of various vitamins, including vitamin E, in preterm formula is greater than that found in term infant formula owing to preterm infants' limited stores and wide variability in absorption. Vitamin D content is also high for promotion of bone mineralization. Owing to the lower birth weight and initial hemoglobin concentration of preterm infants, iron has been added to preterm infant formulas to provide approximately 2 mg/kg of iron per day when fed at a level of 120 kcal/kg.[50]

Discharge preterm formulas for infants weighing less than 2,000 g provide additional calories and nutrients to promote optimal growth during the first year of life. Several studies have demonstrated benefits with their use, including improved weight gain and linear growth[64]; improved calorie, calcium, and phosphorus intakes[65]; and improved bone mineral content.[66] The use of discharge preterm formulas such as EnfaCare (Mead Johnson, Evansville, IN) and Similac NeoSure (Ross Products Division, Abbott Laboratories, Columbus, OH) has become standard practice in most neonatal intensive care units. These formulas are iron fortified and commercially available in the ready to feed 22 kcal/oz form for hospital use and in the powdered form for home use. Infants whose volume intakes continue to be limited owing to cardiorespiratory illness may be fed formulas concentrated to 24 to 30 kcal/oz using alternative mixing methods provided by the manufacturers. Both discharge preterm formulas contain a blend of lactose and glucose polymers and provide 20 to 25% of the fat as MCT oil. Vitamin and mineral levels are greater than those found in standard formulas. Preterm infants consuming a minimum of 165 cc/kg do not require additional multivitamin supplementation.[8]

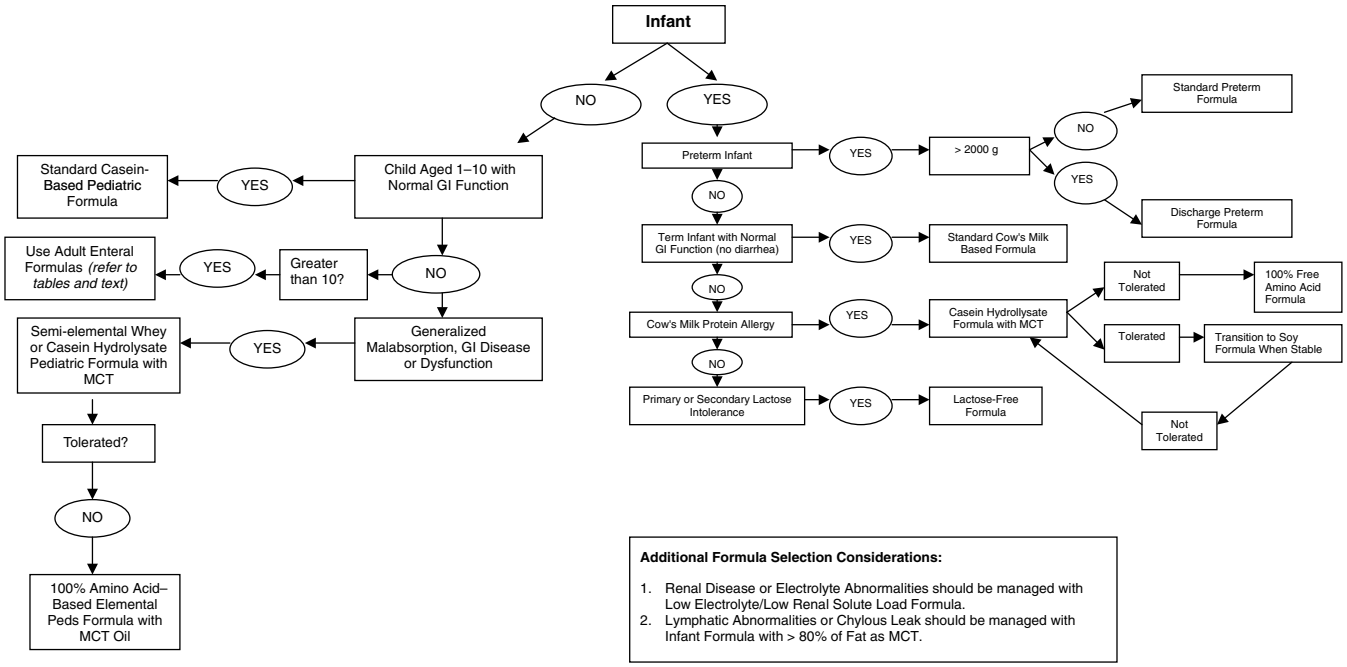

FIGURE 75.4B-1 Appropriate infant and pediatric formulas based on indication for use. GI = gastrointestinal; MCT = medium-chain triglycerides.

TABLE 75.4B-2 INFANT AND PEDIATRIC FORMULAS

PRODUCT NAME	KCAL/ OZ	CARBOHYDRATE (G/100 ML)	FAT (G/100 ML)	PROTEIN (G/100 ML)	MOSM/ KG	NUTRIENT SOURCES (CARBOHYDRATE; FAT; PROTEIN)
Preterm infant formulas						
Enfamil Premature Lipil	24	9.0	4.1	2.4	310	Corn syrup, lactose; MCT, soy, and sunflower oil; whey, casein
Similac Special Care 24	24	8.6	4.4	2.2	280	Corn syrup, lactose; MCT, soy and coconut oil; whey, casein
EnfaCare 22 Lipil	22	7.9	3.9	2.1	230	Maltodextrin, lactose; MCT, sunflower oil, soy, and coconut oil; whey, casein
Similac NeoSure 22	22	7.7	4.1	1.9	250	Maltodextrin, lactose; soy and coconut oil, MCT; whey, casein
Term infant formulas*						
Enfamil Lipil 20	20	7.3	3.5	1.4	300	Lactose; palm olein, soy, coconut, and sunflower oil; whey and casein
Similac Advance 20	20	7.2	3.6	1.4	300	Lactose; high-oleic safflower, coconut, and soy oil; whey, casein
Enfamil Lactofree	20	7.3	3.5	1.4	250	Corn syrup solids; palm olein, soy, coconut, and sunflower oil; whey and casein
Carnation Good Start	20	7.5	3.4	1.5	265	Lactose, maltodextrin; high-oleic safflower, palm olein, soy, and coconut oil; whey hydrolysates
Soy infant formulas†						
Prosobee 20	20	7.1	3.4	1.7	200	Corn syrup solids; palm olein, soy, coconut, and sunflower oils; soy protein + L-methionine
Isomil 20	20	6.9	3.4	1.6	200	Corn syrup, sucrose; high-oleic safflower, coconut, and soy oil; soy protein + L-methionine
Carnation Alsoy	20	7.4	3.3	1.9	200	Corn, maltodextrin, sucrose; palm olein, soy, coconut, and sunflower oil; soy protein + L-methionine
Specialized infant formulas†						
Nutramigen	20	7.4	3.4	1.9	320	Corn syrup, tapioca starch; palm olein, soy, coconut, and sunflower oil; casein hydrolysate
Pregestimil	20	6.9	3.8	1.9	320	Corn syrup, tapioca starch; MCT (55%), corn, soy, and sunflower oil; casein hydrolysates and amino acids
Alimentum	20	6.8	3.8	1.9	370	Tapioca starch, sucrose; MCT (50%), safflower and soy oil; casein hydrolysates and amino acids
Portagen	20	7.8	3.2	2.4	230	Corn syrup, lactose, sucrose; MCT (88%), corn oil (12%); sodium caseinate
Neocate	20	7.8	3.0	2.1	375	Corn syrup solids; safflower and soy oil, MCT (5%); free amino acids
Pediatric enteral formulas						
Kindercal with Fiber	31	13.5	4.4	3	325	Maltodextrin, sucrose; MCT, canola and high-oleic sunflower oil; calcium and potassium caseinates
PediaSure with Fiber	30	10.9	5.0	3	345	Corn syrup, sucrose, lactose; high oleic safflower and soy oil, MCT; sodium caseinate and whey
Peptamen Junior	30	13.7	3.9	3	260–360	Maltodextrin, corn starch; MCT, soy and canola, lecithin; hydrolyzed whey
Neocate Junior	30	10.4	5.0	3	607	Corn syrup solids; MCT, canola and safflower oil; free amino acids
EleCare	30	10.7	4.76	3	596	Corn syrup solids; high oleic safflower and soy oil, MCT; free amino acids

MCT = medium-chain triglyceride.

Enfamil products are Mead Johnson, Evansville, IN; Similac products are Ross Products Division, Abbott Laboratories, Columbus, OH; Carnation Infant Formula Products are Nestle Carnation, Wilkes Barre, PA.

*Term infant formulas are available in 24 kcal/oz ready to feed for hospital use.

†Can be prepared to 24 kcal/oz by adding less water to concentrate or powder base.

Breast milk continues to be the preferred EN source for preterm and sick neonates because it provides numerous nutritional, immunologic, and psychosocial advantages over formulas. Breast milk contains numerous trophic peptides, such as epidermal growth factor, which enhance GI growth and development.[67] Preterm breast milk is higher in protein, sodium, chloride, magnesium, and iron than mature human milk and is thus more suitable for the enteral feeding of the preterm infant.[50] Despite these advantages, preterm milk is still relatively deficient in calcium and phosphorus for the needs of the growing preterm infant.[8,50] Breast milk fortification is generally recommended for preterm infants (1) born at fewer than 34 weeks gestation, (2) born at less than 1,500 g, and (3) receiving parenteral nutrition for more than 2 weeks. Commercially available fortifiers include Enfamil Human Milk Fortifier (Mead Johnson), Similac Human Milk Fortifier (Ross Products Division, Abbott Laboratories), and Similac Natural Care (Ross Products Division, Abbott Laboratories), a liquid fortifier mixed 1:1 with pumped breast milk. The addition of one packet of Enfamil Human Milk Fortifier to 25 mL of human milk increases the caloric density by 4 kcal/oz and also increases the levels of protein, calcium, phosphorus, and other minerals. Most notably, the Enfamil fortifier contains added iron equal to that of iron-fortified term formulas and additional fat, 20% of which comes from MCTs. Beneficial outcomes in terms of infant growth, development, and nutritional status have resulted from fortification of breast milk.[68,69]

Term Infant Formulas: Standard, Soy, and Specialized

Term infant formulas meet the nutritional requirements of term infants during the first year of life. The protein, carbohydrate, and lipid macronutrient sources vary depending on whether the formula is standard, soy based, or partially hydrolyzed. The protein source may be casein and whey, soy protein isolate, or hydrolysates of casein or whey.[70,71] Infant formulas contain a blend of vegetable oils as the fat source and either lactose, glucose polymers, sucrose, or a combination of these as the carbohydrate source.[72,73] Vitamins and minerals are added to all infant formulas in accordance with the recommendations set by the American Academy of Pediatrics (AAP) and the Infant Formula Act of 1980.[74,75] Specialized whey hydrolysate formulas have resulted in reduced incidence of intolerance in infants with a family history of allergy.[76–78] Follow-up formulas for infants 4 months or older follow the European Society of Pediatric Gastroenterology and Nutrition guidelines for follow-up formulas[79] and the US Food and Drug Administration (FDA) nutritional requirements guidelines. Specialized milk-based formulas such as lactose-free formulas and formulas with added rice starch such as Enfamil AR (Mead Johnson) have been introduced to manage GI intolerance and reflux. Infant formulas generally have a caloric density of 20 kcal/oz but can be concentrated to 24 kcal/oz or greater using both concentration and the addition of caloric additives to meet the needs of infants with cardiorespiratory illness or failure to thrive. The use of sterile liquid ready to feed or concentrate is recommended by the FDA for the preparation of infant formulas within the institutional setting.[80]

Specialized formulas such as soy formulas, partially hydrolyzed formulas, and elemental formulas are indicated for a variety of uses. Soy formulas are used in the management of primary and secondary lactase deficiency and galactosemia.[81–85] Specialized formulas such as Nutramigen (Mead Johnson), Pregestimil (Mead Johnson), and Alimentum (Ross Products Division, Abbot Laboratories) are indicated for infants with allergies to intact protein of cow's milk or soy and generalized malabsorption, respectively. Portagen (Mead Johnson), which contains 88% of the fat as MCT oil, is used in the management of severe steatorrhea or chylous leak.[82,86] Finally, elemental formulas such as Neocate (SHS North America, Gaithersburg, MD) are used in the management of infants with severe protein allergies who are intolerant of hydrolysate formulas.[87,88]

Formulas for Children 1 to 10 Years of Age

Over the past 15 years, a number of pediatric enteral formulas, including polymeric, semielemental, and elemental formulas, have been developed for the support of children with a variety of disease states.[89] Figure 75.4B-1 presents an algorithm for selection of an appropriate pediatric formula based on GI function. Polymeric pediatric formulas meet the specialized needs of the 1- to 10-year-old child and are available in the tube feeding and flavored varieties and with or without fiber. The caloric and nutrient density and the osmolality and macronutrient sources can be found in Table 75.4B-2. Pediatric patients with GI disease or severe protein allergies may require EN support with a semielemental or an elemental formula. These formulas contain either peptides, free amino acids, or a combination of these, and part of the fat is provided as MCT. These formulas are also lactose and fructose free to optimize tolerance.

ADULT ENTERAL TUBE FEEDING FORMULAS

Children over the age of 10 years may be effectively managed with an adult enteral formula selected to meet the child's individual nutritional needs. Table 75.4B-3 lists the nutrient sources in a variety of selected adult formulas. These adult formulas are generally categorized into standard polymeric, semielemental, elemental, and specialized. Standard polymeric formulas contain mixtures of protein isolates, oligosaccharides, vegetable oil, MCTs, and added vitamins and minerals.[2,90,91] Soluble and insoluble fiber is added in a variety of forms. It serves as a fuel source for colonic mucosal cells and may also decrease the severity of diarrhea.[92] Older children and adolescents with markedly elevated calorie and protein requirements who require fluid restriction may be optimally managed with high-calorie, high-nitrogen formulations.[93] Semielemental and elemental formulas have been used effectively for the continuous enteral feeding support of patients with Crohn disease, CF, and short-gut syndrome[94–96] because nitrogen is more rapidly and effectively absorbed in the compromised bowel in the form of di- and tripeptides.[97,98]

TABLE 75.4B-3 SELECTED ADULT ENTERAL FORMULAS

PRODUCT NAME	KCAL/ CC	CARBOHYDRATE (G/1,000 ML)	FAT (G/1,000 ML)	PROTEIN (G/1,000 ML)	MOSM/ KG	NUTRIENT SOURCES (CARBOHYDRATE; FAT; PROTEIN)
Standard enteral formulas						
Isocal	1.06	135	44	34	270	Maltodextrin; soy, MCT; sodium and calcium caseinates and soy protein isolate
Osmolite	1.06	151	35	37	300	Maltodextrin; high-oleic safflower, canola, MCT; lecithin; sodium and calcium caseinates, soy protein
Nutren 1.5	1.5	169	68	60	510	Maltodextrin; MCT, canola, corn, soy lecithin; calcium and potassium caseinates
Nutren 2.0	2	196	106	80	745	Maltodextrin; MCT, canola, corn, soy lecithin; calcium and potassium caseinates
Osmolite HN	1.06	144	35	44	300	Maltodextrin; high-oleic safflower, canola, MCT; lecithin; sodium and calcium caseinates, soy protein
Osmolite HN Plus	1.2	139	35	49	360	Maltodextrin; high-oleic safflower, canola, MCT, lecithin; sodium and calcium caseinates, soy protein
Fiber-containing formulas						
Ultracal (cellulose and soy fiber)	1.06	142	39	44	360	Maltodextrin; canola, MCT, high-oleic sunflower, corn oil; milk protein concentrate and casein
Jevity (soy fiber)	1.06	155	35	44	300	Maltodextrin, corn syrup; high-oleic safflower, canola, MCT, lecithin; sodium and calcium caseinates
Nutren 1.0 with Fiber (soy polysaccharide)	1	127	38	40	320–380	Maltodextrin, corn syrup; canola, MCT, corn, soy, lecithin; calcium-potassium caseinates
Probalance (soy polysaccharide + gum arabic)	1.2	156	41	54	350–450	Maltodextrin, corn syrup solids; canola, MCT, corn, soy lecithin; calcium-potassium caseinates
IsoSource 1.5 (soy fiber + guar gum)	1.5	170	65	68	650	Hydrolyzed corn starch, sucrose; canola, MCT, soybean oil; sodium and calcium caseinates
Semielemental and elemental formulas						
Peptamen	1	127	39	40	270-380	Maltodextrin, corn starch; MCT, soybean, soy lecithin; enzymatically hydrolyzed whey
Peptamen 1.5	1.5	188	56	68	550	Maltodextrin, corn starch; MCT, soybean, soy lecithin; enzymatically hydrolyzed whey
Subdue	1	127	34	50	440–525	Maltodextrin, modified corn starch; MCT, canola, high-oleic sunflower, corn; hydrolyzed whey protein concentrate, casein hydrolysate
Vital HN	1	185	10.8	42	500	Maltodextrin, sucrose; safflower oil, MCT; partially hydrolyzed whey, meat, soy, free amino acids
Specialized adult enteral formulas						
Impact (immune enhancing)	1	130	28	56	375	Hydrolyzed corn starch; palm kernel, sunflower, menhaden oil; sodium and calcium caseinates, arginine
Crucial (immune enhancing)	1.5	135	68	94	490	Maltodextrin, corn starch; MCT, fish oil, soybean, soy lecithin; hydrolyzed casein, L-arginine
Nutri-Hep (hepatic)	1.5	290	21	40	690	Maltodextrin, modified corn starch; MCT, canola, soy lecithin, corn oil; amino acids, whey (50% branched-chain amino acids)
Suplena (renal—predialysis)	2	256	96	30	600	Maltodextrin, sucrose; high-oleic safflower, soy, lecithin; sodium and calcium caseinates
Nepro (renal—dialysis)	2	222	96	70	665	Corn syrup, sucrose, FOS; high-oleic safflower, canola, lecithin; calcium, magnesium and sodium caseinates
Respalor (pulmonary)	1.5	146	68	75	400	Corn syrup, sucrose; canola, MCT, high-oleic safflower, corn oil; calcium and sodium caseinates
Pulmocare (pulmonary)	1.5	106	93	63	475	Sucrose, maltodextrin; canola, MCT, corn, high-oleic safflower, lecithin (55% of kcal/fat); caseinates
Choice DM (glucose intolerance)	1.06	119	51	45	300	Maltodextrin; canola, high-oleic sunflower, corn oil; milk protein concentrate; fiber: soy fiber and cellulose
Glucerna (glucose intolerance)	1	96	54	42	355	Maltodextrin, fructose; high-oleic safflower, canola oil, lecithin; sodium and calcium caseinates

FOS = fructose oligosaccharide; MCT = medium-chain triglyceride.

Osmolite, Jevity, Vital HN, Glucerna, Pulmocare, Suplena, and Nepro products are Ross Products Division, Abbott Laboratories, Columbus, OH; Isocal, Ultracal, Subdue, Respalor, and Choice DM are Mead Johnson, Evansville, IN; the Nutren products, Probalance, Crucial, Nuri-Hep, and the Peptamen products are Nestle Clinical Nutrition, Deerfield, IL; Isosource products and Impact are Novartis Nutrition, Minneapolis, MN.

Specialized enteral formulas have been designed for the nutritional support of patients with a variety of specific diseases. Glutamine, arginine, ω-3 fatty acids, nucleotides, and other pharmacologic additives are provided in some formulas.[2] These formulas are expensive, and their clinical efficacy over standard polymeric formulas for the management of clinical conditions, including trauma, sepsis, diabetes, and renal failure, remains controversial.[99–108]

Oral Supplements and Modular Components

Milk-based and polymeric formulas may be used as oral supplements and are usually of moderately high lactose and residue owing to their high lactose content. Oral supplements such as Carnation Instant Breakfast (Nestle Clinical Nutrition) mixed with milk are often better accepted by children than are the lactose-free commercial supplements. Flavored polymeric formulas such as Boost (Mead Johnson) and Ensure Plus (Ross Products Division, Abbott Laboratories) are well accepted and palatable. Table 75.4B-4 presents the nutrient content of a variety of oral supplements.

Owing to the unique and often elevated nutritional requirements of the enterally fed pediatric patient, modification of enteral formulas with modular components is often necessary.[109] In these clinical situations, standard and specialized infant and pediatric formulas may be supplemented with caloric modulars, including carbohydrate, fat, and protein modules. Table 75.4B-5 reviews the caloric density and nutrient composition of selected modular products.

Gastrostomy and NG and NJ Feedings

When the requirement for EN support has been established, the optimal route of delivering nutrients must be determined. Many practitioners recommend the placement of NG or NJ tubes when the estimated course of therapy will not exceed 1 to 3 months. If the risk of aspiration is not significant, gastric feedings are preferable owing to the bactericidal effects of acid, the action of lingual lipase, ease of management, and ability to use bolus feedings. If GER is present, aspiration is a significant risk, and the duration of tube feeding may be relatively short. In this situation, NJ feeding is preferable to NG feeding. Tubes made of polyurethane and silicone rubber are soft and pliable and may be left in place for indefinite periods of time. Polyvinyl chloride tubes become stiff and nonpliable when left in place for more than a few days; however, they are useful for intestinal decompression or short-term feeding. They should be changed every 2 to 3 days to avoid skin necrosis or intestinal perforation. Some feeding tubes made of polyurethane or silicone rubber have a weight at the tip that makes them useful for duodenal or jejunal feedings. Tube sizes of 5F to 8F are appropriate for most pediatric patients. The weight on tubes that are 7F or 8F may be too great for easy passage in a young infant.

Children who require long-term tube feeding are candidates for placement of a gastrostomy tube. GER, which may occur in neurologically disabled children or even in normal infants following gastrostomy tube placement, may necessitate an operative antireflux procedure (eg, Nissen fundoplication). Although the procedure is effective in reducing GER, postoperative complications can be troublesome. Intractable retching episodes, dumping syndrome, continued problems with swallowing, impaired esophageal emptying, slow feeding, and gas bloating have all been reported. Controversy currently exists over the necessity of an antireflux procedure in neurologically impaired children who require a feeding gastrostomy. Our current policy when there is a question of GER with continuous or bolus enteral feedings is to administer the feeding on a trial basis through a NG tube before a decision is made on the need for a Nissen fundoplication. We do not feel that preoperative endoscopy or pH probe studies allow one to predict who will have pulmonary complications with GER. Indeed, many times GER improves, especially with continuous feedings.

Percutaneous endoscopic gastrostomy (PEG) tubes can be placed without a laparotomy and, in some older adolescents, without general anesthesia. PEG tubes can also be placed fluoroscopically without endoscopy. The most frequent complication of percutaneous gastrostomies appears to be localized cellulitis. This may be controlled by careful attention to adjusting the tension on the external bolster, which will vary during the postoperative period depending on edema at the insertion sight. There is controversy as to whether preoperative antibiotics prevent postoperative

TABLE 75.4B-4 SELECTED ORAL SUPPLEMENTS

			GRAMS PER SERVING		
PRODUCT NAME	SERVING SIZE, ML (OZ)	KCAL PER SERVING	CARBOHYDRATE	FAT	PROTEIN
Boost Drink	237 (8)	240	40	4	10
Ensure	237 (8)	240	40	6	9
Resource Standard	237 (8)	240	40	6	9
Boost High Protein	237 (8)	240	33	6	15
Boost Plus	237 (8)	360	45	14	14
Ensure Plus	237 (8)	360	50	11.5	13
Carnation Instant Breakfast (mixed with low-fat milk)	270 (9)	250	39	5	12
Carnation Instant Breakfast (no sugar added)	270 (9)	190	24	5	12
Mighty Shake	120 (4)	200	32	5	6
Mighty Shake (sugar free)	120 (4)	200	18	10	8

Boost products are Mead Johnson, Evansville, IN; Ensure products are Ross Products Division, Abbott Laboratories, Columbus, OH; Carnation products are Nestle Clinical Nutrition, Deerfield, IL; Mighty Shakes are Hormel Healthlabs, Austin, MN.

TABLE 75.4B-5 SELECTED CALORIC AND NUTRIENT MODULAR PRODUCTS

PRODUCT NAME	CALORIC DENSITY	NUTRIENT COMPOSITION
Polycose Powder	8 kcal/tsp	Glucose polymers
Polycose Liquid	2 kcal/cc	Glucose polymers
Light Karo Syrup	4 kcal/cc	Corn syrup, sugar, vanilla
Microlipid	4.5 kcal/cc	Safflower oil emulsion
Vegetable oil	8.6 kcal/cc	Oleic, linoleic, linolenic acids
Resource BeneProtein	25 kcal/scoop	Whey protein isolate, 6 g/scoop
Duocal	14 kcal/tsp	Corn starch, vegetable oil, MCT

Polycose is Ross Products Division, Abbott Laboratories, Columbus, OH; Microlipid is Mead Johnson, Evansville, IN; Resource Beneprotein is Novartis Nutrition, Minneapolis, MN; Duocal is SHS NorthAmerica, Gaithersburg, MD.

local cellulites. PEGs are sometimes contraindicated after previous abdominal surgery, in the presence of an abdominal tumor or significant organomegaly, or when obesity complicates placement.

Another complication of PEG placement is inadvertent perforation of a loop of bowel, generally the transverse colon. The colon may be enlarged if there is preoperative constipation and also may enlarge owing to excessive gas production, generally from air swallowing. Occasionally, this occurs if a child cries and swallows air for an extended period just prior to the procedure. Skillful, rapid placement of intravenous lines for sedation and other placating tactics may minimize this. Careful observation of the gas pattern during transillumination of the stomach prior to tube placement can also hint at inadvertent colon enlargement.

The gastrostomy button is a feeding device that can be used to form an effective one-way valve at the gastrostomy site. These products fit flush with the skin and attach to commercial feeding tubes that lock onto the button in a variety of ways. The button is less prone to accidental removal. However, the valve system makes button devices difficult to use for decompression of the stomach unless a tube is inserted through the valve directly into the stomach. It is possible to modify the external PEG tube into a button using a commercial conversion kit. This temporary button may last up to a year after initial PEG placement. It must be removed endoscopically by pulling it out through the mouth. It can then be replaced with a standard button.

Two types of buttons are currently available on the market. One has an inner deformable bolster that must be stretched with a trocar and forcibly inserted into the gastrostomy orifice. There is a 2 to 5% risk of tearing or perforating the site during insertion. It has the advantage of being very durable and not prone to breakage. The other variety of button has an inflatable bolster that is easier to insert. After insertion, the balloon is inflated. The inner seal provided by the inflatable bolster products is somewhat adjustable by varying the amount of water used to inflate the bolster. A disadvantage is that the balloon or the button itself is more prone to breakage and generally must be changed every 3 months.

If short-term enteral support is necessary and GER, delayed gastric emptying, or chronic pancreatitis is present, transpyloric jejunal feedings are an alternative. Placement of transpyloric nasoduodenal or NJ tubes is more complicated than NG tube placement and requires confirmation of position by radiography or pH analysis of aspirates. Placement of transpyloric tubes can be facilitated by the use of fluoroscopy and intravenous metoclopramide. Special catheters that measure pH using an electrode system are also available to confirm placement. Transpyloric tubes can also be placed endoscopically through existing gastrostomies. Extreme care must be exercised to be certain that retching or emesis has not moved the tip of the tube into the esophagus. Retrograde continuous delivery of formula into the esophagus virtually ensures aspiration. When tubes are placed beyond the pylorus, gastric decompression may be required to prevent distention that could impair small bowel motility or lead to aspiration. Feeding jejunostomies generally do not tolerate large bolus feeding over short intervals without producing dumping syndrome.

Two different methods are employed for delivery of enteral feedings. Intermittent bolus feedings deliver the formula over a period of time similar to that for an oral feeding (ie, 10–20 minutes). This technique is simple, requires minimal supplies, and may facilitate the transition to home care. Intolerance of this method is indicated by gastric residuals, malabsorption, dumping syndrome, aspiration, or persistent regurgitation. Bolus feeding is not well tolerated when feedings are delivered distal to the pylorus. When there is intolerance of intermittent bolus feeding, continuous infusion using an infusion pump is an alternative. When compared with hourly bolus feeding in adult burn patients, continuous feeding resulted in fewer stools and reduced the time to reach nutritional goals. Continuous feeding appears to be particularly beneficial when used for patients with impaired absorption, such as chronic diarrhea or short-bowel syndrome.[110,111] For chronic diarrhea, the reason for success of continuous feeding may be related to decreased gastric distention, which, in turn, affects the gastrocolic reflex. In some patients, this lack of gastrocolic reflex may potentiate constipation, which is a frequent complication of enteral feedings. Also, lack of gastric distention may decrease the usual postcibal GER, which is directly correlated to increases in feeding volume.[112]

We have found that chronic constipation is often an occult complication of enteral feedings that is manifest by early satiety, distention, and poor gastric emptying or even emesis. Often it is unsuspected because overflow diarrhea is present. An abdominal radiograph and/or digital examination will often reveal large amounts of fecal material. Disimpaction with enemas and establishment of regular

bowel movements using routine laxative administration is often extremely beneficial.

Similar symptoms of emesis and diarrhea during EN may also be observed with bacterial overgrowth. Bacterial overgrowth may occur as a result of altered anatomy, disorganized motility, and/or chronic acid inhibition. It may be diagnosed by enteral intubation and culture or inferred from high basal or early postcibal breath hydrogen analyses. However, neither of these measurements totally excludes bacterial overgrowth. Therefore, we prefer an empiric trial of treatment, generally with metronidazole for anaerobic bacteria or, less commonly, trimethoprim-sulfamethoxazole for gram-negative overgrowth. When the problem is recurrent, therapy with regular 3- or 4-day courses of treatment every 3 to 4 weeks allows for smoother progression of feedings. Alternatively, use of a probiotic such as *Lactobacillus* GG may be of benefit. We have also observed in two patients that use of a high-fat formula seemed to decrease the troublesome recurrent symptoms of bacterial overgrowth. This might be due to slower motility or less carbohydrate available as bacterial substrate.

WATER

It must be emphasized that the most important nutrient deficiency to be avoided is water deficiency (dehydration or tube feeding syndrome) Often this occurs insidiously over several days or even months. Those patients who are unable to voluntarily control their water intake, owing to limitations on absorption, developmental immaturity, or neuromuscular diseases, are at particular risk for the development of tube feeding syndrome. This deficiency will become particularly critical during times of increased water losses owing to fever, vomiting, or diarrhea. Even ambient weather conditions can contribute to deficiency. The patient discharged to a home without air-conditioning during the summer months may have an enormously increased requirement for water. If the patient wears diapers, it is useful to ask the caregiver how many urine voids there are during the day. If the diaper contents are always mixed urine and stool, it is important to ask how many "urine-only" diapers are changed during the day. During routine visits to the physician, urine-specific gravity, serum sodium, and blood urea to creatinine concentrations should be studied in a flowchart representation to help spot trends.

The practice of adding supplemental calories and electrolytes to feedings can exacerbate tube feeding syndrome water deficiency by producing increased GER[112] or diarrhea. Simplistically, clinicians often feed to the point of emesis or diarrhea in an attempt to maximize weight gain. This puts the patient at particular risk for tube feeding syndrome. The goal should be steady, modest weight gain with positive fluid balance.

Mechanical complications are also common with enteral feedings. The small-bore tubes can easily become clogged or kinked. Clogged feeding tubes can be a major problem, requiring repeated reinsertions. Newer enteral feeding tubes have wider openings to diminish clogging. Additional ports at the connection site allow for medication administration and flushing without interruption of the feeding.

To prevent clogging, liquid medications should be used whenever available. If medication in tablet form is necessary, it should be crushed to a fine powder. Adequate suspension in solution can sometimes be achieved by allowing the tablet to dissolve in water rather than attempting to dissolve the crushed tablet. Medications that congeal, such as Metamucil or cholestyramine, easily clog small-bore tubes and should be avoided when possible. If they are necessary, these medications should be administered and cleared quickly. Cholestyramine products that have aspartame instead of sugar are often finer powders and less likely to clog the tube. Feeding tubes should be flushed with water before and after intermittent bolus feedings and periodically (every 4 to 6 hours) during continuous feeding. An investigation of nine nontoxic substances (including digestive enzymes, proteolytic enzymes, and cranberry juice) theoretically useful in clearing clogged feeding tubes demonstrated that successful declogging occurred with chymotrypsin, papain, and distilled water. Preventing feeding tubes from clogging is easier than attempting to clear them.[113] Other mechanical complications include irritation from transnasal tubes, which can produce sinusitis, otitis media, GER, and nasopharyngeal and gastric irritation.

SUMMARY AND CONCLUSIONS

We have discussed the indications for specialized enteral formulas and routes of administration. The enteral route is the preferred route of nutrient administration. Even in the face of relative compromise of the GI tract, specialized products and techniques promote positive nutrient balance. Partial use of the enteral route during parenteral nutrition prevents atrophy of the intestine and reduces the tendency toward the cholestasis associated with intravenous feeding. If possible, the oral route is preferable, and appetizing, nutritious foods should be emphasized. Enteral feeding is cheaper, simpler, more effective, and safer than parenteral feeding.

Virginia A. Stallings, MD

SPECIAL DIETARY NEEDS

Malnutrition in children with chronic gastrointestinal disorders includes underfeeding (protein-energy malnutrition [PEM]) and overfeeding (overweight or obesity). In childhood, malnutrition is characterized by growth failure (weight, height/length), behavioral and cognitive deficits, and increased susceptibility to infections secondary to immune system dysfunction. Repeated infections may further alter nutrient intake and requirements, making this a vicious cycle. PEM often occurs as a result of inadequate nutrient and energy supply or in response to an injury or illness with increased requirements in a marginally nourished child. Malnutrition is common in hospitalized pediatric patients, with an estimated prevalence of 25 to 60% in North America.[1,2] Therefore, it is essential to meet the special nutrition needs of children with significant medical conditions. An overview of the nutritional considerations for selected disease states is presented in Table 75.5-1.

In many disease states, PEM occurs as food intake fails to increase in response to the increased energy and nutritional demands of inflammation and/or malabsorption. Most illnesses exert some effect on nutrient status and requirements. In certain disorders, the ability of the body to use specific nutrients may be altered (eg, vitamin E deficiency seen in abetalipoproteinemia). Nutritional deficiencies can have long-lasting effects, especially in growing children. Therefore, it is important to thoroughly understand the pathophysiology of the patient's disorder and its impact on nutritional status as part of nutrition support planning. Because drug therapy is part of the management of many diseases, drug–nutrient interactions must be considered. Medication side effects, as well as therapeutic effects, may contribute to changes seen in nutritional status owing to anorexia, nausea, vomiting, diarrhea, malabsorption, and maldigestion.[3,4]

Previously, the 1989 Recommended Dietary Allowances (RDAs) guided macronutrient and micronutrient intake for healthy children and those with acute and chronic illness. The RDAs have been replaced by the new Dietary Reference Intakes (DRIs). The DRIs are evidence based and represent recommendations for healthy US and Canadian populations for nutrient intake for good health, as well as for the prevention of chronic disease.[5] Additional information on nutrient requirements of children is available in Chapter 75.3, "Nutritional Assessment and Requirements."

The role of nutrition in disease and disease prevention is recognized in the medical community. Studies have shown that poor nutritional status negatively affects health outcomes in chronic disorders of childhood such as pulmonary status in patients with cystic fibrosis[6] and survival rates following a liver transplant.[7] Additionally, foods such as those containing prebiotics and probiotics may be used to modulate disease activity and the immune system. Many children with chronic diseases require additional calories, as well as other specific dietary interventions, to achieve optimal growth and development. These therapeutic diets are modifications of a normal diet pattern and are intended to counteract specific nutrient inadequacies that are associated with the disease states. An example is the provision of a high-protein diet in patients with protein-losing enteropathy. Some disease states such as acute diarrhea require dietary modifications for a limited time. A lactose-free diet in patients with acute diarrhea may provide symptomatic relief. However, for the majority of children with chronic diseases, the dietary modifications will be long term and will require follow-up as well as ongoing age- and culturally appropriate education. Re-evaluation of the diet therapy and monitoring of nutrient and nutritional status are essential to ensure adherence and comprehension. The goal is optimization of micronutrient and macronutrient intake based on age, nutritional status, and medical condition. Nutritional assessment plays a key role in achieving this goal.

Specific Aspects of Nutrition Assessment

Detailed information on nutritional assessment in infants, children, and adolescents is available in Chapter 75.3. Nutrition assessment is a component of the medical physical examination for all children, especially for those with chronic disease. Monitoring nutrition status is critical to ensure that the patient's nutritional goals are met. A registered dietitian often contributes to this assessment, which includes nutrition-focused medical and nutrition history, including infant feeding history, typical current intake, food aversions, allergies or intolerances, recent weight loss or gain, chewing and swallowing difficulties, and dietary, vitamin, mineral, or herbal supplements. Physical examination and growth assessment include anthropometric measurements: weight, height or length, head circumference, body mass index (for children > 2 years), midarm muscle circumference, triceps skinfold thickness, an assessment of fat and muscle stores, and signs of

TABLE 75.5-1 SELECTED DISEASE CONDITIONS AND RELATED NUTRITIONAL CONSIDERATIONS

CYSTIC FIBROSIS
High-calorie, high-fat diet
Salt replacement, especially in hot weather
Evaluation of essential fatty acids and bone health
Fat-soluble vitamin supplementation
Enzyme therapy for pancreatic insufficiency
Oral supplements for calories
INFLAMMATORY BOWEL DISEASE
High-calorie diet
Lactose-free diet
Vitamin B_{12} supplementation with ileal disease
Vitamin D, calcium, iron, zinc, folic acid supplementation
Multivitamin supplementation
Elemental diet for inducing remission and providing caloric support
Bone disease evaluation
CONGENITAL HEART DISEASE (in infants)
High-calorie formula in infants
Concentrated formulas
Fortified breast milk in infants
Tube feeds
Sodium restriction
Fluid restriction
CANCER
High-calorie diet
Oral supplements
Tube feeds
Parenteral nutrition for extensive nausea and vomiting
Appetite stimulants
Small, frequent feedings
RENAL DISEASE
Fluid restriction
Fortified breast milk or concentrated formula
Sodium restriction
Provide RDA for protein
Phosphorus restriction
Phosphorus binder
Supplement with vitamin D, calcium
Bone disease evaluation
LIVER DISEASE
Fluid restriction for end-stage disease
Fat-soluble vitamin/multivitamin supplementation
Fat malabsorption may occur with biliary atresia or Alagille syndrome
Evaluation of essential fatty acid status
Evaluation of bone health
Protein restriction with encephalopathy
Adequate calories and protein for growth
METABOLIC DISORDERS
Dietary restriction of the offending nutrients
Adjusted intake of offending amino acids and fats to promote optimal growth and development
Monitor compliance to diet
Replacement of deficient coenzymes
CEREBRAL PALSY
Supplemental tube feeds
Fiber-containing formula
Speech evaluation if chewing/swallowing difficulties
May require modified diet (puree, thickened liquids, etc)
Supplemental multivitamin and minerals
Ketogenic diet (patients with intractable seizures)
Bone disease evaluation
DIABETES MELLITUS
Blood glucose control
Dietary balance with regularly scheduled meals and snacks
Meal planning, carbohydrate counting, insulin education when indicated
Monitor cholesterol and triglycerides and recommend low-fat diet when indicated
Adequate calories for proper growth and development
CELIAC DISEASE
Gluten-free diet
Lactose-free diet may be indicated until complete mucosal healing
Possible infant sensitivity to cow's milk protein
Vitamin and mineral therapy
Adequate calories for catch-up growth
Bone disease evaluation
Monitor compliance to diet

RDA = Recommended Dietary Allowance.

micronutrient excesses and deficiencies. Alternative anthropometric measures for linear growth (lower leg length and upper arm length) should be performed on patients who are unable to stand. A midarm circumference may be a useful measure to follow in patients with significant dependent edema that results in an unreliable weight. This measurement can be done every 2 weeks in infants and every 4 weeks in children and adolescents as a gross estimate of growth and response to therapy. To ensure reliability and accuracy, an experienced clinician should obtain these measurements using quality calipers that have been maintained regularly. Signs of malnutrition may be identified with physical assessment of body fat and muscle stores, the oral cavity, skin, hair, and eyes.

Evaluating pubertal development is also an important part of nutritional assessment. For those patients at nutritional risk, resting energy expenditure measurements by indirect calorimetry are recommended to determine individual caloric needs. Obtaining a dual-energy x-ray absorptiometry (DXA) scan provides body composition information such as fat and muscle stores and bone health. Biochemical analysis, including prealbumin, albumin, electrolytes, minerals (calcium, phosphorus, and magnesium), trace minerals, iron studies, and liver function tests, is important in selected clinical settings. Specific nutrient analysis will depend on the underlying disease state (eg, triene-to-tetraene ratio to evaluate for essential fatty acid deficiency in cystic fibrosis or serum alkaline phosphatase, parathormone, vitamin D [25-hydroxy and 1,25-dihydroxy], calcium, and phosphorus to evaluate for rickets).

Specific Dietary Therapy by Nutrient Groups

Dietary therapy during chronic illness is directed at providing calories, macronutrients, and micronutrients to support normal growth and, in many cases, nutritional rehabilitation. In an effort to meet the increased nutritional needs associated with chronic illness, infants and children may require dietary modifications. Typically, infant formulas are calorically concentrated from the standard 20 calories per ounce to 27 calories per ounce by mixing with less water. When higher caloric content is required, additional macronutrients can be added, usually in the form of modular components. The addition of carbohydrate, protein, and fat modular components to increase the caloric density of a formula is a com-

mon practice in pediatric nutrition support and is indicated for patients who are unable to meet nutrient needs with standard amounts of formula. Attention must be paid to the renal solute load when concentrating formulas, especially for patients with renal dysfunction. Generally, caloric density should be advanced by 2 to 4 calories per ounce in a 24-hour period as tolerated. The selection of the modular component (carbohydrate, protein, or fat) is dependent on the clinical situation. See Table 75.5-2 for a list of some commonly used modular components and their indications.

CARBOHYDRATES

The DRIs state that 45 to 65% of total calories should come from carbohydrates (Tables 75.5-3 and 75.5-4).[5] No more than 25% of total calories is recommended as added sugars because more may result in reduced intakes of certain micronutrients.[5] A number of popular weight loss diets recommend very low intakes of carbohydrate. A growing body of scientific evidence has shown an increased risk for adverse health effects with chronic consumption of any diet that has a pattern of increased or decreased micronutrients. Therefore, low-carbohydrate weight loss diets are not recommended for growing children. An exception is the ketogenic diet, which provides the majority of calories from fat with minimal protein and carbohydrate and is used to treat children with intractable seizure disorders. The DRIs recommend that children > 1 year consume at least 130 g of carbohydrates each day. Adequate intake of carbohydrate is specifically important for brain health and to spare metabolism of protein for energy.

Human milk and most infant formulas contain 40 to 50% carbohydrate, with lactose being the primary source. Lactose plays a key role in infant feeding because it maintains lactobacilli in the gut, thereby preventing the growth of less desirable bacteria. Lactose also lowers the pH of the intestinal contents, thereby providing the optimal calcium absorption environment. Lactose intolerance commonly occurs in older children and adolescents. In infancy, lactose intolerance is often secondary to damage to the intestinal epithelium following acute gastrointestinal infections and celiac disease. Symptoms include bloating, flatulence, and diarrhea with ingestion of lactose-containing foods. Treatment may include supplemental lactase enzymes, restrictions of dietary lactose (lactose-free formula, reduced-lactose diet), and provision of adequate calcium and vitamin D intake. These conditions are discussed in more detail elsewhere in this text. See Table 75.5-5 for a list of selected common infant and childhood formulas and indications for use.

A well-appreciated role of dietary carbohydrates is in blood glucose control in diabetes. Nutritional management for children with diabetes includes carbohydrate counting and distribution of carbohydrates evenly throughout each meal or snack of the day. The number of carbohydrate

TABLE 75.5-2 SELECTED THERAPEUTIC MODULAR DIET COMPONENTS

MODULAR COMPONENT	INDICATION	CARBOHYDRATE	PROTEIN	FAT	CALORIC DENSITY
Polycose liquid (glucose corn polymer)	Added to supplements and formulas or foods to increase calories	X			2 kcal/mL
Polycose powder (glucose corn polymer)	Added to supplements and formulas or foods to increase calories	X			23 kcal/tbsp
Duocal powder (SHS Ltd, Rockville, MD, USA) (corn syrup solids; vegetable, corn, coconut oil)	Added to supplements and formulas or foods to increase calories	X		X	42 kcal/tbsp
Promod powder (whey protein)	Added to oral supplements, enteral tube feedings, or food to increase protein		X		28 kcal/scoop; 5 g protein/scoop
Additions (must be mixed with hot food) (corn syrup solids, whey protein isolate, canola oil, soy lecithin)	Added to foods to increase calories and protein	X	X	X	43 kcal/tbsp; 2.5 g protein/tbsp
MCT oil (fractionated coconut oil)	Added to formulas or tube feedings to increase calories; often used for fat malabsorption disorders; does not contain essential fatty acids			X	7.7 kcal/mL
Microlipids (safflower oil)	Added to formulas or tube feedings to increase calories; also used in treatment or prevention of fatty acid deficiencies; contains essential fatty acids			X	4.5 kcal/mL
Vegetable oil (canola, corn, soybean, safflower, or sunflower)	Added to formulas and foods to increase calories			X	8.3 kcal/mL
Margarine, butter (long-chain triglycerides)	Added to foods to increase calories			X	102 kcal/tbsp

MCT = medium-chain triglyceride.

TABLE 75.5-3 DIETARY REFERENCE INTAKES: RECOMMENDED INTAKES FOR INDIVIDUALS FOR MACRONUTRIENTS

AGE GROUP	CARBOHYDRATE (g/d), AI OR RDA	FAT (g/d), AI	PROTEIN (g/d), AI OR RDA
Infants			
0–6 mo	60 (AI)	31	9.1 (AI)
7–12 mo	95 (AI)	30	13.5 (RDA)
Children			
1–3 yr	130 (RDA)	ND	13 (RDA)
4–8 yr	130 (RDA)	ND	19 (RDA)
Males			
9–13 yr	130 (RDA)	ND	34 (RDA)
14–18 yr	130 (RDA)	ND	52 (RDA)
19–30 yr	130 (RDA)	ND	56 (RDA)
Females			
9–13 yr	130 (RDA)	ND	34 (RDA)
14–18 yr	130 (RDA)	ND	46 (RDA)

AI = Adequate Intake; ND = not determinable; RDA = Recommended Dietary Allowance.

servings is adjusted in relation to a child's growth and energy needs.

There are other clinical disorders in which digestion or absorption of carbohydrate is altered, resulting in carbohydrate intolerance. These can be seen in children with transient lactase deficiency owing to mucosal damage from an acute viral illness and newly diagnosed patients with celiac disease with villous atrophy and congenital/genetic disorders (eg, sucrase-isomaltase deficiency, alactasia, and glucose-galactose malabsorption). In addition, some metabolic disorders of carbohydrate metabolism such as aldolase-B deficiency, fructose 1-6-diphosphatase deficiency, and galactosemia require the elimination of certain carbohydrates. Table 75.5-5 lists selected enteral products that have been developed to accommodate these dietary restrictions.

Humans cannot digest and absorb many plant carbohydrates. The DRIs define fiber as the nondigestible carbohydrate and lignin components from the plant cell wall that are composed of soluble and insoluble fiber. This includes fiber contained in oat and wheat bran. Soluble fiber is fermented by colonic bacteria and converted into short-chain fatty acids that are subsequently absorbed by the colon. In this process, fructo-oligosaccharides (FOSs) are formed and promote the growth of probiotic bacteria. FOSs have been shown to be beneficial in inflammatory bowel disease (IBD). Functional fiber is the dietary fiber that has potential beneficial physiologic effects and includes FOS, pectins, and gums.[5]

The potential health benefits of certain dietary fibers include a role in the management of diabetes by delaying glucose uptake and reducing the insulin response. In addition, certain dietary and functional fibers may have a protective effect against coronary heart disease by decreasing serum cholesterol levels. Fiber also delays gastric emptying, which may play a key role in weight control by increasing satiety.[8–10] In children, the consumption of fiber is important to prevent constipation, which accounts for 25% of pediatric gastroenterology office visits.[11] The 2002 DRIs provide the first recommendation for dietary fiber intake and refer to total fiber (sum of dietary fiber and functional fiber) (Table 75.5-6). These recommendations were generated in response to evidence that shows an increased risk for heart disease when low-fiber diets are consumed.

PROTEIN

Protein intake should constitute 5 to 35% of total daily calories (see Tables 75.5-3 and 75.5-4). Protein requirements are altered in many pediatric illnesses. Inborn errors of amino acid metabolism require that certain dietary proteins be restricted to minimize exposure to indicated amino acids. Care must be taken in these conditions to ensure an adequate energy and total protein energy intake to support normal rates of growth. Examples include phenylketonuria, maple syrup urine disease, propionic acidemia, and methylmalonic acidemia. Table 75.5-5 lists selected enteral products that have been developed to accommodate these dietary restrictions.

In chronic renal failure not requiring dialysis, the DRI for protein should be provided to ensure adequate growth. No data exist to show that protein restriction below the DRI delays the progression of renal disease. Restricting dietary phosphorus also leads to protein restriction. For those children undergoing dialysis, it is important to supply adequate amounts of protein to compensate for protein lost in the dialysate.

Protein requirements are increased in the pediatric patient with burn injury owing to an accelerated breakdown of tissue and from protein losses from the wound before skin grafting. Failure to meet protein requirements can decrease wound healing and increase the risk for infection.

Selected amino acids may become conditionally essential during periods of rapid growth and serious illness (trauma, severe infection, and cancer). This occurs because synthetic rates do not adequately increase during periods of increased requirements. Arginine is a precursor of nitric oxide, and it modulates hepatic protein synthesis, mediates the vasodilatory effects of the endotoxins, and reduces tumor and bacterial growth.[12] Enteral arginine supplementation has been shown to be most beneficial in adult postoperative, critically ill, and trauma patients.

TABLE 75.5-4 DISTRIBUTION RANGES FOR MACRONUTRIENT INTAKE

MACRONUTRIENT	RANGE (PERCENT ENERGY)	
	CHILDREN, AGE 1–3 YR	CHILDREN, AGE 4–18 YR
Fat	30–40	25–35
ω-6 Polyunsaturated fatty acids (linoleic acid)	5–10	5–10
ω-3 Polyunsaturated fatty acids (linolenic acid)	0.6–1.2	0.6–1.2
Carbohydrate	45–65	45–65
Protein	5–20	10–30

*These products are not completely hypoallergenic.

This chart does not represent a comprehensive list of enteral products but rather a listing of commonly used enteral products. Note that in some special circumstances, an adult formula (used in children > 10 years old) may be used in children < 10 years old under the close supervision of a registered dietitian. Computerized diet analysis is required in these instances to determine nutrient imbalance.

Glutamine is the most abundant nonessential amino acid and is a precursor for glutathione, and it, too, may be conditionally essential during selected clinical conditions. It has a major role as an energy source for enterocytes, colonocytes, lymphocytes, and macrophages.[13,14] It may reduce bacterial translocation in the gut, thereby reducing the risk of bacteremia and consequent mortality in adult patients with cancer undergoing chemotherapy. Glutamine supplementation has been found to be safe in premature infants,[12,15,16] to be beneficial in patients with short-bowel syndrome, to improve nitrogen balance in critically ill and postsurgical patients,[17] to preserve gastrointestinal mucosal structure,[18] and to decrease sepsis and shorten the hospital stay in some adult bone marrow transplant patients.[19] Glutamine is currently added to some specialized enteral formulas and parenteral nutrition solutions for patients with short-bowel syndrome and those undergoing bone marrow transplants. It is unstable in solution, but newer formulations of glutamine dipeptides are stable, allowing its addition to enteral products.

Taurine is essential for the conjugation of bile acids early in infancy, especially in small premature infants. It is added to infant formulas at concentrations similar to those in breast milk and at higher levels in premature infant formulas. Carnitine is important for intracellular fatty acid oxidation and energy production. It is a nonessential amino acid but may become conditionally essential when requirements increase. Carnitine has been used in the treatment of various genetic defects in organic and fatty acid metabolism in pharmacologic doses. Nucleotides are important during periods of metabolic stress and rapid growth. Beneficial effects on the immune system have been observed,[20] and infant formulas are now supplemented with nucleotides at concentrations seen in human milk.

FAT

It is recommended that 20 to 40% of total daily calories come from dietary fat (see Tables 75.5-3 and 75.5-4). Certain inborn errors in fatty acid oxidation require restriction of dietary fats. Deficiency of the essential fatty acids linoleic and linolenic acids results when adequate long-chain fat is not provided in the diet. Table 75.5-5 lists selected enteral products that have been developed to accommodate these dietary restrictions. Recently, there has been an increased interest in two fatty acids that occur naturally in breast milk. Docosahexaenoic acid (fish and organ meat) and arachidonic acid (meat, eggs, and milk) are ω-3 and ω-6 polyunsaturated fatty acids that are important constituents of the brain and the

AI = Adequate Intake; ND = not determinable. AI based on 14 g total fiber/1,000 kcal and average kcal intake for age range; decrease fiber goal if kcal intake is less than amount recommended for age.

retina. Arachidonic acid is essential for growth and functions as a precursor for eicosanoids. Several infant formulas are now supplemented with docosahexaenoic acid and arachidonic acid.

Essential fatty acid deficiency (EFAD) occurs in patients receiving long-term parenteral nutrition without adequate intravenous fat, with prolonged fasting, or with extended use of a formula predominantly containing medium-chain fats. In addition, EFAD may occur in patients who have fat malabsorption. Signs of EFAD include poor growth, thrombocytopenia, and rough, scaly skin. EFAD is commonly diagnosed by a serum triene-to-tetraene ratio of greater than 0.4. Fatty acids are precursors of prostaglandins and leukotrienes. The ω-3 fatty acids have been shown to affect the clinical course of patients with IBD, rheumatoid arthritis, cardiovascular disease, and respiratory distress syndrome.[21–24]

Medium-chain triglycerides (MCTs) are found in coconut oil and contain fatty acids with a chain length of 6 to 12 carbons. MCTs are absorbed directly into the portal system and do not require bile salts for absorption. Typical diets do not contain large amounts of MCTs; however, they are often used as an energy source and as a component of specialized diets for patients with fat malabsorption or pancreatic insufficiency.

MICRONUTRIENTS

Supplemental vitamin and mineral use is increasing,[25,26] and there is much interest in the role of the antioxidants (vitamins A, E, and C; selenium; and β-carotene) for disease prevention. Additionally, there is evidence to support increased use of specific vitamins and minerals in specific disease states. Examples include conditions in which deficiencies exist owing to malabsorption, as seen in patients with cystic fibrosis and cholestatic liver disease who need fat-soluble vitamin supplementation. Certain micronutrients are required as cofactors for enzyme reactions in a variety of metabolic disorders, such as the role of thiamine in Kearns-Sayre syndrome.[24] Supplemental micronutrients may also be required to counterbalance the depletion caused by medications, for example, folic acid and sulfasalazine in patients with IBD. Enhanced outcomes in certain disease states can also be related to supplemental micronutrients such as vitamin A supplementation of extremely low birth weight infants with bronchopulmonary dysplasia[27] and to treat ichthyosis and psoriasis.[28] The general public is using supplements in variable dose ranges without medical supervision, and the US Food and Drug Administration does not regulate these products. Serious adverse side effects have been reported with the use of these dietary supplements.[29]

Evidence is accumulating to support the use of specific micronutrients in the prevention and treatment of adult chronic disease. Many of these diseases, especially atherosclerotic cardiovascular disease and osteoporosis, begin in childhood. This leads to consideration of whether prevention measures should be initiated in children. The Dietary Guidelines for Americans recommend consuming a balanced diet and five servings of fruits and vegetables a day to provide sufficient levels of micronutrients.[30] Further research is required to evaluate whether dietary modifications in children may help prevent the development of adult chronic diseases.

The following examples help illustrate how certain micronutrients have been used to treat and prevent diseases. Vitamin E has been shown to decrease atherosclerotic heart disease[31] and lung cancer.[32] Riboflavin has been used to decrease migraine headaches.[33] Patients with infantile lactic acidosis, skeletal myopathy, and Leigh disease can improve following riboflavin administration.[34] Nicotinic acid is used to treat atherosclerotic heart disease.[35] The benefits of folic acid are seen not only in megaloblastic anemia but also in pregnancy, in which a decrease in spontaneous abortion is noted. Periconceptional folate decreases birth defects, especially neural tube defects. Public health policy worldwide recommends that women in the childbearing age group should be supplemented with folate.[36] Folate supplementation also reduces homocysteine levels, and trials are under way to see if this effect will reduce cardiovascular disease risk.[37] Folate has been shown to be effective in the prevention of certain types of cancer.[38] In the United States, grains intended for processed foods are fortified with folate.

Glucose tolerance has been shown to improve with the use of chromium. This effect is due to improved efficiency of insulin and improved blood lipid profiles. Adult subjects with some degree of impaired glucose tolerance were more responsive to the effects of chromium, and no effect was seen in those with normal glucose tolerance. Improved glucose control was also seen in patients with diabetes mellitus.[39] Zinc supplementation has been used in diarrhea and pneumonia prevention.[40] Beneficial effects of zinc supplementation are also seen in growth, neuropsychological performance, fetal growth, and birth outcomes.[13] The benefits of iron supplementation in infants and children with iron deficiency anemia are well known, with improvement

in work capacity, behavior and cognitive function, body temperature regulation, immunity, and resistance to infections.[41] The use of calcium and vitamins in osteoporosis prevention is discussed later in the chapter.

Evidence suggests that antioxidant levels are decreased in chronic disease.[42,43] Oxidative stress that occurs in chronic inflammation leads to increased requirements of antioxidant vitamins and consequent depletion, resulting in a relative deficiency state. Vitamin A, β-carotene, and vitamin C are added to specialty formulas (for trauma, critical care, and IBD) to enhance healing and reduce inflammation.

Transforming growth factor-β_2 is a cytokine that is present in human milk and gut epithelial cells. It has anti-inflammatory effects, reduces epithelial permeability, and regulates cellular growth. It has been added to formulas used to treat children with IBD, with preliminary reports suggesting improved mucosal healing.[44–46]

COMPLEMENTARY AND ALTERNATIVE MEDICINE

Complementary and alternative medicine (CAM) covers a broad range of healing philosophies and therapies that are not commonly part of mainstream Western (conventional) medicine. This includes diet-based therapies that often employ herbal and botanical supplements. Concerns about the use of CAM in pediatric health care relate to the potential of CAM products to adversely influence growth and development. Limited efficacy and safety information is available. Dosing information for body size and herb–drug interaction is also unavailable.

CAM use in pediatric patients with IBD has been reviewed.[47] It was noted that 50% of patients used CAM therapies, which included nutritional supplements (43%), special diets (22%), alternative health systems (8%), and herb medicines (5%). No association was seen with a history of previous surgery and hospitalizations. Higher use was noted among patients receiving immunomodulatory therapy, suggesting that patients who are more ill may be more likely to seek adjunctive therapies. In an international CAM study, in patients with IBD, 41% used CAM (megavitamin therapy in 19%, dietary supplements in 17%, and herbal medicine in 14%). The reasons for CAM use included a history of previous side effects from conventional medications, hope for a cure, and prescribed medications not working as well as anticipated. Additionally, 59% of respondents not taking CAM were interested in learning about it, suggesting that patients with chronic illness are interested in CAM.[48]

The use of herbal compounds is increasing in pediatric and adolescent patients,[49] with limited scientific data to guide this use. Epogam (Scotia Pharmaceuticals Ltd, Auckland, Australia) evening primrose oil treatment was evaluated in pediatric patients with atopic dermatitis and asthma. Increased plasma essential fatty acid levels and significant improvement were seen with eczema symptoms in the subjects who received primrose oil, but no differences were seen between the control and treatment groups with reactive airways disease.[50] Certain oils (evening primrose, borage, and black currant) have anti-inflammatory effects and have been used in rheumatoid arthritis. The active ingredient is γ-linolenic acid (18:3, ω-6), which is anti-inflammatory and immune regulating.[51,52] Trials of probiotics and fish oil in adult patients with IBD have suggested potential efficacy, but similar studies have yet to be done in children.

Probiotics are recognized as being beneficial in normal health (maintaining a healthy gastrointestinal ecosystem) and for immune modulation and disease prevention.[53,54] Probiotics help control gastrointestinal inflammation, normalize mucosal function, and down-regulate hypersensitivity reactions. They have been used for the treatment of infectious diarrhea, IBD, radiation-induced diarrhea, traveler's diarrhea, antibiotic-associated diarrhea, *Helicobacter pylori* infection, and food allergy, with varying success.[55,56] There are several proposed mechanisms of action. These include stimulation of the immune response to pathogens, competition for nutrients required for the growth of pathogens, synthesis of compounds that inhibit or destroy pathogens, competitive inhibition of bacterial adhesion, normalizing intestinal permeability, altering gut flora, decreasing intestinal inflammatory responses, and controlling the balance between pro- and anti-inflammatory cytokines. *Lactobacillus acidophilus*, *Lactobacillus* GG, *Lactobacillus planatarum* 299V, *Bifidobacterium bifidum*, *Bifidobacterium longum*, *Streptococcus thermophilus*, *Enterococcus faecium* SF68, and *Saccharomyces boulardii* are among the probiotics that have been studied.[13,57]

Prebiotic compounds (FOS) support the growth of probiotic organisms and are found in foods (eg, onions, artichokes, and bananas). They are not digested in the small bowel and pass into the colon, where they are metabolized into short-chain fatty acids, promote sodium and water absorption, and serve as an energy source for colonocytes. Their use has been studied in constipation, irritable bowel syndrome, and lipid metabolism and necrotizing enterocolitis.[58,59] They have a low cariogenic potential, improve lipid metabolism, protect against colorectal cancer and infectious colitis, increase the bioavailability of calcium and magnesium, and may enhance host defenses.[60–62] Fructans (inulin and oligofructose) and soybean oligosaccharides are among the prebiotics that have been added to foods.[63,64] In both human and animal studies, beneficial effects have also been seen in calcium, magnesium, zinc, and iron nutriture.[65,66]

BONE HEALTH

Bone tissue is continuously being laid down during infancy, childhood, and adolescence, so disease processes that affect the normal pattern of bone accretion will affect ultimate bone health. Peak bone mass (PBM) is the maximum amount of bone mineral that is achieved during the life cycle in all bones in the body. It determines bone health later on in life, and it has been noted that 90% of PBM is achieved by 18 years of age.[67,68] Childhood and adolescence are crucial periods for bone health, not only for healthy children but also for those with chronic disease. Factors

adversely affecting bone development include poor weight and height gain, delayed puberty, immobilization, reduced weight-bearing activity, malnutrition, insufficient calcium intake, vitamin D deficiency, inflammatory conditions, high levels of circulating cytokines, and corticosteroid use.[69]

Bone disease is often suspected when a radiograph is obtained for an unrelated reason and is reported to be "osteopenic." Plain films should not be used to screen for bone disease because these radiographic changes represent a late effect. Indeed, bone disease should be suspected long before a radiograph shows "washed out" bones. In instances in which bone disease is suspected, a DXA assessment should be conducted. This is a safe test, with approximately only one-twentieth of the radiation of a chest radiograph and less radiation than a transcontinental airplane flight. The results are expressed in terms of bone mineral content in grams and bone mineral density (BMD) in g/cm^2. New technology allows for quick scanning of the patient. In children and adolescents, lumbar spine and whole-body scans are obtained. Sufficient normative data using the current technology do not exist for infants and children less than 4 years of age. Reference data are available for lumbar spine scans, and the results are expressed in terms of standard deviation or z-scores. Normative data do not exist for whole-body scans. DXA also evaluates body composition as fat and lean body mass. The use of DXA for body composition analysis has been validated, and DXA is an accepted modality to determine body composition.[70–73]

Although a valuable diagnostic tool, DXA does have some drawbacks. Interpretation of scans is sometimes difficult, especially if there is delayed growth and a significant difference between chronologic age and height age. This is especially true in the patient with delayed pubertal development. Additionally, the reference data for the lumbar spine scans are based on relatively small numbers of subjects. Studies are in progress to combine data sets, collect additional data, and thus improve the reference standards. DXA has clinical value in many disease states. There may be difficulty interpreting the DXA scan in the clinical setting of delayed puberty and growth. In these cases following BMD over time, taking into account that increases in BMD may just be due to maturation and growth and not necessarily due to therapy is important.

Therapy for bone disease is limited in pediatric patients. Important therapeutic options include (1) improving nutritional status and normalizing weight and height; (2) controlling the underlying chronic disease and decreasing inflammation and malabsorption; (3) ensuring adequate or therapeutic intake (diet and/or supplements) of calcium, vitamin D, magnesium, and vitamin K and monitoring levels as indicated; (4) monitoring pubertal status and optimizing pubertal development; and (5) increasing weight-bearing physical activity as appropriate. Those pediatric patients with significantly abnormal BMD and those with increased fracture risks should be prescribed noncontact, weight-bearing physical activity. There are limited data regarding intervention studies using the antiresorptive medications commonly used in adults, and routine use in pediatric patients is not advised at this time.

Osteopenia[74,75] and vertebral compression fractures[76] have been shown in children with IBD. Possible reasons for the osteopenia include malnutrition, poor dietary intake, malabsorption, inflammation, and elevated cytokine levels.[77] Medications can also affect BMD, for example, glucocorticoids and immunosuppressives, which are frequently used in children and adolescents with more severe forms of the disease.[74,75,78] Although lower BMD z-scores have been noted, once these results have been adjusted for bone age, the difference between control subjects and patients is less.[79] Similarly, bone disease has been noted in patients with chronic liver disease.[80] Possible factors include malnutrition, micronutrient deficiency, and malabsorption of vitamins D and K.[81,82] Despite normalizing vitamin D levels, some patients still persist in having bone disease.[83] Bone disease has also been noted in patients following liver transplant, but in children, improvement in BMD frequently occurs.[84–86] Bone disease is also seen in patients with celiac disease.[87] A gluten-free diet may result in some improvement in BMD.[88–90]

CONCLUSION

Nutritional therapy is important in the treatment and prevention of many disorders. This chapter has attempted to provide guidelines for nutritional therapy in selected pediatric disorders and to illustrate how the manipulation of macronutrients and micronutrients can be used in disease treatment and rehabilitation. There is an increase in the use of CAM in the United States, and many pediatric patients, including those with gastrointestinal diseases, are using CAM. Familiarity with these modalities and an open climate for discussion with patients are key to optimal patient care. The foundation for healthy bones is laid down in childhood and adolescence. Attention must be paid to the prevention and treatment of bone disease in those patients with chronic gastrointestinal disease.

6. *Protective* Nutrients

Judith A. O'Connor, MD, MS
Elizabeth C. Utterson, MD
Nancy F. Krebs, MD, MS

The gastrointestinal (GI) tract is a major interface between the host and the environment. It has a dual function, acting as the portal of entry for nutrients used for cell growth and function while serving as a barrier for noxious agents. The epithelial cells and other cells of the GI mucosa rely on nutrients supplied from both the bloodstream and intestinal lumen. These nutrients serve to preserve the integrity and function of the GI mucosa. Protective nutrients or "functional foods" are terms used to describe nutrients or foods that have an effect on the physiologic function of the GI mucosa that is separate from their established nutritional functions.[1] The cells of the GI tract are capable of specific adaptive responses to ingested nutrients. Undernutrition, starvation, inflammation, and noxious agents impair intestinal adaptation and mucosal integrity. The physiologic function of the GI mucosa also varies with age, specifically the premature intestine, infantile intestine, and adult GI tract.[2] Thus, human adult clinical trials may not be relevant to infants or children. Animal studies have suggested that the presence of luminal nutrients is important to intestinal mucosal metabolism, regardless of overall nutritional status.[3,4] Human studies have often not been conclusive and suffer from uncontrolled variables. This chapter reviews the basic physiologic development of the gut and the purported effect of protective nutrients on cell function and immunity. Candidate protective nutrients reviewed include glutamine, arginine, polyunsaturated fatty acids (PUFAs), nucleotides, and zinc. The roles of prebiotics, non-nutritive ingredients in foods that foster growth of beneficial bacteria, and transforming growth factor-β (TGF-β) are briefly explored.

EFFECT OF NUTRITION OR INFLAMMATION ON GUT DEVELOPMENT AND FUNCTION

Because the GI tract undergoes postnatal maturation, the importance of protective nutrients on mucosal integrity may vary with postgestational age. The basic structure of the GI tract is the crypt-villus unit. Mucosal cells are formed at the base of the crypt and, once formed, migrate to the villus tip. During this migration, the cell functionally matures and develops a thick microvillus membrane with numerous glycoprotein enzymes.[2,5,6] These enzymes function in digestion, absorption, and antigen recognition. When the cell reaches the villus tip, programmed cell death occurs, and the cell is extruded. Cell division requires 24 hours, whereas cell migration requires 3 to 6 days.[6] In states of malnutrition, inflammation, or toxins, there is an imbalance of cell renewal and cell death.

Malnutrition resulting from starvation results in a thinning of the mucosa and muscularis. There is a marked increase in the cell-cycle time, which decreases crypt cell proliferation or cell renewal, resulting in a shortening of both the villi and crypts.[7] As a consequence of reduced protein synthesis, there is a decrease in disaccharidase activity.[8] Additionally, decreased cellular immunity and secretory immunoglobulin A produce an environment conducive to bacterial overgrowth.[9] Bacterial overgrowth may produce mucosal injury and bile salt deconjugation, resulting in steatorrhea, diarrhea, and increased nutrient loss.[10] Many chronic disorders, such as Crohn disease, liver or renal disease, malignancy, cystic fibrosis, and celiac disease, are exacerbated by undernutrition and produce a lesion morphologically similar to marasmus.

Diseases that result in protein deficiency often cause a flat villus lesion. The mucosal thickness appears normal owing to marked elongation of the crypt.[11] This flattening results from alterations in protein metabolism, such as hypoalbuminemic protein-calorie malnutrition (kwashiorkor), or an inflammatory response to a specific protein, as in celiac disease, allergic enteropathy, or severe cow's milk or soy protein intolerance. Additionally, profound inflammation or infection may produce a similar lesion. Morphologically, there is an increase in the crypt-to-villus ratio. Physiologically, there is a reduction of the absorptive surface, resulting in a loss of disaccharidase activity and of mucosal integrity. Clinically, this is manifested as malabsorption of macro- and micronutrients.

The intestinal mucosa is highly dynamic in terms of cell renewal and response to nutrients, circulating or local hormones, and neurohumoral influences.[12] The presence of specific glycoprotein enzymes varies with gestational age, and gene expression can also be affected by diet. Expression of the disaccharidase sucrase-isomaltase is modulated by dietary source. Diets high in sucrose and fructose induce gene transcription, whereas diets low in these nutrients have a decreased enzymatic specific activity.[13] Mucosal development and integrity of the gut are dependent on numerous endogenous factors, such as thyroxine, cortisol, gastrin, enteroglucagon, pancreatic

glucagon, growth hormone, and epidermal growth factor.[14] Neurohumoral influences include enteroglucagon, gastrointestinal inhibitory peptide, motilin, and neurotensin. These agents also influence gastric, pancreatic, and biliary secretion.

Human clinical trials cannot control for the various factors affecting gut development and integrity; therefore, the results of clinical studies are often difficult to interpret. Nutrients that may be advantageous in a preterm infant may have no observable advantage for children or adults. Nutrient supplements may be beneficial, harmful, or unhelpful depending on the underlying status of the GI mucosa and the specific disease. Intestinal mucosal requirements may be different in disorders resulting from intestinal inflammation or septic shock compared with requirements for recovery from massive surgical resection, ischemia, toxic injury, or physiologic stress from severe burns. Thus, published human studies evaluating protective nutrients and factors must be interpreted cautiously, and the results cannot be extrapolated to patients of different ages or disease states. Additionally, animal models used to study these factors may not be applicable for human requirements or disease states.

PROTECTIVE NUTRIENTS

Functional food ingredients and nutrients may influence intestinal growth, maturation, and adaptation. Essential nutrients are those that are required for physiologic function and cannot be endogenously synthesized. In states of immaturity or severe catabolism, intracellular stores of specific essential nutrients may become depleted and lead to deficiency, and/or existing biosynthetic pathways of normally nonessential nutrients cannot meet increased metabolic demands. These nonessential nutrients then may become "conditionally essential" and may be potentially useful ingredients in functional foods.

GLUTAMINE

Glutamine is the most abundant amino acid in the human body. It is defined as a nonessential amino acid because it can be synthesized by a wide variety of tissues rich in glutamine synthetase. Glutamine, a structural component of proteins, functions in nitrogen transfer between tissues, is a precursor in the synthesis of nucleotides, and serves as an important nutrient for renal excretion of ammonia.[15] Importantly, glutamine also serves as the substrate for production of glutathione, a crucial antioxidant found in high concentrations in the GI mucosa. Inhibition of its synthesis results in mucosa degeneration, diarrhea, and growth failure.[16,17] Animal studies suggest that GI epithelial cells are highly dependent on glutathione, and oral or intravenous administration of glutathione may be protective against toxicity associated with inflammatory disease, ischemia, oxidative damage, chemotherapy, and radiation.[18]

Glutamine is of interest as a protective nutrient because it is the major fuel source for rapidly dividing cells such as GI epithelial cells, lymphocytes, fibroblasts, and reticulocytes.[16] Although glutamine is an abundant nonessential amino acid, it has been proposed to become a conditionally essential amino acid in catabolic conditions. In severe catabolic stress, humans show an increased efflux of glutamine from skeletal muscle and hepatocytes.[18] Severely ill patients nutritionally dependent on total parenteral nutrition (TPN) are at risk for glutamine deficiency owing to the combination of increased turnover, reduced dietary intake, and absence of this amino acid in parenteral solutions. Glutamine is relatively unstable and is therefore not included in standard intravenous protein solutions.[19] Premature or very low birth weight infants are also at risk for nutritional insufficiency and catabolism. Sparse energy reserves are rapidly depleted, and enteral sufficiency is delayed owing to the immaturity of the GI tract. Additionally, full enteral feeding is often delayed owing to the risk of necrotizing enterocolitis (NEC).

Some adult human studies have shown that glutamine-supplemented TPN has significantly reduced hospital-acquired infection, decreased gut permeability to lactulose, and improved nitrogen balance and protein synthesis after bone marrow transplant.[20,21] Other studies have shown no advantage from enteral or parenteral glutamine supplementation on clinical infections after bone marrow transplant in adults[22] or children (Krebs N, et al, unpublished data, 2000). Enteral supplementation of very low birth weight infants resulted in improved tolerance to enteral feedings and a decrease in the incidence of hospital-acquired infection.[23]

Numerous animal and human studies support a benefit of supplemental glutamine on gut function, including reversal of gut atrophy associated with TPN, radio- or chemotherapy, improved immune function, and reduced episodes of bacterial translocation and sepsis.[16] Although several studies suggest that glutamine supplementation is advantageous, problems with sample size, randomization, and comparable control groups limit interpretation. For example, studies using glutamine-supplemented TPN have been designed to provide isonitrogenous amino acid solutions to patients, but different amino acid admixtures were also used to ensure adequate intake of essential amino acids without excessive nitrogen intake in the test groups. A recent review of clinical trials of glutamine supplementation highlights the challenges of conducting adequately controlled human studies.[24] Short-term studies using intravenous glutamine have generally reported no safety concerns. An exception may be with preexisting liver disease, in which case, further elevation of transaminases has been observed.[24,25] With the putative beneficial effects from controlled trials, glutamine-supplemented enteral formulas are now available (Table 75.6-1). Although glutamine supplementation in parenteral nutrition remains investigational, newer approaches using glutamine dipetides, which have better solubility and heat stability, are expected to enable the development of glutamine-enriched enteral formulas. Well-designed and -controlled trials will be necessary, however, to determine whether such formulations will benefit clinical outcomes.

TABLE 75.6-1 COMMERCIALLY AVAILABLE FORMULAS CONTAINING PROTECTIVE NUTRIENTS

FORMULA	MANUFACTURER	FORM	AMINO ACID SUPPLEMENT	OMEGA-3 PUFA
Vivonex–Pediatric Vivonex–Plus Vivonex–TEN	Novartis Nutrition	Powder	L-Glutamine + L-arginine	–

NA = not added; PUFA = polyunsaturated fatty acid.

ARGININE

Arginine is a nonessential amino acid important in the transport, storage, and excretion of nitrogen. Similar to glutamine, arginine has been postulated to be a conditionally essential amino acid under conditions of catabolic stress.[26] The importance of arginine as a protective nutrient is related to its role as a precursor of nitric oxide (NO). Arginine is converted to NO via a family of enzymes, the nitric oxide synthases (NOSs). There are two identified forms of NOS: the constitutive form (cNOS) and the inducible form (iNOS). Calcium and calmodulin activate cNOS, whereas iNOS is calcium independent. cNOS produces small amounts of NO, which acts as a biologic mediator previously referred to as endothelium-derived relaxing factor. NO derived from vascular endothelium plays an important role in maintaining baseline vasodilator tone. NO derived from cNOS is secreted from peripheral nonadrenergic-noncholinergic neurons meditating neurogenic vasodilatation and regulating various GI, respiratory, and genitourinary tract functions.[27] Compared with cNOS, iNOS is found in a wide variety of cells, including macrophages, neutrophils, mast cells, fibroblasts, hepatocytes, vascular endothelial cells, smooth muscle cells, and cardiac myocytes. Inflammatory cytokines and bacterial endotoxins induce iNOS, whereas glucocorticoids inhibit the induction of iNOS but have no effect on the activity of either the constitutive or the inducible enzyme.

The role of arginine and NO and its relation to immunity and inflammation have been studied in various animal models. Animals supplemented with arginine have higher thymic weight and thymic lymphocyte counts and improved wound healing.[28,29] Tumor-bearing rat models have decreased tumor protein synthesis with improved whole-body protein synthesis. Intestinal integrity was improved with arginine supplementation in rodents subjected to intestinal ischemia, radiation, resection, or transplant.[16] Additionally, bacterial translocation was decreased in rats recovering from radiation enteritis receiving supplemental arginine.[26]

Inflammatory bowel disease (IBD) and neonatal NEC are examples of two human disease states marked by inflammation and increased intestinal permeability. The role of iNOS in adult chronic IBD has been investigated using surgically resected intestine obtained from patients suffering from active ulcerative or Crohn colitis. When compared with intestine resected from adults for other reasons, there was a marked increase in iNOS expression in patients with colitis compared with control specimens.[30] Low levels of serum arginine[31] and glutamine have been demonstrated in premature infants prior to and during an episode of NEC. Using a hypoxia-reoxygenation–induced NEC model in young mice, supplemental arginine or carnitine greatly attenuated hypoxia-induced tissue damage.[32] In a recent prospective double-blind randomized placebo-controlled arginine supplementation trial, 152 premature infants were followed for 28 days. There was a significantly lower incidence of NEC in the arginine-supplemented group. Serum arginine levels decreased in all infants who developed NEC; however, they were significantly higher in the supplemented group than in the control group.[33] Although NEC resembles IBD microscopically, the histopathologic response may result from different mechanisms. Additionally, the apparent protective role of arginine in NEC may not be related to NO production but to other functions of arginine, such as the production of glutamine, nucleotides, and polyamines. Thus, the role of NO and its production from cNOS or iNOS is not completely defined because it appears that NO has both anti- and proinflammatory effects.

Human clinical trials have evaluated arginine supplementation in healthy adults and healthy adult surgical patients. Dietary supplementation in these patients increased lymphocytic immune response and increased exhaled NO.[34] Many clinical trials using arginine supplementation in adult patients at risk of intestinal stress because of trauma, cancer, or critical illnesses have been reported.[16] It is difficult to compare results owing to the variety of other nutrients supplied in these so-called "immune-enhancing" formulations. Two meta-analyses comparing commercially available formulas

have been published. An analysis of 12 trials with a total of 1,557 patients[35] and 22 trials among 2,419 patients[36] showed a decrease in the length of hospitalization, duration of ventilator support, and lower overall infection rates in patients receiving an arginine-supplemented diet. The effect on mortality was not clear. In planned subgroup analysis, patients who were undergoing elective surgery benefited more than did critically ill patients. These studies suggest that the use of arginine-supplemented formulas may be beneficial for discreet patient conditions such as surgical or cancer patients. Further studies are needed to ensure that there is no detrimental effect from such formulas in septic patients or solid organ transplant recipients. Although several supplemented formulas designed to enhance immune function are commercially available (see Table 75.6-1), indiscriminate use of these formulas is not justified.

LONG-CHAIN PUFAS

Long-chain PUFAs are essential for membrane structure, fluidity, and function, specifically in neural and retinal tissues. PUFAs are precursors for the production of prostaglandins, prostacyclins, thromboxanes, and leukotrienes. PUFAs are divided into two broad classes: ω-3 and ω-6 fatty acids. Omega-3 fatty acids are represented by α-linolenic acid (ALA), whereas ω-6 fatty acids are represented by linoleic acid. This nomenclature refers to the location of the first double bond from the methyl terminus. Mammals are unable to insert double bonds into fatty acid molecules closer than the 9 position and thus are dependent on dietary consumption of these essential fatty acids (EFAs). Linoleic acid is found abundantly in the seeds of most plants and is especially high in corn, safflower, and soy oils but is present in only limited amounts in coconut, cocoa, and palm oils. ALA is found in soy and canola oils, as well as marine plants, algae, and phytoplankton. ALA is transformed in the marine food chain, and its derivatives are present in large quantities in some fish oils. Omega-6 fatty acids are the most abundant PUFAs in the Western diet. It is estimated that over the last 100 years, the ratio of consumption between ω-6 and ω-3 PUFAs has changed from 1 to 20:1. This change is associated with the increased use of vegetable oil and changes in agriculture practices. Domestic beef are fed grain rich in ω-6 fatty acids, and modern aquaculture produces fish that contain less ω-3 fatty acids than fish grown in the wild.[37]

Animal cells modify these EFAs into long-chain PUFAs by elongation, desaturation, and β-oxidation. Linoleic acid is modified to arachidonic acid (AA). ALA is modified to eicosapentaenoic acid (EPA) and docosahexaenoic acid (DHA). Premature infants may be limited in their ability to make EPA and DHA from ALA,[38] although quantitative data are very limited. Importantly, ω-6 long-chain PUFA derivatives induce a stronger inflammatory response than ω-3 fatty acid derivatives.

The nutritional importance of specific fatty acids was first reported in weanling rats fed a fat-free diet. These animals developed scaly skin, tail necrosis, impaired fertility and growth retardation, which was reversed or prevented with the addition of either linoleic acid or ALA to their diet.[39] EFAs were initially considered of marginal importance for humans. Infants fed either a fat-free milk–based formula or lipid-free parenteral nutrition developed growth failure and dry thickened skin, which was primarily associated with linoleic acid. ALA deficiency resulted in more subtle clinical symptoms affecting neurodevelopment, visual function, and a peripheral neuropathy.[40]

EFA concentrations in breast milk vary with diet. In breast milk from women in most Western countries, the ratio of AA to DHA is 2:1, whereas in women in Asian or fish-eating communities, the ratio is 1:1 or lower.[37] Determination of the optimal ratio of EFAs awaits further studies. Although the addition of PUFAs to commercially available formulas (Table 75.6-2) may better mimic human breast milk and increase measured fatty acids in plasma and erythrocyte membrane phospholipids, the long-term functional significance of these findings is presently unclear.

Laboratory studies on animal models and clinical trials in human adults suffering from IBD have investigated the immunomodulatory effects of ω-3 PUFAs. The conflicting results in reducing inflammation, prolonging remission, or decreasing steroid requirements are likely due to the multifactorial nature of the disease and the complexity of the immune system.[38] Clinical studies vary in the disease type (Crohn disease or ulcerative colitis), disease location and activity, and the composition and dose of fatty acids supplied. The role of ω-3 fatty acids for the treatment of IBD has yet to be defined.

The role of PUFAs as a protective nutrient in NEC has been investigated in a hypoxia-induced mouse model of NEC. Mice fed a diet deficient in ω-3 fatty acids developed more severe ischemia and had increased levels of platelet activating factor and leukotriene B_4 than did control animals.[41] In a human clinical trial, preterm infants were fed a diet supplemented with egg phospholipids, which contain increased levels of esterified choline, AA, and DHA. When compared with infants fed a nonsupplemented formula, there was significantly less stage II and III NEC.[42] The advantages of routine supplementation for gastrointestinal protection are not clearly defined for preterm and term infants. Special conditions such as NEC and IBD warrant further carefully designed studies.

TABLE 75.6-2 PEDIATRIC FORMULAS CONTAINING POLYUNSATURATED FATTY ACIDS VERSUS HUMAN MILK*

POLYUNSATURATED FATTY ACID	HUMAN MILK	ENFAMIL LIPIL	SIMILAC ADVANCE	PREMATURE ENFAMIL LIPIL
Docosahexaenoic acid	0.15–0.3	0.32	0.15	0.33
Arachidonic acid	0.5–0.6	0.64	0.40	0.67

*Numbers represent percentage of fatty acid content.

NUCLEOTIDES

Nucleotides are nonprotein nitrogen compounds composed of a nitrogenous base, a pentose sugar, and one or more phosphate groups. Nucleotides serve as nucleic acid precursors, physiologic mediators, components of coenzymes, and sources of cellular energy and participate in immunity. Nucleotides can be synthesized de novo, but the process is metabolically costly. An alternative mechanism is the salvage pathway, where preformed nitrogen bases or nucleosides are converted to nucleotides. Nucleotides have been postulated to be conditionally essential during severe malnutrition, rapid cellular growth, or severe disease states. Therefore, nucleotides may also be conditionally essential in conditions such as prematurity, small for gestational age infants, severe diarrhea, short-gut syndrome, NEC, intestinal transplant, or IBD.

Much of the interest in nucleotides arose from the observation that the nucleotide content of human breast milk is significantly higher than that of cow's milk protein formulas. The nonprotein nitrogen content of human milk is approximately 25 to 30% of the total nitrogen content. Nucleotides comprise 2 to 5% of the nonprotein nitrogen. In contrast, nonprotein nitrogen accounts for only 2% of the nitrogen content of cow's milk.[43] Additionally, the nucleotide profile differs in cow's milk compared with human milk, with a lower proportion of cytidine and adenosine derivatives in cow's milk.

Beneficial effects of dietary nucleotides have been demonstrated in several animal models. Dietary nucleotides have been associated with increased mucosal deoxyribonucleic acid (DNA), protein synthesis, villus height, enterocyte proliferation and maturation, and reduced bacterial translocation during recovery from malnutrition.[44–46] Dietary nucleotides promote healing of small bowel ulcers in experimental ulcerative ileitis, decrease the inflammatory response to ischemia and reperfusion, and improve morphologic development of small intestinal mucosa after transplant.[47–49]

The beneficial effects of supplemental dietary nucleotides in humans are less certain. Initial reports suggested that infants fed a nucleotide-supplemented formula (NSF) had an increase in stool bifidobacteria and enterobacteria that mimicked human milk–fed infant stool microflora.[50] In contrast, a more recent study reported that infants fed NSF had reduced amounts of bifidobacteria and enterococci and increased amounts of *Bacteroides* and *Escherichia coli* when compared with human milk–fed infants.[51] Increased postprandial mesenteric artery blood flow has been demonstrated in both term and preterm infants following NSF formula compared with either human milk–fed or nonsupplemented formula-fed infants.[52] Infants fed NSF had an increased antibody response to *Haemophilus influenzae* type b and diphtheria but not to tetanus or oral polio vaccine.[53]

NSF first became available in Japan in 1965 and in the United States in 1989.[53] Currently, most infant formulas contain supplemental nucleotides. To date, no deleterious effects have been reported. The European Commission's Scientific Committee for Food has provided several published guidelines for nucleotide supplementation suggesting that the total nucleotide concentration should be less than 1.2 mg/100 J, which is the same order of magnitude as the free nucleotides in human milk. The latest recommendations from the United States suggest a maximum of 5 mg/100 J for term infant formula and 7 mg/100 J for preterm infant formula.[54] Human milk is considered to be the gold standard for infant nutrition. Thus, the rationale for nucleotide supplementation of infant formula is to mimic the composition of human milk. Because the role of human milk nucleotides for breastfed infants is not known, the indications for nucleotide supplementation of infant formula and the optimal amounts remain somewhat controversial.[55]

ZINC

As an essential trace element, zinc is second only to iron in its abundance in the human body and has a very broad range of functions. For example, approximately 80% of total-body iron in the human is localized to the erythrocyte mass alone, whereas similar total amounts of zinc are spread among thousands of proteins.[56] Zinc functions as a cofactor to more than 100 metalloenzymes involved in DNA synthesis and repair, cellular integrity, bone and liver metabolism, and multiple dehydrogenase and carboxypeptidase reactions.[57] As a component of the zinc finger transcription factors, zinc is critical to both transcription and regulation of gene expression and to cell differentiation and proliferation in rapidly turning over tissues such as the bone marrow, thymus, and GI tract. Acrodermatitis enteropathica is a congenital defect of zinc absorption and transport and represents the prototype of severe zinc deficiency. Affected infants have a characteristic erythematous, vesiculobullous, pustular rash, which is most prominent around the orifices, along with mucous membrane damage, alopecia, nail loss, growth retardation, diarrhea, and recurrent infections. Acquired zinc deficiency is often of mild to moderate severity and typically results from inadequate intake of bioavailable zinc or from excessive losses. Mild zinc deficiency is associated with growth impairment, anorexia, and immune dysfunction, with impairment of both T- and B-cell function in animal models and pediatric populations. Zinc deficiency has been associated with a wide range of malabsorptive conditions, including protein-energy malnutrition, short-gut syndrome, celiac disease, cystic fibrosis, or IBD. Zinc deficiency is associated with decreased resistance to parasitic, fungal, and viral infections.[58] Complicating the assessment of zinc status in disease conditions are the lack of a sensitive biomarker of zinc status and the hypozincemia resulting from redistribution of circulating zinc in conjunction with the acute-phase response. These realities result in dependence on response to carefully controlled zinc supplementation trials to demonstrate preexisting zinc deficiency.[59]

Consideration of the role of zinc as a protective nutrient for the GI tract is particularly complex owing to the circular relationship between zinc deficiency, which causes diarrhea, and diarrhea, which may cause zinc deficiency. The critical role of the GI tract in normal zinc homeostasis is well established, both in terms of absorption of dietary

zinc and modulation of secretion and reabsorption of endogenous intestinal zinc. Thus, pathologic conditions of the GI tract predictably perturb zinc homeostasis and predispose the individual to zinc deficiency, possibly by morphologic changes that alter transit, permeability, and/or absorptive surface, thereby interfering with absorption of exogenous zinc and reabsorption of endogenous zinc. On the other hand, zinc deficiency is associated with induction of proteins that may increase fluid and possibly endogenous zinc secretion into the GI tract. Candidate proteins that have been proposed include uroguanylin and iNOS, both of which reportedly have increased expression during zinc deficiency. The effects of zinc deficiency on the immune system or on the integrity of the mucosal surface may also have adverse effects on the GI tract and predispose the individual to diarrhea.[60]

Regardless of the questions remaining about mechanisms, there is now little doubt that zinc supplementation in vulnerable populations reduces the severity of diarrhea. In a pooled analysis of randomized blinded controlled zinc supplementation trials conducted in developing countries, infants and children who received zinc supplements had a significant reduction in the length of an episode of acute diarrhea, a decreased probability of developing chronic diarrhea, and a lower probability of associated morbidity compared with children who did not receive supplemental zinc.[61] Although the dietary intake and the nutritional status of the subjects in these studies were generally not characterized in detail, they were presumed to have a high prevalence of zinc deficiency, and the positive response was interpreted to be due to correction of the deficiency rather than a pharmacologic effect of the supplement. Since this pooled analysis, similar findings have been reported in other settings of poverty and high infectious burden.[62,63] Ongoing studies are also investigating the role of zinc-supplemented oral rehydration formulas for the treatment of acute diarrhea in developing countries.[16]

Among the most urgent remaining issues are identification of the populations at most risk for zinc deficiency and therefore to be targeted for interventions; the optimal doses, modes, and schedules of supplemental and therapeutic zinc; and, ultimately, identification of sustainable and culturally appropriate strategies to reduce the prevalence of zinc deficiency through changes in dietary practices. In addition to the exigency for eradication of zinc deficiency on a global basis, there is also substantial need for investigations to clarify the potential contribution of perturbations in zinc homeostasis to some of the clinical manifestations of other GI diseases, including especially those with chronic inflammatory components. Investigations to better characterize mechanisms of altered GI function in relation to zinc metabolism and homeostasis will be especially important to optimally define the role of zinc in therapy.

PREBIOTICS

Prebiotics are nondigestible food ingredients that promote the growth and/or activity of natural or supplemented beneficial bacteria residing in the colon, thus enhancing the health of the host (see Chapter 77.2, "The Pediatric Ostomy").[64] Criteria for a classification as a prebiotic are as follows: the substance should not be hydrolyzed or absorbed in the upper GI tract; it is selectively beneficial for growth of commensual bacteria in the colon; and it alters the flora to a healthy balance by inducing favorable luminal or systemic effects in the host.[65] Prebiotics have many of the same attributes of dietary fiber, with an added benefit for selective colonic bacteria, and include short-chain carbohydrates such as inulin and fructo-oligosaccharides (FOSs), soybean oligosaccharides, and galacto-oligosaccharides (GOSs).[65] The putative nutritional and physiologic effects of prebiotics include alteration of the composition of colonic flora, effects on bowel function, enhanced bioavailability of minerals (especially calcium), and possibly beneficial effects on lipid metabolism and on the risk of colon cancer.[66]

The fructans, which include inulin and FOS, have been extensively studied and are naturally present in more than 36,000 plant species as storage carbohydrates.[65] The most popular natural sources of these indigestible ingredients include wheat, onion, bananas, garlic, tomatoes, and chicory. In addition to their natural availability in foods, prebiotics have been used in food manufacturing for calorie reduction. Used as a replacement for fat and sugar in foods such as ice cream, dairy products, confections, and baked goods, they not only add fiber but also maintain a creamy, fat-like feel in the mouth of the consumer.[16]

GOSs are among numerous disaccharides primarily found in human milk,[67] and it seems likely that they survive digestion in the GI tract of the human infant.[68–70] Colonic bifidobacteria possess an enzyme that facilitates preferential use of the oligosaccharide and thereby allow a prebiotic effect of the GOSs. The GOSs thus comprise one of the components of breast milk that facilitates the preferential growth of *Bifidobacterium* and *Lactobacillus* in the colon[67] and may also provide anti-inflammatory effects in the intestine.[71] These protective colonic bacteria ferment the prebiotic substance to release lactic and acetic acid and thus create a desirable acidic environment. There is intense interest in the potential for addition of oligosaccharides to infant formula to provide some of the protective function of human milk. One randomized, double-blinded trial comparing an infant formula containing a mixture of GOSs and FOSs to a similar standard formula without these additives found a higher proportion of bifidobacteria in the infants' stools after 6 weeks of consuming the supplemented formula.[72]

There are few studies of prebiotic therapeutic efficacy in children. A double-blind, randomized, controlled study compared the use of oligofructose-supplemented formula and unsupplemented formula among 123 nonbreastfed infants. The supplemented formula group had a decrease in both the severity and duration of acute diarrhea episodes.[73] A large-scale community-based randomized controlled trial of oligofructose-supplemented infant cereal conducted in infants from a shantytown near Lima, Peru, was not associated with any benefit on the prevalence of

diarrhea, use of health care resources, or response to immunization. The Peruvian infants were between 6 and 12 months of age and were receiving both human milk and complementary foods. The authors concluded that the effects of breastfeeding may mitigate the potential benefit of prebiotic supplementation.[74] Thus, despite the purported benefits of prebiotic consumption, large-scale clinical studies demonstrating the beneficial effects of prebiotics in children are currently lacking.[67] This is likely to remain an area of strong clinical interest, however, because of the potential positive effects on GI health and function.

TRANSFORMING GROWTH FACTOR-β

TGF-β has been shown to antagonize certain proinflammatory cytokines, including interferon-γ, tumor necrosis factor-α, and interleukin-2.[75] Many different authors have proposed that the intestinal mucosa is under a state of "controlled inflammation" owing to exposure to a large variety of antigens.[76] Interferon-γ is known to stimulate the expression of major histocompatibility (MHC) class II proteins on the surfaces of cells. This expression attracts inflammatory mediators to the location of the MHC class II proteins within the small intestine, resulting in inflammation. Enteral formulas that contain certain bioactive molecules may be therapeutic by stimulating the maturation and differentiation of cells and by modulating the immune and inflammatory responses.[75]

Enteral nutrition may pose fewer potential side effects than the current medication treatments used for IBD. Formulas that include bioactive molecules such as TGF-β have been developed for this purpose. In an uncontrolled study, 29 children with active Crohn disease received a TGF-β–supplemented formula. Clinical remission was achieved in 79% of children after 8 weeks of therapy. There was a reduction of interferon-γ and interleukin-8 messenger ribonucleic acid, suggesting an immunologic downregulation.[76] Randomized controlled clinical trials are needed to confirm these findings and to support the routine use of TGF-β–supplemented formulas as a primary treatment for IBD.

SUMMARY

This chapter summarized some of the published animal and human studies evaluating various protective nutrients and substances in relation to maintaining health and function in the GI tract. Some nutrients seem promising for specific disease states, whereas others appear safe but have minimal clinical impact. Despite great strides in medical molecular biology over the last decade, particularly in genomics and proteomics, the ability to detect clinically important changes in GI function remains limited. Clinical trials are often poorly designed and suffer from inadequate numbers and a lack of appropriate control population. Despite the relative lack of controlled studies and questionable clinical efficacy, commercial products containing "protective nutrients" are actively marketed. Indiscriminate use of these products is not warranted. Large carefully designed randomized multicenter studies are needed to further investigate the health claims of these products and to better quantify their potential for primary or adjunctive clinical treatments.

CHAPTER 76

DRUG THERAPY

1. *Immunosuppressive Therapies*

Sue J. Rhee, MD
Athos Bousvaros, MD

Significant progress continues to occur in the medical treatment of autoimmune diseases and graft rejection. Drugs previously studied in clinical trials (eg, mycophenolate, infliximab, sirolimus) have now received regulatory approval from the US Food and Drug Administration (FDA) and are being increasingly used in the treatment of a variety of autoimmune diseases and transplant rejection. Genotyping and blood level metabolite monitoring of 6-mercaptopurine (6-MP) and azathioprine now enable the clinician to improve efficacy and decrease the risk of side effects such as pancytopenia. In addition, basic scientists have continued to elucidate the cellular and molecular mechanisms of T-lymphocyte activation, graft rejection, and tolerance to foreign antigens.

There are three principal uses of immunosuppressive therapies in medicine: prevention of organ transplant rejection, treatment of diseases with a presumed autoimmune etiology, and treatment of graft-versus-host disease. In the case of organ rejection, the primary goal of immunosuppression is to abolish the normal host response against foreign tissues. In contrast, the treatment of autoimmune diseases involves the control of an aberrant immune response that has developed against the host's own tissues.

This chapter first reviews components of the immune response that are potential targets for immunosuppressive therapies. The second portion of the chapter reviews currently available and commonly used immunosuppressive agents. The emphasis is on the mechanisms of action and the pharmacology of these agents. Clinical uses in pediatric gastrointestinal disease are discussed in a limited manner. For further information regarding the therapy of specific diseases, the reader is referred to other chapters within this textbook. Lastly, novel immunotherapies not currently in widespread use are considered.

COMPONENTS OF THE IMMUNE RESPONSE

Immunosuppressive medications block both "classic" immune responses (ie, the response of the immune system to a foreign pathogen or self-antigen) and "nonclassic" immune responses (ie, those seen in rejection, the response of the host's immune system to an allogeneic graft). Classic immune responses are characterized by major histocompatibility complex (MHC)-associated antigen presentation (Figure 76.1-1): CD4 T lymphocytes (which include most T helper [Th] cells) recognize peptides presented by antigen-presenting cells (APCs) expressing MHC class II molecules, whereas CD8 T lymphocytes (which include most suppressor and cytotoxic T cells) recognize antigenic peptides in association with MHC class I expressing cells.[1] In contrast, transplant rejection involves alternative immune responses, including the attack of graft tissue and endothelium by preformed immunoglobulin (Ig)G antibodies (hyperacute rejection), attack of donor tissues by CD4 and CD8 T cells (acute rejection), and the stimulation of fibrosis by leukocytes producing fibrogenic cytokines (chronic rejection). The modes of T-lymphocyte activation also vary in rejection and may include antigen presentation by APCs of the donor graft, and direct recognition by T lymphocytes of MHC molecules without antigen.[2] In general, the magnitude of the immunologic response observed in rejection (allogeneic response) is much greater than that seen in an immune response to microbial infections.

COMPONENTS OF THE CLASSIC IMMUNE RESPONSE

Antigen Uptake and Delivery. An immune response is a humoral and cellular response to either a self- or a foreign antigen, with most antigens being protein fragments (peptides), proteins, or polysaccharides. The classic immune response is summarized in Table 76.1-1 and described in the following subsections. Foreign antigens, including bacteria and viruses, inhaled antigens (pollen), or ingested antigens (foods or toxins), can be prevented from eliciting an immune response by the barrier function of mucosal epithelia. In the digestive tract, gastric acid and pancreatic enzymes degrade bacterial and food antigens,

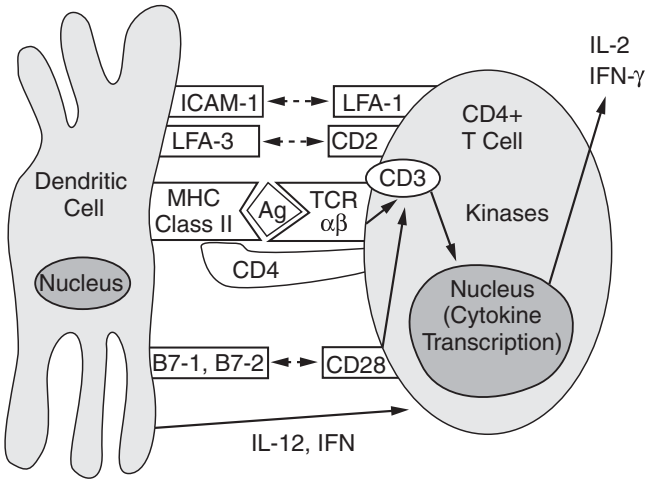

FIGURE 76.1-1 Molecular interactions involved acquired immunity: antigen presentation and helper (CD4) T-cell activation. An antigen-presenting cell (APC; eg, a dendritic cell) endocytoses a dietary or bacterial antigen, digests the protein via endosomes into smaller peptides, and binds the antigen (Ag) to major histocompatibility complex (MHC) class II molecules. The MHC-Ag complex travels to the surface of the APC. Here the MHC-Ag complex binds to the CD4 T cell via the T-cell receptor (TCR). The CD4 molecule strengthens the APC–T-cell interaction by binding to MHC class II. Additional binding occurs by the association of accessory molecules on the APC and T cell, respectively, including intercellular adhesion molecule 1 (ICAM-1)–lymphocyte function–associated antigen (LFA-1), LFA-3–CD2, and B7–CD28. Additional cytokines released by the dendritic cell may determine which cytokines the T cell produces (eg, secretion of interleukin [IL]-12 and interferon [IFN] may promote a T helper 1 cytokine [IL-2, IFN-γ] pattern). The MHC-TCR reaction is the first signal initiating T-cell activation, and B7-CD28 costimulation provides the second signal. If these two events occur, cell signaling via the T cell–CD3 complex and ζ chain occurs (see Figure 76.1-2), resulting in phosphorylation of kinases, cytokine gene transcription through nuclear factor κB, and cytokine synthesis and release.

and intestinal mucin and epithelial cells physically block the passage of antigen. In addition to a simple barrier function, intestinal epithelial cells digest pathogens via intracellular lysosomes and secrete chemokines such as interleukin (IL)-8, which, in turn, recruit polymorphonuclear leukocytes and other cells of the immune system.[3,4] The barrier function of human mucosal epithelia is augmented by secretory IgA, by the cytotoxic properties of intraepithelial lymphocytes, and by the secretion of antimicrobial cryptdins by Paneth cells.[5,6] Both transplanted organs and tissues attacked in autoimmune disease are already located within the host. Therefore, prevention of antigen passage across epithelia will not ameliorate the immune response seen in these disorders.

Antigen Processing and Presentation. The two principal classes of mature T lymphocytes are CD4 cells (which help recruit and activate calls that kill extracellular pathogens) and CD8 cells (which kill cells infected with intracellular pathogens). Helper T cells of the CD4 phenotype are essential in stimulating the inflammatory response to antigen, regulating antibody production, stimulating cytotoxic (CD8) T-cell responses, and recruiting effector cells (such as cytotoxic T cells, neutrophils, and eosinophils). However, CD4 T lymphocytes do not directly bind or respond to antigen unless the antigen is bound to the surface of an APC. APCs are characterized by their ability to phagocytose proteins or peptides, degrade them intracellularly, complex these peptides with proteins of the MHC class II (human leukocyte antigen [HLA] molecules -DP, -DQ, and -DR), and transport these proteins in association with MHC class II molecules to the cell surface of the APC.

The "professional" APC of the body is the dendritic cell. Dendritic cells endocytose antigen and present to T cells via MHC class II molecules (adaptive immunity; see below) and also recognize bacterial constituents (eg, lipopolysaccharide) via either Toll-like receptors present on the plasma membrane or caspase-recruitment domain/nucleotide-binding oligomerization domain receptors in the cell cytoplasm (innate immunity).[7,8] In either case, a dendritic cell stimulated with antigen will express increased levels of costimulatory molecules on the cell surface and also produce cytokines that down-regulate or up-regulate inflammation. The dendritic cell is perceived as a gatekeeper cell, which determines whether an antigen generates an immune response or tolerance (ie, the absence of an immune response).[7] In addition to dendritic cells, other APCs include B lymphocytes, monocytes, and macrophages.[1]

Once ingested, antigen is degraded by proteases in intracellular vesicles termed endosomes. Simultaneously, class II molecules manufactured in the endoplasmic reticulum are transported into the endosomes in association with a transport protein called the invariant chain. Once inside the endosome, invariant chain is cleaved, the MHC class II molecule binds to the antigenic peptide, and the MHCII-peptide complex is transported to the surface of the dendritic or other APC.[9]

Once the antigen-MHC complex has been transported to the surface of the APC, the complex then interacts with the T-cell receptor (TCR) on the surface of the CD4 Th cell (see Figure 76.1-1). The principal component of the TCR is a heterodimeric complex consisting of two covalently linked chains (either the α/β chain or the γ/δ chain). The other components of the TCR complex are the CD3 molecule and the TCR ζ protein; these two proteins mediate intracellular signaling by activation of tyrosine kinases. Binding between the T cell and the APC is strengthened by accessory molecules on the surface of the T cell (eg, CD4, CD28, leukocyte

TABLE 76.1-1 COMPONENTS OF THE IMMUNE RESPONSE

Antigen uptake across mucosal surfaces

Leukocyte homing and adhesion to tissues
Effector cell recruitment
Cytokine and chemokine production
Release of inflammatory mediators (eg, prostaglandin, leukotriene, complement)

function-associated antigen [LFA]-1, and CD2), which bind to corresponding ligands on the surface of the APC (class II MHC, B7, intercellular adhesin molecule 1 [ICAM-1], and LFA-3, respectively; see Figure 76.1-1).[10,11]

To initiate intracellular events that result in CD4 T-lymphocyte activation, at least two binding events (signals) must occur between the molecules on the surface of the APC and the T cell. The first signal is initiated by binding between the peptide-MHC complex on the APC and the TCR-CD4-CD3 complex on the T cell (Figure 76.1-2). Antigen binding to the TCR initiates a cellular signal transmitted through the CD3 molecular complex to intracellular tyrosine kinases. However, stimulation of a T cell by this signal alone does not induce an immune response and may even result in anergy (ie, the absence of an immune response). The second signal in T-cell activation is a co-

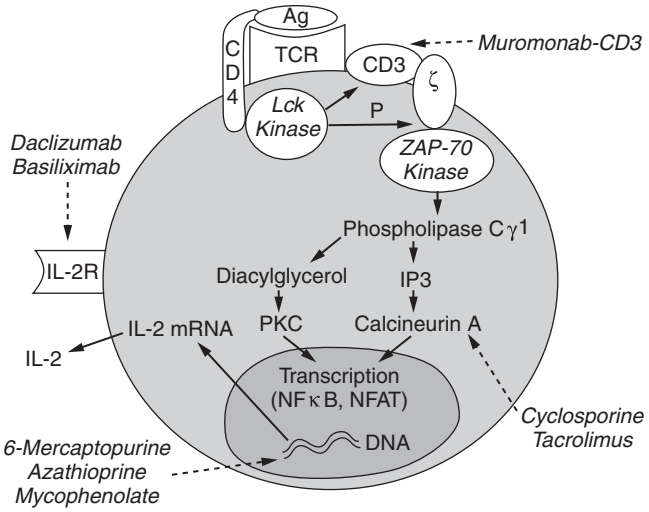

FIGURE 76.1-2 Signal transduction pathways involved in T-lymphocyte activation and sites of action of immunosuppressive therapies. Binding of antigen (Ag) (in association with major histocompatibility complex proteins) to the T-cell receptor (TCR)-CD4-CD3 complex activates intracellular tyrosine kinases. The CD4 molecule is closely associated with the lymphocyte-specific protein tyrosine kinase (Lck), which, in turn, phosphorylates intracellular portions of the CD3 molecule and the ζ chain. The ζ chain, in turn, activates the ZAP-70 kinase, which results in the activation of phospholipase Cγ1. The activated phospholipase converts inositol biphosphate into inositol 1,4,5-triphosphate (IP_3), which, in turn, activates calcineurin A in the cytosol. Calcineurin A is essential in dephosphorylating transcription factors such as nuclear factor κB (NFκB) and nuclear factor of activated T cell (NFAT), which allows the factors to travel to the nucleus. A second pathway activated by phospholipase C and important in promoting transcription involves diacylglycerol and protein kinase C (PKC). The end result is increased intranuclear transcription factor activity, deoxyribonucleic acid (DNA) synthesis, and cytokine (eg, interleukin [IL]-2) production. Cyclosporine and tacrolimus inactivate calcineurin A and inhibit cytokine transcription. Azathioprine, 6-mercaptopurine, and mycophenolate inhibit DNA synthesis. Muromonab-CD3 (OKT3) is a monoclonal antibody that binds to the CD3 molecule, resulting in removal of T lymphocytes from the circulation in vivo. In contrast, the antibodies daclizumab and basiliximab bind to IL-2 receptors (IL-2R) that are present only on activated T lymphocytes. mRNA = messenger ribonucleic acid.

stimulatory signal provided by other APC–T-cell membrane interactions. Although a number of costimulatory signals have been identified, the most important is the interaction between B7 (CD80 or CD86) on the APC with CD28 on the T cell. This interaction promotes T-cell differentiation and cytokine secretion. Additional events include the binding of CD40 on APCs with CD40 ligand on T cells, which may serve to increase the expression of B7 molecules on the APC surface. Cell-cell adhesion is strengthened by binding between ICAM-1 (CD54) on the APC with LFA-1 (CD11a/CD18) on the T cell.[12,13]

T-Lymphocyte Activation. If antigenic stimulation and costimulation occur, a signal is transduced through the CD3 complex, characterized by phosphorylation of tyrosine molecules in the CD3 and ζ chains (see Figure 76.1-2).[14] Subsequently, tyrosine kinases, including lymphocyte protein tyrosine kinase (Lck) and ζ-associated 70 (ZAP-70), are activated and induce phosphorylation of phospholipase Cγ1, which, in turn, converts inositol 4,5-biphosphate to inositol 1,4,5-triphosphate (IP_3).[13,15] IP_3 formation results in increased cytosolic free calcium from intracellular stores and activation of the molecule calcineurin.

A second intracellular signal transduction pathway initiated by phospholipase Cγ1 involves the molecules diacylglycerol and protein kinase C (see Figure 76.1-2).[16,17] These pathways are separate but synergistic, and inhibition of one or the other may abrogate T-cell activation. Calcineurin and protein kinase C enzymes, in turn, promote increased transcription of cytokine gene products mediated by nuclear binding factors, including nuclear factor of activated T cell (NFAT) and nuclear factor κB (NFκB). A third T-cell activation pathway triggered by antigen recognition involves a group of kinases termed mitogen-activated protein (MAP) kinases, which, in turn, activate the transcription factor activator protein 1(AP-1).[18]

Activation of T cells is characterized by increased T-cell deoxyribonucleic acid (DNA) synthesis and proliferation, increased protein synthesis, increased production of cytokines, and increased production of cytokine receptors. Cell membrane proteins (activation markers) present on the surface of activated T cells include the IL-2 receptor CD154 (ie, CD40 ligand, a molecule that promotes B-cell differentiation), CD45RO (a marker for memory T cells), trace amine receptor 1, and signalling lymphocyte activation molecule (a transmembrane receptor that, when activated, induces interferon [IFN]-γ production).[17,19] In addition, activated T cells express a ligand for the protein Fas. Binding of Fas to Fas ligand results in caspase activation and T-cell apoptosis, thereby helping to clear kill activated T cells that have been repeatedly stimulated by antigen.[20] Of importance in immunosuppression, the molecules cyclosporine and tacrolimus (FK506) both inhibit T-lymphocyte activation by decreasing the activity of calcineurin and intranuclear levels of NFAT (see Figure 76.1-2).[21]

Based on studies performed with murine T-lymphocyte clones, Th (CD4) lymphocytes have been categorized into two broad types. Th1 cells promote cellular immune responses and delayed-type hypersensitivity by secreting

IL-2, IFN-γ, and tumor necrosis factor (TNF)-β, whereas Th2 cells promote humoral responses by secreting IL-4, -5, -10, and -13.[22] IL-4, -5, and -13, in turn, promote B-lymphocyte differentiation into plasma cells and antibody synthesis. Both Th1 and Th2 T-cell subsets develop from naive CD4 cells, depending on the type of antigens processed by dendritic cells or macrophages. A Th1 cytokine response promotes macrophage activation with the aim of eliminating intracellular microbes, whereas a Th2 response results in mast cell activation, clearing of parasites, and allergic reactions.[23] Two other groups of regulatory T-cell subsets, Th3 and CD4+CD25+ cells, decrease inflammation and promote tolerance by secreting anti-inflammatory cytokines, such as transforming growth factor-β (TGF-β) and IL-10.[23] Th1 cells are implicated in the pathogenesis of Crohn disease, whereas Th2 cells have been implicated in the pathogenesis of ulcerative colitis and allergic disorders.

Development of Humoral Immunity. In contrast to T lymphocytes, which require processed antigen presented through peptide and MHC, B lymphocytes recognize protein antigen via Ig molecules directly on the cell surface (Figure 76.1-3). Mature B lymphocytes with surface Ig are present in the peripheral blood, spleen, lymph nodes, and lymphoid follicles. Surface Ig on the B-cell membrane binds antigen and provides an initial stimulus for B-cell lymphocyte activation. The antigen–surface Ig complex results in tyrosine phosphorylation, activation of downstream kinases and phospholipase C, and activation of transcription factors. If an activated B cell is to further differentiate into an Ig-producing plasma cell, it requires both physical contact with a T-cell membrane and stimulation by exogenous cytokines produced by T cells (see Figure 76.1-3). IL-2, -4, and -5 promote B-cell proliferation and differentiation, whereas IL-6 perpetuates proliferation of antibody-secreting B cells.[24]

All B cells are initially programmed to synthesize IgM. For a B cell to switch its class of antibody produced to IgG or IgA (isotype switching), several other molecular stimuli need to occur. The CD40 ligand (glycoprotein 39, CD154) is a molecule on the surface of the T cell that binds to CD40 on B cells. This interaction promotes B-cell activation and differentiation and isotype switching from IgM to IgG, IgA, or IgE (see Figure 76.1-3). Conversely, the CD40-CD154 interaction also promotes activation of CD4 T cells. Deficiency of this molecule results in an unusual form of immunodeficiency, termed the hyper-IgM syndrome.[25] Cytokines such as IL-4 are responsible in switching B cells from IgM to IgE production, and TGF-β has been shown to play a role in B-cell switching to IgA production.[26]

Homing and Adhesion. Immune cells that react to a tissue protein must leave the systemic circulation and bind to the tissue or region where they exert their effects. A large number of molecules mediate adhesion between the circulating lymphocytes and the vascular endothelium, extracellular matrix proteins, and tissues. These molecules have been divided into three superfamilies based on their protein structure: the integrin superfamily (including the molecules very late activation [VLA]-1 through VLA-6 and LFA-1), the Ig superfamily (including the molecule ICAM-1), and the selectin superfamily (including the molecules L-selectin and E-selectin).[27,28] Among the more important interactions mediated by adhesion molecules, the β_1 integrin VLA-4 binds the protein vascular cell adhesion molecule 1 (VCAM-1) on the surface of activated endothelial cells. This reaction is blocked by the monoclonal antibody natalizumab (see section entitled "Natalizumab [Antegren]"). The selectin family of molecules, including L-selectin and E-selectin, also promotes binding of lymphocytes to vascular endothelial cells.[27] Soluble cytokines and chemokines promote stronger cell adhesion by increasing the expression of integrins on the cell surface.[29]

Cytokine and Chemokine Production. Activated cells of the immune system, including macrophages, monocytes, and B and T lymphocytes, produce a large number of multifunctional cytokines and chemokines. These can be functionally categorized into Th1-type cytokines, which stimulate cell-mediated immunity and cytotoxicity, and Th2-type cytokines, which stimulate humoral immunity and allergic responses.[30,31] These molecules promote activation of cells of the immune system, recruitment of effector

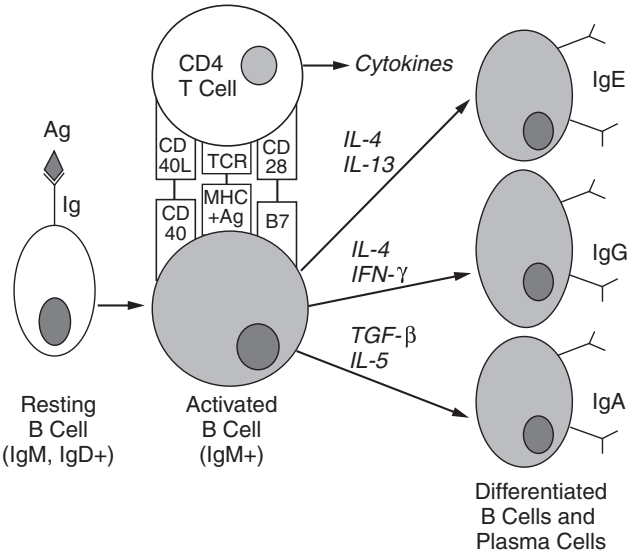

FIGURE 76.1-3 B-cell differentiation and the role of T helper cells. For a resting B cell to differentiate into an antibody-producing plasma cell, three steps are necessary. The first step involves binding of antigen (Ag) onto immunoglobulin (Ig) molecules on the surface of the B cell, which provides an initial signal for B-cell activation. The second step involves physical contact with a T helper lymphocyte, which further activates both the B and the T cell. The three major molecular interactions mediating the B- and T-cell contact involve the CD40-CD40 ligand, major histocompatibility complex (MHC) + antigen with the T-cell receptor (TCR), and B7-CD28. This physical contact promotes B-cell proliferation and differentiation. The third step in B-cell differentiation involves cytokine stimulation. The activated T cell may produce different cytokines, which promote Ig class switching (isotype switching). Differentiation into IgE-producing B cells and plasma cells are promoted by interleukin (IL)-4 and IL-13, IgG-producing B cells are promoted by IL-4 and interferon-γ (IFN-γ), and IgA-producing B cells are promoted by transforming growth factor-β (TGF-β) and IL-5.

cells such as neutrophils and eosinophils, and the production of acute-phase reactants by the liver. Many cytokines have both proinflammatory and anti-inflammatory effects. For example, IL-2 promotes differentiation of Th1 cells, which, in turn, mediate macrophage activation. However, IL-2 can also have anti-inflammatory effects, such as promoting lymphocyte apoptosis and increasing the population of CD4+CD25+ (suppressor type) T cells.[32] Cytokines such as IL-1 and TNF-α mediate the clinical effects (including fever, diarrhea, and hypotension) seen in rejection, shock, and sepsis.[33] IL-5 recruits eosinophils, whereas IFN-γ activates macrophages to phagocytose and kill microbes. Regulatory T lymphocytes release molecules that inhibit inflammation, including IL-10 and TGF-β.[34] Oral tolerance to an antigen develops when dendritic cells exposed to dietary antigens produce IL-10 and TGF-β.[35]

Other Inflammatory Events. The recruitment of effector cells, including eosinophils and neutrophils, together with complement fixation by IgG, follows B- and T-lymphocyte activation. A group of soluble chemoattractant molecules termed chemokines (eg, eotaxin, IL-8) are released by dendritic cells and T cells to recruit eosinophils and neutrophils to the site of inflammation.[36,37] Chemokines also promote the growth of new blood vessels (angiogenesis) and secretion of matrix metalloproteinases.[38] Neutrophils, mast cells, and eosinophils are considered effector cells. Their products (including prostaglandins and leukotrienes by neutrophils, prostaglandins and histamine by mast cells, and eosinophilic chemotactic factor and major basic protein by eosinophils) cause many of the end-stage characteristics of inflammation, including fever, pain, swelling, erythema, cramping, and diarrhea.[39] However, because these events occur late in the inflammatory cascade, therapies targeted against these late manifestations of inflammation (eg, 5-aminosalicylate derivatives, sodium cromolyn, or lipoxygenase inhibitors) are generally less effective at controlling inflammation than immunosuppressive agents that work earlier in the proinflammatory cascade.

Allogeneic Immune Response

The allogeneic immune response to a foreign allograft is a far stronger immune reaction than the classic response to an antigen, involving up to 2% of the total T-lymphocyte population.[40] Multiple mechanisms occur by which a transplanted organ is rejected. First, CD8 cytotoxic lymphocytes from the recipient recognize MHC class I molecules on the surface of the donor tissue. These MHC class I (HLA-A, -B, and -C) molecules differentiate self from nonself, and, in the case of transplant rejection, the HLA molecules of the donor graft are inevitably different from those of the host. The cytotoxic CD8 lymphocytes then bind and destroy foreign cells through the release of cytotoxic molecules (including perforins and granzymes).

Whereas CD8 T cells mediate much of the tissue damage seen in rejection, CD4 T cells are probably even more important. In CD4 knockout mice, allografts are retained indefinitely.[41] In contrast, CD8 knockout mice can still reject allografts. This suggests that CD4 T cells mediate allograft rejection via either stimulation of antibody production or the generation of other cytotoxic leukocytes. The rejection effects of CD4 T cells include enhancing antigen presentation by APCs and promoting the survival and proliferation of cytotoxic T cells and the secretion of proinflammatory cytokines. In addition, CD4 T cells induce dendritic cells to produce IL-12, which induces the proliferation of CD4 cells with a Th1 phenotype.[40,41]

In allograft rejection, CD4 Th cells produce lymphokines such as IL-2 and IFN-γ, which recruit and activate more cytotoxic T cells, thereby propagating both cellular and humoral immune responses. CD4 cells can be activated in one of two ways. The indirect pathway (classic antigen-presenting pathway) involves antigen presentation of foreign (donor) antigens by recipient APCs to recipient CD4 cells. In the indirect pathway, the donor antigens are bound to recipient MHC and are presented to recipient T cells in a way similar to that of a microbial peptide. The second (direct) pathway is unique to transplant recipients and involves recognition of the intact unprocessed MHC of donor APCs by recipient CD4 T cells. The direct T-cell recognition of allogeneic MHC molecules is evaluated by using a mixed lymphocyte reaction.[42]

Despite the complexities and differences between the classic immune response to tissues seen in autoimmune disease and the allogeneic immune response seen in rejection, the final common pathway of both responses involves mononuclear cell activation, generation of proinflammatory lymphokines, and generation and recruitment of cytotoxic effector cells (including macrophages, killer T cells, neutrophils, mast cells, and eosinophils). The most potent immunosuppressive agents currently in use (including cyclosporine, tacrolimus, and monoclonal anti-CD3) either remove host T-lymphocyte populations or inhibit T-lymphocyte activation.

Some individuals, however, develop the ability to tolerate a foreign graft with minimal or no immunosuppression, a condition termed chimerism or transplant tolerance. Tolerance is an ideal outcome because it allows retention of a graft without the long-term toxicity of immunosuppression. Potential mechanisms for inducing tolerance in the host include stimulation of the TCR without the delivery of a second costimulatory signal, infusion of immunosuppressive cytokines at the time of graft delivery, and the promotion of T-cell apoptosis via the Fas–Fas ligand interaction. Another approach to promoting graft tolerance involves the infusion of donor bone marrow cells at the time of solid organ transplant.[43,44] Although the exact mechanism of chimerism or tolerance is not known, it most likely involves the development of a population of CD4 T cells that down-regulate the immune response.[41] At this time, no reliable method exists to consistently promote tolerance in human liver and small bowel transplant recipients.

COMMONLY USED IMMUNOSUPPRESSIVE THERAPIES

Corticosteroids

Corticosteroids are natural or pharmacologically modified molecules that are derivatives of cortisol, which is synthe-

sized from its precursors cholesterol and pregnenolone in the adrenal cortex. Corticosteroids have 21-carbon atoms, with a 2-carbon chain attached at position C_{17} of the sterol molecule; they differ from androgenic steroids, which are 19-carbon steroids.[45] Corticosteroids have a wide variety of endocrinologic, anti-inflammatory, and immunosuppressive effects. Commonly used immunosuppressive corticosteroids, their half-lives, and relative potencies are shown in Table 76.1-2.

Mechanism of Action. Corticosteroids are transported through the circulation to tissues by steroid binding proteins. They then dissociate from the binding protein, cross the cell membrane, and bind to nuclear receptors. The steroid-receptor complex stimulates the production of the NFκB inhibitor IκB, which down-regulates NFκB (the transcription factor that is critical in promoting synthesis of cytokines; see Figure 76.1-3). The end result is decreased synthesis of a wide variety of proinflammatory cytokines, including IL-1, IL-2, TNF-α, and IFN-γ.[46]

Corticosteroids reduce the numbers of lymphocytes in the circulation. In addition, corticosteroids decrease prostaglandin and leukotriene production by blocking arachidonic acid synthesis through effects on the enzyme phospholipase A_2.[47] Corticosteroids do not inhibit phospholipase A_2 directly but rather potentiate the release of lipocortin, a powerful inhibitor of phospholipase A_2.[48] Corticosteroids also down-regulate leukocyte recruitment into inflamed areas by modulating chemokine production.[49] Therefore, corticosteroids have multiple immunosuppressive and anti-inflammatory effects and act on multiple levels of the proinflammatory cascade.

Pharmacology. Corticosteroids are well absorbed from the gastrointestinal tract, principally from the proximal jejunum[50]; up to 30% of corticosteroids are absorbed from retention enemas.[51] In the systemic circulation, 90% of cortisol is bound to serum albumin and corticosteroid binding globulin. Cortisol and other corticosteroids are metabolized by both reduction and glucuronidation in the liver. Inducers of hepatic conjugation, including phenobarbital and rifampin, increase hepatic metabolism and excretion of steroids.[45] Although the plasma half-life of cortisol and other steroids is less than 5 hours, the biologic half-life (as measured by adrenal suppression and tissue effects) is far longer (see Table 76.1-2).[45] The most prominent pharmacologic effect of corticosteroids, suppression of the hypothalamic-pituitary adrenal axis, can occur with as little as 5 days of high-dose (50 mg/d) oral prednisone and is almost universally seen with 14 days of therapy.[50,51]

Adrenal suppression with corticosteroid therapy is assessed by screening of morning cortisol levels or more formal assessment after adrenal stimulation with metyrapone or corticotropin.[52] The degree of adrenal suppression is a function of the dose of the steroid, the mode of delivery, the half-life of the steroid, and the frequency of the doses given. Therefore, twice-daily dosing of prednisone, even with a lower dose, increases the degree of adrenal suppression, and alternate-day prednisone therapy reduces the adrenal suppression. In contrast, alternate-day treatment with dexamethasone has significant side effects because of its longer half-life.[45,51] Inhaled corticosteroids, such as beclomethasone, which are given twice per day to asthmatics, can suppress pituitary function and inhibit linear growth.[52,53] As little as 3 mg/m^2 of prednisone given daily for any longer than 6 months may decrease growth.[54] In contrast, there is no evidence that low-dose alternate-day prednisone therapy results in suppression of growth velocity.

Adverse Events. The large number of side effects (Table 76.1-3) seen with chronic high-dose steroids limits both the dose and duration of therapy.[50] Some side effects (eg, hypertension, fluid retention, diabetes mellitus) may be seen within 2 weeks of the onset of treatment, but most side effects are seen with prolonged (> 1 month) treatment. Loss of trabecular bone and a decrease in bone density occurs in adults treated with more than 7.5 mg/d of prednisone, with the greatest degree of bone loss occurring during the first

TABLE 76.1-2 COMMONLY USED GLUCOCORTICOID PREPARATIONS

few weeks of therapy, when dosages are highest.[55,56] Aseptic necrosis of the hip is also reported to complicate long-term corticosteroid use, but this may be related, in fact, to the underlying disease process.[57] The child on chronic steroid therapy is at increased risk for opportunistic infection, such as disseminated varicella. Ideally, children should be immunized against varicella prior to the institution of corticosteroid therapy. An unexposed, unimmunized child should receive zoster Ig after exposure and acyclovir for active infection. Gastrointestinal side effects (peptic ulcers and pancreatitis) occur only rarely.[58]

Another adverse event of corticosteroid therapy is the development of corticosteroid dependence or corticosteroid resistance. In both autoimmune hepatitis (AIH) and inflammatory bowel disease, the proportion of patients relapsing after weaning or cessation of corticosteroids is greater than 70%.[59,60] In adults with asthma, corticosteroid resistance is associated with decreased levels of the glucocorticoid receptor and increased expression of the cytokine transcription factor AP-1 and other phosphorylated signaling proteins.[61,62] Thus, patients who are corticosteroid resistant may acquire a population of leukocytes resistant to the pharmacologic effects.[63]

Clinical Indications. Corticosteroids are used to treat a wide variety of gastrointestinal diseases, including allergic and eosinophilic gastroenteritis, graft-versus-host disease, liver transplant rejection, inflammatory bowel disease, and AIH. Corticosteroids have no proven efficacy in the therapy of many gastrointestinal diseases, including Reye syndrome, fulminant liver failure, primary sclerosing cholangitis (PSC), Ménétrier disease, and Whipple disease.

Inflammatory Bowel Disease. Corticosteroids are used as induction therapy in moderate to severe active ulcerative colitis. For patients with severe colitis, intravenous methylprednisolone twice daily in a total daily dose of 40 to 60 mg (or 1–2 mg/kg/d) is used, whereas for patients with moderate colitis, 1 mg/kg/d up to 40 mg/d of prednisone is used. Assuming that remission is achieved, one author recommends that the prednisone dosage be reduced by 5 to 10 mg/wk to 20 mg/d and then decreased by 2.5 to 5 mg each week until complete withdrawal of the prednisone.[55] Some clinicians prefer to taper to a dose of between 10 and 20 mg and then wean to an alternate-day regimen. For patients with ulcerative proctitis or left-sided colitis, the use of topical hydrocortisone enemas or foam preparations (Cortenema, Cortifoam) may induce and maintain remission with fewer systemic side effects.[64]

Two large studies in adults have demonstrated the superiority of corticosteroids over placebo in the treatment of active Crohn ileitis and ileocolitis.[65,66] In both the National Cooperative Crohn's Disease Study and the European Cooperative Crohn's Disease Study, 60 to 80% of patients treated with prednisone for approximately 4 months entered remission compared with 30 to 40% of patients given placebo. However, up to 30% of patients persist with active disease despite steroid treatment (ie, corticosteroid resistance), and another 30% of patients will relapse within 1 to 3 months of steroid discontinuation (corticosteroid dependence).[60,67] Risk factors for the devel-

opment of corticosteroid dependence include smoking, young age, and colonic Crohn disease.[68]

Whether alternate-day steroid administration helps prevent the relapse of Crohn disease is controversial. Early studies suggested that alternate-day prednisone was useful in preventing relapse in Crohn disease or ulcerative colitis, but this approach has not been validated in a long-term prospective placebo-controlled trial.[69,70] Given the availability of other effective maintenance therapies, such as 6-MP, this strategy is unlikely to become the subject of a randomized controlled trial.

Autoimmune Hepatitis. AIH is characterized by a mixed cellular inflammatory infiltrate of the hepatic portal areas and parenchyma and by the presence of hypergammaglobulinemia. Older children and teenagers often have anti–smooth muscle antibodies in the serum, whereas younger children frequently present with anti–liver-kidney microsomal antibodies.[71] Prednisone at a dose of 40 mg/d in adults or 1 mg/kg/d in children will improve both symptoms and biochemical parameters of AIH and prolong survival. The response rate to corticosteroid induction in AIH exceeds 80%.[72,73] As with inflammatory bowel disease, AIH has a high rate of relapse once steroids are either tapered or discontinued.[59,74] Therefore, steroids should be slowly tapered over a 2- to 3-month period to a low daily dose while monitoring liver biochemistries and serum Ig levels. To maintain remission once corticosteroid weaning is undertaken, physicians frequently add azathioprine (1.5–2 mg/kg/d) to the therapeutic regimen because azathioprine has been shown to be effective in preventing relapse.[75] Cyclosporine and tacrolimus have been used with success to treat corticosteroid-resistant cases of AIH.[76,77]

Eosinophilic Esophagitis. This increasingly recognized condition presents in children with symptoms of solid food dysphagia, heartburn, and dyspeptic symptoms. Affected individuals frequently have an atopic history. Endoscopy demonstrates a thick, irregular esophageal wall, and biopsies demonstrate large numbers of eosinophils.[78] Both oral prednisone and swallowed fluticasone successfully treat this condition.[79] Teitelbaum and colleagues demonstrated that induction therapy with fluticasone results in improved symptoms and decreased numbers of antigen-presenting T cells.[80] Although fluticasone therapy relieves symptoms, it may be complicated by the development of *Candida* esophagitis. Moreover, relapse following the cessation of therapy is frequent.

Budesonide (Entocort)

Budesonide is a synthetic corticosteroid structurally related to 16α-hydroxyprednisolone. An enteric-coated form designed for controlled ileal release is available in the United States, whereas budesonide enemas also are available in Canada and many European countries. The mechanism of action is similar to other corticosteroids, but because of the rapid first-pass metabolism, budesonide may have fewer corticosteroid-associated side effects.

Pharmacology. Budesonide is available in two principal forms: an oral form (3 mg controlled ileal release capsule), which provides controlled release into the ileum and cecum, and an enema (2 mg/100 mL) designed for drug delivery into the left colon. In both children and adults, budesonide has a low systemic bioavailability (approximately 10 to 15% of the ingested dose). However, following ingestion of a single 9 mg dose of budesonide, plasma cortisol is decreased by approximately 50% in adults and 60% in children.[81] After enema infusion, maximum plasma concentrations of 3 nmol/L are achieved 90 minutes after rectal administration. In the body, budesonide is rapidly metabolized to 6β-hydroxybudesonide and 16α-hydroxyprednisolone, which have 1 to 10% the glucocorticoid activity of budesonide. The elimination half-life of budesonide is approximately 3 hours.[82]

Adverse Effects. Because of the low systemic bioavailability and rapid metabolism of budesonide, it has been proposed to have fewer side effects than conventional corticosteroids. Volovitz and colleagues found no growth suppression in 15 children with asthma who inhaled 100 μg of budesonide 4 times daily for 3 years or longer.[83] In contrast, two asthma studies documented decreased adrenal cortisol output following a 1.2 mg oral dose of budesonide.[84,85] A number of studies in adults with ulcerative colitis suggest that the enema form of budesonide does not decrease basal plasma cortisol levels but may decrease adrenal gland reserve, as measured by adrenocorticotropic hormone testing.[82]

A number of clinical trials in adults using oral budesonide as induction and maintenance therapy in Crohn disease suggest that steroid side effects (moon face, acne, hirsutism) are reduced, but not eliminated, in patients receiving budesonide.[86] In one multicenter study, 67% of patients receiving prednisone (40 mg/d) compared with 44% of patients receiving budesonide (9 mg/day) reported cushingoid side effects.[87] The long-term effects of budesonide on bone density are unclear. In one study, methylprednisolone was noted to impair osteoblast activity (as measured by serum osteocalcin), whereas budesonide did not.[88]

Clinical Use. The principal gastrointestinal indication for use of budesonide has been in the therapy of Crohn disease and ulcerative colitis. Budesonide enemas (2 mg/100 mL) are effective in treating distal ulcerative colitis.[89] For Crohn disease in adults limited to the ileocecal region, 9 mg of budesonide given orally has comparable efficacy to 40 mg/d of prednisone.[90] However, oral budesonide may be less effective than prednisone for disease involving the distal colon and rectum.[87] Lower-dose budesonide (either 3 mg or 6 mg/d) may have some efficacy in the maintenance of remission, but this is controversial. In three identically designed studies, patients were randomized to placebo, budesonide 3 mg/d, or budesonide 6 mg/d. Two studies noted that budesonide prolonged the time to relapse, with the 6 mg/d dose being more effective.[91,92] However, a third study showed no difference in the median time to relapse between groups.[86]

There are extensive data on inhaled budesonide in children with asthma but less information on children with inflammatory bowel disease. In an initial randomized comparison of budesonide and prednisone for the treatment of children with active Crohn disease, budesonide 9 mg/d and prednisone 40 mg/d had comparable response rates after 12 weeks of therapy.[93] However, a subsequent retrospective study by the same investigators suggested that prednisone was more effective induction therapy for active Crohn disease, with a response rate of 77% for prednisone versus 48% for budesonide. In addition, prednisone was effective as rescue therapy in 73% of children who did not achieve a remission with budesonide.[94]

Although budesonide may be less effective as an induction agent, it has the benefit of producing fewer cosmetic side effects, such as moon face, acne, and hirsutism.[93] Whether budesonide suppresses growth with long-term use remains unclear. A large cohort of asthma patients treated with inhaled budesonide and followed for a mean of 9 years demonstrated reduced growth velocity initially but achieved normal final adult height.[95] Kundhal and colleagues described a cohort of children with Crohn disease treated with budesonide who demonstrated a reduced height velocity (mean 2.3 cm/yr) while on therapy.[96] It is unclear from this study, however, whether the growth suppression was secondary to the drug itself or subclinical disease activity. There are limited data on bone turnover and osteoporosis in budesonide-treated children, but results from asthmatics suggest that budesonide likely causes less bone resorption than prednisone.[97]

Cyclosporine (Sandimmune, Neoral)

Cyclosporine is a cyclic 11–amino acid peptide produced by the fungus *Tolypocladium inflatum Gams*. Its potent immunosuppressive properties revolutionized the field of transplant in the early 1980s and made it possible for solid organ transplant (including liver and small bowel transplant) to become a recognized mode of therapy for specific illnesses. Dosages, adverse effects, and pharmacokinetics of cyclosporine and other immunomodulatory agents are summarized in Table 76.1-4.

Mechanism of Action. Cyclosporine enters the cytosol of T cells and binds to the cytosolic protein cyclophilin A (Cyp-A). In the cytoplasm, the cyclosporin A–cyclophilia complex binds to the calcium-dependent phosphatase calcineurin (see Figure 76.1-2). The calcineurin molecule is essential in T-lymphocyte activation and in the transcription of cytokines by Th cells because it dephosphorylates the transcription factor NFAT, thereby facilitating migration of NFATs across the nuclear membrane, leading to decreased transcription and release of IL-2 and other proinflammatory cytokines.[21,98] Of note, only calcium-dependent pathways of T-lymphocyte activation are affected by cyclosporin A. Activation of T lymphocytes via the cell surface molecule CD28 (a calcium-independent process) is not inhibited by cyclosporin A.[99]

The most prominent immunologic effect of cyclosporine is the suppression of IL-2 release by Th cells, resulting in marked inhibition of cell-mediated immunity. The synthesis and release of other cytokines, including IL-6 and -8, are also impaired.[98] Cyclosporin A exhibits a wide variety of other effects on nonhelper T cells (Table 76.1-5). Cyclosporin A impairs the cytotoxic action of CD8 (killer) T cells.[100] Paradoxically, in some animal models, cyclosporin A prevents the development of tolerance and can exacerbate autoimmune disease by blocking the suppressive effects of CD8 suppressor T cells.[101] Cyclosporine also modulates antibody production by B lymphocytes, as well as the release of proinflammatory and chemotactic cytokines by mast cells. Although the in vitro effects of cyclosporine are varied, the net effect of cyclosporine administration to humans is to suppress the cellular immune response without lowering antibody levels.[98,102]

Pharmacology. Cyclosporine is a highly lipophilic molecule. The initial formulation of cyclosporine (Sandimmune, Sandoz Pharmaceuticals Corporation, East Hanover, NJ) consisted of cyclosporine in an oil base. Thus, the oral absorption was dependent on intact fat absorption and bile flow, and the bioavailability of this formulation was quite low (approximately 20–30%). The bioavailability was further impaired in conditions that reduced fat absorption, such as cholestasis and enteropathies.[103] Coadministration of oral D-α-tocopheryl polyethylene glycol 1000 succinate (TPGS) (the water-soluble vitamin E derivative) increases the oral bioavailability of oil-based cyclosporine.[104]

In the late 1990s, an oral-microemulsion formulation of cyclosporine (Neoral, Sandoz Pharmaceuticals Corporation) was made available and is now almost exclusively used by liver and renal transplant centers.[105] The new formulation has improved bioavailability, thus necessitating a reduction in drug dosage of approximately 10 to 15% when patients are converted from the oil-based product.[98] In liver transplant recipients, the frequency of graft survival and patient survival is similar regardless of the formulation.[98] Adverse effects are also comparable in both Sandimmune- and Neoral-treated patients.[106]

Cyclosporine has a large volume of distribution (ranging from 3 to 5 L/kg in adults) and is 90% bound to plasma proteins and erythrocytes. Cyclosporine is hydroxylated and demethylated in the liver and excreted in the bile, with less than 10% of each dose excreted in the urine. Clearance of the drug is biphasic, with an initial elimination half-life ($t_{1/2\alpha}$) of 1.2 hours and a terminal elimination half-life ($t_{1/2\beta}$) of 8 to 27 hours. As a result of dependence on hepatic metabolism, cyclosporine can be used even in patients with renal failure. However, drugs that induce P-450 microsomal enzymes (including phenobarbital, phenytoin, and carbamazepine) decrease cyclosporin A concentrations, whereas compounds that inhibit P-450 enzymes (including ketoconazole, erythromycin, and grapefruit juice) increase cyclosporin A concentrations (Table 76.1-6).[98,103]

The exact protocol for monitoring of cyclosporine levels varies between transplant centers. Traditionally, trough values of cyclosporin A levels are obtained, with a target

TABLE 76.1-4 COMMONLY USED IMMUNOSUPPRESSIVES (PHARMACOLOGY)

DRUG	DOSAGES	HALF-LIFE	METABOLISM AND EXCRETION	ABSORPTION/ BIOAVAILABILITY	DRUG INTERACTIONS	COMMENTS
Cyclosporin A (CyA)	5–10 mg/kg/d orally twice a day (adjust by blood levels); intravenous dose approximately 30% of oral dose	10 h (range 4–48 h)	Hydroxylation and methylation; 95% biliary excretion < 5% urinary excretion	Poor (~ 30%); dependent on bile flow, intestinal absorption; microemulsion (Neoral) has improved absorption.	See Table 76.1-6; multiple medications will either increase or decrease half-life	Liver failure increases half-life
Tacrolimus (FK-506)	0.2–0.4 mg/kg/d orally twice a day (adjust by blood levels)	9 h (range 5–16 h)	Bound to erythrocytes; whole blood levels are 10 times serum levels; 99% hepatic metabolism (hydroxylation/ demethylation) absorption	Poor (~ 30%); less dependent on bile flow or mucosal integrity than CyA	See Table 76.1-6; multiple medications will either increase or decrease half-life	Intravenous form is more toxic than oral; useful in liver bowel transplant because of more reliable oral absorption
Methotrexate	15 mg/m^2/wk intramuscular or subcutaneous	Biphasic: initial phase 1.5–3.5 h; final phase 8–15 h	Hepatic 7-hydroxylation; intracellular polyglutamate formation; 60–90% renal excretion; < 10% biliary excretion	Poor (30–50% absorbed by gut)	Sulfonamides, salicylates, tetracycline, phenytoin may displace methotrexate from plasma proteins	Bioavailability decreases with increasing oral dosage; may enter pleural or ascitic fluid
6-Mercaptopurine (6-MP)	1.5–2.0 mg/kg orally once a day	Triphasic 45 min, 2.5 h, and 10 h	Degradation by xanthine-oxidase *S*-methylation in liver; 40% renal excretion	Variable (10–50% absorbed)	Allopurinol, probenecid, increase level	Wide genetic variations in metabolism, determined by thiopurine methyltransferase activity
Azathioprine	2.–2.5 mg/kg/d orally once a day	5 h	Metabolized to 6-MP, 6-thioinosinic acid	Well absorbed from the gastrointestinal tract	See 6-MP	See 6-MP
Mycophenolate mofetil	20 mg/kg/d in 2 divided doses	18 h (adult)	Hepatic glucuronidation 90% renal excretion	99% bound to plasma albumin		Significant gastrointestinal side effects in 20–30% of patients
Sirolimus (rapamycin)	2–5 mg/d, adults 3 mg/m^2, children	60 h	Hepatic by CYP3A4; excretion by P-glycoprotein	15% oral bioavailability; food interferes with absorption	Multiple, including cyclosporine and other drugs metabolized by cytochrome 3A4	Hyperlipidemia and myelosuppression major side effects

CyA = cyclosporin A; 6-MP = 6-mercaptopurine.

TABLE 76.1-5 IMMUNOLOGIC EFFECTS OF CYCLOSPORIN A

CELL	EFFECTS
CD4 T cell	Decreases IL-2, IFN-γ release Decreases IL-2 receptor expression
Cytotoxic T cell	Decreases proliferation Decreases IL-2 responsiveness Possible decrease in cytotoxicity
B cells	Decreases activation gene expression Decreases anti-immunoglobulin responsiveness
Mast cells	Decreases TNF-α release

IFN = interferon; IL = interleukin; TNF = tumor necrosis factor.

therapeutic range of 150 to 400 µg/L. However, because the half-life is variable, trough values poorly predict the actual concentration of the drug over time (area under the curve [AUC]) and correlate less well than true AUC in predicting rejection or nephrotoxicity.[98] For this reason, many centers calculate AUC by performing a trough level and levels 2 hours and 4 hours after a dose.

Adverse Effects. Cyclosporine, even at therapeutic levels, has a wide variety of adverse effects and toxicities (Table 76.1-7). Nephrotoxicity, manifested by a decrease in creatinine clearance and a rise in serum creatinine, occurs in 25 to 75% of patients. Nephrotoxicity usually reverses on discontinuation of the drug or lowering of the dose. Other adverse effects include hypertension, neurotoxicity, insulin-dependent diabetes mellitus, elevated transaminases, hirsutism, and gingival hyperplasia.[102] In liver transplant recipients receiving cyclosporine, up to two-thirds of patients will have bacterial infection and up to 20% will have infections with opportunistic pathogens such as cytomegalovirus, Epstein-Barr virus, *Candida* species, and *Aspergillus*.[107] Lymphoproliferative disorders also occur in patients receiving cyclosporine, usually correlating with serologic or molecular evidence of Epstein-Barr virus infection.[108] Although lymphoproliferative disease can be reversible if immunosuppression is halted, in a minority of patients, the disease progresses to lymphoma.

Clinical Uses. Cyclosporine has been used primarily in the prevention of rejection in liver transplant recipients. More recently, it has been applied to autoimmune liver and bowel diseases, including AIH, ulcerative colitis, Crohn disease, and autoimmune enteropathy. In pediatric liver transplant recipients, cyclosporine is typically begun on the first postoperative day. Whereas the old preparation (Sandimmune) was given intravenously, the microemulsion preparation (Neoral) can be given orally or via nasogastric tube. In the early post-transplant period, clinicians adjust the cyclosporine dosage to maintain a trough level between 150 and 250 ng/mL, as determined by high-performance liquid chromatography. The oral maintenance dosage of cyclosporine is approximately 5 to 10 mg/kg/d in two divided doses, but higher doses may be necessary with the older preparation.[109] In one Canadian study, 32 children undergoing liver transplant were randomly assigned to receive either the lipid-soluble form or the microemulsion in the post-transplant period. Pharmacokinetic studies performed 3 weeks after transplant demonstrated that patients receiving the microemulsion had a mean 8-hour AUC of 950 µg/L/h compared with 300 µg/L/h with the standard formulation.[110] Thus, in children, the Neoral microemulsion gives higher levels of cyclosporine for a longer period of time. However, it remains unclear if this pharmacokinetic benefit translates into improved graft and patient survival.

Two studies emphasize the efficacy of cyclosporine in children with AIH. Debray and colleagues used cyclosporine (mean dose 4.7 mg/kg/d) alone as primary induction therapy in children with type 2 AIH and obtained remission in six children. In another portion of the same study, the authors successfully used cyclosporine (5.6 mg/kg/d) to induce remission in five patients with type 2 AIH resistant to steroids and azathioprine.[111] In another study, 30 patients with AIH were given cyclosporine as monotherapy for 6 months. Twenty-five of the 30 children had normal alanine transaminase (ALT) levels within 6 months.[112] Therefore, early use of cyclosporine can induce remission in AIH without the use of high-dose corticosteroids.

Dosages used in the therapy of Crohn disease and ulcerative colitis are lower. Brynskov and colleagues demonstrated that an oral dose of 5 to 7.5 mg/kg/d promotes remission of Crohn disease in 22 of 37 adults with steroid-refractory Crohn disease.[113] In contrast, a large multicenter placebo-controlled study using low-dose (2.5 mg/kg) cyclosporine as an adjunct to standard treatment for adults with Crohn disease did not demonstrate any benefit of low-dose cyclosporin A.[114]

For ulcerative colitis, Lichtiger and colleagues demonstrated that intravenous cyclosporin A was effec-

TABLE 76.1-6 IMPORTANT DRUG INTERACTIONS WITH CYCLOSPORINE OR TACROLIMUS

CLASS OF MEDICATION	RAISES CYCLOSPORINE AND TACROLIMUS LEVELS	LOWERS CYCLOSPORINE AND TACROLIMUS LEVELS
Antimicrobials	Erythromycin, clarithromycin, clotrimazole, ketoconazole, itraconazole, fluconazole, doxycycline	Isoniazid, nafcillin, rifampin
Antihypertensives	Diltiazam, verapamil, nicardipine	
Anticonvulsants		Phenobarbital, primidone, carbamazepine, phenytoin
Other	Amiodarone, methylprednisolone, danazol, grapefruit juice, sirolimus	Octreotide, St. John's wort

CMV = cytomegalovirus; EBV = Epstein-Barr virus.
*More common with tacrolimus.
†More common with cyclosporine therapy.

tive treatment in steroid-refractory fulminant colitis. In this trial, 9 of 11 adults treated with cyclosporin A responded within 7 days compared with 0 of 9 receiving placebo.[115] A subsequent study suggested that intravenous cyclosporine (4 mg/kg/d) is effective as monotherapy compared with corticosteroids in the treatment of ulcerative colitis, with a response rate of 60%.[116] In children, given either orally or intravenously at a dose of 4 mg/kg, cyclosporine will bring about remission of ulcerative colitis in up to 80% of children.[117] However, withdrawal of the medication both in children and in adults is associated with a high rate of relapse, even if azathioprine is added as maintenance therapy. Long-term remission rates (> 1 year) are less than 50%.[118] Because the remission induced by cyclosporine is short, it remains a matter of debate whether the benefits of short-term remission outweigh the complications of potent immunosuppressive therapy.

Cyclosporine also has been used to treat autoimmune enteropathy, an idiopathic intestinal inflammatory disease occurring in young children in association with antienterocyte antibodies and evidence of systemic autoimmunity (including renal disease, diabetes, and arthritis). Two groups have treated patients with autoimmune enteropathy with cyclosporin A and noted improved growth and increased nutrient absorption.[119]

Cyclosporine has been used in conjunction with corticosteroids for the treatment of graft-versus-host disease, although the benefit over corticosteroids alone is unclear.[120,121] However, in one study comparing tacrolimus with cyclosporine for prophylaxis of graft-versus-host disease, the incidence of graft-versus-host disease was 18% in the tacrolimus group compared with 48% in the cyclosporine group.[122]

Tacrolimus (FK506, Prograf)

Tacrolimus is a macrolide lactone produced by the fungus *Streptomyces tsukubaensis*. The principal uses of tacrolimus include primary therapy in liver, bowel, and liver-bowel transplants; treatment of cyclosporine-refractory organ rejection; and treatment of graft-versus-host disease. Although the molecule is structurally different from cyclosporine, tacrolimus also works by inhibiting cytokine transcription via calcineurin (see Figure 76.1-3).

Mechanism of Action. Tacrolimus is a lipid-soluble molecule that is internalized into the intracellular compartment of the lymphocyte. Once in the cytosol, tacrolimus complexes with a group of proteins termed FK binding proteins (FKBP, especially FKBP-12). In a manner similar to that of cyclosporine, the tacrolimus-FKBP complex binds calcineurin to inhibit the calcium-dependent pathway of lymphocyte activation. Tacrolimus inhibition of calcineurin results in decreased levels of the NFAT and decreased transcription of T-cell activation genes.[123] Transcription of cytokines produced by activated T cells, such as IL-2, is also drastically decreased. Therefore, T-cell lymphocyte proliferation and cytokine production are blocked by tacrolimus.[124] As with cyclosporine, calcium-independent mechanisms of T-lymphocyte activation are not affected by tacrolimus. In addition to effects on T lymphocytes, tacrolimus inhibits B-cell proliferation and the production of IgM and IgG. At higher doses, tacrolimus also inhibits cytokine production by monocytes and prostaglandin production by mast cells.[125,126] Although tacrolimus and cyclosporine have similar immunologic effects, work in animal models and in humans suggests that tacrolimus also inhibits anti-inflammatory cytokines, such as IL-10, whereas cyclosporine has stronger effects on humoral immunity.[127,128]

Pharmacology. Tacrolimus is 10 to 100 times more potent than cyclosporine. The oral bioavailability of tacrolimus is similar to that of cyclosporine (approximately 30% absorption), but tacrolimus is less dependent on bile flow than cyclosporine for absorption. In fact, tacrolimus absorption is independent of the presence of bile acids, and absorption is less affected by enteropathies. However, coadministration with foods will decrease bioavailability. Once absorbed, tacrolimus is distributed in tissues and in erythrocytes, with a volume of distribution of approximately 1 L/kg.[123]

As with cyclosporine, metabolism of tacrolimus occurs almost exclusively in hepatocytes, with demethylation and hydroxylation occurring via the cytochrome P-450 system. The half-life of tacrolimus is variable, with a mean of 12 hours in both adult and pediatric transplant recipients. Although the half-life is unchanged in renal disease, even mild hepatic impairment will significantly prolong the

half-life. Drugs that inhibit P-450 metabolism, such as ketoconazole and erythromycin (see Table 76.1-7), will raise tacrolimus levels, whereas drugs that accelerate P-450 metabolism decrease tacrolimus levels.[124] Children require higher mg/kg doses than adults because of more rapid drug clearance and higher volumes of distribution.[129] McDiarmid and colleagues compared the dose requirements and clearances of the pediatric and adult liver transplant patients. The overall mean pediatric oral dose for the first year was 0.46 mg/kg/d, a dose approximately three times the mean adult dose.[130]

Toxicities of tacrolimus are similar to those seen with cyclosporine (see Table 76.1-7). Side effects include nephrotoxicity, electrolyte abnormalities (hypokalemia, hypomagnesemia), diabetes mellitus, tremor, hypertension, diarrhea, post-transplant seizures, and lymphoproliferative disease. In addition, patients receiving tacrolimus are predisposed to opportunistic bacterial, viral, and fungal infections. Some side effects seen with cyclosporin A, including hirsutism, coarsening of facial features, and gingival hyperplasia, are not seen with tacrolimus.[124] Cardiomyopathy, a rare but serious complication of tacrolimus therapy, typically resolves after lowering the dose of tacrolimus or changing to cyclosporine.[131]

Clinical Uses. The principal indication for the use of tacrolimus is in the prevention of solid organ transplant rejection.[132] As primary therapy immediately after liver transplant in children, tacrolimus is usually given in a dose of 0.3 mg/kg/d, and the dosage is adjusted to give a whole blood level between 10 and 15 µg/L. Over the first few months after transplant, the drug dosage is weaned to achieve levels of 5 to 10 µg/L. Concomitant therapies include corticosteroids, azathioprine, or mycophenolate mofetil; corticosteroids are weaned over time. A European multicenter trial reported that patients treated with tacrolimus (vs cyclosporine) are more likely to wean off corticosteroids.[133] In one pediatric series, 233 children were given tacrolimus as primary therapy, and, when compared with historical controls treated with cyclosporine, the patient survival was 86% in the tacrolimus group versus 69% in the cyclosporine group. However, this difference may simply reflect improved care of liver transplant patients over time.[134] Histologic rejection rarely occurs in children receiving tacrolimus as primary therapy.[135] Tacrolimus has also been used as rescue therapy for children who have developed either chronic rejection despite cyclosporine therapy or adverse effects of cyclosporine.[136,137]

Tacrolimus has been the mainstay of antirejection therapy for patients having received bowel, combined liver and bowel transplants, or multivisceral transplants.[138] In these settings, tacrolimus is usually given with other concurrent immunosuppression, such as corticosteroids and monoclonal antibodies (eg, daclizumab). Initially, levels may need to be kept higher (eg, 15–25 µg/L) to prevent bowel rejection.[139] Both rejection and lymphoproliferative disease occur more commonly in this patient population.

Tacrolimus has also been employed in a wide variety of nontransplant conditions, including as an alternative to cyclosporine in both type 1 and type 2 AIH.[72,140] Children with autoimmune enteropathy that is resistant to cyclosporine can develop restoration of bowel function and histologic improvement after tacrolimus therapy.[141,142] Open-label studies suggest that tacrolimus is effective in treating severe mucosal and fistulizing Crohn disease, but the rate of adverse events is high.[143,144] In a multicenter open-label experience of tacrolimus in the treatment of severe ulcerative colitis and Crohn colitis in children, 70% of patients responded, but more than 50% underwent colectomy within a year.[145] In graft-versus-host disease, tacrolimus can stabilize or improve cases refractory to cyclosporine; however, in one open-label study of 39 patients, the long-term response was approximately 30%.[146]

Azathioprine (Imuran) and 6-MP (Purinethol)

Both azathioprine and 6-MP are purine derivatives that are incorporated into DNA and inhibit DNA synthesis. Azathioprine is metabolized in vivo to 6-MP, and its biologic effects are essentially identical to those of 6-MP; therefore, both the mechanisms of action and the toxicities of these drugs are identical. In contrast to 6-MP, azathioprine is metabolized more slowly and has a longer half-life. Therefore, azathioprine has been more widely used as an immunosuppressive agent in transplant recipients. Both drugs are useful in the treatment of liver transplant rejection, as well as in the therapy of inflammatory bowel disease and chronic active hepatitis.

Mechanism of Action. 6-MP is converted to 6-thioguanine (6-TG) ribonucleotides by the enzyme hypoxanthine-guanine phosphoribosyltransferase (HGPRT). The ribonucleotides produced by HGPRT are then incorporated into the DNA of rapidly dividing cells and are cytotoxic. In vitro, 6-MP can inhibit Th cell–dependent Ig production. In addition, 6-MP inhibits Ig production by IL-6–stimulated B-cell lines.[147,148]

Pharmacology. The absorption of 6-MP from the gastrointestinal tract is variable; as little as 10% or much as 50% may be absorbed. In contrast, azathioprine is well absorbed from the gastrointestinal tract. 6-MP is primarily metabolized in the liver, but up to 40% can be excreted in the urine.

There are three major pathways of 6-MP metabolism (Figure 76.1-4). The first route involves transformation by HGPRT and other enzymes into 6-TG nucleotides. Because inhibition of lymphocyte proliferation depends on 6-TG, concentrations of 6-TG in the body may predict the therapeutic efficacy of 6-TG. A second metabolic pathway involves breakdown of 6-MP via xanthine oxidase to 6-thiouric acid; because xanthine oxidase can be inhibited by allopurinol, this drug is relatively contraindicated by individuals taking 6-MP. The third pathway is the principal route of catabolism of 6-MP and involves *S*-methylation by the enzyme thiopurine methyltransferase (TPMT) to generate 6-methylmercaptopurine (6MMP).[147]

The half-life of 6-MP is triphasic, with the half-life of the final phase being 10 hours. Allopurinol increases levels of 6-MP by inhibiting xanthine oxidase metabolism. In

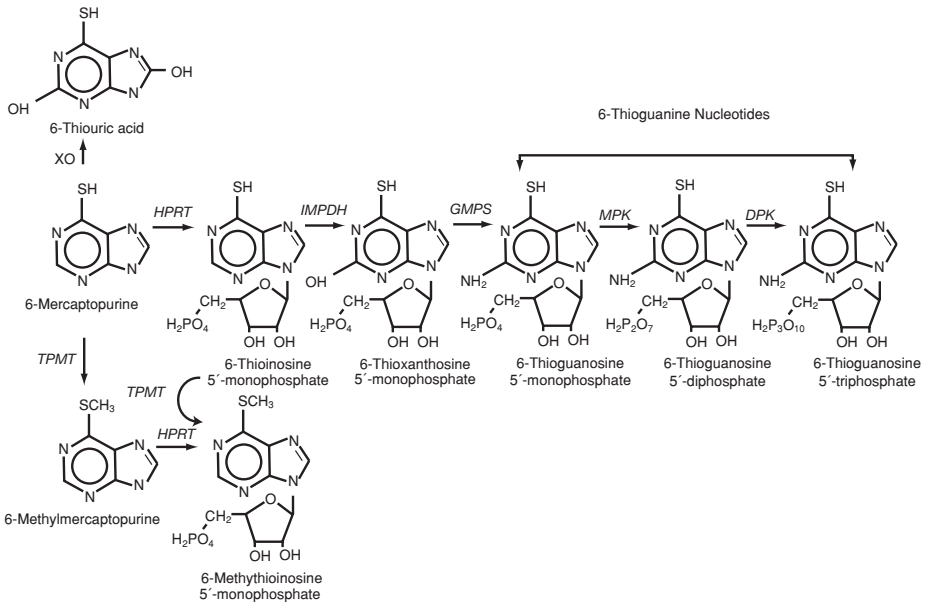

FIGURE 76.1-4 Metabolism of 6-mercaptopurine (6-MP). The initial metabolism of 6-MP may occur via one of three competing enzymatic pathways: thiopurine methyltransferase (TPMT), xanthine oxidase (XO), and hypoxanthine phosphoribosyltransferase (HPRT). Further metabolism of the thinucleotide is catalyzed by inosine monophosphate dehydrogenase (IMPDH) and guanosine monophosphate synthetase (GMPS) to produce 6-thioguanine nucleotides, which are principally responsible for the immunosuppressive effects of 6-MP. Reproduced from Cuffari C et al,[147] with permission of Dr. E. Seidman and BMJ Publishing Group.

addition, probenecid increases the level of 6-MP by inhibiting urinary excretion.[148] There is extensive variability in TPMT activity in human hepatocytes, presumably on the basis of genetic polymorphisms. Approximately 90% of individuals have normal or high TPMT activity and break down 6-MP at a normal rate. Those patients with high TPMT activity have lower concentrations of 6-TG. Lennard and colleagues reported that patients with higher TPMT activity have a higher relapse rate of acute lymphoblastic leukemia, suggesting that the more rapid metabolism of the drug leads to decreased efficacy.[149] Ten percent of individuals have low TPMT activity and have higher concentrations of 6-TG in their tissues and greater potency of the drug; however, this subset of patients may also be at increased risk of myelosuppression. Approximately 0.3% of individuals have negligible TPMT activity, this group is at the highest risk of developing myelosuppression associated with very high 6-TG levels.[147,150] Laboratory tests to determine TPMT genotype, blood TPMT activity, and 6-TG levels are now commercially available.

Adverse Effects and Toxicity. The principal toxic effects of 6-MP are myelosuppression, pancreatitis, elevated transaminases, increased risk of viral infection, and a theoretical increased risk of lymphoma. In one large series of inflammatory bowel disease patients taking 6-MP, 4% developed pancreatitis, up to 10% developed systemic infections, and 1 patient in 400 developed a cancer potentially attributable to the therapy.[151] Whether 6-MP increases the risk of lymphoma remains controversial. Connell and colleagues tracked 755 adults who received 2 mg/kg of azathioprine for up to 15 years (median 12.5 months) and found no increased risk of cancer.[152] However, an increased incidence of Epstein-Barr virus–associated lymphoma was reported in a cohort of 1,200 adults with inflammatory bowel disease treated with either 6-MP or azathioprine.[153] Kirschner described a case series of 95 children who received 6-MP or azathioprine for a mean of 2.2 years. Overall, 82% of children tolerated 6-MP, with the most common complications being elevated aminotransferases (13% of patients), leukopenia (10%), infections (8%), nausea (5%), and pancreatitis (4%).[154]

Clinical Utility. *Inflammatory Bowel Disease.* 6-MP came into widespread use for the treatment of Crohn disease after 1980, when a randomized placebo-controlled trial demonstrated a 70% response rate in patients with steroid-refractory Crohn disease.[155] It is now recognized that 6-MP has multiple beneficial effects in the therapy of inflammatory bowel disease, including a decrease in disease activity, steroid-sparing effects, and the healing and closure of fistulae. In children and adolescents, treatment of Crohn disease with 6-MP (at a dose of 1.5 mg/kg/d) results in similar improvement and response rates.[156] However, there is a 3- to 4-month lag time between the initiation of 6-MP treatment and a clinical response. A 6-TG level of > 235 pmol/10^8 erythrocytes appears to correlate with an improved clinical response.[147,157,158] A subset of patients who may be resistant to treatment with 6-MP includes those with low levels of 6-TG nucleotides and a high ratio of 6MMP to 6-TG, suggesting rapid breakdown of 6-MP and a decrease in levels of active metabolites.[159] 6-TG has been associated with an increased risk of liver toxicity, so this drug cannot be recommended for use.[160]

Children with Crohn disease may benefit from the early use of 6-MP as a maintenance agent. In an important study by Markowitz and colleagues, 55 children with newly diagnosed Crohn disease were induced with prednisone and then randomized to either 6-MP or placebo as the steroid therapy was withdrawn. After 18 months, the relapse rate was 9% in the 6-MP group compared with 47% in the placebo group. In addition, the 6-MP–treated group received a lower cumulative dose of corticosteroids over the 18-month period.[161]

Another potential use of 6-MP in Crohn disease is the prevention of postoperative disease recurrence. One retrospective study in children suggested that early use of 6-MP decreases the recurrence risk in patients undergoing ileal

or colonic resection.[162] Another study suggested that azathioprine heals recurrent ileitis developing in the neoterminal ileum.[163]

Azathioprine also has been widely used in the therapy of inflammatory bowel disease. The results suggest clinical efficacy comparable with that of 6-MP. In one study of the pharmacokinetics of azathioprine, oral azathioprine achieved 6-TG levels comparable to those of 6-MP, although name brand azathioprine (Imuran) gave higher 6-TG levels than the generic drug.[164] In adults with Crohn disease, high-dose intravenous azathioprine is reported to shorten the time to remission.[165] A case series reporting azathioprine use in children with steroid-refractory inflammatory bowel disease identified a response rate of 75%.[166]

Few controlled trials have been performed to evaluate the efficacy of 6-MP or azathioprine in ulcerative colitis. Roughly 60% of patients with ulcerative colitis refractory to steroid tapering demonstrate an apparent clinical response to 6-MP (as defined by both improvement in clinical symptoms and a decrease in steroid dosage).[167] Another study reported a comparable response rate to 6-MP in children with ulcerative colitis.[168] 6-MP and azathioprine maintenance therapy may be particularly useful following treatment of severe colitis with cyclosporine.[118] A small case series of three children suggested that intravenous azathioprine can be effective as primary therapy for fulminant colitis.[169] It is unclear whether therapy with immunosuppressive agents such as 6-MP and azathioprine increases the risk of colon cancer in children with ulcerative colitis. However, for some patients, such therapy is beneficial and can allow the children and the family to psychologically prepare themselves for colectomy.

Liver Disease. Azathioprine is used in liver transplant patients in conjunction with cyclosporine and prednisone (triple-drug immunosuppression); the usual dose used is 1 to 2 mg/kg/d. Azathioprine is not effective in treating acute rejection. The use of azathioprine and the duration of therapy varies with individual transplant centers; some centers discontinue use of the drug within a year of transplant.[170] A retrospective study by van Hoek and colleagues found that patients receiving azathioprine were less likely to develop ductopenic rejection and vanishing bile duct syndrome, 14 of 66 patients (21%) without azathioprine, compared with 1 of 98 patients (1%) receiving 2 mg/kg/d of azathioprine.[171]

Complicating the use of azathioprine in liver transplant recipients is the occasional development of azathioprine-induced hepatotoxicity, including cholestasis, peliosis hepatis, nodular regenerative hyperplasia, and veno-occlusive disease. Withdrawal of azathioprine in patients with azathioprine-associated induced hepatitis generally results in an improvement of liver enzyme tests within a week.[172]

Azathioprine also has been widely used in the treatment of steroid-refractory autoimmune chronic active hepatitis.[173] Traditionally, the therapy of this entity involved high-dose steroid therapy with a slow steroid taper. However, many patients relapse once the steroid dose is tapered. Chronic active hepatitis can be kept in prolonged remission if patients continue to take azathioprine.[75] Thus, a commonly used alternative to prednisone as monotherapy for AIH involves the addition of 50 mg, or more, of azathioprine as a maintenance agent. In adults who relapse on low-dose azathioprine, the dose may be increased up to 150 mg/d.[72] Since up to 80 to 90% of children with autoimmune chronic active hepatitis relapse once corticosteroids are tapered, azathioprine is useful in the treatment of pediatric type I and type II AIH. The addition of azathioprine will also decrease the long-term toxicities and growth-impairing effects of chronic corticosteroid therapy in childhood.

Methotrexate

In 1948, methotrexate was used by Sidney Farber to treat pediatric leukemia. Since then, it has been discovered that lower doses of this drug could also be used to treat autoimmune diseases such as psoriasis, PSC, and primary biliary cirrhosis (PBC). In 1989, the first open trial using methotrexate in patients with refractory inflammatory bowel disease was conducted.

Mechanism of Action. Methotrexate is an inhibitor of the enzyme dihydrofolate reductase and decreases the synthesis of the reducing agent tetrahydrofolate. Tetrahydrofolate is essential in the synthesis of thymidylate, a pyrimidine nucleoside required for DNA synthesis. At high doses, methotrexate inhibits DNA synthesis and is cytotoxic to rapidly proliferating cells. At low dosages, however, methotrexate has no cytotoxic or antiproliferative effects. Instead, methotrexate polyglutamates increase intra- and extracellular levels of adenosine by indirectly inhibiting adenosine deaminase. In neutrophils, this effect leads to a diminished oxidative burst, decreased adhesion to endothelial cells, and decreased production of leukotriene B_4 and TNF-α. In monocytes and macrophages, adenosine inhibits expression of TNF-α, IL-6, and IL-8 and promotes transcription of the anti-inflammatory agents IL-10 and IL-1 receptor antagonist.[174,175]

Pharmacology. Methotrexate can be administered orally, subcutaneously, intramuscularly, or intravenously. The enteral bioavailability varies widely between 45 and 100%.[176] Although oral methotrexate generally has good bioavailability at doses < 15 mg, higher doses can result in poorer absorption. Therefore, high-dose methotrexate is traditionally administered parenterally. The steady-state volume of distribution is approximately 1 L/kg. Although methotrexate undergoes 7-hydroxylation in the liver, the bulk of its excretion (80–90%) occurs in the urine. Less than 10% of methotrexate is excreted into the bile, and there is essentially no extrahepatic circulation. Methotrexate has a biphasic half-life, with the initial phase being 1.5 to 3.5 hours and the terminal half-life 8 to 15 hours.[177] The half-life is increased in patients with renal failure. There is evidence that certain other chemotherapeutic agents, such as cytarabine, lower red blood cell methotrexate levels, but it is unclear whether lower blood levels decrease drug efficacy because methotrexate levels are not routinely monitored.[178]

Adverse Effects and Toxicity. The most common side effects of methotrexate include anorexia, nausea, stomatitis, diarrhea, hepatitis, renal toxicity, bone marrow suppression, opportunistic infections, and, possibly, neoplasm. Severe toxicity usually occurs when high-dose methotrexate is given to treat hematologic malignancies. If leucovorin rescue is not given to patients undergoing high-dose methotrexate therapy, the consequences can be fatal. For autoimmune diseases, however, far lower doses are used, and the primary toxicity of concern has been hepatic fibrosis.[179]

Several studies in patients with rheumatoid arthritis or psoriasis receiving low-dose methotrexate suggest that over a period of years, fatty change in the liver, hepatic lobular necrosis, fibrosis, and cirrhosis rarely occur. As the use of methotrexate has increased, it has become evident that clinically serious liver disease is far less common in patients with rheumatoid arthritis compared with those with psoriasis. Therefore, the recommendations for monitoring by the American College of Rheumatology differ from those of the American Association of Dermatology, with pretreatment liver biopsy recommended only if there is prior excessive alcohol consumption, chronic hepatitis B or C infection, or persistently abnormal baseline aspartate aminotransferase (AST). During therapy, serum AST, ALT, and albumin are monitored at 4- to 8-week intervals. Subsequent liver biopsy is recommended only if the AST is abnormal in 5 of 9 determinations within a 12-month period (6 of 12 determinations if tests are obtained monthly) or if the serum albumin is below normal.[180] Because there is a lack of correlation between liver function abnormalities and liver histology in patients with psoriasis, some physicians still suggest that a liver biopsy be performed after each cumulative dose of 1 to 1.5 g of methotrexate.[181] The effects of methotrexate on liver histology may be formally classified using published criteria.[181]

Until recently, few data regarding hepatotoxicity in patients receiving methotrexate for inflammatory bowel disease have been available.[182] In a study of 32 patients with inflammatory bowel disease receiving a cumulative methotrexate dose of ≥ 1,500 mg, liver chemistry tests were obtained before and during therapy. Twenty patients underwent liver biopsies and had little hepatoxicity despite cumulative doses up to 5.4 g. Although the majority of biopsied patients had mild to moderate steatosis or portal tract inflammation, only one had evidence of fibrosis.[183] In a recent review, it was recommended that liver function tests be checked every 3 months in patients with inflammatory bowel disease receiving methotrexate. If there is an elevation of transaminases, they should be checked monthly. If they are elevated on three consecutive tests or are > 120 IU/L on any one occasion, methotrexate should be stopped or a liver biopsy performed. Some still suggest that surveillance biopsies be considered after 1.5 g of methotrexate or 2 years after starting treatment, whichever is sooner.[184]

Guidelines for biopsy in children are not well established. In one study, 33 children with juvenile rheumatoid arthritis receiving methotrexate (duration of therapy 17–140 months) underwent liver biopsy; 18% had histologic changes, including hepatocellular inflammation or mild fibrosis. In this study, elevated AST or ALT was the best predictor of histologic abnormalities.[185]

In addition to hepatotoxicity, hypersensitivity pneumonitis is a rare but potentially life-threatening event that occurs in < 1% of patients on methotrexate. The onset of fever, cough, shortness of breath, tachypnea, or hypoxia should prompt further evaluation with a chest radiograph and formal pulmonary function testing, and the methotrexate should be discontinued.[186] There have also been case reports of patients on low-dose methotrexate having an increased susceptibility to opportunistic infections, including herpes zoster and *Pneumocystis carinii*. Therefore, although methotrexate is considered to be a less potent immunosuppressive agent than cyclosporine or tacrolimus, the risk of opportunistic infection is still present.

Clinical Uses. In 1989, Kozarek and colleagues used parenteral methotrexate to treat 21 patients with steroid-refractory ulcerative colitis and Crohn disease. Sixteen of 21 subjects had clinical and endoscopic improvement with decreased diarrhea, lowering of the corticosteroid dose, and improvement in disease activity index parameters.[187] Subsequently, the same investigators demonstrated, in an open-label trial, that patients who failed 6-MP or azathioprine therapy could respond to parenteral methotrexate. Further follow-up studies suggest that Crohn disease patients can be maintained in remission with methotrexate, whereas ulcerative colitis patients tend to relapse and require colectomy.[187]

In 1995, Feagan and colleagues conducted a large multicenter trial of intramuscular methotrexate (25 mg weekly) for active Crohn disease. Methotrexate was more effective than placebo in achieving remission (39% vs 19%, respectively) and reducing requirements for prednisone.[188,189] A subsequent multicenter study was conducted to determine the use of methotrexate in the maintenance of remission in Crohn disease. Patients with chronically active Crohn disease who had entered remission after 16 to 24 weeks of treatment with 25 mg intramuscular methotrexate once weekly were included in this study. At week 40, 65% of the methotrexate-treated patients were in remission compared with 39% who received placebo ($p = .01$). Less than 50% of the patients in the methotrexate group had relapsed by the end of the 40 weeks. In addition, fewer patients in the methotrexate group required prednisone for relapse compared with the placebo group (28% vs 58%; $p = .01$). Although nausea and vomiting occurred more frequently among patients receiving methotrexate, none had a severe adverse event. Therefore, patients with Crohn disease can achieve remission with methotrexate therapy, and a low dose is effective in maintaining remission.[190]

In children, Mack and colleagues conducted an open-label trial of methotrexate (15 mg/m^2/wk subcutaneously) in 14 patients with inflammatory bowel disease who had failed 6-MP therapy. After 3 months of therapy, seven patients had inactive Pediatric Crohn's Disease Activity Index (P-CDAI) scores, six still had active P-CDAI scores, and one patient died (most likely unrelated to the methotrexate).[191]

Methotrexate also has been used to treat PBC and PSC. However, studies of methotrexate efficacy in the treatment of PBC have given conflicting results.[192–194]

In a randomized double-blind trial involving 24 patients with PSC, those on methotrexate had lowering of alkaline phosphatase levels but no improvement of liver histology. However, these patients had advanced liver disease, with 50% having cirrhosis at the start of therapy.[195] In another study of 19 patients with PSC, the use of methotrexate, in combination with ursodeoxycholic acid (UDCA), was associated with toxicity without further improvement in liver biochemistries compared with UDCA alone.[196] Therefore, there is little evidence that methotrexate is of benefit in the treatment of PBC or PSC.

Mycophenolate Mofetil (CellCept)

Mycophenolate mofetil (MMF) is an antiproliferative agent that inhibits lymphocyte DNA synthesis and that was given FDA approval in 1995 for the treatment of renal transplant rejection. The drug is now undergoing widespread use in renal, heart, and liver transplant recipients and has been preliminarily studied in inflammatory bowel disease.

Mechanism of Action. MMF is an ester prodrug of the immunosuppressant mycophenolic acid. MMF inhibits lymphocyte proliferation by blocking the de novo synthesis of guanosine nucleotides from inosine via reversible inhibition of the enzyme inosine monophosphate dehydrogenase (IMPDH). Mycophenolic acid is a more potent inhibitor of the type II isoform of IMPDH, which is found in activated lymphocytes, as opposed to the type I isoform, which is expressed in most cell types.[197] Unlike other cell types that can use a salvage pathway for synthesis of guanosine, B and T lymphocytes are dependent on the de novo pathway for generation of guanosine. The effects of this drug are wide ranging and include inhibition of cytotoxicity by T lymphocytes and the inhibition of antibody production by B cells. In vitro, MMF inhibits DNA synthesis and the proliferation of peripheral blood lymphocytes in response to both T- and B-cell mitogens. In addition, MMF alters cell adhesion and decreases the recruitment of inflammatory cells into target tissues by inhibiting glycosylation of adhesion molecules.[198]

Pharmacokinetics. Oral MMF is generally well absorbed, even though intake with food will decrease absorption. The volume of distribution is approximately 3.6 L/kg in healthy adults. In the body, MMF is rapidly converted to mycophenolic acid, the active metabolite. Enterohepatic cycling contributes about 40% to the AUC of mycophenolic acid.[199] Elimination of mycophenolic acid involves glucuronidation by the liver, with renal elimination of more than 90% of the glucuronidated compound and fecal excretion of the remainder. The half-life of the mycophenolic acid is approximately 18 hours in adults. Patients with renal failure (Cr_{Cl} < 25 mL/min) have an increased AUC and a prolonged half-life. In children, AUC increases with increasing age, suggesting that young children metabolize the drug more rapidly.[198,200] Most studies in adults agree that therapeutic drug monitoring can help to avoid adverse effects and optimize immunosuppression. There is increasing evidence that children may benefit from the same monitoring, particularly in the early postoperative period. A trough of 2 to 5 mg/L and an average AUC_{12} of 59 mg/L/h, corresponding to 50% inhibition of IMPDH, is proposed to be sufficient for immunosuppression.[199]

Adverse Effects. The principal side effects of MMF are gastrointestinal and hematologic. Gastrointestinal side effects, including diarrhea, constipation, nausea, dyspepsia, vomiting, esophagitis, and ulcers, occur in up to 30% of patients. Severe neutropenia may occur in up to 2% of patients receiving MMF. Anemia, thrombocytopenia, and leukopenia also occur in 10 to 25% of patients, a rate comparable to that seen with azathioprine.[198] Opportunistic infections (including cytomegalovirus, herpes zoster, and herpes simplex infections) and malignancies (including lymphoproliferative disease and lymphoma) also occur in transplant patients treated with MMF.

Clinical Use. MMF was first studied as a supplemental antirejection medication in renal transplant patients. In a multicenter trial, MMF at doses of 2 or 3 g/d combined with cyclosporine and steroids reduced the incidence of acute rejection to 31% compared with 47% in patients receiving azathioprine.[201] Multiple studies in liver transplant patients also suggest that MMF can provide effective rescue therapy in patients who develop chronic rejection.[202] In one study, 12 of 19 patients who had failed treatment with azathioprine, prednisone, and cyclosporine had complete histologic resolution of rejection when converted from azathioprine to MMF (from 0.25 to 2 g twice a day).[203]

In a study using MMF as part of induction therapy, 350 liver transplant patients were randomized to receive either double-drug therapy (tacrolimus and steroids) or triple-drug therapy (tacrolimus, steroids, and MMF 1 g twice a day). Patients in the double-drug arm who developed acute rejection received MMF as rescue therapy. The rate of rejection was significantly lower at 3 months in the group that received triple-drug therapy ($p < .03$). However, there was no difference in the overall rejection rate or graft survival at the end of follow-up (mean 33.8 ± 9.1 months). This study suggests that MMF does not need to be started immediately post-transplant but can be added to the drug regimen if rejection develops.[202,204] In a prospective study comparing the efficacy of MMF versus azathioprine in 63 liver transplant patients, who also received thymoglobulin and methylprednisolone, there was a trend toward a lower incidence of acute rejection in the MMF group ($p = .06$). There was, however, a decreased rate of thrombocytopenia in patients who received MMF compared with those who received azathioprine (19% vs 47%, respectively).[205] In a pediatric series of 26 patients, MMF (10–12.5 mg/kg/dose twice a day), the combination of microemulsion cyclosporine and prednisone, was found to be effective primary antirejection therapy, with only 20% of patients needing conversion to tacrolimus for persistent rejection.[206]

MMF also has been used as adjunctive therapy in adults with Crohn disease with variable success.[207,208] In one open-label trial involving six patients with refractory

perianal or ileal Crohn disease unresponsive to azathioprine, patients were given 1 g twice a day of MMF. All six patients improved, and four entered full remission.[207] A larger randomized trial involving 70 patients used MMF or azathioprine as a steroid-sparing agent. Response rates, tolerability, and side effects were comparable in both arms of the trial.[208] In an open-label trial, 11 patients with Crohn disease and 13 with ulcerative colitis were treated with MMF 2 g/d and prednisone (starting dose of 60 mg/d followed by a taper of 5 mg/wk to reach a final dose of 5 mg/d). Four patients with Crohn disease and six with ulcerative colitis achieved remission at 3 months. However, remission was maintained in only one Crohn disease patient at the end of the 6-month study.[209]

A pilot study comparing MMF versus azathioprine in 24 patients with active ulcerative colitis found that 42% (5 of 12) of patients who received MMF and prednisolone achieved remission in the first 4 weeks and remained in remission at 1 year. When compared with the azathioprine and prednisone group, however, the rates of remission were lower, the number of relapses higher, and the number of patients weaned off steroids lower. Current data suggest that in inflammatory bowel disease, MMF should only be used as a rescue therapy if more conventional immunomodulatory agents (eg, 6-MP, azathioprine, methotrexate, infliximab) are ineffective or not tolerated.[210]

Although the frequency of intestinal transplant is increasing, there still are limited data regarding the use of MMF in this setting. In one center's experience with 77 intestinal transplant patients, there did not appear to be improved graft survival with MMF compared with three other treatment arms. In addition, it was noted that patients who received MMF tended to have a higher incidence of graft-versus-host disease and post-transplant lymphoproliferative disease compared with the other treatment regimens.[211]

Sirolimus (Rapamycin, Rapamune)

Sirolimus is a hydrophobic macrocyclic lactone produced by *Streptomyces hygroscopicus*. Although structurally similar to tacrolimus, the mechanism of action and adverse effect profiles of the two drugs are quite different. Sirolimus is a potent immunosuppressive drug that has been used in renal transplant and is being increasingly studied in liver transplant as well.

Mechanism of Action. Sirolimus, like tacrolimus, readily penetrates the plasma membrane and binds to FKBP12. Whereas tacrolimus blocks cytokine gene transcription by binding calcineurin, the sirolimus-FKBP12 complex binds to a specific cell-cycle regulatory protein, mammalian target of rapamycin (mTOR). This binding to mTOR then leads to suppression of cytokine-driven (IL-2, -4, -7, and -15) T-cell proliferation, interrupted progression from the G_1 to the S phase of the cell cycle, and inhibition of IL synthesis.[212]

Pharmacokinetics. Sirolimus is manufactured as an oral solution and as a tablet, which are bioequivalent in nature. The oral bioavailability is 14%, and there is rapid intestinal absorption. Intake with food and drugs such as cyclosporine, diltiazem, and ketoconazole will increase exposure to sirolimus. There are interactions with drugs metabolized by cytochrome P-450 3A.[213] More than 90% of drug is excreted in feces, with urine representing only a minor route of elimination (2.2%). The mean half-life is 60 hours, but there is significant interpatient variation, particularly in patients with hepatic impairment and in children. For this reason, therapeutic drug monitoring is recommended.[214]

Adverse Effects. The principal adverse effects associated with sirolimus include hyperlipidemia and bone marrow suppression. Sirolimus raises high-density lipoproteins in serum but also produces much greater elevations of low-density lipoproteins, cholesterol, and triglycerides.[215] Hyperlipidemia occurs in about 40% of renal transplant recipients receiving sirolimus.[214] Bone marrow suppression is reversible and concentration dependent and occurs in 61% of sirolimus-treated patients. Inhibition of critical cytokine signals that promote maturation and proliferation of bone marrow precursors are likely responsible for sirolimus-related myelosuppression. Patients with trough levels ≥ 15 ng/mL tend to have an increased risk for lipotoxicity and myelotoxicity. Other less common adverse effects include diarrhea, epistaxis, noninfectious pneumonitis, arthralgia, and potentiation of adverse reactions to cyclosporine, namely hypertension, acne, and hirsutism.[214,215] The incidence of post-transplant lymphoproliferative disorders in renal transplant patients receiving sirolimus was not significantly different compared with placebo ($p = .162$).[216]

Clinical Uses. Sirolimus has recently been studied in phase III trials in renal transplant and has been used in liver and small bowel transplant. In a multicenter, double-blind, placebo-controlled trial of 576 renal transplant patients, subjects treated with cyclosporine and corticosteroids were then randomly assigned to receive either placebo or sirolimus at either 2 mg/d or 5 mg/d. The primary composite end point (ie, first occurrence for biopsy-confirmed acute rejection, graft loss, or death) at 6 months post-transplant was lower in the sirolimus-treated groups compared with the placebo group. Also, the incidence of biopsy-proven rejection at 12 months was lower in both of the sirolimus groups (2 mg/d and 5 mg/d) compared with the placebo group (24.7% and 19.2% vs 43.3%; $p \leq .002$).[216]

Flechner and colleagues conducted a prospective randomized trial of sirolimus versus cyclosporine in 61 adult primary renal transplant patients treated with basiliximab and MMF.[217] There was no statistically significant difference in the 1-year patient survival, graft survival, and biopsy-confirmed acute rejection rates between the two study arms. At 6 and 12 months, the sirolimus-treated patients had significantly better serum creatinine levels and creatinine clearances compared with cyclosporine-treated patients. This would suggest that calcineurin inhibitor drug avoidance with sirolimus provides comparable immunosuppression while diminishing the nephrotoxic side effects.

A pilot study of 15 liver transplant patients suggested that sirolimus reduces the incidence of rejection when added to prednisone and cyclosporine.[217] In a retrospective review of 14 liver transplant patients with renal insuffi-

ciency or acute mental status impairment, immunosuppression with MMF, corticosteroids, and sirolimus (dose between 1 and 4 mg/d) was used. Six patients developed acute rejection; however, only one required antilymphocytic therapy. The findings suggest that sirolimus may be an alternative immunosuppressive agent when calcineurin inhibitors are undesirable or contraindicated.[218] In another study, 39 liver transplant patients were treated with either tacrolimus or cyclosporin A and sirolimus (dose 2 mg/d), with a 3-day tapered dose of steroids. Patient and graft survival rates were identical to those of historical controls. The incidence of rejection and muromonab-CD3 use was lower than that of historical controls. These findings suggest that liver transplant may be successfully performed with sirolimus and minimal corticosteroid use.[219]

Florman and colleagues have reported on intestinal transplant patients treated with tacrolimus-based immunosuppression and steroids. In addition, subjects received either sirolimus and basiliximab or daclizumab. There was a decreased incidence of rejection among the sirolimus-treated group both at 30 days ($p < .002$) and at 90 days ($p < .02$). There was no significant difference in actuarial 1-year patient survival or graft survival.[220]

Infliximab (Anti-TNF, cA2, Remicade)

Infliximab is a murine-human chimeric monoclonal antibody directed against TNF-α. Over the past decade, infliximab has been used extensively in the treatment of inflammatory conditions such as rheumatoid arthritis and Crohn disease.

Mechanism of Action. TNF-α is a potent proinflammatory cytokine whose effects are mediated by ligation to the receptors, tumor necrosis factor receptor (TNFR)-I and TNFR-II. In addition, both monocytes and lymphocytes express a membrane-bound form of TNF-α that is thought to activate other cells by direct cell-cell contact. When bound to soluble TNF-α, infliximab is able to neutralize its effects, preventing release of other cytokines, such as IL-6.[221] When bound to the membrane-bound form of TNF-α, infliximab is able to fix complement and mediate destruction of TNF-α–producing cells such as T lymphocytes and is thereby able to induce apoptosis of macrophages.[222,223]

Pharmacokinetics. Infliximab is administered as an intravenous infusion, usually given over 2 hours. Recommended adult dosing is as follows:

1. Fistulizing Crohn disease: 5 mg/kg given at weeks 0, 2, and 6
2. Moderate to severe Crohn disease, induction: 5 mg/kg given at weeks 0, 2, and 6
3. Moderate to severe Crohn disease, maintenance: 5 mg/kg every 8 weeks

Infliximab is distributed primarily within the vascular compartment. Serum concentrations of infliximab may be detected up to 8 to 12 weeks after infusion.[224]

Adverse Effects. Infusion reactions are a well-described complication of infliximab therapy, occurring in 4 to 13% of adult patients (Table 76.1-8). Reactions may be immediate or delayed and range in degree from a mild reaction to anaphylaxis. Typical immediate reactions include flushed sensation, shortness of breath, dizziness, hypotension, hives, nausea, vomiting, rash, and numbness. Delayed reactions include joint pain or swelling, rash, and fever. For immediate reactions, patients generally respond to a decreased rate of infusion. Occasionally, however, diphenhydramine or even epinephrine may be required.[225]

Other adverse effects include a risk for reactivation of tuberculosis (TB), development of autoantibodies, risk for infection, and risk of malignancy. Between 1998 and 2002, 101 cases of TB were reported in patients receiving infliximab.[226] Current recommendations include screening for TB prior to the initiation of infliximab therapy.

In the ACCENT I trial of 573 patients with Crohn disease receiving infliximab as a maintenance therapy, 32% had infections (most commonly, upper respiratory tract and urinary tract infections) requiring treatment. More serious infections occurred in 4% of patients.[227]

The development of antinuclear antibodies (ANAs) and rare cases of lupus-like syndrome have been reported. A recent report of 125 patients with Crohn disease receiving infliximab found that 56.8% of patients have developed a positive ANA (titer > 1:40) during treatment. To date, two patients developed symptoms, which resolved after the cessation of therapy.[228] The clinical implication of an elevated ANA in the absence of symptoms has yet to be determined. Eight cases of lymphoma, occurring a median of 6 weeks after initiation of the infliximab treatment, were reported to the FDA between May 1999 and December 2000. There are insufficient data to determine if infliximab directly contributed to the development of the malignancy.[229]

Clinical Use. Infliximab was first used for Crohn disease in 1993.[230] Since then, it has been employed in the treatment of adults with moderate to severe Crohn disease and/or fis-

TABLE 76.1-8 ADVERSE EFFECTS REPORTED IN INFLAMMATORY BOWEL DISEASE AND RHEUMATOID ARTHRITIS PATIENTS TREATED WITH INFLIXIMAB

Infusion reactions	Chest pain, dyspnea, vomiting, urticaria, anaphylaxis
Immune-mediated reactions	Aseptic meningitis
	Antinuclear antibodies and lupus-like syndrome
	Adult respiratory distress syndrome
Opportunistic infections	Tuberculosis, histoplasmosis, *Salmonella*, *Listeria*, *Cryptococcus*, cytomegalovirus, aspergillosis
Hematologic	Neutropenia, thrombocytopenia
Other	Headache, nausea, upper respiratory infection, pharyngitis, sinusitis

Adapted from Cunnane G et al,[275] Cheifetz A et al,[276] Lee JH et al,[277] and Lipsky PE et al.[278]

tulizing disease with inadequate response to more conventional therapies. In a retrospective review of 19 pediatric children with Crohn disease who received one to three infusions of infliximab at a dose of 5 mg/kg over a 12-week period, there was a reduction in the P-CDAI in all patients.[231] In a prospective open-label trial of a single 5 mg/kg infusion of infliximab in 15 children with medically refractory Crohn disease, 14 of 15 (94%) had a decrease of both P-CDAI and daily steroid use. Ten patients (67%) achieved complete remission by 10 weeks.[232] In a multicenter, open-label, dose-blinded trial, 21 pediatric patients received a single infusion of infliximab at a dose of 1, 5, or 10 mg/kg. Improvement in the P-CDAI was observed with all infliximab dosages (median improvement 50%). All achieved clinical response, and 10 of 21 (48%) achieved clinical remission. Adverse events included upper respiratory tract infection, pancreatitis, sinusitis, and appendicitis.[224]

Although infliximab has been effective in inducing clinical response and remission after a single infusion, the benefit of infliximab as maintenance therapy is not as well established. In a multicenter randomized controlled trial of 573 adults with active Crohn disease, subjects received an initial 5 mg/kg infusion and then were randomized to receive repeat infusions of placebo or 5 or 10 mg/kg of infliximab at 8-week intervals. Patients receiving infliximab as maintenance infusions were more likely to maintain remission and to discontinue steroids compared with those who received placebo. However, a cautionary note is highlighted by two patients who died from sepsis.[227]

Randomized trials have not yet established efficacy of infliximab in ulcerative colitis. Nonetheless, initial studies suggest that infliximab may be effective in the treatment of this disease. A double-blind placebo-controlled trial of infliximab conducted in 11 patients with severe, active, steroid-refractory ulcerative colitis was terminated early because of slow enrolment. Nevertheless, 4 of 8 patients who received infliximab were considered treatment successes compared with none of the 3 receiving placebo.[233] In another study, eight patients with refractory ulcerative colitis scheduled for surgical colectomy were treated with a single 5 mg/kg infusion of infliximab. All patients experienced marked improvement in clinical symptoms, colonoscopic findings, and histopathology.[234] Nine children with moderate to severe ulcerative colitis unresponsive to conventional therapies were treated with infliximab infusions. Seven (77%) patients had improvement in activity of their disease at a median follow-up of 20 weeks.[235]

The formation of antibodies to infliximab (ATI) is associated with an increased risk of infusion reactions and diminished efficacy of repeated infusions. The use of concurrent immunosuppressants and the administration of a second infusion of infliximab within 8 weeks of the first both reduce ATI formation.[236] In a cohort of 125 patients with Crohn disease treated with infliximab, ATI were detected in 61% of patients. The presence of antibody was associated with an increased risk of infusion reactions and a reduced duration of response to treatment.[237] Another study found that 19 of 53 patients (36%) developed ATI. Loss of initial response and incidence of infusion reactions were strongly related to ATI formation. Following this finding, 80 patients were randomized to receive intravenous hydrocortisone 200 mg or placebo prior to infusions of infliximab. At week 16, whereas ATI levels were lower among hydrocortisone-treated patients (1.6 vs 3.4 µg/mL, $p = .02$), there was no reduction in infusion reactions.

Antilymphocyte Antibody Preparation: Muromonab-CD3 (Orthoclone, OKT3, Monoclonal Anti-CD3)

Polyclonal antisera to human T cells (antilymphocyte globulins) were developed in the 1970s for the treatment of organ rejection and hematologic malignancies. However, such preparations were variable in their potency (because they were prepared by generating immune responses in vivo in animals) and contained extraneous antibodies. Muromonab-CD3 is a purified monoclonal IgG2a antibody obtained from murine ascites directed against the CD3 antigen on human T lymphocytes. Treatment with muromonab CD3 results in the short-term depletion of systemic T lymphocytes and a dramatic inhibition of lymphocyte cytotoxic reactions. This drug is now accepted therapy for the treatment of acute cellular graft rejection.

Mechanism of Action. Muromonab-CD3 binds to virtually all differentiated human T lymphocytes through the CD3 molecule. The CD3 complex is essential for signal transduction between the TCR and the intracellular kinases, resulting in T-lymphocyte activation. In vitro effects of anti-CD3 are complex; anti-CD3 can cause polyclonal T-lymphocyte activation, but only when a second signal (such as phorbol myristate acetate or a monocyte–T-cell interaction) is delivered in addition to the anti-CD3. In vivo, however, muromonab anti-CD3 opsonizes T cells; the coated T cells are subsequently removed by cells of the reticuloendothelial system or lysed by complement. Within 1 hour of muromonab-CD3 administration, CD3+ T lymphocytes are cleared from the systemic circulation.[238]

Pharmacologic Aspects. Muromonab-CD3 must be given intravenously to prevent degradation. Goldstein and colleagues demonstrated in adult renal transplant recipients treated for rejection that a once-daily dose of 5 mg maintains a steady-state level of 800 to 1,000 µg/L, a level adequate to block cytotoxic T-cell function and facilitate T-cell clearance.[239] Cessation of treatment results in a rapid return of peripheral blood CD3 T cells, which reach normal levels within a few days. Therefore, muromonab-CD3 must be administered for 10 to 14 days to have a sustained effect. Alloway and colleagues demonstrated that a lower dose of muromonab-CD3 (2 mg daily) as prophylactic therapy for rejection of renal allografts is as efficacious as the higher (5 mg) dose.[240] Dosage for smaller pediatric recipients is 2.5 mg/d (weight < 30 kg) and 5 mg/d for those with body weight > 30 kg.[241]

Adverse Effects. The adverse effects of muromonab-CD3 require that the first few doses be given in hospital and currently limit this therapy to transplant recipients

(Table 76.1-9). The administration of muromonab-CD3 is associated with a variety of adverse effects known as the cytokine release syndrome. This occurs as a result of the systemic release of cytokines (including TNF-α and IFN-γ) by activated or lysed T lymphocytes.[242] Symptoms generally include fever, chills, shortness of breath, nausea, vomiting, diarrhea, headaches, and myalgias. Less commonly, patients experience wheezing, thrombocytopenia, hypertension, and rash.[238] More serious, and rarer, complications of muromonab-CD3 include pulmonary edema (which generally develops in patients with fluid overload) and aseptic meningitis.[238]

Long-term side effects include overwhelming infection with conventional and opportunistic pathogens (particularly herpes simplex virus and cytomegalovirus).[243,244] In addition, treatment with anti-CD3 places transplant patients at increased risk for the development of lymphoproliferative disease or other hematologic malignancies.[245]

TABLE 76.1-9 ADVERSE EFFECTS OF MUROMONAB-CD3 (OKT3)

"First-dose syndrome": > 50% of patients
Fever
Chills
Tremor
Dyspnea
Wheezing
Nausea/vomiting
Diarrhea
Rash
Joint pain
Tachycardia, hypertension (rare)
Pulmonary edema (rare)
Aseptic meningitis
Interstitial nephritis
Infections (especially cytomegalovirus, adenovirus, herpes simplex)
Lymphoproliferative disease

Adapted from Todd P and Brogden R,[238] McDiarmid S et al,[243] and Fung J and Starzl T.[249]

Clinical Use. Pediatric gastroenterologists use muromonab-CD3 almost exclusively in the treatment of liver transplant recipients. Currently, muromonab-CD3 is used to treat episodes of acute rejection usually after courses of high-dose steroid therapy have failed. The drug also is useful in patients who have renal dysfunction, which limits the use of cyclosporine.[243]

Treatment of acute rejection with muromonab-CD3 reverses rejection up to 70 to 80% of cases in adult series and improves allograft survival.[246] A randomized trial found muromonab-CD3 better than high-dose steroids (73% vs 23% response rate) in treating the first episode of rejection following liver transplant.[247] However, a large pediatric study using muromonab-CD3 to treat liver transplant rejection reported a success rate in treating rejection of only 59%. In addition, the majority of patients still had greater than 5% CD3+ cells in their peripheral blood during therapy. The investigators concluded that pediatric patients may be less responsive to muromonab-CD3 than are adults.[243]

Administration of a second course of muromonab-CD3 is less effective than the initial course of therapy owing to the development of anti-idiotype antibodies, which inactivate the molecule. Antibody production can be measured, however, and patients who develop only low-titer antibodies after the first course of muromonab-CD3 may be successfully treated with a second course.[238,248] Muromonab-CD3 also has been used as prophylaxis in the immediate postoperative period following liver transplant.

Although clearly effective in prevention of rejection, muronomab does not appear to offer any demonstrable benefit over conventional immunosuppression (calcineurin inhibitor, azathioprine, and prednisone). The cost and future risks of opportunistic infections and malignancy limit its use.[249]

IL-2 Receptor Antibodies

Another target for monoclonal antibodies is the IL-2 receptor (IL-2R). T cells involved in acute rejection are characterized by increased expression of activation markers such as IL-2R. The IL-2R is composed of three chains (a 55 kD α chain, a 75 kD β chain, and a 64 kD γ chain) and is present on activated T cells. Binding of IL-2 to IL-2R results in T-cell proliferation and clonal expansion of activated T lymphocytes. Anti–IL-2R antibodies (antibodies to the α chain of the IL-2R) are designed to provide greater selectivity against only those lymphocytes directly involved in the immune response because resting T lymphocytes express low levels of the IL-2R.

IL-2R antibodies were initially developed for use in induction protocols for renal transplant patients. There have been good results in this setting, with a decreased incidence of acute rejection and minimal side effects. More recently, use has been applied to the prophylaxis of acute rejection in liver transplant patients. Two antibodies are now commercially available, both of which contain the hypervariable regions of the murine anti–IL-2R antibody (anti-Tac) involved in binding the α subunit. The main differences between the two are the half-life, the proportion of murine to human sequences, and the affinity to its target.[250]

Daclizumab (Zenapax). In a study by Koch and colleagues, the pharmacokinetics and pharmacodynamics of daclizumab in liver transplant patients were investigated. Patients were given daclizumab at a dose of 1 mg/kg within 6 hours of graft reperfusion on day 0 and then a dose of 0.5 mg/kg on day 4 following transplant. This dosing regimen provided effective blockade of the IL-2Rα for at least 14 days after transplant. CD25+ cells are decreased for 28 days following administration of daclizumab. Whereas the half-life of daclizumab in renal transplant patients is 273 hours, in liver transplant patients, it is significantly shorter (99 hours). Drug clearance through drained ascites, postoperative blood loss, or loss of antibody into intercellular and extravascular spaces may account for this difference. To date, no human antibody responses against daclizumab have been reported.[250]

An initial study by Hirose and colleagues investigated the use of daclizumab (1 mg/kg on day 0 then at 2-week intervals for a total of five doses) as part of an induction therapy with mycophenolate and corticosteroids but with-

out calcineurin inhibitors. Treatment with daclizumab in the absence of calcineurin inhibitors was ineffective, with a 100% acute rejection rate. One possible explanation was inadequate dosing of daclizumab.[251] In a subsequent study of 39 adult liver transplant patients, daclizumab was used as adjunctive therapy to an induction regimen of corticosteroids and cyclosporine or tacrolimus. The daclizumab group experienced less acute rejection (18% vs 40%; $p = .02$) in the first 6 months compared with the control group.[252] Heffron and colleagues conducted an open-label prospective study of daclizumab in pediatric liver transplant recipients. Twenty patients received a single dose of daclizumab (1 mg/kg) within 24 hours after liver transplant, and tacrolimus was withheld for 7 days following surgery. A historical control group of patients who received tacrolimus immediately following tranplant was used for comparison. Both groups of children also received mycophenolate and corticosteroids. There were fewer episodes of acute rejection in the daclizumab-treated group compared with historical controls ($p = .002$).[253]

Basiliximab (Simulect). In comparison with daclizumab, basiliximab has a shorter half-life (approximately 6.5 days in renal transplant patients) and is less humanized but has a higher affinity for IL-2Rα. The role of basiliximab in liver transplant is still being developed. In a multicenter randomized controlled trial, 381 adult liver transplant patients received basiliximab 20 mg on days 0 and 4 in addition to cyclosporine and corticosteroids. There was a decreased acute rejection rate in patients receiving basiliximab (33.1% vs 47.6%; $p = .034$).[254] In a smaller study, seven pediatric liver transplant recipients with steroid-resistant rejection received one or two doses of basiliximab (10 mg for patients < 30 kg, 20 mg for patients > 30 kg; doses were given 3 to 7 days apart). Primary antirejection therapy consisted of cyclosporine, azathioprine, and prednisolone in four patients and tacrolimus and prednisolone in three others. All had received high-dose steroids for acute rejection and were converted to tacrolimus, followed by the addition of mycophenolate. Five of the patients had improvement, as measured by biochemical responses and by liver biopsy. There were no immediate side effects associated with basiliximab. However, two children went on to develop chronic rejection and subsequently died.[255]

OTHER AGENTS

Leflunomide (Arava)

Leflunomide is a relatively new immunosuppressive agent that inhibits dihydroorotate dehydrogenase.[256] It is an isoxazole derivative that is converted by first-pass metabolism in the liver and gut to an active metabolite, A77 1726, which inhibits de novo synthesis of pyrimidines.[257] In addition, leflunomide also inhibits lymphocyte activation by blocking intracellular tyrosine kinases.[258] In rat xenograft models, leflunomide is effective antirejection therapy.[259] More recently, the active metabolite of leflunomide was shown to halt the replication of herpes viruses, particularly cytomegalovirus and herpes simplex virus.[260]

In 1998, leflunomide was approved in the United States for the treatment of rheumatoid arthritis. A 2-year double-blind randomized controlled trial compared the efficacy of leflunomide versus methotrexate in 235 patients with rheumatoid arthritis. The results demonstrated that leflunomide is safe and equally effective treatment for active rheumatoid arthritis compared with methotrexate. Adverse effects reported include upper respiratory tract infections, diarrhea, nausea and vomiting, rash, reversible alopecia, and transient elevations in liver enzymes.[261]

Efficacy trials have not yet been reported in human transplant recipients. One study by Williams and colleagues, however, reports experience with leflunomide in both renal and liver transplant patients with regard to pharmacologic properties. There was marked interpatient variability (> 300%) in the dose required to reach a targeted serum level. The terminal half-life also varied between 5.2 and 15.1 days. In renal transplant patients, the principal side effect observed was anemia, and in those with liver transplants, there were elevations of serum transaminases.[262]

Thalidomide (Thalomid)

Thalidomide (α-*N*-phthalimidoglutarimide) is a glutamic acid derivative with multiple biologic properties. It is a sedative, a teratogen, an inhibitor of angiogenesis, and an inhibitor of TNF-α production.[263] A number of open-label trials purport that thalidomide is efficacious in a variety of autoimmune and intestinal conditions, including erythema nodosum, aphthous stomatitis, Behçet syndrome, human immunodeficiency virus (HIV)-associated mucosal ulceration, and graft-versus-host disease.[263] Open-label trials also suggest that up to 50% of patients with Crohn disease refractory to other therapies will respond to thalidomide. The drug is typically started at a dose of 50 mg in adults and advanced as high as 200 mg, with clinical improvement usually occurring about 4 to 6 weeks after instituting therapy.[263,264] The primary side effect of thalidomide is neurotoxicity. In addition, the drug is contraindicated in women of childbearing age because of severe limb deformities (phocomelia) in the fetus. Because of the toxicities, this agent should be used with caution in patients with intestinal inflammation.[265,266]

Etanercept (Enbrel)

Etanercept is a genetically engineered fusion protein composed of two identical chains of the recombinant human TNFR p75 monomer that is fused to the Fc domain of human IgG1. This protein binds to and inactivates TNF and lymphotoxin, a cytokine that activates lymphocytes. One of the potential benefits of etanercept is that it does not contain nonhuman material, thereby rendering it less immunogenic. There is extensive clinical experience in the treatment of rheumatoid arthritis with etanercept. More recently, its use in the treatment of refractory Crohn disease also has been studied. In an open-label trial, 10 patients with active Crohn disease were treated with subcutaneous etanercept (25 mg) twice weekly for 12 weeks. Although there was an improvement in CDAI in 6 of 10 patients ($p < .03$), there was no improvement in follow-up terminal ileal or colonic

biopsies. In addition, all patients who initially responded to therapy reported relapse of symptoms within 4 weeks after discontinuation.[267] In a randomized, double-blinded, placebo-controlled trial of 43 patients with moderate to severe Crohn disease, subcutaneous etanercept (25 mg) was administered twice weekly. There was no difference in clinical response at week 4 in patients treated with etanercept compared with placebo (39% vs 45%; $p = .763$). In addition, there was no clear benefit for fistulizing Crohn disease. Common adverse events include injection-site reactions, headache, asthenia, abdominal pain, and skin rash.[268] A report of two patients with Crohn spondyloarthropathy found that although these patients experienced complete resolution of spinal pathology with etanercept, the activity of the Crohn disease did not improve. These findings indicate that binding of TNF alone is not sufficient to ameliorate the inflammatory response in the intestinal mucosa.[269]

Natalizumab (Antegren)

Natalizumab is humanized monoclonal antibody targeted against α_4 integrin. The integrins are a group of heterodimeric proteins composed of noncovalently bound α and β chains that promote cell-cell or cell-matrix adhesion. The α_4 integrins heterodimerize with either α_1 or α_7 subunits. Integrins containing the β_1 subunit are also known as the VLA antigens and are the predominant integrin found on the surface of T lymphocytes. $\alpha_4\beta_1$ (VLA-4) is expressed only on leukocytes and mediates their attachment to endothelial cells via binding to VCAM-1. VCAM-1 is expressed on cytokine-activated endothelial cells and is one of the principal surface proteins that regulates trafficking of lymphocytes to the endothelium. In the gut, the $\alpha_4\beta_7$ integrin binds to mucosal addressin cell adhesion molecule (MAdCAM-1), which mediates homing of T cells to sites of inflammation in the intestinal tract.[270] MadCAM-1 expression is enhanced in inflammatory bowel diseases.[271]

Natalizumab is effective in controlling the exacerbations of inflammatory bowel disease. In a double-blind placebo-controlled dose-ranging multicenter trial of natalizumab of 248 adults with active Crohn disease, clinical responses were higher in all three natalizumab groups at weeks 4, 6, and 8 than in the placebo group. The highest rate of remission (71%) occurred at 6 weeks in the group of patients given two infusions of 3 mg/kg. Drug-associated adverse events were mild; two patients had infusion reactions during the second infusion, and one of these patients developed antinatalizumab antibodies.[272] In a pilot study, 10 patients with ulcerative colitis had improved clinical scores 2 and 4 weeks after a single (3 mg/kg) infusion of natalizumab.[273]

Rituximab (Rituxan, Monoclonal Anti-CD20)

Rituximab is a chimeric (mouse-human) monoclonal antibody that binds to the CD20 antigen on the surface of B lymphocytes. Binding results in antibody-dependent and complement-dependent cytotoxicity. Initially, rituximab was used to treat low-grade B-cell lymphomas but more recently has been used in the treatment of post-transplant lymphoproliferative disease. In one case series reporting six pediatric liver transplant recipients with Epstein-Barr virus–associated post-transplant lymphoproliferative disease, rituximab was given intravenously (375 mg/m^2 once a week for a total of 4 weeks in four patients and a total of 3 weeks in the other three). Infusion with rituximab was associated with complete remission in five patients. Disappearance of tumor masses occurred within 1 to 2.5 months after initiating treatment. Adverse effects included headaches, hypogammaglobulinemia, transient neutropenia, and one case of anaphylactic reaction.[274]

CONCLUSIONS

The optimal treatment of organ rejection and autoimmune diseases continues to evolve dramatically. Newer immunosuppressive agents are effective and potent and seem to have fewer adverse effects, at least in the short term. Instead of agents with broad physiologic and immunologic effects (eg, corticosteroids, azathioprine, calcineurin inhibitors, cyclosporine), the clinician can now use monoclonal antibodies that target one point in the T-cell activation pathway (eg, sirolimus), one cytokine (eg, infliximab, anti-TNFα), or one cell type (eg, rituximab, anti-CD20 B cells). The principal drawback of these new agents is that patients receiving the recombinant proteins develop antibodies, which puts them at risk for infusion reactions, decreased antibody efficacy, and, possibly, other autoimmune disorders. It remains to be seen whether the favorable safety profile of these new biologics will persist with long-term follow-up. Currently, however, these new medications have dramatically improved the quality of life for children and adolescents following organ transplant and those with refractory inflammatory bowel disease.

2A. *Antimicrobials*

Michael R. Millar, MB, ChB, PhD, FRCPath
Mark Wilks, BSc, Dip Bacteriol, PhD

This section deals with antibiotic modulation of the pattern of colonization at a site or sites within the gastrointestinal tract. Eradication of single pathogens such as *Helicobacter pylori*, *Giardia lamblia*, and parasitic worms from the gastrointestinal tract by antimicrobials is covered in other sections.

The gastrointestinal tract provides the major reservoir of colonizing microorganisms. Determinants of bowel colonization are poorly understood but include mode of delivery (vaginal/cesarean), diet, health status, age, travel, and gastrointestinal physiology and pathology. The impact of the bowel flora on the human host is complex, with a wide range of metabolic, nutritional, and immunologic effects.[1] In health, the bowel flora provides many benefits for the host, including competitive exclusion of pathogens, the recovery of usable energy sources from cellulose, and provision of butyrate to the colonic mucosa. The gastrointestinal microflora and interactions with the mucosa are reviewed in Chapter 2, "Intestinal Flora and Microbial Epithelial Interactions."

Determinants of the resistance of the microflora to perturbation are poorly understood. There is broad agreement that increasing diversity of an ecosystem promotes stability and increases the resistance to perturbation,[2] yet administration of most antimicrobials, by a systemic route to most individuals, will lead to modulation of the bowel flora. Microbial colonization of the gut with commensal flora benefits the host by preventing colonization or overgrowth with pathogens,[3] so it follows that use of antimicrobials for the prevention or treatment of disease can lead to a detrimental change in colonization.[4] The concept of colonization resistance is often taken to imply that the intestinal flora, once established, is relatively static. However, molecular analysis of the bifidobacterial and lactobacillus composition of the microflora in humans suggests that this may not be so and that the pattern of bacterial flora is dynamic in healthy people, regardless of selection pressure caused by the use of antimicrobials.[5] Gastrointestinal side effects are a common consequence of use of antimicrobials. The most frequent side effects are changes in bowel habit and overgrowth with fungi, and a large proportion of these disturbances probably result from alterations of the bowel flora.

The clinical consequences of use of antimicrobials reflect not only modulation of the distribution of microorganisms in the gastrointestinal tract but also changes in microbial physiology and the production of microbial virulence determinants, such as lipopolysaccharide, toxins, and colonization factors.[6–10] Antimicrobials, by modifying microbial metabolic activities, can induce changes in intraluminal conditions, for example, pH, which may also have profound effects on microbial growth and physiology and modify the interaction with the host.[11] Acquisition of antibiotic resistance may be associated with changes in the production of microbial virulence or colonization factors.[12] Even a subinhibitory concentration of antibiotics can have major effects on the transcription of bacterial genes.[13]

There is increasing evidence that the early pattern of colonization is an important determinant of development of the intestine.[14,15] Gram-positive bacteria, such as *Lactobacillus* spp and *Bifidobacterium* spp, may have a role in the prevention of the development of atopy.[16] Neonatal antibiotic treatment of mice leads to a long-term T helper 2 skewed immunologic response, which can be prevented by the introduction of intestinal bacteria.[17]

The effect of administration of antimicrobials in the peripartum period on the early pattern of colonization in the newborn has not been extensively studied, but there is some support for the idea that use of antibiotics in the peripartum period alters the pattern of subsequent microbial colonization and the risk of systemic infection of the newborn.[18] The effects of antibiotic treatment may be more marked in infants than in adults. In a recent study of the fecal flora of 1- to 3-month-old infants, bifidobacteria and lactobacilli were suppressed to undetectable levels in most infants during treatment with amoxicillin, pivampicillin, cefaclor, cefadroxil, erythromycin, or cotrimoxazole. [19]

Antimicrobials may facilitate the acquisition of novel colonizers, a strategy that can be used to facilitate bowel colonization by probiotic strains, but can also reduce the infective inoculum of microbial pathogens.[20] Antimicrobials also provide a selection pressure for colonization or overgrowth of the gut with antimicrobial-resistant microorganisms. The density and diversity of the microflora facilitate the spread of transmissible genetic elements,[21] so the gastrointestinal tract can become a major reservoir for antimicrobial-resistant bacteria and resistance genes, with important consequences for both the colonized individual and others. This is particularly important in hospital environments, such as intensive care units. In preterm infants cared for in a neonatal intensive care unit, use of antibiotics for suspected or proven episodes of infection encourages colonization with a limited range of antibiotic-resistant bacteria, while at the same time the opportunities are reduced

for acquisition of bacteria that normally colonize healthy infants. The intestine, as a major reservoir for antibiotic-resistant bacteria, can predispose the individual infant to systemic infection but also puts at risk other infants in the hospital setting.[22,23] The abnormal pattern of colonization also has been implicated in the pathogenesis of neonatal necrotizing enterocolitis (NEC).[24]

Older infants and children nursed in intensive care units generally arrive in the unit with a complex gastrointestinal microflora but while in hospital acquire novel colonizers, which are frequently antibiotic resistant. Changes in gastrointestinal motility, use of drugs that reduce gastric acid production, and use of biomedical devices such as nasogastric tubes also contribute to modification of the gut flora in children nursed in intensive care units.

CLASSES OF ANTIBIOTIC

A wide range of antimicrobials are available, including β-lactams (cephalosporins and penicillins), related compounds such as carbapenems and monobactams, and macrolides, quinolones, aminoglycosides, tetracyclines, and peptides. Few novel classes of antimicrobial agent have been marketed over the last 10 years, and most that are currently marketed are representative of classes of antimicrobial agents that have been available for over 20 years.

PENETRATION OF THE GASTROINTESTINAL TRACT BY ANTIMICROBIAL AGENTS

The main routes by which antimicrobial agents reach the lumen of the gastrointestinal tract are by oral ingestion, in bile, by transudation across the gut wall, and by rectal administration. Erythromycin, ampicillin-related drugs (including ureidopenicillins), and rifamycins are excreted in high concentrations in bile. In contrast, sulfonamides, chloramphenicol, and aminoglycosides are relatively poorly excreted in bile.

DETERMINANTS OF ANTIMICROBIAL ACTIVITY

Antimicrobial agents differ in the extent to which they impact on the gastrointestinal flora. Activity is dependent on a wide range of factors, including drug characteristics such as spectrum of activity, modes of administration, and routes of excretion (bile, urine) and the extent to which there is an enterobiliary circulation. Important factors specific to individuals include diet, transit time, intraluminal conditions (eg, pH, redox potential, ionic conditions, nonspecific binding to macromolecules such as proteins and mucins, presence of inhibitors, degrading enzymes, growth substrate availability, and bacterial growth phase), and bowel flora components and complexity. For example, the concentration of divalent cations, such as calcium, is an important determinant of the activity of gentamicin, iron may interfere with the activity of tetracyclines, and sulfonamides are inhibited by para-aminobenzoic acid. Some antimicrobials, such as colistin, are rapidly inactivated.[25]

EFFECTS OF ANTIMICROBIAL AGENTS ON THE MICROBIAL FLORA OF THE GASTROINTESTINAL TRACT

The impact of antimicrobials on the culturable components of the oral and fecal flora has been extensively studied,[26–28] frequently in healthy adult volunteers. On the other hand, relatively little is known about the impact of antimicrobial agents in patients with specific disease states or at less accessible sites, such as the small intestine and proximal colon. Attempts to describe the impact of antimicrobials on the flora at inaccessible sites using both in vitro continuous culture and animal models demonstrate that the fecal flora does not accurately represent changes in other parts of the gastrointestinal tract.[29]

Recent molecular studies from subjects undergoing colonoscopy confirm that whereas the fecal flora is different from that of the colon, mucosa-associated bacteria are relatively uniformly distributed along the colon.[30] There is some evidence that host-related factors are important in determining the intestinal microflora, and, as a result, attempts to modulate the gut flora in different individuals may give quite variable results.[30]

In vitro models are an attractive approach for studies of bowel flora modulation by antimicrobials but also may not accurately describe changes in vivo. For example, studies of microbial responses in models of the gastrointestinal flora in vitro have historically used planktonic (ie, free floating) populations of bacteria.[31,32] In contrast, in vivo bacteria usually grow in surface-associated communities referred to as biofilms.[33] Biofilm growth may prove an important element in the pathogenesis of intestinal infections.[34] Bacteria growing in biofilms show important differences from planktonic cells in metabolic activity, gene transfer, and susceptibility to both antimicrobial agents and host defense factors.[35,36]

Another area of uncertainty is the impact of antimicrobials on the unculturable components of the gastrointestinal flora. Recent molecular studies suggest that 50 to 90% of the human fecal flora is unculturable using conventional techniques.[37,38] Current technology precludes studies of the unculturable components of the bowel flora of more than a few individuals. Accordingly, there is little information on the impact of antimicrobials on the uncultured components of the bowel flora. It may be that the use of nucleotide sequence arrays will facilitate further research in this area.

Most studies have concentrated on the impact of antimicrobials on facultative gram-positive cocci (such as staphylococci, enterococci, and streptococci), Enterobacteriaceae, anaerobic species (such as clostridia) and yeasts, and the emergence of antimicrobial resistance. In general, bacteria that are susceptible to the antimicrobial agent administered tend to decrease in numbers, and those that are resistant increase in numbers. For example, administration of penicillin reduces the numbers of strep-

tococci in the mouth, whereas the numbers of Enterobacteriaceae increase. There is considerable interindividual variation in the effect of antimicrobial exposure on the microflora. In addition, antimicrobials within the same class may vary in their impact on the bowel flora.[39] The results of individual studies also will vary depending on the population studied and on the constituents of the microflora, such as the proportion of resistant components. Some of the effects of antimicrobial administration cannot be explained by antimicrobial susceptibility. For example, oral vancomycin reduces the numbers of *Bacteroides* spp despite poor antimicrobial activity in vitro.[40] Some antibiotics, such as macrolides, have effects on gastrointestinal motility through binding and activation of the motilin receptor,[41] and these changes can modify the bowel flora indirectly.

It is still widely assumed that there is a direct and exclusive relationship between the use of a particular antimicrobial agent and the development of resistance. This assumption underlies antibiotic use policies of clinics and hospitals and even national policies. However, it has been known for more than two decades that, at least in the case of Enterobacteriaceae, development of multidrug-resistant strains is generally not the result of accumulation of single point mutations. Instead, there is simultaneous acquisition of genetically linked resistance genes carried on transmissible genetic elements such as transposons, integrons, and plasmids.[42,43] Extensive horizontal gene transfer allows passage of resistance in the intestine between both closely related and distantly related bacteria.[21] Earlier assumptions that bacteria pay a fitness penalty in maintaining antimicrobial resistance in the absence of any selective pressure have proven to be incorrect.[42,44]

USE OF ANTIBIOTICS FOR PREVENTION OR TREATMENT OF DISEASE

Antimicrobials may be used to eradicate a specific pathogen from the gastrointestinal tract (see specific sections) or to modulate the pattern of colonization at a site or sites in the gastrointestinal tract. Antimicrobials may be prescribed for the prevention or treatment of disease and may be used as a sole treatment strategy but are also commonly used in combination with other strategies. Some classes of antimicrobial have highly selective activities, so, for example, aztreonam is active only against gram-negative bacteria, and there are a number of agents with specific activity against gram-positive bacteria. These agents may have a particular role in elucidating the contribution of specific elements of the bowel flora to the pathogenesis of disease.

Table 76.2A-1 summarizes the bowel flora activities of selective antimicrobials and potential indications for their use in the prevention or treatment of disease. Some recently introduced antimicrobials have not been evaluated for bowel flora modulation, and some classes of agent have bowel flora activity only when administered orally or rectally, such as glycopeptides. Carbapenems do not reach high intraluminal concentrations so may have less impact on the bowel flora than antimicrobials such as cephalosporins, which have a similar spectrum of activity.

TREATMENT OF CONDITIONS ASSOCIATED WITH ABNORMAL DISTRIBUTION OF BACTERIA IN THE GASTROINTESTINAL TRACT

There is evidence that some groups of patients with small bowel bacterial overgrowth may benefit from use of antimicrobials over weeks or months.[45–48] However, there are few long-term follow-up studies of patients treated for small bowel stasis. Relapse of symptoms is common unless underlying defects can be corrected. Recent studies do not support the use of small bowel decontamination following liver transplant.[49,50]

Antimicrobials chosen for control of small bowel bacterial overgrowth include tetracyclines, quinolones such as ciprofloxacin, and metronidazole. Each of these classes of agent has a different spectrum of activity and produces a different range of effects on the fecal flora of healthy volunteers. There are no randomized trial data available regarding the comparative efficacy of agents used to treat and control small bowel bacterial overgrowth.

TABLE 76.2A-1 BOWEL FLORA ACTIVITIES OF SELECTIVE ANTIMICROBIALS AND POTENTIAL INDICATIONS FOR THEIR USE IN THE PREVENTION OR TREATMENT OF DISEASE

ANTIMICROBIAL AGENT	BOWEL FLORA ACTIVITY	POTENTIAL INDICATIONS
Cephalosporin	Broad (depends on cephalosporin); generally includes gram-negative bacilli; staphylococci	Prophylaxis of infection—surgery, intensive care (selective decontamination)
Monobactam (aztreonam)	Gram-negative bacilli	? Prophylaxis of necrotizing enterocolitis
Aminoglycosides	Oral administration—gram-negative bacilli; staphylococci	Prophylaxis of infection— surgery, ? neonatal necrotizing enterocolitis, intensive care (selective decontamination)
Penicillins	Broad (depends on penicillin); penicillinase inhibitors further broaden spectrum (tazobactam, clavulanate)	Same as for cephalosporins
Quinolones	Gram-positive bacilli; staphylococci	Small bowel overgrowth; prophylaxis of infection—surgery, immunocompromised
Tetracyclines	Broad	Small bowel overgrowth
Metronidazole	Anaerobes	Small bowel overgrowth
Azole antifungals		Prevention of fungal infection

PROPHYLAXIS OF INFECTION IN THE IMMUNOCOMPROMISED HOST

Antifungal agents have been used to prevent fungal overgrowth of the gastrointestinal tract and thereby reduce the risk of both local and systemic fungal infections in a wide variety of groups of immunocompromised patients, such as in patients being treated for malignancies and those with human immunodeficiency virus (HIV) infection. A recent systematic review concluded that systemic antifungal prophylaxis reduces the severity of oral mucositis and the frequency of oral candidiasis in patients treated with chemotherapy for cancer.[51] Systemic antifungal prophylaxis probably also prevents invasive fungal infection in patients with neutropenia.[52] Antimicrobials also have been used to prevent gram-negative sepsis in patients undergoing treatment for cancer, particularly hematologic malignancies.[53] However, there are concerns that this approach increases the likelihood of serious infection involving antimicrobial-resistant strains and modification in the pattern of infecting agents causing disease, with marginal benefit for patient outcomes.[54,55]

PROPHYLAXIS OF INFECTION IN THE INTENSIVE CARE UNIT

Selective decontamination of the digestive tract has been advocated as a strategy to reduce the risk of ventilator-associated pneumonia in patients undergoing intensive care. The aim of selective decontamination of the digestive tract is to reduce colonization of the upper gastrointestinal tract with aerobic gram-negative rods and *Candida* species. Selective decontamination of the digestive tract involves the administration of a topical antimicrobial preparation to the oropharynx, usually combined with a systemic antimicrobial agent. The use of selective decontamination of the digestive tract has been subject to a number of meta-analyses.[56] The implementation of a selective decontamination of the digestive tract strategy carries considerable costs. Between 13 and 39 patients would require selective decontamination of the digestive tract to prevent one death from ventilator-associated pneumonia.[57] The methodologic quality of these studies also has been criticized.[58] Moreover, there are concerns about the long-term consequences of selective decontamination of the digestive tract on levels of antimicrobial resistance.[59,60] Given that critically ill patients are so heterogeneous and that the antibiotic treatments may be quite different (in duration, type of antibiotic, and route of administration), it is hardly surprising that no overall consensus has emerged. In the largest single trial of selective decontamination of the digestive tract (546 predominantly surgical adult patients), mortality was reduced significantly (number needed to treat = 12). In this study, there was no observed increase in colonization by resistant gram-negative organisms, but there was increased colonization of all patients by ciprofloxacin-resistant coagulase-negative staphylococci and enterococci.[61] Concerns about antibiotic resistance could be reduced if oropharyngeal decontamination alone were enough to improve survival. In a recent study of oropharyngeal decontamination, the incidence of ventilator-associated pneumonia was reduced, but overall patient survival was not improved.[62]

PROPHYLAXIS AND/OR TREATMENT OF INFLAMMATORY BOWEL DISEASE

In animal models of inflammatory bowel disease, the colonizing microflora has an important etiologic role.[63,64] However, evidence supporting the role of antimicrobial agents in the treatment or prevention of inflammatory bowel diseases in humans is limited.[65–68] Metronidazole, in high doses, has been shown to modify the course of Crohn disease in some patients, such as those with perianal fistulae.[69] There is little evidence of a role for antimicrobial agents in the control or treatment of ulcerative colitis.[70] The use of live microbial feed supplements (probiotics) has been shown in one randomized controlled trial to benefit patients with pouchitis.[71] Antimicrobial agents also can be used to facilitate probiotic colonization, and it may be that in the future, attempts to modify the luminal flora to benefit patients with inflammatory bowel disease will use an approach in which antimicrobial agents are first used to facilitate subsequent colonization with probiotics.

PROPHYLAXIS OF INFECTION ASSOCIATED WITH ABDOMINAL SURGERY

There is an extensive literature and broad agreement on the benefit of antimicrobial agents for the prophylaxis of infection associated with gastrointestinal tract surgery.[72–74] Current recommendations are that there should be a suprainhibitory concentration of appropriate antimicrobial agents present at the site of operation and at the time of bacterial contamination of the operative site. There is little evidence that extending prophylaxis beyond the period of operation is of any benefit, and it may be of harm.[75] Antimicrobial agents chosen for prophylaxis should be active against both facultative bacteria and strict anaerobes. Metronidazole alone is less effective than when it is combined with an agent active against facultative bacteria, such as a cephalosporin. However, the optimum regimen for prophylaxis in the perioperative setting has not been defined.

NEONATAL NECROTIZING ENTEROCOLITIS

Attempts to reduce the incidence of NEC by the oral administration of antibiotics have not provided conclusive results. This subject has been systematically reviewed,[76] with the conclusion that the incidence of NEC may be reduced by the oral administration of antibiotics, but also concluding that there are concerns about the selection of antibiotic-resistant bacteria and identifying a need for further studies of sufficient size and duration to allow the risks and benefits to be assessed. The antibiotics used to treat infants for episodes of suspected sepsis may also modify the bowel flora and influence the incidence of NEC.[77] There are no randomized comparative studies of antimicrobial efficacy in the treatment of neonatal NEC.

SHIFTING THE FLORA TO A MORE HEALTHY COMPOSITION

Recent research suggests that the pattern of bowel colonization, particularly in early life, may have an important influence on subsequent health and disease, such as on the risk of development of atopy.[78] The use of antibiotics to modulate the bowel flora of healthy individuals with a view to long-term health benefits, however, has not been systematically investigated.

It is now well established that there are major differences between the intestinal flora of formula-fed and breast milk–fed infants. These differences are particularly marked in very low birth weight infants.[79] The mode of delivery also is important, and babies born by cesarean section have a different flora, which persists at least until 6 months after birth, presumably owing to the use of prophylactic antibiotics (a single dose of ampicillin) and reduced exposure to the mother's bacterial flora at the time of delivery.[80]

There is no agreement regarding the age at which the intestinal microflora becomes comparable to that of an adult. In a recent study using viable bacterial counts, 16S ribosomal ribonucleic acid, and generic probes, it was found that there were higher numbers of bifidobacteria and clostridial species in the pediatric population compared with healthy adults. Most strikingly, the carriage of Enterobacteriacae was 100-fold higher in children (16 months to 7 years) than in healthy adults (21–34 years).[81]

PROMOTING COLONIZATION OF PROBIOTICS

Antimicrobial agents may have a role in changing patterns of colonization to a more healthy composition and perhaps facilitate colonization of the intestinal tract by probiotic bacteria. There is a need for further research in this area.

CONCLUSIONS

Antimicrobial agents can be used to modify the gastrointestinal flora in ways that may benefit the host, such as for prophylaxis of infection associated with gastrointestinal tract surgery. Antibiotics may also have other indirect effects on the flora that are not readily apparent. Current strategies emphasize the eradication of pathogens or suppression of flora rather than modulation to a more healthy composition. Future strategies may well see the use of antimicrobial agents to facilitate colonization of the bowel with microbes that contribute to the maintenance of health (ie, probiotics) rather than simply for the eradication or suppression of those microbes that cause disease.

2B. *Probiotics*

Erika Isolauri, MD, PhD
Seppo Salminen, PhD

Probiotics are live microbial food supplements or components of bacteria that have been demonstrated to have beneficial effects on human health. Oral introduction of probiotics reinforces various lines of gut defense, including immune exclusion, immune elimination, and immune regulation. Probiotics also stimulate nonspecific host resistance to microbial pathogens and thereby aid in their eradication. Correction of the properties of unbalanced indigenous microbiota forms the rationale of probiotic therapy. The application of probiotics currently lies in reducing the risk of diseases associated with gut barrier dysfunction; the most fully documented probiotic intervention is the treatment and prevention of acute infectious diarrhea. Recent clinical and nutritional studies and characterization of the immunomodulatory potential of specific strains of the gut microbiota, beyond the effect on the composition of the microbiota, may lead to future applications not only for different infectious diarrheas but also for allergic and inflammatory diseases.

The probiotic potential of strains differs; different bacterial species, and even strains of the same species, are each unique and have defined adherence sites, specific immunologic effects, and varied effects in the healthy versus the inflamed mucosal milieu. Current probiotic research aims at characterization of the healthy individual gut microbiota and understanding the microbe-microbe and host-microbe interactions. The goal is to use the defined microbiota both as a tool for nutritional management of specific gut-related diseases and as a source of novel microbes for future probiotic bacteriotherapy applications.

HEALTHY GUT MICROBIOTA

The human gastrointestinal tract harbors a complex collection of microorganisms, which form a typical individual microbiota for each person.[1] This specific microbiota is dependent on genetic factors and the environment. The total number of microbes in the intestinal tract is estimated to reach 10^{12} bacteria per gram of intestinal contents. Several hundred bacterial species can be identified using traditional culture methods.[1] The development of novel means of characterizing gut microbiota, in particular molecular methods, has uncovered new microbial species in intestinal mucosa and contents.[1,2]

The microbiota is metabolically active, and its composition is related to multiple disease states within the intestine and also beyond the gastrointestinal tract. Components of the human intestinal microbiota or organisms entering the intestine may, however, have both harmful or beneficial effects on human health.

The basis of healthy gut microbiota lies in early infancy and the initial process of intestinal colonization. The generation of immunophysiologic regulation in the gut depends on the establishment of indigenous microbiota.[3–5] The microbiota of a newborn develops rapidly after birth and is initially strongly dependent on the mother's microbiota, mode of delivery, and birth environment.[6] Subsequently, feeding practices and the home environment of the child influence the composition. Major changes in the composition occur during breastfeeding, weaning, and introduction of solid foods.[6,7]

The establishment of the gut microbiota has traditionally been considered a stepwise process with facultative anaerobics such as the enterobacteria, coliforms, and lactobacilli first colonizing the intestine with rapid succession by bifidobacteria and lactic acid bacteria.[7–9] New molecular methods indicate, however, that lactic acid–producing bacteria account for less than 1% of the total microbiota in infants, whereas bifidobacteria can range from 60 to 90% of the total fecal microbiota in breastfed infants.[2,10] Moreover, the new techniques indicate that the greatest difference in the microbiota of breastfed and formula-fed infants lies in the bifidobacterial composition of intestinal microbiota, whereas the lactic acid bacteria composition appears to be rather similar. *Bifidobacterium breve*, *Bifidobacterium infantis*, and *Bifidobacterium longum* are frequently found in fecal samples of breastfed infants, whereas the most common lactobacilli in breastfed and formula-fed infant feces constitute *Lactobacillus acidophilus* group microorganisms such as *L. acidophilus*, *L. gasseri*, and *L. johnsonii*.[10,11]

Healthy microbiota is defined as the normal microbiota of an individual that both preserves and promotes well-being and absence of disease, especially in the gastrointestinal tract.[12] The collective composition of the colonizing strains in infancy also provides the basis for healthy gut microbiota later in life. In addition, the development of the disease-free state of the gut lies in the host-microbe interaction in infancy.[13,14]

DEFINITIONS OF PROBIOTICS

The history of probiotics dates back to ancient times, but the scientific work on health benefits was initiated by Metchnikoff early last century.[15] Health-promoting fermented foods are used for the treatment and prevention of infant diarrhea in countries around the world without knowledge of the specific microbial composition of such products.[16] Beneficial bacteria in fermented foods that promote health have only more recently been called probiotics. These have been variously defined, according to their initial application, in animal feeds. For the purpose of human nutrition, a probiotic is currently defined as a live microbial food ingredient beneficial to health.[12] However, inactivated probiotic bacteria also may have beneficial health effects. The history of the definition and the current status are presented in Table 76.2B-1.[15,17–22]

Probiotics were initially selected to provide strains with good food-processing conditions, but, more recently, the physiologic properties of probiotics in the human gastrointestinal tract have formed the basis for selection. These criteria have been redefined to include the healthy human intestinal or mucosal microbiota as the main source of new strains. At present, emphasis is placed on survival in the gut, acid and bile stability, temporary colonization of the mucosal surfaces in the intestinal tract, and fecal recovery of the administered probiotic to define the dosage needed for individual target uses.[23] The most frequently used genera fulfilling these criteria are lactobacilli and bifidobacteria. Currently, most probiotics have been selected from members of normal healthy adult microbiota.

RATIONALE FOR PROBIOTIC INTERVENTION IN PEDIATRIC PRACTICE

The therapeutic and prophylactic interventions by probiotics derive from the concept of a well-functioning gut barrier and a normal balanced microbiota. In addition to its principal physiologic function, digestion and absorption of nutrients, the intestinal mucosa provides a protective interface between the internal environment and the constant challenge from antigens of the external environment, also carrying defense mechanisms against infectious and inflammatory diseases.

Gut microbiota as a component of intestinal barrier has been considered as a physiologic blockade to foreign substances such as antigens. One current view focuses on communication between the host and the resident commensal microbes.[22] This interaction manifests best during early infancy, when the colonization process governs the development of intestinal integrity and host immune defense mechanisms.[3–5] Conversely, the genetic background of the host and development of the immune system influence the collective composition of the intestinal microbiota.

In several gut-related inflammatory conditions, the healthy host-microbe interaction is disturbed, and inflammation is accompanied by an imbalance in the intestinal microbiota in such a way that an immune response may be generated against resident bacteria. For example, an altered gut microbiota is reported in patients with rotavirus diarrhea, inflammatory bowel diseases, rheumatoid arthritis, and allergic diseases,[23] implying that the normal gut microbiota constitutes an ecosystem responding to inflammation both in the gut and elsewhere in the human body. Normalization of the properties of an unbalanced indigenous microbiota by specific strains of the healthy gut microbiota constitutes the rationale for probiotic therapy. Such an approach with oral introduction of specific probiotics may halt the vicious circle in inflammation.

The probiotic effects in conditions involving impaired mucosal barrier function, particularly infectious and inflammatory diseases, lie in normalization of increased intestinal permeability and altered gut microecology, improvement of immunologic barrier functions of the intestine, and alleviation of intestinal inflammatory responses.[22,23]

Although it is well documented that balanced normal microbiota may become aberrant and immunogenic secondary to gut-related disease, it is not known whether changes in the composition of the microbiota can be a primary cause of disease. Such associations recently have been suggested in allergic disease[22] and autism.[24] Differences in the neonatal gut microbiota, in particular the bal-

TABLE 76.2B-1 CURRENT UNDERSTANDING AND HISTORY OF PROBIOTIC DEFINITIONS

DEFINITION	SOURCE
Specific bacteria in yoghurt fermentation balance intestinal microbiota	Metchnikoff (1907)[15]
Substances excreted by one protozoan to stimulate the growth of another	Lilly and Stillwell (1965)[17]
Substances that have a beneficial effect on animals by contributing to the balance of the intestinal biota	Parker (1974)[18]
Live microbial feed supplements that beneficially affect the host animal by improving the intestinal microbial balance	Fuller (1989)[19]
Mono- or mixed cultures of live microorganisms that, when applied to humans, affect beneficially the host by improving the properties of the indigenous microbiota	Huis in't Veld and Havenaar (1991)[20]
Live microbial food ingredients that are beneficial to health (efficacy and safety scientifically documented)	Salminen et al (1998)[12]
Live microbial cell preparations or components of cells that have a beneficial effect on human health	Salminen et al (1999)[21]
Specific live or inactivated microbial cultures that have documented targets in reducing the risk of human disease or in their adjunct treatment	Isolauri et al (2002)[22]

ance between *Bifidobacterium* and *Clostridium* microbiota, may precede the manifestation of the atopic responder type with heightened production of antigen-specific immunoglobulin E antibodies, suggesting a crucial role of the balance of the indigenous intestinal bacteria for the maturation of human immunity to a nonatopic mode.[25] These observations underline the importance of the need for precise characterization of healthy versus aberrant microbiota development and composition. This requires thorough investigation of the infant microbiota by up-to-date techniques; in particular those based on molecular techniques including ribosomal ribonucleic acid sequencing. Indirect methods, such as fecal microbial enzyme activities,[26] may also reflect differences in microbiota development.

CLINICAL EVIDENCE OF PROBIOTIC EFFECTS IN CHILDREN

The potential health effects of normal gut microbiota must be demonstrated by well-controlled clinical and nutritional studies in human subjects.[27] So far, several clinical studies have investigated the use of probiotics, principally lactobacilli and bifidobacteria, as dietary supplements for the prevention and treatment of various gastrointestinal infectious and inflammatory conditions (Table 76.2B-2).

Acute Enteritis

The currently accepted guidelines for treatment of acute diarrhea are based on correcting the dehydration by oral rehydration solutions. In addition, immediately after the completion of oral rehydration, full feedings of a previously tolerated diet can be reintroduced. Well-controlled clinical studies have shown that probiotics such as *Lactobacillus rhamnosus* GG, *Lactobacillus reuteri*, *Lactobacillus casei* Shirota, and *Bifidobacterium lactis* Bb12 can shorten the duration of acute rotavirus diarrhea,[23] above the beneficial effect of rapid refeeding, and thus constitute safe adjunct nutritional management of the condition.

In patients hospitalized for acute rotavirus diarrhea, *L. rhamnosus* strain GG (ATCC 53103) as a fermented milk or as a freeze-dried powder reduced the duration of diarrhea compared with the placebo group given a fermented and then pasteurized milk product.[28] This result has been confirmed in subsequent studies.[29,30] Moreover, probiotics reduce the duration of rotavirus excretion in stools.[31] A multicenter study by the European Society for Pediatric Gastroenterology, Hepatology, and Nutrition working group tested the clinical efficacy and safety of a probiotic administered in an oral rehydration solution.[32] In rotavirus diarrhea, but not in nonspecific or bacterial diarrhea, a decrease in the number of diarrhea episodes was observed. The study also confirmed the safety of administration of a probiotic in an oral rehydration solution and prevention of the evolution of rotavirus-induced diarrhea toward a protracted course. These studies have invariably evaluated patients with mild or moderate dehydration. A recent randomized placebo-controlled study in severely dehydrated male children under 2 years of age showed no clinical benefit of supplementing oral rehydration with *Lactobacillus* GG.[33]

Probiotics, specifically *Bifidobacterium bifidum* (later renamed *B. lactis*) and *Streptococcus thermophilus*, are also effective in the prevention of acute infantile diarrhea.[31] *Lactobacillus* GG supplementation resulted in a decrease in the incidence of diarrhea in undernourished, nonbreastfed Peruvian children followed for 15 months.[34] *Lactobacillus* GG also reduces the incidence of nosocomial diarrhea but has no effect on the prevalence of rotavirus infection.[35] Recently, Mastretta and colleagues confirmed the result when assessing the effects of *Lactobacillus* GG and breastfeeding on nosocomial rotavirus infections in 220 hospitalized infants during one rotavirus epidemic season.[36] The frequency of nosocomial rotavirus infection was 28%. This probiotic preparation was ineffective, whereas breastfeeding was effective in reducing the risk of rotavirus infection.

The effect of probiotic therapy (see Table 76.2B-2) in diarrhea has been explained by a reduction in the duration of rotavirus shedding, normalization of gut permeability

TABLE 76.2B-2 TARGETS OF PROBIOTIC THERAPY

EFFECT	METHOD OF ASSESSMENT	OUTCOME
Nutritional management of disease	Randomized double-blind clinical studies	Reduction in the duration of symptoms
Diarrhea		Eradication of the infectious agent
Allergic/inflammatory diseases		Symptom score
Control of disease activity/reactions/ relapses/inflammation	Clinical follow-up studies	Reduction of disease activity indices specific for the condition
	Crossover challenge studies (double blind, placebo controlled)	Reduction of proinflammatory cytokines specific for the condition and site
Enhanced host defense	Intestinal permeability	Promotion of immunologic and nonimmunologic barrier function
	Immunomodulation in vitro/in vivo	
	Gut microbiota aberrancy	Generation of anti-inflammatory cytokines
Reduction in risk of disease	Randomized double-blind, placebo-controlled study	Reduction in the frequency of the condition after appropriate follow-up
Diarrhea		
Allergic disease		
Gut microbiota stabilization	Modern techniques of evaluation of the gut microecology	Balanced microbiota appropriate for age
Regulation of bowel movement		
Comparative exclusion		

Adapted from Isolauri E et al.[22,23]

caused by rotavirus infection, and an increase in immunoglobulin (Ig)A-secreting cells against rotavirus.[14,23] Moreover, the ability of specific probiotics to increase the expression of mucins may contribute to the barrier effect but also to inhibition of rotavirus replication.[37]

Antimicrobial treatment disturbs colonization resistance of the gut microbiota,[1] which may induce clinical symptoms, most frequently diarrhea. The incidence of diarrhea after single antimicrobial treatment and the effect of probiotics was evaluated in children with no history of antimicrobial use during the previous 3 months.[38] The frequency of diarrhea was 5% in the group given *Lactobacillus* GG and 16% in the placebo group ($p = .05$), supporting the efficacy of probiotics. *Lactobacillus* GG, compared with placebo, reduces stool frequency and increases stool consistency during antibiotic therapy in children aged 6 months to 10 years given oral antibiotics in an outpatient setting.[39] In addition, there are preliminary reports on resolution of *Clostridium difficile* diarrhea and colitis in adults.[40]

The value of probiotic preparations for the prophylaxis of traveler's diarrhea has been studied using *Lactobacillus acidophilus*, *B. bifidum*, *Lactobacillus bulgaricus*, and *S. thermophilus*, but the results have been conflicting, likely owing to differences in probiotic species and vehicles used, in dosage schedules, as well as varying travel destinations with different causes of diarrhea.[12]

Inflammatory Bowel Diseases

An increasing number of clinical and experimental studies demonstrate the importance of constituents within the intestinal lumen, in particular the resident microbiota, in driving the inflammatory responses in these diseases. Intestinal microbiota appears to be responsible for deep colonic lesions and severe inflammatory response.[41] Probiotic bacteria may counteract the inflammatory process by stabilizing the gut microbial environment and the intestine's permeability barrier and by enhancing the degradation of enteral antigens and altering their immunogenicity. Another explanation for the gut-stabilizing effect could be improvement of the intestine's immunologic barrier, particularly intestinal IgA responses. Probiotic effects may also be mediated via control of the balance between pro- and anti-inflammatory cytokines.[14,23]

Preliminary reports indicate benefit in reversing some of the immunologic disturbances characteristic of Crohn disease.[23] In addition, reductions in disease activity and increased intestinal permeability have been achieved in pediatric patients with Crohn disease by probiotic intervention.[42] In adults operated on for the condition, however, *Lactobacillus* GG failed to prevent endoscopic recurrence during 1 year of follow-up.[43] A recent study provides evidence for treatment with a nonpathogenic *Escherichia coli* in maintaining remission in ulcerative colitis.[44] In a clinical trial in adults, a preparation containing four strains of lactobacilli (*L. casei*, *L. plantarum*, *L. acidophilus,* and *L. delbrückii* subsp. *bulgaricus*) and three bifidobacteria strains (*B. longum*, *B. breve*, and *B. infantis*), together with *Streptococcus salivarius* subsp. *thermophilus*, is encouraging for prevention of relapses of chronic pouchitis.[45]

Additional, controlled prospective data in human inflammatory bowel diseases are required to define the effects of specific probiotic strains on distinct forms of inflammatory bowel disease and attendant complications.

Allergic Diseases

The prevalence of atopic diseases, atopic eczema, allergic rhinoconjunctivitis, and asthma appears to have increased over this century throughout the industrialized world.[46] These conditions are associated with the generation of T helper (Th) cell 2–type cytokines, including interleukin (IL)-4, IL-5, and IL-13, which promote IgE production and eosinophilia.[46] Initial signals to counter IL-4, and thereby IgE and atopy, and IL-5–generated eosinophilic inflammation may stem from components of the innate immune system, which generates the necessary initial steps for the targeted and specific function of the adaptive immune system.[22,46]

Two structural components of bacteria, the lipopolysaccharide portion of gram-negative bacteria (endotoxin) and a specified CpG motif in bacterial deoxyribonucleic acid (DNA),[47,48] activate immunomodulatory genes via Toll-like receptors (TLR4 and TLR9, respectively) present on macrophages and dendritic and intestinal epithelial cells[49,50] and elicit an immunosuppressive effect on intestinal epithelial cells by inhibition of the transcription factor nuclear factor-κB signaling pathway.[51] Specific strains of the gut microbiota contribute to a T regulatory cell population amenable to oral tolerance induction[13] and counter allergy by the generation of IL-10 and transforming growth factor-β.[52,53] These activities are associated with suppression of proliferation of Th cells and reduced secretion of proinflammatory cytokines,[53–57] with control of IgE responses[58] and reduced allergic inflammation in the gut.[59] However, different *Lactobacillus* and *Bifidobacterium* strains appear to induce distinct and even opposing responses.[60,61] Thus, specific strains of the gut micobiota and probiotics may play a crucial role in determining the Th1/Th2-driving capacity of intestinal dendritic cells. In parallel, recent observations indicate that the cytokine production patterns induced by intestinal bifidobacteria are strain specific.[22] The results of clinical studies evaluating the effects of probiotics in allergic disease appear to substantiate this suggestion.

In one prospective study, the intestinal microbiota from 76 infants at high risk of atopic diseases was analyzed at 3 weeks of age by conventional bacterial cultivation and two culture-independent methods.[25] A positive skinprick reaction at 12 months was observed in 29% of the subjects. At 3 weeks of age, the bacterial cellular fatty acid profile in fecal samples differed between those infants later developing atopic sensitization and those not developing atopy. Fluorescence in situ hydridization was used to show that atopic subjects have more *Clostridium* species and fewer *Bifidobacterium* species in stools compared with nonatopic subjects.[25] Differences in the neonatal gut microbiota thus appear to precede the manifestations of atopy, suggesting a crucial role of the balance of indigenous intestinal bacteria for the maturation of human immunity to a nonatopic mode.

Improvement in the clinical course of atopic eczema and cow's milk allergy is observed in infants when given probiotic-supplemented extensively hydrolyzed formula compared with placebo-supplemented formula.[59,62] In parallel, markers of systemic[62] and intestinal[59] allergic inflammation were reduced (see Table 76.2B-2). Similar results have been obtained in milk-hypersensitive adults.[63] In these subjects, a milk challenge in conjunction with a probiotic strain prevented the immunoinflammatory response characteristic of the response without probiotics.

The preventive potential of probiotics in atopic diseases has been demonstrated in a double-blind, placebo-controlled study.[64] Probiotics administered pre- and postnatally for 6 months to children at high risk of atopic diseases reduced the prevalence of atopic eczema to half compared with infants receiving placebo.[64] Moreover, the effect extends beyond infancy.[65]

WHAT IS REQUIRED FOR FUTURE PROBIOTICS?

Research interest in the science of nutrition is currently directed toward improvement of defined physiologic functions beyond the nutritional impact of food, including the potential to reduce the risk of diseases. This is also the focus for probiotic research. Future probiotics must have more thoroughly defined mechanisms either to control specific physiologic processes in the evolution of disease for at-risk populations or in the dietary management of specific diseases (Figure 76.2B-1).

Prerequisites for probiotic action include survival in and adhesion to specific areas of the gastrointestinal tract and competitive exclusion of pathogens or harmful antigens.[66] These processes may depend first on specific strain characteristics and second on the age and the immunologic state of the host (Table 76.2B-3). Some probiotic strains adhere better to the small intestine, whereas others bind specifically to different parts of the large intestine.[67] It is likely that strains also adhere differently to healthy versus damaged mucosa.[68] It has also recently been demonstrated that strains with lower total in vitro binding capacity may still effect high competitive exclusion of pathogens or harmful bacteria,[66] indicating a need for further characterization of in vivo adhesion properties to develop preclinical selection methodologies for candidate probiotic strains.

Genetically modified bacteria evincing improved or added functional properties may also achieve probiotic effects. These include probiotics encoding mammalian genes to produce and secrete functional anti-inflammatory cytokines, such as *L. lactis* engineered to produce IL-10 locally.[69] Other methods of probiotic modification are exposure of the microorganism to sublethal stress such as acidic conditions or heat to improve survival in the gastrointestinal tract and tolerance to stress and thereby to furnish the organism with improved competitiveness against pathogens in the intestinal milieu.[70–72] Inactivation may also have potential in the modification of probiotics. The use of inactivated instead of viable microorganisms would have merit in terms of safety, longer shelf-life, and less interaction with other components in food products.

Owing to limited availability of controlled data in humans, more research is required on the effects of specific probiotic strains, in particular when there are modifications of components of these bacteria. Probiotic effects appear to be strain specific.[60,61] Indeed, the effects of even closely related strains can be counteractive. No single probiotic strain alone can influence all of the multifactorial processes controlling the intestinal milieu. Therefore, targets of probiotic intervention should be clearly identified and effective strains and specific strain combinations must be developed with desired properties for both nutritional management and the control of human diseases (see Figure 76.2B-1).

SAFETY ASPECTS OF PROBIOTIC THERAPY

Probiotic therapy forms a relatively new treatment modality for gastrointestinal disorders. The ingestion of large numbers of viable bacteria requires strict assurance of both acute and long-term safety. Probiotics currently used have been assessed as safe for use in fermented foods, but, generally, the safety assessment of microbial food supplements is not well developed.[73] The ability of probiotic strains to survive in gastric conditions and to strongly adhere to the intestinal epithelium may entail a risk of bacterial translocation,[74] bacteremia,[75] and sepsis.[76]

Reports from countries with high probiotic consumption suggest that current preparations are safe for their intended uses.[75,76] However, patients with severe underly-

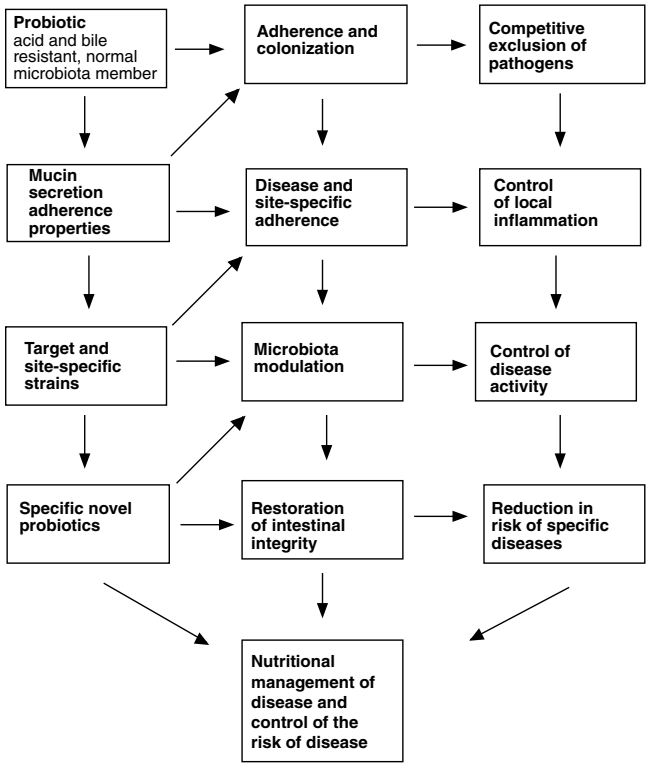

FIGURE 76.2B-1 The selection and use of specific probiotic strains and some targets in disease risk reduction symptom management.

TABLE 76.2B-3 PROPERTIES OF PROBIOTICS TO BE ASSESSED DURING THE DEVELOPMENT OF NEW STRAINS AND NEW APPLICATIONS

PROPERTY	TARGET AND METHOD
Species specificity	Source or origin; healthy human gut microbiota as the source
Resistance to pH	Model systems for gastric and bile effects
Adhesion to intestinal mucosa	Several model systems to be used (eg, cell cultures, mucus, intestinal segments) Fecal recovery in human subjects
Competitive exclusion	In vitro and in vivo model systems for pathogen adherence exclusion
Immune regulation	In vitro and human studies
Generation and balance of cytokines	Cytokine profile Contact with immune cells Adhesion related to immune effects Improvement of gut barrier and permeability disorders
Safety	Exclusion of antibiotic resistance and virulence factors and postmarket surveillance
Technological properties	Stability and activity throughout the processes
Efficacy assessment	Human clinical intervention studies with final product formulations; at least two independent studies to prove efficacy in target populations and safety in all consumer groups

Adapted from Salminen S et al[12] and Isolauri E et al.[22]

ing diseases, particularly immunocompromised subjects, appear to carry an increased risk of bacteremia associated with the use of some current probiotics.[75,76] Translocation of intraluminal bacteria may be one risk factor, but recent data also suggest that some probiotic strains directly interfere with host innate immune functions.[77]

Genetically modified microorganisms could be developed for use in foods. Developments in this area also may provide medical applications. However, a safety concern is the potential for the transfer of antibiotic resistance from modified organisms to gut pathogens.[78] Selection procedures have been developed to monitor the absence of antibiotic resistance, thus far specifically for *Lactococcus*.[79] The use of inactivated bacteria as probiotics has been advocated because their consumption may be safer than the use of viable bacteria.[23] However, information on the effects of inactivation methods on cell wall structure and composition is scarce. Such concerns are not limited to heat treatment; detrimental effects also may be expected in response to lyophilization and irradiation.[80]

To conclude, specific probiotics offer a tool for modification of the gut barrier and microbiota. The microbes used must be obtained from acceptable sources with scientifically proven safety and efficacy to guarantee their application in infectious, allergic, and inflammatory diseases.

3. *Motility*

Frances Laura Connor, MBBS, FRACP
Carlo Di Lorenzo, MD

As discussed in Chapter 4, "Motility," the mixing and propulsive actions of the gut are the result of coordinated activity in the enteric nervous system (ENS), modulated by hormones and central nervous system (CNS) input. The ENS contains complex motility "programs" for activities such as the interdigestive migrating motor complex (MMC) and the gastrointestinal components of emesis. Over 30 definite and putative neurotransmitters have been identified in the gut (see Table 4-2, Chapter 4). In many cases, a single neurotransmitter may stimulate several different receptors on different target tissues (nerves, smooth muscle) to produce different effects. As the rapidly advancing discipline of neurogastroenterology expands our understanding of motility and signaling within the gut, many new targets are being identified for specific therapeutic intervention.

This chapter provides an overview of the many drugs currently available and in development for modulating gastrointestinal motility. For each agent, the mechanism of action is briefly discussed, followed by a review of the currently available clinical experience. Wherever possible, data from pediatric trials are reported. However, in many cases, especially with newer medications, in which only scanty or no data exist for pediatric patients, data from trials in adults are discussed. The identification of effective pharmacologic therapies for pediatric gastrointestinal motility disorders using prospective randomized controlled trials has been identified as a research priority in the recently released research agenda of the North American Society of Pediatric Gastroenterology, Hepatology and Nutrition (NASPGHAN).[1]

Disorders of motility result in abnormalities of contraction amplitude, frequency, or coordination. Although many older motility drugs had nonspecific effects, affecting only contraction amplitude and/or frequency, newer agents also enhance the coordination of gastrointestinal contractions, greatly enhancing their therapeutic utility. The development of drugs targeting specific receptor subtypes in the ENS and enteric smooth muscle has reduced the incidence of systemic side effects that limited the use of previous agents. Drugs that alter motility fall into two broad categories: prokinetics and antimotility agents or antispasmodics. Also, it is increasingly apparent that many patients with motility disturbances also suffer from visceral hypersensitivity. Several of the newer motility drugs have additional antinociceptive qualities. The major drugs in each category are listed in Tables 76.3-1 (prokinetics) and 76.3-2 (antispasmodic and antimotility agents).

PROKINETICS

Prokinetic drugs may stimulate motility by direct actions on enteric smooth muscle or by interacting with the neurons of the ENS. Drugs currently in use include dopamine D_2 receptor antagonists, motilin agonists, 5-hydroxytryptamine subtype 4 (5-HT_4) agonists, and anticholinesterases. The final common pathway of all of these drugs is the M_3 muscarinic acetylcholine receptor on enteric smooth muscle cells.[2]

Dopamine Antagonists

Under normal physiologic conditions, dopamine inhibits the release of acetylcholine in the myenteric plexus by acting at presynaptic D_2 dopaminergic receptors. D_2 receptor antagonists such as metoclopramide and domperidone have prokinetic effects, enhancing the release of acetylcholine.[3] Domperidone is a specific D_2 antagonist, whereas metoclopramide also stimulates 5-HT_4 receptors and is an antagonist at 5-HT_3 receptors.[3]

Metoclopramide. The prokinetic effects of metoclopramide are primarily in the upper gut.[4] In addition to its peripheral effects, metoclopramide crosses the blood-brain barrier and exerts central antiemetic effects. This CNS activity may lead to side effects such as sedation, restlessness, and insomnia. Most concerning are dystonic reactions, such as oculogyric crisis and opisthotonos, which occur more frequently in children than in adults.[5] Tardive dyskinesia has been reported and may be permanent.[6] Rare side effects include neuroleptic malignant syndrome and methemoglobinemia. Despite its drawbacks, metoclopramide is one of the few prokinetic agents available at present. Although metoclopramide is widely used for its antiemetic action, the following focuses on its use as a prokinetic agent.

Randomized controlled trials of high-dose (1 mg/kg) intravenous metoclopramide have shown efficacy in improving delayed gastric emptying in children.[7] Recent experience in adult patients suggests that subcutaneous injection of metoclopramide may be effective in treating gastroparesis[8] and nausea.[9,10] Subcutaneous administration circumvents the problems of unpredictable oral drug bioavailability encountered in patients with severe motility disorders. Although this route of administration is less attractive in pediatric patients, it may well be acceptable to diabetic patients with symptomatic gastroparesis. However, further data from randomized double-blind placebo-controlled trials are required.

TABLE 76.3-1 PROKINETIC DRUGS

DRUG	RECEPTOR	EFFECT ON MOTILITY	REDUCES VISCERAL HYPERSENSITIVITY	POTENTIAL INDICATIONS
Metoclopramide	D_2 receptor antagonist, 5-HT_4 agonist, 5-HT_3 antagonist	↑Motility: proximal > distal[4]	Possible[178–180]	Foregut dysmotility syndromes: GERD, gastroparesis, nausea
Domperidone	D_2 receptor antagonist	↑Motility: proximal > distal gut[4]	Possible[181]	Foregut dysmotility syndromes: GERD, gastroparesis, nausea
Erythromycin	Motilin receptor agonist	↑ Motility: proximal > distal[182]	No; possible worsening[183]	Foregut dysmotility syndromes: gastroparesis, postprandial hypomotility
Octreotide	Somatostatin receptor agonist	Stimulates phase III of MMC, beginning in duodenum[50]; antimotility effects (see Table 76.3-2)	Yes[55]	Small intestinal hypomotility, prevention of bacterial overgrowth, pseudo-obstruction, dumping syndrome, visceral hypersensitivity
Cisapride	5-HT_4 receptor agonist, 5-HT_3 receptor antagonist	↑Motility: proximal > distal gut[4]	No[184]	Foregut dysmotility syndromes: gastroparesis, postprandial hypomotility, pseudo-obstruction, possible role in constipation
Tegaserod	5-HT_4 receptor, potent partial agonist	↑Enhances gastric motility, stimulates peristaltic reflex and intestinal secretion, shortens colonic transit time[91,92]	Yes[92]	Constipation-predominant IBS in adult women
Bethanecol	Muscarinic receptor agonist	↑Contraction amplitude but not transit[97–99,185]	No; increased sensitivity[185]	GERD
Neostigmine	Anticholinesterase	↑Motility and transit: colonic > proximal[185–187]	No; increased sensitivity[185]	Acute colonic pseudo-obstruction, episodic pseudo-obstruction
Baclofen	$GABA_B$ receptor agonist	↓Transient lower esophageal sphincter relaxations[107,108]	Possible (effective in neuropathic pain)[188,189]	GERD
Phenylephrine (topical)	α_1-Adrenergic agonist	↑Internal anal sphincter pressure[119,120]	No data	Fecal incontinence

GABA = γ-aminobutyric acid; GERD = gastroesophageal reflux disease; 5-HT = 5-hydroxytryptamine; MMC = migrating motor complex.

TABLE 76.3-2 ANTIMOTILITY AND ANTISPASMODIC DRUGS

DRUG	MECHANISM OF ACTION	EFFECT ON MOTILITY	REDUCES VISCERAL HYPERSENSITIVIY	POTENTIAL INDICATIONS
Loperamide	Mu opioid agonist	↓ Bowel motility and ↑ anal sphincter tone[4]	Yes[190]	Diarrhea, including IBS-D Hirschsprung disease post–pull-through surgery
Dicylomine, hyoscyamine	Nonspecific muscarinic antagonists	↓ Motility[4]	No data	Decreasing amplitude of painful/noxious visceral contractions, eg, visceral hypersensitivity, IBS, neuropathic pseudo-obstruction
Mebeverine	Complex actions at multiple receptors	Small intestine: mixed effects,[191] colonic motility[192]	No data	Decreasing amplitude of painful/noxious visceral contractions, eg, IBS
Nifedipine, verapamil, diltiazem	L-type calcium channel antagonists	↓ Amplitude contractions[149,150]	No data	Decreasing amplitude of painful/noxious visceral contractions, eg, nutcracker esophagus, diffuse esophageal spasm, esophageal achalasia
Pinaverium	Selective gastrointestinal calcium channel antagonist	↓ Colonic motility[193–195]	No data	Decreasing amplitude of painful/noxious visceral contractions
Peppermint oil	Calcium channel antagonist[157,196]	↓ Motility: upper and lower GIT Esophagus: ↓ simultaneous contractions, ↑ peristaltic contractions	Possible (anesthetic actions)[197]	Decreasing amplitude of painful/noxious visceral contractions, eg IBS, spastic esophageal disorders
Nitrates	Nitric oxide donors	Smooth muscle relaxation	No[198]	Decreasing amplitude of painful/noxious visceral contractions, eg, nutcracker esophagus, diffuse esophageal spasm, anal fissures
Ondansetron	5-HT_3 antagonist	↓ Motility[4,62]	Yes[4,62]	Decreasing visceral hypersensitivity and nausea
Granisetron	5-HT_3 antagonist	↓ Motility[4,62]	Yes[4,62]	Decreasing visceral hypersensitivity and nausea
Alosetron	5-HT_3 antagonist	↓ Motility and tone: slows colonic transit, ↑ fluid absorption[4,92]	Yes[4,92]	Intractable IBS-D in adult women, unresponsive to standard medical therapies
Sumatriptan	5-HT($1_{B/D}$) receptor agonist	↑ Relaxation gastric fundus, colon ↓ gastric emptying[4,62]	No direct effect[199,200]	Increasing gastric receptive accommodation
Octreotide	Somatostatin receptor agonist	↓ Gastric emptying ↓ diarrhea, ↓ intestinal transit, ↓ secretions[54,201]	Yes[55]	Retarding gastric emptying, eg, in dumping syndrome; also reduces visceral hypersensitivity
Glucagon	Glucagon receptor agonist	↓ Motility smooth muscle relaxation	No data	Inhibiting gastrointestinal contractions, eg, during endoscopic procedures
Botulinum toxin	Prevents acetylcholine release from motoneurons	Denervation paralysis smooth muscle	No data	Reducing sphincter tone, eg, esophageal achalasia, anal achalasia, gastroparesis
Clonidine	α_2-Adrenergic agonist	↓ Motility and tone[198, 202]	Yes[55,189,198,202]	Inhibiting noxious/painful gastrointestinal contractions and visceral hyperalgesia, eg, IBS-D
Salbutamol	β-Adrenergic agonist	Smooth muscle relaxation	No data	Inhibiting noxious/painful gastrointestinal contractions, eg, proctalgia fugax

GIT = gastrointestinal tract; 5-HT= 5-hydroxytryptamine; IBS = irritable bowel syndrome; IBS-D = diarrhea-predominant irritable bowel syndrome.

Metoclopramide has proven useful in accelerating the passage of small bowel biopsy capsules in children.[11] Similarly, metoclopramide has been used to assist the placement of transpyloric feeding tubes, although the results of clinical trials are contradictory.[12] Low-dose erythromycin (see below) is more effective for this indication.[12,13]

Although metoclopramide increases lower esophageal sphincter tone in children,[14] the majority of studies have shown little or no effect on gastroesophageal reflux disease (GERD) as measured by prolonged pH monitoring.[14–18] Also, metoclopramide was less well tolerated than placebo, with side effects including irritability and dystonic reactions.[14,15] The current position paper of the NASPGHAN states that although cisapride appears to be a marginally effective prokinetic agent for the treatment of GERD, the effectiveness in children of other prokinetic agents, including metoclopramide, is unproven.[19]

Domperidone. Another dopamine antagonist, domperidone, is available in most countries outside the United States. Unlike metoclopramide, domperidone does not pass the blood-brain barrier, and CNS side effects are rare.[20] Despite this, domperidone does have antiemetic effects, owing to the fact that the chemoreceptor trigger zone is outside the blood-brain barrier, and domperidone exerts its CNS effects here.[20] Domperidone raises lower esophageal sphincter pressure, increases the amplitude of gastric and duodenal contractions, and accelerates small intestinal transit.[21,22]

Domperidone seems effective in gastroparesis. A recent randomized controlled trial demonstrated that domperidone was more effective than cisapride in improving symptoms, diabetic control, gastric emptying, and electrogastrography variables in diabetic children with gastroparesis.[23] As with metoclopramide, there is minimal evidence that domperidone therapy is beneficial in GERD.[19]

Motilin Agonists

The peptide hormone motilin is released by enteroendocrine cells in the small intestine during fasting and has a role in initiating the interdigestive MMC. Motilin excites presynaptic neurons in the ENS to stimulate postsynaptic cholinergic motoneurons and induce phasic contractions in smooth muscle.[24] Motilin also has direct excitatory effects at motilin receptors on gastrointestinal smooth muscle cells, inducing an increase in intracellular calcium.[25] Motilin agonists (motilides) are a promising class of prokinetics that is currently the subject of intensive research.

Erythromycin. Erythromycin is a motilin receptor agonist that in low doses (1–3 mg/kg) stimulates phasic contractions in the stomach identical to spontaneous phase III of the MMC.[26] These activity fronts originate in the antrum and propagate into the small intestine and are inducible in adults and children over 32 weeks gestational age.[27] In premature babies less than 32 weeks gestational age, erythromycin increases antral motility but does not induce MMCs.[28] At higher doses, erythromycin produces uncoordinated high-amplitude antral contractions without propagation in healthy individuals.[29]

Low-dose erythromycin is an effective gastric prokinetic and is useful in the treatment of gastroparesis, as well as for placement of transpyloric feeding tubes[13,30] and for elimination of blood from the upper gastrointestinal tract prior to endoscopy for gastrointestinal hemorrhage.[31,32] In a recent systematic review of trials in adult patients, erythromycin was superior to cisapride, metoclopramide, and domperidone for treatment of gastroparesis.[33] In children, oral erythromycin 1 mg/kg is at least as effective as oral metoclopramide 0.15 mg/kg for emptying the stomach prior to emergency surgery.[34] At a higher dose, erythromycin was associated with increased postoperative vomiting,[35] although higher doses may be necessary in treatment of individuals with severely delayed gastric emptying.

Erythromycin has been extensively studied as treatment for feeding intolerance in patients in intensive care and in premature infants.[36–43] Despite the documented lack of effect on MMCs below 32 weeks, studies on premature babies under this gestation age indicate that low-dose erythromycin is effective in reducing the number of days until full enteral feeding is established.[39–41] The authors commented that this may result in a substantial saving on hyperalimentation.[39] Importantly, there were no significant adverse effects. In particular, no increase in necrotizing enterocolitis was seen. Trials of erythromycin in antimicrobial doses have yielded conflicting results but, in general, have also led to improved feed tolerance.[36,37,39,42]

Other Motilides. Current research aims to develop motilin agonists devoid of antibiotic activity. Clinical trials of ABT-229, an erythromycin derivative, demonstrated enhanced gastric emptying in healthy volunteers.[44] However, there was no symptomatic improvement in randomized double-blind placebo-controlled trials in adults with functional dyspepsia [45] or diabetes,[46] and research on ABT-229 as a gastrokinetic agent has been discontinued.[3] Other nonantibiotic erythromycin derivatives under investigation for their prokinetic effects include EM523,[47] EM574,[48] and GM-611.[49]

Octreotide

Somatostatin is a naturally occurring gastrointestinal peptide hormone that has complex actions in the gastrointestinal tract. It can augment or counteract a wide variety of other peptides and can have both prokinetic and antimotility effects. Octreotide is a long-acting synthetic analog of somatostatin that may be administered by intravenous, subcutaneous, or intramuscular injection.

In children with chronic gastrointestinal disorders, octreotide stimulates phase III of the MMC, beginning in the small intestine, and inhibits gastric contractions.[50] The inhibition of antral activity is reversed by feeding[50] or by pretreatment with erythromycin.[51] Octreotide may be of benefit in chronic intestinal pseudo-obstruction, although clinical trials have been limited to adults with connective tissue diseases.

Because octreotide retards gastric emptying, therapy should ideally be given to patients who are receiving post-gastric feeds, such as transpyloric or jejunostomy feeding.

Alternatively, combination therapy with erythromycin may be of benefit because the suppressant effect of octreotide on gastric motility is counteracted by erythromycin.[52] Conversely, octreotide enhances the prokinetic effects of erythromycin in patients with intestinal pseudo-obstruction[52] and on gastric emptying in normal subjects.[53]

Despite stimulating phase III of the MMC, octreotide also has antidiarrheal effects. It inhibits small bowel transit[54] and intestinal and pancreatic secretions. In the colon, octreotide inhibits the postprandial tonic response, whereas phasic pressure activity is increased. Octreotide also has antinociceptive effects that may increase its therapeutic utility in diseases with a component of visceral hyperalgesia.[55]

Because of its inhibitory effects on gastric emptying, octreotide is beneficial in dumping syndrome,[56] reducing the duration of the fed pattern and hastening the return of the MMC after a meal.[57] However, data in children are lacking.

The predominant adverse effects of octreotide include pain at injection sites and gastrointestinal disturbance. Occasionally, hyper- or hypoglycemia, hypertension, headache, dizziness, fatigue, hepatic dysfunction, and cholelithiasis may occur. Theoretically, long-term use of octreotide could inhibit growth by suppressing growth hormone secretion, although this has not occurred in several children treated with octreotide for gastrointestinal diseases.[58–61]

5-HT_4 Agonists

Serotonin (5-HT) is ubiquitous throughout the gastrointestinal tract and is important in modulating motility through its actions at several different receptors (Figure 76.3-1). There is currently intense research interest in developing drugs that manipulate motility by stimulating or antagonizing gastrointestinal serotonin receptors. Several classes of serotonergic agonists and antagonists are discussed in this chapter, including 5-HT_4 agonists and antagonists of 5-HT_3 and 5-$HT_{1B/D}$ receptors. Stimulation of 5-HT_4 receptors initiates peristaltic contraction. These receptors are located on neurons in the myenteric plexus and on smooth muscle cells (see Figure 76.3-1).[62] Stimulation of cholinergic neurons at 5-HT_4 receptors results in acetylcholine release and enhanced contraction.[62]

Cisapride. Cisapride is a partial 5-HT_4 receptor agonist and a 5-HT3 antagonist with some affinity for dopamine D_2, 5-HT_2 receptors, and α-adrenoceptors.[63] Cisapride enhances gastric emptying in normals and in patients with gastroparesis. It increases lower esophageal sphincter tone and improves esophageal acid clearance, reducing esophageal acid exposure. Despite these effects, its clinical utility in unselected children with GERD is not supported by a recent systematic review.[64] This may be because cisapride has no effect on transient lower esophageal sphincter relaxations (TLESRs), the predominant mechanism of gastroesophageal

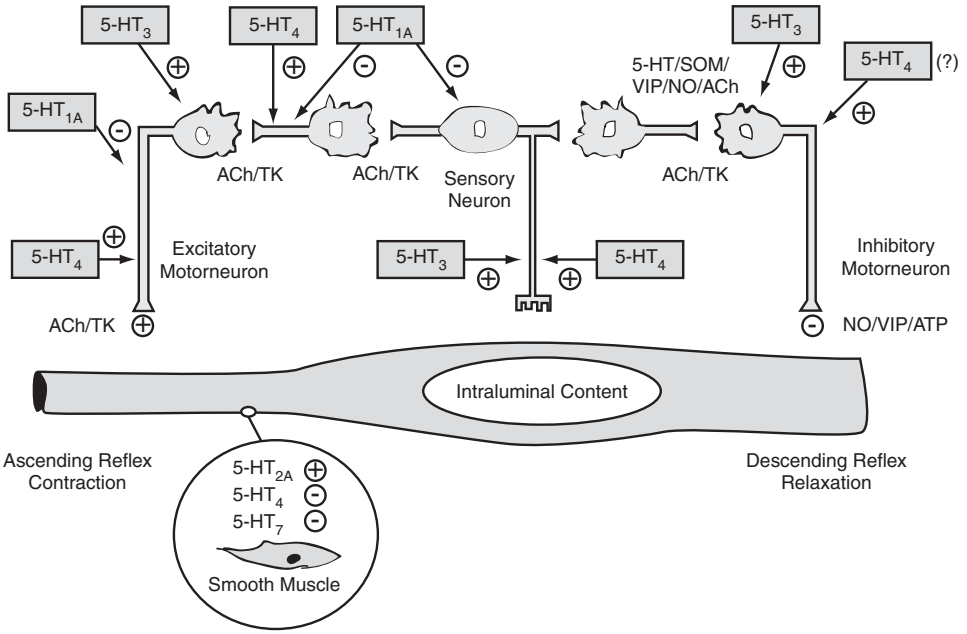

FIGURE 76.3-1 Modulation of intestinal motility by serotonergic receptors. Distention by intraluminal contents stimulates sensory neurons (intrinsic primary afferent neurons), which trigger an ascending excitatory reflex (leading to contraction) and a descending inhibitory reflex (leading to relaxation). Transmitters released by interneurons in the ascending reflex include acetylcholine (ACh) and substance P, whereas descending interneurons belonging to different subpopulations may use serotonin (5-hydroxytryptamine [5-HT]), somatostatin (SOM), vasoactive intestinal polypeptide (VIP), nitric oxide (NO), ACh, and other mediators as transmitters. Excitatory motoneurons release ACh and tachykinins (TK) at the neuromuscular junction, whereas inhibitory motoneurons may release NO, VIP, or adenosine triphosphate (ATP), depending on the gastrointestinal tract level and on the animal species. 5-HT_3 and 5-HT_4 receptors have an excitatory effect on enteric neurones, whereas 5-HT_{1A} receptors inhibit transmitter release. Serotonergic receptors may also directly contract or relax smooth muscle cells via 5-HT_{2A}, 5-HT_4, and 5-HT_7 receptors. + indicates stimulation; – indicates inhibition; (?) indicates limited data. Reproduced with permission from De Ponti F and Tonini M.[62]

reflux (GER).[65,66] Evidence for a beneficial effect of cisapride on reflux and feed intolerance in neonates is similarly contradictory.[67–71] In contrast, cisapride has proven effective in randomized trials in selected subsets of patients with reflux disease. In particular, cisapride improves symptoms, intraesophageal pH indices, and requirements for bronchodilator and steroid medication in patients with chronic respiratory symptoms and GER.[72–74]

Despite its documented efficacy in the treatment of gastroparesis,[33] a recent randomized trial demonstrated that domperidone is more effective for this indication in children.[23] Cisapride stimulates small intestinal motility and has been used in children with chronic intestinal pseudo-obstruction.[75–78] Response to therapy, as measured by the ability to tolerate enteral feeding, was predicted by the presence of phase III of the MMC in antroduodenal motility studies.[78] Cisapride is superior to placebo in the management of constipation.[79] However, owing to the risks of cardiac toxicity, use for this indication should be discouraged.

Cisapride Cardiotoxicity. Cisapride prolongs the Q–T interval in a dose-dependent manner, resulting in potentially fatal arrhythmias, including ventricular tachycardia, ventricular fibrillation, and torsades de pointes. From July 1993 to December 1999, 341 such cases were reported, including 80 deaths. In approximately 85% of these cases, the events occurred when cisapride was used in patients with known risk factors.[80] Patients most at risk include those who are receiving high doses or who have congenital or acquired long Q–T syndrome. Drugs that interfere with the metabolism of cisapride by the cytochrome P-450 (CYP)3A4 system potentiate cisapride cardiotoxicity and are contraindicated in patients on the medication. These include macrolide antibiotics, azole antifungals, and nonsedating antihistamines. Grapefruit juice also increases cisapride bioavailability by inhibiting CYP3A4.[81]

Until recently, it was unclear whether cisapride cardiotoxicity was a result of 5-HT_4 receptor stimulation or the molecular characteristics of cisapride and other members of the benzamide class. Clinical and experimental evidence now supports the latter theory. Clinical trials of tegaserod, a selective 5-HT_4 receptor agonist, showed no alteration of Q–T interval versus placebo in over 2,500 subjects.[82] In contrast, cisapride possesses class III antiarrhythmic properties and prolongs the action potential duration through blockade of distinct voltage-dependent K^+ channels, thus delaying cardiac repolarization and prolonging the Q–T interval.[83] Concurrent use of cisapride is therefore contraindicated in children receiving class III antiarrhythmic agents. To put the potential for cisapride cardiac toxicity in perspective, a critical analysis of safety data by Vandenplas showed that there were two instances of serious ventricular arrhythmia, Q–T prolongation, or sudden death reported for every million patients treated for a month, of which more than 85% could be related to known risk factors.[84]

Importantly, intravenous erythromycin at antimicrobial doses[85,86] and domperidone[87,88] have both been associated with prolongation of Q–Tc and cardiac arrhythmia.

Safety concerns about cisapride cardiotoxicity resulted in its withdrawal from sale in North America, most European countries, and Australasia. In some countries, including the United States, patient access to the drug is now restricted to investigational limited access programs. Patients must meet strict eligibility criteria, have failed other treatment options, and be stringently monitored. In pediatrics, cisapride is available under such programs for refractory GERD, pseudo-obstruction, and neonatal feeding intolerance, although specific details vary between countries.

Other side effects of cisapride include transient diarrhea; flatulence; borborygmi or abdominal cramps; CNS disturbances such as seizures, behavior disturbance, and extrapyramidal effects; and a dose-related increase in urinary frequency. Because of the importance of the liver and kidneys in its metabolism and excretion, the dosage should be reduced in patients with hepatic or renal insufficiency.

Other Benzamide Derivatives. Newer members of the benzamide class, all unavailable in the United States at present, include mosapride, renzapride, levosulpiride, and KDR-5169.[89] KDR-5169 is a 5-HT_4 agonist with dopamine D_2 receptor antagonist properties. In a recent animal study, it was extremely effective in treating gastroparesis, accelerating gastric emptying to supranormal levels.[89] The authors speculated that the increased efficacy of KDR-5169 over cisapride may have been due to more potent antagonism of D_2 receptors because combination therapy with cisapride and domperidone (a D_2 antagonist) has previously been shown to improve gastric emptying versus cisapride alone.[90]

Tegaserod. Tegaserod (HTF 919) is a specific 5-HT_4 antagonist recently licensed for the treatment of constipation-predominant irritable bowel syndrome (IBS-C) in adult women. Like cisapride, it accelerates gastric emptying and promotes gastrointestinal transit.[91,92] Unlike cisapride, tegaserod has no cardiotoxicity,[82] requires only twice-daily dosing, and does not cross the blood-brain barrier to cause CNS side effects. Clinical trials in adults with IBS-C indicate that tegaserod improves constipation, bloating, and overall symptom scores.[4,92] Diarrhea, abdominal cramping, headache, flatulence, and fatigue are the major associated adverse effects, resulting in discontinuation of the medication in 10 to 15% of patients.[93,94] The potential clinical use of tegaserod for GER was studied in adults with mild to moderate GERD. Tegaserod reduced esophageal acid exposure by 50%,[95] possibly by reducing the incidence of postprandial transient lower esophageal relaxations and/or by accelerating gastric emptying.

Prucalopride. Prucalopride (R0-93877) is another 5-HT_4 partial agonist that also accelerates gastrointestinal transit and has proven useful in treatment of constipation in adults. However, further clinical development of this compound has been suspended pending the results of toxicity studies owing to concerns about carcinogenesis in animals and possible cardiac effects.[96]

Bethanecol

Bethanecol is a choline ester that stimulates muscarinic cholinergic receptors. It increases the amplitude of contractions throughout the gastrointestinal tract and raises lower esophageal sphincter tone.[97–99] Contrary to previous reports, it does not accelerate gastric emptying or gastrointestinal transit in adults or children.[7,99,100] Two trials evaluated its utility in pediatric GERD and demonstrated modest benefits, no greater than that achieved with antacids.[101,102] Its usefulness is also limited by side effects, including abdominal cramps, watery diarrhea, bradycardia, hypotension, urination, sweating, and bronchoconstriction.

Neostigmine

Neostigmine is a peripheral anticholinesterase. By inhibiting degradation of acetylcholine, it enhances cholinergic activity at nicotinic receptors in the myenteric plexus and muscarinic receptors on gastrointestinal smooth muscle. Neostigmine accelerates gastrointestinal transit, especially in the colon. It has proven efficacy in reversal of acute colonic pseudo-obstruction (Ogilvie syndrome), with colonic decompression occurring within minutes of drug administration in prospective randomized double-blind placebo-controlled studies.[103,104] Side effects were limited to mild abdominal cramping and bradycardia, which were responsive to atropine. This simple, effective therapy may now become the standard of care for acute colonic pseudo-obstruction in adults[105]; however, further data on pediatric patients are required. It has been suggested that the longer-acting anticholinesterase pyridostigmine may be beneficial for the outpatient management of gastrointestinal motility disturbances.[106]

Baclofen

Although not strictly a prokinetic, baclofen increases lower esophageal sphincter pressure and inhibits TLESRs by simulating the actions of the inhibitory neurotransmitter γ-aminobutyric acid in the brainstem.[107,108] This agent is being explored for its role in reducing gastroesophageal reflux. In the meantime, this mechanism is of potential benefit to neurologically handicapped children receiving baclofen for spasticity, possibly counteracting their known tendency to pathologic GER. Trials of baclofen in pediatric GERD are ongoing.

Other drugs have been shown to inhibit TLESRs and GER, including cholecystokinin A antagonists,[109] atropine,[110] morphine,[111] and nitric oxide synthase inhibitors.[112] The search for specific agents for pharmacologic suppression of TLESRs is currently the subject of intense research activity.

Opioid Agonists

The Mu-opioid agonist fedotozine has both antinociceptive and promotility effects. Although the antinociceptive properties are mediated by stimulation of Mu-opioid receptors, it is likely that the prokinetic effects of fedotozine are due to a different mechanism, direct smooth muscle excitation.[113] In clinical trials of adults with IBS, fedotozine was superior to placebo in reducing abdominal pain and bloating.[114]

Cholecystokinin Antagonists

Although not currently available outside therapeutic trials, this class of agents is expected to reach the public some time in 2004.[4] Cholecystokinin (CCK) is released from the gut in response to fat and protein in food. CCK_A receptors on visceral afferents in the gut mediate sensations of satiety and gastric receptive relaxation via a vagal reflex. Stimulation of CCK_A receptors in the gallbladder and pancreas causes release of digestive juices. Whereas CCK_A receptors mediate stimulation of duodenal activity, CCK_A stimulation relaxes the lower esophageal sphincter, stomach, and colon via a nitric oxide–dependent mechanism.[115–117] CCK_A antagonists such as loxiglumide and dexloxiglumide reduce TLESR, promote gastric emptying, shorten colonic transit time, and increase the number of bowel movements.[4,109,118]

α-Adrenergic Agonist: Phenylephrine

Topical phenylephrine increases anal sphincter tone in normals[119] and in patients with incontinence owing to low resting sphincter pressure.[120] In an initial trial, low concentration (10%) phenylephrine was ineffective in patients with incontinence owing to low resting anal sphincter pressure.[121] However, this concentration was effective in treating fecal incontinence after ileoanal anastomosis.[122] Research on the use of topical phenylephrine for fecal incontinence owing to internal anal sphincter incompetence is ongoing.

ANTISPASMODICS AND ANTIMOTILITY DRUGS

Opioid Agonist: Loperamide

Loperamide is a specific agonist at peripheral Mu-opioid receptors that has both antinociceptive and antimotility actions. Because it does not pass through the blood-brain barrier, CNS effects, including the potential for addiction, do not occur. The overall effect of loperamide is to delay gastrointestinal transit. Although loperamide stimulates gastrointestinal contractions, there is a disruption in the normal propulsive patterns of motility, leading to increased transit time.[3] The safety and efficacy of loperamide in treatment of diarrhea are well established, with the caveat that no hypomotility agent is recommended in the context of acute infective diarrhea in children or dysentery at any age.

Anticholinergics

Anticholinergic medications have traditionally been used as antispasmodics. Blocking the action of acetylcholine at smooth muscle reduces the amplitude of gastrointestinal contractions, and this has been particularly useful in dysmotility syndromes characterized by excessive contractile activity. Older anticholinergic medications include scopolamine, dicyclomine, and hyoscyamine. Their therapeutic utility was limited by their nonspecific actions and unwanted side effects caused by antagonism of muscarinic receptors outside the gastrointestinal tract. These include dry mouth, tachycardia, blurred vision, and urinary difficulties. Toxicity has been a particular problem in children, with reports of serious side effects and anticholinergic poi-

soning.[123–127] Despite their widespread use, there are very few randomized controlled trials of anticholinergic drugs for gastrointestinal motility disorders in children.[128] A recent systematic review of 18 randomized controlled trials of antispasmodic and anticholinergic drugs in IBS concluded that, overall, the trials were of suboptimal methodologic quality. Evidence of effectiveness for these agents in IBS was inconsistent, and adverse effects limited their use.[92]

M_3 Muscarinic Antagonists

Recently, more specific anticholinergic drugs have been developed that target the M_3 muscarinic receptor responsible for gastrointestinal contraction.[129] M_3 receptors are also found in the bladder (and these drugs have been employed in enuresis and urinary incontinence); however, they are not present in the heart, and cardiovascular side effects do not occur.[130] Examples are zamifenacin and darifenacin, which both inhibit contractile activity throughout the small and large bowel.[4] In a multicenter double-blind parallel-group placebo-controlled study of adult patients with IBS, zamifenacin profoundly inhibited colonic motor activity without significant extraintestinal side effects.[130]

Mebeverine

Although mebeverine has some antimuscarinic activity, it is far less potent than atropine. The spasmolytic action of mebeverine is the result of at least three additional mechanisms. Mebeverine has a direct musculotropic action involving calcium ion exchange and stabilization of excitable membranes, a local anesthetic action, and also potentiates sympathetic inhibition of gastrointestinal contraction owing to blockade of noradrenaline uptake into sympathetic nerve endings.[131–133] Mebeverine seems effective in reducing diarrhea and global symptom scores in adults with IBS; however, data from children are scant.[128]

5-HT_3 Antagonists

Alosetron is a 5-HT_3 antagonist that inhibits colonic transit and reduces colorectal hypersensitivity, probably by inhibiting 5-HT_3 receptors on vagal afferents and in the CNS.[4] In the colon, it delays transit and decreases wall tension and sensitivity to distention.[4,92,134] It is effective in female adults with diarrhea-predominant IBS (IBS-D), improving stool consistency and frequency and reducing pain and urgency.[4,92] The most commonly reported side effect was constipation. Owing to reports of rare severe side effects, including ischemic colitis and severe constipation, alosetron was temporarily withdrawn from sale in 2000. In 2002, it was reintroduced for use in women with severe IBS-D who have failed to respond to conventional IBS therapy. The recommended adult dosage is 1 mg twice daily, and the agent should be avoided in patients with constipation.

5-HT_1 Antagonist

Originally developed to treat migraine headaches, the 5-$HT_{1B/D}$ antagonist sumatriptan also has effects on gastrointestinal motility. This agent enhances postprandial gastric fundic relaxation and reduces symptoms of early satiety in patients with functional dyspepsia.[135] Although sumatriptan inhibits gastric motility, it stimulates small intestinal contractions, causing premature phase III of the MMC after subcutaneous injection in fasting individuals.[136] Despite increasing lower esophageal sphincter tone, sumatriptan increases postprandial reflux episodes via an increased incidence of TLESRs and delayed gastric emptying.[137]

Botulinum Toxin

Botulinum toxin (BT) type A is widely used for reduction of muscle spasticity in children with cerebral palsy or strabismus. The toxin binds irreversibly to presynaptic cholinergic nerve terminals, where it prevents the release of acetylcholine, causing paralysis by functional denervation. These effects persist for several months, with reversal dependent on sprouting of new terminal axons.

Gastrointestinal uses of BT revolve around the injection of sphincters[138] and include cricopharyngeal dysphagia,[139] achalasia of the esophagus,[140] spastic esophageal disorders,[141] gastroparesis (pyloric injection),[142] anal achalasia,[143] and fissure in ano.[144] In children with persistent obstructive symptoms after anal pull-through procedures for Hirschsprung disease, BT injection of the internal anal sphincter has been advocated as an effective and atraumatic alternative to myectomy.[145,146] Current pediatric data on the use of BT for gastrointestinal disorders are limited to individual case reports and small series. Larger randomized placebo-controlled trials are needed to fully define efficacy, dosage interval, side-effect profile, and cost effectiveness.

Clinical use of BT in thousands of patients for musculoskeletal disorders and cosmetic applications suggests that BT is extremely well tolerated. Repeated use has been associated with the development of antibodies to BT and reduction of the magnitude and duration of clinical effects. The possibility of distal or systemic paralysis is extremely unlikely given that the estimated lethal dose is 40 U/kg (intramuscularly or intravenously),[147] and doses of 100 U (one vial) or less are sufficient for gastrointestinal interventions. Even if inadvertently injected into the bloodstream, this dose is unlikely to have significant effects.[138] Adverse reactions related to the physiologic effect of BT include occurrence of GER symptoms after lower esophageal sphincter injection. Transient incontinence of flatus and stool has been reported after anal sphincter injection in children with anal hypertonia after surgery for Hirschsprung disease[146] and in adults treated for anal fissure.[148] Adjacent regions may be affected, for example, with the development of dysphagia after head and neck injections for cervical dystonia.

Calcium Channel Blockers

Nonselective: Nifedipine, Verapamil, and Diltiazem. Calcium channel antagonists reduce the amplitude of gastrointestinal contractions.[149,150] There are anecdotal reports of their successful use in children with esophageal motility disorders, such as diffuse esophageal spasm and nutcracker esophagus, and with severe antral spasms.[151–153]

Selective: Pinaverium Bromide. This agent inhibits gastrointestinal contractions by preventing influx of calcium into myocytes. Most of the orally administered dose remains in the gut, resulting in antispasmodic effects at doses that do not cause cardiovascular disturbance.[154] Pinaverium reduces postprandial colonic activity in patients with IBS[155] and has been successful in reducing pain in trials of adult patients with IBS.[156]

Peppermint Oil

In vitro, peppermint oil inhibits smooth muscle contraction in a manner similar to that of the dihydropyridine calcium antagonists by reducing calcium influx.[157] This results in reduced contraction amplitudes at the lower esophageal sphincter,[158] stomach,[159] and small intestine[159] and prevents colonic spasm.[160,161] However, other therapeutic effects are likely. In a study of adults with diffuse esophageal spasm, peppermint oil converted simultaneous to peristaltic contractions and alleviated chest pain, without any reduction of peristaltic amplitude.[162] In a manometric study of peppermint oil and caraway oil, the duration of phase III of the MMC was shortened, in addition to reductions in contraction amplitude and frequency. A nonenteric coated preparation had more rapid effects and more marked suppression of gastric contractions than an enteric coated preparation.[159] In recent systematic reviews, peppermint oil was found to be efficacious in the treatment of IBS in children and adults.[163,164]

Nitrates

Nitric oxide donors such as glyceryl trinitrate and isosorbide dinitrate have been used to reduce the intensity of gastrointestinal contractions in the treatment of fissure in ano, anal achalasia, and spastic disorders of the esophagus.[144,165,166] Side effects such as hypotension and headache are frequently reported and require careful dosage titration.[151] As a result, these agents are probably best used on a short-term or "as required" basis.

Glucagon

Glucagon relaxes smooth muscle throughout the gastrointestinal tract. Pharmacologic uses of glucagon as an antispasmodic include inhibition of small intestinal contractions during endoscopic retrograde cholangiopancreatography and relaxation of the esophagus in cases of impacted foreign bodies. Interestingly, recent prospective randomized double-blind placebo-controlled trials in children and adults failed to show any benefit of glucagon over placebo for this indication.[167,168]

Adrenergic Agonists and Antagonists

α_2-Adrenoceptors mediate sympathetic nervous system inhibition of motility in vivo.[169] α_2-Adrenergic agonists such as clonidine are being investigated for their antidiarrheal and antinociceptive actions.[55] However, the use of clonidine in gastrointestinal motility disturbance has been limited by marked intraindividual variation in response[170] and the potential for systemic hypotension.

The β_2-receptor agonist salbutamol, when administered by an inhaler, is effective in reducing the duration of severe pain in proctalgia fugax.[171–173] However, this agent does not affect resting anal pressure between attacks,[171] and the mechanism of action of salbutamol in this condition is unknown. Because attacks of proctalgia fugax are associated with increased anal tone,[174] salbutamol probably acts to reduce abnormal excessive contractions during attacks.

Other Antispasmodic Drugs on the Horizon

Other antispasmodic, motility-inhibiting drugs currently being developed include neurokinin$_2$ antagonists (such as MEN-10627 and MEN-11420) and β_3-adrenoreceptor agonists (eg, SR-58611A). Both groups are able to decrease painful contractile activity in the gut without significantly affecting other bodily functions.[175]

CONCLUSION

Owing to the recent explosion in knowledge about the ENS and gastrointestinal motility, therapeutic options for patients with motility disturbance are rapidly expanding. New agents are being tested, and many older drugs, previously used for diseases as diverse as asthma, depression, and arterial hypertension, are being assessed for their utility in the gastrointestinal system. Because symptoms of most gastrointestinal motility disorders fluctuate over time and there may be a significant placebo effect on both symptoms and motility indices,[176] any new therapies require thorough evaluation in appropriately sized randomized placebo-controlled trials. As with any chronic disease, the importance of an effective physician-patient relationship in caring for patients with motility disturbance cannot be overstated. Pharmacologic therapy for functional bowel disorders is best administered as part of a biopsychosocial approach.[177]

4. Pharmacologic Therapy of Exocrine Pancreatic Insufficiency

Geoffrey Cleghorn, MBBS, FRACP, FACG

The exocrine pancreas is involved in both the digestion and absorption of orally ingested nutrients. Normally, the fluid and exocrine secretions from the pancreas are secreted in great excess following a meal, and, in fact, before clinical manifestations of exocrine pancreatic insufficiency become manifest, over 98% of the gland's function needs to be lost.

Pancreatic fluid has two major components: a fluid consisting primarily of a solution of sodium bicarbonate and an enzyme component consisting of about 20 digestive enzymes and cofactors. The alkaline fluid serves to neutralize gastric acid entering the duodenum and helps to provide an adequate intraluminal pH for the optimal function of the pancreatic digestive enzymes. These enzymes provide the major route for intraluminal digestion of dietary proteins, triglycerides, and carbohydrates and are also involved in the cleavage of certain vitamins, such as A and B_{12}. Therefore, failure of the exocrine pancreas to secrete adequately its enzyme- and electrolyte-rich fluid can lead to major nutritional disturbances that manifest clinically as steatorrhea and azotorrhea, with resultant growth failure.[1] In addition to the obvious lack of intraluminal digestive activity as a result of the enzyme deficiencies, the failure of bicarbonate secretion also has major effects on both intraluminal pH and enzyme activity. An abnormally low pH can be seen in the late postprandial period, which reduces lipid digestion by inactivating pancreatic lipase and also by precipitating bile salts.

Not all diseases involving the exocrine pancrease have equal effects on both the enzyme component and the electrolyte component of the gland's secretion. In general, patients with cystic fibrosis (CF) have major deficits in both enzyme and electrolyte secretion, although there is a wide range of abnormalities; however, patients with Shwachman-Diamond syndrome have intact fluid and electrolyte secretion with marked disturbances in enzyme output.

CF is the most common cause of exocrine pancreatic insufficiency in childhood. Therefore, it is patients with CF who most commonly require oral pancreatic replacement therapy with pancreatic enzymes. Irrespective of the etiology of pancreatic failure, current replacement therapy with oral pancreatic enzymes, although far from ideal in many patients, remains the most important method of correcting the nutritional effects of maldigestion. Despite considerable improvements in the efficacy of pancreatic replacement therapy, it remains difficult to correct malabsorption completely in all patients owing to the many factors adversely affecting the function of exogenously administered enzymes.

Because the major clinical manifestation of pancreatic failure is steatorrhea with large, bulky, malodorous stools, early management protocols of patients with pancreatic insufficiency relied heavily on severe restriction of dietary fat. A low-fat diet did indeed produce socially more acceptable stools, but it also severely restricted calories and essential fatty acids, which contributed significantly to clinical malnutrition and disease morbidity. Use of a low-fat diet in the management of pancreatic failure is no longer considered acceptable; in fact, some centers advocate the use of a high-fat diet, in conjunction with optimal pancreatic enzyme replacement therapy, to maximize total energy absorption.

PANCREATIC ENZYME REPLACEMENT

Extracts of pancreatic enzymes from animal sources have been available for almost a century and have been used clinically for a variety of conditions. However, in spite of their recognized importance, the use of pancreatic enzymes is still not without its difficulties (Table 76.4-1). Commercial enzyme supplements do not have an indefinite shelf life, and, for this reason, patients should be warned not to stockpile large quantities of enzymes. In fact, many commercially available supplements are initially packed with much

TABLE 76.4–1 FACTORS ADVERSELY AFFECTING THE EFFICIENCY OF PANCREATIC ENZYME REPLACEMENT THERAPY

PHARMACOLOGIC PHASE
Enzyme source (porcine, bovine, fungal)
Enzyme stability
Particle size of microspheres
Inadequate enzyme concentration
Inappropriate oral administration
Poor compliance
GASTROINTESTINAL PHASE
Inactivation by gastric acid
Insufficient mixing with chyme
Delay in gastric emptying
Prolonged acidic intraluminal pH
Bile acid precipitation
Abnormal intestinal motility
Proteolytic destruction of lipase

higher protease and lipase values than their listed potencies to allow for this decline. Thomson and colleagues showed a decline of up to 20% in enzyme activity over an 8-month period in several different enzyme preparations, even though all were within the expiration date quoted by the manufacturers.[2] The earliest pancreatic extracts contained low concentrations of active enzymes. Furthermore, only minimal amounts of these were available for intestinal digestion because of gastric inactivation with acid and pepsin, with degradation of lipase and trypsin occurring below pH 4.5 and 3.5, respectively. Even the more active preparations in current use are rapidly degraded in the stomach when unprotected; up to 90% of ingested lipase and 80% of ingested trypsin have been found to be degraded prior to entering the ligament of Treitz.[3]

Broadly speaking, research has focused on three avenues of approach in improving nutrient absorption in patients with pancreatic insufficiency. First, because the older enzyme preparations were highly variable in enzyme content, the more modern approach has been to provide increased concentration of enzyme (up to 20,000 lipase units) in a single capsule or tablet.[4] Second, methods of protecting enzymes from gastric inactivation have been refined. Intensive research has also been aimed at manipulating the acid-alkaline imbalance in both the gastric and intestinal phases of enzyme activity. Third, attempts have been made at improving bile salt function.

Protective barriers were first used to make the enzyme preparations more resistant to acid inactivation. Initially, this was attempted by coating enzyme tablets with an acid-resistant material, but it was soon discovered that these preparations were no better than conventional preparations, and, in some cases, the steatorrhea was worse. This was thought to be due to both inefficient mixing of the tablet with the ingested chyme in the stomach and failure of liberation of the active enzyme in the duodenum secondary to slow release of the active ingredients. In fact, these tablets were not infrequently seen intact in the stools of patients taking them.[5]

To improve delivery of enzymes to the small intestine, a number of commercial pharmaceutical companies developed techniques capable of coating small "microspheres" with an acid-resistant coating.[6–12] The microspheres, in turn, were packaged in a gelatin capsule. The rationale behind this preparation is that the acid-resistant layer around the small spheres prevents acid-peptic degradation within the stomach, but their small size permits passage with chyme into the duodenum. When exposed to duodenal contents with a pH in excess of 5.5, the acid-resistant coating breaks down, releasing active pancreatic enzymes. This exposure may not occur in the proximal duodenum, however, because in CF, the postprandial intraluminal duodenum pH can frequently be below 5.0 for long periods of time. Thus, continued enzyme protection from the highly acidic milieu in the duodenum by the acid-resistant coating may allow for more distal bioavailability. The size of the microspheres also appears to be very important for adequate function. Several groups have shown that digestion in pancreatic insufficiency is more effective with microspheres of less than 1.4 mm compared with larger preparations, supporting the belief that microspheres of this size or smaller will optimally mix with the meal and empty the stomach together with the chyme, improving their digestive efficacy.[4]

Despite these advances in the use of microspheres, there is still some doubt over the reliability of gastric emptying. A study of 12 CF patients has shown considerable variation in gastric emptying and intestinal transit for food and pancreatic microspheres, with enzyme pellets generally emptying from the stomach more rapidly than the food.[13] This mismatch of emptying can be as high as 60 minutes in some patients, which will have obvious ramifications on the amount and timing of the enzyme replacement therapy.

Use of these enteric-coated microspheres has resulted in considerable improvement in fat absorption over that with conventional enzyme therapy.[7] A study has shown that CF patients with refractory malabsorption on conventional enzyme therapy derive significant benefit, with decreased steatorrhea and creatorrhea, using fewer capsules.[7] Other studies have found better compliance and improved absorption with these preparations, except in a minority of patients who appear to have acidic small intestinal contents, thereby preventing dissolution of the acid-resistant coating. Thus, there are few current uses for noncoated enzyme replacement therapy, although even with these modern preparations, some patients still have significant malabsorption.

In addition to acid-peptic denaturation and particle size, rapid proteolytic degradation of lipase, particularly by chymotrypsin, in the proximal small intestine is another important factor that limits the efficacy of pancreatic enzyme replacement therapy. Attempts at protecting lipase from this degradation using protease inhibitors have shown enhancement of lipolysis throughout the entire length of the small intestine.

The number of capsules required depends on the amount of active enzymes in the particular commercial preparation and also on the type and quantity of the meal to be consumed. To abolish malabsorption, the amount and concentration of enzyme present in the duodenum must be 5 to 10% (40–60 IU/mL intraluminal lipase concentration) of the quantities of endogenously secreted enzymes usually present in normal individuals after postprandial stimulation of the pancreas.[3] In an adult, assuming no inactivation of enzymes in the stomach and duodenum, approximately 25,000 to 40,000 U of lipase must be taken with an average meal.[14] In reality, the quantity of enzymes required becomes much higher (perhaps up to 10-fold) if one considers the degree of gastric inactivation and the consumption of a high-energy diet. There is, however, enormous patient to patient variability, and each patient and meal must be considered individually. In general, however, in light of findings regarding fibrosing colonopathy,[15] the daily dose of pancreatic enzymes for most patients should remain below 10,000 U of lipase/kg (Table 76.4–2).

Enzymes derived from porcine sources are the current standard treatment of exocrine insufficiency. Supplementation with enzymes from different species has also been suggested as a method of achieving improved digestion.

TABLE 77.4–2 SUGGESTED DAILY REQUIREMENTS OF PANCREATIC ENZYME REPLACEMENT THERAPY

AGE (YR)	APPROXIMATE DAILY FAT INTAKE (G)*†	DAILY LIPASE UNITS (000S)† (MAXIMUM DAILY DOSE 10,000 U LIPASE/KG/D)
0.0–0.5	25	12.5–25
0.5–1.0	30	15–30
1–3	35	17.5–140
4–6	50	25–200
7–10	60	30–240
11–14	90	45–360
15–18	110	55–440

*Assume 40% of total energy needs.
†In cystic fibrosis, multiply by a factor of 1.5.

Enzymes from bovine sources have been considered but discarded owing to their inferior lipase content and hence increased tablet requirement.[16] Acid-resistant lingual lipase has been proposed as an enzyme worthy of further consideration and investigation. In a preliminary study in animals, lingual lipase was found to be stable in the stomach under both fasting and fed conditions but to be less stable in the duodenum; however, to date no worthwhile clinical trials have been undertaken or reported.[17,18] Lipases derived from fungi have also been examined for their acid-resistant properties, with these experimental studies possibly becoming forerunners of in vivo human work examining pancreatic enzyme supplementation containing "foreign" enzymes. Fungi, such as *Rhizopus arrhizus*, *Candida cylinderaza*, and *Aspergillus niger*, are potential sources of lipase, which differs from lipases of animal origin in that fungi provide greater amounts of acid-stable lipase activity in the stomach; however, they appear to be highly sensitive to denaturation by even low concentrations of bile acids. Despite early promise in vitro, early in vivo studies have failed to extend their clinical usefulness.[19–21]

Lipases derived from bacteria are, however, more promising in their efficacy. Unlike fungal lipases, lipase of bacterial origin appears to be resistant to both acid and alkaline inactivation as well as being stable in the presence of both proteolytic enzymes and bile salts.[22–24] These recent studies have suggested that lipase derived from *Burkholderia plantarii* has far greater lipolytic activity than conventional porcine products, holding out the potential for a dramatic reduction in the quantity of individual tablets required for equivalent lipase activity, but, to date, no human trials have been reported.[23,24]

It is also now possible using recombinant deoxyribonucleic acid (DNA) techniques to produce human acid-stable lipases because the gene for human gastric lipase has now been transfected and expressed using recombinant adenovirus in a variety of animal models.[25,26] Similarly, application of bioengineered, acid-resistant human gastric lipase is also being actively explored in in vitro studies, but, to date, human trials are still pending in these areas.[27,28]

Irrespective of the enzyme preparation used and the amount given, it is imperative that the enzymes be delivered in sufficient amounts to the small intestine to facilitate digestion. It is insufficient simply to take a handful of enzymes at the beginning or end of a meal and hope that this will result in optimal pancreatic replacement. For optimal efficacy, it has been suggested that enzymes be distributed throughout the meal and taken in several small aliquots. This, in theory, allows for adequate dispersal within the stomach throughout the meal and therefore allows for maximum exposure of that particular meal to the ingested enzymes. However, as mentioned above, there is still no certainty that the enzymes will both mix completely with the food and also empty from the stomach uniformly.

MONITORING ENZYME EFFICACY

The simplest method of monitoring the effectiveness of the enzyme replacement therapy is to regularly monitor the patient's growth (in particular weight) and also the nature and consistency of the stools. In general, it is not very difficult to ascertain by history alone if a patient's enzyme dosage is insufficient on the basis of a stool history, but the associated history of abdominal pain is far less helpful. However, it is much more difficult to gauge on the basis of history alone whether a dosage is, in fact, excessive. More precise, yet still very qualitative, to perform is a quantitative assessment of fat absorption pre- and postenzymes with a fecal fat analysis. Each individual requires an objective, quantitative assessment of fecal fat losses as a percentage of fat intake at baseline and after any major adjustments in enzyme replacement therapy. Quantitative fecal fat estimation is the one reliable method, but there are practical limitations. Breath tests for the detection of pancreatic insufficiency have also been developed.[29,30] Cholesteryl octanoate breath testing using a carbon 14 or carbon 13 label has been shown to monitor intraluminal enzymatic activity in both controls and patients with pancreatic insufficiency after treatment with different forms of enzyme replacement. Fecal chymotrypsin and elastase 1 measurements have also been suggested but are still only in research use. Others have suggested that the pancreatic Schilling test is also a means of assessing replacement therapy.[31] This is based on the relationship between the pancreatic output of trypsin and the urinary excretion of cobalamin.

SIDE EFFECTS

Enzyme therapy is not without potential problems in that, being concentrated proteolytic packages, enzymes have the potential for causing quite marked oral excoriation if chewed or held within the mouth too long. This is a particular problem in small infants, in whom gum or mouth injury frequently occurs; with rapid transit through the intestinal tract, anal excoriation has also been observed.

Hyperuricemia and uricosuria are believed to result from the high purine content of the conventional enzyme preparation. Obviously, the greater the dose, the higher the incidence of these biochemical abnormalities. Allergic responses such as bronchospasm, nasal irritation, and repeated coughing may develop, not only in the patients receiving the

enzymes but also in any susceptible caregiver coming into repeated close contact with the enzyme preparations. These allergic reactions were much more prevalent with the nonencapsulated forms of the enzyme preparations.

The antigenicity of the pancreatic extracts should not be underestimated. Anaphylaxis has been observed in patients and caregivers exposed to the enzymes, particularly in a powdered form. Each capsule is a potent source of foreign protein, and small but significant amounts are absorbed into the body. Couper and Quirk and their colleagues studied two groups of CF patients using an enzyme-linked immunosorbent assay[32,33] specifically to detect immunoglobulin G (IgG) antibody directed against porcine trypsin. No antibodies were detected in patients prior to commencement of enzyme replacement, but 96% had developed porcine trypsin-binding IgG within a few years. This antibody production may possibly accentuate immune complex disease progression, which is well known in CF.

After its initial description and significant concerns, fibrosing colonopathy continues to generate debate as to its true place in the cystic fibrosis arena. First reported in 1994, fibrosing colonopathy is characterized by marked submucosal fibrosis with thickening of the muscularis propria and chronic inflammation chiefly affecting the cecum and ascending colon.[34] Typically, fibrosing colonopathy occurs in younger children, although it has been described arising de novo in a young adult patient with CF. Symptoms suggestive of colonic obstruction (abdominal pain and vomiting) occur within a few months after starting high-dose pancreatic enzyme replacement therapy. A systematic review of 114 accredited CF care centers in the United States revealed 31 proven cases of fibrosing colonopathy, with a strong relationship found between the occurrence of the fibrosing colonopathy and the total daily dose of the enzyme replacement.[34] This study showed that for patients taking more than 50,000 U of lipase/kg/d, the incidence of fibrosing colonopathy requiring surgery was about 3.8 per 1,000 patients per year of use, suggesting that most patients should remain below 10,000 U of lipase/kg/d.

The exact etiology of fibrosing colonopathy remains obscure. The appearance of this condition in cystic fibrosis patients initially appeared to coincide with the introduction of the "high-dose" enzyme preparations, with some patients consuming in excess of 20,000 IU lipase/kg/d. Interestingly, since the more conservative use of pancreatic enzymes, in particular, the high-dose preparations, there has been a reduction in the reported frequency of the problem.

Initially, it was suggested that the acid-resistant coating of the microspheres and tablets containing a methacrylic acid copolymer coating, Eudragit L (Röhm GmbH & Co., Darmstadt, Germany), was implicated.[35] Eudragit L has been shown to be toxic to rat intestine, causing mucosal ulceration and submucosal edema and fibrosis identical to the lesions seen in patients described in the literature. More recently, however, fibrosing colonopathy has been reported in patients not using this coating[34] and, in fact, not using pancreatic enzymes at all,[36,37] which highlights the continuing uncertainty of its etiology.

ADJUNCTIVE THERAPY TO ACID-BASE EQUILIBRIUM

The alternative method of improving the efficiency of the ingested pancreatic enzymes has been to modify the acid-base balance within the gastrointestinal tract. The H_2 receptor antagonists, such as cimetidine or ranitidine, have been used to diminish the secretion of gastric acid, thereby successfully decreasing the gastric inactivation of the ingested enzymes with resultant improvement in nutrient absorption.[7,14,38–42] Because enteric-coated microspheres are pH dependent and rely on a luminal pH of greater than 5.5 for dissolution of the acid-resistant coating, it is possible that jejunal hyperacidity may further hinder their activity. It has been shown that postprandial jejunal "hyperacidity" does occur in patients with CF, with 40% of a test meal entering the jejunum at a pH below 5.[38] At this pH, bile acids precipitate out of the aqueous solution, leading to a reduction in the aqueous phase bile acid concentration. In addition, lipase activity, which is extremely pH sensitive, is considerably reduced.

Cimetidine has been shown to increase jejunal pH, thus increasing aqueous phase bile acid concentration.[40] In a study of adult CF patients receiving noncoated enzymes, 60% of the test meal entered the jejunum at a pH less than 5, compared with only 17% in healthy subjects. There was a significant decrease in lipase activity and a decrease in aqueous phase lipid concentration, but the decrease in bile acid precipitation did not reach statistical significance. With the introduction of cimetidine, however, there was significantly less bile acid precipitation, and this resulted in improved lipid solubilization, suggesting that the efficacy of pancreatic enzyme therapy is limited both by exogenous enzyme inactivation in the stomach and by the pH-dependent environment within the proximal small intestine and that these effects were both improved by the addition of cimetidine. Data suggest that patients who had significant steatorrhea while taking enteric-coated microspheres also had improved nutrient absorption with the addition of cimetidine.[41] This improvement could result from both the prevention of gastric inactivitation and the reduction in small bowel hyperacidity levels, thus affecting the solubilization of bile salts.

Because the major effect of the addition of cimetidine appears to be improvement of the small intestinal alkalinity, it is not unreasonable to presume that the addition of antacids of bicarbonate therapy may have some merit. Graham found that the concurrent administration of enzymes with either sodium bicarbonate or aluminium hydroxide yields a greater reduction in steatorrhea than do enzymes alone.[38] Durie and others reported 21 patients with CF in whom sodium bicarbonate (15 g/m^2/24 h) was an effective adjunct to enzyme therapy. These workers found that sodium bicarbonate or cimetidine (20 mg/kg/d) had equivalent beneficial effects as adjuvant therapy, but when both drugs were given simultaneously, there was no further improvement in nutrient absorption.[41] The choice of antacid does appear to be critical.[38]

The proton pump inhibitors, with more potency and duration of action compared to H_2 receptor antagonists,

have also been used as an adjunctive therapy.[43] They have been shown to increase the efficacy of enteric-coated enzyme capsules dramatically and achieve near-normalization of fat absorption.[44,45] In addition to their effect on gastric acid secretion, they also have a profound effect on gastric volume, which may help to prevent dilution of the enzymes. The marked reduction in gastric pH may also see an increased postprandial duodenal pH, assisting in the effectiveness of the enzyme therapy. Further studies have shown that adjuvant therapy with the protein pump inhibitor lansoprazole in young CF patients with persistent fat malabsorption decreased fat losses and improved total body fat. In addition, lung hyperinflation was also decreased in the study patients, which may partly explain the improvement in inspiratory muscle performance.[46]

Yet another approach to adjuvant therapy is with the use of prostaglandin agents.[47] Prostaglandins of the E and I series inhibit basal and stimulate gastric acid secretion both in vivo and in vitro. In the dog, either prostaglandin E_2 or PGI_2 inhibits gastric acid secretion stimulated by food, histamine, pentagastrin, or reserpine. The mechanism by which natural prostaglandins and their analogs inhibit gastric acid secretion is still unknown, but one possibility is that there is direct inhibition of parietal cells by prostaglandins acting from the gastric lumen.[48]

Another mechanism through which prostaglandins might affect gastric secretion is suppression of gastrin release. It has been shown that methylated prostaglandin E analogs given orally in dogs and humans cause a marked suppression of gastrin response to a meal.[49] An important addition to the effect of gastric acid secretion is the effect of prostaglandins, particularly the methylated analogs, in stimulating mucus and bicarbonate secretion. This may account for the reduction in luminal acidity observed with the administration of these prostaglandins.

Prostaglandin therapy may have some inherent advantages over certain H_2 receptor antagonists as adjuvant therapy in CF patients. Cimetidine may interfere with the metabolism of certain drugs by inhibiting cytochrome P-450 oxygenase in the liver.[38] In CF patients, these potential drug interactions may assume some clinical importance by inhibiting metabolism of certain bronchodilators, notably theophylline. Because it has no human interactions with cytochrome P-450, misoprostol may be superior as long-term adjuvant therapy in CF.

BILE ACID DYSFUNCTION

In addition to manipulating the acid-alkaline balance in the upper small intestine, other researchers have explored the possibility of improving nutrient absorption with the addition of exogenous taurine.[50–53] As a result of large fecal losses of bile acids, patients with CF develop an increased ratio of glycine to taurine in conjugated bile acids. It has been proposed that correction of this elevated ratio by oral taurine supplements may improve absorption and, ultimately, nutrition by potentiating bile salt micelle formation. Taurine, which is more soluble in an acidic environment, has been administered to patients with CF in doses of 30 mg/kg/d, and there has been significant improvement in fat absorption in patients on enzyme supplementation.[51] Supplementation with taurine significantly reduced the glycine-to-taurine ratio and bile acid losses in the stools.[51] A further disadvantage of preponderant glycine bile salts conjugates is that they are partly and passively absorbed in the proximal portion of the small intestine. Because taurine conjugates are predominantly absorbed in the ileum and are more resistant to bacterial degradation, they are more available to form mixed micelles with fat that may have escaped intestinal absorption more proximally.

5. Acid-Peptic Disease

Frédéric Gottrand, MD, PhD
Christophe Faure, MD

The clinical spectrum of acid-peptic disease in children includes reflux esophagitis,[1] gastric and duodenal peptic ulcer disease,[2] gastritis and gastropathy,[3] duodenitis, and rare entities such as Zollinger-Ellison syndrome. Several chapters of this book specifically address the pathogenesis, diagnosis, and treatment of some of these diseases (see Chapter 29.1, *Helicobacter pylori* and Peptic Ulcer Disease," and Chapter 29.2, "Other Causes"). The purpose of this chapter is to focus on the pharmacologic aspects of the principal drugs used for acid-peptic diseases, including the mechanism of action, pharmacokinetic and pharmacodynamic data, efficacy, and side effects based mainly on information available in studies on children.

Two major developments have been observed in the management of acid-related disorders during the last 15 years represented by proton pump inhibitors (PPIs) and *Helicobacter pylori*. PPIs irreversibly bind to the H^+-K^+ adenosine triphosphatase (ATPase) enzyme complex and extensively inhibit acid production, revolutionizing the management of hyperacidity diseases. *H. pylori* has been shown to be the leading cause of primary peptic ulcer and chronic-active (type B) antral gastritis.[4] The eradication of this organism dramatically reduces the recurrence of gastric and duodenal ulcers both in adults and in children. These two factors have profoundly changed the natural history and epidemiology of acid-peptic disease in adults, mainly gastroesophageal reflux and peptic ulcer diseases, as well as diagnostic tests and therapeutic strategies, demonstrated by the dramatic decrease of surgical indications in this group of diseases. However, several childhood peculiarities and as yet still unresolved questions limit extensive use of antisecretory drugs in children. Peptic ulcer disease is rare in children, and the role of *H. pylori* in nonulcer dyspepsia in this age group remains a matter of debate. Therefore, recommendations for treatment remain limited to a selected number of patients, and use of PPIs for long-term management of gastroesophageal reflux disease (GERD) is still not recommended in children.

PROTON PUMP INHIBITORS

PPIs (omeprazole, lansoprazole, pantoprazole, rabeprazole, and esomeprazole) inhibit gastric acid secretion by selectively acting on gastric parietal cell H^+-K^+ ATPase, which is the enzyme involved in the last step of acid secretion by parietal cells (Figure 76.5-1).[5]

In contrast to histamine$_2$ (H_2) receptor antagonists, inhibition of gastric acid secretion by PPIs is independent of the pathway of stimulation. PPIs are highly selective and effective in their action and have a few short- and long-term adverse effects. These pharmacologic features have made the development of PPIs the most significant advancement in the management of acid-peptic–related disorders in the last two decades. Although numerous adult studies have been published, there are still few large studies with significant patients enrolled and no randomized controlled comparative studies in childhood.[6] It should be emphasized that almost no clinical or pharmacologic data are available in infants under 1 year of age. Although several different PPIs are available on the market (Table 76.5-1), only two of them, namely omeprazole and lansoprazole, have been studied in childhood. The following section focuses mainly on those drugs that are the only two approved for use in children (with restriction on age, indication, or type of administration according to different countries).

Mode of Action

PPIs form a group of compounds called substituted benzimidazoles, which concentrate within the intracellular canaliculi of parietal cells, irreversibly bind to the H^+-K^+ ATPase enzyme complex, and extensively inhibit acid production. PPIs differ from each other by the molecular structures bound to the pyridine and benzimidazole components of the molecule (Figure 76.5-2).[7] This explains differences in pharmacologic properties, but all of the PPIs

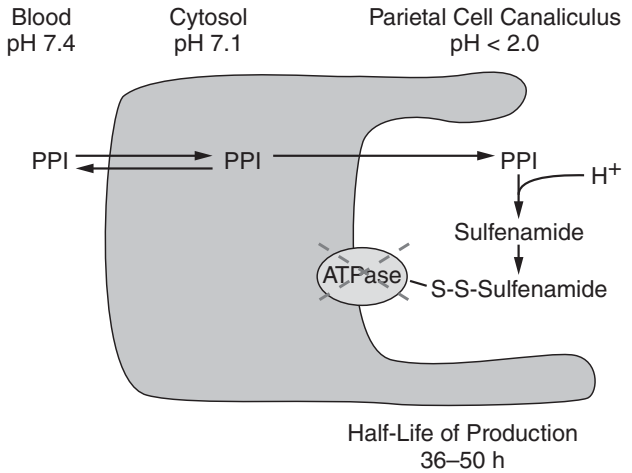

FIGURE 76.5-1 Mechanism of action of antisecretory drugs. ATPase = adenosine triphosphatase; PPI = proton pump inhibitor.

have the same mechanism of action. Because they are weakly basic compounds (the pKa value of the pyridine nitrogen being close to 4.0), they are maximally protonated in environments of high acidity (which is exclusively found in the intracellular canaliculi of actively secreting parietal cells and within the stomach cavity). PPIs can be considered prodrugs because in highly acidic environments, protonation of the molecule results in a series of reactions that ultimately produces the active form of the PPI (see Figure 76.5-2).[7] The active cyclic sulfenamide then binds permanently to exposed cysteine thiol groups on the luminal surface of the H^+-K^+ ATPase enzyme. Once covalently bound, the H^+-K^+ ATPase enzyme becomes nonfunctional, and activity returns only by parietal cell synthesis of new H^+-K^+ ATPase enzyme systems. The turnover of the H^+-K^+ ATPase is constant, with a half-life of about 48 hours in adults. The maturation of turnover is unknown in infants and children. The best access of the drug to the H^+-K^+ ATPase situated on the luminal side of the secretory membrane of the gastric parietal cells is provided by a meal, which is the strongest physiologic event inducing the exteriorization of the H^+-K^+ ATPase.[8]

Given orally, PPIs can be prematurely converted to the active form in the acidic environment of the stomach. They are prepared as capsules containing protective enteric-coated granules or as enteric-coated tablets. In these forms, absorption begins only in the higher pH environment of the duodenum. They are almost completely absorbed in the small intestine.[7]

PHARMACOKINETIC PROPERTIES

Most of the data on the pharmacokinetics of PPIs have been obtained in adult volunteers and adult patients with peptic ulcer disease. However, recent studies have provided extensive observations on the pharmacokinetics for omeprazole and lansoprazole in children.[9–16] Data are lacking on rabeprazole and esomeprazole in children; some data have recently been published on pantoprazole.[17]

PPIs are metabolized by the hepatocyte cytochrome P-450 isoforms CYP2C19 and CYP3A4 to inactive metabolites (sulfide, sulfone, and hydroxymetabolites) excreted in urine. A comprehensive comparative review on the pharmacokinetics of omeprazole, lansoprazole, pantoprazole, and rabeprazole has been published on adults.[7] Schematically, the drugs are quickly absorbed (T_{max} = 1–3 hours), with bioavailability varying between them (omeprazole 35–65%, lansoprazole 80–91%, and pantoprazole 57–100%). They are rapidly metabolized (half-time [$T_{\frac{1}{2}}$] = 0.6–2 hours). The antisecretory effect of PPIs is independent from plasma concentration but is correlated with the area under the plasma concentration time curve (AUC).[8] This has also been shown in children.[9]

In addition, in children and adolescents, the pharmacokinetic parameters have been reported in the same range as those in adults for omeprazole[10,11] and lansoprazole,[9,12–14] with variations according to age for omeprazole. Andersson and colleagues have reported a significant difference in $T_{\frac{1}{2}}$ between children aged 1 to 6 years and chil-

	R_1	R_2	R_3	R_4

Lansoprazole	H	H	CH_3F_2O	CH_3
Pantoprazole	CF_2HO	H	CH_3O	CH_3O
Rabeprazole	H	H	$CH_3O(CH_2)_3O$	CH_3

FIGURE 76.5-2 Chemical formula of proton pump inhibitors (PPIs) and the mechanisms of action of enzyme (H^+-K^+ adenosine triphosphatase [ATPase])-inhibitor complex formation. Reproduced with permission from Gibbons TE and Gold BD.[6]

dren aged 7 to 12 years, with an increasing metabolism of omeprazole in the younger age group.[10] In neonates less than 10 days old, Anderson and colleagues reported a trend toward a prolonged $T_{\frac{1}{2}}$ for intravenous omeprazole.[15] This variability of metabolism related to age has not been reported with lansoprazole, for which data are available in children between the ages of 1 and 17 years.[9,12–14] All of these studies show a pharmacokinetic profile for lansoprazole similar to that of adults. Interindividual variability of pharmacokinetic parameters is wide in adults, as in children, and may explain to some extent the variations observed in the dosage requirement of the PPIs.

For both omeprazole and lansoprazole, there are almost no pharmacokinetic data available for neonates and infants under 1 year of age.

In addition to these maturation differences, pharmacokinetic parameters in children may be affected, as in adults, by genetic variability of the enzyme systems. Indeed, CYP2C19 displays a known genetic polymorphism,[18] and differences in pantoprazole, omeprazole, and lansoprazole disposition have been demonstrated with the AUC that are fivefold higher in poor metabolizers than in extensive metabolizers.[19] Clinically, poor metabolizers (a poor metabolizer phenotype occurs in 1% of blacks, 2–6% of whites, 15% of Chinese, and 23% of Japanese) have been shown to experience superior acid suppression (with omeprazole and lansoprazole) compared with extensive metabolizers, without an increase in the incidence of adverse effects.[7] Thus far, there is no toxicity issue that warrants dosage adjustment of pantoprazole in poor metabolizers.[20]

Other maturation factors may also affect the metabolism of PPIs, such as the rate of renewal of the proton pumps in the parietal cell. In patients with hepatic impairment, the AUC values increased to the same extent as observed in poor metabolizers, with no need to adjust the dosage, although caution should be exercised when giving PPIs to patients with severe hepatic insufficiency. No dosage adjustment of PPIs is required in patients with renal insufficiency[21] or on hemodialysis.[22]

Pharmacodynamic Properties

Pharmacodynamic Efficacy of Omeprazole. Omeprazole is available for oral and intravenous administration. In children, most data were obtained after oral administration, and a mean daily dose of 1 mg/kg body weight was required to obtain a sustained efficacy over 24 hours.[16,23–26] However, in a multicenter study of children aged 1 to 16 years using esophageal pH monitoring below a pH of < 4 for less than 6% of a 24-hour period, the healing dosage varied from 0.7 to 3.5 mg/kg/d. Overall, in this study, more than 75% of the patients required 1.4 mg/kg as the healing dosage.[10]

When the oral route cannot be used, it is necessary to inhibit acid secretion via intravenous administration of omeprazole, which is not approved for use in the United States and Canada. In children, the dose of 40 mg/1.73 m^2 (1.17 mg/kg) was required to achieve a gastric pH over 4 during more than 90% of a 24-hour period following omeprazole intravenous administration.[11]

Pharmacodynamic Efficacy of Lansoprazole. In adults, a daily dosage of 30 mg of lansoprazole, that is, about 17 mg/m^2, has been found to be effective and safe in inhibiting gastric acid secretion and healing acid-related lesions. This dosage was effective in numerous randomized double-blind trials and has been recommended for the treatment of duodenal ulcer and reflux esophagitis in adults.[27] In children, as for omeprazole, the efficacy of lansoprazole on gastric acid secretion studied by gastric pH monitoring has been shown to vary widely among the patients studied: about 40% of children responded to the dose of 0.73 mg/kg (equivalent to the adult dose, ie, 17 mg/m^2), 26% responded to 1.44 mg/kg, and 35% failed to respond to this doubled dose.[9] This variability can be ascribed in part to differences in pharmacokinetics: the AUC of lansoprazole showed a significant positive correlation with gastric acid inhibition, and the AUC was significantly greater and the oral clearance was not significantly lower in the patients who did than in those who did not respond to the lower dose (0.73 mg/kg, ie, 17 mg/m^2). Thus, failure to respond to the lower dose may be ascribed to reduced bioavailability and/or to faster metabolism of the drug. Patients with these characteristics may require a higher dose to achieve the desired antisecretory effect.[9]

Pharmacodynamic Efficacy of Pantoprazole. In a recent study, oral pantoprazole (20 mg daily) provided gastric acid control in 15 pediatric patients with reflux esophagitis.[17]

Clinical Efficacy

The major use of PPIs in pediatrics has been the management of peptic esophagitis and peptic ulcer disease and for eradication of *H. pylori* infection. No controlled or open studies of the use of PPIs in the management of extraesophageal manifestations of gastroesophageal reflux such as otorhinolarygologic or respiratory symptoms have been performed.

Peptic Esophagitis

Most of the studies performed in children with gastroesophageal reflux assessed healing of esophagitis to define the efficacy of omeprazole[23–26,28–31] and lansoprazole.[9,13,32,33] In a review of omeprazole use in the treatment of acid-related disorders in children for the period 1986 to 2000, marketed and extemporaneous formulations of omeprazole were used at dosages of 5 to 80 mg/d (0.2–3.5 mg/kg/d) for periods ranging from 14 days to 36 months. The initial dose most consistently reported to heal esophagitis and provide relief of symptoms of gastroesophageal reflux appears to be 1 mg/kg/d.[34] A similar response was observed with omeprazole[26] among the responders to lansoprazole; 80% of children had healing of their esophagitis after 4 weeks of treatment.[9] Overall, for both omeprazole and lansoprazole, studies performed in children showed that in patients with adequate acid suppression (ie, receiving an appropriate dosage), the healing rate of peptic esophagitis is more than 75% after 4 to 8 weeks of treatment; the clinical symptoms improve in the same time period.[16,17,23–26,28,29,31,32] How-

ever, it should be emphasized that if one considers the initial dose (ie, 0.7–1 mg/kg) in these pediatric studies, the response rate is, as expected, lower (around 50%). In a recent small study, oral pantoprazole (20 mg daily) given to 15 pediatric patients with reflux esophagitis provided healing of the esophagitis in 52% of patients.[17]

Gastric and Duodenal Ulcers. Although rare in pediatrics, PPIs have been used in the treatment of gastric and duodenal peptic ulcers. Low doses (0.3–0.7 mg/kg) were required to achieve healing.[16,25]

H. *pylori* Eradication. Although there are still no clear recommendations on the treatment of *H. pylori* in childhood,[4,35–37] triple therapy using a PPI and two antibacterial agents is considered the treatment of choice.[35,38] However, several nonrandomized studies have also shown a high eradication rate with two antibiotics combining metronidazole or tinidazole and amoxicillin for 2 to 4 weeks.[39] As in adults, treatment failures are mainly explained by poor compliance and resistance of *H. pylori* to antibiotics. The only double-blind trial published in children showed an eradication rate of 74.2% with 1 week of triple therapy including omeprazole, clarithromycin, and amoxicillin compared with an eradication rate of 9.4% in children receiving placebo, clarithromycin, and amoxicillin.[40] This study demonstrated the low eradication rate with two antibiotics used for 1 week, including clarithromycin, and confirmed the efficacy of PPIs associated with antibiotics in *H. pylori* infection in children.

Safety

Short-Term Safety. PPIs are well tolerated by most patients. The principal side effects are mild to moderate headaches, abdominal pain, vomiting, and diarrhea (Table 76.5-2).[9] In the double-blind study previously mentioned comparing omeprazole, clarithromycin, and amoxicillin with placebo, clarithromycin, and amoxicillin in *H. pylori*–infected children, adverse events were reported in 24% of patients in both groups but remained mild.[40] No adverse effect was reported even in children who received a high dose of intravenous omeprazole.[11] A small reversible elevation of transaminases has been reported.

Prolonged periods of hypochlorhydria may lead to gastric bacterial overgrowth, as was noted in adults[41] and neonates.[42] Although the clinical effect of this overgrowth remains unclear, this suggests that in critically ill patients and neonates, if required, the intravenous administration of PPIs should be as short as possible because of the prolonged inhibition of the gastric acid secretion.

TABLE 76.5-2 FREQUENCY OF SIDE EFFECTS ASSOCIATED WITH OMEPRAZOLE AND LANSOPRAZOLE IN CHILDREN

EVENT	OMEPRAZOLE (%)	LANSOPRAZOLE (%)
Headache	0–2	0–3
Constipation	0	0–5
Diarrhea	0–1	0–9
Vomiting	0–0.3	0–4
Dizziness	0	0–2
Insomnia	0	0–2
Total	0–2	0–15

Long-Term Safety. Although PPIs have been available for more than 15 years and are widely used in adults, with an excellent long-term safety profile, few data are available on infants and children regarding long-term use (eg, more than 6 months) of these potent acid-suppressing agents. Because of experimental data provided in newborn rats, there are concerns regarding the consequences and effects on the gastric mucosa of the increased gastrin levels (two- to fivefold rise in half of the treated patients). The trophic effects of gastrin lead to stimulation of the enterochromaffin-like cell population and hyperplastic changes in parietal cell mass. Carcinoid tumors have been observed in animals treated lifelong with high-dose omeprazole or an H_2 receptor antagonist. Although enterochromaffin-like hyperplasia has been observed in adults, carcinoid tumors have been reported only once in adults.[43] The trophic action of gastrin on digestive epithelium has not been implicated in the development of gastric or colonic adenocarcinoma in animal and adult safety studies.[44,45] However, fundic polyps and nodules have been reported in children who received omeprazole for more than 6 months.[46] The effect of long-term omeprazole therapy (4–7 years) on the ratio of G (gastrin secretion) to D cells (somatostatin secretion) was studied in 6 children.[47] The mean G-cell number and the ratio of G to D cells showed a significant increase for omeprazole compared with baseline levels. In adults, studies have shown an increased incidence of gastric atrophy associated with long-term use of PPIs, especially in the presence of *H. pylori* infection.[44] However, similar studies are still lacking in children.

Long-term acid suppression may promote the production of *N*-nitrosamine compounds in the stomach secondary to bacterial overgrowth. These compounds are considered carcinogenic.

Suppression of acid secretion may theoretically lead to malabsorption of vitamin B_{12} and maldigestion of proteins. Except for patients with Zollinger-Ellison syndrome, long-term treatment with PPIs is not considered a causal factor of vitamin B_{12} deficiency.[48] Moreover, Evenepoel and colleagues have shown the influence of PPIs on protein digestion.[49] Clinical consequences in children are currently unknown.[50]

In vitro data have shown that osteoclast activity may be inhibited by omeprazole without an influence on bone turnover in children during short-term treatment.[51]

Overall, one should consider that long-term use of PPIs in children is safe but requires careful long-term follow-up.[45]

Drug Interactions. Although most PPIs interact with the cytochrome P-450 system, no clinically important interactions have been observed between PPIs and other drugs.[8,52–55] However, omeprazole may increase the plasma concentration of diazepam, phenytoin, carbamazepine, and warfarin.[7]

Dosage and Administration

PPIs are available per os in capsules containing protective enteric-coated granules or as an enteric-coated tablet. An intravenous formulation is available for omeprazole and pantoprazole. The granules and tablets should not be crushed, chewed, or dissolved because gastric acid secretion may alter the drug's action.

The capsules can be opened, and for children who are unable to swallow capsules or tablets, the microgranules may be administered per os or via a feeding tube, in suspension in an acidic medium such as fruit juice, yogurt, or applesauce. A "homemade" liquid formulation, produced by dissolving the drug in 8.4% bicarbonate solution, has been used in some reports.[56] However, a recent study performed in adults has shown that the pharmacokinetic parameters (absorption) of these simplified suspensions were altered when compared with the regular administration of a capsule. This was particularly true with the simplified omeprazole.[57] Pediatric pharmacokinetic, pharmacodynamic, and efficacy studies with these alternative oral preparations are lacking, preventing them from being recommended. Owing to the activation of the proton pumps in the pre- and postprandial periods, PPIs should be administered just before or during meals.

The intravenous formulation should not be administered per os because gastric acid secretion alters the drug.

Omeprazole. The usual recommended starting dosage of omeprazole is 1 mg/kg once daily (eg, 10 mg for children 10 to 20 kg and 20 mg for children weighing more than 20 kg).

Although not registered in all countries, intravenous omeprazole should be given once daily 40 mg/1.73 m^2 (eg, 1 mg/kg).[11] Because the benefit of a loading dose of intravenous omeprazole was demonstrated in adults,[58] it has been suggested to use a loading dose of 40 mg/0.73 m^2 repeated after 12 hours to achieve a rapid antisecretory effect in similar critical situations in pediatric patients.[11]

Lansoprazole. The usual recommended starting dosage is 1 mg/kg once daily (eg, 15 mg for children ≤ 30 kg in weight and 30 mg for those weighing > 30 kg[59]). This drug is not yet labeled in all countries for use in children.

For both omeprazole and lansoprazole, it should be emphasized that the optimal dose may vary among patients and that, in case of a lack of efficacy, one must be aware that almost 25% of patients may require a double dosage. In the absence of a clinical response to the starting recommended dose, it is suggested to check very carefully with caregivers regarding the mode of administration of the PPIs. If this is correct, doubling the dosage should be suggested.

Pantoprazole. Data are currently lacking on recommended dosages for intravenous pantoprazole in children.

H_2 RECEPTOR ANTAGONISTS

The first H_2 blocker licensed was cimetidine, in 1976, followed by ranitidine and later famotidine and nizatidine (see Table 76.5-1). Experience with other H_2 receptor antagonists, such as roxatidine and ebrotidine, is very limited or nonexistent in children. Although PPIs have now supplanted these drugs for the treatment of acid-peptic disease because of their higher efficacy and excellent tolerance, the large experience of more than 20 years of use of H_2 receptor antagonists on millions of patients has provided considerable insight into the efficacy, pharmacology, and long-term tolerance in adults and children.[60–67] A large number of studies in adults have established that PPIs are more effective in decreasing acid secretion and have better clinical efficacy than H_2 receptor antagonists; however, there are no published articles on children that specifically address this question. Ranitidine, famotidine, and nizatidine are preferred over cimetidine because cimetidine interferes with the cytochrome P-450 enzyme and demonstrates more central nervous system, gastrointestinal, and endocrine side effects than the other H_2 blockers. In parallel with the increase of self-medication of ranitidine in adults, there is also a movement toward the treatment of symptoms in children regardless of the presence or absence of esophagitis. However, the pharmacokinetic and pharmacodynamic effects of over-the-counter H_2 receptor antagonists in the pediatric population remain largely unknown.[63]

Pharmacodynamic Properties

The H_2 receptor antagonists are competitive inhibitors of histamine-stimulated acid secretion; however, they have limited effects on acid secretion that is induced by meals or other stimuli. In most of the pediatric studies, a good correlation has been demonstrated between the median plasma ranitidine concentration and the pharmacodynamic parameter elevation of intragastric pH. The gastric pH typically rose above 4 when the plasma ranitidine concentration approached 100 ng/mL.[60,63,64] Pediatric subjects with suspected abnormal acid reflux aged 4 to 11 years received a single dose of 75 mg of ranitidine. The intragastric pH began to rise approximately 30 minutes after dosing with ranitidine to a peak of pH 4. Ranitidine, 75 mg, significantly increased the intragastric pH throughout the 6-hour evaluation period.[63] The return toward baseline after 5 hours suggests the potential utility of dosing more frequently than every 12 hours. In contrast to PPIs, tolerance and rebound effects may occur with the use of H_2 receptor antagonists. Tolerance to the antisecretory effects of H_2 receptor antagonists has been demonstrated in adults and appears to develop quickly in 3 days. The mechanisms are not fully understood but may be related to the upregulation of enterochromaffin-like cell activity.[68] However, no data are available in pediatrics. The occurrence of a rebound hypersecretion effect should be taken into account when discontinuing the drugs, which therefore should be progressively withdrawn.[69,70]

Pharmacokinetic Properties

Studies of pharmacokinetics of H_2 receptor antagonists have been conducted in infants and children.[60,64,65,67] Overall, the parameters are similar to those of adults, with a reasonable absorption after oral dosing. Absorption is not affected by food. Peak blood levels are achieved within 1 to 3 hours after an oral dose. These drugs are well distributed

throughout the body and cross the blood-brain barrier. After oral administration, cimetidine, ranitidine, and famotidine undergo "first-pass" hepatic metabolic alteration that reduces their bioavailability by 50%. Protein binding is low (15%). H_2 receptor antagonists are eliminated by a combination of renal excretion and hepatic metabolic degradation. Sixty to 80% of orally administered cimetidine and ranitidine is cleared by the liver. In contrast, after intravenous administration, they are eliminated principally through renal excretion. Dose reductions are thus recommended for patients with renal insufficiency.

After a single dose of 75 mg of ranitidine in children aged 4 to 11 years, the median C_{max} value of 477 ng/mL occurred 2.5 hours after dosing, and the median half-life was 2.0 hours.[63] In infants, the half-life is higher (3.5 hours).

Clinical Efficacy

Although no controlled trials are available in children, oral ranitidine therapy has been useful in pediatric practice for the treatment of GERD and peptic ulcer diseases.[60–62] Cucchiara and colleagues showed that high-dose (20 mg/kg/d) ranitidine was as effective as omeprazole in peptic esophagitis.[61]

Tolerability

The side effects of H_2 receptor antagonist are reported in Table 76.5-3. The majority of pediatric clinical trials with ranitidine have reported few side effects or abnormal laboratory values. As for PPIs, raising the gastric pH may result in the overgrowth of pathogenic bacteria in the digestive tract.[41,42] It has been shown in neonates that the length of hospital stay, increased gastric pH, period of antibiotic therapy, and ranitidine use were independently associated with an increased colonization rate.[42]

Interactions between H_2 antagonists and other drugs have been extensively reviewed.[71] It is widely held that cimetidine is a more important antagonist of other drugs than the other H_2 antagonists (Table 76.5-4); however, the clinical relevance of many of the interactions with cimetidine is marginal. In neonates, cimetidine should be used cautiously in patients concurrently receiving theophylline, phenytoin, or caffeine because it may prolong the half-life of those drugs.[72]

Dosage and Administration

The recommended oral dosage of H_2 blockers is summarized in Table 76.5-5. Ranitidine (5–10 mg/kg), given orally daily, divided into two or three doses, produces a symptomatic and endoscopic improvement in erosive esophagitis in children.[73] Pharmacodynamic data on ranitidine suggest that a dosing period of 6 to 9 hours may provide a more effective control of intragastric acidity.[63,73] In patients with renal impairment, the dosage should be adjusted: if the creatinine clearance is 10 to 50 mL/min, the dosage should be decreased to 75% of normal dosage; if the creatinine clearance is < 10 mL/min, the dosage should be decreased to 50% of normal dosage.

The recommended dosages of intravenous cimetidine are 5 to 10 mg/kg/d every 8 to 12 hours in neonates and 10 to 20 mg/kg/d every 6 to 12 hours in infants.[72] Intravenous cimetidine may be infused preferably over 15 to 30 minutes because rapid injection has been associated with cardiac arrhythmias and hypotension. It also may be given by continuous infusion. In premature infants and neonates, ranitidine is usually given intravenously or, rarely, intramuscularly at a dosage of 1 to 2 mg/kg/d divided every 6 hours. The maximal intravenous dosage is 6 mg/kg/d divided every 6 hours. Intravenous continuous infusion is

preferred over intermittent dosing at a dosage of 1.44 to 4 mg/kg/d (maximum 6 mg/kg/d).[72] It can be administered in a parenteral nutrition solution. Famotidine can be given intravenously either at a dosage of 0.3 mg/kg every 8 hours (maximum 2.4 mg/kg/d) or by continuous infusion of 1 to 2 mg/kg/d over 24 hours. It can be administered in a parenteral nutrition solution.[72]

ANTACIDS

Antacids include carbonate and bicarbonate salts (eg, $NaHCO_3$ and Ca^- or $MgCO_3$), alkali complexes of aluminum and/or magnesium (eg, aluminum and magnesium hydroxides), aluminum and magnesium phosphates, magnesium trisilicate, and alginate-based raft-forming formulations. They are used for the symptomatic treatment of heartburn and esophagitis. Experience with antacids is limited in infants. Their efficacy in buffering the gastric acidity is strongly influenced by the time of administration and requires multiple administrations. Dimethicone is used in some regions for regurgitation, although there are no reliable studies demonstrating its efficacy in the treatment of gastroesophageal reflux in infants. Although often classified as an antacid, it acts more as a feed thickener because it contains more than 50% of bean gum and has hardly any acid-neutralizing properties.

Pharmacodynamic Properties

All antacids have a nonsystemic mechanism of action. They chemically neutralize gastric acid. The key therapeutic advantage of antacids is their rapid onset of action. Antacids act within minutes to an elevated intragastric pH above 3.5 and provide symptomatic relief. Hence, their action is limited by the capacity to maintain an elevated pH in the presence of continued physiologic acid secretion and by normal gastric emptying. Alginate-based raft-forming preparations have a quite different mode of action. In the presence of gastric acid, alginates precipitate, forming a gel. Alginate-based raft-forming formulations usually contain sodium or potassium bicarbonate; in the presence of gastric acid, the bicarbonate is converted to carbon dioxide, which becomes entrapped within the gel precipitate, converting it into a foam that floats on the surface of the gastric surface, providing a relative pH-neutral barrier.[74]

Clinical Efficacy

Double-blind studies in adults have shown that alginate-based raft-forming preparations are superior to placebo in relieving the symptoms of heartburn.[74] However, studies in infants and children remain limited (six studies including a total of 303 patients, only one being double blind) and had various study designs (open-label prospective study, comparison of two different dosages of alginate, comparison of placebo, famotidine, or cisapride).[75–80] Their efficacy as monotherapy or in combination with prokinetics for gastroesophageal reflux is not convincing.[81,82]

Tolerability

Because absorption from aluminum-containing antacids may cause serum aluminum concentrations to approach levels reported to cause osteopenia and neurotoxicity, chronic antacid therapy is not recommended.[83] Gaviscon contains a considerable amount of sodium carbonate, so its administration may increase the sodium content of the feeds to an undesirable level, especially in preterm infants (1 g of Gaviscon contains 46 mg of sodium, and the suspension contains twice this amount). Algicon, which has a better taste than Gaviscon, has a lower sodium load but a higher aluminum content. Occasional formation of large bezoar-like masses of agglutinated intragastric material has been reported in association with Gaviscon use.[81,82] Side effects include diarrhea with magnesium-rich preparations and excessive absorption of aluminum in infants.[81,82] The presence of aluminum and magnesium in the majority of antacids means that such products have the potential to chelate drugs in the upper gastrointestinal tract.[71] The

TABLE 76.5-5 RECOMMENDED ORAL DOSAGE OF H_2 RECEPTOR ANTAGONISTS

H^2 RECEPTOR ANTAGONIST	RECOMMENDED DOSAGE IN NEONATES	RECOMMENDED DOSAGE IN CHILDREN	RECOMMENDED DOSAGE IN ADULTS
Cimetidine	5–10 mg/kg/d bid or tid; 10–20 mg/kg/d bid or tid in infants	20–40 mg/kg/d bid or tid	600–1,600 mg/d once or bid or tid
Ranitidine	2–4 mg/kg/d divided every 6 h	5–10 mg/kg/d tid	150–600 mg/d once or bid
Nizatidine	—	10 mg/kg/d bid	150–300 mg/d once or bid

Adapted from Bell SG[72] and Rudolph CD et al.[73]

drugs most frequently affected in this way include the quinolone antibacterial agents, didanosine, azithromycin, tetracycline, and the H_2 antagonists.[71] The effects of antacids on the pharmacokinetics of other drugs vary widely according to the type of antacid and time dosage of the administration of the other drug, ranging from no effect to an 85% decrease in bioavailability.[71] For example, a single dose of an aluminum-magnesium antacid was reported to reduce the area under the serum concentration time curve of cimetidine (23%), ranitidine (26%), famotidine (19%), and nizatidine (12%).[84] Separating the administration of antacid from that of another drug by 2 hours usually eliminated any interaction.

Dosage and Administration

Because alginate-based raft-forming preparations need to float on the gastric contents for effectiveness, the time at which this medication is taken is of great importance. Optimal benefit is achieved when alginate-based raft-forming preparations are taken following a meal. Under fasting conditions or when taken just prior to or with a meal, alginate-based raft-forming preparations were reported to empty from the stomach with a $T_{\frac{1}{2}}$ of 20 to 30 minutes.[74] When dosed 30 minutes following a meal, alginate-based formulations empty from the stomach with a $T_{\frac{1}{2}}$ of 180 minutes.

PROSTAGLANDIN ANALOGUES

Misoprostol is a prostaglandin E_1 (PGE_1) analogue that is primarily used to prevent nonsteroidal anti-inflammatory drug (NSAID)-induced gastropathy in patients at high risk. Although initial animal studies showed considerable promise in the treatment of acid-peptic disease, studies in human have not confirmed any clear advantage of the PGE_1 analogues over the H_2 blockers, and their clinical efficacy is now attributed primarily to their antisecretory activity. Since the recent advent of cyclooxygenase 2–selective inhibitors, such drugs are now used less frequently in adults.

Pharmacodynamic Properties

PGE_1 analogues bind to E-type receptors on basolateral parietal cell membranes, distinct from those at which the anti–H_2 receptor antagonists act, thereby inhibiting cyclic adenosine monophosphate–mediated acid production. In addition to blocking acid secretion and gastrin production, these agents may directly enhance mucosal protection through various mechanisms (increase of gastric mucus secretion, bicarbonate secretion, mucosal blood flow, and epithelial regeneration).

Pharmacokinetic Properties

At present, pharmacokinetic data for misoprostol derive from studies in animals and healthy adult volunteers only.[85] Following oral administration, it is rapidly absorbed and de-esterified to its acid form, with peak concentration being reached in 30 to 60 minutes. This free acid metabolite remains as potent as the parent drug in inhibiting acid secretion. It is 85% protein bound. Binding is not affected by age or other drugs. Further metabolism probably takes place in the liver and the kidneys. Biphasic elimination occurs, with a terminal half-life of about 1.5 hours. By 8 hours, 90% of a single oral dose is excreted, mostly in the urine. No parent drug is recovered.[86]

Clinical Efficacy

In adults, studies comparing omeprazole with misoprostol or ranitidine for NSAID ulcer prevention in true NSAID ulcers have shown that omeprazole is equal to full-dose misoprostol for ulcer healing and to the lowest useful dose of misoprostol for ulcer prevention.[87] Misoprostol (at dosages ranging from 400 to 800 µg/d in adults) is an effective form of therapy for preventing NSAID-induced gastroduodenal lesions. However, high-dose misoprostol seems adequate only for the prevention of ulcer complications, mainly in high-risk NSAID users.[88] An analysis of pooled data from comparative studies on omeprazole versus ranitidine, misoprostol, and sucralfate shows a therapeutic advantage in favor of the PPI, ranging from 10 to 40%.[88] In long-term prevention studies, omeprazole (20 mg/d) and pantoprazole (40 mg/d) have also been shown to reduce the risk of gastric and duodenal ulcers and NSAID-related dyspepsia. Current data from recent comparative studies of omeprazole (20 mg/d) versus ranitidine (150 mg/d) and misoprostol (200 µg/d) showed that after 6 months of follow-up, the PPI was significantly superior to control drugs in reducing the risk of both gastric and duodenal ulcers. Thus, available data are undoubtedly in favor of the PPIs as well-tolerated and effective drugs in the prophylaxis and treatment of NSAID-related mucosal lesions in the gastrointestinal tract.[88] Experience in children is much more limited and was mainly focused on children with rheumatologic disease.[89–91] Misoprostol appears to be effective in the treatment of gastrointestinal symptoms in children receiving NSAIDs and to result in a significant increase in the hemoglobin concentration.[90,91] Misoprostol was also shown to improve fat absorption in cystic fibrosis patients with pancreatic insufficiency with residual malabsorption on standard enzyme therapy.[92]

Tolerability

In children, as in adults, misoprostol is usually well tolerated. The side effects are limited and mild. The most frequent adverse event is self-limited diarrhea,[89] and a significant elevation in the eosinophil count has been occasionally reported.[92] Prenatal exposure to misoprostol has been associated with Möbius disease and limb defects. Vascular disruption has been proposed as the mechanism for these teratogenic effects.[93] Apart from a possible interaction with propanolol, no major drug interactions have been reported.[94]

Dosage and Administration

The recommended dosage in adults is 100 µg four times a day for prevention and 200 µg orally four times a day for treatment of NSAID digestive lesions. In children, a mean dosage of 300 $\mu g/m^2/d$ has been proposed.[89]

COATING AGENT

The coating agent sucralfate is a basic aluminum salt of sucrose octasulfate. At an acid pH, it polymerizes to form

a white paste-like substance that adheres selectively to ulcer or erosions via an electrostatic attraction between the negatively charged sucralfate polyanions and the positively charged protein moieties exposed by the inflamed mucosa. At these specific sites, sucralfate acts as a protective barrier by slowing back-diffusion of acid, pepsin, and bile salts. It also directly inhibits the binding of pepsin to ulcer protein and, like cholestyramine, adsorbs free bile salts. Gastric pH does not appear to affect sucralfate binding to the ulcer bed. Other important effects of sucralfate include increased bicarbonate and mucus production, enhanced epithelial cell renewal, and restoration of a normal transmucosal potential difference. Sucralfate also protects the gastric mucosa against damage induced by ethanol, bile acids, and NSAIDs and prevents stress ulceration in critically ill patients. Despite its aluminum hydroxide components, sucralfate does not increase gastric pH or act as an antacid at the usual therapeutic doses. The drug has no apparent effects on gastric acid secretion, gastrin release, or upper gastrointestinal motility. Thus, hypochlorhydria and concomitant bacterial overgrowth do not occur.

Pharmacodynamic Properties

Little, if any, sucralfate is absorbed after oral administration owing to its high polarity and poor solubility. It is absorbed as an aluminum base and sucrose octasulfate, with the latter excreted unchanged in urine because it cannot be metabolized.

Pharmacokinetic Properties

A study of the interaction of gastrointestinal agents in the presence of sucralfate has shown the adsorption of musculotropic and cholinolytic spasmolytic drugs on sucralfate.[95] Similarly, the absorption of certain drugs, such as warfarin, digoxin, and phenytoin, may be decreased when sucralfate is given concurrently. Although aluminum absorption is not significantly increased in patients with normal renal function, it has been shown that the use of sucralfate for stress ulcer prophylaxis in patients requiring hemofiltration results in toxic elevations in plasma aluminum levels.[96] Alternative agents should be considered for prophylaxis in these patients.

Clinical Efficacy

Several studies in adults have shown that sucralfate (1 g orally before meals and at bedtime) is significantly better than placebo and equivalent to cimetidine and ranitidine in the healing of duodenal and gastric ulcers. Maintenance therapy with sucralfate decreases the recurrence rate of both gastric and duodenal ulcers. Sucralfate may also protect the patient from NSAID-induced gastroduodenal lesions. An analysis of pooled data from comparative studies on omeprazole versus ranitidine, misoprostol, and sucralfate shows a therapeutic advantage in favor of the PPI, ranging from 10 to 40% for preventing NSAID-induced gastroduodenal lesions.[88] Sucralfate is also superior to placebo and is as effective as cimetidine in the treatment of reflux esophagitis.[97] Sucralfate can prevent stress ulceration in critically ill patients. Recent data have also shown clinical efficacy of sucralfate topically to treat or prevent mucosal lesions from various origins (ie, stomatitis, mucositis, or pouchitis).[98,99]

Tolerability

Sucralfate is relatively free of side effects, the only major one being constipation, which occurs in about 2 to 3% of patients. Nausea and headaches occur much less frequently. Sucralfate causes bezoars, especially when given to patients in intensive care units (especially in premature and neonates),[100] and diarrhea.[101] Patients with renal failure treated with sucralfate are exposed to aluminum toxicity.[102] Aluminum accumulation has been observed in critically ill children with acute renal failure.[103]

The presence of aluminum and magnesium in sucralfate means that this drug has the potential to chelate drugs in the upper gastrointestinal tract, as for other antacids (see above).[71] Hypophosphatemia may also result from sucralfate's action as a phosphate binder.

The influence of sucralfate on the incidence of ventilator-associated pneumonia and the incidence of upper airway colonization in critically ill children remains poorly studied in childhood.[104]

Dosage and Administration

Sucralfate is available as tablets or suspension, both of which have better acceptance and compliance in children. To minimize the risk of decreased absorption of other drugs given concurrently, it is recommended to take sucralfate at least 2 hours apart from the other drugs.

BISMUTH

Bismuth compounds have been used for centuries to treat various diseases, from digestive diseases (gastric and duodenal ulcer, dyspepsia, infectious diarrhea) to infectious (scabies, malaria, syphilis), skin (eczema, pemphigus), and general disorders (lupus erythematosus, hypertension, edema).[105] Use of bismuth progressively declined in the last 30 to 40 years because its mode of action remained unknown and therapeutic benefits were unproved. Moreover, reports of encephalopathy associated with ingestion of various bismuth salts in large quantities over long periods in France and Australia in the early 1970s contributed to the dramatic reduction of its use and led to the interdiction of use both in adults and children in several countries by the appropriate national drug authorities. In the last decade, a renaissance of the use of some bismuth compounds has taken place. Bismuth subsalicylate and colloidal bismuth subcitrate have been demonstrated to effectively treat traveler's diarrhea[106–108] and *H. pylori* infection in association with antibiotics and/or antisecretory drugs.[39,109,110]

Pharmacodynamic Properties

Bismuth acts to coat areas of mucosal ulceration and inflammation, thereby preventing further epithelial injury by luminal acid and pepsin. Bismuth preparations have also demonstrated inhibitory effects on the growth of *H. pylori* in vitro and in vivo.[105]

Pharmacokinetic Properties

Taken orally, bismuth salts are essentially insoluble in water. Bismuth salts are nearly completely hydrolyzed by gastric hydrochloric acid to form precipitate, namely Bi_2O_3 (oxide), $Bi(OH_3)$ (hydroxide), and BiOCl (hydroxychloride). Small quantities of the ingested bismuth compounds remain nondissociated and enter the small intestine, where reactions with other anions take place to form bismuth subcarbonate and bismuth phosphate salts, which, like their parent compounds, are highly insoluble.[105] Delivered to the colon, the still nondissociated part of the ingested bismuth salts and the generated bismuth compounds react with hydrogen sulfide, which is also insoluble in water. Its black color is responsible for the darkening of the stool that occurs during bismuth salt medication. Because the ingested bismuth salts and the bismuth compounds formed in the gastrointestinal tract are highly insoluble in water, less than 1% of the bismuth is absorbed by the small intestine. The exact site and mechanisms by which bismuth is absorbed by the small intestinal mucosa are not known.[111] Some substances, such as the sulfhydryl group–containing compounds sorbitol and lactic acid, are able to enhance bismuth absorption. Ranitidine may enhance bismuth absorption from colloidal bismuth subcitrate by reducing gastric acidity, maintaining colloidal bismuth subcitrate as a soluble colloid.[112] Enhanced bismuth absorption has been reported in patients with colitis or other mucosal abnormalities.[113] Once absorbed, bismuth is distributed to different organs (kidney, lung, spleen, liver, brain, and muscle). Bismuth is eliminated from the body by two routes: two-thirds in the urine and one-third in the feces.

Clinical Efficacy

Several studies have recently highlighted the therapeutic effects of bismuth salts on infectious diarrhea,[106–108,114] microscopic colitis, and pouchitis. Both bismuth subsalicylate and colloidal bismuth subcitrate have been shown to heal duodenal and gastric ulcers, but the relapse rate when these therapeutic agents are used alone is unacceptably high. In association with antibiotics, bismuth salts have been shown to eradicate *H. pylori* infection, and the relapse rate of primary ulcer is reduced when *H. pylori* is eradicated.[39,109,110] However, no controlled studies in children comparing bismuth association with other therapeutic regimens in *H. pylori* infection or peptic ulcer disease are yet available. Ranitidine bismuth citrate contains 128 mg of bismuth, 110 mg of citrate, and 162 mg of ranitidine in each tablet. The recommended dosage in adults is two tablets per day, in association with two antibiotics (amoxicillin and tinidazole or metronidazole). Experience in children remains very limited.[109]

Tolerability

Bismuth encephalopathy has been reported in adults receiving large quantities of bismuth (most of the time as automedication) for months, even years, mainly with bismuth subgallate. All of these patients had high bismuth concentration in serum, but no relationship could be demonstrated between elevated blood concentrations and the severity of encephalopathy.[115] Individual susceptibility factors have been suggested, a hypothesis being that bacterial overgrowth proved or suspected in most of the cases reported could lead to conversion of bismuth salts to neurotoxic substances in the colon.[105] Observing that neurologic and psychiatric symptoms were described only in patients taking more than 1.5 g of bismuth metal per day, Lechat and Kisch arbitrarily stated that a dose less than 1.5 g of bismuth metal is safe in adults.[116] In the same way, comparing the bismuth blood concentration of asymptomatic adult patients on bismuth therapy with that of patients with bismuth encephalopathy, Hillemand and colleagues concluded that a bismuth blood concentration below 50 µg/L should be regarded as a safe level.[117] Such studies are completely lacking in childhood. Frequent side effects are dark stools, blackening of the tongue, and diarrhea.[109]

In children, rare cases of acute renal failure after overdose have been reported.[118,119]

Dosage and Administration

Most of the national drug agencies in Europe and other developed countries prohibit the use of bismuth salts in children. Colloidal bismuth subcitrate and bismuth subsalicylate are, however, the most popular forms of bismuth used in children. A liquid 1.75% preparation of bismuth subsalicylate is usually prescribed at a dosage of 30 mL taken orally four times daily for a period of 6 weeks.[120] Colloidal bismuth subcitrate tablets are given at a dosage of 480 mg of Bi_2O_3/1.73 m^2 of body surface three to four times daily for 4 to 6 weeks.[110]

6. *Alternative Medical Treatment*

Nadeem Ahmad Afzal, MBBS, MRCPCH, MRCP(UK)
Robert B. Heuschkel, MB, BS DRCOG, MRCPCH

The term complementary and alternative medicine (CAM) is commonly used to encompass approaches to health care not included in our understanding of "conventional" medicine. There is no sharp demarcation between the two, but perhaps it is easier to define CAM if we define what falls within the domain of conventional medicine. "Western," "mainstream," "orthodox," and "allopathic" medicine are all terms synonymous with conventional medicine. Interestingly, the boundaries of conventional medicine may vary greatly between countries, cultures, classes, and individuals. These boundaries also change with time because many alternative therapies are gradually adopted by conventional practitioners. Probably the best example of such change is the use of probiotics. These have become much more common in conventional medicine and are now considered much less of an "alternative" therapy. This ever-changing interface makes it all the more important for practitioners of conventional medicine to be alert to practices that may, in time, start appearing among their own therapies. Needless to say, there is an almost insatiable demand for therapies that lie just outside the domain of conventional medicine. Patients may place enormous, and frequently inappropriate, faith in these alternative therapies, which, by their very nature, may inspire hope beyond the rational expectations one might have of any conventional therapy.

Perhaps the most comprehensive definition of CAM was first coined by O'Connor, and it has since been adopted both by the National Centre for Complementary and Alternative Medicine (NCCAM) in the United States and the Cochrane database in the United Kingdom[1]:

> Complementary and Alternative Medicine (CAM) is a broad domain of healing resources that encompasses all health systems, modalities, and practices and their accompanying theories and beliefs, other than those intrinsic to the politically dominant health system of a particular society or culture in a given historical period. CAM includes all such practices and ideas self defined by their users as preventing or treating illness or promoting health and well-being. Boundaries within CAM and between the CAM domain and that of the dominant system are not always sharp or fixed.[1]

More recently, the term "integrative" medicine has been used. This style of practice combines the use of mainstream medical therapies with those CAM therapies for which there is high-quality scientific evidence on safety and efficacy. The focus is therefore more on the quality of available evidence for a particular therapy rather than on the type of therapy or the practitioner prescribing it.

Over the last decade, use of CAMs has increased worldwide. In 1990, the US population was making more visits to practitioners of alternative medicine than to their primary care physicians. By 1997, out of pocket expenditure for alternative medicines in the United States had increased by over 45% to about 27 billion dollars, similar to out of pocket expenditure for all US physician services.[2]

Whereas several studies have now addressed the use of CAM in adult patients, few have done so in children. Spigelblatt and colleagues showed that 11% of over 1,000 Canadian children attending routine outpatient clinics were using CAM, with chiropractic, homeopathy, naturopathy, and acupuncture accounting for more than 80% of use.[3] In this study, children who used CAM were older than nonusers, had better educated mothers, and tended to have parents who also used CAM. Almost 90% of parents opted to use conventional medicines first, suggesting that CAM be used in conjunction with it. In a review of Australian children with asthma aged 1 to 16 years, 55% used an additional alternative therapy, whereas 46% of those with childhood-onset malignancies used at least one form of CAM.[4,5]

For the purposes of this chapter, we are not including pre- and probiotic use in our definition of CAM. Both entities have, over the last few years, moved squarely into conventional gastroenterologic practice. However, in some fields, such as constipation, they are still felt to be complementary therapies, and, as such, we briefly discuss them. The maintenance of a normal healthy gut flora has become central to the management of many gastrointestinal pathologies, and the manipulation of gut flora with pre- and probiotics is dealt with elsewhere in the text in much greater detail.

USE OF CAM IN GASTROINTESTINAL DISORDERS

In this chapter, we focus on the currently available evidence for CAM use in the areas of inflammatory bowel disease (IBD), constipation, acute gastroenteritis, and liver disease.

Search Strategy

We conducted a thorough search of the literature using the following on-line databases: *MEDLINE*, *PsycINFO*, *Allied and Complementary Medicine*, *Psychological Abstracts*, *CINAHL*, and the *Cochrane Database of Systematic Reviews*. The MeSH terms "homeopathy," "'naturopathy," "comple-

mentary therapies," "alternative therapies," "acupuncture," "acupuncture therapy," "'spiritual therapies," "'music therapy," "laughter therapy," "aromatherapy," "medicine, herbal," "'medicine, chinese traditional," "drugs, chinese herbal," "medicine, ayurvedic," "massage," and "phytotherapy" were used in a *MEDLINE* search, in conjunction with the term "gastrointestinal diseases." Almost 2,500 references were found, with 203 being clinical trials published in English with an available abstract. All of the latter were reviewed to select 58 articles that were felt to be relevant to this publication. These references were then reviewed in full where possible. Additional references were identified by manual searching of bibliographies from recent review articles, and further citations were received from experts in the field.

Inflammatory Bowel Disease

There is considerable evidence of CAM use in patients with IBD. However, there are very few studies documenting the efficacy in different disease types. There are no studies of efficacy in children with IBD, yet there is some preliminary information on the prevalence of its use in this population.

Heuschkel and colleagues carried out a survey of CAM use in children and young adults with IBD in three centers of pediatric gastroenterology (Boston, Detroit, and London, UK)[6]; 208 questionnaires were completed, and the frequency of CAM use in this population was 41%. The most common therapies were megavitamin therapy (19%), dietary supplements (17%), and herbal medicines (14%). Parental CAM use and the number of adverse effects from conventional medicines were predictors of CAM use (odds ratio [OR] = 1.9, 95% confidence interval [CI] = 1.2–3.1, $p = .02$; OR = 1.3, 95% CI = 1.2–1.5, $p < .001$, respectively). The most important reasons respondents gave for using CAM were side effects from prescribed medicines, prescribed medicines not working as well as they had hoped, and hoping for a cure. Almost 60% of respondents not taking CAM were interested in learning more about it. These results are broadly similar to those found in adults with IBD, in which 51% of patients reported some CAM use in the previous 2 years.[7]

Verhoef and colleagues recently explored how often CAM providers see patients with IBD and how ready they were to recommend therapies.[8] The group interviewed 66 chiropractors, 19 pharmacists, 16 herbalists, and 15 health food store employees in Calgary, Alberta. Most respondents had seen patients with IBD, and over 80% of each group, except pharmacists (only 10%), would treat these patients or recommend a therapy. Almost all chiropractors used spinal manipulation, whereas other practitioners recommended a wide variety of interventions. Most of the respondents viewed their own recommendations as moderate to very effective. It is clear from these types of data that a significant amount of information is being given to adults (and probably children) with IBD outside the physician-patient consultation.[9] Much of this information is also not discussed with the practitioners prescribing conventional therapies, potentially leading to significant drug interactions and to issues around long-term compliance with orthodox therapies.

Very few rigorous human intervention studies have been carried out with CAM, and almost all of these have been done with adult patients. There is also some limited laboratory and animal evidence accumulating, providing initial insights into the possible mechanisms underlying specific therapies.

Recently, Langmead and colleagues reviewed the in vitro antioxidant effects of six herbal remedies used by patients with IBD; these included slippery elm (derived from the bark of the slippery elm tree), fenugreek (an ayurvedic therapy), Mexican yam (a tropical staple), devil's claw (the root of an African flower), tormentil (a European flower), and Wei Tong Ning (a traditional Chinese herbal therapy).[10] All of these herbs are likely to contain numerous antioxidant compounds. Orange juice was used as a phytic control and 5-acetylsalicylic acid (5-ASA) as a positive control. Like 5-ASA, slippery elm, devil's claw, tormentil, and Wei Tong Ning all had dose-dependent antioxidant properties, whereas all of the herbs and 5-ASA also had dose-dependent peroxyl-radical scavenging effects. Detection of reactive oxygen metabolites was significantly reduced if inflamed mucosal biopsies were incubated with 1 in 100 dilutions of all herbs except Mexican yam and orange juice. This in vitro evidence provides intriguing evidence that substances present in certain diets or used as alternative therapies may have direct anti-inflammatory effects on an inflamed mucosa.

There is some work in animals focusing on individual herbs and plant compounds, assessing their efficacy in different mouse models of colitis. Among others, *Cordia myxa* fruit, polygalae root, and tryptanthrin all appear to have anti-inflammatory effects, with down-regulation of interferon-γ occurring in several disease models.[11–13]

There is further evidence from animal work that polyphenols in green tea, already thought to have some preventive role in carcinogenesis, may regulate tumor necrosis factor-α (TNF-α) production by their effect on the core molecule nuclear factor-κB.[14,15] A dose of 0.5 g/kg body weight of green tea polyphenols reduced the serum TNF-α concentrations by 80% and prevented induced lethality in mice. A further study has extended these findings, showing that the spontaneous colitis of interleukin-2 knockout mice is ameliorated by regular supplementation with green tea polyphenols over a 6-week period.[16]

Two studies report the efficacy of the Chinese herbal remedies Kui Jie Qing (KJQ) and Yukui Tang in the treatment of active ulcerative colitis (UC).[17] The authors used KJQ enemas for 20 days in 95 patients with UC, comparing the response with that of 11 controls. They showed 95% "effectiveness" compared with 53% using sulfasalazine, prednisolone tablets, and KJQ enemas. In a second study, 118 patients with UC received KJQ orally with herbal decoction enemas and 15 mg oral prednisolone, neomycin sulfate, and sulfasalazine. This group was compared with 86 patients receiving a similar treatment but without KJQ. Again, an "efficacy" rate of 84% was reported in the treated group compared with 60% in controls.

A randomized, double-blind study treated 153 patients with active UC in three different groups. Group 1 received

Jian Pi Ling and a retention enema of *Radix sophorae flavescentis* and Flos Sophora (RSF-FS) per night. Group 2 received sulfasalazine plus a retention enema of dexamethasone, whereas group 3 was randomized to placebo plus the same retention enema (RSF-FS) given to group 1.[18] The remission rates of groups 1 and 3 were 53.1% and 19.0%, respectively, with only 27.7% responding to treatment with conventional medications. The outcome measures in both of these studies were not clearly stated and were all recorded in an unblinded fashion, hence casting some doubt on the dramatic results.

An oral formulation of the Indian gum resin *Boswellia serrata* (900 mg/d) was compared with oral sulfasalazine (3 g/d) in the treatment of moderately active UC. Both treatments were effective in this study, with 14 of 20 of those receiving *B. serrata* achieving a clinical remission at 6 weeks compared with 4 of 10 given sulfasalazine.[19] Boswellic acids are thought to inhibit leukotriene synthesis by noncompetitive inhibition of 5-lipoxygenase, thereby leading to their anti-inflammatory effects on chronic inflammation in UC.[20]

Wheat grass juice has been reported as effective compared with placebo in a small but carefully conducted study on 24 adults with left-sided UC.[21] Patients treated with 100 mL of wheat grass juice for 1 month had significant improvements in rectal bleeding, abdominal pain, and disease activity scores. In addition, there was a trend toward sigmoidoscopic improvement at follow-up. Again, it is the antioxidant and anti-inflammatory properties of components such as the flavonoids, which are known to be active in the arachidonic acid pathway, that are felt to be responsible for the therapeutic effects.

There may be further mechanisms at play in some food derivatives. A pilot study, still awaiting placebo-controlled confirmation, has shown germinated barley foodstuff to be effective in achieving both clinical and endoscopic improvement in adults with treatment-resistant active UC. Much, if not all, of the effect of this treatment may be due to the inherent prebiotic properties, which increase colonic short-chain fatty acid concentrations significantly.[22]

There is an almost complete absence of well-controlled trials assessing the impact of neuromodulation on patients with IBD. Patients and their physicians have long been aware of the association between emotion, stress, and disease activity in IBD. An early randomized controlled trial on the impact of stress management in 80 patients with IBD did suggest a significant reduction in disease-specific activity. There was also a reduction in stress indices in adults who received six classes on stress management.[23]

There are only anecdotal reports of either mind-body influences or stress contributing to the degree of mucosal inflammation in IBD. Whorwell and colleagues did study the effect of three hypnotically induced emotions (excitement, anger, and happiness) on distal colonic motility in 18 adults with irritable bowel syndrome.[24] Anger and excitement increased the colonic motility index, pulse, and respiratory rate, providing some hard, albeit limited, data on this association. Further studies are required to identify suitable patients and provide more convincing evidence on the efficacy of these therapies.

Constipation

There is already a complete dearth of good-quality data on the conventional therapies used in the management of constipation in children, so it will come as no surprise that there are no controlled prospective trials on any complementary therapies and that all available evidence is anecdotal.

Anthraquinones are known to be the active components in senna and aloe (sap of aloe leaves) and have stimulant laxative properties. Their abuse, however, has been associated with an increased risk of colorectal cancer (OR = 3.4).[25] Ispaghula husk and the plant polysaccharide psyllium can be used as effective bulking agents. Odes and Madar compared capsules containing celandine, aloe vera, and psyllium with placebo in a randomized controlled trial of 35 adults over 28 days. The treated group had an increase in bowel movements, softer stools, and less laxative dependence than the placebo group, yet abdominal pain remained unchanged in both groups.[26]

A Thai plant containing anthraquinone, *Cassia alata*, was tested against *Mist. alba* and placebo in a blinded controlled multicenter trial. Eighty adults with a 72-hour history of constipation were randomized into three groups, and each received a single dose of treatment. Over 80% of adults in the *Cassia alata* and *Mist. alba* groups had passed stool within 24 hours compared with 18% in the placebo group.[27]

The centuries-old liquid ayurvedic medicine *Misrakasneham* (containing a mixture of herbs, castor oil, and ghee) was compared with a conventional senna-based laxative in a controlled trial for treatment of opioid-induced constipation in adults with advanced cancer.[28] Fifty patients were randomly allocated to the treatment group, receiving the treatment in incremental doses if necessary over 14 days. After the study period, 69% and 85% of the senna and the ayurvedic therapy groups, respectively, reported satisfactory bowel movements, a difference that was not statistically significant. However, the *Misrakasneham* was well tolerated, quicker acting, and cheaper than the senna.

Brazelli and Griffiths, in a Cochrane review, looked at the effects of behavioral and/or cognitive interventions for the management of defecation disorders in children.[29] Sixteen randomized trials with a total of 843 children met the inclusion criteria. Sample sizes were generally small. Interventions varied among trials, and few outcomes were shared by trials addressing the same comparisons. The synthesis of data from eight trials showed higher rather than lower rates of persisting problems up to 12 months when biofeedback was added to conventional treatment (OR = 1.34, 95% CI = 0.92–1.94). In two trials, significantly more encopretic children receiving behavioral intervention plus laxative therapy improved at both the 6-month (OR = 0.51, 95% CI = 0.29–0.89) and the 12-month follow-up (OR = 0.52, 95% CI = 0.30–0.93) compared with those receiving behavioral intervention alone. Similarly, in another trial, the addition of behavior modifications to laxative therapy was associated with a marked reduction in children's soiling episodes (OR = 0.14, 95% CI = 0.04–0.51). The reviewers concluded that there is no evidence that biofeedback training adds any benefit to conventional treatment in the management of encopre-

sis and constipation in children. However, there is some evidence that behavioral intervention plus laxative therapy, rather than behavioral intervention or laxative therapy alone, improves continence in children with primary and secondary encopresis.

Probiotics have been used for treatment of constipation, but there are no reports in the literature of their use in children. There is one randomized controlled trial reporting their use in the elderly. Ouwehand and colleagues enrolled 28 elderly subjects in an open-label parallel study.[30] In addition to a placebo group, two groups received different strains of probiotic over a 4-week period. The subjects receiving the *Lactobacillus rhamnosus/Propionibacterium freudenreichii*–supplemented juice exhibited a 24% increase in defecation frequency, although there was no overall reduction in laxative use. Trials are now in progress assessing the impact of nonabsorbable prebiotic sugars such as inulin and fructo-oligosaccharides on children with idiopathic constipation.

Abdominal massage has been used for centuries in the treatment of constipation. It has recently regained popularity, and Ernst completed a systematic review of controlled clinical trials of this therapy.[31] He was able to select only four studies from the available literature, yet even these were heterogeneous in trial design, patient sample, and type of massage used. He concluded that massage therapy may be a promising treatment for chronic constipation, yet, inevitably, more rigorous trials should evaluate its true value.

Dolk and colleagues assessed the effect of yoga on the puborectalis muscle in nine patients with severe defecation difficulties secondary to puborectalis dysfunction (puborectalis paradox).[32] Having had electromyography (EMG) of the striated anal sphincter muscles, patients were offered training in yogic techniques of relaxation and muscle control to change the activity of the pelvic floor muscles during attempted defecation. Five patients completed the training program of 20 2-hour sessions and were re-examined clinically and with EMG. One patient regained a normal EMG pattern, but none of the patients improved clinically.

Kesselring and colleagues reported on the role of foot reflexology (FR) on well-being, voiding, bowel movements, pain, and/or sleep in women who underwent an abdominal operation.[33] One hundred and thirty subjects were randomized into three groups. For 5 days, they were exposed to 15 minutes of FR, foot/leg massages (FMs), or interview alone, respectively. The results showed that women in the FR group were more able to void without problems after the indwelling catheter had been removed than were women in the comparison groups. There was also a tendency in the FR group for the indwelling catheter to be removed earlier than in the other groups. In comparison, the FR subjects slept worse than the others. FM showed significant results in subjective measurements of well-being, pain, and sleep.

Liver Disease

Medicinal properties of the milk thistle plant (*Silybum marianum*) have been extensively researched. The active ingredient is silymarin, a mixture of at least four closely related flavonolignans, which appears to be antihepatotoxic owing to the antioxidant- and membrane-stabilizing properties of its components.[34]

The most dramatic reports of its use are in patients poisoned with the deathcap mushroom *Amanita phalloides*. In animal studies, dogs were given lethal doses of *A. phalloides*, 85 mg/kg, and were then randomized to receive either silymarin or placebo 5 to 24 hours after ingestion. None died in the treated group compared with 4 of 12 in the untreated group. This was supported in the treated group by improvement in hepatic enzymes and less necrosis on liver biopsy.[35] There are no randomized trials in humans, but there are various case series and retrospective studies supporting the usefulness of milk thistle in treatment of amanita poisoning.[36]

Liu and colleagues reported the efficacy and safety of Chinese herbal remedies in the treatment of asymptomatic carriers of hepatitis B.[37] Despite some methodologic problems, the "Jianpi Wenshen recipe" appeared to be significantly better than interferon for clearance of serum hepatitis B surface antigen (HBsAg) (relative risk [RR] = 2.40, 95% CI = 1.01–5.72) and hepatitis B e antigen (HBeAg) (RR = 2.03, 95% CI = 0.98–4.20), as well as in the seroconversion of HBeAg to anti-HB_e (RR = 2.54, 95% CI = 1.13–5.70).

In a further Cochrane review of Chinese medicinal herbs in the treatment of chronic hepatitis B infection, of nine randomized trials included in the review, only one was considered to have adequate methodologic quality.[38] Ten different medicinal herbs were tested in these nine trials. Fuzheng Jiedu Tang was significantly better in clearing serum HBsAg, HBeAg, and hepatitis B virus deoxyribonucleic acid (DNA) compared with placebo. In a further randomized trial of 94 patients, kurorinone was found to be as effective as interferon-α in clearing HBeAg and hepatitis B virus DNA over a 12-month follow-up period.[39]

In the treatment of hepatitis C, 4 of 10 trials were considered to be of adequate quality for assessment.[40] When Bing Gan Tang was used in conjunction with interferon-α, it cleared serum hepatitis C virus ribonucleic acid (RNA) (RR = 2.54, 95% CI = 1.43–4.49) with normalization of serum alanine aminotransferase (ALT) (RR = 2.54, 95% CI = 1.43–4.49) better than interferon-α alone. The herbal mixture "Yi Zhu decoction," when compared with glycyrrhizin plus ribavirin, was significantly better at clearing serum hepatitis C virus RNA and normalizing ALT levels. In addition, Yi Er Gan Tang had a significant advantage over silymarin plus glucurolactone in normalizing serum ALT.

Although many of these data are intriguing, the lack of prospective randomized studies seriously limits any widespread clinical application. Caution is also indicated in view of the completely unknown adverse-effect profile of these medications.

Ayurvedic medications have also been used in the treatment of hepatitis. Despite initial hopes that the herb *Phyllanthus amarus* might reduce the carriage of surface antigen in carriers of hepatitis B, other studies have failed to show a similar improvement.[41,42] One study has shown *Phyllanthus urinaria* to be more effective than *P. amarus*.[43]

Acute Gastroenteritis

There is now extensive evidence in the literature about the use of probiotics in the treatment of acute gastroenteritis, especially in children. This is covered in greater detail elsewhere in the text.

Homeopathy is widely used in the treatment of gastroenteritis in children, and Jacobs and colleagues reported two double-blind placebo-controlled randomized trials to assess its efficacy in the treatment of childhood diarrhea.[44] Eighty-one children from Leon, Nicaragua, age 6 months to 5 years of age, received individualized homeopathic medicine daily over a period of 5 days. Standard treatment with oral rehydration treatment was also given. There was a statistically significant decrease in both the duration of diarrhea (less than three unformed stools daily for 2 consecutive days) and in the number of stools per day between the two groups after 72 hours of treatment. The same study was then repeated in 126 children from Kathmandu, Nepal.[45] This study revealed similar results, and a Kaplan-Meier survival analysis of the duration of diarrhea showed an 18.4% greater probability that a child would be free of diarrhea by day 5 with homeopathic treatment ($p = .036$).

Izadnia and colleagues reported the effective use of brewer's yeast for treatment of *Clostridium difficile* gastroenteritis in rats, with both brewer's yeast and *Saccharomyces boulardii* attenuating *C. difficile*–induced colonic secretion in the rat.[46] Hyperimmune cow's colostrum has also been used with some success in randomized trials of *Rotavirus* diarrhea in children.[47] However, bovine immunoglobulins are more easily digested by human trypsin and chymotrypsin and should thus have little or no effect on small intestinal function.[48]

Loeb and colleagues have shown, again in a randomized trial, that a tannin-rich carob pod, together with oral rehydration solution, led to a significantly quicker resolution of viral or bacterial diarrhea compared with oral rehydration solution alone.[49]

A combination of berberine and tetracycline was shown to significantly decrease the volume and frequency of diarrheal stools, the duration of diarrhea, and the requirement for intravenous and oral rehydration fluid in adults with cholera. However, neither berberine nor tetracycline was found to be better than placebo in treating noncholera diarrhea.[50]

Although not strictly used in acute infective gastroenteritis, psyllium was successful in reducing symptoms in 20 of 23 children with chronic nonspecific diarrhea.[51] Wenzl and colleagues showed that stool looseness is determined by the ratio of water to insoluble solids in the stools; therefore, diarrhea can also be the result of low output of insoluble solids, and psyllium may act by increasing these insoluble solids.[52]

ADVERSE EFFECTS

It is a popular belief that CAM therapies are natural products and therefore safe. Although this may apply to many CAM therapies, the recent explosion in CAM use has been paralleled by an increasing number of serious adverse events reported in the world literature. In the absence of any large prospective studies that systematically collect and report safety data, the vast majority of adverse events are reported as case reports, therefore clearly providing a gross underestimate of the actual incidence of adverse events related to CAM use.

Bensoussan and colleagues conducted a survey of reported adverse events in the use of traditional Chinese medicine in Australia.[53] Practitioners did report some adverse events with use of acupuncture (fainting, nausea and vomiting, and increased pain) and consumption of Chinese herbal medicines. However, these side effects were very uncommon when compared with those of practices in conventional medicine. An average of one adverse event was reported for 8 to 9 months of full-time practice (ie, 1 adverse event in 633 consultations). This type of study is clearly flawed in many ways, with significant bias again likely to significantly underestimate the incidence of adverse events. There is thus little reassurance both for practitioners of conventional medicine and for the consumers of CAM therapies that these therapies are as free from hazard as they are often purported to be.

Although most herbal remedies used in children at home appear to be safe, allergic reactions and cases of anaphylaxis have been reported.[54] The most frequently reported adverse effects include diarrhea, nausea, and vomiting, and although many herbs preferentially affect the digestive tract, most of their adverse effects are self-limiting.[55]

Adverse effects on liver function may be more serious, with hepatotoxicity secondary to ingestion of Chinese herbs being well described (Table 76.6-1). In Africa and Central America, toxicity can be endemic in areas where particular plants are consumed on a daily basis. Liver transplant has been necessary in cases of fulminant hepatic failure secondary to herbal remedies.[56]

The potential toxicity of pyrrolizidine alkaloids in herbal teas was recognized over 40 years ago. These can result in centrilobular necrosis, portal hypertension, veno-occlusive disease, and an increased risk of hepatocellular carcinoma.[57] In cases of suspected poisoning, it is important that some of the ingested product is retrieved and analyzed. It may be useful to save blood and urine for later analysis. Once the offending agent is identified and further intake is prevented, treatment of these cases is mostly supportive. Suspected poisoning should always be considered in patients presenting with unexplained hepatitis, although the offending constituent is identified in a minority of cases only.

In view of the widespread and self-directed use of herbal preparations, consumers and clinicians alike need to be increasingly aware of these potentially hepatotoxic products.

McGuire and colleagues reported a case of fatal hypermagnesemia secondary to the cardiac complications of high doses of magnesium oxide.[58] This had been given to a child with mental retardation, spastic quadriplegia, and seizures as part of a regimen of megavitamin and megamineral therapy and without the knowledge of the patient's physician.

Homeopathic medicines are generally considered to be nontoxic owing to the degree of dilution these medicines

TABLE 76.6-1 LIST OF HERBAL TREATMENTS WITH ADVERSE EFFECTS ON THE LIVER

BOTANICAL NAME	COMMON NAME	USE	SIDE EFFECTS	REFERENCE
Teucrium chamaedrys	Germander	Antipyretic, obesity	Hepatitis	69
Lycopodium serratum	Jin Bu Huan	Analgesic	Hepatitis	70
Cassia augustifolia	Senna	Laxative	Hepatitis	71
Atractylis gummifera	White chameleon	Antipyretic purgative	Hepatitis	72
Larrea trientata	Chapparal	Anti-inflammatory	Cholestatic hepatitis	73
Senecio crotolaria	Herbal tea	Tonic	Veno-occlusive disease	74

undergo. Massage therapies are also generally considered to be safe, although a hepatic hematoma has been reported after deep abdominal massage.[59]

In 1986, Stryker and colleagues reported six cases of acute hepatitis B after receiving acupuncture treatment in a chiropractic clinic over a period of 6 months.[60] In these cases, acupuncture needles were reused after overnight sterilization using 1:750 solution of benzalkonium chloride. Practitioners now use disposable needles to eliminate this risk.

Dunbabin and colleagues reported a case of lead poisoning in a 37-year-old man after the intake of some Indian ayurvedic medications. The tablets contained a very high concentration of lead, and the patient required chelation therapy.[61]

The majority of complementary therapies are taken as adjuncts to conventional therapies. As a result of this, and the fact that very few patients inform their physicians of concomitant use, there is now an increasing list of known interactions between certain remedies and commonly prescribed medications in pediatric gastroenterology (Table 76.6-2).

Plants undergo several processes before manufacturing of the final product. During this period, they are at risk of adulteration, deterioration, and contamination. Adulteration is more likely to occur with certain herbs, which are expensive and in short supply. Many countries of origin do not have a well-enforced code of good manufacturing practice, and remedies may be adulterated, with steroid and nonsteroidal anti-inflammatory drugs being the most commonly detected.

Plants may be misidentified at the time of picking, their true names misspelled or even mistranscribed during export. Proper identification of herbs is, of course, particularly important, particularly for the accurate reporting of adverse effects.[62]

The final concentration and quality of the active ingredient are determined by many different factors, not least of which are the local environmental conditions (availability of water, sunshine, and rainfall in some areas). Stringent collection and packaging measures with batch to batch analysis of the active ingredient in the final product are important.

Ginenoside is the biologically active glycosylated steroid in ginseng, which is commonly used and prescribed. It was examined in 50 commercial brands sold in 11 countries. In 44 of these products, the concentration of ginenoside ranged from 1.9 to 9% w/w; six products contained no ginenoside, with one of these six containing large amounts of ephedrine.[63] A series of five adults developed heavy metal poisoning in the United Kingdom from Indian ethnic remedies; the products used had lead concentrations varying from 6 to 60% w/w.[64]

In addition to the contamination of products, ingredients may be substituted without adequate research into their safety or efficacy. *Stephania tetrandra* was an active ingredient in a Belgian slimming treatment. This was, however, replaced by *Aristolochia fangchi* without a change in the brand name, and its use resulted in nine cases of rapidly progressive interstitial nephritis in young

TABLE 76.6-2 INTERACTIONS BETWEEN CONVENTIONAL DRUGS USED IN PEDIATRIC GASTROENTEROLOGY AND HERBAL REMEDIES

HERB	CONVENTIONAL DRUG	CONSEQUENCE/EFFECT ON CONVENTIONAL THERAPY
Licorice	Spironolactone, prednisolone	Antagonistic effect; hypokalemia; increased salt and water retention
Echinacea	Anabolic steroids, methotrexate, immunosuppressants	Hepatotoxicity; theoretically may interfere because echinacea is an immune stimulant
St. John's wort	Cyclosporine	Reduced blood levels
Feverfew, garlic, ginkgo, ginger, and ginseng	Warfarin	Increased effect
St. John's wort, saw palmetto (containing tannic acid)	Iron	Inhibits absorption
Ephedra	Corticosteroids	Increased excretion
Xaio chai hu tang (sho-saiko-to)	Corticosteroids	Reduced blood levels

Adapted from Zou L et al,[75] Miller,[76] and Fugh-Berman A.[77]
Known herbal treatments that are cytochrome P-450 inhibitors: (1) ginkgo biloba (ginkgolic acids I and II); (2) kava (desmethoxyyangonin, dihydromethysticin, and methysticin); (3) garlic (allicin); (4) evening primrose oil (*cis*-linoleic acid); (5) St. John's wort (hyperforin and quercetin).

women. Laboratory analysis revealed it to contain a nephrotoxic component, aristolochic acid. To date, 80 cases have been identified. More than half of these patients have developed renal failure.[65]

Although the production of many CAM therapies is now more closely scrutinized, their final distribution can lead to further misinformation and subsequent confusion for the consumer. With the explosion of information sources on the Internet, it has become impossible to control or regulate many of the claims being made about remedies that are now sourced from around the world. Ernst and Schmidt investigated Internet advice offered by "medical herbalists" to a pregnant woman for the herbal treatment of morning sickness.[66] Search engines were used to find relevant Web sites, and all potential electronic mail addresses were contacted. Herbalists gave a wide range of differing advice, with less than one in three cautioning potential consumers about adverse effects.

Many complementary therapies, particularly those involving the administration of products encompassed by the term "dietary supplement," can continue to avoid the costly validation and safety studies that are required of conventional pharmaceutical products by relying on legislation passed in the United States in 1994 (Dietary Supplement Health and Education Act, 1994). Although this loophole exists, it is unlikely that manufacturers of dietary supplements will embrace the high cost of the formal drug trials and the research and development that are required of their colleagues in the pharmaceutical industry.

THE FUTURE OF CAM

LEGISLATION

United States. CAM use has been increasing rapidly in the United States. The majority of expenditure for these therapies is made by individual third-party payers. This fact and the lack of evidence-based practice prompted Congress to create the NCCAM at the National Institutes of Health. NCCAM's mission is "to explore complementary and alternative healing practices in the context of rigorous science; to educate and train CAM researchers and to disseminate authoritative information to the public and professionals."[67] Although the budget for NCCAM has increased to 70 million dollars in the year 2000, it is still insufficient for exhaustive studies in all complementary therapies. Currently, scientific research is broadly aimed at publicly relevant therapies. These include, among others, characterizing the active components of cranberry that may help prevent urinary tract infections, finding out more about meditation through the use of functional magnetic resonance imaging, investigating the biologic and chemical activity of red clover for use in women's cardiovascular health, and studying the effects of ginseng in an animal model of diabetes.

United Kingdom. In contrast to the United States and most European countries, there are almost no regulations governing the work of CAM practitioners in the United Kingdom. In 1997 and 2000, the Centre for Complementary Health Studies (UK) surveyed over 50,000 practitioners from 140 professional health bodies. There was a great variation in practicing standards. Homeopathic, osteopathic, and chiropractic practice have their own self-regulated professional bodies, and there has now been a move in the House of Lords that training courses for different CAM practitioners should become standardized and implemented by their respective professional bodies. There has also been a move to establish a body similar to the NCCAM to sponsor well-funded good-quality research into complementary therapies.

RESEARCH INTO CAM

Research in CAM generally suffers from different difficulties than does research into conventional medicines. Whereas in conventional medicine, direct comparison of the efficacy of two drugs is frequently possible, this is often not feasible with CAM therapies. Therapies in CAM may be based on whole systems; for example, ayurvedic medical therapy may include a combination of oral medicines, massage, and yoga exercises. This makes comparative studies very difficult because only certain aspects of a therapeutic approach are generally tested at any one time against a certain conventional medicine. Randomization leads to the paradox that much of CAM therapy relies on patient choice and individually tailored treatment programs, thereby making larger randomized studies extremely difficult to complete. Furthermore, diagnoses in CAM frequently rely on reported symptoms rather than on the pathogenesis of an underlying disease. Thus, two patients with the same disease process but differing symptoms might receive entirely different complementary therapies. Nonetheless, studies must continue to be carefully designed and carried out to overcome the above problems, thus ensuring that the best possible evidence informs our clinical decisions.

CONCLUSIONS

A Cochrane analysis of the literature for articles published on CAM from 1966 through 1996 shows that the total number of articles listed in *MEDLINE* rose to a peak of 400,000 additions by 1996, with only 1,500 per annum being indexed under alternative medicine.[68] Before 1986, only 2% of the latter were clinical trials in alternative medicine, with an increase to 10% by 1996. With the worldwide growth in interest, it is imperative that research on complementary medicines should be conducted using stringent criteria, as used in research on conventional therapies. Only in this way will it be possible to fully exploit the wealth of products and therapies at our disposal. The trend toward a more evidence-based approach in this discipline is vital if the move toward a more integrated type of health care provision is to occur.

It is now clear that clinicians can no longer ignore the potential benefits and occasional risks of CAM, making it necessary for us to familiarize ourselves with all of the therapies that our patients may be taking.

7. Adherence to Medical Regimens

Eyal Shemesh, MD

Nonadherence to (noncompliance with) medical recommendations is a leading cause of morbidity and mortality in a wide array of disease processes and in all age groups.[1–8] These diseases include disorders of the gastrointestinal tract.[9–13] Nonadherence is specifically thought to be prevalent during the adolescent years.[1,10,11,14] Hence, it is frequently encountered by pediatricians. Adherence is especially important in patients who have a chronic medical illness, who need to adhere to medications and dietary regimens over a long period of time, and whose health outcome is closely related to following the recommendations.

Extant data strongly suggest that nonadherence is a significant cause of morbidity and mortality in several patient groups, such as post-transplant patients.[2,3,15–18] Yet the assessment and treatment of nonadherence are rarely approached in a systematic way in clinical practice.

This chapter reviews the definition and characteristics of nonadherence, its prevalence, ways to assess it, developmental considerations in adherence behavior, risk factors that predispose a patient to become nonadherent, and methods that are thought to improve adherence. Most of the discussion is not disease specific. However, specific examples, or a concise summary of issues that are unique to children who suffer from specific illnesses of the gastrointestinal tract, are included when relevant.

Nonadherence is a leading reason for poor outcome in a variety of disease processes. It can be improved in many cases. It is important to study it and to incorporate adherence assessments and interventions into routine practice. Very little has been done to date to address this important phenomenon in a concerted fashion. This chapter is intended to increase awareness of nonadherence as a mediator of outcome and to provide a framework for a rational approach to its assessment and treatment.

DEFINITION

Nonadherence to medical recommendations happens when a patient does not follow the recommendations that are given by physicians, nurses, or other medical professionals. Nonadherence could be related to a wide array of recommendations. These could be, for example, dietary recommendations, scheduling recommendations (clinic visits, imaging tests), and recommendations to take medications. Adherence to one type of recommendation (ie, coming to clinical visits as scheduled) does not necessarily imply adherence to another type of recommendation (ie, taking the medications as prescribed[19]). The treatment of gastrointestinal illnesses, such as celiac disease, frequently includes a dietary modification, which is a lifestyle change. Adherence to such lifestyle changes may be quite different from adherence to medications, which does not require a major change in lifestyle and habits. Even within one general type of recommendation, adherence may vary (ie, a patient may adhere to an immunosuppressant regimen but not to a prescribed vitamin pill, even though both are prescribed by the same clinician). Hence, adherence should be defined narrowly, in relation to a specific recommendation. I decided to focus the discussion in this chapter primarily on nonadherence to medications. This is done for clarity and also because more data are available on this particular type of adherence.

A strict definition of nonadherence is of very limited use in clinical practice. This is because it is quite likely that every once in a while, a patient who suffers from a chronic medical condition will not take the medications exactly as prescribed, and most clinicians will not call this behavior "nonadherence." The following example illustrates this principle: a patient who had a liver transplant has been prescribed tacrolimus every 12 hours. This patient occasionally (ie, every weekend) takes the medications on a slightly different schedule (ie, 8 am and 10 pm instead of 7 am and 7 pm). Most clinicians will not consider this slight variation to be nonadherence, and most would probably not think that this patient should be treated for it. Yet, by a strict definition, during the weekend this patient is nonadherent to the recommendation that the medication should be taken every 12 hours.

Hence, there should be a defined threshold beneath which a nonadherent behavior is acceptable. This threshold has not been prospectively determined in any gastrointestinal disease process. It is possible that certain illnesses require different levels of adherence. For example, a patient who is suffering from autoimmune hepatitis and has been transplanted will be expected to adhere to an immunosuppressant regimen more closely than a patient who had extrahepatic biliary atresia and was transplanted as well. This is because the disease process could recur in autoimmune hepatitis but not in extrahepatic biliary atresia, and strict adherence is mandatory to avert that possibility in the first, but not the second, patient.[18]

One way in which an adherence threshold level can be determined (ie, "it is okay for this patient to forget to take the medication once a week but not twice a week") is by determining at what point medical adverse events are likely. The danger of waiting for the actual occurrence of the adverse event to make this determination is obvious. Rather than waiting until some medical emergency has happened owing to nonadherence (ie, a flare of Crohn disease), a better method would be to predetermine a level of acceptable adherence for each patient or group of patients, assess it frequently, and try to act *before* the medical event has happened.

The way in which nonadherence is defined could have far-reaching consequences. For example, studies done by pharmaceutical companies sometimes set a threshold of 70% adherence for inclusion in a study that examines the effects of a certain medication against a placebo. Although it is indeed imperative to include only patients who actually take the medications in such studies, this approach is not supported by specific evidence as far as gastrointestinal illnesses in children are concerned. There are no data that demonstrate that 70%, or any particular percentage, should be the adherence threshold in any of these illnesses. Furthermore, this arbitrary cutoff point skews the study population by excluding nonadherent patients from the final analysis. Hence, if a medication seems less potent or not potent when used in standard practice rather than in the context of a research protocol, nonadherence could be a contributing factor.

To summarize, nonadherence should be defined in relation to a specific recommendation. It should include a threshold (ie, What degree of nonadherence is permissible?). In determining the threshold, the clinician should take the illness involved into account. Because no empiric data are available regarding the desirable threshold, clinicians must use their judgment and experience to decide what level of adherence is acceptable for each patient.

EXTENT OF THE PROBLEM

Nonadherence to medical recommendations has been reported to be a leading cause of morbidity and mortality in several chronic disease processes, such as ulcerative colitis,[12,13] celiac disease,[9–11] and survivors of liver transplant.[16] Nonadherence may be associated with grave consequences, and it may be quite frequent in children and adolescents (see below). A recent study reported 34 episodes of nonadherence among 28 pediatric liver transplant recipients, leading to acute cellular rejection and recurrent hepatitis in 16 patients, death in 2 patients, and loss of 5 transplants.[16] Our retrospective study of adolescent liver transplant recipients showed that a protracted course of nonadherence led to retransplant and death in several patients.[18] Interestingly, in that study, the rate of documented nonadherence exceeded 50% of the sampled adolescents. Among ulcerative colitis patients, nonadherence to medications was associated with a fivefold increase in the risk of recurrent disease by the end of 12 months of follow-up.[13] These and other data strongly suggest that nonadherence is a common and dangerous phenomenon in patients who are suffering from chronic illnesses of the gastrointestinal tract.

Yet nonadherence is rarely systematically addressed in clinical practice. The following sections review some of the difficulties that are encountered on the way to a rational approach to the detection and treatment of nonadherence.

DEVELOPMENTAL CONSIDERATIONS

A child's cognitive, emotional, and social development may alter adherence behavior. It is quite possible that the same child will be nonadherent at one point and adherent at another, in tandem with specific maturational and developmental stages. The following are a few specific examples of how different developmental stages[1,14] can affect nonadherence, its assessment, and its treatment.

One point is the shift of control, or responsibility, from parent to child. At a certain age or developmental stage, the child becomes responsible for taking his/her medications. Before that stage, it is the responsibility of the parent to administer them. It is obvious that in the treatment of an 8-month-old infant, the parents are the focus of assessment and treatment if nonadherence becomes a problem. In such a case, it is the parent's adherence to administering the medications that should be addressed. On the other hand, a parent may have very little input in affecting the adherence of an 18-year-old adolescent who is in college and is not living with the parent. Hence, somewhere between infancy and young adulthood, the main burden of adherence shifts from parent to child. Assessment and treatment of nonadherence should also shift their focus at that stage. Yet there are virtually no published empiric data about the average age at which this shift occurs. In a survey of 81 patients and their caretakers that was done at the Mount Sinai Medical Center's liver post-transplant clinic, the median age at which parents and children reported that the responsibility for taking the medications is in "transition" was 12 years old, but there was significant variability (range of reported age of transition = 9 to 16 years old). In this cohort, therefore, early adolescence is the time at which the shift in responsibility occurs. Therefore, it may be useful to review the medication regimen in detail with the child and family as the child approaches this age, perhaps even in the context of a dedicated "transitional" visit.

Another important aspect is the development of a child's body image as an essential part of emerging self-esteem during adolescence. Physically disabled children, who may suffer, for example, from disfiguring postoperative scars, reduced weight, or delayed hormonal maturation (as in cases of malnutrition or gut absorptive defects), may not be able to form a positive body image of themselves.[20–22] These patients may become nonadherent to recommendations that are perceived as disfiguring, such as prescriptions of steroid medications and surgery.[22]

Lastly, because of the significant psychosocial changes that children go through on the way to becoming young adults, nonadherence in a child should be viewed as a potentially transient problem. It depends on the child's particular circumstances, cognitive abilities, and emotional status at each point in time. Hence, the labeling of a patient, rather than the patient's behavior, as "nonadherent" is rarely justified. Therefore, clinicians should be encouraged to keep trying to improve adherence by offering counseling, advice, or sometimes specific psychiatric help. At some point, a child may become receptive to a treatment modality that has not been successful before because of different circumstances or cognitive abilities. The following case report illustrates this general principle:

M is a 21-year-old patient who had her first liver transplant when she was 15 years old owing to fulminant hepatic failure caused by a psychoactive medication used to treat attention-deficit/hyperactivity disorder. Following the transplant, she was recovering well until about 1-year post-transplant, when a rejection episode was diagnosed by biopsy, following an elevation in hepatic enzymes. The patient's blood level of tacrolimus at admission was zero, and M disclosed that she was not taking her medication as prescribed. A psychiatric consultation was obtained, and a depressive disorder was diagnosed. The adoptive parents, at the time, were overwhelmed and stated that they could not be responsible for monitoring the child's adherence. Family sessions were conducted, an antidepressant was prescribed, and the patient was discharged. Following discharge, adherence was monitored closely by direct questioning at each clinic visit and medication blood levels. A psychosocial intervention included family sessions and educational efforts aimed at the parents and the child. For 2 years, the medical course was unremarkable. The psychiatric symptoms improved, and adherence was restored. However, when M approached 18 years of age, she moved out of her parents' home to live with her boyfriend. She started to miss clinic visits and seemed more depressed, and her medication blood levels became erratic. She was eventually admitted again for a second rejection episode related to nonadherence. Two more episodes followed in the span of less than a year. An antidepressant was prescribed but not taken. Because of progressive liver damage, retransplant became the only way to keep this patient alive. An extensive psychosocial evaluation was conducted again, and the patient was diagnosed with a depressive disorder (adjustment disorder with depressed mood). The boyfriend's parents, who were supportive but not well informed about the patient's condition, were engaged in sessions and encouraged to take an active supportive role. They ensured adherence to medications, including adherence to the antidepressant. The patient became adherent again for several months prior to a retransplant. One year following the second transplant, the patient was taking her medications and was doing well both medically and psychologically. A re-evaluation found that her mood disorder was in remission.

ASSESSMENT

There is no gold standard for the measurement of adherence, and each proposed method has its shortcomings. Table 76.7-1 summarizes frequently used methods, their strengths, and their weaknesses. Below are specific comments about several methods that are in use.

SELF-REPORT

When compared with objective measures of adherence, data suggest that self-reports are not a sensitive and reliable way in which to assess adherence.[23–26] Self-reports that are obtained in the context of an interview may be an exception.[27,28] Self-reports may still have a place in assessment because a patient's report that he/she *does not* take the medications is generally considered reliable.[26] The part that is not thought to be reliable is the patient's report that he/she *is* taking the medication. Hence, self-report measures may be considered a relatively easy screening method that will identify some but not all cases of nonadherence.

Pill Counts

Pill counts, obtained through a manual count at every clinic visit, are an objective method. A patient may engage in a variety of behaviors that would invalidate this method as a measure of adherence. For example, a patient may remove pills but not take them or take the correct number of pills at an incorrect time.[19] This method will therefore identify patients who are nonadherent, provided that they are not actively concealing it. Routine use of this method is time-consuming. It has not been empirically validated in children who suffer from gastrointestinal illnesses.

Electronic Event Monitoring Devices

Electronic event monitoring devices (eg, MEMS Caps, a product of AARDEX/APREX, Switzerland) are pill boxes with electronic caps that register each opening of the device (for dispensation of a pill). A dedicated software translates the pill box readings into an output chart that gives information about the number and timing of openings. Figure 76.7-1 represents the MEMS readings that were obtained for the patient who was described above shortly before retransplant. It is easy to note that adherence was restored in that patient in December 2001 following the intervention.

Although this method has been described as the state-of-the-art adherence monitoring method, it is not free of bias. Patients may open the pill box but not remove a pill, or they may discard the pill after removing it. Electronic monitoring provides a way to ascertain precisely when a bottle was opened. However, data are lacking about the importance of this precise information. It is possible that taking an immunosuppressant 10 hours as opposed to 12 hours apart does not really constitute a significant adherence problem. The precise threshold at which timing becomes important is not well defined. Finally, although electronic monitoring carries the promise of an objective method that is much harder to "fool" than pill counts, its use was not validated against other acceptable methods of adherence monitoring or clinical outcome in children who suffer from gastrointestinal illnesses.

Prescription Refill Rates

Prescription refill data have been used for the detection of nonadherence[29] and, in some instances, have been reported to be more reliable than patients' self-reports.[30] To use this method, the clinician needs to be able to communicate with the pharmacy, or pharmacies, that the patient is using. Patients are likely to request a refill a few days before they run out of their medications, so the refill rate is only a crude estimate of the time the patient ran out of his/her supply. Further, refilling a prescription is not synonymous with having taken the previously prescribed dose. Hence, prescription refill rates are an objective but crude, and sometimes inaccurate, method of detection.

TABLE 76.7-1 METHODS THAT ARE FREQUENTLY USED TO ASSESS ADHERENCE

ADHERENCE ASSESSMENT METHOD	STRENGTHS	WEAKNESSES	COMMENT
Subjective methods	Easy to obtain	Less reliable than objective methods	
Patient/parent self-report	(1) Easy to obtain; (2) specific (if the patient reports not taking the medication, this report is usually reliable)	Not sensitive (a report that the patient is taking the medication may not be reliable)	Interview results are probably more reliable than questionnaire results
Clinician report	Easy to obtain	(1) Not reliable in predicting nonadherence as judged by objective measures; (2) clinicians' disagreement is a problem (different adherence ratings by different clinicians)	Correlates with health outcome measures (clinicians are more likely to detect nonadherence after an adverse health event has happened as a result of the nonadherence)
Objective methods	More reliable than most subjective methods	Require time and resources	
Medication levels (in blood, urine, or saliva)	Indicates actual intake	(1) Costly; (2) some medications do not have a readily available assay; (3) requires obtaining a biologic specimen; (4) level may at times be affected by metabolic processes, not just by intake	Measurement of the degree of fluctuation between individual levels may be a more accurate representation of adherence over time
Measurement of metabolites of a medication	Reflects intake during a relatively long period of time (not just a single dose)	(1) Costly; (2) assay may not be available; (3) metabolism may be affected by factors other than intake	For example, azathioprine metabolites
Pill counts	Easy to perform and the least expensive method	Patients may discard pills without taking them	
Electronic monitoring devices	Provide specific data about the time in which a medication was taken	Patients may discard pills without taking them (but it is harder to "fool" the electronic device than it is to "fool" a pill counter)	May be too sensitive in some instances (ie, it does not really matter, sometimes, when exactly a patient has taken the medication)
Assessment of the biologic effect of the medication	Addresses the desired outcome of a medication and hence also assesses the effectiveness of the regimen	(1) A lack of biologic effect could be due to other factors (such as a biologic resistance to the medications); (2) assays may not be available	An example: an assessment of thromboxane production values in patients who are prescribed aspirin
Prescription refills	Inexpensive	May not reflect actual intake	

Medication Blood Levels

Medication blood levels may be used for determination of nonadherence. The use of a blood level drawn only once may be misleading. This is because some fluctuation is permissible. An incidence of forgetting to take the medication once may be erroneously counted as nonadherence when using this method. My colleagues and I therefore previously argued that an evaluation of the fluctuation of medication blood levels over time is a better predictor of nonadherence, except in the rare case of a patient who is never taking the medication (this patient will have a consistent level of zero without any fluctuation).[31] We compared standard deviations of consecutive blood levels in pediatric liver transplant recipients.[31] A higher standard deviation and, therefore, more fluctuation between individual measures was deemed to be indicative of nonadherence and was shown to be consistent with a panel assessment of adherence in the same subjects. It is important to note that this method assumes that medication blood levels are closely related to intake. This was shown to be the case for tacrolimus but is not true for cyclosporine.[31] Hence, fluctuations in cyclosporine blood levels cannot be used as a reliable adherence detection method. This method will not identify patients who take their medication only prior to clinic visits ("white coat adherence"[32]).

Metabolites

Metabolites are levels of a medication degradation or metabolic products. Metabolite levels of azathioprine have been used to assess the degree of adherence to this medication.[33] The benefit of using this method is that metabolites accumulate over time, and hence their level reflects the level of medication intake over a period of time, not just recent intake (as is the case with medication blood levels). This method may be less sensitive than others in that only a significant deviation from the prescribed regimen will be detected. It is also usually quite expensive. Further, drug metabolism may be affected by factors other than intake (eg, level of activity of an enzyme that is responsible for the metabolite that is being measured) and may therefore differ between patients.

Clinicians' Assessment of Adherence

Clinicians' assessment of adherence, although used in a few adherence studies, was, in fact, not shown to be a particularly reliable method for the detection of nonadherence.[19,34] It may be more reliable in the most severe cases, and it does

take into account the health status of these patients. My colleagues and I previously reported a perfect agreement in a post hoc blind assessment of the most severe cases of nonadherence in pediatric liver transplant patients among a clinician panel composed of two hepatologists and a nurse.[31] Agreement was reached only for the most severe cases, however. The use of clinicians' assessments of adherence has not been validated in children who suffer from gastrointestinal illness. Taken together, extant data suggest that clinicians' assessments are not a particularly reliable method of detection of nonadherence, with the possible exception of the detection of the most severe cases.

Finally, nonadherence has been described as dynamic in nature.[19] A patient may present as nonadherent at one point in time and adherent at another. Therefore, clinicians' assessments, or indeed any method used to measure adherence, must be examined repeatedly over time rather than at only one time point.

RISK FACTORS

Many risk factors have been reported to be associated with nonadherence to medications.[1,2,14,18] Only some of these are reviewed below. The factors are grouped into those that are associated with the illness, the treatment, the patient, the social milieu, and the clinic/clinician. These groups overlap, and factors may belong to more than one group.

Factors Related to the Illness

Specific medical illnesses may predispose a patient to become nonadherent by virtue of their course or associated features. For example, some medical illnesses are associated with cognitive decline (eg, subacute hepatic encephalopathy as a complication of chronic liver disease). Nonadherence to medications was found to be increased in instances in which the cognitive abilities of a patient are diminished.[35–37] Therefore, diseases that are associated with cognitive decline may be associated with nonadherence owing to this decline. Another example relates to the course of the illness. The management of adherence in patients who suffer from a chronic (as opposed to acute) medical condition is thought to be different in focus and duration.[38] Thus, the characteristics of the illness process, such as chronicity, may influence the risk of nonadherence.

Factors Related to the Treatment

The characteristics of the treatment regimen may determine the likelihood that a patient will adhere to it. Treatments that are time-consuming, require a high level of organization (ie, multidrug regimens), and require a high level of motivation all carry an increased risk of nonadherence.[37,39,40] Treatments that have a severe spectrum of side effects were sometimes,[41–43] but not always,[18,44,45] reported to carry a higher risk of nonadherence; for specific regimens or illnesses, side effects may not independently constitute a significant risk factor for nonadherence. The nature of the recommendation is also important; lifestyle changes (ie, dietary) are thought to be hard to achieve, perhaps because lifestyle changes require a more complex behavior.[46]

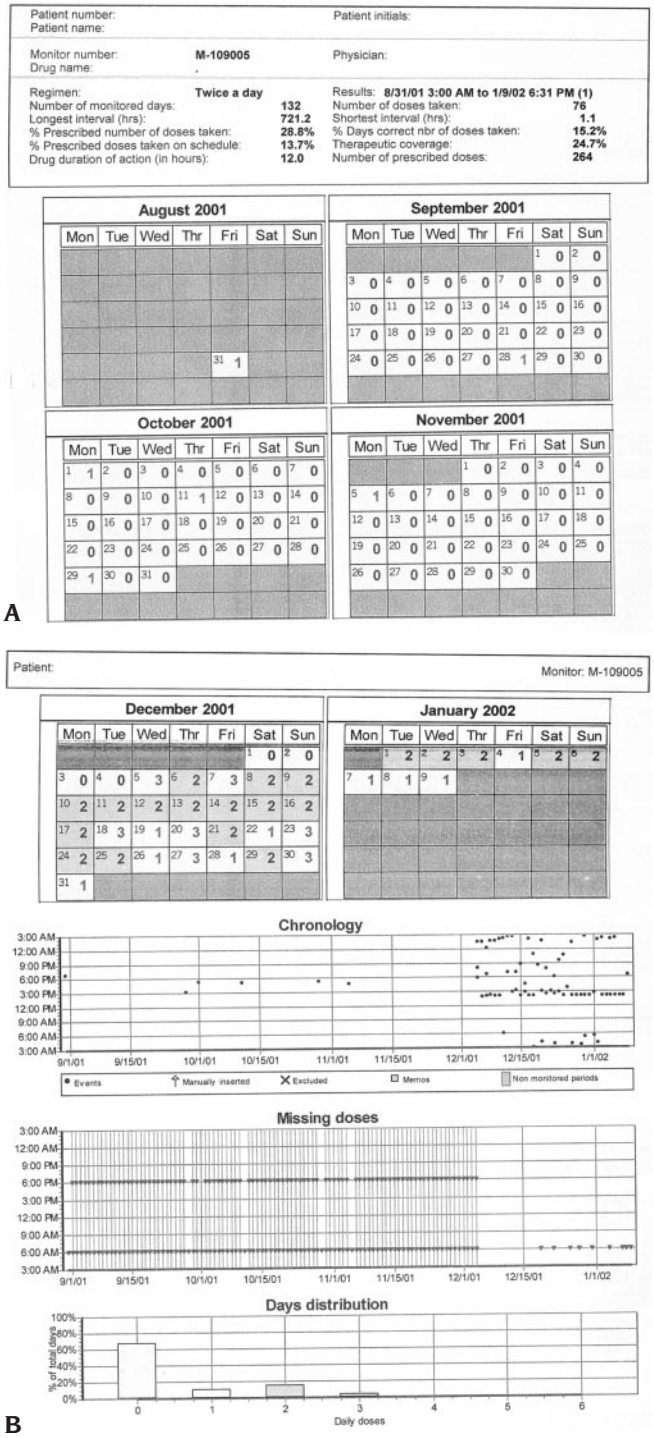

FIGURE 76.7-1 Output data from an electronic monitoring device (MEMS-IV, child resistant, a product of AARDEX/AAPREX). The device was used to monitor adherence to tacrolimus in the patient whose history is presented in the chapter. *A* includes basic patient information (deleted in this case), information about the medication that was used, basic statistics about the number and timing of doses, and data for September through November 2001. Each square represents the number of times the medication bottle was opened on a given day (should be twice a day for this regimen). *B* includes the calendar reports for December and January, the time-scatter (chronology) of the doses that were taken, and a representation of the missing doses. This patient was nonadherent until the beginning of December 2001, at which point she started taking the medications. An intensive psychosocial intervention occurred during the last week of November.

Factors Related to the Patient

Psychopathology, for example, the occurrence of depressive disorders[47–49] and post-traumatic stress disorder,[31,50] was consistently found to be related to nonadherence. A history of child abuse,[18] drug use,[18] reported feeling of "lack of control,"[51–53] and the use of avoidant coping[50,53] have all been implicated in nonadherence.

Social Factors

In young children, it is plausible that any of the above factors that apply to a child's parent will constitute a risk factor for the child's nonadherence (ie, parental psychopathology, depression, etc). A lower socioeconomic status is sometimes implicated as a risk factor.[54–57] A lack of social support (ie, only one parent lives at home or no caretaker lives at home) is also a predictor of nonadherence.[18,50,58]

Factors Related to the Clinic or the Clinician

A lack of empathy on the part of the clinician and a lack of trust between the patient and the clinician have been implicated in patient's nonadherence.[59–60] Lack of appropriate information about a medication is also a plausible reason for nonadherence, but lack of information alone may not be a sufficient cause for nonadherence in many cases.[61] Finally, the characteristics of the clinic itself (ie, time spent with patients, kind of illness that is addressed, awareness of adherence as a therapeutic goal, convenience of clinic hours, gender of clinicians) can be important to the development of adherence behavior in patients.[62]

TREATMENT

Treatment of nonadherence is best conceptualized as a stratified effort. It should begin with preventive efforts that are aimed at every patient and are expected to improve adherence in the clinic or practice as a whole. The preventive effort should also create a mechanism for early identification of nonadherence that needs to be further addressed. Specialized treatment strategies for identified or suspected cases that have not improved by using the general preventive model should then be offered.

Preventive Measures

The hallmarks of this part of an effort to improve adherence are (1) creation of a systematic method to assess patient's adherence as part of the general clinical care (ie, routinely asking about it, routine medication blood level determinations); (2) provision of general and specific education about medication-taking that is repeated frequently and targeted to the developmental stage of the child at the time the education is given; and (3) prospective assessment of risk factors that are known or suspected to be related to nonadherence and addressing these risk factors as they become known and before nonadherence develops.

Specialized Treatments

Nonadherence can be managed in several ways once diagnosed or even when suspected but not confirmed. Available treatment strategies have been grouped below to treatments that focus on patient education and awareness, treatments that focus on the adherence behavior itself, and treatments that seek to improve risk factors that are considered to be the main reason for nonadherence in a particular patient. These specialized treatment strategies are time-consuming and sometimes require a highly skilled individual to deliver it. However, the provision of such care may have a profound impact on adherence and outcome in selected patients.

Patient and Parent Education

It is hoped that education about the illness is provided to all patients, adherent or not, during the routine medical management of their illness. This section addresses a more intensive educational approach intended for confirmed or suspected nonadherent patients. The components of this approach are the assessment of the patient's (and parent's) actual understanding of the prescribed regimen, its administration, and the reasons for it; the correction of any misinformed notions that are discovered; and an open discussion about the ways in which the medication is being taken, how it can be better integrated into a patients' lifestyle, and what concessions or resources are needed to make medication-taking possible. Thus, education in this model is an interactive process in which the clinician tries to identify the cognitive and procedural needs of the patient and address them. Such an approach may also increase the patient's confidence in the clinician and enhance the collaboration between the two. Educational approaches have been shown to have limited but significant effects on adherence.[63,64] Because they are relatively straightforward and not labor intensive, they should be attempted in most cases as a first line of treatment. However, it should be emphasized that education alone is not sufficient in many instances.[61]

Behavioral Modification Strategies

In this model, the adherence behavior itself is addressed. Behavior modification strategies can be used to implement a reward system for adherence (ie, a patient who is suffering from Crohn disease is rewarded with a sticker every day in which he is able to take his medications without being reminded, by an extra hour of play before bedtime on the weekend if all of the week's stickers have been collected). Parents are sometimes reluctant to implement behavioral techniques because they think that the child is suffering so much already and do not want to start being cruel or engage in strict disciplinary action against him/her. A medically ill child, however, frequently must follow very strict nutritional, medication-taking, and scheduling routines, for which a high level of discipline is required. The point to emphasize is that reinforcements are the best way to achieve a behavioral goal. Negative reinforcements or "strict discipline" is not always necessary.

Behavioral methods could also include a change in the frequency in which the patient is seen in the clinic to improve the physician's control on adherence (ie, more frequent assessments of medication metabolites and liver enzyme profiles in a pediatric hepatology clinic). Behav-

ioral methods may sometimes necessitate the involvement of another caretaker or a therapist if the primary caretaker is unable to implement these methods consistently. For example, a school nurse may be enlisted to monitor and implement adherence to medications that are taken during school hours. Behavior modification strategies have been shown to dramatically improve an array of behaviors and have been reported as helpful in improving adherence.[65,66] However, these methods have not been rigorously evaluated in the improvement of adherence in children who are suffering from diseases of the gastrointestinal tract.

Although behavioral methods may well be successful in improving adherence, they require a specifically trained individual who is typically required to serve as a "coach" to patients and parents. This individual may not be readily available in many clinics. Also, the implementation of a successful behavioral plan may be harder to achieve in a context in which a child is chronically ill and a parent is reluctant to be "cruel," as mentioned above. Finally, because strict adherence to the behavioral intervention is required for success, it may at times be hard to implement these methods in patients who are nonadherent to recommendations to begin with.

Strategies Aimed at the Improvement or Elimination of Risk Factors

There are many known or suspected risk factors for nonadherence, as mentioned above. A thorough discussion of methods that may be used to address each of these risks is well beyond the scope of the present review. The main point is that significant risk factors do exist and that these may be highly modifiable.

For example, the treatment of a specific psychiatric disorder such as a major depressive disorder or posttraumatic stress disorder[31,67] may improve adherence. Improvement of social stressors and provision of safety, such as the treatment of ongoing child abuse,[18] may be reasonably expected to improve adherence as well. The identification and management of risk factors related to the child and his/her environment should therefore be attempted. In a child, the assessment of risk should extend at least to the primary caretakers as well.

CONCLUSIONS

Nonadherence to medical recommendations is a significant, and mostly modifiable, risk factor for increased morbidity and poor outcome in many patient groups. The assessment of nonadherence and its management in children are complicated and not well standardized. The child's developmental stage affects adherence behavior, and the target for intervention frequently includes not only the child but also the caretakers. There are no "gold standard" methods for assessment of nonadherence. Yet several objective and subjective methods do exist. The management of nonadherence includes preventive, nonspecific efforts that start with proper patient education and rapid identification of suspected cases and specialized treatment strategies that focus on education, behavior management, and addressing specific risk factors. Knowledge of the methods that are described in this review is expected to give practitioners the initial tools and confidence to deal with nonadherence as an important aspect of patient care.

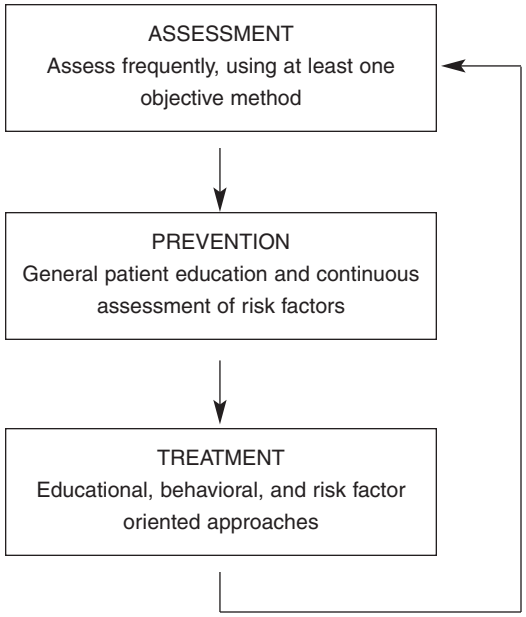

FIGURE 76.7-2 Suggested clinical approach to the management of nonadherence.

The present textbook includes, in most chapters, a discussion of effective and sometimes innovative treatment strategies for children who suffer from gastrointestinal illnesses. These treatments include medications, dietary restrictions, surgical procedures, and other modalities. Although areas of medicine have advanced tremendously in the development of such strategies, these treatments will remain effective in practice only if they are adhered to. Extant data establish that complete adherence is, in fact, very hard to attain in clinical settings. Therefore, adherence should not be assumed. Rather, the attainment of adherence to recommendations must be included as a treatment goal. Figure 76.7-2 summarizes in a concise algorithm the clinical approach that was described in this chapter. Implementation of this approach would ensure a clinical focus on adherence. It could also facilitate research efforts that will provide crucial information about the validity and applicability of assessment and treatment methods that were discussed in this chapter.

CHAPTER 77

MANAGEMENT OF SURGICAL PATIENTS

1. *Complications after Gastrointestinal Surgery*: A *Medical* Perspective

Samuel Nurko, MD, MPH

Advances in pediatric surgery and in postoperative care have allowed the survival of children who were born with complex congenital anomalies. As more children survive and grow older, new long-term medical problems are arising, and new therapies are often needed. The pediatric gastroenterologist has to deal with some of these specific problems, particularly as they relate to the surgical correction of esophageal, hepatobilliary, intestinal, or anorectal malformations.

The purpose of this chapter is to describe some of the long-term medical complications seen in children after surgery in the alimentary tract. The following discussion deals specifically with representative problems after surgical therapy for gastroesophageal reflux (GER), imperforate anus, and Hirschsprung disease. The long-term problems after the correction of other surgical conditions such as tracheoesophageal fistulae and hepatobiliary malformations, as well as the treatment of short gut, are dealt with in other chapters.

SURGERY FOR GER

Antireflux surgery is a successful way to treat intractable GER. Fundoplication is the third most commonly performed general surgical procedure in some institutions,[1,2] and the Nissen operation is the most common type performed (Figure 77.1-1).[3,4] In both children and adults, postoperative results after a Nissen operation are satisfactory in 74 to 94% of patients.[1–3,5–7] Operative mortality is low, usually less than 1%.[2] A substantial late death rate (16–24%) has been reported in some series, but this is usually secondary to the underlying diseases.[1–3,6,7]

Even though many centers report excellent results, it is known that antireflux surgery can have a significant amount of side effects, varying from minor to severe (Tables 77.1-1 and 77.1-2).[2,4,8–10] A recent multicenter retrospective review of 7,467 patients (56% neurologically normal and 44% neurologically abnormal) operated on over 20 years reported that in the neurologically normal children, there was a good to excellent result in 95%, with major complications in 4.2%. These compared with a

Dumping syndrome

reported 84.6% good result in those with neurologic problems and a complication rate of 12.8%. The most common complications reported were recurrent reflux from wrap disruption in 7.1%, respiratory symptoms in 4.4%, gas bloat in 3.6%, and intestinal obstruction in 2.6%. Postoperative deaths occurred in 0.07% of normal versus 0.8% of neurologically abnormal children, whereas the incidence of reoperation was 3.6% in normal and 11.8% in neurologically abnormal patients.[2]

Children with underlying neurologic abnormalities have a higher incidence of complications.[1,2,4,8,11–14] Some authors have suggested that they have more than twice the complication rate, three times the morbidity, and four times the reoperation rate.[4,14] Some authors have attempted to do a direct comparison of the outcome between children with and without neurologic problems. Dedinsky and colleagues reported a large series of 429 fundoplications, of which 297 were done in children who were neurologically impaired.[15] This last group accounted for all 4 postoperative deaths, 24 of 28 wrap herniations, and most of the reoperations. Similar findings were reported by Pearl and colleagues when they compared the outcome in 81 normal children with the outcome in 153 patients who were neurologically impaired.[14] They showed that there was a morbidity of 12% versus 24%, a rate of reoperation for a failed fundoplication in 5% versus 19%, and an aspiration-induced mortality of 1% versus 9%. Because of all of the above findings, it has even been suggested that neurologic status is the major predictive factor of failure of antireflux surgery in children.[14]

Another high-risk population in which the outcome after fundoplication is not as good as that in neurologically normal children is those patients with esophageal atresia repair.[16] It has been reported that only 40% have excellent results and that many require reoperation.[3,4,17,18] The use of partial wraps has therefore been advocated in these patients.[17]

The surgical approach to children who require fundoplication has been changing in recent years with the advent of minimally invasive surgery.[19] The experience with laparoscopic procedures in children has been accumulating in recent years, and the results are similar to those found in adults.[19–26] Laparoscopic surgery has been successful even in small babies (3 kg), children less than 1 year,[24] children with neurologic problems,[22] and children with respiratory disease.[27] There are no prospective studies in children that have compared the open with the laparoscopic technique. There are limited studies in which the laparoscopic technique has been compared with retrospective "open" procedures.[20] Collins and colleagues, in a cohort of 120 children, compared the operative time, complication rate, and hospital stay between children who had a laparoscopic procedure and a retrospective control group who had undergone an open operation.[20] They found a slightly lower complication rate and a significant decrease in hospitalization after laparoscopy. In a large series of 220 patients aged 5 days to 18 years, an intraoperative complication rate of 2.6% and a postoperative complication rate of 7.3%, which included 7 patients with a breakdown of the fundoplication, 5 patients with gagging and retching, 2 patients with gastroparesis, and 4 patients with severe dysphagia, were reported.[19] It is becoming apparent that laparoscopic fundoplication is the procedure of choice in many centers and is slowly becoming the norm.

The most common problems after fundoplication are shown in Table 77.1-1 and are similar independently if the operation is open or performed laparoscopically.[20,21,28] The physiopathology of these symptoms may be multifactorial, and Table 77.1-2 suggests the different mechanisms by which some of the most common symptoms may be produced.

SMALL BOWEL OBSTRUCTION

This is one of the potentially serious complications after fundoplication.[2,3,15,29–31] Ashcraft reported in a recompilation of series with Nissen fundoplication that from a total of 1,319 patients, 43 had small bowel obstruction (3.2%),[29] and of 7,467 patients, Fonkalsrud and colleagues described it in 2.6%.[2] It has been suggested that the incidence of this complication is higher if other procedures are performed at the same time as the fundoplication. In these instances, the incidence has been reported to be as high as 10% compared with an incidence of 1.8% when only a fundoplication is performed.[29,32] This complication needs to be recognized promptly because it can be associated with significant morbidity and mortality. It has been reported that from one-third to one-fifth of patients who develop intestinal

TABLE 77.1-2 COMMON CLINICAL SYMPTOMS AFTER FUNDOPLICATION AND THE POSSIBILITIES THAT NEED TO BE CONSIDERED

VOMITING	DYSPHAGIA	GAS BLOAT	IRRITABILITY
Gastroesophageal reflux	Tight fundoplication	Tight fundoplication	Gastroesophageal reflux
Tight fundoplication	Peptic stricture	Delayed gastric emptying	Wrap herniation
Wrap herniation	Primary motility problem	Impaired gastric accommodation	Dumping syndrome
Small bowel obstruction		Visceral hyperalgesia	Small bowel obstruction
		Small bowel obstruction	Visceral hyperalgesia

obstruction may die if it is not promptly recognized. It can occur in the immediate postoperative period or many years thereafter. This complication has to be suspected when there is abdominal distention and pain, persistent vomiting (if the fundoplication is loose enough), and evidence of obstruction. Sometimes it is difficult to diagnose, particularly in severely impaired patients or when the patient cannot vomit, so there has to be a high index of suspicion. A delay in diagnosis and treatment will inevitably lead to bowel necrosis and death, and the treatment is surgical.

REAPPEARANCE OF GER

The return of symptoms compatible with GER usually indicates that the operation has failed. The incidence of GER can occur in the immediate postoperative period (surgical failure) or much later. The information about surgical failure is limited. In one series of 385 children evaluated by pH probe within 12 weeks postoperatively, GER was documented in 2.9%.[33] Most late cases in which symptoms recur happen in the first 1 to 2 years after the operation,[2,6,31] and it has been reported that in up to one-third of patients, the symptoms of GER become apparent after an episode of forceful emesis.[31] The incidence varies among series. It was described in 7.1% of 7,467 patients[2] and in 29 (12%) of 242 patients.[13]

Caniano and colleagues were able to identify the cause for the appearance of recurrent GER in 86% of children in their series: "slipped" fundoplication in 15, no fundoplication visualized in 2, and paraesophageal hernia in 1.[31] It is not known why wrap disruption occurs, but mental retardation, pulmonary dysfunction, and the presence of a seizure disorder are all risk factors.[13] It is also possible that the surgical technique may also have an influence, with the possibility that an inadequate mobilization of the gastroesophageal junction, fundus, and cardia has occurred, particularly in children with increased intra-abdominal pressure owing to movement disorders, aerophagia, or constipation.[13]

If the patient returns with symptoms that are compatible with reflux, an upper gastrointestinal (UGI) series needs to be obtained (Figure 77.1-2). The presence or absence of the wrap should be determined, and the functional integrity can be grossly examined. If there is evidence of wrap disruption (see Figure 77.1-2B) and of free-flowing reflux, it can be assumed that the fundoplication is not working, and antireflux therapy should be initiated. If it is necessary to judge the state of the esophageal mucosa, an endoscopy can then be performed. If, on the other hand, the UGI seems to show an intact wrap (see Figure 77.1-2A) and no evidence of GER, a pH probe study or an esophageal impedance will actually show the amount of reflux the patient is experiencing and give an assessment of acid clearance. An endoscopic procedure will then show if there has been esophageal damage. There is no need to perform esophageal manometry in these patients. Manometric studies should be performed, however, if a new surgical procedure is being contemplated or if there is the possibility that the patient has a primary esophageal motility disorder.

Once the diagnosis of recurrent GER is made, aggressive medical therapy needs to be instituted,[4,10] and a trial of gastrojejunal feeds may be necessary in those patients at risk of pulmonary complications, particularly in children with severe neurologic problems (see Figure 77.1-2).

If the reflux proves to be refractory, the patient seems to be aspirating, or new complications arise (eg, Barrett esophagus), a reoperation should be considered. In cases in which the main indication of a failed fundoplication and the need for reoperation is the presence of respiratory problems, a full assessment of oral motor function needs to be done because some of the symptoms may be due to inability to handle oral secretions, particularly in neurologically impaired children. The use of jejunal feedings can be used as a therapeutic trial before a reoperation is performed. Also, in those high-risk patients with recurrent GER and aspiration secondary to poor oral-motor function, the long-term use of jejunal feedings may be the best option because the performance of a fundoplication may alter esophageal clearance of saliva and exacerbate the problem. This is particularly important in patients with documented esophageal dysmotility.

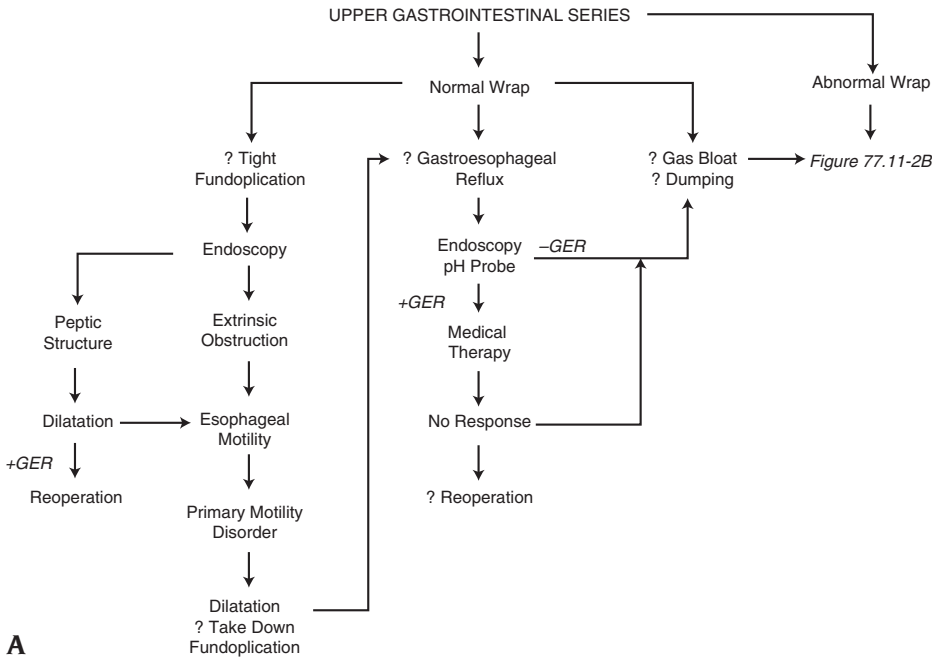
Wheatley and colleagues described their experience in the treatment of 29 patients with recurrent GER after fundoplication.[13] They found that medical management was successful in controlling the symptoms in 11 of 29 (38%) patients. In another study, Caniano and colleagues reported that 21 of 364 (6%) patients who had a fundoplication required a reoperation because of GER recurrence.[31]

DYSPHAGIA

Dysphagia has been the most common problem after the Nissen operation and the symptom most commonly associated with long-term unsatisfactory results.[5,6,34] Some authors have suggested that more than 50% of patients have some degree of solid food dysphagia even after a follow-up of 20 years, but most report an incidence that varies from 0 to 40%.[6,35] The exact incidence of postoperative dysphagia is difficult to establish, but it has been suggested that its prevalence is higher in those children who have undergone a Nissen fundoplication when compared with those who have undergone fundoplications that are considered "more floppy," such as Thal, Toupet, or Rosetti.[36] In the largest pediatric series of 7,467 patients, dysphagia attributed to esophageal obstruction was reported in 2.4%.[2]

The dysphagia may be related to either a wrap that is too tight around an esophagus with good peristaltic function or secondary to a functional obstruction created by the inability of a damaged esophagus to produce enough force to propel the food into the stomach (see Table 77.1-2 and Figure 77.1-2A).

The role that preoperative esophageal peristalsis plays in the development of dysphagia has been controversial.[34,37] It has been suggested that even though there are no prospective data, care should be exercised when a fundoplication is performed in patients with abnormal esophageal peristalsis.[34,37] Low and colleagues reported in a series of patients who underwent secondary operations



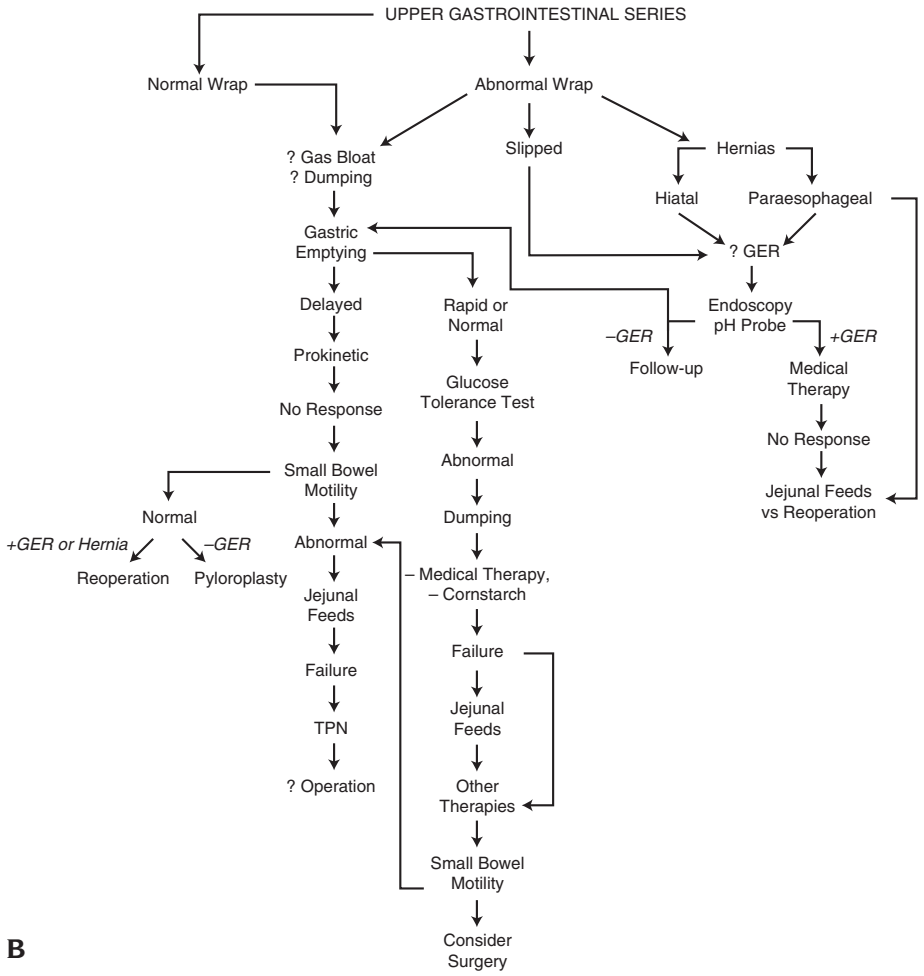


FIGURE 77.1-2 Algorithm for the evaluation and treatment of patients with problems after fundoplication. *A*, An approach in which the upper gastrointestinal series (UGI) has shown the presence of a normal wrap. *B*, This figure focuses on patients in whom the UGI has shown an abnormal wrap. GER = gastroesophageal reflux; TPN = total parenteral nutrition.

for failed Nissen procedures that six patients presenting with severe postoperative dysphagia had evidence of primary esophageal motility disorders (four with collagen vascular diseases and two with achalasia) that were not diagnosed before surgery, [38] indicating the importance of assessing esophageal motility before the operation.[37] In children, this problem is commonly found after patients with scleroderma or tracheoesophageal fistulae have undergone fundoplications.[17] Also, because of the possibility of creating a functional obstruction in a dysmotil esophagus, an esophageal motility test should be performed before the operation in those children in whom esophageal dysfunction is suspected.[37]

The relationship between preoperative esophageal motor abnormalities and postoperative dysphagia has been questioned.[34,39,40] A study after a laparoscopic Nissen operation in 81 adults who had baseline esophageal motility showed no difference in the prevalence of dysphagia up to a year after the operation (12.5% vs 15%) when comparing the 48 patients with normal motility with the 33 patients with abnormal esophageal function.[34] The authors suggested that there was poor correlation between the preoperative manometry and outcome and that abnormal esophageal peristalsis is not a contraindication to performing the operation.[34] Another recent prospective randomized clinical trial of 200 patients randomized either to Nissen (360°) or Toupet fundoplication (270°) studied esophageal motility before and after the surgery. They found that preoperative esophageal dismotility reflected more severe disease but did not affect postoperative clinical outcome. In 85%, the motility remained unchanged because it was not corrected by the fundoplication (independent of the surgical procedure performed). In 20 patients, the motility improved, whereas in 9 patients, it worsened. The authors concluded that preoperative esophageal dysmotility requires no tailoring of the surgical management.[39]

The dysphagia in many cases is transitory[5] but at times can be very severe, leading to significant dietary restrictions. The presence of dysphagia in the immediate postoperative period may be secondary to edema or transient esophageal hypoperistalsis (particularly if the operation is performed through the thoracic approach).[3] The management has to be conservative, allowing time for the edema to subside. However, if the dysphagia persists or is severe, it may be necessary to consider that the operation is too tight, and further evaluation will be necessary.

The best way to investigate patients with dysphagia is to perform a barium study to fully assess the anatomy (see Figure 77.1-2A). This study will help delineate the wrap and assess if there is obstruction. It can also detect the presence of peptic strictures. A better functional assessment of emptying can be performed with esophageal scintigraphy and can be a useful way to follow patients if dilatations are performed. An esophageal motility should be performed in cases with severe symptoms. This allows the definition of lower esophageal pressure and identifies the presence or lack of peristalsis. Endoscopy may be useful to assess if there is fibrosis or other complications from GER (eg, peptic stricture, esophagitis, Barrett adenocarcinoma). If there is evidence of poor emptying and primary motility disorders, attempts to lower the functional obstruction should be undertaken. If the motility is normal, dilatation should be attempted, and if dilatation is necessary soon after the operation, great caution needs to be exerted because it has been shown that if done forcefully, it can lead to disruption of the repair.[35] The results after endoscopic dilatation in adults have been satisfactory.[35] In a series of 35 patients, dysphagia resolved in 52%, and there were no disruptions of the fundoplictions or GER. The results varied according to the radiologic appearance of the fundoplication. In those patients with a slipped operation, endoscopy relieved the dysphagia in only 27%, as opposed to 67% of those with intact fundoplication.[35] If symptoms persist after dilatation or the patient has other symptoms associated with a tight wrap (such as gas bloat), a revision of the surgery may be necessary. In general, this is not very common. Spitz and colleagues reported that only 1.2% of patients required a reoperation because of dysphagia.[12]

GAS BLOAT SYNDROME

Gas bloat syndrome is characterized by distention, inability to vomit, abdominal pain, and, in children, severe retching, gagging, and irritability.[11] Its duration is variable, but it can last for many hours and be severe enough for patients to seek medical attention. Many long-term studies of patients who have undergone Nissen fundoplication have reported that gas bloat syndrome can occur from 2.8%[3] to 50%[6] of cases. The exact incidence of this problem is difficult to assess, particularly because some surgeons routinely add a decompression gastrostomy at the time of the operation.[29] In one study of 106 patients, 2 required the placement of a late gastrostomy because of this problem,[41] and Fonkalsrud and colleagues reported that even though they routinely use a gastrostomy in children less than 3 years, gas bloat still developed in 12 patients following removal of the tube.[42] The problem with gastric distention cannot be minimized because it has been reported that death can occur secondary to gastric necrosis.[43] In their report of 7,467 patients, Fonkalsrud and colleagues reported gas bloat syndrome in 3.6% (2–10%) and suggested that the incidence was higher in those centers in which the gastric emptying procedure was rarely used.[2]

The physiopathology is not well characterized.[6] Patients who develop the syndrome tend to have GER associated with activation of the emetic reflex (pallor, sweating, retching, and forceful vomiting).[11] Most likely it is related to the presence of an increased amount of gastric air,[44] compounded by an inability to vomit or belch, impaired gastric accommodation,[5,45] gastric hypersensitivity,[5] and slow gastric emptying.[3,5,6]

It has been shown that many children with gas bloat syndrome have delayed gastric emptying (see Figure 77.1-2B).[3] In a retrospective review of fundoplications performed in 92 patients with delayed gastric emptying, the authors compared the outcome between those who also had a gastric emptying procedure and those who did not. They showed a higher incidence of recurrent reflux in

those without a gastric emptying procedure (35 vs 18%).[46] Because of the possibility of this association, the performance of a pyloroplasty in conjunction with a fundoplication has been suggested when delayed gastric emptying is found preoperatively.[3,13,47]

It has also been shown that fundoplication may induce gastric myoelectrical disturbances that may correlate with the development of retching.[48] In one study, the authors showed that children who retch preoperatively were three times more likely to retch after the operation and that 25% of neurologically impaired children may start to retch after the operation. Sixty percent of neurologically impaired children had gastric dysrhythmias before the operation compared with 20% of neurologically normal children. These findings suggest a loss of central inhibitory mechanisms that may result in the inappropriate activation of the emetic reflex, which may be heightened by antireflux surgery.[48]

The role that small bowel motility plays in the development of this symptom is also not clear. In one study, 25 of 28 symptomatic children after fundoplication had abnormalities in antroduodenal motility. The most common abnormality found was an absence of the migrating motor complex in 12 children, whereas 6 children had postprandial hypomotility; other nonspecific abnormalities included clustered, retrograde, and tonic contractions.[49] It is unclear if the abnormalities were present before the operation or are a result of it, although the authors suggested that because the abnormalities found were similar to those seen in chronic intestinal pseudo-obstruction, it is likely that they predated the operation, suggesting that those children had a more generalized gastrointestinal dysfunction and not only GER. In that case, the performance of a fundoplication, with the elimination of the ability to vomit, could be expected to worsen symptoms such as retching and abdominal distention. This observation needs to be taken into account when the performance of a fundoplication is being considered in children with generalized symptoms of gastrointestinal dysfunction, and an antroduodenal motility may be a useful test to perform in those cases before the operation to exclude the possibility of pseudo-obstruction.

Recently, it has been suggested that gastric hypersensitivy may also play a role. Studies using the Barostat technique have documented that adult patients after fundoplication may have a lower threshold for postprandial discomfort and abnormal gastric postprandial relaxation.[5,50] This represents an emerging field of study, and treatments to decrease the hyperalgesia may be needed.

The medical therapy for gas bloat syndrome has included the use of motility and simethicone-containing agents. Cisapride has been used with success, particularly in children with delayed gastric emptying. Attempts to decrease air swallowing should be undertaken, and the status of vagal function can be determined by using sham feeding or Congo red testing. The tests have been found to be useful in adults, but no information is available in children.[6]

The inability to vomit and belch is rarely incapacitating enough to require another operation. At times, it may be necessary to perform a temporary gastrostomy.[3] It has been reported that the symptoms disappear if the fundoplication is undone, although if the patient has underlying dysmotility or there was vagal nerve damage, they may persist after reoperation.[29] If there is evidence of delayed gastric emptying, it is possible to consider the performance of a pyloroplasty[3,42] without taking down the fundoplication (see Figure 77.1-2B).

Treatments to decrease the gastric hyperalgesia and improve gastric accommodation may be beneficial.[5] Because 5-hydroxytryptamine $(HT)_1$ receptors may be involved in gastric accommodation,[51] the use of 5-HT_1 agonists may be attempted. Cyproheptadine may be tried. In adults, 5-HT_{1D} agonists such as sumatriptan or 5-HT_{1DA} agonists such as buspirone have been attempted with some success in patients with dyspepsia as a way to increase postprandial fundic relaxation.[5,51,52] The visceral hyperalgesia may also be treated with medications such as anticholinergic agents.[5] Because tricyclic antidepressants such as amitriptyline have been shown to be useful in the treatment of the visceral hyperalgesia that can be seen in functional bowel disorders in adults,[5,53] they may be useful in children with severe hyperalgesia postfundoplication.[5] Future studies with new medications that change the threshold of sensation, such as 5-HT_3 antagonists or 5-HT_4 agonists, will be conducted in the coming years and will determine if these medications will be useful in the treatment of these children.[5]

HERNIAS AND OTHER PROBLEMS WITH THE FUNDOPLICATION

Herniation of the fundoplication is another common complication, and it represents the most common indication for late reoperation. Spitz and colleagues described their findings during reoperation of those patients in whom the initial operation failed and found that the most frequent finding in 25 patients (14%) was a prolapse of the wrap into the posterior mediastinum through an enlarged hiatus with or without a paraesophageal hernia.[12] In only two patients, the wrap was too tight, and in only two patients, the wrap was partially disrupted, leading to recurrent reflux. There are two principal types of herniation distinguished by the localization of the gastroesophageal junction.[54] In the first type, there is herniation of the entire wrap and gastroesophageal junction into the chest,[54] usually presenting as recurrent GER, and in the second or paraesophageal type, there is a posterolateral herniation of a portion of the wrap, with the gastroesophageal junction remaining within the abdomen (see Figure 77.1-2B). This latter type seems not to be associated with reflux but has the risk of incarceration/strangulation or bleeding.[30]

It can be argued that the herniation of the entire wrap usually indicates a failure of the surgery. Some studies, however, have shown that not all patients with this problem have recurrent symptoms of reflux.[6] If this type of hernia is found, the patient needs to be worked up for GER, and the presence of other symptoms should be ascertained (see Figure 77.1-2B). In the absence of any significant symptoms or of pathologic reflux, its presence is probably

not important, but if significant problems are associated with its presence, a new operation may be necessary.

The significance of a paraesophageal hernia is more important. It is more common,[14] it is the primary reason for reoperation in some series,[3,14,30] and its appearance seems to be related to a failure to perform an adequate crural repair.[13,30,54] Pearl and colleagues reported after doing a recompilation of 2,142 cases postfundoplication that a wrap herniation occurred in 117 cases (18.3%) and accounted for 63% of reoperations.[14] Fonskalrud and colleagues reported that 11 (2.6%) of their patients developed this complication and that all required surgical correction.[42] It has also been reported that in neurologically impaired children, herniation occurred in 38%[14] and that the incidence of wrap breakdown/paraesophageal hernia and small bowel obstruction after Nissen fundoplication in this group of children is disturbingly high.[1,14]

The paraesophageal hernias usually increase over time and can produce symptoms, which may include GER, dysphagia, chest pain, bleeding from the hernia sac, or even ischemia of the gastric segment involving the hernia.[1,14] In smaller children or children with severe neurologic impairment, the only manifestation may be severe irritability. The demonstration of these hernias is done with the performance of a UGI (see Figure 77.1-2B). This test allows the visualization of any obstruction to esophageal emptying and will help delineate gastric anatomy; the presence, status, and location of the fundoplication; and any other gastric problem. Endoscopy may help evaluate the state of the herniated gastric mucosa and if there is ischemic damage.

The treatment of paraesophageal hernias has to be tailored to the individual patient (see Figure 77.1-2B). If there is evidence of recurrence of GER, aggressive medical therapy needs to be started, but if the associated symptoms are severe or there is evidence of inflammation or bleeding in the herniated segment, a reoperation needs to be performed. If the hernia is small and the patient is asymptomatic, conservative management with close follow-up should be undertaken.

FISTULA FORMATION

The performance of a Nissen fundoplication has been associated with the occurrence of fistula formation. The fistulae usually occur between the fundic wrap and other abdominal and mediastinal structures. Gastrodiaphragmatic, gastroaortic, gastrobronchial, gastrocardiac, and gastrocutaneous fistulae have been described.[14,55] The clinical presentation varies depending on the localization of the fistula, but it may be life-threatening when it involves the great vessels. When these are diagnosed, they need to be surgically treated.

DUMPING SYNDROME

Dumping syndrome refers to the symptom complex that results from the rapid transit of food into the small bowel[56–60] and is one of the most common causes of morbidity after gastric surgery.[61] It has been estimated that between 25 and 50% of all patients who have undergone some type of gastric surgery have some symptoms of dumping, although only 1 to 5% have serious disabling symptoms.[58,61] In children, dumping has been described almost exclusively as a postoperative complication of Nissen fundoplication, but the exact incidence is not known.[2,56,57,59–66] In the article by Fonskalrud and colleagues, they described a postoperative transient dumping syndrome in 0.9% of 7,467 fundoplications (0–5%).[2] In a study of 50 patients, Samuk and colleagues reported dumping in 30% (15 patients).[59]

The syndrome is characterized by both gastrointestinal and vasomotor complaints (see Table 77.1-2). Gastrointestinal symptoms include postprandial fullness, crampy abdominal pain, nausea, vomiting, and explosive diarrhea. In younger children, aversion to food, failure to thrive, and retching may be part of the clinical picture.[56,57,60,62] Vasomotor symptoms include diaphoresis, weakness, dizziness, flushing, palpitation, and a desire to lie down. In infants and children, the typical symptoms appear during or after feeding and include irritability, pallor, perspiration, tachycardia, lethargy, diarrhea, and vomiting.

Dumping has been classified into early and late forms based on the timing of onset of symptoms after a meal.[56,57,61] The early symptoms occur soon after eating (10–30 minutes) and can be a mixture of both gastrointestinal and vasomotor complaints. These include abdominal distention and discomfort, nausea, borborygmus, tachycardia, pallor, diaphoresis, somnolence, and, occasionally, syncope.[56–58] The late symptoms, in contrast, are mainly vasomotor and occur from 2 to 3 hours after eating. These include diaphoresis, weakness, dizziness, flushing, palpitations, and, usually, hypoglycemia.[56–58,60,61]

The pathophysiology of dumping syndrome is multifactorial. It seems to be related to alterations in gastric emptying, and its incidence and severity appear to be proportional to the rate of emptying.[56–58,60,61] The symptoms of early dumping are usually produced by the rapid emptying of hyperosmolar chyme into the small bowel. The osmotic effects of these foodstuffs drag large quantities of fluid from the intravascular space into the bowel, resulting in rapid small bowel distention and an increase in both the amplitude and the frequency of bowel contractions.[56,57,60,61] This bowel distention may be responsible for the gastrointestinal symptoms, such as diarrhea, bloating, and crampy abdominal pain. This sequestration of fluid into the bowel depletes circulating blood volume[60,61] and may be responsible for the vasomotor symptoms. The postprandial release of gut hormones is also enhanced,[56–58,60] and the release of enteroglucagon, glucose-dependent insulinotropic peptide, pancreatide polypeptide, vasoactive intestinal polypeptide, gastrin-releasing peptide, serotonin, bradykinin, motilin, and neurotensin is higher in patients with dumping syndrome than in asymptomatic patients after gastric surgery.[61]

Late dumping symptoms seem to be related to the development of hypoglycemia.[56–58,60,62] It has been suggested that the rapid gastric emptying results in the delivery of unusually high concentrations of carbohydrates to the small bowel, leading to hyperglycemia and to an exuberant post-

prandial insulin release.[58,60] This insulin release results in late hypoglycemia, which leads to vasomotor symptoms.[58,61] The hypoglycemia may persist after the disappearance of the circulating insulin, suggesting that the counterregulatory response to low blood sugar may also be inadequate.[56–58,60]

The reactive hypoglycemia that is observed is probably related to a continuing cellular glucose uptake after insulin has been cleared from the circulation.[58,60] Once the hypoglycemia has developed, spontaneous corrections do not generally occur, particularly in children.[58] Rivkees and Crawford showed that the glucagon levels did not increase in response to hypoglycemia during challenge tests, and their data suggest that the counterregulation was disturbed primarily because of the blunted response of glucagon.[58] This lack of glucagon response may be related to the release of other incretin hormones, such as glucagon-like peptide, which has been shown to be elevated in patients with dumping syndrome. The reactive hypoglycemia may also be related to the ingestion of other dietary components, such as protein.[60]

As can be appreciated, the symptoms of dumping syndrome are nonspecific. The diagnosis has to be suspected in patients who have had a Nissen fundoplication and present with any of the gastrointestinal or vasomotor complaints mentioned above (see Table 77.1-2). The possibility of late hypoglycemia has to be considered, and direct questions about the presence of diaphoresis, irritability, or lethargy need to be asked. In those patients who have a G tube, its position needs to be determined because if the tube has migrated into the duodenum, the patient may present with a dumping-like picture that is related to the administration of the feeds directly into the duodenum.[60] Because of the nonspecific nature of the symptoms, and particularly because dumping can present like other complications mentioned in this chapter, the workup has to include a UGI to evaluate the anatomy and the status of the fundoplication, as well as to establish if a pyloroplasty was performed (see Figure 77.1-2B). The measurement of gastric emptying is very useful.[56] A gastric emptying scan will show a rapid gastric emptying time, although it is worth mentioning that it may be normal if the test meal is of insufficient volume to reproduce the patient's symptoms.[56,59,67]

The measurement of serum glucose in the first hour after meals will usually reveal the presence of hyperglycemia and serves as a good screening measurement. The presence of late hypoglycemia is also an indicator that the patient may be suffering from "late dumping." The diagnosis can be made accurately by using a glucose tolerance test (see Figure 77.1-2B).[56–60,62] Ideally, it can be combined with simultaneous measurements of insulin, so the presence of the hypoglycemia can then be correlated to the insulin levels.

Once the diagnosis has been made, treatment needs to be instituted. Dietary manipulation is the mainstay of therapy and the most effective way to control the symptoms and avoid the late hypoglycemia.[56] When the symptoms are not very severe, it is recommended that the patients eat small frequent "dry" meals and avoid simple sugars. It has also been suggested to add fiber and to increase complex carbohydrates (such as raw vegetables), dietary proteins (such as fish and chicken), and fat (to gain more calories and to decrease gastric emptying).[56,57,59–62] In children, particularly those with neurologic problems and an inability to eat complex meals and those who are fed mainly liquid diets through a gastrostomy tube, the dietary therapy is much more complicated.[60,62] Attempts to reduce the volume of the feeding, either by continuous infusion or by more frequent feedings, should be done first and can be successful in some patients.[58,60] At times, it is necessary to change the feeding regimen and give the infusions over 24 hours because the dumping may reappear if the feeding volume is increased to give only nightly feedings. Taking into account the proposed physiopathology for the occurrence of the delayed hypoglycemia, attempts to reduce the hyperinsulinism have been undertaken.[60] This has been successfully done with the use of formulas with added uncooked cornstarch, which permits the delivery of small amounts of glucose at a steady rate over a long period of time.[60,62,65] Gitzelmann and Hirsig compared the effects of the administration of a formula with cooked or uncooked starch in two infants with dumping and showed that only the uncooked starch controlled the late hypoglycemia and dumping syndrome.[65] Usually, the formula used has to contain the lowest amount of refined carbohydrate, and the uncooked corn starch is added to provide the equivalent to hepatic glucose production,[68] the same way it is added in patients with glycogen storage disease. The use of uncooked cornstarch usually allows the patient to be bolus fed, avoiding the initial hyperglycemia and the delayed hypoglycemia.[60,62,65,69] Other dietary additives, such as pectin, guar gum, and glucomannan, have also been tried.[60,61]

In an effort to reduce late hypoglycemia, acarbose, an α-glucosidase inhibitor, has been used.[57,70] Acarbose delays the conversion of oligosaccharides to monosaccharides and attenuates postprandial increases in blood glucose.[57,70] Ng and colleagues reported on the successful use of acarbose for the treatment of hypoglycemia.[57] They reported six children in whom acarbose was started at 12.5 mg and increased upward until hypoglycemia was controlled. The final dose ranged from 12.5 to 50 mg per feeding. The only side effect was flatulence, but other side effects can include diarrhea and abdominal distention.[57] It is recommended that if acarbose will be used, liver function tests need to be monitored because there have been reports of elevated enzymes during its administration.[57]

Because the physiopathology of dumping is multifactorial, it would be simplistic to think that if one deals only with the glucose homeostasis problems, most of the symptoms, particularly of early dumping, will be controlled. These are probably more related to the duodenal distention and to the gut hormone production mentioned above. Recently, octreotide acetate (Sandoz, East Hanover, NJ), a long-acting somatostatin analogue, has been used with some success in adults with severe dumping syndrome.[61,71] It probably acts by slowing gastric emptying, inhibiting insulin release, and decreasing enteric peptide secretion.[61,71] Several anecdotal reports and four controlled randomized trials have documented the short-term

efficacy of octreotide treatment in patients with severe dumping syndrome.[61,71] In general, octreotide improves the symptoms in more than 90% of patients with severe symptoms. In all studies, the acute administration significantly reduced the symptoms and the scores, but it is unclear if the chronic administration will prove to be as beneficial as the acute therapy. No pediatric experience is available in dumping syndrome, but octreotide has been safely used for the treatment of other pediatric conditions, particularly gastrointestinal bleeding.[72]

If the symptoms are severe and intractable, a surgical option may be considered. Many different options have been designed, including procedures to decrease gastric emptying, such as a reconstruction of the pyloroplasty, or if the patient has had a gastroenteroanastomosis, a reduction of the size of the stoma.

REOPERATION FOR FAILED PRIMARY ANTIREFLUX REPAIRS

The selection of patients who need further surgical therapy remains a challenging problem.[2,6,46] Reoperative antireflux surgery is complicated and difficult and should be preceded by a complete investigation to ensure that symptom interpretation is correct and that no other coexistent abnormality in gastric emptying or antroduodenal or esophageal motility exists (see Figure 77.1-2). Preoperative investigation should include UGI, endoscopy, gastric emptying analysis, 24-hour pH probe, and esophageal motility. If a more diffuse motility problem is suspected, an antroduodenal motility test should also be performed, and a glucose tolerance test should be undertaken if dumping is a possibility. An assessment of oral pharyngeal coordination and the ability to swallow needs to be done, and a trial of jejunal feeds should be initiated when it is not clear if the symptoms are related only to GER or also to an inability to handle oral secretions. Frequently, it is beneficial to use jejunal feedings while the patient is being evaluated, and in some children, the use of gastrojejunal tubes may be a good long-term option.[46] Different authors have reported that a second operation is required from 1.6 to 12% in children without other underlying problems,[13,31,46,73] although in neurologically impaired children, the incidence of reoperation has been as high as 16%.[31,73] In a series of 7,467 children, Fonkalsrud and colleagues reported a reoperation rate in 3.6% (2–10%) of neurologically normal children and 11.8% (6–24%) in those with neurologic impairment.[2]

The results of a second operation will also vary depending on the underlying problem. Studies have shown that the increase in preoperative complications, including complete vagotomy, is significantly increased during the second procedure.[38] In children, the incidence of postoperative complications after reoperation also seems to be higher. Caniano and colleagues reported that a second operation was associated with a 14% incidence of intraoperative complications and a 43% incidence of postoperative morbidity.[31] The main complications were prolonged ileus, pneumonia, small bowel obstruction (19%), wound infection, and pneumothorax, and intraoperative blood loss was substantially higher. Most authors report that for children who have undergone a second operation, the results have also been satisfactory from 70 to 80%.[2,13]

EVALUATION OF PATIENTS WITH PROBLEMS AFTER A FUNDOPLICATION

Table 77.1-2 presents the different possibilities that the clinician needs to entertain when confronted with a patient who has problems after fundoplication. Figure 77.1-2 shows an algorithm for the evaluation and treatment of children who present with complications after fundoplication.

Briefly, after a careful analysis of the symptoms, the workup can start with the performance of a UGI. As shown in Figure 77.1-2A, if there is evidence that the wrap is too tight and that there may be a functional obstruction to esophageal emptying, an endoscopy should be performed to see if there is a peptic stricture or an extrinsic compression. If there is no evidence of stricture, an esophageal motility should be performed to assess the possibility of a primary motility disorder. If after the UGI the wrap is intact and there does not seem to be a functional obstruction, the workup needs to proceed, depending on the main symptoms. If the symptoms are mainly those compatible with recurrence of GER, an endoscopy and pH probe or esophageal impedance should be performed (see Figure 77.1-2A). If, on the other hand, the main symptoms are related to gas bloat or possible dumping, gastric emptying should be performed first (see Figure 77.1-2B).

As shown in the algorithm, if there is evidence of GER, medical therapy should be undertaken, and if there is no response, a new operation should be considered. On the other hand, when evaluating for gas bloat (see Figure 77.1-2B), if the gastric emptying is delayed, a prokinetic agent should be tried. If there is no response, a pyloroplasty can be considered, but a small bowel motility study should be performed first to exclude the presence of pseudo-obstruction. If there is evidence of rapid emptying, the most likely diagnosis is dumping syndrome, and a glucose tolerance test should be done (see Figure 77.1-2B).

As can be appreciated in Figure 77.1-2B, if after the UGI there is evidence that the wrap has either slipped or there is evidence of a hernia, further evaluation for GER or the presence of complications should be undertaken, and if there is evidence of recurrence, bleeding, or mucosal compromise, a reoperation should be performed. In all cases, the administration of jejunal feedings needs to be carefully considered as an alternative to a reoperation, particularly in those children with severe esophageal dysmotility, high surgical risk, or chronic aspiration of their own oral secretions.

HIRSCHSPRUNG DISEASE

Hirschsprung disease is a congenital illness in which varying degrees of aganglionosis occur in distal segments of the intestinal tract.[74] Because these abnormal segments are unable to relax during peristalsis, they are spastic and pro-

duce mechanical obstruction.[75–77] The treatment of Hirschsprung disease is surgical.[78–81] The basic principle for definitive surgical therapy is resection of the aganglionic segment followed by a pull-through of ganglionic bowel down to the anus.[75,82] Surgery for Hirschsprung disease generally results in a satisfactory outcome,[79,82,83] and it has been suggested that the outcome after each commonly performed procedure is comparable.[79,82,83] There are, however, some patients who continue to have long-term difficulties (Table 77.1-3). Some studies have suggested that the prevalence of problems is much higher than previously anticipated.[84–87] The most common symptoms are diarrhea, constipation, and, sometimes, intermittent colitis (see Table 77.1-3).[84,87–89]

The most commonly used operations include the Swenson (rectosigmoidectomy), Duhamel (retrorectal transanal pull-through), and Soave (endorectal pull-through) (Figure 77.1-3). In the Swenson pull-through (rectosigmoidectomy), the rectum is removed and the normal ganglionic bowel is anastomosed to a 1 to 2 cm rectal cuff.[76,90,91] It requires a combined abdominoperineal approach, is probably the most difficult, and requires extensive pelvic dissection, so injury to the sacral innervation of the bladder and ejaculatory mechanisms is possible (see Figure 77.1-3). In the Duhamel (retrorectal transanal pull-through) procedure, the aganglionic rectum is left in place, and normal ganglionic bowel is pulled down behind the rectum and through an incision in the posterior rectal wall at the level of the internal sphincter.[92–94] The original Duhamel procedure was an anastomosis of the ganglionated proximal bowel to the closed native rectum at the anal verge. Dilatation of the defunctioned rectum by fecal retention in the blind loop led to the Martin modification, which added a proximal suture anastomosis of anterior native rectum to the pulled-through colon, following which the septum was crushed by a spur clamp.[82] A rectum of expanded size with an anterior aganglionic wall and a posterior ganglionic wall is therefore created.[82] This operation eliminates the need for much of the pelvic dissection needed in the Swenson procedure (see Figure 77.1-3).[94] The endorectal pull-through, as originally described by Soave and modified by Bole, is the third alternative.[82] In the modified Soave procedure, there is no need to do any pelvic dissection. In this procedure, the mucosal lining of the rectum is removed, the ganglionic colon is pulled through the rectal muscular tube, and a primary anastomosis is done within 1 cm of the anal verge (see Figure 77.1-3).[82,95,96] The modified Soave procedure is easy to perform, and with it there is no need to do any pelvic dissection.

The outcome after these procedures is similar. It is difficult to compare the results obtained with the different operations because they have usually been done by different surgeons, in different institutions, and at different times, and it is possible that the incidence of complications after the different procedures is closely related to the skill of the individual surgeon.[89] There are some reports in which the experience with individual operations performed by the same surgeon have been reported, and these are useful to obtain an idea of the type of long-term complications that

can be seen with them. In a large multicenter report of 880 Swenson procedures that spanned four decades, it was reported that there was a 1% mortality, with a 6% incidence of an anastomotic leak and a late incidence of strictures of 8%.[97] Soiling was significant in 13%, and in 39%, enterocolitis was observed, leading to a 7% incidence of secondary sphincterotomies. They reported that 20 years after the operation, 90% had satisfactory bowel function.

There are several studies that describe the long-term results after Duhamel.[98–99] Ehrenpreis and colleagues reported their long-term experience after the Duhamel procedure.[98,99] The overall mortality rate in 352 operations was 2.8%, of which the late mortality was 1.1%. The most common postoperative complication was fecaloma formation, particularly in the early periods after the operation. In their first follow-up report, they found a fecaloma in 9 of 30 patients and fecal incontinence in 12 of 30 patients.[98] On long-term follow-up, however, 15 years later, fecaloma formation was not a significant problem (1/10), and fecal incontinence had decreased to 2 of 30 patients.[74] These findings suggest that over time, patients who undergo the Duhamel procedure tend to improve. In a recent long-term study, 91 children post–Duhamel procedure were compared with 22 healthy children. Outcome scores were significantly worse in the Hirschsprung disease group, and only 42% of patients overall and 79% of those above 14 years had a satisfactory outcome.[100] Some have suggested that the Duhamel procedure is associated with less risk of overall complications but may have a greater risk for postoperative enterocolitis.[92]

Tariq and colleagues described their long-term experience after the Soave procedure.[96] They described the follow-up of 53 survivors, and 18% had diarrhea with intermittent incontinence and 9.4% required a second pull-through, in this case a Duhamel procedure. Other series have described that up to 22% of the patients suffered from constipation at 3 years, with 18% with diarrhea and incontinence, although 82% had a satisfactory result.[101] After endorectal pull-through, it has also been reported that anastomotic stenosis occurs with an incidence that varies from 9 to 24%[96,101,102] and that even after dilatation, a mild residual stricture persists in 3%.[101]

As can be appreciated, it is difficult to directly compare the results of various operations. There are few truly comparative studies. Probably the largest compilation of patients, 1,196 children, and comparison between treatments were reported by Kleinhaus and colleagues.[89] They obtained information in an extensive survey of the members of the surgical section of the American Academy of Pediatrics. They reported results in 390 patients after the Swenson procedure, 339 patients after the Duhamel procedure, and 187 patients after the modified Soave procedure. Complications after the procedures included a disrupted anastomosis in 11.2% after the Swenson, 2.4% after the Duhamel, and 5.8% after the Soave procedure. This carried a mortality of 11% after the Swenson procedure, and 27% of patients with disrupted anastomosis after the Swenson procedure required a major surgical procedure. Anal stenosis was mild (requiring only dilatation) in 5.2% after the Swenson, 2.9% after the Duhamel, and 5.2% after the Soave procedure and severe (requiring reoperation) in 4.3%, 2.6%, and 4.2%, respectively. After the Swenson procedure, there was a 15.6% incidence of postoperative enterocolitis and 3.2% of incontinence compared with 5.9% and 1.1% after the Duhamel procedure and 2.1% and 1.1% after the Soave procedure.

Most studies report short-term follow-up, and there are few long-term studies. Long-term survival is excellent, although sudden death from enterocolitis may occur years after successful surgical reconstruction.[103,104] Most series describe an overall good outcome in more than 90% of the patients, but many recent studies have shown a higher than anticipated incidence of problems, particularly persistent obstruction, fecal incontinence, or enterocolitis (see Table 77.1-3),[75,79,84,105] and they seem to indicate that any operation is associated with long-term morbidity.[100,106,107] In a series that followed patients from 1 to 30 years, Mishalany and Wooley reported the follow-up of 62 patients, of whom 14 had a Duhamel, 15 a Swenson, and 33 a Soave pull-through.[88] Approximately 23 to 50% felt that they had normal bowel movements, and the rest had various degrees of problems in defecation. Subjectively, half of the patients in the Duhamel and Soave groups and one-third in the Swenson group considered their stooling pattern normal. Of the whole group, 18 had one bowel movement per day, 15 had one every other or more days, and 29 had an increased frequency ranging from 2 to 7 per day. In 20 patients, there was evidence of postoperative enterocolitis, regardless of the type of operation (3 after the Duhamel, 7 after the Swenson, and 11 after the Soave procedure). Another study of the long-term quality of life in 178 patients showed that 76% had between one and five stools a day and 58% had normal stool consistency.[79] Full fecal continence was present in 75%, whereas 19% had minor degrees of leakage, and the rest had severe problems. The degree of stool control improved with age. Whereas 52% were fully continent below 4 years of age, 87.5% between age 9 and 12 years had full control. Neurologic impairment and length of the agangliotic segment beyond the rectosigmoid appeared to influence functional outcome. Enterocolitis was present in 16% at presentation and in 6% postoperatively. The long-term functional results were comparable for the Soave and Duhamel procedures, but children after the Swenson procedure had less favorable results. Growth was similar to the normal population, although younger patients had a tendency to be smaller. Delayed developmental milestones were present in 8%. Satisfactory school performance was achieved in 74%. Ninety-four percent of the patients appeared to be well adjusted, and five patients had severe behavioral problems. After the Soave procedure, there was a lower incidence of constipation, sexual dysfunction, and micturition problems. Duhamel patients tended to have more constipation, whereas the Swenson procedure was associated with more abdominal distention, micturition problems, and cuff strictures.

In another long-term study of 19 adolescents, it was found that 32% had significant impairment of continence

but no more psychopathology or psychosocial dysfunction when compared with healthy controls. Fecal incontinence was associated with poorer psychosocial functioning and parental criticism, and psychosocial functioning was significantly correlated with the degree of fecal incontinence.[106] Another long-term follow-up of 45 patients after the Swenson procedure showed that 51.1% had bowel dysfunction, with 37.8% suffering from fecal soiling. Because of poor fecal continence, 55.7% had to restrict their foods, 13.3% had school absence, and 15.6% had problems with peer relationships.[84]

COMMON PROBLEMS FOUND AFTER SURGICAL TREATMENT FOR HIRSCHSPRUNG DISEASE

Obstructive Symptoms

From the postoperative symptoms that can be found in children who have undergone surgical treatment for Hirschsprung disease, the presence of recurrent obstruction is one of the most common and difficult to manage (see Table 77.1-3).[75] Obstructive symptoms may be related either to an anatomic problem that is producing an obstruction[108] or to functional alterations (Figure 77.1-4).[79,109]

The most common anatomic problem that can be encountered is the presence of anal stenosis.[79,89] This complication seems to be more common after Soave pull-through and can usually be managed only with a dilatation program, although a secondary surgical procedure may be necessary.[89] Kleinhaus and colleagues reported that anal stenosis occurred in 5.2% after the Swenson procedure, 2.9% after the Duhamel procedure, and 19% after the Soave procedure.[89] The incidence of reoperation because of the presence of stenosis also varied between techniques, being 4.3%, 2.6%, and 5.2% after the Swenson, Duhamel, and Soave procedures, respectively. Postoperative strictures can also occur at other sites, particularly in the segment that has been pulled through. These are most likely related to ischemic events; they respond rarely to dilatation and usually require surgical correction.

Most patients with obstructive symptoms do not have stenosis. A variety of functional problems that can be found are related to the residual abnormal function of the intestine after surgical correction (see Figure 77.1-4).[79,106] Moore and colleagues found that of 107 patients followed for at least 4 years, 14.9% had recurrent episodes of gaseous distention and symptoms suggestive of persisting obstruction in the absence of an anatomically defined problem.[83]

The first consideration must be that the patient continues to have the presence of residual aganglionosis because of an inadequate initial repair. The exact incidence of this complication is difficult to establish because it depends on the surgeon and the surgical technique. Soave found that in 5 of 271 patients, the aganglionic segment was not completely removed proximally at the time of the initial operation.[102] This possibility needs to be excluded early in the evaluation of these children, and a barium enema will show if there is evidence of a transition zone. Often it is necessary to perform rectal biopsies to establish the presence of ganglion cells. It is important to remember that in some corrective surgeries, such as the Duhamel, a piece of aganglionic segment is always left as part of the surgical technique, so I recommend obtaining biopsies in all four quadrants. It can therefore be appreciated that the decision about what to do if there are no ganglion cells in the biopsies depends on the type of initial operation that the patient

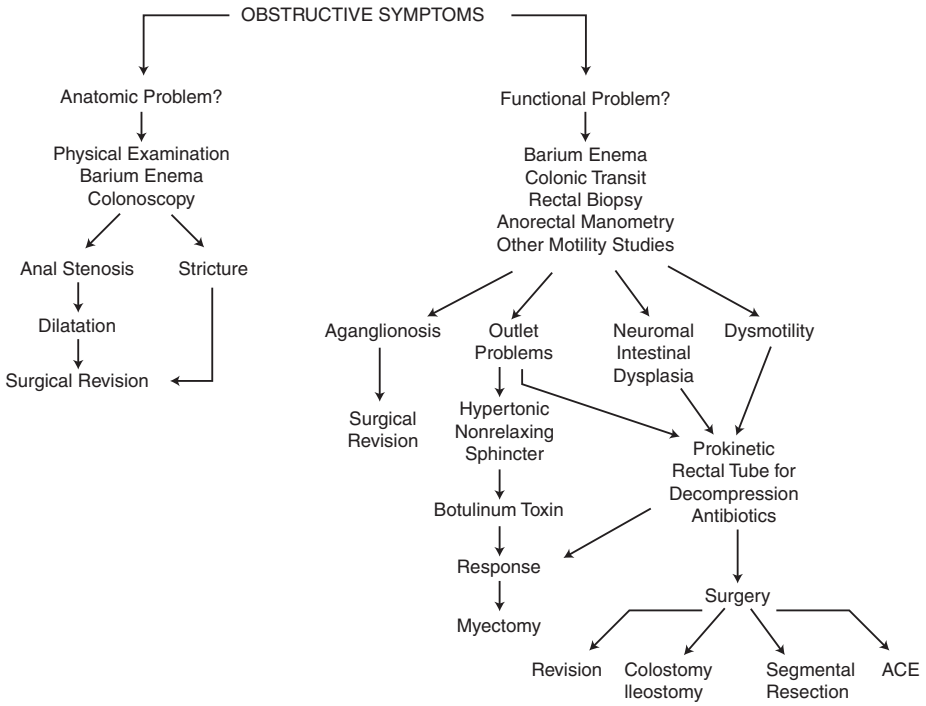

FIGURE 77.1-4 Algorithm for the evaluation and treatment of patients with obstructive symptoms after surgical repair for Hirschsprung disease. ACE = antegrade colonic enemas.

underwent. If there is evidence that a full aganglionic segment was left behind, the treatment needs to be surgical.

The finding of acquired or secondary aganglionosis following pull-through procedures is a rare occurrence, but it has been well described.[83,110] The patients described have developed obstructive symptoms that on evaluation were found to have aganglionosis in a pulled-through bowel that had previously been found to have ganglion cells. This complication has been reported following any of the different corrective procedures,[110] and it should be considered in any patient operated on for Hirschsprung disease in whom recurrent or obstructive symptoms persist. Multiple theories have been proposed for this development, but most authors believe that it is secondary to an increased susceptibility of neural tissues (including the plexuses of ganglion cells) to a hypoxic insult.[83,110] An alternative explanation is that there is postoperative cell death caused by the pull-through of abnormally innervated bowel (eg, the transitional zone or neuronal intestinal dysplasia [NID]).[109] If aganglionosis is suspected, a barium enema may show a transition zone, and rectal suction biopsies at different levels will be necessary to confirm it.

Some reports have suggested that NID type B may be present in more than 20% of cases with Hirschsprung disease.[83,109,111–114] Anorectal manometry is not useful in the diagnosis of NID,[115,116] so a full-thickness rectal biopsy is necessary.[111] The value of a suction rectal biopsy for the diagnosis of NID is controversial, and recent studies have shown that they may not be useful in its recognition.[111,117] Furthermore, there is still controversy regarding the significance of NID or if it truly represents a distinct clinicopathologic entity.[111,114,117] Of 47 cases of Hirschsprung disease, Hanimann and colleagues reported that 11 patients (23%) had associated NID and that after a mean follow-up of 5 years, there were no differences in the symptoms when comparing patients with NID with those without it.[112] Recent studies have reported that histologic criteria were not helpful in predicting clinical outcome and suggested that the finding of NID should not influence clinical management.[111,117]

Independent of the controversy, it is clear that some children may have abnormalities in the histologic examination of the residual colon and that these histologic abnormalities may be associated with symptoms.[113,117,118] Therefore, in children with obstructive symptoms after operation, it is advisable to perform a full-thickness rectal biopsy and to stain it with acetylcholinesterase or other special stainings. In these children, conservative management is indicated.[111,115,116] However, if symptoms are severe and dysmotility is clearly associated with the abnormal segment, surgical resection may be necessary.[118,119]

Persistent internal anal sphincter (IAS) dysfunction is another reason for the obstructive symptoms. This dysfunction is sometimes referred to as "internal sphincter achalasia"[120] and is related to specific abnormalities in IAS innervation. Some studies suggest that there is an intrinsic problem in the IAS in which there is an inability to respond to nitric oxide.[77] The above finding, namely that nitric oxide fails to relax the IAS of patients with Hirschsprung disease, suggests that a primary defect within or around the myocytes of the sphincter and a separate abnormality of the IAS is compatible with some of the long-term obstructive symptoms that are frequently seen.[77,79,86,120,121] It is possible that the IAS pressure produces a functional outflow obstruction that, with time, leads to colonic dilatation and a less efficient peristalsis to expel stool.[83,120,122] The persistent chronic obstruction from the IAS may also lead to recurrent enterocolitis or bacterial overgrowth with stasis.[83,120,122] It is sometimes difficult to establish who are the patients in whom the symptoms are related to IAS problems. In one study in which children with obstructive symptoms were compared with those without symptoms, IAS pressure and other manometric findings were the same.[83] In some patients with obstructive symptoms, however, the high-pressure zone was longer, the sphincter pressure was higher, and there was evidence of prolonged transit times.[83] Because of these sphincteric abnormalities, some authors have suggested that an internal sphincter myotomy or myectomy needs to be performed in those patients with postoperative obstructive symptoms that have not responded to medical management.[100,22,123] Myectomy has been shown to significantly decrease IAS pressure.[123] Even though the initial experience reported a poor response after myectomy,[96] recent reports have shown it to be useful in the treatment of these children.[122,123] Sphincter-dividing procedures are not always effective; they affect the sphincter permanently and can rarely be associated with fecal incontinence. There is now growing experience that the injection of intrasphincteric botulinum toxin (Botox) can be used to temporarily decrease the pressure of the sphincter.[86,120] The mechanism of action of *Clostridium botulinum* toxin has been studied extensively.[86] Botulinum toxin has been used extensively in children with skeletal muscle problems and recently in the treatment of achalasia[124] and patients with chronic anal fissures.[125] Because it weakens the muscle in a transient fashion, it could be used to produce a "medical" myectomy, therefore allowing the evaluation of sphincter pressure reduction without permanent sphincter destruction.[86,120] In a prospective study of 18 children who were injected with botulinum toxin, the authors reported that 4 had no improvement in bowel function, 2 had improvement for less than 1 month, 7 had improvement for 1 to 6 months, and 5 had improvement more than 6 months. Nine of those with symptomatic improvement longer than 1 month had sphincter pressures measured, with a documented decrease in eight. Five with no significant clinical improvement had pressure measurements, with a decrease in three. There were no adverse effects associated with botulinum toxin injection. Four children had new encopresis postinjection, which was mild and resolved in each case. Repeated injections were often necessary.[86,120] The botulinum toxin injection seems to be safe, and no major side effects have been reported when it is used in skeletal muscle or the lower esophageal sphincter. Therefore, it is possible that botulinum toxin is useful as a way of predicting which children may benefit from myectomy or as a therapeutic modality in selected patients, in particular those with recurrent enterocolitis or intractable obstructive symptoms.

The obstructive symptoms may also be related to abnormal upper gastrointestinal motility.[87,126,127] It has been shown that years after the surgical resection, children with Hirschsprung disease can have evidence of esophageal, gastric, or small bowel dysfunction, suggesting that children with Hirschsprung disease may have underlying motility disorders in segments not involved by aganglionosis.[87,126–128]

The establishment of the cause of obstruction can usually be accomplished with the use of simple tests (see Figure 77.1-4). As can be appreciated, the treatment will depend on the etiology (see Figure 77.1-4). In general, and while the workup is in progress, close attention to rectal decompression and treatment of symptoms suggestive of enterocolitis are necessary. A barium enema will help define the anatomy and the appearance of the pull-through and determine if there is a stricture, a new transition zone, or a megacolon. Radiopaque transit studies will detect delays. A rectal biopsy with acetylcholinesterase staining will allow the detection of residual or new aganglionosis or neuronal dysplasia, and anorectal and colonic manometry will allow further assessment of motor function.[128,129]

Using the techniques mentioned above to evaluate patients with obstructive symptoms, Moore and colleagues found that of 107 patients followed at least 4 years, 14.9% had recurrent episodes of gaseous distention and symptoms suggestive of persisting obstruction, in the absence of an anatomically defined problem, and they all had evidence of radiologic megacolon and delayed colonic transit.[83] The reason for this delay was related not only to findings in anorectal function but also probably to abnormal or residual disease in the intestinal wall. Anorectal manometry detected four patients in whom the high-pressure zone was too long, and they all responded to myectomy. They performed histologic evaluation of rectal biopsies and found that in 56% of the patients with obstructive symptoms, there were changes compatible with NID,[109,118] and in another 25% of patients, they detected postoperative aganglionosis. The authors concluded that an aggressive and systematic approach for the evaluation of patients with obstructive symptoms allows the determination of the etiology in most patients and therefore guides their treatment. Recently, in an effort to define the physiology underlying the persistent symptoms in children with Hirschsprung disease, Di Lorenzo and colleagues suggested that colonic motility helps explain the pathophysiology and direct the treatment.[128] They studied 46 symptomatic patients and identified 4 motility patterns: (1) high-amplitude propagated contractions (HAPCs) migrating through the neorectum to the anal sphincter, associated with fecal soiling in 18 patients; (2) normal colonic motility associated with retentive posturing in 9 patients; (3) absence of HAPCs or persistent simultaneous contractions over two or more recording sites in 15 patients; and (4) normal colonic motility and a hypertensive anal sphincter (80 mm Hg) in 4 patients. As can be appreciated, the treatment of obstructive symptoms depends on the etiology (see Figure 77.1-4). If there is an anatomic problem (eg, a stricture), it needs to be corrected. If there is no evidence of anatomic problems and the colonic transit study and anorectal manometry indicate that the obstruction is distal, aganglionosis needs to be considered.[83,102] Biopsies of the distal anastomotic site need to be performed. If aganglionosis is present, the aganglionic segment needs to be removed, or if it is short, a myectomy may be considered.[83] If the patient has neuronal dysplasia, I recommend the use of a prokinetic agent, and I and others have had good results with cisapride.[83] If the anorectal manometry indicates a nonrelaxing sphincter, suggesting that the obstruction is at the level of the IAS, steps to decrease sphincter pressure need to be undertaken.[83] A trial of botulinum toxin injection should be undertaken.[86,120] Repeated injections may be necessary. If the injection of botulinum toxin fails, a myectomy needs to be considered.[130] If there is evidence of aganglionosis, the segment needs to be resected.[130,131] At times, it may be necessary to perform a new pull-through procedure, particularly if there is residual aganglionosis, stricture, or a fistula or if the pull-through anastomosis is too high.[130] In one series, 23 of 68 patients after a Soave procedure and 15 of 39 after a Duhamel procedure required a reoperation. For unclear reasons in this series, the incidence of reoperation is very high, but, overall, 90% were cured after the reoperation.[130] In another report of 22 reoperations followed for a mean 6.5 years, 75% showed good results.[132]

Finally, it may also be necessary to resect dysfunctional bowel.[128] It has been postulated that colonic motility allows the detection of the abnormal segments guiding the surgical intervention.[128] In their series, 15 patients with abnormal colonic motility underwent colonic resection of the abnormal segment with good results. Long-term follow-up and larger studies are needed before the exact role that colonic resections will play in the management of these patients is defined. Finally, for patients with severe problems, it may be necessary at times to create a colostomy or ileostomy.

In recent years, antegrade colonic enemas (ACEs) have been developed as an effective way of treating constipation and fecal incontinence in different conditions, including Hirschsprung disease.[133–135] The ACE procedure produces a continent conduit from the skin to the cecum that can be catheterized for self-administration of enemas.[135–139] In short-term studies, the ACE has been shown to be very effective in children with Hirschsprung disease in whom a permanent colostomy was being considered for the treatment of refractory constipation or incontinence.[135,136] Data for long-term follow-up are not yet available, and close follow-up is needed because in some patients, the enemas may not give the desired results because they are working against a hypertonic, nonrelaxing sphincter.

Fecal Incontinence

Another common problem that may be encountered is fecal incontinence in the absence of fecal impaction (see Table 77.1-3).[84,105,140] Even though long-term studies usually report fecal incontinence in 2.5 to 13% of patients,[75,104,140] a study designed specifically to establish the extent of incontinence found it in 80% of patients.[105] In 53%, it was significant, and in 27%, it was less severe. Contrary to other

reports, the incontinence did not diminish with increasing age.[89] The mean age of the patients was 10.1 ± 3.6 years, and there were no differences in the age at the definitive surgery, sex, extent of aganglionosis, type of surgery, or early or late postoperative complications when comparing those with or without incontinence. The survey of the surgical section of the American Academy of Pediatrics reported that fecal incontinence occurred in 3.2% of patients after the Swenson procedure compared with 1.1% after Duhamel and 2.1% after Soave.[89] One long-term study has indicated that of 282 patients after the Swenson procedure, 90% had normal bowel habits, 3.2% had permanent soiling, and 2 patients had a permanent colostomy because of the incontinence,[90] whereas another study has found that in 185 cases after the Duhamel procedure, 8% had severe incontinence and 27% had used enemas in the past.[141] It has been reported that after the Soave procedure, 18% had diarrhea and incontinence, although 82% had a satisfactory result.[101] Mishalany and Wooley reported the follow-up of 62 patients after different procedures (14 Duhamel, 15 Swenson, and 33 Soave).[88] Approximately 23 to 50% felt that they had normal bowel movements, and the rest had various degrees of problems in defecation. Subjectively, half of the patients in the Duhamel and Soave groups and one-third in the Swenson group considered their stooling pattern normal. Approximately 50% were not totally continent. Half of the Duhamel, one-third of the Swenson, and slightly more than half of the Soave group considered themselves completely continent, and the incontinence ranged from moderate soiling several times a day in 28 patients to total incontinence in 3 patients.

The physiopathology of the incontinence not associated with constipation is not well understood. By doing anorectal manometry, Mishalany and Wooley found that 10% of patients were not able to increase external sphincter contraction and that 50% after the Duhamel or the Swenson procedure and 30% after the Soave procedure experienced an inability to have rectal sensation.[88] Both of those abnormalities have been shown in other populations to be associated with fecal incontinence.[142,143] In a study of 54 adult patients (mean age 29 years), there was a positive correlation between functional outcome and anal resting pressure. The low resting pressure reflects IAS dysfunction, which may be caused by operative trauma.[140] Other abnormalities that have been associated with incontinence in Hirschsprung disease patients are related to the ability of the IAS to relax after balloon distention. The presence of the rectoanal inhibitory reflex has been variable; it is usually absent and in most studies does not seem to be correlated with outcome.[83,88] Recently, Di Lorenzo and colleagues suggested that fecal incontinence can result from the presence of HAPCs that migrate all the way through the neorectum to the anal sphincter.[128] In normal patients, the HAPCs stop in the sigmoid, never reaching the rectum. In their series, 18 children had fecal soiling that occurred when an HAPC was present and migrated all the way down through the neorectum.

Independent of the physiopathology, the treatment of the fecal incontinence is complex. The main objective is to produce social continence. Biofeedback has been used successfully in these children and has focused on trying to improve sensation abnormalities and increase muscle strength. Other treatments that have been used have included the use of enemas, the bowel management tube,[144] or, recently, ACEs.[145]

When evaluating patients with fecal incontinence, the first thing that needs to be established is if this is related to overflow incontinence and encopresis or abnormalities in anorectal or colonic function. The use of physical examination, colonic transit studies, abdominal radiography, and particularly manometry will allow this differentiation. If constipation seems to be the cause, laxatives need to be initiated. On the other hand, if there is fecal incontinence not related to constipation, enemas to maintain the rectosigmoid empty, together with diet manipulation, and biofeedback therapy need to be instituted. In those patients in whom the HAPCs migrate all the way down through the neorectum, an anticholinergic agent or loperamide may be useful.[128] Particularly in patients with total colonic aganglionosis, the use of loperamide may be needed[146] at the same time as the use of rectal tubes allows complete evacuation.

Enterocolitis

Enterocolitis continues to be the major cause of both morbidity and mortality in Hirschsprung disease.[103,104,147–149] It has been shown that this can occur before or after surgical treatment[103,104,148,149] in 2 to 33% of patients, with a mortality that ranges from 0 to 30%.[75,147–150] In a retrospective review of 105 cases, enterocolitis occurred in 32%.[148,149] It has been suggested that postoperative development of this complication is the most reliable indicator of the successful relief of the low intestinal obstruction present in this patients.[89,148,149,151] In the survey of the surgical section of the American Academy of Pediatrics, it was reported to be present in 15% after Swenson repair, in 5.9% after Duhamel repair, and in 1 to 2% after a modified Soave procedure.[89] Klein and Phillipart reported that enterocolitis occurred a mean of 0.51 episodes per patient after the Swenson procedure, 1 episode per patient after the Duhamel procedure, and 0.21 episodes after the Soave procedure.[94] Enterocolitis tended to be more frequent in premature infants and patients with long-segment Hirschsprung disease. The usual clinical presentation consisted of fever, abdominal pain, and diarrhea. In a recent study of 168 patients with Hirschsprung disease, enterocolitis presented with abdominal distention in 83%, explosive diarrhea in 69%, vomiting in 51%, fever in 34%, lethargy in 27%, rectal bleeding in 5%, and colonic perforation in 2.5%.[150] Chronic diarrhea was present in 54% and delayed growth in 44%. The occurrence of explosive diarrhea in any patient with Hirschsprung disease should suggest the diagnosis, even in the absence of systemic symptoms.[103,104,147,149,150] The presence of postoperative enterocolitis needs to be recognized promptly because the child can present initially with mild symptoms that are followed by a rapid fulminating course that may lead to death.[103,104,147,149,150] The pathogenesis is not fully understood.[149,152] In a retrospective review of cases with postoper-

ative enterocolitis, the risk was significantly increased by mechanical factors related to anastomotic complications and intestinal obstruction.[148] In general, it appears that fecal stasis facilitates bacterial overgrowth and subsequent mucosal invasion. There may be an association between enterocolitis and the presence of *Clostridium difficile*,[149,151] although recent reports indicate that in up to two-thirds of patients, stool cultures are negative.[150] The enterocolitis secondary to *C. difficile* may be more fulminant,[103] with rapid progression, shock and prostration, and, eventually, death.[103,149,151] Other organisms that have been associated with enterocolitis include rotavirus, retrovirus, *Pseudomonas*, or *Escherichia coli*.

The diagnosis of enterocolitis needs to be suspected early. Appropriate stool tests for identification of *C. difficile* and stool cultures for other pathogens need to be obtained. The diagnosis may be helped by using abdominal radiographs, in which the presence of an intestinal cutoff sign and at least two air-fluid levels strongly suggests the diagnosis.[147,150] The barium enema usually shows colonic dilatation and modularity and speculation of the rectal mucosa, with significant narrowing.[147,150] Endoscopic examination will show colitis and will detect the presence of pseudomembranes. Conservative management in the hospital is usually necessary. The treatment of choice includes fluid and electrolyte support, antibiotics, and the use of transrectal decompression either by tube or by sphincter dilatation.[75,147,149,150,153] Antibiotics against *C. difficile* and bowel flora should be empirically started as soon as the appropriate cultures are obtained.[147,153] The rectal decompression may need to be accompanied with the use of saline irrigation to evacuate the retained stool and gas.[75,103,149,150,153] It has also been described that some patients have frequent relapses, and this is usually related to chronic obstruction from a nonrelaxing sphincter.[120,149] It has been suggested that in them, the chronic or intermittent use of metronidazole may be beneficial,[149] and the administration of botulinum toxin has been successful in the prevention of the recurrent episodes. Some authors have advocated the use of a myectomy.[149] If the problem persists, it may be necessary to consider a surgical approach, which may include a diverting ostomy.

Total Colonic Hirschsprung Disease

Patients with transition zones in the small bowel account for 5 to 10% in most large series.[154,155] The complications found in patients with total colonic Hirschsprung disease are more severe when compared with those with shorter segments.[154,155] Preoperative complications continue to plague these patients,[154,155] and their mortality continues to be high.[89,154,155] In the survey of the American Academy of Pediatrics, there was a mortality of 47% (42 of 90).[89] Improvements in parenteral and enteral nutrition, as well as in surgical techniques, have recently decreased it.[154,155]

The surgical therapy initially includes and ileostomy. Later an endorectal pull-through, along with total colectomy, and the long side-to-side anastomosis with aganglionic bowel are the most commonly used procedures.[154,155] In a recent review of the treatment of 48 patients, 6% had died early, and 85% underwent a pull-through (38 with the Duhamel procedure, with 13 having the Martin modification and 3 a Soave procedure).[155] Long-term follow-up was available in 27 patients, of whom 19 (70%) required additional surgical procedures. In six patients, a permanent stoma was necessary. Two patients who underwent the Martin modification required resection of the side-to-side anastomosis because of intractable diarrhea, and the authors concluded that there was no advantage to its performance. At 5-year follow-up, 82% had fecal incontinence, but by 10 and 15 years, the incontinence had decreased to 57% and 33%, respectively. At 15 years, over half of the patients were below the 2nd percentile for weight and one-quarter were below the second percentile for height.[155] Fecal incontinence is common, and failure to thrive and malnutrition have been described, as well as disturbances in electrolyte balance, lipid metabolism, and vitamin B_{12} absorption.[154] One of the main problems in these children is residual obstruction that leads to intestinal dilatation, diarrhea, and postoperative enterocolitis. In these patients, intermittent antibiotics and a rectal tube with irrigation need to be used chronically for decompression. If it is clear that the patient has a functional obstruction at the level of the sphincter, a procedure to relieve the obstruction may be indicated. Until recently, a myectomy was the procedure of choice, but the use of botulinum toxin is an alternative that will provide only a temporal effect.[120] These interventions need to be performed in patients who have been fully evaluated because fecal incontinence may result after the procedure. With aggressive follow-up and nutritional support, as well as treatment of obstructive episodes, most patients who survive will eventually attain normal growth and the ability to feed enterally.

IMPERFORATE ANUS

The treatment of children born with anorectal malformations continues to be a challenging problem.[156–158] The term "anorectal malformation" encompasses multiple congenital defects with varying degrees of involvement, and many authors have stressed the complexity of the anatomic, physiologic, psychological, and social aspects that come into play in the management of these children.[158–161] The main objective of treatment is to achieve fecal continence.[157] Proposed treatments for these malformations have included simple perineal operations for benign defects ("low"), abdominal pull-through for more complicated defects ("high"), the sacral approach devised to preserve the puborectalis muscle (Figure 77.1-5), and combined approaches such as the abdominoperineal, sacroabdominoperineal, or sacroperineal approaches.[161,162] Even though today's surgical management permits the survival of virtually all patients,[158,161] it has been reported that only 25 to 75% of the operated patients have an acceptable stool continence following surgery,[156,161,163] particularly those patients with the high-type anomalies.[157] The highest incidence of incontinence seems to occur in male patients who have a rectobladder-neck fistula.[156,158,164] These patients usually have very poor muscle structures, a flat (round) bottom, and a narrow pelvis, with little space

for satisfactory levator reconstruction behind the rectum.[156–158] Recent developments in the surgical technique, particularly the development of the posterior sagittal anorectoplasty,[156,157,161,165–167] have improved some of the results, but fecal incontinence and stricture formation continue to be a problem after the newer operations.[156,158,168]

After long-term follow-up, postoperative results in children with imperforate anus vary according to the type of the original malformation and probably according to the age of the patient. It has usually been mentioned that fecal continence and bowel control improve with time and usually reach their maximum around puberty.[157–159] It has been the usual experience that patients with a good anatomy and adequate treatment become continent much earlier,[157,159] whereas those with the worst results usually do not improve spontaneously. In general, even after the new operations, it has been suggested that 25% of children will suffer from fecal incontinence, and 25 to 30% will have other forms of defecation disorders, such as constipation, soiling, and incontinence associated with episodes of diarrhea.[156,157] In the longest series, Pena and Hong described their experience with 1,192 children whose imperforate anus was repaired using the posterior sagittal approach.[158] They found that 75% had voluntary control of the bowel movements, with half of that group still soiling their underwear occasionally. Therefore, only 37.5% of all cases were considered totally continent.[158] Constipation was the most common sequela, and urinary incontinence was common after the repair of cloacas. Twenty-five percent suffered from fecal incontinence but improved once they were subjected to an aggressive bowel program, including an appendicostomy.[158] Molander and Frenckner described the long-term follow-up (18–35 years) of 29 patients operated on for high imperforate anus.[166] They found that 9 had a permanent colostomy as a consequence of severe fecal incontinence, 6 were the only totally continent patients, 6 had occasional accidents that made them wear sanitary napkins, 2 had constant incontinence, and 4 had a moderate degree of incontinence. In another report with an 8- to 20-year follow-up of 104 children with imperforate anus, Holschneider found that only 6 of 69 patients with a high anomaly had a normal or near-normal continence and that 20 of 104 children had uncorrectable urinary incontinence, suggesting also that a high percentage of these patients continues to have severe problems after long-term follow-up and does not improve spontaneously.[167]

Most information comes from those children with high malformations, and it has been suggested that those with low malformations have a better prognosis. Recent studies, however, suggest that they continue to have long-term problems, particularly constipation.[158,169–171] Ludman and Spitz reported that 28% had compromised continence, with up to 25% continuing to experience difficulty with constipation and 7% requiring enemas on a regular basis.[170] A recent long-term report of 44 girls with low malformations reported that 89% were successfully toilet trained but that 47% experience at least occasional soiling or episodes of fecal incontinence.[171] In a study that compared bowel function in 40 patients with low malformations with that of healthy controls, Rintala and colleagues found that 52% had a normal function indistinguishable from the controls.[169] Constipation requiring dietary or medical treatment was present in 42% compared with 7% of the controls, whereas soiling was present in 10%.

Long-term problems with fecal incontinence can have major effects on the development of the children.[107,161,163,172] In a recent long-term survey, Glinn-Pease and colleagues reported that almost half (47%) of parents report problems with bowel function (constipation, diarrhea, or soiling).[161] Most children had a normal growth and were of average intelligence, and scores for math and reading, as well as of adaptive behavior, were age appropriate. They found that 18% had learning disabilities and 18% had some degree of social maladjustment. Of interest is the fact that children with fecal incontinence represented 60% of the patients with behavior problems, suggesting that the frequent association of fecal incontinence with behavioral dysfunction may indicate that these children may benefit from psychological testing. In an interesting study in which 61 patients were observed for 2.5 to 24 years, Ditesehim and Templeton showed that in chil-

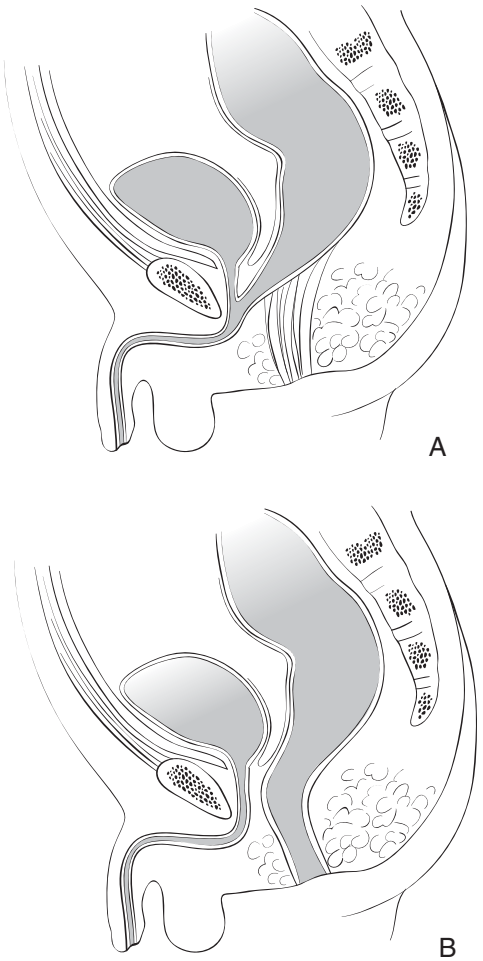

FIGURE 77.1-5 Schematic representation of a rectourethral fistula preoperatively and postoperatively. *A*, Rectourethral bulbar fistula. *B*, Repaired defect. Adapted from Pena A. Atlas: surgical management of anorectal malformations. Heidelberg (Germany): Springler Verlag; 1990.

dren older than 10 years, the quality of life was directly related to their fecal continence, whereas in younger children, their quality of life was better than their continence, indicating that in the younger children, the families tend to be more patient and use special stratagems to minimize incontinence problems: liners in the underpants, enemas, meticulous perineal hygiene, and avoidance of certain foods.[159] It seemed that after age 10, children with incontinence could not be shielded by parents and were not well tolerated by teachers and peers. In fact, in this older group, only 5 of 30 children had greater social adaptability scores than fecal continence scores, and children with a poor fecal continence score faced such severe social problems that they often requested aggressive medical or surgical interventions, including the performance of a colostomy. This study emphasizes the importance of continuing follow-up of these children and for aggressive evaluation of children with fecal incontinence. It is then clear that fecal incontinence is a socially disabling problem in children and remains a challenging problem.[107,156,157,159,163] A recent report of 33 adolescents status post repair of imperforate anus, with a median age of 15 years, found that 73% had flatus incontinence, whereas 70% had persistent dysfunction with staining. Fifty-eight percent met the criteria for a psychiatric diagnosis, and impairment of psychosocial function was found in 73%. The degree of psychosocial impairment correlated significantly with fecal incontinence and flatus incontinence.[163] The authors pointed out that in addition to soiling, staining and fear of flatus are associated with psychiatric and psychosocial dysfunction.[163]

The genesis of these problems is not clear.[107] In a study that compared outcome between children with Hirschsprung disease and children with low anorectal malformations, it was found that even though the degree of fecal dysfunction was similar in both groups, there were differences when comparing both groups. The duration of anal-invasive treatment procedures, particularly anal dilatation, was the most significant negative predictor of the adolescent's mental health, whereas chronic family difficulties and parental warmth, together with the current bowel function variables, best explained the variance in psychosocial outcome.[107] The authors concluded that anal dilatation and continence dysfunction have a negative impact on mental health and psychosocial functioning.[107] They suggest that the use of anal dilatations needs to be reevaluated, particularly in older children.

A recent study of 160 children 6 to 18 years with fecal incontinence after surgery found that the way in which children dealt with the problem could be grouped into three phases.[172] In phase 1, around 6 to 7 years of age, boys were largely unaware of the unsociable nature of their condition, whereas girls were sensitive and withdrawn. In phase 2, between 8 and 11 years of age, boys used overt denial, whereas girls used secretiveness. In phase 3, from 12 years to adolescence, both sexes were marked by continued covert denial and eventual acceptance of their disability.[172] The authors pointed out that the coping mechanisms reflected a complex interrelationship between the characteristics of the child, the family, the social environment, and the unsociable and embarrassing nature of fecal incontinence. Parents' perceptions of how others would react to a child with incontinence influence the children's coping behaviors. Frequently, the emphasis on the need to be secretive (to avoid ridicule) exacerbated the child's awareness of having a shameful disability.[172] Coping with children with fecal incontinence also poses a number of problems to teachers and schools. These children generally look healthy and do not have a visible handicap, and the condition is usually considered taboo. Despite efforts by all concerned, keeping the child's condition secret is difficult, and for a number of children, the problems at school become so acute that some children are removed from it.[172]

MANAGEMENT OF COMMON PROBLEMS

Fecal Incontinence

The management of fecal incontinence is difficult.[135,156,157,160,161,173] Multiple attempts to control it have been done, starting with medical manipulations,[156,157,161] followed by surgical options such as colostomy, grafts, or reoperations.[156,157,164,174]

The physiopathology of fecal incontinence is multifactorial and is not well understood. It has been suggested that good bowel control is the result of the integrity of anatomic structures and the physiologic mechanisms involving three main factors: sensation, bowel motility, and voluntary muscles.[156,157] The presence of fecal incontinence could be related, on the one hand, to abnormalities in the muscle or its innervation[157,168,175] or intrarectal sensation but on the other hand to overflow incontinence from constipation and a lack of bowel motility.[156,176] Pena and colleagues suggested that patients with incontinence can be classified into the following groups: (1) those with a poor surgical repair who may require a reoperation, (2) those with poor functional prognosis who mostly have a tendency either to diarrhea or to constipation, and (3) those with overflow secondary to a dilated sigmoid colon. This distinction is important because the approach and treatment of the patient vary according to the nature of the problem (Figure 77.1-6).[157]

One of the main problems in the evaluation of fecal soiling is that even though there are many tests that try to obtain an objective assessment of anorectal function (eg, defecography, barium enema, manometry, anal endosonography, electromyography [EMG], nuclear medicine, computed tomography [CT], and magnetic resonance imaging [MRI]), each one studies only a specific aspect of a very complex function.[157,177] To evaluate the state of pelvic and anal muscles, as well as the position of the rectum after the operation, imaging techniques such as CT scan[168] and MRI have been used.[177,178] It has been suggested when comparing both techniques that MRI may be superior in the delineation of the pelvic muscles, and another advantage may be that it allows the detection of other unsuspected malformations, particularly tethered cord, or urinary tract problems and also because it does not involve ionizing radiation.[156,178] In general, it has been suggested that the

main advantage of the imaging techniques rests in their ability to help evaluate patients who have been previously operated on and are having fecal incontinence because it allows the differentiation between poorly developed muscles and improper placement of the neorectum.[159,178]

Anal endosonography has also been shown to be useful in these patients.[177,179] In a study comparing anal endosonography with EMG and anorectal manometry in 15 patients, endosonography detected the external anal sphincter in all patients. The distribution image was inadequate in high anomalies. For the external anal sphincter, the endosonographic findings corresponded well to the EMG. The IAS was identified in five patients with high anomalies and in one patient with intermediate anomalies, although only one of the six patients had relaxation by manometry. The authors suggested that the IAS findings did not correspond to the manometry.[177]

However, even though these techniques are very useful in delineating the anatomy, there does not seem to be a good correlation between the anatomic findings and the degree of fecal continence.[158,180] Anorectal manometry is a useful technique to evaluate the state of intrarectal pressure and sensation, as well as of the voluntary muscles.[143,181–185] I and others have found that patients with repaired imperforate anus have significant abnormalities in anorectal function.[143,182–185] The threshold of sensation and the maximum tolerable pressure in the high type are significantly higher than those in the low type were, and the rectal compliance in the high type is significantly lower than that in the low type. It has been found that patients with imperforate anus had a shorter and weaker intra-anal pressure and that patients with high anomalies had abnormalities in voluntary control and sensation.[183,186] Iwai showed an increase in the EMG activity of the external sphincter after voluntary contraction in the patients with imperforate anus, independent of the type of the malformation.[182] Molander and Frenckner suggested that in normal children, fecal continence correlated with the presence of the inflation reflex,[187] and they found that those postoperative patients in whom the inflation reflex was demonstrated had good Kelly scores, independent of the type of anorectal malformation. They also found that in contrast to normal subjects, the electrical activity of the external anal sphincter in children with high anomalies remained stationary in spite of further rectal filling. More sophisticated EMG studies showed that the number of spike bursts in the high and intermediate anomalies was significantly higher than those in the low type. A recent study of 45 patients measured pudendal nerve motor latency, spinoanal responses, and evoked potentials of the cauda equina.[85] The authors showed that patients with imperforate anus had latencies that were significantly prolonged when compared with controls.[85] Compared with normal values, the spinal central conduction time in patients was increased by 278%,

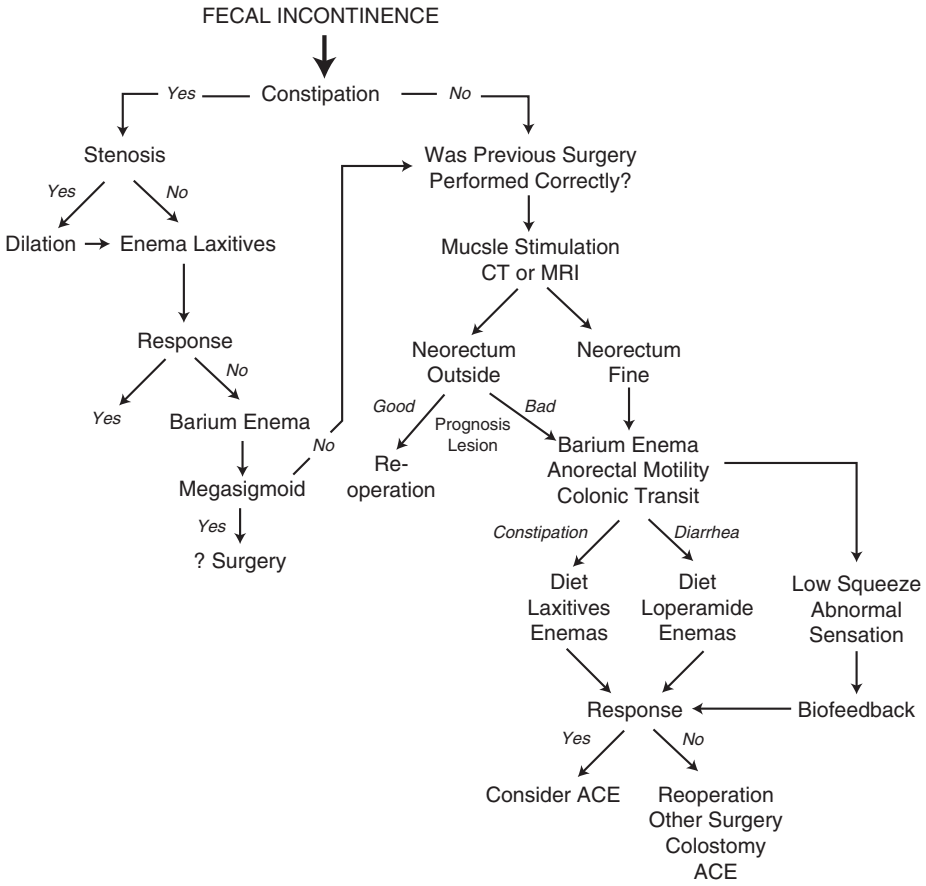

FIGURE 77.1-6 Algorithm for the evaluation and treatment of patients with fecal incontinence after surgery to correct imperforate anus. ACE = antegrade colonic enemas; CT = computed tomography; MRI = magnetic resonance imaging.

the latency of pudendoanal reflex by 232%, the latency of spinoanal response by 180%, and the latency of cauda equina evoked potential by 146%. There was also a negative correlation between the latencies and the clinical scores. The authors concluded that these patients have widespread and serious lumbar and sacral nerve lesions that probably have an impact on fecal continence.[85]

There are few long-term functional studies. Iwai and colleagues studied 27 patients and compared manometric results after surgery with those obtained 3 years later.[188] Manometrically, they found that 7 of 11 patients with a high anomaly had a high-pressure zone in the anal canal and only 1 of 11 patients had an anorectal reflex on the first examination and 3 on the second examination. All patients with intermediate and low anomalies had an anorectal reflex present. Overall, the authors concluded that incontinent patients had a lower anorectal pressure than controls or continent patients. Hedlund and colleagues described the long-term manometric investigation in 30 patients 5 to 10 years after posterior sagittal anorectoplasty.[184] They found that the sensation was within the normal range and that 9 of 30 patients had a rectoanal inhibitory reflex. They also found that soiling was common in patients with low anal resting tone and low squeeze pressures.

It can therefore be concluded from all of the above studies that fecal incontinence is usually related to low voluntary and intra-anal pressure and to abnormal sensation.[166] The role that colonic motility plays in these patients is also becoming increasingly more clear. It has been suggested that abnormal colonic transit is present in patients with either high or low anomalies.[189] The authors found that after using the saturation technique, patients had a significantly longer transit time compared with controls.[189] There was no difference when comparing total transit between those with low or high anomalies, but patients with low malformations have delays in the rectosigmoid segments, whereas those with high anomalies have a more generalized delay.[189] The authors found that the functional outcome was strongly related to the degree of these motility disturbances. Recently, by using colonic motility, it has been suggested that another mechanism that exacerbates incontinence is the presence of HAPCs that migrate in 80% of the subjects to the neorectum.[175] This suggests that it is possible that fecal soiling occurs when the HAPCs propel stool to a low-pressure anus that is unable to accommodate to maintain continence.[175]

Most of the above discussion has been related to the fact that the fecal incontinence of these children is usually the result of abnormalities in anorectal function. There are cases, however, in which there is fecal soiling as a result of overflow incontinence from constipation.

Constipation

Constipation can be a significant functional long-term problem after the posterior sagittal approach or in any operation in which the rectum has been preserved.[156–58,169,174,176,190] In a series of 1,192 patients, Pena and Hong found a 48% incidence of constipation.[158] This varied according to the type of malformation: vestibular fistula, 61%; bulbar urethral fistula, 59%; rectal atresia/stenosis, 57%; imperforate anus without fistula, 55%; perineal fistula, 50%; long cloaca, 48%; prostatic fistula, 45%; short cloaca, 39%; and bladder-neck fistula, 15%.[158]

The physiopathology of the constipation is probably multifactorial.[157] Abnormal myenteric plexus innervation and smooth muscle have been described in rectal dissections.[190] There are cases in which the distal rectosigmoid may become atonic and baggy.[156,157,169,174,190,191] The degrees of rectal dilatation and dysfunction vary, and it has been shown by Rintala and colleagues that the grade of rectal dilatation prior to closure of the colostomy had a positive correlation with the severity of the constipation and that the occurrence of constipation was clearly related to the presence of a functioning IAS.[176] The main problem with the atonic rectum is that it is nonfunctional and has no peristaltic activity,[157,191] so in those patients with atonic rectum in which there is IAS activity, there may be a functional obstruction to rectal emptying causing significant constipation.

The presence of Hirschsprung disease needs to be excluded because aganglionosis has been observed in some patients with imperforate anus.[192]

Treatment of the Fecal Incontinence. The treatment of fecal incontinence has to be tailored to the specific problem presented by the patient. When examining a patient, one has to make the distinction between the different groups (see Figure 77.1-6). This distinction can usually be made on clinical grounds and using simple tests. If the subject has good bowel control potential, good sphincters, a good sacrum, and a malpositioned rectum, a reoperation needs to be considered. One must suspect that overflow incontinence from constipation is present when the child presents with a history of malformation with a "good" prognosis. A colonic transit study may be performed and a barium enema obtained to detect the presence of a megarectum and megasigmoids. On the other hand, if the impression is that the patient is suffering from fecal incontinence not related to constipation, it may be necessary to perform MRI or CT to further delineate the anatomy, to confirm that the neorectum is well placed, and to exclude a tethered cord.[193] If the previous operation is satisfactory, an anorectal manometry will then be necessary to delineate the degree of anorectal abnormalities and the possibility of performing biofeedback therapy.

If one suspects that the fecal soiling is secondary to overflow incontinence from constipation, then medical treatment with diet and bulk laxatives, followed by stimulant laxatives and enemas, needs to be instituted.[157,175] A multidisciplinary approach that also includes behavioral interventions has also been shown to be effective.[173] In those patients with megasigmoid and intractable symptoms even after aggressive medical therapy, resection of the baggy atonic rectosigmoid or sigmoid may be the only effective treatment.[156,157,174,191] Rintala and colleagues reported that 13 of 26 patients responded favorably to dietary manipulations and the use of bulk laxatives, and the researchers were later able to wean all medications.[176] In 11 patients, these measures failed, so enemas and stimulant laxatives were necessary; of those patients, 6 could not wean the medica-

tion without experiencing a relapse. Finally, two patients did not respond to medical therapy and underwent surgical resection, which relieved the constipation, although they continued to have inadequate fecal continence and to use enemas to stay clean. On the other hand, Cheu and Grosfeld reported three children with intractable constipation in whom the resection of the baggy rectum resulted in disappearance of the constipation and therefore in a normal fecal continence.[191] Pena and colleagues have questioned the wisdom of dissecting both the sigmoid and the rectum, and they reported the successful treatment of three patients in whom they only resected the sigmoid, preserving the rectum.[157,174] These authors suggested that all patients with fecal incontinence should have a barium enema, particularly those born with malformations and with the potential for good continence, and that if a megasigmoid is found and medical therapy fails, a sigmoid resection with rectal preservation should be performed without subjecting the patient to another pull-through.

On the other hand, if the soiling is the result of a lack of good muscles, an abnormal sacrum, a defect with poor prognosis, or an abnormal sensation, an aggressive bowel program needs to be instituted.[157,175] An attempt to make the stools more solid should be undertaken because liquid stools usually leak out without the patient's perception. The problem tends to be worse in those patients who were subjected to an operation in which the rectosigmoid was resected, such as after abdominoperineal procedures and endorectal dissections. These patients usually suffer from "diarrhea" and increased colonic motility and pass stool constantly. One approach to these patients involves the use of antimotility agents such as loperamide,[157,194,195] which decreases colonic transit and changes anorectal function, together with the use of bulking agents in the diet. In a study in which loperamide was administered to eight patients with fecal incontinence after rectoplasty for high imperforate anus, four had a significant decrease in the amount of soiling.[195]

Also, besides decreasing stool output, an attempt to keep the distal part of the colon empty needs to be undertaken, and the use of enemas and suppositories is useful.[157,158] At times, it is necessary to use large enemas or colonic irrigation.[157,158] Pena and colleagues have developed a program in which the parents are taught to clean the colon every day with the use of an enema or some form of colonic irrigation.[157,158] The problem is usually much more difficult to control in those children with absent sacrum and worse neurogenic abnormalities because they are unable to hold the enemas or the suppositories. For these patients, the use of a continence enema has proven very beneficial.[144] The success of the retrograde application of enemas or suppositories to achieve continence has changed the quality of life of these patients. However, the problem with this approach lies in the fact that a helper is needed, so independence is not achieved.

Pena and colleagues found that of 172 patients with fecal incontinence who were not candidates for a reoperation or a sigmoid resection, 44 had predominantly constipation and incontinence, whereas 128 had a tendency to diarrhea.[157] The first group was treated with enemas, with a 93% success rate, whereas those in the second group were treated with constipated diets and drugs to slow down the motility. The authors reported a success rate of 88%.

Another option for the treatment of fecal incontinence is biofeedback therapy.[196] Even though the mechanisms of fecal continence are still not well defined, studies in patients with fecal incontinence owing to a variety of different etiologies have suggested that it tends to occur in patients in whom the maximum squeeze pressure is low or in whom the sensation threshold is high. Attempts to correct both abnormalities have usually led to an improvement in the fecal incontinence.[142,156,181,197] Biofeedback for fecal incontinence has been successfully used in the treatment of patients with peripheral nerve impairment, such as diabetes mellitus and multiple sclerosis, myelomeningocele,[142] or after anorectal surgery.[181] In children, it has been successfully used for the treatment of myelomeningocele,[142] in patients with ileoanal anastomosis,[197] and, recently, in children with imperforate anus.[181,196] Most studies suggest that approximately 50 to 90% of patients with incontinence respond to biofeedback,[198,199] and in a review of all published studies in which biofeedback was performed in adults to treat fecal incontinence, the technique was successful in 79.8% (in 257/322 patients).[198]

The information on the use of biofeedback for the treatment of imperforate anus is limited. Arnbjornsson and colleagues performed biofeedback training in patients with incontinence.[165] They found a correlation between clinical improvement and EMG increase after voluntary contraction and EMG tonic activity, with 7 of 11 patients showing a decrease in fecal incontinence, 1 worsening, and 4 no change. No correlation was made with pressure changes. Worona and colleagues have also studied the effect of a biofeedback program on the manometric and clinical outcome of 54 patients with imperforate anus and fecal incontinence.[181] After multimodal treatment, including biofeedback, there was a significant improvement in 82% of the patients, and 34.5% became completely continent. There was a significant decrease in the number of accidents/day, laxatives/week used, number of enemas/week, and sensation threshold and a significant increase in squeeze pressure, total duration of squeeze, and duration of maximum squeeze. Ninety-two percent of the patients maintained their improvement for more than 6 months. Newer biofeedback techniques have used portable EMG machines with similar results.[196,200]

When all attempts to improve the fecal incontinence have failed, the option of a repeat surgical procedure needs to be considered.[201] This is particularly important in those children who were operated on years ago, for whom the performance of a posterior sagittal anorectoplasty may be beneficial, or in those in whom the initial repair might have been technically inadequate.[157] Candidates for a reoperation are those with good sphincters, a good sacrum, a good prognosis–type defect, and a mislocated rectum.[157] Brain and Kiely recently described 12 patients who underwent the procedure because of severe fecal incontinence after the original anal reconstruction.[202] They found that only two patients achieved good results, two others

improved, and the rest remained incontinent. On the other hand, Pena and colleagues found that patients with a normal sacrum and fecal incontinence operated on elsewhere who underwent a posterior sagittal anorectoplasty achieved marked improvement in 45%, some improvement in 37%, and no improvement in 18%.[157,203] In contrast, a marked improvement in only 20%, some improvement in 30%, and no improvement in 50% were achieved in patients with an abnormal sacrum.[157] A report of 20 patients who were reoperated on showed that of 16 incontinent patients, 12 achieved continence and 4 some improvement; of those with fecal impaction, 2 achieved daily bowel movements, and 2 remain with mild constipation.[201] Resection of a dilated sigmoid (megasigmoid) has been suggested for those patients in whom there is overflow incontinence, good sphincters, a good sacrum, a good prognosis defect, and a preserved rectum.[157]

Knowing the success that the application of retrograde methods has on producing evacuation and continence, the idea of performing procedures that will allow the anterograde delivery of the enemas was brought forward, and the ACE procedure was proposed. As mentioned above, the ACE procedure has been developed to produce a continent conduit from the skin to the cecum that can be catheterized for self-administration of enemas.[131,139,145,157,204,205] The procedure can be performed with open surgery,[145,157] laparoscopically,[206] or percutaneously either by radiologic methods[131,135,136] or endoscopy.[137] The main disadvantage of the surgical approach is that it requires a laparoscopy or laparotomy, which, in many of the children who require this procedure, involves major surgery because they have usually had other surgical procedures. The advantage is that it can be done at the same time as the creation of a urinary conduit and that there is no indwelling device. The percutaneous approach can be done either radiologically[136] or endoscopically,[137] and its advantage is that it does not involve surgery, so the recovery time is very fast. The main disadvantage is that a device is left in place, which is not always acceptable to the patients.

Independently of the technique used, the patient is then able to administer an enema in an antegrade fashion. This allows the patient to be predictable and independent. The ACE procedure has been used in children with fecal incontinence secondary to different etiologies[135,136] but most commonly with spina bifida,[139,205,207] other neurogenic problems,[135] and also imperforate anus.[136,145,156–158,204,207] Even though some have suggested that the procedure should be performed only in those patients in whom the fecal incontinence and constipation have been controlled with bowel management,[156–158] recent experience has shown that it is also successful in those who do not respond to enema therapy[136] or even in those children with a poor prognosis.[204]

Overall success rates have been described as ranging from 60 to 90%. In a review of the literature, of 149 reported patients, 88% were completely continent and 12% were partially continent.[135] The most common solutions used are polyethylene glycol, tap water, saline, and phosphate enemas.[135,139,157,158,204] The use of tap water has been associated with hyponatremia,[133] so it is preferable to administer saline. The type, volume, and frequency must be individualized for each patient,[135] although they usually vary from 400 to 2,500 mL.[133,135] The patient sits on the toilet, administers the irrigation, and usually has complete evacuation in 30 to 60 minutes.[135] The most common complications have been stomal stenosis,[134] leakage at the surgical site,[145] or difficulty with catheterization.[208]

Recently, it has been suggested that the placement of an irrigation button in the sigmoid may be as effective as the ACE performed in the cecum.[138,209] The experience is very limited. The main theoretic disadvantage of pursuing that approach is that, most likely, laxatives will still be needed to allow the stool to move from the cecum to the sigmoid colon. More information is needed before this procedure can be recommended.

Several other surgical procedures have been recommended for patients with postoperative incontinence. Some are designed to increase the anorectal angle or reinforce the existing musculature.[210] Some authors have advocated the use of gracilis muscle transposition for the treatment of children with intractable fecal incontinence and evidence of a lack of muscle function.[210] The results have been mixed. In one series, however, Sonnino and colleagues reported their long-term experience in seven patients with gracilis transposition in whom there was severe fecal incontinence, a lack of adequate sphincteric function, and a properly positioned neorectum before the new procedure.[210] They all became continent after the procedure with a mean follow-up of 0.5 to 12.5 years. It is important to note, however, that this type of operation should not be performed if one determines that the neorectum is malpositioned, in which case, a posterior sagittal approach as a redo operation is still recommended.

For those patients who have failed all therapies and continue to have severe fecal incontinence, a permanent colostomy may be necessary.[157,158] Even though the performance of a colostomy may represent a chronic disability and loss of hope of a perfect cure; it may reduce the practical and emotional strain of soiling and invasive treatment procedures, both for the patients and the parents.[107] In fact, Lask and colleagues reported in a controlled study of psychosocial adjustment to stoma surgery for childhood inflammatory bowel disease that there was no evidence that the surgery was psychologically harmful to psychosocial adjustment, self-esteem, or quality of life.[211] They concluded that as long as children are well prepared and followed up carefully and sensitively, stoma surgery should not be deferred for fear of adverse psychological consequences.

It is difficult to estimate the exact incidence of children who have required colostomy. In a long-term follow-up reported by Molander and Frenckner, 9 of 29 patients had a permanent colostomy; the patients in this study, however, were operated on before the new techniques for the treatment of these children were available.[166] In a series of 348 patients, Pena and colleagues reported that they had to perform this procedure in 7 children.[157] Of those, 6 had diarrhea and incontinence as the main symptoms.

Summary on the Approach to the Patient with Fecal Incontinence. Figure 77.1-6 presents an algorithm for the treatment and evaluation of children with postoperative problems. When a patient is referred for the evaluation of fecal incontinence, the following questions need to be addressed:

1. Is the patient having overflow incontinence from constipation? If so, is there a massive dilatation of the rectosigmoid?
2. What is the status of the sacrum? Does the patient have more than two or three missing vertebrae?
3. What is the state of anorectal functioning? Is there a tethered spinal cord?
4. Was the original repair done properly? Is there evidence of stenosis or malposition of the neorectum?

In general, this information can be obtained from the history and physical examination and with the performance of some basic tests. The physical examination should provide information about the state of the anoplasty (particularly as it relates to stenosis), the presence of the midline groove and the anal dimple, and the status of the perineal musculature. A thorough neurologic examination will provide information about deficits in the sacral innervation. The abdominal examination will show the amount of fecal material that is present and should detect the presence of big stool masses.

A plain abdominal radiograph will provide information related to the amount of fecal material present. An anorectal manometry will be useful to evaluate intrarectal sensation, as well as the functioning of the IAS and the strength of the squeeze pressure.

If the patient has severe incontinence that is resistant to medical therapy and surgical options are being considered, the performance of a barium enema may be useful. This test will detect the presence of rectosigmoid dilatation in those patients with severe overflow incontinence from a nonfunctioning segment. In those patients in whom the sigmoid was resected in the initial pull-through, the barium enema will usually show a nondistended colon with normal haustration down to the perineum.

If it is necessary to establish the position of the neorectum in relation to the pelvic musculature, an MRI will be useful. An MRI will also show the presence of spinal cord tethering. At times, it may be necessary to perform electrical stimulation of the perineal region to try to identify where the muscle contractions are occurring in relation to the pull-through.

All of the information obtained after evaluation will allow a better understanding of the physiopathology of the fecal incontinence of the patient. If there is overflow incontinence, attempts to increase stool evacuation need to be undertaken. This may involve dilatation of the anus (if it is stenotic), the use of laxatives and particularly enemas, or sigmoid resection if the constipation is intractable and there is massive dilatation by barium enema. On the other hand, if the patient has fecal incontinence without constipation and a properly performed operation, a biofeedback and behavioral program should be undertaken. This should be accompanied by the use of bulking agents, colonic irrigations, and, usually, loperamide. If one is successful in maintaining a clean rectosigmoid, the incontinence will usually be controlled, independently of the muscle abnormalities. The performance of an ACE procedure needs to be considered, both in those who have achieved continence with enemas and in those in whom the bowel program has not been successful. In those patients with lesions that have been associated with a good prognosis, if the fecal incontinence persists or if there is evidence that the neorectum may not be positioned properly, a redo operation should be considered.[157] Finally, if the neorectum is in a good position but the patient has sacral abnormalities, poor muscles, and a flat perineum and continues to have incontinence independently of the therapy, the possibility of a different type of surgical procedure or the creation of a permanent colostomy will need to be considered.

SUMMARY AND CONCLUSIONS

As more children with complex congenital anomalies survive, new and long-term medical problems are arising. An attempt has been made in this chapter to analyze the long-term complications after surgery for some common and representative pediatric surgical procedures that are directly related to the gastrointestinal tract. The main focus has been to describe usual postoperative problems after surgery for gastroesophageal reflux, Hirschsprung disease, and imperforate anus. Practical aspects regarding their clinical presentation have been reviewed, and suggestions for the evaluation and therapy of these children have been proposed (see Figures 77.1-2, 77.1-4, and 77.1-6). Some general principles can be mentioned. Throughout the years, it has been learned that even though the surgical procedures are usually necessary, there has to be a balance between an attempt to follow physiologic principles and avoiding the creation of more problems. This may not always be possible, particularly when the patient's deficits are extensive, as in cases of fundoplication in children with severe neurologic impairment and esophageal dysmotility, patients with high imperforate anus without sacrum, or patients with total colonic aganglionosis. In most cases, however, recent advances have allowed for a better postoperative outcome, particularly in the area of anorectal malformations.

The pediatric gastroenterologist therefore needs to be familiar with the type of surgical procedures that can be performed, their indications, and their most common postoperative problems. An attempt should be made to participate with our surgical colleagues in deciding the best approach to therapy, particularly after the initial surgical procedures have failed.

2. The Pediatric Ostomy

Catherine Cord-Udy, MBBS, FRACS(Paed Surg)
Erica Thomas, RGN, RSCN, DPNS, BSc(Hons)
Sarah Hotchkin, RN

A stoma can be a beneficial and life-changing surgical intervention for many chronic and acute gastrointestinal disease processes. It is a safe and effective way of diverting the fecal stream and allowing the bowel to heal while continuing enteral feeding. Indications vary depending on the age of the child, but a poorly created, poorly sited stoma can be a nightmare for both children and their family.

The first recorded formation of a colostomy on an infant was by the French surgeon Duret, in 1798,[1] when he successfully carried out the procedure on a 3-day-old infant with an imperforate anus. Although the basic principles and surgical technique have changed little over time, probably the single most significant development in pediatric stoma care has been the shift in emphasis from the earliest attempts of surgical intervention to cure or control the disease to the acknowledgment of the importance of the patient's quality of life after surgery. The identified need for education and support of the child and family before and after surgery has led to the creation of multidisciplinary teams of pediatric surgeons, pediatric stoma care nurses, dietitians, and gastroenterologists, all of whom play an important part in the rehabilitation of the child and family back into the community.

The aim of this chapter is to give an overview of the indications for stoma formation, describe the common types of stomas, and provide surgical tips for creating a good stoma. Practical advice will be included on coping with stomal complications and an understanding of the effect that a stoma has on both the child and the family, in particular the adolescent, who faces disturbance of body image and difficulty with emerging sexuality.

NUMBER OF PATIENTS

It is estimated that as many as 80,000 people in the United Kingdom have a stoma,[2] with only a small percentage of these being pediatric patients. Anecdotal evidence suggests that each regional center within the United Kingdom will see 40 to 100 new cases each year across the pediatric age range. The majority of stomas (76%) are formed in the first 6 weeks of life, 5% from 3 months to 1 year of age, 8% from 2 to 7 years of age, and the remaining 11% from the age of 8 to 16 years.[3]

TYPES OF STOMAS

The term *stoma* derives from the Greek meaning "mouth" or "opening" and is described as "an artificial opening established surgically between an organ and the exterior."[4]

Jejunostomy

The highest-output stoma is a jejunostomy, in which the stoma is sited in the jejunum. It is usually problematic owing to high fluid and electrolyte loss; therefore, enteral feeding cannot be established.

Ileostomy

An ileostomy is a stoma formed in the ileum and can be either divided (ie, two ends spatially separated) or formed as a loop. It is our view that the bowel is not completely defunctioned by a loop because spillover of feces can occur, but it does give a blowhole effect.

Colostomy

A colostomy is the formation of a stoma into the colon, and it is commonly sited in either the transverse or sigmoid colon and again can either be divided or formed as a loop. The lower down the bowel the stoma is placed, the less difficulty is faced with sodium and fluid imbalance because of the retained length of functioning bowel.

Antegrade Colonic Enema

The antegrade colonic enema was first developed by Malone in which one end of the appendix is reimplanted in a nonrefluxing manner into the cecum and the other end is brought out onto the abdominal wall as a continence stoma.[5] Surgical variations have been developed on this technique, but the basic function is to form an access port into the cecum. An alternative is the cecostomy button.[6] The procedure may be considered in children with anorectal anomalies, Hirschsprung disease, or spina bifida or in those children with chronic idiopathic constipation as an alternative to a permanent stoma or rectal washouts.

INDICATIONS FOR STOMA FORMATION

The Neonate

An acute stoma may be necessary in the following neonatal conditions: necrotizing enterocolitis, anorectal anom-

alies, Hirschsprung disease, complicated meconium ileus or failure to decompress the bowel after administration of Gastrografin, some intestinal atresias, and milk curd obstruction. Acute, short-term stomas may be situated within the wound to avoid a further site and therefore additional abdominal scars. Often the size of the abdomen in preterm babies makes siting near the umbilicus unavoidable, although still workable, and therefore avoids a second wound. Whatever the type of stoma, there needs to be an appreciation of the fragility of the blood supply to the mesentery of the neonatal bowel, with meticulous dissection and as limited as possible devascularization of the ends of the bowel. Historically this was why loop stomas were preferred.[7]

A neonate with gut dysmotility associated with, for example, gastroschisis or malrotation may need an end ileostomy to allow enteral nutrition to be established while the small bowel recovers function, without having to work against an ileocecal valve and unused colon. This may be required for several years and therefore should be properly sited by the stoma care nurse if possible.

The Older Child

An acute stoma in the older child may be necessary in the following conditions: trauma sustained either rectally or abdominally; some intra-abdominal catastrophes such as intussusception or volvulus associated with malrotation, in which viability of the bowel is doubtful; ulcerative colitis with toxic megacolon or intractable bleeding; perianal sepsis in the immunocompromised oncology child or those with severe neutropenic enterocolitis associated with therapy; acute abdominal abscess; or perforation in Crohn disease.

A semiurgent stoma may be considered in the following conditions: chronic constipation, pseudo-obstruction, children with Hirschsprung disease in whom the bowel has not decompressed, and children born with anorectal anomalies who continue to have problems with constant soiling. Severe refractory ulcerative colitis will require a subtotal colectomy and formation of an end ileostomy, as will familial adenomatous polyposis[8] because of the risk of malignancy.

PREOPERATIVE CARE

Stoma Siting

It is important that, whenever practicable, patients have access to a stoma care nurse specialist for information, advice, and siting preoperatively. This is not always achievable because many stomas in children are formed as an emergency; therefore, there is little time for discussion and siting in relation to the position of the stoma, but the following principles of stoma siting should be adhered to whenever possible (Table 77.2-1).

Careful siting should involve the cooperation and consent of the patient (depending on the child's age). It is important to remember that the shape of the abdomen alters when the patient is lying, sitting, or standing and in thin or obese children. Each stoma site therefore needs to be tailored to the individual's needs, and, when possible, patients should be given the chance to familiarize themselves with the stoma bag by applying it to the site, so as to predict any potential problems with positioning. As Black noted, "There is nothing that can compensate for a badly sited stoma, achieving the correct site will have an enormous influence on the individual's post-operative rehabilitation, ability to manage his/her own care and ultimately their quality of life."[9]

Bowel Preparation

For the emergency stoma, there is no time to adequately prepare the bowel. For those children undergoing elective surgery, 24 to 48 hours of clear fluids and oral laxatives are often adequate; however, rectal washouts may be required to empty the bowel, but these should not be attempted on those at risk of perforation (eg, the immunocompromised child or the child with diffuse inflammatory bowel disease).

Psychological Preparation

The majority of congenital abnormalities requiring stoma formation are not apparent until after birth, therefore allowing parents no time to prepare for the consequences of giving birth to a baby with a disability.[10] It is often difficult for parents to understand the medical terminology being presented to them. Every family will have its own means of understanding the information provided, and, wherever possible, time should be allowed for questioning, preparation, and acceptance of the need for surgery. Sometimes this is realistically impossible when faced with a sick neonate or an adolescent trauma victim.

Even in these emergency situations, parents are entitled to feel that they have adequate information about the procedure to make an informed choice about their child's care. Parenthood can be traumatic and stressful at the best of times, and the support received from staff in the initial stages can make all the difference[11] as to their acceptance of the stoma after surgery.

When stoma surgery is planned, the method of preparation used should be related to the time frame available and the age of the child. A number of books and dolls are available through various organizations (see contact addresses) that can allow even a young child to come to some level of understanding of what is about to happen. Experienced play therapists and pediatric nurses can use play acting and painting to help the child become involved in the decision-making process.[12]

TABLE 77.2-1 AREAS TO AVOID IN STOMA SITING

Waistline
Hip bones
Previous scars
Groin area
Fat folds and bulges
Umbilicus
Under pendulous breasts
Areas of skin irritation (psoriasis, eczema, skin allergies)
Positioning of artificial limbs
Areas in which there would be difficulties if weight gain or loss occurred

Postoperatively, the older child who has suffered the consequences of inflammatory bowel disease, with pain, repeated hospitalization, polypharmacy, and exclusion from their peers, may see surgery as a relief and an opportunity to start living again. The desire for a cure often clouds many teenagers' judgment as to their true feelings about their altered body image, which tends to emerge months after surgery, when the true picture of their new life becomes apparent.

Access to the Internet can provide teenagers with information that they may feel too embarrassed to ask for (Table 77.2-2), and many self-help organizations have sites for the young adult ostomist. Approximately 20% of patients with a stoma experience clinically significant psychological symptoms postoperatively; commonly, these are anxiety and adjustment disorders.[13]

CULTURAL ISSUES

When caring for the child and family, it is important to take into account their religious, cultural, and individual needs. There may be a number of questions, such as "Is there any animal content in the makeup of the appliance being used?" According to Muslim culture, the left hand is used for cleansing and the right hand is used for meeting and greeting. This therefore requires special allowance when teaching stoma care if the left hand is the nondominant hand. The prolonged fasting during Ramadan can result in increased levels of dehydration and constipation. Children with a stoma can often be exempt from their religious duties at this time or at least be allowed some flexibility. Discussion with their religious leader can help in assistance and guidance.

COMPLICATIONS OF STOMA SURGERY: PRACTICAL ADVICE

Many of the complications listed below can be avoided by careful consideration of the site of the stoma and care being taken by the surgeon when surgically creating the stoma spout itself and its positioning in relation to the abdominal wound. Different complications can be seen at different time scales following surgery.

Avascular Necrosis

Stomas initially are often dusky and bruised in appearance, but many recover without any problems. Technical attention must be paid to preserving a good blood supply to the active stoma by not strangulating it either with a misplaced suture, closing the abdomen too tightly, or by placing the mesentery under tension. The mucus fistula can be placed in slightly less healthy bowel, understanding that it may fibrose down, but it will preserve bowel length that would otherwise have been sacrificed in closure.

Stomas in neonates are usually covered only with a small piece of Jelonet (Smith and Nephew Healthcare Ltd, Hull, UK) and gauze to allow clear observation until the stoma becomes active. The first appliance in all age groups should always be clear-fronted and drainable with no flatus filter; this allows clear visual access and the ability to record the volume of stool passed and monitor any wind produced.

Care should be taken to protect the stoma in neonates when undergoing phototherapy because "sunburn" of the mucosa (black appearance) can result, and incubators can often dry out the stoma. Covering the stoma with Jelonet and gauze can prevent this.

Dehiscence

Complete dehiscence is when the stoma wound breaks open and a further portion of the bowel can extrude from the wound. This is unusual and requires surgical revision, and it is more likely to occur if the two stoma ends are crowded into too small a wound so that skin bridges between them fail to heal. Wound dehiscence is more likely if there is heavy soiling with fecal matter and a malnourished child or premature baby. A superficial dehiscence is more common and usually responds to topical packing, without revision being required.

Bleeding

Bleeding can be peristomal, from erosions or ulcers (usually secondary to bag placement and local trauma). Parents should be warned to expect some bleeding when the stoma is wiped clean because of surface trauma or if the infant is crying when the appliance is being changed because tension on the sutures occurs owing to the increase in intra-abdominal pressure.

Bleeding may be a symptom of the intrinsic pathology of the sick child, but it is important to beware of parastomal varices that can accompany total parenteral nutrition–induced liver failure and portal hypertension. These can bleed exsanguinating amounts of blood rapidly. Local pressure and resuscitation with comprehensive blood products can be lifesaving.

Stenosis

Ischemia to the bowel end is one of the most common causes of stenosis. Closing the abdominal wall too tightly

around the stoma can cause an ischemic effect and can also tighten the abdominal exit site, causing stenosis.

A narrowing of the outlet of the stoma through the abdominal wall can cause an obstruction, often with output fluctuating from little to excessive. Translocation of bacteria can occur at the site, and the patient can become toxic and unwell, often with subsequent line sepsis. If this is suspected, the stoma should be digitally probed to check its patency and may require dilation (not in the neonate), although surgical revision is usually required.

A loopogram radiologic study can show dilatation, but it is a good precaution to cover the procedure with intravenous antibiotics to avoid translocation of bacteria and septicemia.

Necrosis following an infection around the stoma can result in narrowing at the entrance, causing acute abdominal pain and no activity or difficulty in passing stool. Colostomy patients should be advised to keep the stool soft by consuming additional fluids (especially in warm weather) and avoid a high-fiber or bulky diet.

Prolapse

Prolapse of the bowel can be quite dramatic (Figure 77.2-1). This is more common with loop enterostomies, especially in the distal limb, but can occur with end stomas, especially those in a very dilated bowel as it returns to normal size. Fixing the bowel to the muscle fascia in four quadrants goes some way to preventing prolapse.

Small prolapses can be ignored if easily reduced, but an irreducible stoma needs attention to avoid bowel compromise: application of fine sugar granules followed by manual reduction or warm saline gauze and slow pressure usually achieves a result. The sugar causes a fluid shift across the bowel wall via an osmotic gradient, causing the stoma to shrink.[14]

Failure to reduce the stoma requires urgent surgical intervention and, occasionally, revision. A chronic prolapse can be encircled with a nonabsorbable suture, as in a Thiersch suture for rectal prolapse. Refashioning of the stoma is sometimes the only option, and, if required, a new site is preferable. Adolescents who have difficulty with accepting their body image because of the prolapsed stoma may request revision.

When the stoma has prolapsed, it may be difficult to apply the original size appliance; therefore, increasing the size of the aperture can sometimes prevent the stoma from suffering trauma to its edges.

Retraction

Retraction of the stoma can be due to inadequate length of bowel pulled under tension, subsequent adhesions, or the disease process recurring, such as Crohn strictures. The stoma can become indrawn and flush with the skin, causing excoriation and problems with leakage. Although retraction can sometimes resolve spontaneously, revision may be required to make management of the stoma easier, and adequate spouting initially can make this less of a problem, even for colostomies.

Another cause can be from the child gaining a lot of weight after surgery, causing the stoma to become level with the abdominal wall; therefore, the feces has difficulty draining away from the appliance, causing pooling of stool (pancaking) under the appliance. In older children, a convex appliance can assist in pushing the stoma out and thus creating a moat effect to promote better drainage (pastes may help make the appliance stickier).

Incisional or Parastomal Hernia

This is not a big problem in young people because of the natural strength of the abdominal wall, but it may become a problem in those who have undergone repeated abdominal surgery or in those who are overweight.

The weakness in the closure of the abdominal wall adjacent to the stoma can result in an incisional hernia. This is more common in a very dilated bowel that returns to size, but it is also more frequently seen in children with Down syndrome who have required stoma formation owing to poor collagen and therefore poor healing. If troublesome, revision may be required; otherwise, it can be ignored, although bag application can be difficult.

Intestinal Fistula

A leak of intestinal contents from a fistula adjacent to the stoma can result from an anchoring suture placed too deeply or from the disease process recurring in Crohn disease. Intra-abdominal fistulae need to be revised urgently, but a small external fistula can be of little consequence.

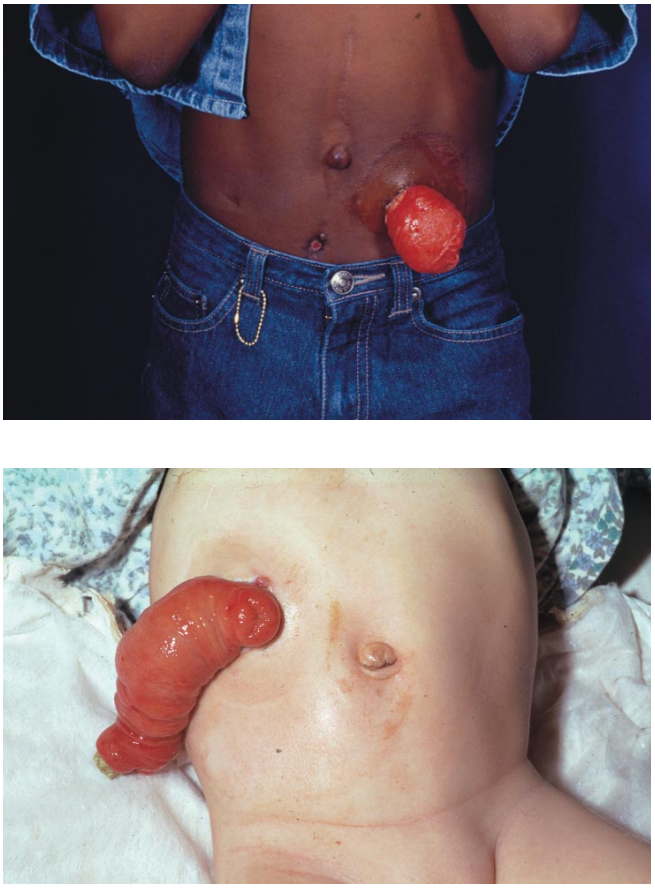

FIGURE 77.2-1 End sigmoid colostomy prolapse in two children.

Mucocutaneous Separation

This results when the stoma edge comes away from the surrounding skin, leaving a shallow cavity around the stoma. It is a particular problem in neonates owing to insufficient bowel mobilization at the time of surgery, causing undue tension on the stoma sutures, which anchor it to the skin. Sore skin around the stoma can result from leakage of stool under the flange; the developing trough can be filled with hydrocolloid gel or paste to promote granulation tissue, and the appliance aperture can be cut to incorporate this.

Dehydration and Electrolyte Imbalance

Every effort should be made to site the stoma as far as practicable down the bowel, and in the immediate postoperative period, close attention to fluid balance must be maintained to avoid electrolyte imbalance. Once on a full enteral diet, the urine should be monitored to ensure that adequate sodium levels are maintained. Supportive parenteral nutrition or fluids may be required for some time in children with acute high intestinal stomas. Enteral nutrition in children with jejunostomies should be given as a low continuous volume to keep the enterohepatic circulation going and decrease cholestasis; it also maintains nutrition to the enterocytes but avoids excessive fluid problems by limiting the input.

Oral sodium supplements are needed almost always in children with ileostomies and even with some colostomies. The infant's or child's growth can be severely impaired by low total-body sodium.

Diversional Colitis

This can occur in the defunctioning bowel owing to stagnation of the contents and a lack of topical nutrition to the enterocytes, with the child experiencing painful discharge and bleeding. Short-chain fatty acids can be instilled into the defunctioning limb with a good result; this is usually given daily for 1 week, with the amount dependent on the length of bowel involved, and then repeated as necessary until under control.[15]

The passage of mucus from the rectum is not uncommon, with older children reporting the urge to defecate. For the occasional rectal discharge, a plain saline washout through the defunctioning stoma or rectum may alleviate the problem, although too frequent washouts can have the undesirable effect of increasing mucus production. Bleeding from the rectum may be an indication of recurrence or continuation of active inflammatory bowel disease.

Skin Problems

An entire atlas has been developed about abdominal stomas and their skin disorders.[16] Soreness can result from an allergic reaction or sensitivity to the adhesive part of the appliance (contact dermatitis), with the outline of the appliance clearly visible following removal. Changing the appliance used can usually resolve the problem; otherwise, barrier films or hydrococolloid dressing used under the appliance can reduce contact and therefore the likelihood of a reaction. Topical steroids should be used with extreme caution because they can result in the peristomal skin becoming very fragile.

Fungal infections often respond to topical nystatin or cotrimoxazole, or a single dose of fluconazole may be required orally if severe.

Effluent dermatitis, inflammation, or excoriation caused by leakage of stool directly onto the peristomal skin is more common in ileostomy patients owing to the liquid consistency damaging the skin on contact. Gut enzymes, particularly protease and amylase found in ileostomy output, can cause fecal irritation by damaging the horny layer of the skin.[17] The cause can be simply that the shape of the stoma has changed, thus allowing fecal fluid to leak under the flange. If this occurs, barrier films can be used to protect the skin.

Poor technique in the fitting of the appliance or the changing shape of the abdomen as children grow may result in the development of troughs and ridges, which prevent the appliance from lying flat against the skin. Pastes or seals can be used to fill uneven areas, allowing the appliance a flat, even surface to which to adhere.

Wet skin under an appliance can be dried using calamine lotion, also giving a soothing effect when the area is itchy. Preexisting skin conditions such as eczema can cause reactions and itchiness from some appliances, and often trial and error is the only way to achieve a solution.

The adhesive quality of the appliance can be increased by warming the appliance either in clasped hands, leaving it on a radiator for a short period of time, or by the use of a hairdryer before sticking it to the skin.

Overfull bags can increase the likelihood of leakage because the weight of the stool pulls the flange away from the skin. Patient education should include the importance of emptying the skin before it becomes no more than two-thirds full.

Granulation tissue may be "normal" and can be controlled with topical oxytetracycline and hydrocortisone (Terra-Cortril), silver nitrate application (with caution), or the regular use of dexamethasone, famycetin, and gramicidin (Sofradex) ointment.

CHOOSING THE RIGHT STOMA APPLIANCE

In the past decade, the choice of stoma appliances for the infant or child has increased dramatically. The following issues should be considered when offering advice to the new ostomist (Table 77.2-3):

- Stoma appliances are made either as a one-piece system; incorporating both the flange and bag (either drainable or closed), or a two-piece system with a separate flange and bag that connect together.

TABLE 77.2-3 FACTORS INFLUENCING CHOICE OF STOMA APPLIANCE

Age and size of the infant/child
Type of stoma: colostomy/ileostomy
Site/position of stoma
Physical/social activities
Dexterity of the child

- One-piece drainable appliances are particularly suitable for infants and younger children who do not have a high level of output. As children grow and their diet becomes more varied, the volume of effluent increases, and with increasing levels of activity, the support and flexibility of a two-piece system may be more suitable, allowing the bag to be changed without the need of the flange to be removed.
- Bags can be drainable for high-output stomas, or if the child has difficulty in emptying the bag, a nondrainable system may be more appropriate. The size or capacity of bags can be varied depending on the activities undertaken (a larger bag may be useful overnight to decrease the need for emptying).
- To combat the effects of flatulence, "flatus filters" are available in many drainable and nondrainable appliances. These do become ineffective when wet; therefore, the outlet should be covered when bathing or swimming.
- Convexity appliances have integral convexity and help create a seal for use with retracted stomas. This system is not recommended in young children because of the risk of pressure ulcer formation, and if used long term in young children, there is also some concern about interruption of muscle growth.
- A wide range of appliances and accessories is available that will cover the individual requirements of most patients. Before finalizing any appliance orders, the opportunity to try different products should be offered because the consumer should have ultimate choice on the system used.

DISCHARGE PLANNING

As the child recovers from surgery, plans should be made for the child to return home. Teaching should involve basic stoma care, knowledge of the practical skills required to change an appliance, possible complications, and whom to reach for advice (Table 77.2-4).

Regular contact should be maintained until the family has the necessary confidence to be totally independent at home. It should be clear to the family how and where additional supplies can be obtained from community services.

Ideally, home visits after discharge offer the family an opportunity to discuss issues that they may have felt unable to question while in the hospital environment. It also provides an opportunity to review bathroom facilities, which may need simple adaptation, and general storage advice for the new equipment.

TABLE 77.2-4 DISCHARGE PLANNING

Discharge teaching should involve
Normal stoma function
Preparation, application, and removal of appliance
Skin care
Where to obtain supplies
Disposal of used appliances
Exemption from prescription charges
Recognizing complications and whom to contact for advice
Dealing with potential problems, eg, leakage, sore skin, odor, and flatus

EDUCATIONAL SUPPORT

Under the guidelines of The United Kingdom Education Act (1981), all children are entitled to an education, and it is the duty of their local educational authority to facilitate the necessary support. The reality is that parents are often "on call" to troubleshoot any problems that occur while the child is at school. The pediatric stoma nurse can offer the child and teachers support in terms of reintegration into the school environment and can educate teaching assistants and carers.

Most head teachers are only too willing to provide access to private toilets away from the main children's facilities, allowing the child to empty or change the appliance in private. The adolescent may have serious problems returning to school with a stoma, and avoidance behavior is common. Postoperative psychological support is often necessary to overcome this awkward period.

NUTRITIONAL CONSIDERATIONS

Concerns about eating and the associated reaction of the stoma are common among new ostomists. Initially, they are constantly aware when the stoma acts and, as a result, are cautious about eating certain foods. Flatus is produced more readily when eating pulses, baked beans, fizzy drinks, and, in some, chocolate. Eating slowly and chewing food well can reduce the amount of air swallowed.

Effluent will contain more fluid when eating spicy foods, fruit, and green vegetables. Eggs, boiled rice, sweetcorn, bananas, and mushrooms will thicken the stool and, in some children, lead to constipation. Foods that are known to cause problems should not be avoided, but by emptying the appliance more frequently or wearing an appliance to accommodate increased output, mealtimes should be more relaxed. It takes about 16 to 22 hours from food being swallowed to it being seen in a colostomy bag—less time with an ileostomy.

Children should be encouraged to experiment to see how their stoma reacts to different food items so that they can remain in control. A healthful balanced diet should always be encouraged. Useful tips in having a stoma can be gleaned from other patients and their families (Table 77.2-5).

TRANSITION OF CARE

The preparation to move from pediatric care to adult-based services can cause great anxiety to many families. For many parents, the security blanket of a pediatric service has enabled them to manage their children's chronic health needs and feel comfortable when attending clinic appointments. The handover of care should be planned and coordinated if possible in a combined adolescent clinic, giving the family the opportunity to meet the new team while maintaining links with the old.

TABLE 77.2-5 HELPFUL HINTS FROM OUR PATIENTS

When gaining confidence in fitting a new bag use a mirror so that you can see what you are doing.
Clean the stoma with gauze swabs because cotton wool balls can leave strands, preventing the bag from sticking.
Storage of appliances should be in a cool, dry area (steamy bathrooms affect the adhesive).
Always have some bags ready cut for those emergency changes; they will always happen.
It is up to you who you tell about your stoma!
To improve the stickiness of the appliance, warm it in clasped hands before applying.
To enable you to see what you are doing, use a clothes-peg to hold clothing out of the way.
If the smell is too offensive, use scented candles in the bathroom when changing the bag.
After the recovery phase of surgery, your stoma's activity will become more predictable. Often it is most active after breakfast.
Beer can give you wind!

3. Psychological Aspects

Steven Schlozman, MD
Suzanne Bender, MD

The psychological effects on pediatric patients who are preparing for or have experienced gastrointestinal (GI) surgery are rich in scope and poor in documentation.[1] Although virtually all clinicians agree that GI surgery poses potentially significant psychological and emotional risks for children and adolescents, the medical and psychological literature addressing these issues continually emphasizes the need for more rigorous studies to ascertain which interventions are most useful for this patient population. Although pre- and postoperative preparations most often include a developmentally driven attempt to demystify the hospital and the operation itself, the existing studies lack methodologic consistency and concrete guidelines.[1,2] Indeed, consulting the existing literature alone leaves one uncertain of how best to help children and adolescents through the ordeals of major and minor GI surgeries.

However, the lack of methodologic consistency contrasts sharply with the wealth of clinical experience that many mental health clinicians have accrued in working with medically ill young people. With regard to GI surgery, a coherent picture of the psychic effects of surgical intervention on younger patients is complicated by the premorbid psychiatric and psychological state, which is itself often a function of the underlying chronic GI illness. Patients with inflammatory bowel disease (IBD), for example, will potentially suffer different psychological effects than patients who are awaiting liver transplant or who suffer from GI tumors. The variety of children in general and the breadth of medical illness in particular make generalizations about this patient population especially challenging.

Nevertheless, clinical experience and a growing appreciation for a biopsychosocial approach *do* yield important guidelines for the care of these young patients. With these concerns in mind, this chapter addresses both general developmentally based observations regarding pediatric patients undergoing GI surgery and specific psychological aspects of common surgical issues seen in patients with IBD and those who receive corticosteroid therapies.

DEVELOPMENTAL APPROACH

The most efficient and accurate approach to medically ill children and adolescents involves careful attention to developmental principles.[3] The effects of major surgical intervention will be different for toddlers than for teenagers, and clinicians must take these differences into account when assessing children in these settings. Although an exhaustive review of child and adolescent development is beyond the scope of this chapter, a brief summary of important differences among children of different ages is important.

Infants and toddlers lack the cognitive skills to understand the gravity of their condition. They rely on their parents and caregivers to relieve immediate suffering and discomfort, and they experience much of the surgical world in terms of the discomfort engendered and the limitations imposed.

Perhaps most importantly, the youngest patients rely on their parents and primary caregivers to keep them safe and to soothe them when they are troubled. Infant–parent attachment can be particularly compromised by severe medical illness, and the hospital staff should work to foster a milieu that allows for as much contact as possible between infant and parent. Parents should remain as close as possible and should interact as much as possible. In this light, fundamental issues such as parent–child physical contact, feeding, and, if possible, breastfeeding should be preserved as much as possible. However, potential exceptions include using parents to restrain older and struggling infants and toddlers during painful procedures. This practice is potentially extremely traumatic for the child and the parent and may prolong and make more dangerous the procedure in question.

As toddlers age, they develop the egocentrism that often defines younger children. They view all events as relating directly to themselves and interpret both bad and good experiences as a function of their own actions. Thus, the toddler often associates unrelated incidents as being causally related, a cognitive style that developmentalists refer to as associative thinking. In the setting of illness severe enough to warrant surgical intervention, toddlers (as well as older patients in more subtle ways) are particularly vulnerable to concluding that their own transgressions have led to their medical predicament. To protect against the damage that these conceptualizations can create, it is often helpful to clarify as much as possible the etiology of a given medical condition and to uncover and correct misconceptions about the cause of illness.

Separation from caregivers and anxieties around bedtime are some of the more common psychological stressors affecting toddlers as they prepare for or recover from surgical procedures. In addition, because they have only recently come to understand that they have control over their body, toddlers often experience insults such as blood draws and even physical examinations as assaults on their entire physical being. To the extent that they can be gently

and consistently prepared before procedures and examinations, they will be protected from a state of constant hyperarousal as they prepare to defend themselves from the onslaught of physicians and technicians.

As children age, their cognitive capacities rapidly develop. They enjoy a growing sense of mastery in understanding the world around them, categorizing and labeling many of the central features of their lives. They will collect baseball cards, know their telephone number, and memorize the names of countless dinosaurs. Medically ill children will often take great pride and comfort in knowing the names of their diseases, of their medications, and of complicated surgical procedures. If a child in this setting expresses interest in what is happening medically, it is developmentally useful to answer as concretely as possible. Simple cause and effect are hallmarks of preadolescent cognitive development, and children in this age group understand, for example, that germs cause disease and that taking out something bad (like a splinter, in more benign settings) can lead to feeling better. However, this cognitive style can lead to psychological distress when there is no clear cause for a given illness. Always tuned into media and popular culture, children may wonder, for example, how they developed cancer without smoking or why they need to go back to the operating room if they diligently followed their postoperative instructions. Parents and clinicians must balance a child's desire to understand the world with helping the child to endure the ambiguities that we all find difficult to tolerate with regard to medical illness.

As children enter adolescence, they develop an increasing capacity to think abstractly and form multiple points of view. An appreciation for rules that more or less dominates preadolescent children develops into a tendency to question rules and restrictions. In this setting, adolescents begin to form a coherent sense of who they are and what matters to them. Although this sense of self seems constantly in flux to many adults, the intense exploration of different values and ideals is a normal adolescent obsession and should not necessarily be taken as a sign of serious difficulty. In addition, adolescents begin to separate themselves from their families of origin. For example, when they are in need, adolescents may increasingly turn to friends or mentors instead of parents. All of these forces can ultimately manifest themselves as apparent rebellion and "acting out" from the rules and values of their own families.

For medically ill children, it is vital that these normal adolescent tendencies not be expressed in terms of worsening medical compliance, both in and out of the hospital. The teenager with a new liver, for example, *must* take her medicines and must *never* experiment with alcohol. Helping adolescent patients to accept their limitations, to understand the necessities of their medical regimen, and to find alternative methods of expressing their individuality is absolutely essential to the successful management of the medically ill teenager.

Having stressed the discrete stages of normal development, it is paramount that one remember that developmental approaches are not static and often overlap. It is not unusual for teenagers to feel that their past transgressions have caused their newly diagnosed malignancy. Indeed, it is their realization that such thoughts are juvenile and immature that compounds their shame as they try to make sense of their predicament. In a similar light, GI concerns such as bowel mastery and control of one's flatulence are mastered early in normal child development. To the extent that GI surgery can compromise bowel control, children and adolescents may find themselves with soiled pants and regressed anxieties. In this sense, earlier developmental concerns are revisited on the recovering patient.

Finally, children often compartmentalize their concerns. There is nothing that is necessarily worrisome about the youngster who worries more about a soccer game than his/her upcoming surgery. Only in rare and specific circumstances is it helpful to force a young patient who appears unbothered to discuss his/her medical condition.

SPECIFIC TREATMENT ISSUES

Given the number and variety of pediatric GI procedures, it is somewhat difficult to generalize with regard to the psychological effects of invasive GI surgery. However, a number of considerations specific to certain GI illnesses have a direct and discernable effect on the psychological well-being of pediatric patients.

For example, children who undergo surgery in the setting of IBD often take varying doses of steroids and immunosuppressing agents. Similar medication regimens exist for children who undergo liver transplant and a scattering of other autoimmune diseases that affect the GI system. Although these medications are extremely important to the medical well-being of the patient, they also carry the potential for substantial psychological risk. Furthermore, virtually every serious GI condition has, in and of itself, potential psychiatric sequelae. As IBD constitutes perhaps the most common indication for pediatric GI surgery, it is helpful for clinicians working with this population to familiarize themselves with both the psychological risks of this condition as they pertain to surgery and the risks associated with medication regimens.

UNIQUE EMOTIONAL STRESSORS IN PEDIATRIC IBD

Children and families coping with IBD face unique emotional stressors and social challenges. When a child with recurrent debilitating colitis has an increase in symptoms, including refractory diarrhea and possibly stooling accidents, it may be intermittently necessary for parents to help with their child's basic toileting hygiene for the first time since toilet-training. As parents feel increasingly helpless as the disease progresses, there is a risk that they may become overcontrolling and overinvolved in an attempt to manage the unmanageable. The pediatric patient with colitis also faces some unusual psychological challenges. For a child who is appropriately increasing her sense of independence as she gets older, a family focus on bowel habits and bowel control may feel overwhelming and humiliating. The familial stance that is most psychologically supportive balances

the child's emotional needs, autonomy, and privacy. Often psychological support provided by a social worker, psychologist, or child psychiatrist can help the family refine an approach that best supports the patient's personal growth.

The social ramifications of colitis are unique. Compared with asthma, which is a common childhood disease that is well known and does not involve any specific toileting needs, colitis is not a disease familiar to most children. It is not an easy disease to explain to one's friends.

When the disease is active, the child's activities may be greatly curtailed owing to abdominal pain or frequent stooling. Embarrassed by their disorder, children may go to great lengths to hide their symptoms from their peers. Children with varied stages of disease, pre- and postoperatively, often worry about soiling their underwear if they do not make it to the bathroom on time. If bathroom access at school is limited, the child may start refusing to go to school to avoid the impending stooling disaster. Importantly, these symptoms can potentially worsen as a function of anxiety regarding an upcoming surgery or as a result of the surgery itself. It is extremely important, therefore, that clinicians be aware of these issues and facilitate the child's development in the context of his/her medical condition.

SCHOOL AND CAMP INTERVENTIONS THAT FACILITATE EMOTIONAL GROWTH AND MINIMIZE ANXIETY

A physician caring for a child with colitis can provide some sound advice about the basic social interventions that can increase a child's confidence at school. Children with IBD should be allowed open access to school bathrooms. They should also be allowed to use the bathroom in the nurse's office if necessary. (Whereas other bathrooms at school may have frequent toilet paper shortages, this one tends to be well equipped.) These children should not be required to ask the teacher or to obtain the one bathroom pass allotted for the classroom to leave the room; they may need every moment available to make it to the bathroom without soiling. Some schools provide a special hall/bathroom pass for these children that they can carry with them at all times.

In some cases, increased academic support may also be indicated. For children unable to carry heavy books back and forth from home to school, two sets of books should be provided. If the diarrhea or abdominal pain increases around a project due date, teachers should be flexible and provide due date extensions as needed. In addition, if a child needs to rush to a bathroom during a testing situation, he should not be penalized and should be allowed extra time to finish the examination.

Whatever unique setup is organized, the planning should be done privately with the children's teacher. If these safeguards are not in place, these children may worry about their bowel habits during the school day rather than focus on school activities. Knowing that they have open access to available restrooms and that the school will be appropriately flexible if their symptoms affect their academic availability can be a great relief that supports normal cognitive and social development.

For camping or portable toilet situations, children with IBD should be armed with flushable wipes and sterile gel hand cleanser to use as needed. For outside activities that may have limited toilet availability, such as rope courses in summer camps, children with IBD should be first in line to complete the activity so that they can make it to the bathroom after the event if necessary. For rowing or other boating events without available bathrooms, the counselor in charge needs to be informed of the patient's medical limitations before the activity rather than during the event because of an acute toilet need. In general, attention should be paid to anticipating and then preventing problems rather than ignoring the possible hazardous situations that may crop up.

POTENTIAL PSYCHIATRIC AND COGNITIVE EFFECTS OF CORTICOSTEROIDS

Many of the GI conditions that lead to surgical interventions are treated with corticosteroids. These medications often carry with them profound psychological impact secondary to side effects such as changes in facial characteristics and weight. Furthermore, these worries can be easily compounded if the child also suffers from psychiatric symptoms caused by the steroids themselves. Finally, patients can exhibit severe psychiatric symptoms as a result of steroid treatment without having a past history of psychiatric vulnerability or psychiatric family history.

Corticosteroids can cause a wide range of psychiatric symptoms that may occur at any stage of treatment, including treatment withdrawal.[4,5] Usually, the worst symptoms are dose related and notable within a few weeks of therapy. During steroid withdrawal, depression and fatigue have also been documented and are not always coincident with evidence of hypothalamic pituitary axis suppression.

Mood lability, irritability, depression, anxiety, and mania have been documented in children and adults during steroid treatment, even at modest doses. Depressed children may become more withdrawn and irritable and have trouble sleeping, eating, concentrating, and feeling motivated. Manic children may develop sleep difficulties and experience increased activity and impulsivity and worsening distractibility. Their mood can be euphoric or extremely irritable.

Patients with a history of post-traumatic stress disorder may have increased depressive symptoms or intrusive trauma memories during steroid treatment. Further, adolescent patients with a previously undisclosed trauma have been noted to become symptomatic during steroid therapy.

Finally, some children may experience cognitive difficulties as a result of steroid treatment. Difficulties with short-term memory and concentration have been reported in the absence of mood symptoms, and often these effects dissipate when the steroid dose is decreased.[4]

NUTRITIONAL SUPPORT

Patients who require GI surgical intervention will sometimes require some form of nutritional support for pro-

longed periods. Although one can imagine the potential psychological effects of these nutritional interventions, again, there is relatively little literature exploring these issues.

As noted above, children with illnesses such as severe IBD already run significant psychological risk. The developmental and emotional toll of these conditions is derived from a combination of the disease symptoms themselves, underlying psychiatric predispositions, and side effects to potentially psychotropic agents such as corticosteroids. Although it is clear that nutritional support can also affect emotional well-being, the etiology of psychic distress as a result of total parenteral nutrition or tube feedings is more subtle and poorly studied. Existing literature suggests relatively good emotional adjustment, although these studies are hampered by the lack of an adequate comparison group and by unclear measurements of psychological effects.[6]

Adequate exploration of these issues is also hampered by the lack of a clear etiologic connection between nutritional support and emotional well-being. Although corticosteroids, for example, directly affect mood and anxiety, evidence for a specific psychotropic effect related to successful nutritional support is somewhat lacking. However, for children who develop vitamin and mineral deficiencies during parenteral or enteral support, there is the possibility that psychological effects will develop as a direct consequence of these nutritional shortcomings.[7,8] In addition, for children already uncomfortable with the developmental and psychological burden of their GI illness, the motivation, patience, and perseverance necessary for successful total parenteral nutrition or enteral support can be particularly challenging.

PSYCHOLOGICAL EFFECTS OF OSTOMIES

Children whose medical conditions necessitate ostomy placement also may suffer emotionally and developmentally as a result of this intervention. Again, a developmental approach is necessary when understanding the potential psychological implications. For younger children, the growing sense of autonomy and pride with regard to appreciation of and control over one's own body is potentially compromised by the placement of ostomy itself. For older children, the growing emphasis on peer conformity and appearance is further threatened by this intervention. As with much of the psychiatric literature concerning severe GI illness, there is a relative shortage of systematic investigations into the effects of ostomy placement in pediatric populations. Nevertheless, much of the literature does support significant need for emotional support and psychoeducation to ensure favorable outcomes.[9–11]

MISCELLANEOUS TREATMENT ISSUES

Other important issues relevant to this patient population include the drug–drug interactions in children who are taking multiple medications. Although an exhaustive list of these interactions is beyond the scope of this discussion, some specific treatment issues deserve mentioning.

First, given the spread of alternative therapies, especially with regard to psychiatric symptoms, it is always important to ask parents and patients whether they take any agents that are categorized as herbal or homeopathic. Although both parents and patients alike may view these agents as benign, many of these therapies have the potential to complicate treatment. For example, St. John's wort, an extremely popular herbal medication purchased at health food stores and taken for depression, also interferes with cyclosporine metabolism.[12] Clinicians have worried about graft rejection in patients who began St. John's wort and subsequently increased the metabolism of their prescribed immunosuppressing agents.

In general, taking a careful psychosocial and medical history helps to make patients and their families more comfortable discussing psychological issues and allows the clinician to screen for psychological distress. Having said this, it is extremely important that seemingly psychological symptoms be examined from multiple perspectives. For example, the youngster who seems lethargic, even in the setting of active depression, should also be examined for a worsening medical condition. All of the antidepressants and psychotherapy in the world will not fully motivate an anemic or otherwise medically compromised child. To this end, a team approach is absolutely essential for the overall health of these young patients.

PRE- AND POSTOPERATIVE MANAGEMENT

As noted above, there is limited methodologic consistency with regard to how best to prepare children and adolescents for GI surgery. Investigations have focused on measurements of pre- and postoperative psychological distress, postoperative pain, overall psychological adjustment, and the extent to which parents effectively cope.[1,2,13]

Studies suggest that 40 to 60% of children experience significant psychological and behavioral distress prior to surgery.[1] However, many studies do not describe in detail the scope or characteristics of these behavioral difficulties. Nevertheless, although these percentages refer to the almost 3 million children per year who undergo any type of surgery, it is reasonable to conclude that all surgeries, including GI procedures, are potentially extremely distressing to children and adolescents.[1]

In spite of these findings, there is little consistency among the approaches used to help quell these concerns. Some institutions use preoperative anxiolytic pharmacologic management, whereas others pursue a psychoeducational approach, preparing youngsters as best as possible for what they can expect both pre- and post-operatively. Many institutions use some combination of behavioral and pharmacologic management, and regimens are often a function of individual preferences among clinicians and, hopefully, a careful assessment of the needs of patients and their families. One large meta-analysis notes that some institutions have favored an overall decrease in preoperative psychological management.[1] These hospitals and clinicians acknowledge that although some form of preoperative management is potentially very helpful, the lack of consistent data supporting any one method of intervention makes much of these endeavors somewhat suspect.[1]

Other investigations have centered on postsurgery analgesic requirements and use, as well as the relative characteristics of parents as they cope with their child's illness and procedures. For example, some small studies note that variables affecting pain medication requirements include the relative invasiveness of surgery, the preoperative psychological state of the patient, and the extent to which parents felt anxious or concerned about the upcoming procedure.[13]

As noted above, the heterogeneity of procedures that can be characterized as GI surgery makes generalizations difficult, and many smaller investigations suggest findings that one can cautiously extrapolate from the specific conditions that they discuss to the more general concerns of the surgical pediatric patient. For instance, a study examining 101 pediatric liver transplant patients found that earlier transplants correlated with increased aggressive behavior and sexual dysfunction.[14] Furthermore, this study found that the surgery itself continued to be an important psychological part of the child's sense of self many years after the procedure. A similar study examined results from psychological projective testing in post–liver transplant children, noting increased negative self-focus and depressive episodes in this patient population.[15] One study has found that children were relatively well psychologically and developmentally when the treating team used a multidisciplinary approach.[16] Although many of these findings seem specific to the extraordinary circumstances surrounding any transplant, it is reasonable to expect earlier major procedures in some instances to interrupt development sufficiently to confer significant and lasting psychological effects. More studies are badly needed to confirm these hypotheses.

Similarly, it is also possible to extrapolate information from other severe illnesses in children to the overall understanding of how pediatric patients might respond to GI surgery. An important finding over the last few years has been a growing recognition that pediatric patients who undergo invasive and side effect–laden treatments such as chemotherapy and massive surgeries are at risk for the development of post-traumatic syndromes, cognitive decline, and depression. In addition, because underlying psychiatric predispositions often express themselves in the setting of external stressors, it is likely that many children will experience their first presentation of major psychiatric conditions such as mood and anxiety disorders in the setting of the stress of a surgical procedure.[17,18] Indeed, one study examining risk factors for the development of post-traumatic stress disorder in children with cancer noted that the most robust predictor was the extent to which the parents felt traumatized. Thus, it behooves any treatment team to soothe the fears and anxieties of parents as well as patients.[19,20]

At this point, it should be noted that there are many relevant studies listed in psychological databases such as *PsychINFO* and relatively few studies in more medically oriented sites such as *MEDLINE* and *Index Medicus*. Indeed, many of the most intriguing investigations are listed as doctoral dissertations, unpublished in other formats as of yet. Clearly, the case can be made that the medical establishment has neglected a more systematic interest in the psychological effects of GI surgery on children.

CONCLUSION

Why the dearth of knowledge? Some clinicians suggest that recent improvements in the overall treatment of drastically ill children have spawned a new interest in understanding the psychosocial effects of severe medical illness in pediatric populations. There may have been a tendency in the past to simply ignore or pay little heed to psychological distress, given other, more pressing medical concerns.[21] After any medical condition serious enough to warrant surgery, many parents and clinicians are, understandably, delighted that the child is simply alive and functioning. This can lead to a relative lack of emphasis on psychological well-being, and many consultation-liaison psychiatrists, psychologists, and pediatricians are only now systematically examining the effects of major medical interventions, such as GI surgeries, on the psychological state of their younger patients. Future studies will undoubtedly yield more specific and important findings, filling an important gap in the understanding of a child's experience in the surgical setting.

INTRODUCTION

PEDIATRIC GASTROENTEROLOGY: A SUBSPECIALTY IN PEDIATRICS "COMES OF AGE"

W. Allan Walker, MD
Ronald E. Kleinman, MD

Early in the twentieth century, pediatrics emerged as a distinct medical specialty, largely focused on infectious diseases and the nutritional support of infants and young children. Pediatric subspecialties have evolved even more recently, over the past 50 years. For the young pediatrician just entering a fellowship in pediatric gastroenterology, it probably seems as if the subspecialty has existed forever. Few realize that even 35 to 40 years ago, those who wished to become pediatric gastroenterologists had to leave pediatrics and enter adult fellowship programs to obtain formal training. In spite of its "youth," the discipline of pediatric gastroenterology, hepatology, and nutrition has established itself scientifically and clinically as a major contributor to the care and well-being of infants, children, and adolescents.

In this introductory chapter of the fourth edition of this textbook, we attempt to summarize the historical evolution of our field, highlighting some of those disorders that have their onset during infancy or childhood or are unique to that age period and that have spurred the development of the discipline. We also review the defining events in the establishment of the subspecialty and speculate on the directions it may follow into the new millennium. All of this serves as a preface to a significantly expanded fourth edition of this textbook. All chapters have been revised and updated to reflect the advances in science and clinical practice that have occurred since the publication of the third edition. The textbook has also been significantly expanded to reflect the extraordinary advances in our understanding of the development and pathophysiology of the gastrointestinal tract at the cellular and molecular levels.

DEVELOPMENT OF PEDIATRIC GASTROENTEROLOGY

The concept of organ-specific subspecialties in medicine began at the end of the nineteenth century. For example, the American Gastroenterological Association was established in 1897 in Philadelphia.[1] It took almost another century before such subspecialties of pediatrics were established. The European and North American societies of pediatric gastroenterology were incorporated in 1967 and 1973, respectively, and, more recently, the Asian Pan Pacific and Latin American societies formally organized. A major impediment to the development of this field was a notion among pediatricians that gastrointestinal conditions could be fully addressed within the purview of general pediatrics. Although this undoubtedly is true for common acute gastrointestinal conditions (eg, neonatal regurgitation and rotavirus gastroenteritis), it quickly became clear that the diagnosis and treatment of chronic, complex, and often debilitating conditions affecting the liver, pancreas, gastrointestinal tract, and nutritional status of pediatric patients required specific knowledge and experience, acquired through specialized training. Heretofore, this need had been filled by gastroenterologists in internal medicine. In general, this approach was acceptable as long as it involved an older child or adolescent. However, these individuals had little or no expertise in managing young patients with gastrointestinal problems unique to pediatrics, for example, inborn errors in bilirubin metabolism, congenital intestinal absorptive defects and other metabolic diseases (eg, α_1-antitrypsin disease [α_1-AT]), and congenital malformations of the liver and gastrointestinal tract. To better serve these patients, pediatricians who left pediatrics to train in adult gastroenterology adapted this training to the care of infants and children. In the early 1970s, small selective divisions of pediatric gastroenterology and nutrition were established in North America and Europe by pediatricians trained in adult gastroenterology programs. These divisions became nascent training centers for future pediatric gastroenterologists. In three short decades, the field has evolved to become an established pediatric subspecialty worldwide.

Evolution of Diagnostic and Therapeutic Approaches to Gastrointestinal Disease States in Children

ogy, and nutrition,[2] lists diagnostic techniques and therapeutic approaches that have helped shape the unique expertise of the pediatric gastroenterologist. We highlight a few representative conditions from this list below. A complete discussion of each disorder is found in subsequent chapters in the book.

Celiac Disease

Celiac disease is a unique genetically predisposed condition that, although lifelong, often presents in infancy and childhood. In postwar Holland, Dicke demonstrated that this chronic, malabsorptive condition associated with severe "failure to thrive" was caused by intolerance to gluten, a major constituent of several grains, particularly wheat.[3] This observation, that a common condition in infants and children was not an infectious gastroenteritis but instead a food intolerance, launched pediatric gastroenterology as a subspecialty of pediatrics in Europe. In 1957, Drs. Jack Sakula, a pediatrician, and Margot Shiner, a gastroenterologist, published a diagnostic technique that could be used to diagnose celiac disease.[4] By successfully modifying the intestinal biopsy capsule designed for adults with a smaller portal, they could obviate intestinal perforation in infants and children and obtain a safe biopsy of intestinal mucosa for chemical or morphologic analysis. This diagnostic procedure, coupled with advances in microanalysis of mucosal enzymes[5] and breath testing, has been the basis for the diagnosis and management of celiac disease as well as acquired and congenital disorders of carbohydrate digestion and absorption for the last three decades.

More recently, celiac disease has been linked to specific human leukocyte antigen (HLA) loci (DQ2 and DQ8), suggesting a genetically based underlying immunologic defect.[6] Currently, it is considered to be an autoimmune disease, with transglutaminase as the putative autoantigen.[7] With modern infant feeding guidelines, including exclusive breastfeeding for 3 or more months, the classic presentation of celiac disease in early infancy (chronic diarrhea or malabsorption associated with severe failure to thrive) is much less common today. As serologic tests with high sensitivity and specificity for celiac disease have come into routine use (IgA antiendomysial and tissue transglutaminase antibodies), subclinical celiac disease and atypical presentations of the disorder have been recognized, and the true prevalence of this disorder has significantly increased.[8] These advances in noninvasive diagnostic tests, along with a better understanding of the pathogenesis of celiac disease, have allowed the pediatric gastroenterologist to manage the disease and its complications more efficiently (see Chapter 44.1, "Celiac Disease").

α1-Antitrypsin Deficiency Disease

In 1969, Sharp and colleagues reported that the inherited disorder α_1-AT deficiency was associated with neonatal hepatitis syndrome, leading to cirrhosis.[9] Subsequently, when the percutaneous liver biopsy technique was adapted for use in infants and children,[3] this condition could be distinguished from other neonatal hepatic conditions, such as biliary atresia. In follow-up studies by Sharp and others, a mutant form of α_1-AT (PiZZ) was identified as a sequestered protein in the endoplasmic reticulum of hepatocytes, and this histopathologic feature became diagnostic of the disease.[10,11] Initially, α_1-AT–associated hepatitis was thought to be due to a failure of its release into the hepatic interstitium to neutralize proteases in the portal circulation that could cause hepatocellular damage.[12] The hepatic lesion has been ascribed to hepatocyte toxicity caused by the retained mutant form of α_1-AT in hepatocytes.[13] However, using sophisticated "cutting edge" cell biologic techniques, Perlmutter and colleagues and others have suggested that the process is much more complex and involves not only accumulation of misfolded mutant forms of α_1-AT in hepatocyte endoplasmic reticulum but also disruption of other subcellular functions leading to liver damage.[14,15] They also suggest that genetic variants of α_1-AT can define phenotypic hepatic disease expression.[16] This common metabolic liver disease can now be distinguished from other liver conditions (eg, tyrosinemia, biliary atresia) and managed in an appropriate prospective manner. Of interest, α_1-AT–deficient liver disease is a common cause of liver transplant in pediatric patients.[17]

Cystic Fibrosis

All now recognize that cystic fibrosis is a genetically determined condition that often presents with pancreatic insufficiency, malabsorption, progressive, obstructive lung disease, and, in some, progressive biliary cirrhosis. Initially, with an incomplete understanding of the pathogenesis of this condition, patients died in childhood from severe lung failure.[18] However, the recent discovery that the cellular membrane transporter of chloride is defective in patients with cystic fibrosis, as well as cloning of the cystic fibrosis transmembrane conductance regulator,[19] promises more effective approaches to management of the pulmonary and gastrointestinal complication of this disorder. The association of genotypes with phenotypes in patients with cystic fibrosis has the potential to facilitate

the diagnosis and management of patients with cystic fibrosis.[20] The obvious extension of having cloned the gene is the potential for gene therapy to prevent the severe complications of the disease. Until this is established, however, patients with progressive disease leading to lung and liver failure may undergo combined lung and liver transplant as the ultimate "rescue" therapy. In addition, new therapeutic approaches to enhancing membrane chloride transport and to the prevention of *Pseudomonas* and other infections of the lung have met with some success.[21] This condition is also an example of a unique pancreatic disorder that presents in infancy and childhood. A complete discussion of the molecular biology of this disorder, its diagnosis, and approaches to treatment is found in Chapter 65.1, "Cystic Fibrosis."

Intrahepatic Cholestasis

Major advances have occurred in our understanding of the molecular mechanisms responsible for the formation and transport of bile in the liver and biliary tract. These are fully described in Chapter 55.6, "Biliary Transport." The recent discovery that the hydrolysis of adenosine triphosphate (ATP) is necessary for cannalicular transport of bile salts led to the finding that bile acid transporters are members of the ATP-binding cassette transporter superfamily of proteins. Many of these proteins, such as the bile salt export pump, have now been identified. Disorders such as Byler disease can now be renamed according to the defects in transport proteins that are responsible for them. This elucidation of the molecular and physiologic process of bile formation sets the stage for extraordinary advances in the diagnosis and treatment of these inherited disorders, as well as a whole host of disorders characterized by cholestasis found in both children and adults.

Technology

Technologic advances have clearly enhanced the ability to diagnose and treat many disorders of the liver, pancreas, and gastrointestinal tract that occur in infancy and childhood. These include the development of improved flexible instruments to perform safe upper tract and ileocolonoscopies on infants and small children.[22] Noninvasive ultrasonography, magnetic resonance imaging (MRI), and other radiologic imaging techniques have evolved to an extraordinary degree over the past quarter decade and have supported the earlier and safer diagnosis of life-threatening disorders of the liver, pancreas, and gastrointestinal tract even in fetal life. The use of parenteral nutrition to support the nutritional needs of infants and children with intractable diarrhea or short-bowel syndrome has been lifesaving.[23] The survival of patients supported by parenteral nutrition has also permitted in-depth molecular and physiologic investigations of a number of disorders, such as microvillus inclusion disease, epithelial cell dysplasia, and chronic intestinal pseudo-obstruction syndrome. Improvements in pediatric surgery and the establishment of liver and small intestinal transplant programs[24] have also helped save the lives of children with major inherited anomalies of the gut and liver and have established the pediatric gastroenterologist/hepatologist as an important member of the tertiary care team at major medical centers.

MAJOR DEFINING EVENTS IN THE SUBSPECIALTY

Centers of Excellence

In the early 1960s, small pediatrics-based centers of excellence in the care of children with gastrointestinal disorders formed and focused on common gastrointestinal problems unique to the referral region. For example, several centers in Europe and the United Kingdom specialized in the care of patients with celiac disease, whereas others in France and the United Kingdom began to attract infants with chronic, life-threatening liver diseases. Ultimately, these centers began to provide care for a broader-based spectrum of gastrointestinal disorders. With increasing interest in pediatric gastroenterology among academic pediatric centers, small "splinter groups" (eg, the "Pediatric Gut Club") began to have organized symposia at national pediatric meetings or as satellite symposia at meetings of adult gastroenterologists. As interest in this pediatric subspecialty grew, the need for a formally organized society emerged.

Pediatric Gastroenterology Societies

The natural evolution of the increasing interest in pediatric gastroenterology was the establishment of formal societies in the late 1960s or early 1970s. The European Society for Pediatric Gastroenterology was established in 1967 and held its first independent meeting in Paris in 1968 with representatives from the Netherlands, Sweden, France, Italy, and the United Kingdom.[25] This society grew steadily over the next three decades into the European Society for Pediatric Gastroenterology, Hepatology, and Nutrition (ESPGHAN), which exists today (currently with almost 600 members). The formal organization of a society has been a catalyst for increased numbers of European and United Kingdom pediatricians choosing to exclusively practice or conduct research in gastrointestinal diseases. Among other benefits, it has also led to the establishment of guidelines for the diagnosis and management of several common pediatric gastrointestinal diseases (eg, celiac disease, gastrointestinal allergy, neonatal hyperbilirubinemia).

The North American Society of Pediatric Gastroenterology, Hepatology and Nutrition (NASPGHAN) was established in 1973 as an extension of the informal Pediatric Gut Club. It sponsored an evening symposium at the annual meeting of the Society for Pediatric Research and American Pediatric Society. As additional physicians with an interest in pediatric gastroenterology or with formal gastrointestinal training joined the Society, the venue for its annual symposium moved to the American Gastroenterological Association's (AGA) national meeting. Finally, in 1984, the Society established its own independent annual meeting, which has occurred yearly since then, either separately or in conjunction with the ESPGHAN. The establishment of a formal society for pediatric gastroenterology in North America has led to subspecialty boards

and multiple formally constituted and recognized training programs (3 years duration) approved by the Accreditation Council on Graduate Medical Education (ACGME). NASPGHAN now has over 1,000 members. In the last two decades, additional international societies have been established in other parts of the world. In 1974, the Latin Society for Pediatric Gastroenterology and Nutrition (LASPGAN) was founded to formalize interaction among pediatric gastroenterologists in countries in South and Central America and to establish exchanges with NASPGHAN.

In like manner, in 1993, the Asian Pan Pacific Society of Pediatric Gastroenterology (APPSPGN) was established as an extension of a group of pediatricians interested in gastroenterology in Asia who had been informally meeting since the 1960s. This society began holding large meetings every other year in venues throughout Asia. In 1994, the Commonwealth Association of Pediatric Gastroenterology and Nutrition (CAPGAN) was founded to include both developing and industrialized countries that are or were part of the British Commonwealth. With the recognition that these new societies represented almost 2,500 physicians worldwide, the decision was made to hold a world congress every 4 years. This began with a highly successful first world congress held in Boston, Massachusetts, in 2000, which had over 3,000 attendees. The next world congress will be in Paris, France, in 2004 and is expected to have even more attendees. These meetings resulted in position papers defining and outlining management of several gastrointestinal conditions that are accepted as standard practice guidelines worldwide.[26] In addition, a Federation of Societies of Pediatric Gastroenterology, Hepatology and Nutrition was formed to coordinate the relationships and joint activities of the four major regional societies. A major benefit of these newly organized relationships has been the fostering of collaborative studies and exchange training programs, as well as greater awareness of major gastrointestinal health problems in developing countries. Recently, the National Institutes of Health (NIH) has made substantial efforts to foster collaborative studies of pediatric gastrointestinal and liver disorders as well. This includes multicenter programs to study acute liver failure, biliary atresia, and nonalcoholic fatty liver disease. These NIH-sponsored programs represent a major milestone in the development of pediatric gastroenterology.

Journal of Pediatric Gastroenterology and Nutrition

In 1982, the *Journal of Pediatric Gastroenterology and Nutrition* was first published as a private journal. In 1991, the journal became the official journal of ESPGAN and NASPGHAN, and, in 1995, the other two societies, LASPGN and APPSPGN, became affiliates with representation on the editorial board. This journal has expanded and now receives manuscripts from clinical and basic research physician scientists worldwide. Through this journal, societies can publish position papers, supplements from major meetings, abstracts from national meetings, and medical opinions from leaders in the field. It has also helped to establish the field of pediatric gastroenterology in the eyes of the medical community worldwide.

Role of Textbooks

Several major textbooks have been published in the field of pediatric gastroenterology. The first textbook in pediatric gastroenterology was published by Roy and colleagues in 1971.[27] In Europe, Anderson and Burke published a similar general text in 1975,[28] and Walker-Smith published a specialized text on diseases of the small intestine in childhood,[29] whereas Gryboski wrote a textbook describing gastrointestinal problems in infancy.[30] The first edition of our textbook was published in 1991,[31] and this effort continues today with the publication of this fourth edition. The proliferation of textbooks of pediatric gastroenterology, hepatology, and nutrition, as well as others that focus on pediatric gastroenterology, hepatology, or nutrition, underscores the assimilation of knowledge on disease states that define the subspecialty of pediatric gastroenterology. The amount of information and expanding literature in this field is accumulating at such a pace that we have decided to update our textbook with each world congress in an effort to provide a current and comprehensive reference for physicians caring for children with gastrointestinal problems.

THE DEVELOPING CHILD: A UNIQUE CHALLENGE TO THE PEDIATRIC GASTROENTEROLOGIST

In the introductory chapter to the third edition of this textbook, Dick Hamilton emphasized that the pediatric gastroenterologist must have an in-depth knowledge of the morphologic and functional development of the gastrointestinal tract to understand and manage gastrointestinal symptoms and disorders in pediatric patients. [32] For example, many infants may have regurgitation during early feeding in infancy.[33] This condition is usually not pathologic and improves with time as the gastrointestinal tract matures. At a later stage in life, however, the same persistent symptoms might portend serious disease such as obstruction or inflammation.[34] Without a complete knowledge of developing gut function in infancy, inappropriate diagnostic interventions could be instituted and unnecessary invasive therapy undertaken.

In contrast, a missed diagnosis of a serious gastrointestinal condition that affects gastrointestinal function could lead to severe "failure to thrive" and, if a chronic condition ensues, to growth retardation. Microvillus inclusion disease, Hirschsprung disease, and other congenital disorders of gut and liver function are examples of disorders that have been identified as a result of an expanding understanding of gut morphogenesis. Furthermore, a chronic condition such as inflammatory bowel disease that interferes with the child's emotional and physical development during the vulnerable period of adolescence might have a lifelong impact on adult stature and psychosocial stability if not treated properly. These problems need a specialized knowledge of the normal expected pattern of physical and psychological development in the pediatric patient and an

appreciation for the impact of chronic or serious illness on the child's quality of life. The pediatric gastroenterologist therefore needs to understand his or her patient population, know the unique age-related conditions that can affect the gastrointestinal tract, and be able to distinguish symptoms and signs that are related to gut development from that of serious disease. Said in another way, certain gastrointestinal signs occurring during different periods of life (infancy, childhood, and adolescence) often evoke a very different differential diagnosis and approach.

Two examples may underscore the uniqueness of caring for pediatric patients with gastrointestinal problems. A major diagnostic problem occurring during childhood that requires careful evaluation by the pediatric gastroenterologist is the child with recurrent abdominal pain (RAP). In most instances, RAP is not due to a serious "organic" gastrointestinal condition but instead may relate to stresses in the child's life, such as school adjustment problems, learning difficulties, a dysfunctional family situation, or a low pain threshold, all manifesting themselves as recurrent gastrointestinal symptoms (eg, pain, diarrhea, constipation).[35] The pediatric gastroenterologist (like his or her counterparts in internal medicine) must be able to separate complaints that originate from a serious physical gastrointestinal disorder (eg, early inflammatory bowel disease, *Helicobacter pylori* gastritis) from functional, often age-related, complaints. He or she must carefully decide on appropriate diagnostic tests without being too invasive or "feeding" into the child's or parent's fear of serious illness. If the symptoms of abdominal pain are diagnosed as functional RAP, the pediatric gastroenterologist must reassure the patient and parents without offending them and prepare an acceptable approach to management. The thoughtful consideration of RAP in this textbook provides a major insight into the diagnosis and management of this condition (see Chapter 14, "Abdominal Pain").

Another condition unique to pediatric gastroenterology is "breast milk colitis."[36] This condition presents with bloody diarrhea in infancy in young infants who are exclusively breastfed. Parents anxious about caring for a vulnerable newborn may overreact, fearing the worst for their baby. As pediatric gastroenterologists, we know that the immaturely developed mucosal immune system in neonates, activated by foreign proteins (cow's milk proteins) present in breast milk from the maternal diet and breast milk cytokines and other active immune factors, can temporarily cause sigmoid-rectal inflammation and blood in the stools. The condition is transient and requires either limiting the maternal diet or temporarily taking the infant off breast milk. Over time, the condition clears, and no residual intestinal problems persist. Our expanding understanding of the maturation and physiology of the gut immune system and the presence and function of biologically active factors in breast milk are areas of unique interest and importance to the pediatric gastroenterologist. With this knowledge and experience, infants with this and other immune-related inflammatory conditions can be spared unnecessary investigation and treatments. What we have just briefly described are but a few examples that underscore the need for subspecialists with formal credentials in pediatric gastroenterology and nutrition.

FUTURE OF THE SUBSPECIALTY: PEDIATRIC GASTROENTEROLOGY IN THE TWENTY-FIRST CENTURY

Having provided evidence for our specialty having "come of age" as an established component of pediatric medicine, let us speculate about the future of our field during the twenty-first century. Advances in medicine and science will make the future practice of pediatric gastroenterology an exciting and fulfilling professional experience. In the last few years, the Human Genome Project has been completed. With this database, we can systematically begin to identify genes that are responsible for organ development, as well as those that cause or influence the development of complex gastrointestinal conditions (eg, *CARD15/NOD2* mutations and Crohn disease). Because so many of the disorders seen by pediatric gastroenterologists have an inherited basis, they serve as biologic examples that lead to significant discoveries regarding the mechanisms of disorders that spread well beyond the sphere of pediatric gastroenterology.

As a result of the advances in molecular genetics, we will also be in a better position to make earlier diagnoses of chronic debilitating conditions (eg, cystic fibrosis, inflammatory bowel disease, celiac disease) before they cause irreversible damage to the pediatric patient. By providing genotype-phenotype associations with genetically determined diseases, we can modify the patient's environment to minimize the severity of disease expression. Patients can be tested for genetic responses to therapeutic interventions (eg, use of 6-mercaptopurine in inflammatory bowel disease patients). Effective gene therapy is clearly within sight. Using molecular and cellular biologic techniques, we can define the precise cellular mechanism of disease and ultimately develop genetic profiles that will allow patients to be identified before disease expression and its consequences occur. The challenge, of course, will be to identify only those who would actually develop disease and not to mislabel the otherwise healthy carrier of "disease-related" genes.

We have now begun to understand how microorganisms and their molecular patterns mediate health and disease in the gastrointestinal tract.[37] Several years ago, a molecular pattern recognition receptor for endotoxin (lipopolysaccharide [LPS]) was identified on intestinal lymphoid cells. This receptor was termed the Toll-like receptor (TLR) because of its conserved structure similar to the Toll receptor in *Drosophila melanogaster*, which determines organism orientation and innate immunity. This receptor was noted to have an intracellular signal transduction schema similar to the interleukin-1β receptor. Interaction with LPS resulted in an up-regulation of nuclear factor κB, an inflammatory cytokine transcription factor, which generated the inflammatory response to endotoxin. This discovery has led to a better understanding of the mechanism of endotoxin-induced shock and new approaches to its prevention. The TLR that principally interacts with LPS

is termed TLR4. In addition to this receptor, which has been cloned, nine other TLRs have been identified and cloned, and other molecular patterns of both gram-positive and gram-negative bacteria, as well as viruses, have been identified as their ligands. This genomic/molecular biologic discovery has opened up the field of innate immunity and has identified the role of the gut epithelium in its effector response. We now have a better sense of how intestinal pathogens and commensal organisms communicate with the gut through the epithelial surface lining or underlying lymphoid elements, with very important future health care implications for controlling infections that originate in the intestine and elsewhere.

As techniques for diagnosis improve and become less invasive (eg, MRI), we can pinpoint gastrointestinal lesions earlier and in smaller infants. New targeted forms of therapy that pose no health risk can be used to mitigate or even prevent disease (eg, probiotics and protective nutrients for preventing inflammatory conditions of the intestine). With a better understanding of the molecular mechanisms of disease and developmental pharmacology, drugs can be designed to treat a condition and, in particular, a specific patient without extensive adverse side effects. These are but a few of the many examples to be found in the following chapters of this textbook of extraordinary advances that will influence the direction of care of pediatric patients with gastrointestinal, liver, pancreatic, and nutritional disorders over the coming years.

SUMMARY AND CONCLUSIONS

In this introductory chapter of the fourth edition of this textbook, we have provided evidence to support the "coming of age" of the subspecialty of pediatric gastroenterology. In a brief summary, we have presented some of the defining "developmental" steps that have led to the formal establishment of the subspecialty of pediatric gastroenterology, hepatology, and nutrition. The importance of understanding the physical and emotional development of the infant and child cannot be overemphasized in the context of investigating and treating gastrointestinal conditions in pediatric patients. Thus, the pediatric gastroenterologist must have a complete understanding of pediatric development and gastrointestinal diseases unique to specific age groups, not only to optimally diagnose and manage symptoms and disorders but also to enhance the quality of life for children and adolescents.

The growth of our subspecialty has been extraordinary to be a part of and to behold. This is a very exciting time for medicine in general, no less so for those who have chosen to focus on the care of infants and children with disorders of the liver, pancreas, and gastrointestinal tract. The growth velocity of the knowledge base in this subspecialty is still increasing, as if it was still in its infancy. It has clearly matured beyond that stage. The current state of the art in the understanding and management of gastrointestinal disorders in pediatric patients is set forth in the current edition of this textbook. We also look forward enthusiastically to future editions and the wonderful, even amazing, advances that they will document.

CONTRIBUTORS

Ana Abad-Sinden, MS, RD, CNSD
Director, Dietetic Internship Program
Pediatric Nutrition Support Specialist
Department of Nutrition Services
University of Virginia Health System
Charlottesville, VA
Nutritional Therapy: Nutrition Support: Enteral Nutrition

David W. K. Acheson, MD, FRCP
Chief Medical Officer
Food and Drug Administration, Center for Food Safety and Applied Nutrition
College Park, Maryland
Infections: Food- and Waterborne Infections

Nadeem Ahmad Afzal, MBBS, MRCPCH, MRCP(UK)
Specialist Registrar
Center for Pediatric Gastroenterology
Royal Free Hampstead National Health Service Trust
London, England
Drug Therapy: Alternative Medical Treatment

Stephen John Allen, MD, MRCP, DTM&H
Honorary Consultant Paediatrician
Department of Paediatrics
Singleton Hospital
Senior Lecturer in Paediatrics
The Clinical School
University of Wales, Swansea
Swansea, Wales
Malnutrition

Karin Andersson, MD
Clinical and Research Fellow
Gastrointestinal Unit
Medical Services
Massachusetts General Hospital
Fellow
Harvard Medical School
Boston, Massachusetts
Infections: Food- and Waterborne Infections

Robert D. Baker, MD, PhD
Co-Director, Digestive Diseases and Nutrition Center
Department of Pediatrics
Children's Hospital of Buffalo
Professor of Pediatrics
Department of Pediatrics
State University of New York at Buffalo
Buffalo, New York
Nutritional Therapy: Nutrition Support: Parenteral Nutrition

Susan S. Baker, MD, PhD
Co-Director, Digestive Diseases and Nutrition Center
Department of Pediatrics
Children's Hospital of Buffalo
Professor of Pediatrics
Department of Pediatrics
State University of New York at Buffalo
Buffalo, New York
Nutritional Therapy: Nutrition Support: Parenteral Nutrition

William F. Balistreri, MD
Director, Division of Pediatric Gastroenterology, Hepatology and Nutrition
Department of Pediatrics
Cincinnati Children's Hospital Medical Center
Dorothy M.M. Kersten Professor of Pediatrics
Department of Pediatrics
University of Cincinnati College of Medicine
Cincinnati, Ohio
Approach to Neonatal Cholestasis

Sanjay Bansal, MD, MRCP
Senior Registrar
Department of Paediatric Hepatology
King's College Hospital
London, England
Acute Liver Failure

Ronald G. Barr, MDCM, FRCPC
Director
BC Research Institute for Children's and Women's Health
Centre for Community Child Health Research
Professor of Pediatrics
Faculty of Medicine
University of British Columbia
Vancouver, British Columbia, Canada
Colic and Gas

Dorsey M. Bass, MD
Attending Physician
Division of Gastroenterology
Department of Pediatrics
Lucile Packard Children's Hospital at Stanford
Associate Professor of Pediatrics
Department of Pediatrics
Stanford University
Palo Alto, California
Infections: Viral Infections

Susan V. Beath, MB, BS, BSc, MRCP(UK), DTM, FRCPCH
Consultant Paediatric Hepatologist
The Liver Unit
The Birmingham Children's Hospital
Honorary Senior Lecturer
The Institute of Child Health
The University of Birmingham
Birmingham, England
Intestinal Failure: Small Bowel Transplant

Dominique C. Belli, MD
Associate Professor
Department of Pediatrics
University of Geneva
Geneva, Switzerland
Gastrointestinal Endoscopy: Upper Gastrointestinal Endoscopy

Suzanne Bender, MD
Staff Psychiatrist, Consultant GI Pediatric Clinic
Department of Psychiatry
Massachusetts General Hospital
Clinical Instructor
Department of Psychiatry
Harvard University Medical School
Boston, Massachusetts
Management of Surgical Patients: Psychological Aspects

Keith J. Benkov, MD
Chief of Pediatric Gastroenterology
Department of Pediatrics
Mount Sinai Medical Center
Associate Professor
Department of Pediatrics
Mount Sinai School of Medicine
New York, New York
Imaging: Cross-Sectional Imaging: Ultrasonography, Computed Tomography, Magnetic Resonance Imaging

Jorge A. Bezerra, MD
Staff Physician
Division of Pediatric Gastroenterology, Hepatology and Nutrition
Cincinnati Children's Hospital Medical Center
Associate Professor of Pediatrics
Department of Pediatrics
University of Cincinnati College of Medicine
Cincinnati, Ohio
Disorders of the Biliary Tract: Biliary Atresia

Julie E. Bines, MD, FRACP
Head of Clinical Nutrition, Consultant Gastroenterologist
Department of Gastroenterology and Clinical Nutrition
Royal Children's Hospital
Associate Professor
Department of Pediatrics
University of Melbourne
Victoria, Australia
Parenteral Nutrition–Associated Liver Disease

Billy Bourke, MD, FRCPI
Consultant Gastroenterologist
Department of Pediatrics
Our Lady's Hospital for Sick Children
Senior Lecturer
Department of Pediatrics
University College Dublin
Dublin, Ireland
Gastritis: Helicobacter pylori *and Peptic Ulcer Disease*

Athos Bousvaros, MD
Associate Director of the Inflammatory Bowel Disease Center
Combined Program in Pediatric Gastroenterology and Nutrition
Children's Hospital Boston
Assistant Professor of Pediatrics
Department of Pediatrics
Harvard Medical School
Boston, Massachusetts
Drug Therapy: Immunosuppressive Therapies

Kevin Bove, MD
Pathologist
Department of Pathology
Cincinnati Children's Hospital Medical Center
Professor
Department of Pathology
University of Cincinnati College of Medicine
Cincinnati, Ohio
Genetic and Metabolic Disorders: Lysosomal Acid Lipase Deficiencies: Wolman Disease and Cholesteryl Ester Storage Disease

John T. Boyle, MD
Division Chief
Division of Pediatric Gastroenterology & Nutrition
Children's Hospital of Alabama
Professor of Pediatrics
University of Alabama-Birmingham School of Medicine
Birmingham, Alabama
Abdominal Pain

Darla J. Bradshaw, BS, RD, CNSD
Clinical Dietitian
Department of Clinical Nutrition
The Children's Hospital of Philadelphia
Philadelphia, Pennsylvania
Nutritional Therapy: Special Dietary Therapy

Annemarie Broderick, MB, BCh, MRCPI, MMedSc
Department of Pediatrics
University College Dublin
Children's Research Centre, Our Lady's Hospital for Sick Children
Crumlin, Dublin, Ireland
Gallbladder Disease

Nicole Brousse, MD, PhD
Professor of Pathology
Department of Pathology
Hôpital Necker-Enfants Malades
Université René Descartes
Paris, France
Enteropathy: Autoimmune Enteropathy

Ross N. Butler, PhD
Chief Medical Scientist
Department of Gastroenterology
Women's and Children's Hospital
Doctor
Department of Paediatrics
University of Adelaide
North Adelaide, South Australia
Breath Analysis

Assad M. Butt, MB, BS, DCH(Lon), MRCP, CPCH
Consultant in Pediatric Gastroenterology and Nutrition
Department of Pediatrics
The Royal Alexandra Hospital for Sick Children
Consultant in Pediatric Gastroenterology and Nutrition
Department of Pediatrics
Brighton and Sussex University Hospitals
Brighton, England
Pancreas: Tumors

Kathleen M. Campbell, MD
Fellow
Division of Pediatric Gastroenterology, Hepatology, and Nutrition
Cincinnati Children's Hospital Medical Center
Fellow
Department of Pediatrics
University of Cincinnati College of Medicine
Cincinnati, Ohio
Disorders of the Biliary Tract: Biliary Atresia

Michael Caplan, MD
Chair, Department of Pediatrics
Evanston Northwestern Healthcare
Associate Professor of Pediatrics
Department of Pediatrics
Northwestern University, Feinberg School of Medicine
Evanston, Chicago, Illinois
Necrotizing Enterocolitis

Helen Carty, FRCR, FRCPI, FRCP, FRCPCH, FFRRCSI(Hon)
Professor of Paediatric Radiology
Department of Radiology
Royal Liverpool Children's Hospital NHS Trust-Alder Hey
Professor of Paediatric Radiology
Department of Medical Imaging
University of Liverpool
Liverpool, England
Imaging: Plain Radiographs and Contrast Studies

David Casson, BA, MBBS, MRCPI
Doctor
Department of Medicine
Royal Liverpool Children's Hospital National Health Service Trust-Alder Hey
Honorary Lecturer
Department of Medicine
University of Liverpool
Liverpool, England
Imaging: Radionuclide Diagnosis

Peter G. Chait, MBBCh(Rand)(D), SA, FRCPR(Eng)
Interventional Radiologist
Department of Diagnostic Imaging
Hospital for Sick Children
Professor
University of Toronto
Toronto, Ontario
Imaging: Interventional Gastrointestinal Radiology

Mei-Hwei Chang, MD
Chair, Department of Pediatrics
National Taiwan University Hospital
Professor
Department of Pediatrics
College of Medicine, National Taiwan University
Taipei, Taiwan
Postnatal Infections: Viral Hepatitis B

Denesh K. Chitkara, MD
Assistant in Medicine
Combined Program in Pediatric Gastroenterology and Nutrition
Children's Hospital Boston
Instructor
Department of Pediatrics
Harvard Medical School
Boston, Massachusetts
Genetic and Metabolic Disorders: Wilson Disease

Erika C. Claud, MD
Associate Neonatalogist
Division of Neonatology
University of Chicago Children's Hospital
Asssitant Professor of Pediatrics
University of Chicago School of Medicine
Chicago, Illinois
Necrotizing Enterocolitis

Geoffrey Cleghorn, MBBS, FRACP, FACG
Senior Specialist
Department of Gastroenterology
Royal Children's Hospital
Associate Professor and Head
Department of Pediatrics and Child Health
University of Queensland
Brisbane, Queensland, Australia
Drug Therapy: Pharmacologic Therapy of Exocrine Pancreatic Insufficiency

Mitchell B. Cohen, MD
Attending Physician
Division of Pediatric Gastroenterology, Hepatology and Nutrition
Cincinnati Children's Hospital Medical Center
Professor
Department of Pediatrics
University of Cincinnati College of Medicine
Cincinnati, Ohio
Secretory Tumors

Frances Laura Connor, MBBS, FRACP
Research Fellow
Division of Pediatric Gastroenterology
Children's Hospital of Pittsburgh
Research Fellow
Department of Pediatrics
University of Pittsburgh School of Medicine
Pittsburgh, Pennsylvania
Motility and *Drug Therapy: Motility*

Andrew B. Cooper, PhD
Research Assistant Professor
Department of Natural Resources
College of Life Sciences and Agriculture
University of New Hampshire
Durham, New Hampshire
Study Design: Methodology (Statistical Analysis, Test Interpretation, Basic Principles of Screening with Application for Clinical Study)

Catherine Cord-Udy, MBBS, FRACS(Paed Surg)
Consultant, Paediatric Surgeon
Department of Paediatric Surgery
The Royal London Hospital
London, England
Management of Surgical Patients: The Pediatric Ostomy

Richard T. Lee Couper, MD
Senior Paediatric Gastroenterologist
Department of Gastroenterology
Women's & Children's Hospital
Senior Paediatric Gastroenterologist
Department of Paediatrics
University of Adelaide
Adelaide, South Australia
Pancreatic Function Tests

Joseph M. Croffie, MD, MPH
Director, Pediatric GI Motility Laboratory
Division of Pediatric Gastroenterology, Hepatology and Nutrition
James Whitcomb Riley Hospital for Children
Associate Professor of Clinical Pediatrics
Department of Pediatrics
Indiana University School of Medicine
Indianapolis, Indiana
Hypomotility Disorders: Idiopathic Constipation

Carla D. Cuthbert, PhD
Fellow, Clinical-Biochemical Genetics
Department of Laboratory Medicine and Pathology
Mayo Medical School
Rochester, Minnesota
Genetic and Metabolic Disorders: Inherited Abnormalities In Mitochondrial Fatty Acid Oxidation

Steven J. Czinn, MD
Chief, Division of Pediatric Gastroenterology
Department of Pediatrics
Rainbow Babies and Children's Hospital
University Hospital Health System
Professor
Departments of Pediatrics and Pathology
Case Western Reserve University School of Medicine
Cleveland, Ohio
Inflammation

Danita I. Czyzewski, PhD
Pediatric Psychologist
Department of Psychiatry/Psychology Service
Texas Children's Hospital
Assistant Professor
Department of Psychiatry and Behavioral Science and Pediatrics
Baylor College of Medicine
Houston, Texas
Nutritional Therapy: Feeding Difficulties

Geoffrey P. Davidson, MBBS, MD, FRACP
Director
Centre for Paediatric and Adolescent Gastroenterology
Women's and Children's Hospital
Professor
Department of Paediatrics
University of Adelaide
North Adelaide, South Australia
Breath Analysis

Guilio De Marco, MD
Clinical Assistant
Department of Pediatrics
Division of Infectious Diseases
Research Assistant
Department of Pediatrics
University Federico II of Naples
Naples, Italy
Persistent Diarrhea

Gustavo Andrade de Paulo, MD, MSc
Hospital Albert Einstein
Endoscopy Unit
Universidad Federal de São Paolo-Escola Paulista de Medicina
Department of Gastroenterology
São Paolo, Brazil
Gastrointestinal Endoscopy: Endoscopic Retrograde Cholangiopancreatography

Lee A. Denson, MD
Attending Physician
Department of Pediatric Gastroenterology
Division of Pediatric Gastroenterology, Hepatology and Nutrition
Cincinnati Children's Hospital Medical Center
Assistant Professor
Department of Pediatrics
University of Cincinnati College of Medicine
Cincinnati, Ohio
Postnatal Infections of the Liver: Other Viral Infections

Anil Dhawan, MD, FRCPCH
Deputy Director
Paediatric Liver Services
King's College Hospital
Honorary Senior Lecturer
Department of Paediatrics
Guy's, King's and St. Thomas' School of Medicine
London, England
Acute Liver Failure

Carlo Di Lorenzo, MD
Director, Motility Center
Division of Pediatric Gastroenterology
Children's Hospital of Pittsburgh
Professor
Department of Pediatrics
University of Pittsburgh School of Medicine
Pittsburgh, Pennsylvania
Motility and *Drug Therapy: Motility*

Conor Doherty, MB, BS, MRCP, DTM&H
Clinical Scientist
Keneba Field Station
Medical Research Council (UK) Laboratories
The Gambia, Africa
Growth Failure

Ranjan Dohil, MBBCh, MRCP(UK)
Staff Physician
Division of Pediatric Gastroenterology
Children's Hospital and Health Center
Associate Clinical Professor
Department of Pediatrics
University of California, San Diego
San Diego, California
Gastritis: Other Causes

Malcolm Donaldson, MD, FRCP, FRCPCH, DCH
Doctor
Royal Hospital for Sick Children
Department of Child Health
Glasgow University
Glasgow, Scotland

Assistant in Medicine
Combined Program in Pediatric Gastroenterology and Nutrition
Children's Hospital Boston
Instructor
Department of Pediatrics
Harvard Medical School
Boston, Massachusetts
Inflammatory Bowel Disease: Ulcerative Colitis

Alison G. Hoppin, MD
Assistant Pediatrician
Combined Program in Pediatric Gastroenterology and Nutrition
Massachusetts General Hospital for Children
Instructor
Department of Pediatrics
Harvard Medical School
Boston, Massachusetts
Obesity and *Intestinal Tumors: Other Neoplasms*

Simon Horslen, MB, ChB, FRCPCH
Associate Professor
Department of Pediatrics
University of Nebraska Medical Center
Omaha, Nebraska
Genetic and Metabolic Disorders: Carbohydrate Metabolism

Sarah Hotchkin, RN
Specialist Sister, Paediatric Surgery and Stoma Care
The Royal London Hospital
London, England
Management of Surgical Patients: The Pediatric Ostomy

Jean-Pierre Hugot, MD, PhD
Professor
Department of Pediatric Gastroenterology and Nutrition
Hôpital Robert Debré
Professor
Faculté de Médecine Bichat
Université Paris VII
Paris, France
Inflammatory Bowel Disease: Crohn Disease

Essam Imseis, MD
Fellow, Divison of Gastroenterology and Nutrition
C. S. Mott Children's Hospital
Department of Pediatrics and Communicable Diseases
University of Michigan School of Medicine
Ann Arbor, Michigan
Hypomotility Disorders: Hirschsprung Disease

Elizabeth Iofel, MD
Attending Physician in Gastroenterology and Nutrition
Department of Pediatrics
Schneiders Children's Hospital North Shore/Long Island Jewish Health System
Assistant Professor
Department of Pediatrics
Albert Einstein College of Medicine
New Hyde Park/Bronx, New York
Postnatal Infections of the Liver: AIDS and Other Immune Disorders

Erika Isolauri, MD, PhD
Professor of Pediatrics
Department of Pediatrics
University of Turku
Turku, Finland
Drug Therapy: Modulation of Intestinal Flora: Probiotics

Shinya Ito, MD
Head, Division of Clinical Pharmacology and Toxicology
Hospital for Sick Children
Associate Professor
Department of Pediatrics
University of Toronto
Toronto, Ontario, Canada
Gastrointestinal Injury: Drug-Induced Bowel Injury

Tom Jaksic, MD, PhD
Attending Surgeon
Children's Hospital, Boston
Associate Professor
Department of Surgery
Harvard Medical School
Boston, Massachusetts
Benign Perianal Lesions

Dominique M. Jan, MD
Visiting Attending Surgeon
Department of Surgery, Center for Liver Disease and Transplantation
New York Presbyterian Hospital
Visiting Professor
Department of Surgery
Columbia University
New York, New York
Pancreas: Congenital Anomalies

Sidney Johnson, MD
Chief Surgical Resident
Department of Surgery
Children's Hospital Boston
Harvard Medical School
Boston, Massachusetts
Benign Perianal Lesions

Christopher D. Jolley, MD
Attending Physician
Division of Pediatric Gastroenterology
Department of Pediatrics
Shands Children's Hospital
Assistant Professor
Department of Pediatrics
University of Florida College of Medicine
Gainesville, Florida
Postnatal Infections of the Liver: Hepatitis C Virus

Nicola L. Jones, MD, FRCPC, PhD
Staff Gastroenterologist
Department of Paediatrics
Hospital for Sick Children
Assistant Professor
Departments of Paediatrics and Physiology
University of Toronto
Toronto, Ontario, Canada
Microbial Interactions with Gut Epithelium

Saul Karpen, MD, PhD
Director, Texas Children's Liver Center
Division of Gastroenterology, Hepatology and Nutrition
Texas Children's Hospital
Associate Professor
Departments of Pediatrics and Molecular and Cellular Biology
Baylor College of Medicine
Houston, Texas
Liver Function and Dysfunction: Bile Formation and Cholestasis

Stuart S. Kaufman, MD
Staff Physician
Department of Gastroenterology
Children's National Medical Center
Medical Director, Small Bowel Transplant Program
Transplant Institute
Georgetown University
Washington, District of Columbia
Intestinal Failure: Outcomes

Richard I. Kelley, MD, PhD
Director
Department of Metabolism
Kennedy Krieger Institute
Professor
Department of Pediatrics
Johns Hopkins University School of Medicine
Baltimore, Maryland
Genetic and Metabolic Disorders: Zellweger Syndrome and Other Disorders of Peroxisomal Metabolism

Deirdre Kelly, MD, FRCP, FRCPI, FRCPCH
Consultant Paediatric Hepatologist
Birmingham Children's Hospital
Professor of Paediatric Hepatology
University of Birmingham School of Medicine
Birmingham, England
Liver Transplant

Paul Kelly, MD, FRCP
Reader
Department of Gastroenterology
Barts & The London School of Medicine
London, England
Gastrointestinal Manifestations of Immunodeficiency: HIV and Other Secondary Immunodeficiencies

Simon Edward Kenny, BSc(Hons), MB ChB(Hons), MD, FRCS(Paed Surg)
Consultant Paediatric Surgeon
Department of Pediatric Surgery
Alder-Hey Children's Hospital
Honorary Senior Lecturer in Paediatric Surgery
Department of Child Health
University of Liverpool School of Medicine
Liverpool, England
Intestine: Congenital Anomalies

Seema Khan, MD
Attending Physician
Division of Gastroenterology and Nutrition
Children's Hospital of Pittsburgh
Assistant Professor
Department of Pediatrics
University of Pittsburgh School of Medicine
Pittsburgh, Pennsylvania
Gastroesophageal Reflux

Barbara S. Kirschner, MD

DEDICATION

To Michael (Pic) Walker and Heather McDonald Walker in celebration of their union and as role models for life.

WAW

I wish to acknowledge my cherished French colleagues, professors Jean Rey, Claude Ricour, and Jacques Schmitz, who encouraged me to enter the exciting field of research and clinical practice in pediatric gastroenterology and nutrition, and Professor Allan Walker, who invited me to be one of the two European associate editors of this fourth edition. To my wife Véronique and our children, Pierre-Arthur, Charles, Alix, and Marine, who have supported me in my work for so many years.

OJG

To Allan Walker, who has inspired all of us in this discipline of pediatric gastroenterology and nutrition with his energy, wisdom, and imagination to dedicate our efforts to improving the lives of children with gastrointestinal, liver, pancreatic, and nutritional disorders; who has been and continues to be my mentor and close friend and a source of sage advice for over 25 years; and who remains the standard bearer for those who wish to advance the science and practice of medicine for pediatric patients. With deep gratitude.

REK

To Megan, David, and Rachael for their support.

PMS

To Julia and Vita with love.

IRS

To my wife Abigail and my daughters Caitlin and Elizabeth for their constant love and support, without which this and many of my other professional activities would not have been possible, and to my many mentors and colleagues in pediatric hepatology, including, most notably, Drs. Frederick Suchy, Peter Whitington, and Alex Mowat.

BLS

PREFACE TO THE FIRST EDITION

Over the last two decades, the field of pediatric gastroenterology has developed from an obscure subspecialty to an essential component of every major academic pediatric program throughout the world. Among the many pediatric texts available, none deals extensively with the pathophysiologic basis of gastrointestinal disease in children of all ages. Contributors to this text have been asked to undertake their writing with a plan to fill this void, extending pathophysiologic considerations to their coverage of diagnosis and management as well. In tandem with development of the subspecialty the literature of gastrointestinal and hepatic entities as they pertain to the pediatric patient has grown. Accordingly, we have prepared an approach to the subject that should provide a reference text for pediatricians, gastroenterologists, and pediatric gastroenterologists alike.

This new multivolume textbook is dedicated to establishing a comprehensive approach to pediatric gastroenterology. Each author was carefully selected to provide an authoritative, comprehensive, and complete account of his assigned topic. We have devised an approach to dealing with the families of children with gastrointestinal diseases, and a pathophysiologic section examines cardinal manifestations of gastrointestinal disease as well as the development of the gastrointestinal tract. These sections help to augment an in-depth approach to disease manifestations and management. A careful and unique approach to diagnosis of gastrointestinal diseases in children follows. Finally, the principles of therapy are explored. We hope and expect that this collective approach will be beneficial to all physicians dealing with gastrointestinal problems in children.

PREFACE TO THE FOURTH EDITION

The fourth edition of this textbook, published in time for the Second World Congress of Pediatric Gastroenterology, Hepatology, and Nutrition, to be held in Paris, France, in July 2004, has been planned to update pediatricians caring for children with gastrointestinal and liver diseases worldwide and to provide the most recent, cutting-edge developments in our field. In a recent article in *Pediatric Research* reviewing the development of our subspecialty, it was stated that evidence for the field "having arrived" as a discipline in pediatric medicine was the publication of a textbook exclusively devoted to pediatric gastroenterology.[1] This edition of the textbook has made major strides in covering the most important aspects of physiology and pathophysiology, clinical presentation of disease, clinical manifestations and management, diagnostic approach, and

principles of therapy. As genetics and molecular biology, as well as areas of interest in certain aspects of disease, have expanded, we have added additional chapters to comprehensively cover these new developments. Conversely, as diseases have become less prevalent, we have decreased their emphasis in the textbook. Hence, we believe that the current edition is up to date with the needs of the field.

With this edition, the editorship of the textbook is being passed to a new generation of experts in the field. We thank Drs. Durie, Hamilton, Walker-Smith, and Watkins for their contributions over the last three editions. Dr. Walker has continued with the fourth edition to pave the way for the new editors: Drs. Kleinman and Shneider from the United States, Dr. Sherman from Canada, and Drs. Goulet and Sanderson from Europe. It is hoped that this textbook will continue in perpetuity under their able leadership.

To keep up with the ever-increasing growth of information in this rapidly advancing field, we have chosen to produce a fourth edition in 2004. The size and content of each section have been modified. This revision is dedicated to the maintenance of a comprehensive approach to the practice of pediatric gastroenterology. Each author, whether newly chosen or retained from the third edition, has been selected because of a particular expertise in a specific field. Each author has provided an authoritative and comprehensive account of his or her topic. For example, in the fourth edition, we have separated pathophysiology from clinical syndromes by establishing Section 2, "Clinical Presentation of Disease," and Section 3, "Clinical Manifestations and Management." We have also added new chapters on study design (outcomes, methodology, and ethics) to the diagnosis section entitled "Diagnosis of Gastrointestinal Diseases" to reflect increasing interest in clinical investigation and the evidence-based approach to disease management. We have also added a section on prebiotics and probiotics to reflect this alternative medical approach to the treatment of pediatric gastrointestinal diseases and have also extended the section devoted to clinical nutrition. We believe that these modifications have resulted in a more "user-friendly" textbook.

To give the readership a perspective on the evolution of this textbook, we have included the preface from the first edition published almost 13 years ago. It has been an exciting adventure for the editors to contribute in a small way to the overall development of the practice of gastroenterology by pediatricians. We hope that you enjoy this latest edition.

The editors wish to again thank Ms. Suzzette McCarron for her organizational talents and her ability to liaise among authors, editors, and the publisher. Without her extensive efforts, this textbook would never have been possible. The editors are also grateful to Mr. Brian Decker, Patricia Bindner, and the able staff of BC Decker Inc for their help and support in further developing this edition and in the publication of this textbook.
