
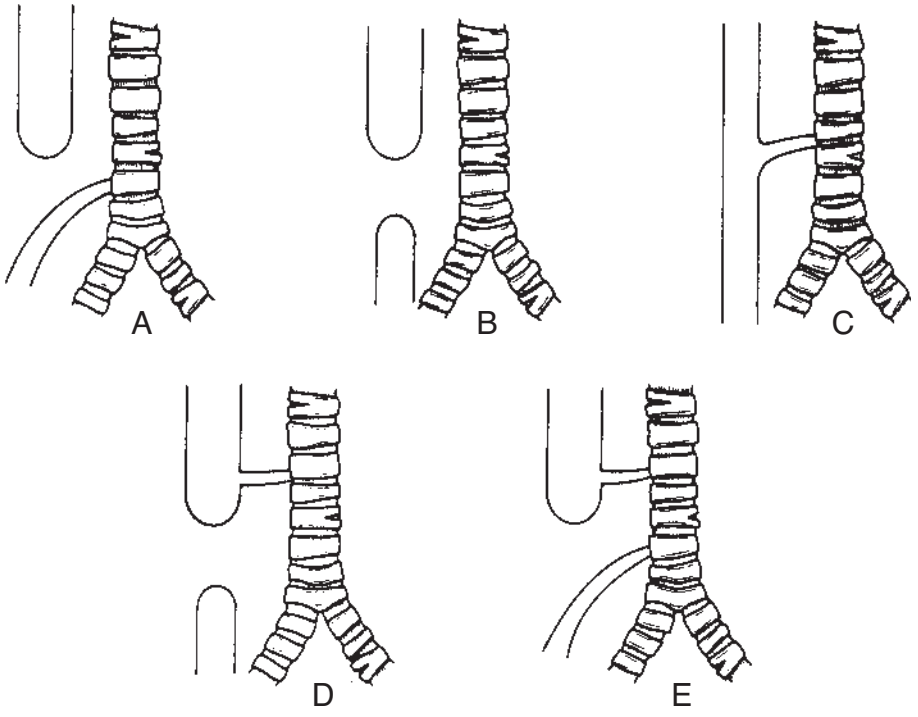

FIGURE 22-1 Types of esophageal atresia with or without fistula. The incidence of each is as follows: *A,* esophageal atresia (EA) with distal tracheoesophageal fistula (TEF), 85%; *B,* EA without TEF, 8%; *C,* isolated TEF, 4%; *D,* EA with proximal TEF, 2%; *E,* EA with distal and proximal TEF, < 1%. By Jean Hyslop, Medical Artist, Royal Hospital for Sick Children, Yorkhill, Glasgow, UK.

The diagnosis is facilitated by the attempted introduction of a nasogastric tube that meets resistance prior to entering the stomach as it coils in the esophagus. A radiograph with the tube in place reveals the coiled esophageal tube. The presence of a TEF is recognized by the presence of intestinal air. The introduction of contrast into the proximal pouch is hazardous owing to the aspiration risk and is typically not warranted. Preoperative bronchoscopy is recommended by some to localize the fistula, exclude an upper pouch fistula, and identify a right-sided aortic arch. Echocardiography is also typically performed preoperatively to assess for associated cardiac defects and determine the laterality of the aortic arch, and thus allow for decision making as to the surgical approach.[45] A right-sided arch occurs in less than 2% of the cases.

The rarer H-type TEF (4%) can be more difficult to diagnose because patients may not be as symptomatic in the immediate newborn period. Patients often present with a history of choking and respiratory difficulty with feeds. They may also have a history of recurrent pneumonia or asthma. Routine esophagography may fail to demonstrate the fistulous connection; therefore, if there is a high index of suspicion, the study should be performed via a nasogastric tube that is slowly withdrawn into the esophagus so that better visualization of the esophageal mucosa can be obtained. Esophagogastroscopy similarly may not be able to visualize the fistula, whereas bronchoscopy is typically the test of choice.

If possible, endotracheal intubation prior to surgey should be avoided because air introduced into the bowel via the TEF can cause abdominal distention and potential perforation.[51] The surgical approach is via a standard extrapleural thoracotomy with division of the fistula and single-layer end-to-end anastomosis using polyglycolic acid sutures. The two ends of the esophagus are typically within 2 cm, allowing anastomosis. Long gap atresias of greater than 2.5 cm pose special problems and may necessitate colonic interposition or pulling the stomach proximately into the chest to allow continuity. The use of drainage tubes or gastrostomy has been abandoned, and early alimentation is practiced.[52] In long gap esophageal atresia with or without TEF in which anastomosis cannot be accomplished despite lengthening myotomies, ligation of the fistula, if present, and gastrostomy with delayed primary repair have been advocated, particularly in small for date or preterm infants. Suctioning of secretions from the proximal pouch or creation of a "spit fistula" is required until subsequent reanastomosis.

Postoperatively, there is a risk of anastomotic leak (10–17%),[52] leading to formation of a salivary fistula, pneumonitis, and/or mediastinitis. Salivary fistula may respond to prolonged parenteral nutrition, ventilatory support, and antibiotics. After the immediate postopera-

tive period, patients are at risk for anastomotic strictures, which may require dilatation, or reanastomosis. If the stricture is resistant to dilatation, it is likely due to concomitant gastroesophageal reflux disease, with acid-related inflammation.

Gastroesophageal reflux is a common problem owing to the impaired esophageal peristalsis. Clinically, the incidence is thought to be between 25 and 40%; however, when pH monitoring is performed, the incidence rises to 70%.[52] Poorly controlled reflux can result in acid-related strictures or life-threatening aspiration pneumonia. Antireflux surgery is considered for those patients with persistent difficulties despite medical therapy. However, fundoplication carries a 25% risk of recurrent reflux, and in these patients with poor esophageal motility difficulty, postoperative dysphagia and food impaction have been observed.[51]

Tracheomalacia or other structural tracheal anomalies can occur in up to 75% of patients.[52] Some may have severe manifestations and require either tracheostomy or aortopexy. Other, less affected individuals have noisy breathing, stridor, or a "barky" cough. Tracheal anomalies appear to occur only in the presence of a TEF and are not seen in isolated esophageal atresia.[52]

Poor outcome is still seen in children with low birth weight (< 1,500 g) and major cardiac anomalies. These risk factors are reflected in the Waterston (Table 22-8) and Spitz (Table 22-9) classification schemes for prediction of outcomes in children with esophageal atresia and TEF. Among the infants in the original Waterston report, group A had a 95% survival, group B had a 68% survival, and 6% of group C survived.[53] With advances in neonatology, reclassification does not include respiratory illness as a separate risk factor. According to the Spitz classification, in the absence of low birth weight and cardiac anomalies (group I), there is a 97% survival, 57% if one risk factor is present (group II), and 22% if both are present (group III).[45]

CONGENITAL LARYNGOTRACHEOESOPHAGEAL CLEFT

The first laryngotracheoesophageal cleft was described by Richter in 1792, who palpated a common cavity at the level of the larynx and hypopharynx in a newborn with feeding difficulties.[54]

The respiratory system develops as a foregut outpouching starting at day 20 of gestation. An abnormality in tracheoesophageal septum formation or progression accounts for a laryngotracheoesophageal cleft involving the tracheal rings. Failure of cricoid fusion may occur following failure of the septum to reach the appropriate level. Absence of cricoid fusion in isolation results in a laryngeal cleft.[54]

Numerous classification schemes have been devised. The most commonly quoted is that devised by Ryan in which type I is a cleft above the cricoid, type II is beyond the cricoid lamina, type III is up to the carina, and type IV is into the mainstem bronchi (Figure 22-2).[54]

Most cases appear to be sporadic; however, a mouse model exists in which a laryngotracheoesophageal cleft is inherited as an autosomal recessive mutation. Laryngotracheoesophageal clefts are seen in up to 50% of patients with Opitz (BBB/G) syndrome. They also are seen with other anomalies, including TEF, anal atresia, malrotation, microgastria, and bronchobiliary fistula. Cardiac anomalies occur in up to one-third of cases and include VSD, PDA, coarctation of the aorta, and transposition of the great vessels. Associations with hypospadia, unilateral lung hypoplasia, and renal agenesis have also been reported.[54]

Neonatal symptoms may be subtle or obvious, with respiratory distress owing to recurrent aspiration pneumonia. One may also see cyanosis, coughing, choking, stridor exacerbated by feeds, sialorrhea, or a weak, toneless, or hoarse cry.

Chest radiography may reveal an aspiration pneumonia, persistent esophageal air, and distended bowel. Nasogastric tubes may be noted to be displaced along the anteroposterior plane on lateral radiography. CT and bronchoscopy can help to define the extent of the laryngotracheoesophageal cleft. The presence of an intact arytenoid fold excludes the diagnosis of a cleft. Swallowing studies with small volumes show simultaneous filling of the esophagus and trachea.[54]

Surgical repair is the definitive treatment. The most common approach is a lateral pharyngotomy through a vertical lateral cervical incision. Care must be taken not to damage the recurrent larygeal nerve on the side opposite the approach. All but the smallest clefts will require tracheostomy, and specialized tubes have been developed to prevent pressure on the posterior wall. Postoperative complications include fistulization, granulation tissue at the repair site, esophageal and subglottic stenosis, nerve injury, and aspiration.[54]

After repair, esophageal dysmotility still places the patient at risk for aspiration. Gastric division with a draining gastrostomy in the proximal segment and a feeding gastrostomy in the distal segment is widely used to protect the esophageal anastomosis. Alternatively, fundoplication with feeding gastrostomy or jejunostomy may suffice. After healing, feeding therapy is often required.[54]

TABLE 22-8 WATERSTON CLASSIFICATION OF INFANTS WITH ESOPHAGEL ATRESIA WITH TRACHEOESOPHAGEAL FISTULA

A	Birth weight over 5.5 pounds and well
B	Birth weight between 4 and 5.5 pounds and well, or higher birth weight with moderate pneumonia and other congenital anomalies
C	Birth weight under 5 pounds or higher birth weight but severe pneumonia and severe congenital anomalies

Adapted from Waterston D et al.[53]

TABLE 22-9 SPITZ CLASSIFICATION OF INFANTS WITH ESOPHAGEAL ATRESIA WITH TRACHEOESOPHAGEAL FISTULA

I	Birth weight greater than or equal to 1.5 kg and no congenital heart disease
II	Birth weight less than 1.5 kg or congenital heart disease
III	Birth weight less than 1.5 kg and congenital heart disease

CHAPTER 23

DISORDERS OF DEGLUTITION

David N. Tuchman, MD

The pediatric patient with impaired swallowing poses a number of unique problems for the clinician. In contrast to adults, issues such as the growth and development of the swallowing apparatus, the development of normal oromotor reflexes, the maturation of feeding behavior, the importance of oral feeding in the development of parent-child bonding, the acquisition of adequate nutrition for somatic growth, and the effects of non-nutritive sucking on growth must be considered in the approach to this group of patients. In addition, some groups of patients with impaired swallowing lack the cognitive skills necessary to follow specific therapeutic recommendations (eg, those in the infant age group and children with central nervous system disease), a situation that complicates patient management.

NORMAL DEGLUTITION

The swallowing apparatus transports materials from the oral cavity to the stomach without allowing entry of substances into the airway. To accomplish safe swallowing, there must be precise coordination between the oral and pharyngeal phases of swallowing so that the pharyngeal swallow is initiated at the appropriate moment after the onset of bolus movement. The passage of an oral bolus without aspiration is the result of a complex interaction of cranial nerves and muscles of the oral cavity, pharynx, and proximal esophagus.[1,2]

Deglutition is generally divided into three phases based on functional and anatomic characteristics: oral, pharyngeal, and esophageal.[1,2] The oral stage, which is voluntary, involves a preparatory phase. In the unimpaired child, the oral cavity functions as a sensory and motor organ, changing the physical properties of the food bolus to make it safe to swallow. The oral bolus is modified to allow passage through the pharynx without entry into the larynx or the tracheobronchial tree. Physical properties of the food bolus altered by oral activity include size, shape, volume, pH, temperature, and consistency.[3]

The food bolus then moves into the pharynx, where the respiratory and gastrointestinal tracts interface. Passage of food through this region requires an efficient mechanism to safely direct food into the esophagus. During the pharyngeal phase, the swallow is reflexive and involves a complex sequence of coordinated motions. The pharyngeal phase, which lasts for approximately 1 second, generally consists of the elevation of the entire pharyngeal tube, including the larynx, followed by a descending peristaltic wave. In the adult, this action takes about 100 ms. Food is then injected from the pharynx into the esophagus forcefully, at velocities as high as 100 cm/s.[4,5] Approximately 600 to 900 ms after the onset of the pharyngeal phase, food passes through the upper esophageal sphincter (UES) and enters the esophagus. The cricopharyngeal (CP) muscle, the main component of the UES, relaxes for approximately 500 ms during the swallow to allow passage of the bolus.[6] Normal adults complete the swallow in approximately 1,500 ms[7]; timing data for children are not well described. Following pharyngeal transit, food enters the esophagus and is transported to the stomach via primary peristalsis. Additional discussions of normal and abnormal motility are given in the section on physiology and pathophysiology in Chapter 4, "Motility."

Upper Esophageal Sphincter: Normal Function

The UES, also known as the pharyngoesophageal segment, is a manometrically defined high-pressure zone located in the region distal to the hypopharynx. Composed of striated muscle, the UES is tonically closed at rest and opens during swallowing, vomiting, or belching.[8] The length of the high-pressure zone in adults is from 2.5 to 4.5 cm, averaging about 3 cm.[8] The length of the CP muscle is about 1 cm; this muscle, therefore, although the main contributor to the UES, is not the only determinant of the high-pressure zone.[8–10] The relative contributions of the inferior pharyngeal constrictor muscle and the muscle fibers of the proximal esophagus to the upper sphincter remain controversial.[11,12]

The structure and function of the UES have been summarized by Lang and Shaker.[13] The cricopharyngeus is structurally and biochemically distinct from the pharyngeal and esophageal musculature. Compared with other striated muscles, the CP muscle is more elastic; it contains large amounts of endomysial connective tissue and sarcolemma, factors that contribute to this elasticity. The length at which the CP muscle reaches its maximal tension is 1.7 times its length; other striated muscles develop maximal tension at resting length. The arrangement of the muscle fibers (parallel and series) and fiber composition may account for the length tension properties. The cricopharyngeus muscle is composed of variably sized

fibers that, unlike the fibers of other striated muscle, are not oriented in strict parallel fashion. The structure of the UES allows it to maintain constant basal tone and to rapidly relax during swallowing, belching, and vomiting.[13] The muscle fibers of the UES are not circumferential but are attached at the anterior end to the lamina of the cricoid cartilage, which functions as the anterior sphincter wall. Because of this connection, the UES moves in conjunction with the laryngeal structures during deglutition.

The pressure profile of the UES is asymmetric, with higher pressures noted in the anterior and posterior directions.[14] Orientation of the recording device must take this into account when pressures are measured in this region. Sleeve manometry has been used to monitor UES pressure in children and to determine the influence of the state of arousal on sphincter pressure values.[15] Table 23-1 reports normal values for the pharyngoesophageal region of control infants, obtained by using a low-compliance, water-perfused manometry system in which the directional orientation of the catheter is maintained.[16] UES function, including values for UES pressure and relaxation, has also been evaluated in preterm infants greater than 33 weeks gestation.[17]

Neurologic control of the sphincter has been reviewed by Palmer[8] and by Lang and Shaker.[13] The CP muscle is innervated by the vagus nerve via the pharyngoesophageal, superior laryngeal, and recurrent laryngeal branches; the glossopharyngeal nerve; and the sympathetic nervous system via the cranial cervical ganglion. Based on functional studies, it is believed that the major motor nerve of the CP muscle is the pharyngoesophageal nerve. Vagal efferents probably reach the muscle by the pharyngeal plexus, using the pharyngeal branch of the vagi.[8] The superior laryngeal nerve may also contribute to motor control of the CP muscle.

Sensory information from the UES is probably provided by the glossopharyngeal nerve and the sympathetic nervous system. Although not completely understood, neurologic connections include visceral afferents that travel to the nucleus solitarius and from there to the nucleus ambiguus. There is probably little or no contribution by the sympathetic nervous system to CP control.[8,18]

The UES responds in a reflexive manner to a variety of stimuli. Balloon distention of the esophagus results in increased UES pressure, which is probably mediated by stimulation of esophageal intramural mechanoreceptors.[19] Motor responses of the UES to esophageal stimuli have been measured following intraesophageal infusion of graded air and liquids (distilled water and apple juice) in healthy preterm infants.[20] A volume-dependent increase in UES pressure was noted for air and liquids. This suggests that UES reflexes are present in the preterm infant to protect the supraesophageal structures. Earlier studies reported that acidification of the esophagus caused an increase in UES tone, suggesting that the UES functions to protect against aspiration following a reflux event. More recent studies have not confirmed this finding. In adult controls and in patients with reflux esophagitis, spontaneous episodes of reflux were not associated with an increase in UES pressure.[21] Similarly, esophageal acidification did not alter UES pressures in either group of individuals. A modified sleeve sensor manometric catheter for measuring UES pressures was used in the latter studies, which might account for differing results.

TABLE 23-1 PHARYNGOESOPHAGEAL MANOMETRIC MEASUREMENTS IN CONTROL INFANTS*

Resting UES pressure (cm H_2O)	28.9 ± 10	(18.0–44.0)
Pharyngeal peristaltic wave		
Amplitude (cm H_2O)	74.7 ± 19.9	(37.0–102.0)
Velocity (cm/s)	8.5 ± 3.6	(3.2–15.0)
Duration (s)	0.59 ± 0.18	(0.3–0.86)

Reproduced with permission from Sondheimer JM. Upper esophageal sphincter and pharyngeal motor function in infants with and without gastroesophageal reflux. Gastroenterology 1983;85:301–5.
UES = upper esophageal sphincter.
*Numbers are mean ± standard deviation; values in parentheses are ranges.

During deglutition, the function of the pharynx changes from that of an airway to that of a foodway. Simultaneous manometry and videofluorography allow investigators to observe intraluminal bolus movement and measure intraluminal pressures during the act of swallowing.[22,23] During the pharyngeal portion of the swallow, there is velopharyngeal closure, opening of the UES, closure of the laryngeal vestibule, and tongue loading. The bolus is propelled into the esophagus by tongue pulsion and pharyngeal clearance. During swallowing, UES relaxation is associated with upward and anterior motion of the cricoid cartilage, which is pulled in an anterior direction by motion of the hyoid bone and contraction of the thyrohyoid muscle.[24] The response of the UES during swallowing is not stereotypical but may be modified by varying bolus size[24]; as bolus volumes increase, the orad excursion of the UES, the opening of the UES, and the duration of sphincter relaxation all increase. These findings suggest that feedback receptors in the oral cavity and pharynx provide afferent signals for modulating central nervous system impulses that give rise to the oral and pharyngeal phases of swallowing.[24]

Proposed functions of the UES include prevention of esophageal distention during normal breathing[8] and protection of the airway against aspiration following an episode of acid reflux.[25–27] As previously noted, the latter remains controversial in adults. Studies in infants have demonstrated that UES pressure increases in response to intraesophageal acidification, suggesting that in this group of patients, the UES may function as a dynamic barrier to acid reflux and may protect against aspiration.[16] However, there was no difference in resting UES pressures between control infants and infants with gastroesophageal reflux.[16] In some infants with pulmonary disease, the UES failed to respond following esophageal acidification. Others have documented qualitative abnormalities of UES function in infants with reflux disease.[28]

Neurology of Deglutition

Miller provides an excellent review of the neurophysiologic control of swallowing.[29] Swallowing may be evoked by stimulating many different central pathways, including the cortex (the region of the prefontal gyri), the subcortex, and the brainstem. The swallowing center can be activated

by afferent impulses from the cerebral cortex (voluntary swallowing) and from peripheral receptors in the mouth and pharynx (reflex swallowing). The corticobulbar impulses trigger and control the initial phases of swallowing but not the later esophageal stages. The cortex is not essential for the pharyngeal and esophageal phases of swallowing. In the human fetus, swallowing occurs prior to the time when the descending cortical-subcortical pathways have fully innervated the brainstem.[30] Deglutition has been noted to occur in infants, with loss of nervous tissue rostral to the midbrain.[31] Higher pathways, however, are important in allowing the voluntary elicitation of deglutition and in integrating facial and oral movements and other responses to swallowing.[1,29] The neurons important to the pharyngeal and esophageal phases of swallowing are located in different regions of the pons[32,33]and medulla.[1,34,35] Lesions placed in the medulla fractionate the sequence of muscle activity during pharyngeal swallowing, suggesting that interneurons located in this region are important to the pharyngeal and esophageal phases; these core interneurons are termed central pattern generators.[30,36] The deglutition center integrates afferent impulses and coordinates the activity of the motor nuclei of the fifth, seventh, tenth, and twelfth cranial nerves. Other activities, such as respiration, are inhibited during swallowing.[37] Swallowing may be evoked by stimulating the oropharyngeal regions innervated by the pharyngeal branches of the glossopharyngeal nerve (ninth cranial nerve) or by the superior laryngeal and recurrent laryngeal nerves of the vagus (tenth cranial nerve). Sensory fibers from these nerves synapse in the nucleus tractus solitarius. Multiple receptive sites that elicit swallowing are present in the oral cavity and pharynx.[29] Once activated, the sequence of muscle activity during the pharyngeal phase remains the same in spite of altering the duration of this phase; this is termed a time-locked sequence.[38,39]

All phases of deglutition may be modified by sensory feedback, although each to a different degree. Oral phase activity is modulated by peripheral feedback received from the touch and pressure receptors in the oral cavity and from the mandible and temporomandibular joints.[40] Feedback from sensory receptors modifies the duration of the pharyngeal phase, the intensity of muscle activity, and the threshold necessary to evoke a response.[6,41–45] Sensory feedback may have therapeutic implications in the clinical management of the swallowing-impaired individual. For example, maintaining jaw control during deglutition may facilitate a safe swallow by improving feedback signals from the mandible or temporomandibular joints, whereas modifying the size of an oral bolus may favorably alter the motor response of the pharynx.

Prenatal Deglutition

Deglutition in utero occurs at approximately 16 to 17 weeks of gestation, although a pharyngeal swallow has been described in a delivered fetus at a gestational age of 12.5 weeks.[46] It is estimated that the normal fetus, at term, swallows approximately 500 to 1,000 mL of amniotic fluid per day. Based on animal studies, the ovine fetus swallows fluid volumes that are greater on a per-kilogram basis than those swallowed by the adult (100 to 300 mL/kg versus 40 to 60 mL/kg).[47] Fetal deglutition plays an important role in amniotic fluid resorption, helping to recirculate urine and lung fluid volumes to the fetus and maintain normal amniotic fluid volume.[48,49] Fetal swallowing may be influenced by a variety of factors, including neurobehavioral changes (such as hypoxia, hypotension, and plasma osmolality), fetal maturation, and volume of amniotic fluid.[47]

Postnatal Development of Deglutition

Changes in Structure. Most changes in the size and relative location of components of the oral and pharyngeal cavities occur during the postnatal period.[50,51] In general, the central mobile elements of the oropharynx in the infant are large in comparison to their containing chambers. For example, the tongue is large compared to the oral cavity, and the arytenoid mass is nearly mature in size, in contrast to the small-sized vestibule and ventricle of the larynx (Figure 23-1).[51]

In the infant, the tongue lies entirely within the oral cavity, whereas the larynx is positioned high in the neck, resulting in a small oropharynx.[52] Between 2 and 4 years of age, the tongue begins to descend so that by approximately 9 years of age, its posterior third is present in the neck.[52] The larynx also moves in a caudal direction. The larynx descends from the level of the third to the fourth cervical body during the prenatal period, an arrangement that persists during infancy.[53] During childhood, the larynx descends to a level opposite the sixth vertebra and finally to the seventh cervical vertebra level in adulthood. As maturation progresses, the face vertically elongates, and the chambers of the oral cavity and oropharynx enlarge (Figure 23-2).[51,54]

Developmental Changes in Feeding Behavior. The development of normal feeding behavior in the infant and child has been reviewed in detail.[51,54] Briefly, in the normal infant, the oral phase of swallowing is characterized by a pattern known as suckle-feeding. Developmental changes in the relationship between suck and swallow, such as the suck-to-swallow ratio and differing rhythmic patterns, have been described in the preterm and term infant.[55,56] Feeding behavior in preterm infants has been assessed by using recording devices to measure pharyngeal pressure, oxygen saturation, heart rate, and nasal airflow. Sucking pressure, frequency, and duration were noted to mature with increases in postconceptual age. In younger infants, swallowing occurred during pauses in respiration but, after 35 weeks of age, occurred mainly at the end of inspiration.[57] Suckle-feeding is followed by the development of transitional feeding (ages 6–36 months) and eventually mature feeding, characterized by biting and chewing. Maturation of feeding behavior occurs mainly as a result of central nervous system development, with motor activity being directed by higher centers such as the thalamus and cerebral cortex.[54]

Nutritive and Non-nutritive Sucking. The pattern of nutritive sucking is characterized by a series of short bursts

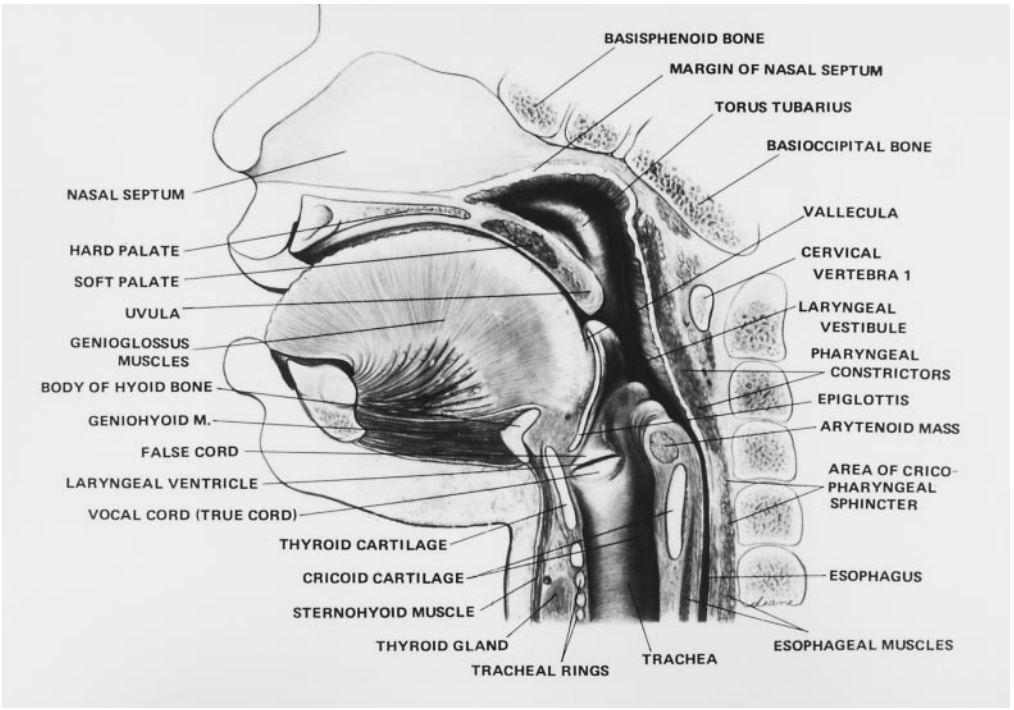

FIGURE 23-1 Drawing of postnatal anatomy of the oral and pharyngeal cavities (see text). Reproduced with permission from Kramer SS. Special swallowing problems in children. Gastrointest Radiol 1985;10:242.

and pauses, occurring at approximately one suck per second.[58] Non-nutritive sucking is defined as rhythmic movements on a nonfeeding nipple. The patterns of non-nutritive and nutritive sucking differ. In non-nutritive sucking, short bursts and pauses occur at a faster frequency.[58] Interestingly, non-nutritive sucking may improve weight gain during gavage feeding in preterm infants. Bernbaum and others studied the nutritional effects of non-nutritive sucking in a group of low birth weight infants receiving formula by an enteral tube and found that, compared with control infants, the group engaging in non-nutritive sucking gained relatively more weight.[59] The mechanism accounting for this weight gain is not clear, although it has been hypothesized that non-nutritive sucking results in more efficient nutrient absorption or a decrease in energy requirements secondary to a lessening of infant activity or restlessness.[60,61]

Non-nutritive sucking may have effects on pulmonary function as well. In preterm infants, non-nutritive sucking is associated with increased transcutaneous oxygen tension and respiratory frequency.[62,63] In contrast, lowered oxygen tension may occur during nutritive sucking, although the mechanism for this effect remains unclear and may not be related to the action of sucking per se.[63]

DISORDERS OF DEGLUTITION IN THE PEDIATRIC PATIENT: CLINICAL OVERVIEW

In the pediatric age group, swallowing disorders rarely present as isolated problems but more often occur in infants and children with multiple impairments. Although accurate epidemiologic data are lacking, underlying conditions that predispose to impaired swallowing in childhood

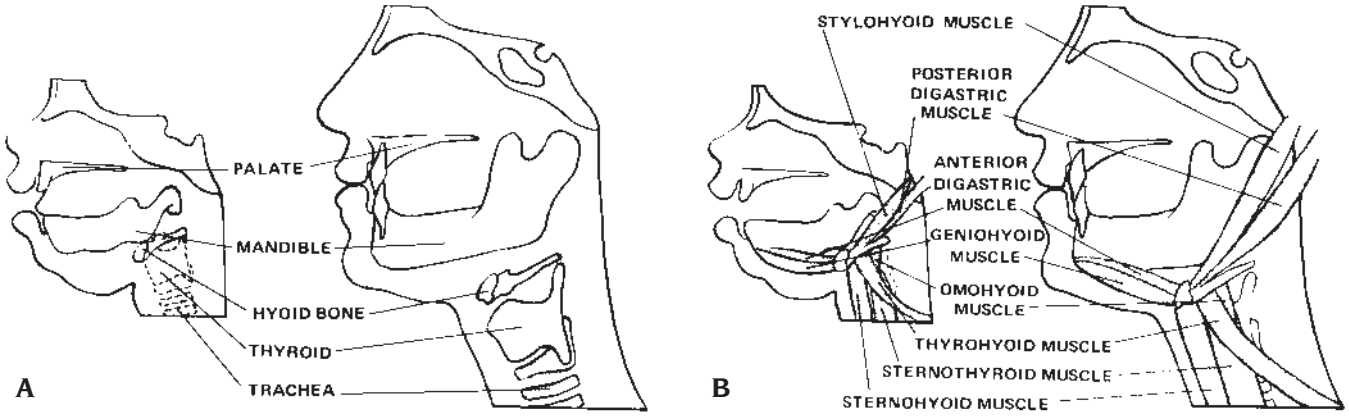

FIGURE 23-2 *A,* Drawing of infant and adult anatomy shows alteration in shape and orientation of the pharynx that accompanies growth and the descent of the larynx. Laryngeal cartilages and hyoid bone are shown in their relationship to the mandible. The airway is depicted (*hatched area*). *B,* Drawing illustrates change in orientation of muscles (*stippled*) that suspend the larynx in the infant and the adult. include central and peripheral nervous system dysfunction, disease of muscle, and structural anomalies of the oral cavity and pharynx. Structural and motor disorders of the esophagus, which may also present with dysphagia, are discussed elsewhere in the text. Other groups at risk for the development of impaired swallowing and its complications include premature infants with poor coordination of breathing and swallowing, infants with long-term deprivation of oral feeding, and infants with chronic pulmonary disease. The spectrum of pediatric swallowing disorders has been reviewed in detail by others.[51,54,64–69] Table 23-2 provides a broad list of disorders that result in impaired deglutition in the pediatric age group.

Complications of Impaired Deglutition

Respiratory complications of impaired swallowing have been reviewed; they include apnea and bradycardia, choking episodes, chronic noisy breathing, reactive airway disease, chronic or recurrent pneumonia, bronchitis, and atelectasis.[70] Aspiration of oral contents may occur directly, that is, in association with a swallow that does not protect the airway. In addition, some patients may be unable to protect the airway from the aspiration of oral secretions. Aspiration may also occur in individuals with impaired swallowing after an episode of gastroesophageal reflux; also, acid reflux may result in bronchospasm, pneumonia, or apnea.[71–73] Unfortunately, in the swallowing-impaired child (and adult), it may be difficult to detect aspiration based on clinical signs and symptoms alone because "silent aspiration" (aspiration without coughing, gagging, and choking) may occur. The prevalence of this condition remains unknown, and predictors of aspiration associated with impaired swallowing have not been clearly defined.

In the severely affected child with impaired swallowing, poor oral and/or pharyngeal function may lead to decreased energy intake as a consequence of prolonged feeding time and the inability to ingest adequate volumes. As a result, protein-energy malnutrition may develop, with deleterious effects on the immune system and on muscle strength. Repeated pulmonary infections may become more debilitating in the face of worsening nutritional status (Figure 23-3).

Another complication of impaired swallowing is sialorrhea, or excessive drooling, defined as the unintentional loss of saliva and other oral contents from the mouth. Drooling usually occurs in patients with neurologic disease complicated by abnormalities of the oral phase of deglutition. Examples of this relationship include cerebral palsy, peripheral neuromuscular disease, facial paralysis, and severe mental retardation.[74] In children who drool, the primary problem is usually related to oromotor dysfunction and not excessive production of saliva.[75] Clinical complications of drooling include soaking of clothes, offensive odors, macerated skin around the mouth and chin, and, if "posterior" drooling occurs, aspiration. In addition to impaired swallowing, the differential diagnosis of drooling includes dentition problems, sinusitis, and the increased production of saliva by the salivary glands. Excellent reviews of this subject include those by Blasco and colleagues[74] and Bailey.[76]

Therapy for the control of drooling may include orosensory motor treatment to improve oromotor skills, medical therapy using anticholinergic medications such as glycopyrrolate, and surgical therapy to redirect the submandibular ducts.[77–80] Anticholinergic side effects (dry

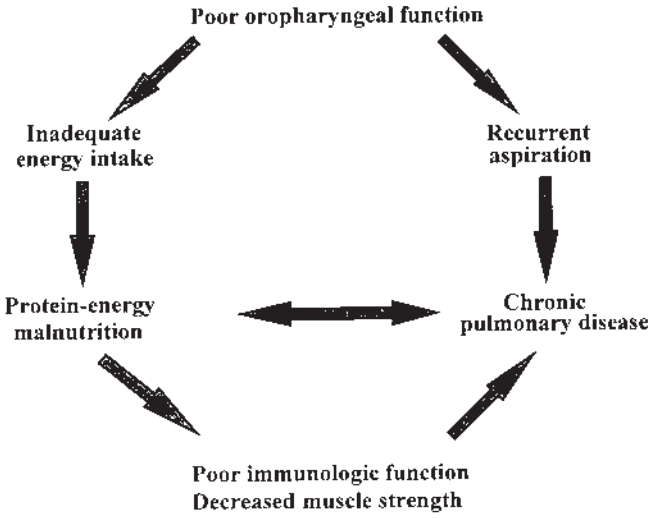

FIGURE 23-3 Clinical sequelae of impaired deglutition.

mouth, thick secretions, urinary retention, flushing) may occur, but these are usually controlled by titrating the dose of medication. Surgical therapy that redirects the flow of saliva posteriorally may increase the flow of liquid to an already compromised swallow and potentially increase the risk of aspiration.

Deglutition in the Preterm Infant

An important clinical issue to consider in the preterm infant is the relationship between deglutition and breathing. Although premature infants are able to suckle-feed at approximately 34 weeks of gestation, successful oral feeding requires the coordination of swallowing and breathing. Poor integration of these activities may result in respiratory difficulties such as aspiration. Wilson and others evaluated the coordination of breathing and swallowing in preterm infants and found that deglutition occurred during both inspiration and expiration and resulted in an interruption of airflow.[81] They concluded that preterm infants are unable to breathe and swallow simultaneously. Shivpuri and coworkers studied the effects of oral feeding on respiratory response in preterm infants and found that tidal volume and respiratory frequency decreased during feeding by continuous sucking, resulting in a decrease of minute ventilation and partial pressure of oxygen.[82] The reader is directed to a review of oromotor function in the neonate.[83]

Critical Period of Learning

A critical period of development refers to a segment of time during maturation when a specific stimulus must be applied to produce a particular action. Inadequate oral stimulation during a critical period may result in difficulty in re-establishing successful oral feeding at a later date. The concept of a critical or sensitive period pertaining to feeding behavior has been reviewed by Illingworth and Lister,[84] and cases of infants and children developing resistance to oral feeding after long-term deprivation of oral stimulation have been reported.[85,86] Successful treatment of this problem has been accomplished by a multidisciplinary feeding team using a behavioral approach.[86]

ISOLATED CP DYSFUNCTION AND CP ACHALASIA

CP dysfunction is usually part of a more global disorder of deglutition also involving the oral phase.[10] CP function may be altered by conditions that affect the central nervous system or cranial nerve function or by conditions that locally involve the function of the muscle or movement of the larynx. Achalasia, meaning failure to relax, does not always accurately describe the type of CP dysfunction present. Nonrelaxation of the sphincter resulting from primary CP disease differs from nonopening of the sphincter secondary to weak forces of propulsion in the proximal pharynx.[34]

Isolated CP dysfunction or achalasia is a rare disorder in infants and children.[87–89] Most patients with CP achalasia present at birth with feeding difficulties, although some may present as late as 6 months of age. Drug-induced dysfunction of the UES has also been reported.[90]

The diagnosis of isolated CP dysfunction is difficult when based solely on radiographic studies. A horizontal bar in the proximal esophagus, representing the CP muscle, may be seen in up to 5% of adults undergoing radiographic examinations for all indications and may also be a normal radiologic sign in infants.[91,92] In some patients with a prominent bar seen on radiographic study, manometric studies have demonstrated normal relaxation and decreased UES pressure.[37,93] Alternatively, manometric studies may be normal in patients with clinical or radiologic evidence of CP dysfunction.[37,94,95] Improvement of CP achalasia may occur spontaneously or after dilatation.[95,96] In some cases, CP myotomy may be required after careful assessment of the patient[97]; surgery is usually contraindicated in patients with gastroesophageal reflux or poor pharyngeal peristalsis.

CLINICAL ASSESSMENT

In clinical practice, disorders of swallowing are often considered in the general context of a feeding disorder. Feeding is a complex process that involves a number of phases in addition to the act of swallowing, including the recognition of hunger (appetite), the acquisition of food, and the ability to bring the food to the mouth. The causes of feeding disorders have been extensively reviewed.[98] The classification of feeding disorders includes the broad categories of abnormalities of structure and function, neurologic disorders, and behavioral feeding disorders.[99]

In the spectrum of feeding disorders, food refusal is a common complaint, but a precise definition of food refusal is not well established. Food refusal may be defined as the developmentally inappropriate intake of food (quality or quantity) for more than 8 weeks (R Wachtel, oral communication, March 1998). Associated symptoms may include behavioral problems such as unusual behaviors at mealtime, an abnormal feeding pattern, and mealtimes that are stressful for the family and child. Food refusal may be secondary to a variety of conditions, including impaired swallowing, mucosal disease of the gastrointestinal tract (eg, reflux esophagitis), behavioral difficulties, and chronic disease (eg, renal, cardiac, and endocrine disease).

Successful evaluation and management of the pediatric patient with impaired swallowing and/or a feeding disorder usually require a multidisciplinary approach. Members of a pediatric "dysphagia" or "feeding" team may include a pediatrician, pediatric gastroenterologist, developmental pediatrician, speech-language pathologist, occupational therapist, and pediatric dietitian. The availability of a pediatric radiologist and an otolaryngologist with experience in the field of pediatric swallowing disorders is essential to assist in the diagnostic evaluation.

The American Gastroenterological Association has published a medical position statement on the management of oropharyngeal dysphagia,[100] and an excellent technical review on the management of oropharyngeal dysphagia accompanies this article.[101] Although concerned mainly with the evaluation and management of adults with dysphagia, the clinical objectives of this statement are applicable to children. The main objectives include the following: (1) determine whether oropharyngeal dysphagia is present and, if so, attempt to identify the etiology; (2) identify the structural etiologies of oropharyngeal dysphagia; (3) determine the functional integrity of the swallow; (4) evaluate the risk of aspiration; and (5) determine if the pattern of dysphagia is amenable to therapy. An algorithm for the evaluation and management of the pediatric patient with possible impaired swallowing is shown in Figure 23-4.

Feeding History

The diagnostic approach to the pediatric patient with impaired swallowing begins with the feeding history, but obtaining an accurate feeding history may be difficult for a number of reasons.[102] First, pediatric patients with severe impairment of swallowing frequently include many with limited cognitive abilities, making direct communication with the patient difficult. As a result, the feeding history must be obtained from individuals directly involved in caring for the child, such as a parent or feeding specialist (eg, a speech-language pathologist or an occupational therapist). Second, severely handicapped children with impaired swallowing may aspirate without coughing, a phenomenon known as silent aspiration (a similar condition has been described in adults).[103–105] Consequently, it is difficult to accurately predict which food substances are swallowed without aspiration solely on the basis of feeding history or clinical examination.

Areas covered in the feeding history include caretakers involved; location or setting for feeding (the nature of which may differ depending on the location, eg, school versus home); method of feeding (eg, type of feeding utensils used); position of the head, neck, and body during feeding; volume of food offered and volume of food tolerated per swallow; presence or absence of chewing; amount of time required to feed; history of dysphagia or odynophagia; pres-

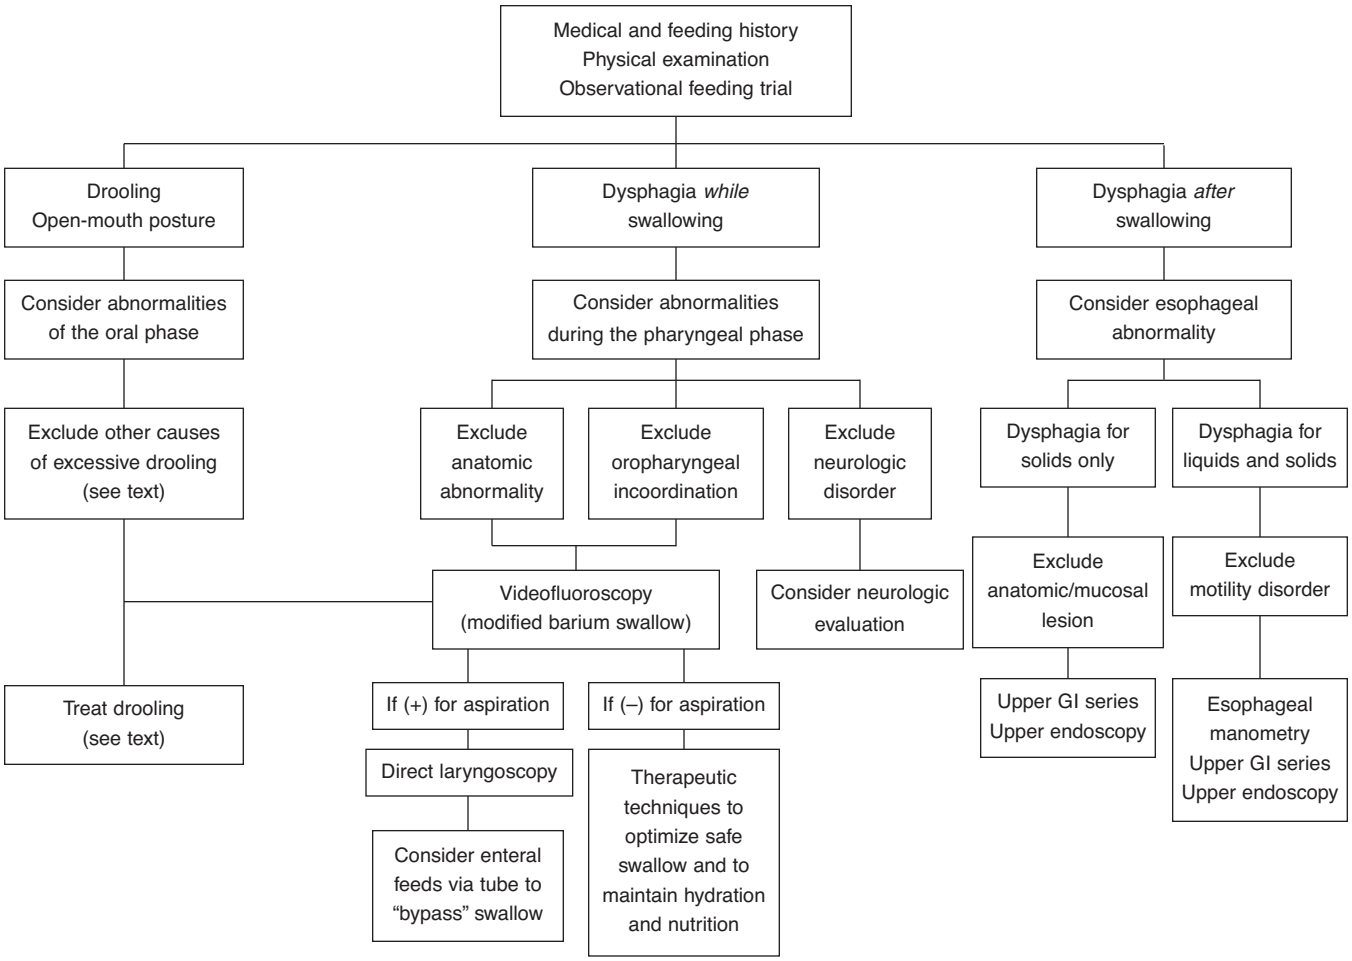

FIGURE 23-4 Algorithm for evaluation and management of the pediatric patient with impaired swallowing. GI = gastrointestinal.

ence or absence of drooling (suggestive of oral phase abnormalities); and history of gagging, choking, or coughing associated with feeding. Determining whether these symptoms occur before, during, or after the swallow helps localize the affected phase.[103] Symptoms that occur prior to the swallow suggest abnormalities of oral control; those that occur during the swallow may indicate pharyngeal phase dysfunction, and gagging and choking just after completion of the swallow probably represent abnormalities of pharyngeal clearance secondary to pharyngeal muscle weakness and/or incoordination or dysfunction of the UES.

In addition to a feeding history, a complete nutritional assessment is essential. Clinical goals should include determining the patient's current nutritional status, estimating energy and protein requirements for establishing optimal growth, and outlining a plan for providing the route and type of feeding. Consultation with a pediatric dietitian will aid in planning a comprehensive nutritional program.

Physical Examination

Physical examination should include the structures of the face, oral cavity, and oropharynx. If structural abnormalities are found and/or are suspected in the pharynx, consultation with an otolaryngologist is indicated. Careful attention should be paid to (a) the presence of an intact soft and hard palate, (b) whether the tongue is midline, (c) the size of the tongue relative to the size of the oral cavity (eg, macroglossia), and (d) the size of the mandible (eg, Pierre Robin syndrome). Head control and head and neck position, particularly when feeding, are also important to note during the examination. It is extremely difficult to swallow with a hyperextended neck, a factor that may be important in the patient with neuromuscular disease (eg, cerebral palsy).

The presence or absence of a gag reflex should be noted, including the existence of a "hyperactive" gag reflex. Lack of a gag reflex is a contraindication to oral feeding, whereas a hyperactive gag may result in significant feeding difficulties. "Hypersensitivity" may involve just the face or oral cavity or may be more pervasive. In infants, oral hypersensitivity is suggested by an aversion to nipple-feeding. In older children, irritability with oral activities such as toothbrushing may suggest hypersensitivity. Children with generalized hypersensitivity may become irritable with any type of sensory stimulation (touch, sound, etc). Issues related to hypersensitivity may be seen in children with developmental disabilities such as autism and cerebral palsy.

Observational Feeding Trial

The diagnostic yield of an observational feeding trial is greatly enhanced if the trial is performed in collaboration with a feeding therapist. During the initial part of the feeding trial, oromotor function is tested by determining the presence or absence of age-appropriate oromotor skills. The acquisition of oral feeding skills and their development have been reviewed in detail by others.[50,106–110] During the feeding trial, the presence of abnormal movements such as jaw thrust, tongue thrust, tonic bite reflex, and jaw clenching is noted. Normal movements seen in the older infant and retained into adulthood include jaw stabilization, chewing, and the ability to lateralize intraoral contents with the tongue. In the impaired patient, normal primitive reflexes or movements (including the phasic bite reflex and suckle-feeding) may extend beyond their expected time of disappearance. During feeding, the positions of the head, neck, and body during swallowing should be noted, as well as abnormal feeding behaviors (such as tongue thrust and averting the mouth) and choking, gagging, or ruminating. A change in voice quality after feeding (such as a "wet," hoarse voice or cry) suggests soiling of the larynx or aspiration.

Diagnostic Tests of Swallowing Function

Specialized tests of deglutition allow broad categorization of swallowing abnormalities. These examinations are mainly descriptive and provide the clinician with limited data regarding specific pathophysiologic mechanisms.

Videofluoroscopy. Videofluoroscopy, or the modified barium swallow, examines swallowing function by visualizing passage of barium-impregnated liquids, pastes, and pureed foods through the oral cavity, pharynx, and esophagus. This is the procedure of choice for evaluating the patient with impaired swallowing[104,110–112] and provides the best means of determining oral, pharyngeal, and esophageal anatomy and function. This study provides objective evidence of oral and pharyngeal incoordination and detects episodes of aspiration, all of which help identify children in whom oral feeding may be contraindicated. Videofluoroscopy is usually performed by a feeding therapist, either a speech-language pathologist or an occupational therapist, in conjunction with a pediatric radiologist. During this procedure, a variety of foods, feeding utensils, and different positions of the head and neck are evaluated to help determine optimal and safe swallowing. Using videofluoroscopy, it is possible to determine whether aspiration occurs prior to, during, or following deglutition.[113] Protection of the airway prior to the swallow is dependent on oropharyngeal coordination and laryngeal elevation. Protection during the pharyngeal phase of swallowing is a result of closure of the laryngeal vestibule secondary to laryngeal elevation, closure of the false vocal cords, and anterior tilting of the arytenoids. Following deglutition, pharyngeal clearance mechanisms help prevent aspiration. The clinical significance of small amounts of aspiration noted on videofluoroscopy deglutition remains unknown. Videofluoroscopy is valuable in the management of swallowing-impaired patients because it aids in determining the bolus characteristics of food that make food safe to swallow (ie, bolus size and consistency).[104] The disadvantages of this procedure include exposure to radiation and lack of quantitative data regarding the function of oral and pharyngeal structures during deglutition. Note that a complete videofluoroscopic examination should include esophagography to evaluate the esophageal phase of swallowing.

Pharyngeal Manometry. Manometry provides quantitative data regarding pharyngeal motor function during de-

glutition, including the amplitude of peristalsis, the speed of propagation of the pharyngeal wave, the response of the UES following deglutition, and the coordination between pharyngeal peristalsis and UES relaxation.[16,28] Recording the response of the pharyngoesophageal region during deglutition is complicated by a number of factors.[114] First, because motor events in the hypopharynx occur at a more rapid rate than in the esophagus, recording equipment with a rapid response time (usually greater than 300 mm Hg/s) is required.[115] Water-perfused catheters with rapid response times are acceptable, but intraluminal pressure transducers provide the most accurate readings. Second, the asymmetric pressure profile of the UES requires that close attention be given to the spatial orientation of the recording device while recording in the UES. Third, there is significant differential axial movement of the recording catheter and oropharyngeal structures during deglutition, which may result in a significant recording artifact.[114,116] A sleeve sensor has been used to monitor UES pressures over time to minimize the effects of catheter and sphincter movement.[46] Manometry does not provide information regarding intraluminal events, such as the movement of fluid in response to recorded pressure changes. The simultaneous recording of videofluoroscopic images and manometric tracings has allowed investigators to correlate motor events with intraluminal movement of substances.[24,117,118]

Ultrasonography. Ultrasonography represents a relatively new diagnostic modality for the evaluation of the swallowing-impaired individual.[119] The motion of structures in the oral cavity such as the tongue and floor of the mouth may be imaged during feeding and deglutition by placing a transducer in the submental region and aiming the beam toward the tongue. This technique has been used to identify feeding movements of oral structures in healthy breastfed and bottle-fed infants.[120] The disadvantages of ultrasonography include poor visualization of the oropharynx (secondary to an acoustic shadow cast by bony structures in the neck) and the lack of standardized measurements.

Nuclear Scintigraphy. Nuclear scintigraphy involves the patient's swallowing a liquid or solid that is labeled with a radiopharmaceutical. Technetium 99m, the radionuclide used in swallowing and esophageal scintigraphic studies, is not absorbed after oral administration and does not become attached to gastrointestinal mucosa. Using a gamma counter and computer processing, regions of interest and selection of time intervals are generated that allow the measurement of transit time and the estimation of intraluminal volumes. Exposure to radiation is less than during analogous fluoroscopic procedures. Problems include poor resolution of the image and poor localization. The technique of nuclear scintigraphy has been reviewed by Cowan.[121] Based on a case report, the radionuclide salivagram has also been used to document aspiration of saliva.[122]

Scintigraphy has been used in adults to assess transit of a liquid bolus through the oropharynx.[123–125] Silver and colleagues attempted to use nuclear scintigraphy to detect and quantify aspiration.[126] Unfortunately, this technique proved to have poor sensitivity for detecting aspiration during swallowing in known aspirators. At present, clinical experience with this technique as a test of swallowing function in children is limited.

Other Tests of Swallowing. Using a stethoscope applied to the neck, the technique of cervical auscultation has been used to study the sounds of swallowing in adults and children.[127,128] Sounds denoting pathologic swallowing have been identified. Cervical auscultation is a noninvasive technique, although the limitations include a lack of standardized measurements and reliance on subjective descriptions of sounds. Recently, workers have performed digital signal processing using an accelerometer placed over the neck to graphically display and quantitatively measure sounds.[129]

A new technique, known as fiberoptic endoscopic evaluation of swallowing safety, allows clinicians to directly observe movements of the anatomic structures involved in the pharyngeal phase of swallowing.[130,131] Using this method, laryngeal penetration (material entering the laryngeal vestibule) and aspiration (material falling below the glottis) can be directly visualized. Episodes can be characterized as occurring prior to and/or following the swallow. Using videotape recording, images obtained during endoscopic evaluation of swallowing provide reproducibility and the ability to closely visualize swallowing events.[132]

A related technique, called fiberoptic evaluation of swallowing with sensory testing (FESST), combines endoscopic evaluation of swallowing with a method that determines laryngopharyngeal sensation.[133] Using the endoscope, air-pulse stimuli are delivered to the pharyngeal mucosa, which is innervated by the superior laryngeal nerves. This allows determination of discrimination thresholds. Laryngopharyngeal sensory capacity is determined by elicitation of the laryngeal adductor reflex, which is a sensorimotor reflex. In adults, FESST is performed at the bedside and has been used as the initial swallowing evaluation for the patient with dysphagia.

TREATMENT

Treatment plans should be developed in the context of a multidisciplinary group. Specific treatment of oral and pharyngeal dysfunction in the neurologically impaired child is not always possible, nor is surgical therapy frequently indicated. Different types of treatment modalities have been discussed in detail by others.[101,134–138] Management techniques involve devising compensatory strategies to minimize swallowing-related complications.[139] Because swallowing abnormalities arise from a diverse group of underlying disorders, management techniques must be individualized. This heterogeneity is also reflected in the fact that patients have differing potentials for recovery. In the patient with acquired brain injury secondary to head trauma, rehabilitation with possible reacquisition of swallowing skills is a major goal; in contrast, compensatory and adaptive maneuvers form the basis for managing the child with severe cerebral palsy.

The management of dysphagia must be considered in the context of the child's level of development and cognitive

TABLE 23-3 IMPAIRED SWALLOWING: MANAGEMENT TECHNIQUES

Alteration of the oral bolus—modify volume, physical properties (eg, consistency, temperature)
Proper intraoral bolus placement
Adjust position of the head, neck, and body during deglutition
Provide jaw control and stabilization during deglutition
Decrease oral hypersensitivity/increase oral hyposensitivity—thermal sensitization/stimulation
Extinguish abnormal feeding behaviors
Swallowing exercises
Tongue resistance/range of motion
Laryngeal adduction
Protection maneuvers—supraglottic swallow procedure
Cricopharyngeal myotomy
Suckle-feeding—valved feeding bottle
Provide alternate means of enteral nutrition
Nasogastric feeding
Gastrostomy tube (surgical or endoscopic)

Adapted from Tuchman DN. Dysfunctional swallowing in the pediatric patient: clinical considerations. Dysphagia 1988;2:203–8.

abilities. The inability of a child to follow directions limits therapeutic maneuvers to passive procedures (eg, bolus modification). Children with intact cognition have the potential to become actively involved with their therapy and learn specific procedures shown to be effective in promoting a safe swallow (eg, the supraglottic swallow procedure).

In general, therapeutic recommendations are based on the patient's ability to swallow safely (ie, the ability of the patient to transfer food from the oral cavity into the esophagus without entry into the larynx or tracheal airway), the patient's nutritional status, the presence of gastroesophageal reflux, and the enjoyment of feeding for parents and the patient.

For a complete discussion of techniques used to facilitate oromotor function in swallowing-impaired infants and children who are receiving some form of either oral feeding or oral stimulation, the reader is referred to Mueller,[109] Morris,[108,140,141] and Ottenbacher and colleagues.[142] Many techniques seek to reduce tactile hypersensitivity, stabilize body position, and optimize the motor response of the oral swallowing mechanism. Modification of the physical characteristics of an oral bolus remains an important part of therapy. The rheologic properties of food have been measured and described.[3] Table 23-3 lists some management options used for children with impaired swallowing. It should be noted that because of a paucity of well-controlled clinical trials, the use of many of these therapeutic maneuvers remains empiric.

CHAPTER 24

GASTROESOPHAGEAL REFLUX

Susan R. Orenstein, MD
Seema Khan, MD

Gastroesophageal reflux (GER) is the movement of gastric contents retrograde into the esophagus; in addition to indicating such individual events, the term is also used to signify a benign but symptomatic condition. Gastroesophageal reflux disease (GERD) comprises the objective pathologic sequelae of such retrograde movement of gastric contents, but the term has also been used more recently to denote symptoms affecting quality of life, without regard to objective evidence of disease.[1] GERD now comprises the most common esophageal disorder, as well as one of the most common disorders of any kind affecting infants and children; in adults, it has been documented to be the most costly gastrointestinal disease, estimated to consume more than $9 billion each year in direct costs.[2] The sparser data available in children indicate similar prevalence and cost issues. Therefore, in both children and adults, the promulgation of guidelines for the diagnosis and therapy of various diseases was applied early to GERD, albeit with awareness of the degree to which the current relative dearth of rigorous pediatric data impairs their reliability for children.[3–6]

PRESENTATIONS AND SYMPTOMS

Esophageal versus Extraesophageal

GERD may present as regurgitation, particularly in younger children; as esophageal symptoms, including chest pain, odynophagia, or dysphagia; as respiratory disease; or as diverse other symptoms or signs, including dental and neurologic manifestations.

Age Related

GERD manifests differently in infants than in older children. Although the pathophysiologic underpinnings of this difference are not completely understood, it is likely that the large nutritional demands for growth and the immaturity of neuromuscular and other systems conspire with dietary and postural provocations to generate the infantile forms, whereas the chronicity of the insults plays an increasingly important role in older children and adults.[7] Thus, regurgitation, crying presumed owing to the pain of esophagitis, and malnutrition in the infant transform into symptoms more predominantly centered on the pain and sequelae of esophagitis in the older child. Similarly, the respiratory presentations of GERD may be more centered on the upper airway and apnea in the infant, whereas in the older child, the lower airway and asthma become more important.

Regurgitation

Regurgitation may produce malnutrition or may be associated with pain. If it is unassociated with objective signs of disease, including malnutrition, pain, or respiratory symptoms, it is generally considered benign GER. Regurgitating infants, without other signs of disease, are generally considered "happy spitters" and are managed nonpharmacologically. Regurgitation may persist in toddlers with GERD, and regurgitation into the mouth with reswallowing is sometimes evident in older children and adolescents with GERD.[8] Regurgitation should be differentiated from vomiting, which has a distinct pathogenesis, including retrograde duodenal peristalsis, but, in practice, this differentiation is commonly ignored, and vomiting is used less specifically to encompass regurgitation. Regurgitation in young infants with GERD is often sufficiently projectile to further complicate this distinction.

Pain

Pain has long been considered the primary symptom of esophagitis, represented by crying in young infants, but the correlation of pain with objective manifestations of endoscopic or even histologic esophagitis is incomplete.[9,10] Infant crying is associated with reflux episodes during video and esophageal pH probe monitoring.[11] On investigation, the esophageal pain symptoms may be disclosed to be associated with erosive changes visualized endoscopically, with histologic changes visualized microscopically, or with no evident changes. Recent awareness of differences in visceral sensitivity among individuals with irritable bowel syndrome and dyspepsia has begun to be applied to those with GERD, although, as yet, this concept has not been widely developed or applied to therapeutic strategies.[10] The differential diagnosis of chest pain in children encompasses esophageal motility disorders and eosinophilic esophagitis.[12–14] The differential diagnosis widens in the youngest children, who have the least ability to communicate discriminatory information.[15] Distinctions between odynophagia (painful swallowing) and dysphagia (difficulty swallowing) may be challenging in nonverbal children but can be useful in focusing the differential diagnosis between inflammatory conditions and motor abnormalities of the esophagus.

Other

Esophageal inflammation caused by refluxed acid may result in erosive esophagitis and produce occult blood loss or hematemesis. Such inflammation, if protracted, can also cause strictures that obstruct the esophagus. Barrett esophagus may be asymptomatic until a stricture, or even adenocarcinoma, causes obstructive dysphagia.

Respiratory symptoms and neurologic symptoms may be the presenting signs of GERD (see below). A variety of other symptoms (such as hiccups, sneezing, drooling, or mouthing) have been described.[11,16]

EPIDEMIOLOGY AND NATURAL HISTORY

Epidemiology

The challenges in identifying the epidemiology of GERD are exacerbated by an evolving definition of the disease, unclear demarcation between physiologic and pathologic reflux, lack of a diagnostic gold standard, and a paucity of incidence and prevalence data.[17] For symptoms of GERD, the general population prevalence in infants and children has been estimated to range from 1 to 8%, depending on the symptom and the severity or frequency queried.[18–20] These estimates are further supported by earlier estimates of the proportion of children and adults presenting for evaluation of, or receiving therapy for, GERD.[21] Similarly, 7% of adults experience daily heartburn.

GERD is associated with many other disorders; these associations devolve from provocations of the pathogenic mechanisms of reflux. Thus, neuromuscular disorders can generate GERD by direct effects on upper gastrointestinal tract motility or indirectly by effects on intra-abdominal pressure and posture. Respiratory diseases can affect abdominal-thoracic pressure gradients and so predispose the patient to GERD.

Natural History

Although regurgitation resolves in most symptomatic infants by 12 to 24 months of age, unselected infants with frequent regurgitation may develop feeding problems in the subsequent year of follow-up.[22] By 9 years of age, children with frequent regurgitation during infancy may be more likely to develop persisting reflux symptoms, a phenomenon exacerbated by maternal smoking and maternal reflux symptoms.[23] Children over 1 year of age without neurologic impairment most commonly have "endoscopy-negative GERD," and their esophageal inflammation, even if present, is unlikely to deteriorate during a mean of 28 months of follow-up.[24] However, half of older children with GERD have a chronic relapsing course.[25] Adults with reflux disease are nearly twice as likely as adults without reflux disease to recall having had symptoms of GERD during childhood.[26]

More severe pediatric GERD, the form detected by the earliest investigators, also persists in a minority beyond a year or two of age, but without therapy leads to definite morbidity and mortality.[27] Although strictures, Barrett esophagus, and adenocarcinoma are rare in childhood, it is likely that GERD, beginning in childhood, predisposes the patient to these complications in adulthood.[28]

PATHOPHYSIOLOGY

Understanding of the mechanisms underlying GER has expanded from the primitive conceptualization of the lower esophageal sphincter (LES) as hyptonic to the more complicated and accurate current model (Figure 24-1).[29,30] This current model incorporates dynamic changes at the gastroesophageal junction (GEJ) involving transient LES relaxations (TLESRs) of a sphincter supported actively by the hiatal crura. These motor mechanisms at the GEJ are impacted by more distal motor mechanisms related to gastric volume-pressure relationships promoting TLESRs and reflux and by more proximal motor mechanisms related to esophageal clearance of the refluxed material. Sensory phenomena have been appreciated recently, both for their role in the pain symptoms of reflux (with or without esophageal inflammation) and for their role as the gastric afferent limb to the TLESR. Whether reflux produces esophagitis depends not only on the frequency and duration of the reflux episodes produced by the above mechanisms but also on the balance between the noxiousness of the refluxate and the counteracting esophageal mucosal protective mechanisms. The genetic and environmental factors that modulate all of these pathophysiologic mechanisms and thus underlie the determination of who becomes diseased are currently receiving attention.

Motor Aspects

Tonic LES pressure is maintained above 4 mm Hg, a level adequate to prevent reflux, in most children, even those with GERD. Most reflux occurs when the LES relaxes transiently in a TLESR; the characteristics and provocations of TLESRs have been reviewed.[31,32] The TLESR can be viewed as an "aborted swallow," with afferents in the gastrointestinal tract proximal to the LES, or, more commonly, as a "belch equivalent" venting gastric pressure, with afferents in the stomach, distal to the LES. The TLESR is mediated primarily through vagal pathways via the brainstem. Acting on either the sensory or the motor arm of the arc or on the central pattern generator, nitric oxide and cholecystokinin A seem to play a positive role in TLESR generation because their antagonists reduce the rate of TLESRs; somatostatin, γ-aminobutyric acid B ($GABA_B$), and opiates have the opposite effect. Agents affecting these sites, such as the $GABA_B$ agonist baclofen, have begun to be explored as therapies for GERD, but with ambiguous results. The central role of TLESRs in GERD is challenged by some reports that indicate that TLESR frequency is equivalent in those with and without GERD; the similar frequencies of TLESRs were accompanied by more frequent acid reflux episodes in the GERD patients in contrast to more gaseous or nonacid liquid reflux in the non-GERD patients, differences postulated as attributable to posture or other factors.[33]

The crural diaphragm that surrounds the LES bolsters its tone, particularly during straining; intricate neural connections ensure that TLESRs are physiologically accompanied by coordinated crural relaxation. This fact underlies the important role of hiatal hernia, particularly in more

severe GERD, when the LES pressure can be overcome by gastric pressure, especially during straining (abdominal wall and diaphragm contraction), even in the absence of a TLESR.[34] In adults, hiatal hernia size correlated with esophagitis severity to a greater extent than did manometric LES pressure or esophageal pH probe–monitored (EpHM) esophageal acid exposure, and hiatal hernia size is one risk factor for esophageal adenocarcinoma.[35,36] The etiology of hiatal hernia is unclear, however. It has been proposed either to cause or to be caused by GERD, and both increased abdominal pressure and esophageal traction have been implicated in generating a hiatal hernia.[37] Although hiatal hernia ("partial thoracic stomach") was the earliest identified pathologic correlate of pediatric GERD, a recent retrospective study identified hiatal hernia in only 6% of 718 children with GERD.[38,39] That study found that children with hiatal hernia manifested more delayed esophageal clearance than those without hiatal hernia. Nearly one-fourth of those with hiatal hernia were neurologically impaired, most of whom were treated with surgical therapy initially; nonoperative treatment resulted in an appreciable failure rate (25%) even in neurologically normal patients.[33] Although it is likely that many children do not manifest symptoms with a hiatal hernia, GERD symptoms that are refractory to medical management in patients with hiatal hernia should be treated surgically.[40]

Aspects of gastric function also provoke or impede reflux by affecting the gastric pressure-volume relationship. The volume of gastric material (ingested, secreted by the stomach, or refluxed from the duodenum) is, in turn, modulated by gastric emptying. Gastric accommodation, the stomach's ability to relax to accommodate increased volume, is a further modifying factor.[41]

Increased meal volume increases the frequency of TLESRs in children, consistent with the mechanisms postulated to underlie TLESRs.[42] By slowing gastric emptying, increased meal osmolality increases the rate of reflux episodes when the sphincter does relax.[42] Delayed gastric emptying per se accentuates the volume refluxed per episode in the postprandial period in children and seems to be associated with more severe GERD.[43] Gastric accommodation, measured by barostat or scintigraphically, likely

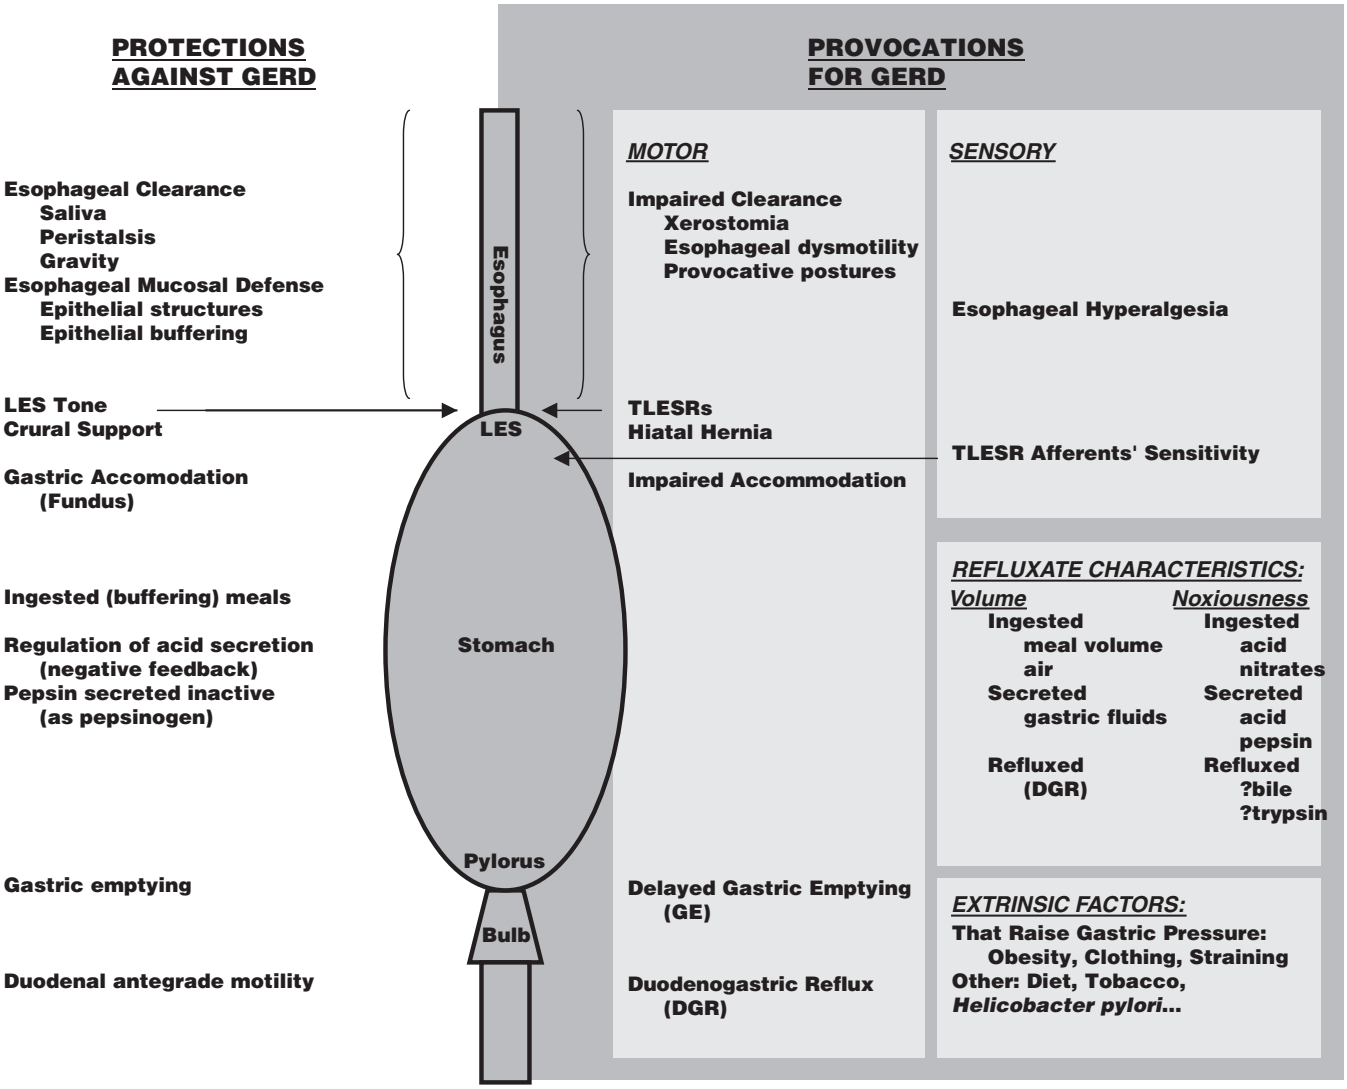

FIGURE 24-1 Cartoon of pathophysiology of GERD. GERD = gastroesophageal reflux disease; LES = lower esophageal sphincter; TLESRs = transient LES relaxations.

impacts the occurrence of TLESRs as a response to a given intragastric volume; the stiffer stomachs (lesser accommodation) of infants than of adults may underlie some of the physiologic reflux of babies.[7] Intragastric pressures are also impacted by extragastrointestinal phenomena: chronically by obesity, tight clothing, or provocative postures; episodically by straining, coughing, or wheezing.[44,45]

Aspects of esophageal motor function determine the clearance from the esophagus of refluxed material.[46] Gravity provides the crude initial component of clearance in upright individuals; infants, who are recumbent for a greater proportion of the day, often lack this component. Esophageal peristalsis clears volumetric reflux not cleared by gravity. Primary peristalsis, peristalsis initiated by swallowing, comprises 90% of all esophageal responses to reflux. Esophageal distention stimulates secondary peristalsis, a backup function that may be particularly important when reflux occurs during sleep.[47] Esophagitis impairs peristaltic function, promoting vicious cycles of worsening esophagitis: 20% of adults with mild and 50% with severe esophagitis manifest failed or hypotensive peristalsis.[48,49] Saliva propelled the length of the esophagus provides a final "wash-down" and neutralizes residual acid. Methods of increasing salivary wash-down of the esophagus have been proposed as therapeutic, and cholinergic prokinetic agents may effect their clearance function by increasing salivation rather than by any change in gastrointestinal motor function.[50,51]

Sensory Aspects

The pain of reflux disease has long been associated with esophageal inflammation in the form of erosive (macroscopic, endoscopic) esophagitis or of histologic (microscopic) esophagitis. Nonerosive reflux disease (dubbed NERD by some) may thus manifest histologic inflammation or regeneration despite the absence of macroscopic changes. Esophageal pain unaccompanied by even microscopic abnormalities suggests mechanisms unassociated with inflammation. Contact of epithelial nerve endings with acid, in the absence of inflammation or regenerative changes, is one potential explanation. Another is that, in some individuals, chest pain is due to visceral hyperalgesia in the esophagus, analogous to the functional pain associated with irritable bowel syndrome or dyspepsia.[52,53]

Although esophageal sensory variations underlie some of the individual differences in the esophageal symptoms of GERD, differences among individuals in the sensitivity of the gastric afferent limb of TLESRs might also produce differences in the frequency of actual reflux episodes from person to person.

Reflux Noxiousness and Esophageal Defense

The components of the refluxate determine its pathogenicity for the esophageal mucosa (and for more proximal sites). An important study in adults found that gastric acid, gastric pepsin, and bile salts transported to the stomach by duodenogastric reflux were important intrinsic components of refluxate, whereas trypsin was seldom found.[54] The study also demonstrated that acid was increased in the esophagus in patients with esophagitis, strictures, and Barrett esophagus; that pepsin was increased (particularly during the night) in patients with strictures and Barrett esophagus; and that bile acids were found in the esophagus of 75% of their patients (particularly during the night) but were at cytotoxic concentrations in only 2% of subjects. Pepsin, when acidified, produces an early, irreversible lesion in the esophageal squamous epithelium, probably by damaging the junctional complex, thus allowing luminal acid greater access to the acid-permeable basolateral membrane and thereby promoting erosive esophagitis.[55] Elevated serum pepsinogen values in neonates with upper gastrointestinal bleeding and esophageal lesions provide further evidence for an important role of pepsin in erosive lesions in children.[56] Because acidity is important in rendering the other components (pepsin, bile salts or trypsin if implicated) pathogenic, therapies directed against acidity are generally effective.

In addition to the intrinsic components, gastric contents are also composed of extrinsic (ingested) material, particularly in the hour or two following a meal. The buffering character of infant milk feeds makes them far less provocative for esophagitis than the acidic liquids consumed by most older children and adults.[7,57] However, adult studies using dual pH probes to analyze the components of refluxate have documented a pocket of acid at the GEJ that escapes the buffering effect of meals, remaining highly acidic (median pH 1.6) compared with the gastric body (median pH 4.7, $p < .001$), and readily traverses the squamocolumnar junction.[58] Of further concern are recent data suggesting that dietary nitrate (commonly derived from green leafy vegetables, particularly when grown with nitrate-based fertilizers) is absorbed, secreted in saliva, reduced by buccal bacteria to nitrite, and further reduced to nitric oxide by acidic gastric juice and ascorbic acid at the GEJ, potentially provoking mutagenesis.[59]

Esophageal defense against noxious refluxate is provided by luminal (pre-epithelial), epithelial, and vascular (postepithelial) factors.[60] Lacking a well-defined surface mucous layer (except possibly in Barrett esophagus) and bicarbonate-secreting surface cells, the luminal defenses of the esophagus are quite limited. The more important epithelial defenses are both structural (apical cell membranes and intercellular junctional structures—both tight junctions and an intercellular glycoprotein material) and functional (acid-buffering mechanisms and two acid-extruding mechanisms—a Na/H exchanger and a Na-dependent Cl/HCO_3 exchanger). The vascular defense is the removal by the blood supply of the excess H+ that enters the epithelium from the lumen.

Genetic

Familial clustering of hiatal hernia, GERD, Barrett esophagus and adenocarcinoma has suggested a genetic predisposition.[61] Genetic linkage analysis identified a locus for a "severe pediatric GERD" phenotype in a group of five kindreds on chromosome 13q14 but excluded the locus in five other kindreds with an "infantile esophagitis" phenotype. It is likely that a disorder as common and as phenotypi-

cally diverse as pediatric GERD will be determined or modified at more than one genetic locus and that responsible genes may affect various aspects of the complex pathophysiology outlined above.

Environmental

Many aspects of the pathophysiology are rather obviously affected by environmental factors, such as dietary factors, habitual postures and activity, or clothing. Increased volume, osmolality, and acidity of the diet are provocative.[42] Supine and seated positions are provocative in infants, compared with the flat prone position, but similar results have not been found in older children and adults.[62] There is some ambiguity regarding whether one lateral position is more provocative than the other; the results are likely affected by meal volume and time postprandial. Increased straining, objectified as rectus abdominis contraction, makes reflux more likely to be propelled from the mouth as regurgitation.[63]

An environmental factor receiving particular attention recently is *Helicobacter pylori*. *H. pylori* gastritis, more common in less developed and less sanitary settings, may progress to atrophic gastritis, thus decreasing the acidity and volume of refluxate.[64] As such, it could be somewhat protective against GERD. Likewise, GERD symptoms and esophagitis may appear after eradication of the organism.[65] *H. pylori* genotypes predisposing the patient to more severe gastric disease may be most protective against GERD.[66]

Special Situations

Nocturnal reflux and reflux in premature infants illustrate some aspects of the pathophysiology of GERD.

In normal children, reflux is uncommon during sleep. Nocturnal reflux does occur in children with GERD, at a time when protective clearance functions, gravitational clearance, swallowing, and salivation are less active.[67,68] Perhaps because of the absence of these protections, nocturnal GERD is associated with increased incidence of complications of GERD: extraesophageal manifestations, Barrett esophagus, and adenocarcinoma. Nocturnal heartburn is associated with sleep disorders, reflux-associated respiratory disorders, and decreased health-related quality of life scores.[69,70]

GER in premature and full-term neonates is particularly challenging because of the dearth of data on which to base management.[71,72] Premature infants have an especially great need for caloric intake for adequate growth contrasted with limited gastric capacity. The relatively large-volume refluxate thus reaches the upper esophageal sphincter (UES) frequently. The response to such refluxate has been described in infants: effective primary and secondary peristalsis and an increase or relaxation in UES pressure.[72] The UES responses can be conceptualized as protecting the airway from refluxate by increased sphincter pressure but relaxing to allow refluxate to escape the esophagus when excessive esophageal pressure is generated by the refluxate. Gravitational provocations to reflux caused by the low torso tone are marked in these young children. Nasogastric tubes, often used to feed premature infants before suck-swallow and gag maturation, may impair refluxate clearance if the tubes are large bore.[73] Reflux is often nonacid at this age because of the very frequent buffered feedings. Chronic lower respiratory disease related to prematurity produces vicious cycles with GERD pathophysiology, to make both worse. Coughing is an uncommon respiratory clearance mechanism in neonates. The limited cross-sectional area of the larynx and upper airway, combined with immature reflexes predisposing the patient to apnea, make upper airway obstruction a particularly hazardous manifestation of GERD at this age: there are suggestions that nonacid reflux may be pathogenic for this manifestation in young infants.[74]

DIAGNOSIS

Historically, diagnostic evaluation of GERD emphasized radiography, then EpHM, and then endoscopy, usually supplemented by histology in children. Nuclear scintigraphy and esophageal impedance measurement provided the ability to evaluate nonacid reflux that EpHM missed. More recently, considerations of cost and invasiveness have motivated less technologic investigations, using validated questionnaires and trials of empiric medical therapy.

Endoscopy

Endoscopy, particularly when supplemented by histology, is the most accurate method of demonstrating esophageal damage by reflux. In a retrospective analysis of 402 neurologically normal children, between 18 months and 25 years of age and without congenital esophageal disease, who were diagnosed to have GERD, erosive esophagitis was reported at endoscopy in more than one-third.[75] The

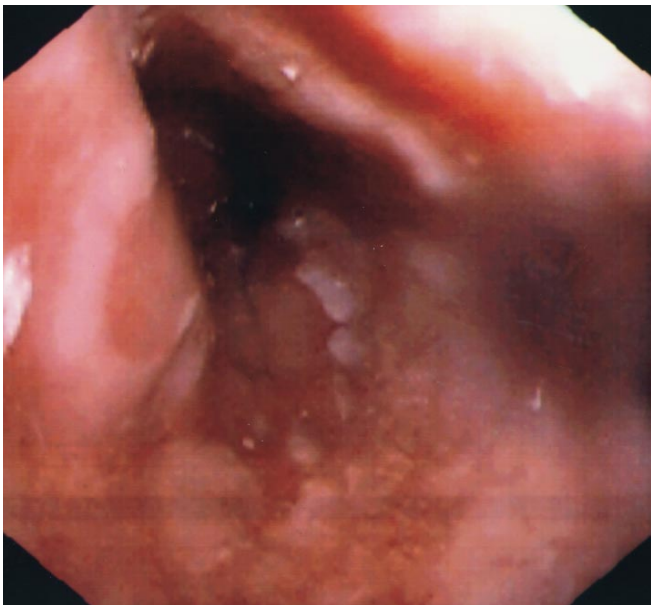

FIGURE 24-2 Endoscopic appearance of Barrett esophagus: salmon-colored patches of columnar mucosa extending proximal to the lower esophageal sphincter as tongue-like projections with surface exudate.

prevalence of erosions increased with age. Strictures were found in 1 to 2%; Barrett esophagus (Figure 24-2) was suspected endoscopically in nearly 3% but was not substantiated histologically by intestinal metaplasia. Optimization and standardization of practice and reporting of endoscopy are unrealized goals in pediatrics; a clinical outcomes research initiative developed in adults is currently being expanded to pediatric practices.[76]

Histology

Microscopic evaluation of biopsy samples from the distal esophagus, but avoiding the most distal area to minimize the false-positive findings at the GEJ, demonstrates abnormalities in many patients who have symptoms but no endoscopically visualized erosions. Infiltration of the epithelium with inflammatory cells, the changes recognizable in esophageal epithelium regardless of orientation of the specimen, received early attention. Neutrophils and eosinophils are not normally present in the epithelium of young children and can be used as indicators of GERD when found even though they are fairly insensitive.[77] Furthermore, eosinophils concentrated above 20/high-power field (or perhaps even above 5/high-power field) are likely to represent eosinophilic esophagitis (see Chapter 25, "Esophagitis"), making them nonspecific for GERD. Intraepithelial lymphocytes ("squiggle cells") are more sensitive than other inflammatory cells but are fairly common; their specificity for GERD remains unclear.

Morphometric histologic parameters require adequate size and proper orientation of the biopsy specimens but seem more reliable for the diagnosis of GERD.[77] They correlate with EpHM documentation of esophageal acid exposure in both adults and infants.[78] The upper limit of normal basal layer thickness and papillary height in infants is 25% and 53%, respectively.

Esophageal pH Probe Monitoring

EpHM (Figure 24-3) has helped to clarify the important role of esophageal acid exposure in GERD. However, many factors contribute to the variability of results in a given patient: technical variability owing to the type of recording equipment or probes, probe placement (methods include radiography, manometry, or regression equations related to patient height), number and placement level of probes (more proximal ones used for airway manifestations of GERD),[79] or duration of recording; patient variability owing to diet, activity, position, and possibly smoke exposure; and scoring systems used (including pH threshold and reflux duration required for an "episode" and the pH data and calculations employed).[80,81] Some scoring systems emphasize early postprandial periods, whereas others emphasize fasting periods. Most analyses place some emphasis on clearance parameters by detailing prolonged acid reflux episodes. Conceptually, one of the most compelling is a method quantifying "area under the curve," such that degrees of acidity, as well as duration of acid exposure, are taken into account; computerized systems will make this scoring system more practical.[80,82]

Although ambulatory and computerized monitoring now simplifies EpHM, the invasiveness and economic and temporal costs of the 24-hour test have prompted more limited and thoughtful use currently. One of the most useful indications is to identify whether acid reflux persists during acid suppression treatment when symptoms have not resolved; therapy can then be augmented or another diagnosis entertained depending on the results. Another

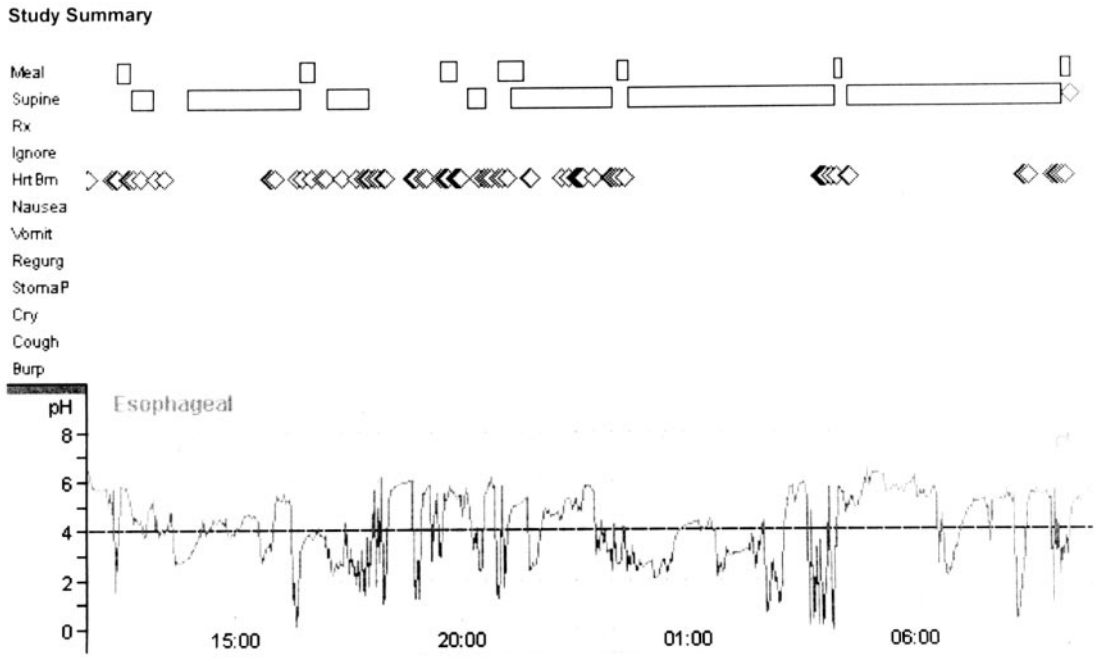

FIGURE 24-3 An intraesophageal pH probe study demonstrating gastroesophageal reflux episodes and relation to meals, position, and symptoms. In this study, reflux index (total time pH < 4) is 29.6%, the longest reflux episode is 64 minutes, and 54 episodes (31.5%) are associated with heartburn. StomaP = stomach pain.

particular use is the temporal correlation of symptoms with acid reflux events.[83]

Radiography

Fluoroscopic evaluation of swallowing and of the upper gastrointestinal tract is often important in the evaluation of the child suspected to have GERD, but radiography is neither sensitive nor specific for diagnosing GERD per se. Fluoroscopy may disclose gastrointestinal obstructions (pyloric stenosis, malrotation with intermittent volvulus) or motor abnormalities (achalasia) that present with symptoms similar to GERD or may demonstrate complications of GERD (strictures—Figure 24-4). Barium esophagography or specialized swallowing studies may be useful in identifying abnormalities of pharyngeal, laryngeal, or upper esophageal function that may prompt aspiration during swallowing and during reflux.

Nuclear Scintigraphy

Scintigraphy, sometimes crudely termed a "milk scan" because of one type of liquid meal used, employs solid or liquid meals labeled with technetium 99m—for its short (6 hour) half-life and limited radiation burden—to assess for delayed gastric emptying, a potential component of the pathophysiology (see Figure 24-1). A second use, based on scintigraphy's ability to demonstrate reflux optimally in the postprandial period (in contrast to EpHM, which is most sensitive during fasting, when gastric acidity is unbuffered), make it potentially complementary to EpHM evaluation.[84] Use in this way, however, requires prolonged restraint of the child and careful, technically demanding analysis and is thus impractical for clinical purposes. The third way in which scintigraphy has been used is to evaluate for aspiration, either with routine upper gastrointestinal scintigraphy or with salivagraphy.[85]

Impedance

Esophageal intraluminal impedance represents another method of demonstrating bolus reflux, without regard for the acidity of the refluxate. Like scintigraphy, it has been shown to be complementary to EpHM: in one study of 50 children monitored with impedance and EpHM simultaneously for about 6 hours, about 15% of impedance-detected episodes were identified by EpHM and about half of EpHM-detected acid episodes were identified by impedance.[86,87] These two tests may be complementary when performed simultaneously, but cumbersome performance and analysis may limit their effective use to research studies.

Miscellaneous Techniques

Esophageal manometry (particularly using Dent "sleeve" components to monitor sphincters) uses an esophageal catheter to demonstrate many of the pathophysiologic components of GERD, such as reduced lower esophageal sphincter tone, frequent TLESRs, and defective esophageal peristalsis. It also can demonstrate volumetric reflux, without regard for acidity, in the form of "common cavity" pressure elevations that are manifest first in the distal esophageal ports and may progress cephalad. However, this technique is cumbersome and of most use for investigative purposes.

Bilirubin monitoring in the esophageal lumen was developed because of the potential pathogenicity of duodenogastric reflux (particularly bile salts) in GERD.[88] However, duodenogastric refluxate does not cause esophagitis except in the presence of acid, so focus on acid reflux remains most useful, and bilirubin monitoring is of most potential interest for research studies.

Surface electrogastrography is a noninvasive technique to detect gastric myoelectrical activity, particularly that generated by the pacemaker interstitial cells of Cajal. It may be useful in identifying gastric myoelectrical abnormalities

FIGURE 24-4 Upper gastrointestinal series illustrating mid- and distal esophageal strictures in a patient with a history of vomiting and dysphagia for solids.

predisposing some children to GERD, but its use thus far is investigational, and it is predominantly used for functional symptoms such as nausea, anorexia, and dyspepsia.[89]

Respiratory Techniques

Laryngobronchoscopy allows visualization of abnormalities of the upper airway that may be predisposing patients to aspiration during reflux or swallowing (eg, laryngeal clefts) or that may suggest acid reflux–mediated damage to the airway (eg, vocal cord erythema or nodules).[90] Bronchoalveolar lavage may be accomplished concurrently to quantify lipid-laden macrophages (suggesting aspiration of lipid-containing material).[91] Flexible endoscopic evaluation of swallowing with sensory testing uses a small nasopharyngeal endoscope to visualize the larynx during swallowing and to test for appropriate reflexes to tactile stimulation of the larynx.[92] This technique has been minimally evaluated in children but can identify abnormalities that may predispose patients to aspiration. Most of these techniques do not distinguish well between aspiration during swallowing and during reflux. The "sleep study" employs EpHM concurrently with polysomnography (usually including electrocardiography, nasal airflow by thermistor or end-tidal CO_2, and respiratory efforts by chest wall impedance) to identify apneic episodes (particularly obstructive ones) that are temporally associated with acid reflux episodes.

Questionnaires

Questionnaires focus on symptoms and avoid costly and invasive diagnostic testing. They may be used to diagnose GERD or to categorize or stratify the disease. They may assess specific disease symptoms or may focus on quality of life (either generic or disease-specific), such that management strategies may be compared as to efficacy. After treatment or passage of time, they may be used to quantify improvement, stability, or worsening of disease. To be useful, questionnaires must be developed and validated using sophisticated methods to demonstrate the accuracy, reliability, and reproducibility (internal consistency, test–retest consistency, and interobserver consistency). Diagnostic questionnaires are tested for content validity, and questionnaires used for the assessment of changes over time must be shown to be responsive to such changes.

The degree to which reflux is common and manifests as symptoms without objective damage makes GERD questionnaires particularly compelling. Questionnaires to assess GERD in adults[93–96] and infants[97] have been validated, and still others are being developed.

Empiric Trial of Therapy

The availability of powerful acid-suppressing pharmacotherapy has prompted the use of a brief trial of the aforementioned therapy as a diagnostic test in adults, and this practice may reasonably be used in children.[98,99] Children whose symptoms clearly respond, particularly those whose symptoms do not recur after a course of some weeks of such therapy, are thus spared more invasive and costly diagnostic testing. Nonresponding or relapsing symptoms should undergo more definitive testing.

DIFFERENTIAL DIAGNOSIS

The differential diagnosis of GERD in children is large and may be categorized based on the presentation (Tables 24-1 and 24-2). Of particular recent interest is eosinophilic esophagitis, which may overlap with GERD in presentation and in histopathology but which must be treated quite differently (see Chapter 25).

THERAPY

The risks and benefits of therapy are increasingly evaluated and compared in terms of cost-effectiveness, with particular focus on quality of life, especially health-related quality of life. Economic considerations are also increasingly invoked. Cost-effectiveness analysis in adult GERD indicates that proton pump inhibitors (PPIs) are the most cost-effective initial and maintenance medical therapy in most situations, although, in some settings, the costs of drugs make histamine$_2$ receptor antagonists (H_2RAs) preferred.[100,101] The situation is probably different in infants, for whom reflux is predominantly of relatively larger volumes of material that is less acidic, so that, theoretically, lifestyle measures and prokinetic agents could be more cost-effective in this age group, although this expectation has not been realized to date.[7]

Lifestyle Measures (Conservative Therapy)

For infants, lifestyle measures have the clearest benefit.[102] Even telephone teaching of these measures may lead to symptom resolution for a sizeable proportion of infants.[103] The prone position clearly produces less reflux than the supine or seated position, but concerns about provocation of sudden infant death syndrome have significantly limited its use during ages when this syndrome is most common. Thickening of infant feeds reduces regurgitation, decreases crying, and increases sleep time.[104] Lower-volume and lower-osmolality feedings also decrease reflux.[42]

Pharmacologic Therapy

Pharmacotherapeutic agents encompass acid-lowering agents, barrier agents, and prokinetic agents (Table 24-3).

Acid-lowering agents are most useful for symptoms and complications that are acid related, such as heartburn and esophagitis. Acid-lowering agents, listed in order of increasing potency, are acid-neutralizing antacids, H_2RAs, and PPIs. In a review of adult studies without regard to dosing or duration of therapy, PPIs were found to produce more patients free of heartburn, more patients healed, more rapid reduction of heartburn, and more rapid healing than H_2RAs or barrier agents.[105] Such comparisons are unavailable for children; it is likely that similar conclusions would be reached for older children, but it is unlikely that most infants require powerful acid suppression.

"Step-up" and "step-down" strategies signify those that start with H_2RA and "step up" to PPI for those who fail to respond adequately versus those that start with PPI and "step down" to H_2RA when patients have responded adequately to the PPI. Optimal strategies for children are unclear. Recommended H_2RA dosing for children has probably generally been too low but is undergoing re-evaluation.

TABLE 24-1 DIFFERENTIAL DIAGNOSIS OF PEDIATRIC GERD: ESOPHAGEAL PRESENTATIONS

DIAGNOSIS	PRESENTATIONS
VOMITING, REGURGITATION	
GI obstruction	Malrotation/volvulus
	Pyloric stenosis
	Stricture
	Annular pancreas
	Duodenal web/stenosis
	Intestinal duplication
	Bezoar
	Superior mesenteric artery syndrome
	Adhesions
Infections	Viral enteritis
	Parasites
Motility disorders	Achalasia
	Enteritis
	Pseudo-obstruction
Food intolerance	Dietary protein allergy
Nonreflux GI inflammation	Peptic ulcer disease/gastritis
	Eosinophilic gastroenteritis
	Hepatobiliary disorders
	Pancreatitis
Functional GI disorders	Rumination
	Cyclic vomiting syndrome
Extragastrointestinal disorders	Metabolic disorders
	Increased intracranial pressure
	Uremia
	Ureteropelvic junction obstruction
	Infections
	Migraines
	Pregnancy
	Toxins
	Munchausen syndrome
	Adrenal insufficiency
ESOPHAGITIS (PAIN AND IRRITABILITY)	"Colic"
	Food intolerance
	Eosinophilic esophagitis
	Gastritis/peptic ulcer disease
	Infections
	Diffuse esophageal spasm
	Hepatobiliary disorders
	Pancreatitis
	Cardiac pain
	Costochondritis
	Visceral hyperalgesia
	Malingering
Dysphagia	Eosinophilic esophagitis
	Achalasia
	Other esophageal motility disorders
	Globus
	Vascular ring (dysphagia lusorum)
Failure to thrive	Feeding disorder
	Malabsorption
	Metabolic disorder
	Chromosomal anomaly/genetic syndrome
	Underfeeding

GERD = gastroesophageal reflux disease; GI = gastrointestinal.

TABLE 24-2 DIFFERENTIAL DIAGNOSIS OF PEDIATRIC GERD: EXTRAESOPHAGEAL PRESENTATIONS

DIAGNOSIS	PRESENTATIONS
APNEA/ALTE	Prematurity
	Broncholpulmonary disease
	RSV, pertussis
	Sepsis
	Seizure
	Cardiac disease
	Laryngotracheomalacia
	Choanal atresia
	Micrognathia
	Macroglossia
	Foreign body aspiration
	Adenoidal and tonsillar hypertrophy
OTOLARYNGOLOGIC PRESENTATIONS	
Otitis	Infections
Sinusitis	Infections
	Allergies
	Cystic fibrosis
	Immotile cilia syndrome
	Immune deficiency
Stridor, hoarseness	Viral croup
	Subglottic stenosis
	Laryngomalacia
	Tracheomalacia

	Foreign body aspiration
	Immotile cilia syndrome
	Postnasal drip
	Pneumonia
	Bronchitis, bronchiectasis
	Cough tic
DENTAL EROSIONS	Acidic foods and drinks
	Acidic medications (chewable vitamin C tablets, aspirin)
	Bulimia
	Rumination

ALTE = apparent life-threatening event; GERD = gastroesophageal reflux disease; RSV = respiratory syncytial virus.

Nocturnal acid breakthrough for patients on PPIs has been treated with bedtime doses of H_2RA, but there is evidence for tachyphylaxis to daily H_2RAs within a week.[106] When adequate doses of PPIs fail to ameliorate symptoms, considerations include incorrect diagnosis, improper administration (should be given just before a meal and not in the presence of antacids or H_2RAs), or genetic variation in hepatic cytochrome P-450-2C19 that results in more rapid metabolism of PPIs. Studies that compare several different PPIs at different doses should be critically evaluated in light of the fact that, for most PPIs, similar doses seem to have similar efficacies (except that esomeprazole, the S-isomer of omeprazole, is considerably more potent than omeprazole on a weight basis). For children unable to take PPI capsules, granules can be administered orally or into the stomach in weakly acidic material such as apple juice or yogurt or into the intestine dissolved in sodium bicarbonate. Pantoprazole is currently the only PPI available in the United States in intravenous formulation.[107–109]

TABLE 24-3 PHARMACOTHERAPY FOR PEDIATRIC GERD

MEDICATIONS	DOSES	SIDE EFFECTS
Acid neutralization		
Antacids	1 mL/kg/dose, 3–8 times/d	Constipation, seizures, osteomalacia, hypophosphatemia (Al); diarrhea (Mg); fluid retention (Na); milk-alkali syndrome (Ca)
Histamine$_2$ receptor antagonists		
Cimetidine	10–15 mg/kg/dose qid: AC, HS	Headache, confusion, pancytopenia, gynecomastia
Ranitidine	3–5 mg/kg/dose bid-tid: AC, HS	Headache, rash, constipation, diarrhea, malaise, elevated transaminases, dizziness, thrombocytopenia
Famotidine	Pediatric doses not defined	Headache, dizziness, constipation, diarrhea, nausea
Nizatidine	Pediatric doses not defined	Headache, dizziness, constipation, diarrhea, nausea, anemia, urticaria
Proton pump inhibitors		
Omeprazole	0.7–3.3 mg/kg/d, 1–2 divided doses: AC	Headache, rash, diarrhea, nausea, abdominal pain, vitamin B_{12} deficiency
Lansoprazole	1.4 mg/kg/d, 1–2 divided doses: AC	Headache, diarrhea, abdominal pain, nausea
Pantoprazole	Pediatric doses not defined	Headache, diarrhea, abdominal pain, nausea, flatulence
Rabeprazole	Pediatric doses not defined	Headache, diarrhea, abdominal pain, nausea
Esomeprazole	Pediatric doses not defined	Headache, diarrhea, nausea, abdominal pain, flatulence, dry mouth, constipation
Barrier agents		
Sucralfate	40–80 mg/kg/d qid: AC, HS	Vertigo, constipation, dry mouth, aluminum toxicity, decreases absorption of concurrently administered drugs
Sodium alginate	0.2–0.5 mL/kg/dose 3–8 times/d PC	Same as antacids
Prokinetics		
Metoclopramide	0.1 mg/kg/dose qid: AC, HS	Drowsiness, restlessness, dystonia, gynecomastia, galactorrhea
Cisapride*	0.2 mg/kg/dose qid: AC, HS	Diarrhea, cramps, cardiac arrhythmias
Erythromycin	3–5 mg/kg/dose tid-qid: AC, HS	Diarrhea, vomiting, cramps, antibiotic effect, pyloric stenosis
Domperidone	Pediatric doses not defined	Hyperprolactinemia, dry mouth, rash, headache, diarrhea, nervousness
Bethanechol	0.1–0.3 mg/kg/dose tid-qid: AC, HS	Hypotension, bronchospasm, salivation, cramps, blurred vision, bradycardia

AC = ante cibum; GERD = gastroesophageal reflux disease; HS = hour of sleep; PC = post cibum.
*Use in the United States restricted through a limited access program supervised by a pediatric gastroenterologist.

Barrier agents include sucralfate, which complexes with the base of ulcers or erosions, so it is most effective in settings in which the esophageal epithelium is broached. Gaviscon forms a different sort of barrier, floating on top of the gastric contents and potentially reducing reflux in that way.

Prokinetic agents have tremendous theoretical benefit in reflux, particularly in young children, but that theoretical benefit has been challenging to demonstrate objectively, and potential side effects and toxicity have limited their use. Bethanechol is without clear benefit and is currently rarely used. Metoclopramide has a narrow therapeutic range, and extrapyramidal side effects are not uncommon. Cisapride and domperidone are generally unavailable in the United States. Low-dose erythromycin may improve gastric emptying by activating motilin receptors, but the potential effects of widespread use of this antibiotic on antimicrobial resistance are of concern.[110] Baclofen, a $GABA_B$ agonist, is being studied as an antireflux agent because of its inhibition of TLESRs.[111]

Surgical Therapy

Fundoplication, the wrapping of the gastric fundus around the GEJ, has been used for decades to treat refractory GERD. Although it is efficacious in many children, complications are common and distressing. Cost-effectiveness analyses suggest that fundoplication is most likely to be favored in patients with anticipated prolonged duration of requirement for therapy: younger patients with GERD. However, its long-term effectiveness is ambiguous; many individuals treated with fundoplication nonetheless require ongoing pharmacotherapy for symptom relief.

Complications are most common in those most likely to require it, that is, those with chronic neurologic or respiratory disease. Complications include persistence of the symptoms prompting surgery (often owing to a loose wrap) or the side effects of the surgery (often owing to a tight wrap).[112,113] More broadly, persistence of the symptoms may be due to a "bad diagnosis," wherein the symptoms prompting surgery were incorrectly attributed to GERD; a "bad patient," whose challenging physiology makes a successful fundoplication difficult; or a "bad therapy" (incompetent to prevent reflux) performed by a surgeon with deficient or inappropriate technique. Side effects of the surgery, in contrast to ineffective surgery, are usually due to a wrap's excessive tightness: an antegrade obstruction that produces dysphagia or a retrograde obstruction that produces gas-bloat. Other complications may be due to vagal injury, producing nausea and vomiting owing to gastroparesis or diarrhea or hypoglycemic symptoms owing to dumping (rapid gastric emptying).

Gas-bloat is common and a particularly challenging side effect of fundoplication because understanding of its pathophysiology is limited, and the management options are limited and often experimental. Symptoms include inability to belch or vomit when needed, retching, gagging, nausea, early satiety, postprandial fullness, and abdominal distention. The pathophysiology of gas-bloat in an individual patient may include gastric hyperalgesia, abnormal gastric emptying,

impaired accommodation, or impaired vagal function. These various causes require different types of pharmacotherapy.

Methods to prevent complications prior to performing fundoplication include (1) careful elimination of nonreflux causes of the symptoms prompting surgery; (2) awareness that failure of aggressive PPI pharmacotherapy to control symptoms suggests a nonreflux cause; (3) careful tailoring of the operation in those predisposed to complications by neurologic or respiratory disease, delayed gastric emptying or retching, short esophagus (from esophageal atresia, stricture, or large hiatal hernia), or esophageal dysmotility (eg, from esophageal atresia); (4) choice of an experienced or closely mentored surgeon; (5) optimal "tightness" of the fundoplication to prevent reflux but avoid dysphagia (eg, looser in those with defective peristalsis); and (6) use of a venting gastrostomy for those predisposed to problems because of lower gastric compliance or capacity (eg, infants). Some surgeons have used preoperative gastric emptying studies to select patients for concurrent pyloroplasty, but, currently, data argue against this practice because fundoplication itself promotes more rapid gastric emptying.

When complications do occur following fundoplication, the diagnosis and competence of the wrap may be re-evaluated with barium fluoroscopy, endoscopy with histology, and pH probe, using other modalities (eg, esophageal or antroduodenal manometry, gastric emptying scintigraphy) as indicated and treating any other diagnosis if found. Conservative management of complications often includes dietary and feeding modifications. Pharmacotherapy is often required for postfundoplication complications, either directed at the recurrent reflux or directed at the specific side effect of fundoplication if one is present. Fundoplication revision, or dilation of a persistently tight wrap, is sometimes needed.[112,113]

Laparoscopic fundoplication can be as effective as open fundoplication in children and associated with more rapid postoperative recovery but requires a surgeon experienced in performing the technique in these small patients.[114]

Endoscopic therapies aimed at the GEJ in patients with reflux eventually may prove useful enough to be applied to children.[115]

COMPLICATED GERD

Esophageal Complications: Strictures, Barrett Esophagus, and Adenocarcinoma

Chronic reflux may result in scarring of the esophagus, producing a stricture. This scarring appears to depend on acid and perhaps on pepsin.[54] These peptic strictures are generally located in the distal third of the esophagus (see Figure 24-4). Rarely in children, these strictures may be accompanied by Barrett esophagus. They should be distinguished from other types of strictures: caustic (generally more proximal), eosinophilic, postoperative/anastomotic, following radiation therapy or sclerotherapy, or (rarely in children) malignant. Peptic strictures should be biopsied below the stricture to confirm the diagnosis of reflux esophagitis and exclude eosinophilic esophagitis, Barrett esophagus, or malignancy. They are treated with a course of endoscopic dilations at increasing intervals, supplemented by aggressive antireflux therapy. Injection of corticosteroids into the stricture at the time of dilation has been used for resistant strictures. Resection or stricturoplasty may be required for those strictures not amenable to dilation or that perforate during dilation. The relative merits of chronic antireflux pharmacotherapy versus fundoplication continue to be debated. A coexisting large hiatal hernia may encourage surgical treatment.

Barrett esophagus is uncommon in children but has been reported.[116] The intestinal metaplasia of the distal esophagus, manifesting endoscopically as salmon-colored tongues of tissue projecting proximally into the paler pink esophagus (see Figure 24-2), increases with age until about the fifth decade, and the density of goblet cells increases in parallel.[28] In children, associated conditions include neurologic disability, chronic respiratory disease, repaired esophageal atresia, chemotherapy for malignancies, and hiatal hernia.[117] Postulated pathogenesis of Barrett esophagus has included genetic influences, reflux of both acid and pepsin, and possibly a decreased sensitivity to reflux events that results in impaired clearance reflexes.[54,61] The importance of duodenogastric reflux of bile (and possibly trypsin) has been debated.[54,118]

Guidelines for the diagnosis of, therapy for, and surveillance for dysplasia and malignancy in Barrett esophagus have been promulgated for adults and may be applicable to children.[119–122] Hiatal hernia size, length of the Barrett esophagus, and severity of acid reflux are all risk factors for esophageal adenocarcinoma; surgical reduction of hiatal hernia and associated fundoplication thus may be indicated in those with hiatal hernia.[36] Because of the apparent insensitivity to reflux in many patients with Barrett esophagus, it is worthwhile to assess the adequacy of therapy with EpHM and to evaluate periodically via endoscopy for regression or progression of the Barrett epithelium and for dysplasia.[123,124] Successful attempts to ablate the specialized epithelium have been reported in adults. Adenocarcinoma is extremely rare in childhood, but it does occur and should be sought in those with Barrett esophagus.[123]

EXTRAESOPHAGEAL GERD

Respiratory Complications and Interactions

Embryonic relationships between the upper gastrointestinal tract and the airway lead to both luminal and neural connections between the two systems. Consequently, GERD provokes and worsens respiratory diseases, both otolaryngologic and lower respiratory tract disorders, and may do so either by aspiration of refluxate, producing inflammatory changes in the lumen, or by reflexive responses of the airway to refluxed material in the esophagus.[125,126] The respiratory diseases, in turn, may worsen GERD. Epidemiologic evidence suggests that GERD, particularly when reflux occurs recumbent and during sleep, is associated with a several-fold increase in sinusitis, laryngitis, asthma, pneumonia, and bronchiectasis.[70,127,128] Data on otitis media are conflicting.[127,129,130] Laryngotracheoma-

lacia and stridor often coexist with GERD; laryngoscopic changes in the posterior larynx suggest laryngeal irritation by GERD; and chronic hoarseness, chronic cough, and chronic sinusitis have apparently been effectively treated by GERD therapy in open-label trials.[131–133] Dental erosions on the lingual aspects of the posterior teeth also may represent extraesophageal GERD (Figure 24-5).[134–136]

Infantile apnea represents a prototypical upper airway response to reflux in the infant, whereas the bronchospasm of asthma represents a prototypical lower airway response to reflux in the older child.[69,74,125,126,137–142] Probable mechanisms for these phenomena have been reviewed.[143,144] Whether aspiration, esophageal airway reflexes, both, or neither is implicated in the pathophysiology of individual cases is challenging to determine. It is likely that most infants with apnea and most older children with asthma do *not* have reflux-induced respiratory disease. Nonetheless, GERD may play an important role in selected cases, which will be resistant to management if GERD is not considered and treated.[137]

Diagnosis of individual patients suspected of GERD-mediated extraesophageal disease is difficult. The presence of concurrent GERD symptoms makes GERD a more likely factor in respiratory disease. It is important to distinguish aspiration during reflux from aspiration during primary swallowing because the therapeutic approach will be different. The diagnostic methods must be tailored to the particular questions raised by the presentation but may include upper esophageal EpHM,[145] fluoroscopy (particularly specialized upper esophageal swallowing studies, sometimes termed "cookie swallow"),[146] scintigraphy to diagnose aspiration (particularly the salivagram[85]) (Figure 24-6), laryngobronchoscopy (to disclose posterior glottic edema, erythema, and nodules and including bronchoalveolar lavage for lipid-laden macrophages or trypsin to assess aspiration),[91,147–149] and flexible endoscopic evaluation of swallowing with sensory testing.[92] Laryngobronchoscopy may be coordinated with endoscopic and histologic evaluation of the upper gastrointestinal tract.[150] Impedance testing discloses nonacid reflux that may be important in infantile apnea.[74] An empiric trial of aggressive antireflux therapy can also be used.

Therapy for extraesophageal manifestations of GERD has been reviewed.[151–153] When GERD is responsible for extraesophageal presentations, it seems that the therapy must be aggressive in terms of both potency and duration to affect the respiratory symptoms. Twice-daily PPIs maintained for at least 3 months are recommended. Fundoplication surgery seems to provide better results, and, in adults, the best surgical results are obtained in patients with nocturnal asthma, onset of reflux symptoms before pulmonary symptoms, evidence of laryngeal inflammation, and a good response to medical treatment. However, the complication rate for fundoplication is greater in children with respiratory disease than in those without.

Neurologic Presentations and Interactions

Neurologically abnormal children have more GERD, and more complicated GERD, than neurologically normal children. Increased gastric pressure mediated by spasticity, chronic supine posturing impairing refluxate clearance, inability to communicate or move to ameliorate symptoms, and possibly other direct effects of neurologic abnormality all predispose patients to more severe GERD. Thus, erosive GERD, strictures, Barrett esophagus, adenocarcinoma, and chronic respiratory manifestations of GERD are all more common in children with neurologic disability.

FIGURE 24-5 Dental imaging showing generalized enamel and dentin erosions at the incisal edges in a patient with gastroesophageal reflux disease. Some dental caries are also present.

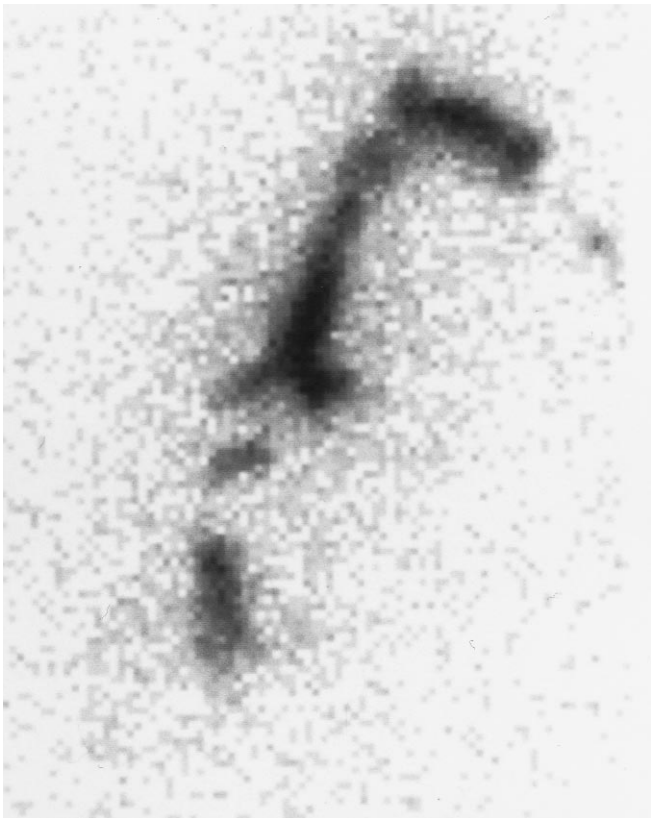

FIGURE 24-6 Salivagram using technetium 99m sulfur colloid–labeled small-volume fluid introduced into the oropharynx produces prompt aspiration extending to the right and left main stem bronchi as seen on posterior imaging of the thorax.

In addition to the impact of neurologic disorders on GERD, GERD may induce symptoms that mimic seizures or neurologic disease. Torso hyperextension ("arching") is a common manifestation of infantile reflux.[11] More unusual and severe manifestations in older children include Sandifer syndrome, a stereotypic torso, and nuchal hyperextension with unclear pathophysiology.[16,154]

GERD, one of the most common and costly disorders afflicting children, presents with a wide array of symptoms, overlaps in presentation with many non-GERD diseases, can be challenging to diagnose, and does not lend itself readily to simple curative therapy. The burgeoning incidence of esophageal adenocarcinoma related to chronic GERD in adults focuses attention on the possible initiation of this cancer in childhood GERD. Further clarifying the pathogenesis of this important disease will have important implications for prevention and treatment.

CHAPTER 25

ESOPHAGITIS

Mike Thomson, MB, ChB, DCH, FCRP, FRCPCH, MD

Pathologic processes in the pediatric esophagus have received a disproportionately small amount of attention until recently, when appreciation of their pathophysiology and concordant clinical importance has been highlighted. This increase in interest and exposure is probably a phenomenon secondary to a number of important factors, which include improved diagnostic yield from relatively recent technical advances in areas such as infant and pediatric endoscopy; advances in fields such as mucosal immunology, allowing for the realization that etiopathologic mechanisms for esophagitis are more complex than simple luminal chemical damage; and a shift in clinical opinion recognizing esophageal pathology as a major cause of nonspecific ubiquitous symptoms such as infant colic, feeding disorders, and recurrent abdominal pain, among others. A state of knowledge such as this has made pediatric esophagitis, until recently, a relatively underdeveloped area of research and clinical understanding, but this is rapidly changing.[1]

It is now clear, therefore, that esophagitis in infants and children has many responsible etiologic pathways that may have complex interactions and hence requires equally complex diagnostic and therapeutic strategies. Such causative factors are now known to include cow's milk protein (CMP) intolerance or allergy; pH-dependent and -independent gastroesophageal reflux (GER); dysmotility of various causes; and infective, traumatic, and iatrogenic causes, among others. Hence, the term "esophagitis" can be used to describe chemical, infectious, inflammatory, ischemic, immunologic, and degenerative abnormalities.[2] Nevertheless, there remains a minor degree of controversy regarding the definition and significance of esophagitis, as assessed by standard diagnostic techniques, including endoscopy and biopsy.[3,4] This chapter attempts to describe basic etiologies and their interactions, symptomatic presentations, timing and choice of diagnostic measures, current practice of therapeutic interventions, and prognosis of and for esophagitis in infancy and childhood.

EPIDEMIOLOGY

This is a relatively gray area in infancy and childhood. Esophagitis occurs throughout the age spectrum of pediatrics and has even been reported as a cause of prenatal gastrointestinal (GI) bleeding.[5] Neonatal esophagitis is well known as a cause of GI bleeding or anemia.[6,7] It is estimated that the prevalence of reflux esophagitis varies between 2 and 5% of the general population[8]; however, few objective data exist to allow determination of esophagitis distribution in childhood. Some limited data are available regarding GER, and in an early study by Carre, 60% of infants were symptom free by 18 months of age, but 10% developed complications.[9] Such studies would now be considered unethical, and, subsequently, other studies assessing outcome with early therapy have indicated that less than 55% would be symptom free by 10 months of age and 81% by 18 months.[10] In a study of 32 older children (3.5–16 years) with GER, 50% had esophagitis, and less than 50% underwent complete resolution or marked symptom resolution over the ensuing 1 to 8 years.[11] Forty percent came off medication, and 40% required ongoing medication for control of symptoms. Two children required fundoplication. Unfortunately, no wider studies are available, and other information on the incidence and prevalence of esophagitis comes from adult studies. These indicate that 48 to 79% of those with GER have esophagitis, with few having symptoms,[1] which is similar to that quoted for infants.[12]

ETIOLOGY AND PATHOPHYSIOLOGY

The etiologies of esophagitis in infancy and childhood can usefully be divided into the following groups:

1. Chemical: (a) owing to refluxed contents from the stomach and duodenum such as gastric acid, pepsin, bile, and trypsin (b) owing to swallowed substances, either intended, such as medications, or accidental caustic ingestion, such as dishwasher liquid
2. Immunologic: owing to specific responses to specific antigens such as CMP or multiple food intolerance or allergy
3. Infective: associated with organisms as diverse as *Helicobacter pylori* and *Candida*, cryptosporidiosis, herpes simplex, and cytomegalovirus (CMV)
4. Traumatic: secondary to intraluminal trauma (eg, long-term nasogastric tube) or irradiation (eg, as part of bone marrow transplant conditioning)
5. Systemic disease manifestation: associated with conditions such as Crohn disease and chronic granulomatous disease
6. Miscellaneous: such as that associated with passive smoking or that occurring in Munchausen syndrome by proxy
7. Idiopathic: idiopathic eosinophilic esophagitis

The etiopathologic role of each of these situations can therefore be usefully discussed under each heading, bearing in mind that an individual child or infant may, of course, have more than one factor contributing to the esophageal insult at any one time (eg, GER and cow's milk–associated esophagitis).

Chemical

Gastroesophageal Reflux. This is dealt with more comprehensively in Chapter 24, "Gastroesophageal Reflux." Nevertheless, a brief summary of the pathophysiology and etiology of GER is pertinent here.

The natural history of GER is to improve with age; however, one important question arises: why do infants (and subsequently a hard core of older children) have a greater propensity toward GER? Differences in the function of the lower esophageal sphincter (LES) have been investigated[13,14]; this is an area that is tonically contracted at rest, with relaxation occurring consequently on an esophageal peristaltic wave. Inhibitory neurotransmitter production is integral to LES relaxation, and the nonadrenergic, noncholinergic neurotransmitter nitric oxide (NO) has received attention in animal[15] and human studies.[16,17] Vasoactive intestinal polypeptide is another candidate undergoing investigation, and the importance of the ontogeny of neuropeptides in the human fetus and infant is becoming increasingly apparent.[18] Rather than a "weak" LES in infants, it is more likely that a combination of anatomic relationships of the LES precluding effective pressure generation and inappropriate LES relaxation is responsible for infantile GER and its subsequent age-related improvement.[19,20] In adults, 90% of the refluxate is cleared in seconds, and the remainder is neutralized by subsequent swallows.[21] Efficiency of esophageal clearance is therefore vitally important in the genesis of esophagitis.

Although work exists suggesting that acid exposure of the distal esophagus induces dysmotility in pediatric patients,[22] allowing the potential for a "vicious cycle" of LES dysfunction to GER to LES dysmotility to further GER to esophagitis and back to LES dysmotility, it is still not clear how an inflamed esophagus further impairs esophageal tone or motility, but emerging work suggests a role for interleukin (IL)-5 and eotaxin in allergic neurohumoral modification and possible gastroesophageal junction (GEJ) inappropriate relaxation, with an interrelation with mast cell degranulation and histamine release to afferent and then efferent neurons, which control transient lower esophageal sphincter relaxation episodes (TLESRs).[23] Inducible nitric oxide synthetase (iNOS) (which is markedly up-regulated in GI inflammatory conditions such as Crohn disease), is important in relaxation of the LES during TLESRs, which are the single most common mechanism underlying GER, but in one study was not up-regulated in the inflamed pediatric esophagus.[24] However, other researchers suggest an increased release of NO in the inflamed esophagus in children.[25] Other factors that affect clearance are posture-gravity interactions; volume, size, and contents of a meal, for example, breast milk[26,27]; defective peristalsis of the esophagus; gastric emptying; and increased noxiousness of refluxate.

Acid, particularly when combined with pepsin, which is most active below pH 2, is known to cause severe esophagitis in animals and humans.[28–31] Even a 24-week gestation infant in an intensive care setting has the ability to lower intragastric pH below 2.[32] Pepsin plays a critical role in esophagitis owing to acidic refluxate; animal work has shown that in dogs and rabbits, infusion of hydrochloric acid alone caused no damage, but in combination with low concentrations of pepsin at pH less than 2, severe esophagitis resulted.[33,34] Proteolysis may allow deeper penetration of harmful refluxate, and the simple notion that acid causes epithelial damage must therefore be questioned in favor of a more complex interplay of a number of noxious stimuli in the pathogenesis of reflux esophagitis in infants and children.

Furthermore, the role of duodenogastroesophageal reflux (DGER) remains controversial[35,36] and has not, to date, been adequately studied in pediatrics. What is clear from adult studies is that alkaline reflux does not correlate well with bile reflux, the former being attributable to reasons other than DGER, such as saliva, food, oral infection, or an obstructed esophagus.[35] In fact, in one study, bile acid DGER correlated well with acid reflux, and those with the more severe esophagitis had greater exposure to the simultaneous damaging effects of both acid and bile acids.[33] Perfusion studies of the rabbit esophagus show that conjugated bile acids in an acidic environment produce mucosal injury, whereas unconjugated bile acids and trypsin are more harmful at more neutral pH values (pH 5–8); therefore, the latter are less likely to cause reflux-associated damage because this is usually an acidic phenomenon.[36] It is further suggested by animal work that the hydrochloride-pepsin damage may actually be attenuated by the presence in the esophagus of conjugated bile acids, but if damage is done to the squamous epithelium, the un-ionized forms of conjugated bile acids at a low pH may be allowed access to mucosal cells and cause damage by the dissolution of cell membranes and mucosal tight junctions.[37–40]

The histologic appearances typical of luminal chemical-induced esophagitis secondary to GER or GER disease are discussed in the diagnosis section of this chapter.

Chemical Esophagitis owing to Swallowed Substances. The importance of caustic ingestion into the esophagus is dealt with comprehensively in Chapter 27, "Injuries of the Esophagus" (Figure 25-1). Ingested materials are usually household or garden substances and are usually markedly alkaline; the common one was dishwasher fluid, often with a pH of 9 or above. However, fortunately, in most countries, this has been replaced with powder, which is less easy to swallow, and even individually wrapped tablets of powder. Acute perforation, mediastinitis, and subsequent esophageal stricture have frequently been seen. The possibility of nonaccidental injury should not be forgotten in this context. It is notable that the rate of subsequent stricture formation is high, and, more recently, a potentially effective postdilation topical application of an antifibrotic, mitomycin C, has shown promise in preventing restenosis and long-term repeated stricture dilation.[41]

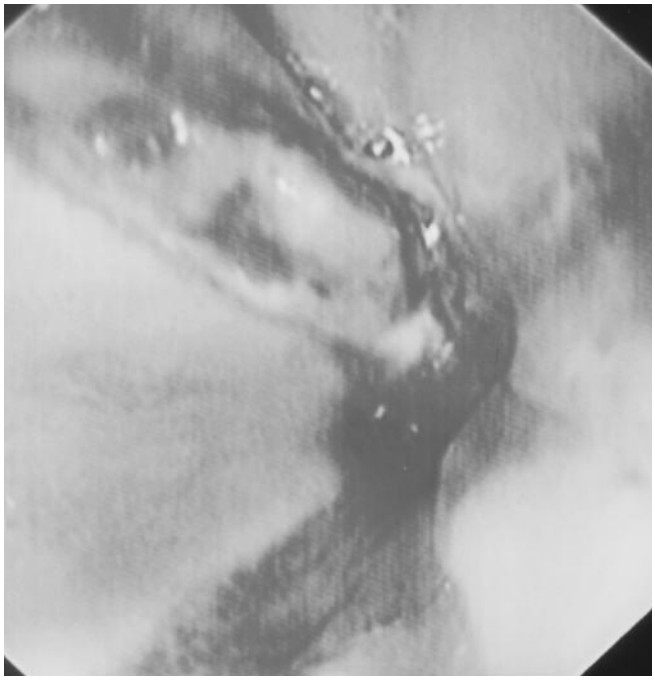

FIGURE 25-1 Example of caustic injury to the esophagus.

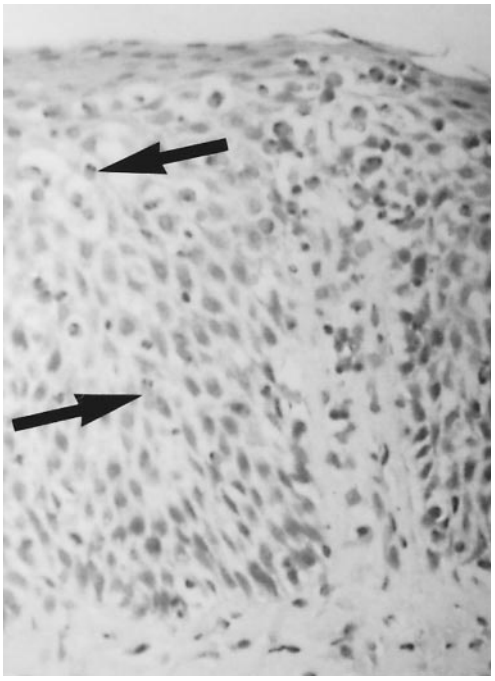

FIGURE 25-2 Esophageal mucosal eosinophilia seen in cow's milk–associated and primary reflux esophagitis and primary eosinophilic esophagitis (hematoxylin and eosin; ×200 original magnification) (eosinophils marked by *arrows*).

Many medications have been associated with esophageal damage and symptoms of esophagitis, and these include tetracyclines (not recommended under the age of 12 years, of course), drugs used in acne therapy, and nonsteroidal anti-inflammatory drugs.[42–45]

Immunologic

Although it is now clear that multiple food antigens may induce esophagitis,[46,47] the most common precipitant is CMP. Standard endoscopic biopsy and histology do not reliably distinguish between primary reflux esophagitis and the emerging clinical entity of cow's milk–associated reflux esophagitis. This variant of cow's milk allergy appears to be a particularly common manifestation in infancy, with symptoms indistinguishable from primary GER but that settle on an exclusion diet.[48] Some differentiation from primary reflux has been suggested on the basis of an esophageal pH testing pattern and a β-lactoglobulin antibody response, although the former has not been substantiated by more than one center.[48,49] There is recent evidence that this esophagitis is becoming a more common presentation of infant food allergy within the developed world and, in fact, may be induced by a variety of antigens in addition to cow's milk.[46,47] Many affected infants have sensitized while exclusively breastfed, and a defect in oral tolerance for low doses has been postulated as the underlying cause.[50,51]

Esophageal mucosal eosinophilia has been described in both suspected cow's milk–associated[46] and primary reflux esophagitis (Figure 25-2),[52] as well as in other conditions, such as idiopathic eosinophilic esophagitis (IEE).[53] However, the density of the eosinophilic infiltrate has been used as a differentiator between allergic esophagitis and IEE, with the latter defined as more than 15 to 20 eosinophils per high-power field (HPF).[54] The clinical significance of eosinophils and their role in the pathogenesis of mucosal injury is poorly understood and the subject of recent debate.[3,4,55] Some have suggested an active role for eosinophils in the inflammatory process of esophagitis and have supported this with the observation of activation of the eosinophils by electron microscopic criteria.[56] In addition to dietary exclusion of cow's milk,[46,48] oral steroids can induce remission of symptoms with decreased mucosal eosinophilia[48,53] suggesting a pathoetiologic role for eosinophils. In addition to eosinophils, intraepithelial T lymphocytes, known as cells with irregular nuclear contours (CINCc), have also been implicated as markers of reflux esophagitis.[57,58] In adults, such cells are of memory phenotype and display activation markers,[59] although little is known of their pediatric equivalents.

A variety of immunohistochemical markers have been used to examine the esophageal mucosa, including eotaxin, a recently described eosinophil-specific chemokine (Figure 25-3),[60] and markers of T-cell lineage and activation. Despite the mild histologic abnormality in CMP-associated esophagitis, an increased expression of eotaxin colocalized with activated T lymphocytes to the basal and papillary epithelium has been shown,[61] distinguishing this from primary reflux esophagitis. The molecular basis of the eotaxin up-regulation in cow's milk protein–sensitive enteropathy (CMPSE) is unknown. However, there is evidence from murine models of asthma that antigen-specific up-regulation of eotaxin expression can be induced by T cells and blocked by anti-CD3 monoclonal antibodies. This suggests the possibility of a distinct mechanism in CMPSE, in which mucosal homing to the esophagus occurs of lymphocytes activated within the small intestine. This may explain the seemingly counterintuitive finding of basal, as opposed to superficial, chemokine

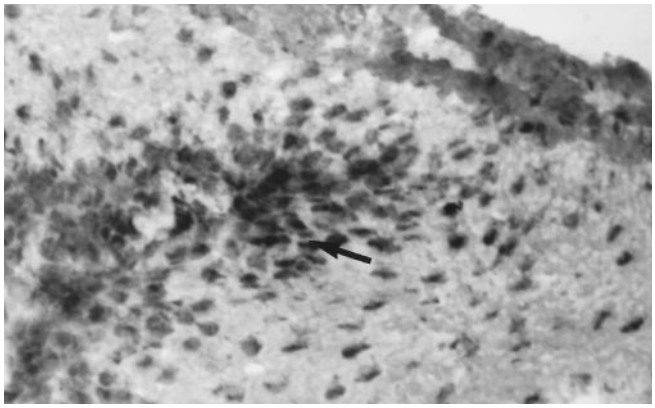

FIGURE 25-3 Eotaxin, a recently described eosinophil-specific chemokine (×200 original magnification) (darker staining area marked by an *arrow*).

expression and the common occurrence of mucosal eosinophilia in this condition. The esophageal motility disturbance of CMPSE-associated esophagitis is thus suggested to occur as a neurologic consequence of the inflammatory infiltration induced from lamina propria vessels into the epithelial compartment.[62] This proposed mechanism contrasts with the current concept of luminally induced inflammation found in primary reflux esophagitis and is consistent with the characteristic delayed onset and chronic nature of cow's milk–associated reflux esophagitis. The up-regulated expression of epithelial human leukocyte antigen (HLA)-DR suggests that the cytokine secretion profile of these cells includes interferon-γ, and thus a mixed T helper (Th)1-Th2 pattern is likely (IL-5 secretion is also likely in view of the frequent mucosal eosinophilia), and it may thus be relevant that small intestinal mucosal lymphocytes in infants with CMPSE show both Th2 skewing and low transforming growth factor (TGF)-β expression.[63] It seems, therefore, that there is a characteristic esophageal mucosal immunohistochemical profile in cow's milk–associated reflux esophagitis. Up-regulation of basal eotaxin expression and focal distribution of T-cell lineage and activation markers suggest a mechanism of mucosal homing of cow's milk–sensitized cells from the small intestine in the pathogenesis of CMPSE-associated esophageal reflux, in a manner distinct from luminally mediated primary reflux esophagitis. It has also been suggested that increased numbers of mucosal mast cells allow a distinction to be made between allergy-induced and reflux-induced esophagitis.[64] Much work is required in this area and is ongoing.

Infective

The majority of infective esophagitis that occurs is in the immunocompromised child and is due to such agents as herpes simplex, CMV, *Candida,* and others. Mucosal damage owing to physical or chemical causes may predispose the patient to opportunistic infection. Oral herpes or *Candida* may offer some clue to etiology, and the older child will often complain of odynophagia or dysphagia. Diagnosis may be made on endoscopy with biopsy, but brushings may offer a greater diagnostic yield.

Viral esophagitis is usually due to herpes simplex, CMV, and, occasionally, varicella zoster.[65–67] Herpes simplex esophagitis can occur in those with normal immune function[68] but is more often seen in those who are immunocompromised; in one series, 10% of post–liver or –kidney transplant recipients had herpes or CMV esophagitis,[69] and it is also commonly seen in pediatric human immunodeficiency virus (HIV) infection.[70] Use of prophylactic acyclovir is conjectural but may be of some benefit.

Diagnosis of herpes esophagitis is often difficult because the characteristic nuclear inclusions and multinucleate giant cells may not be seen in endoscopic biopsies; however, a prominent mononuclear cell infiltrate is described as characteristic (Figure 25-4).[71] It may be that the esophagus is particularly vulnerable in the GI tract owing to affinity of the herpes virus for stratified epithelium. Typically, roundish distinct disseminated lesions with yellowish borders are seen and have been termed "volcano ulcers" (Figure 25-5),[72] although early in the presentation, vesicles may be noted. Although the inflammation can resolve spontaneously in the immunocompetent, in those with poor immune function, acyclovir and a high index of suspicion are recommended.[72] Resistance to acyclovir has been described, in which case, foscarnet is the agent of choice.[73] CMV esophagitis is confirmed by basophilic nuclear inclusions on biopsy of the edge of the ulcers, which are similar in appearance to herpetic ones. CMV is predominantly found in immunocompromised individuals, and treatment is with ganciclovir or foscarnet.[67] Hemorrhage, fistulae, and esophageal perforation in adults with viral esophagitis are described.[74,75] Acute HIV infection can also cause esophagitis.[76]

Candida, the most common infectious cause of esophagitis, has the classic appearance of white plaques on the mucosa, which cannot be washed or brushed off, unlike food or milk residue, and which often extend up to the upper third of the esophagus (Figure 25-6).[77] Oral *Candida* is not predictive of esophageal involvement except in the immunocompromised host, but even in these children, extensive esophageal involvement is seen in the absence of oral candidiasis.[78] Mucositis and a white cell count less than 0.5×10^6/L predisposes patients with leukemia to can-

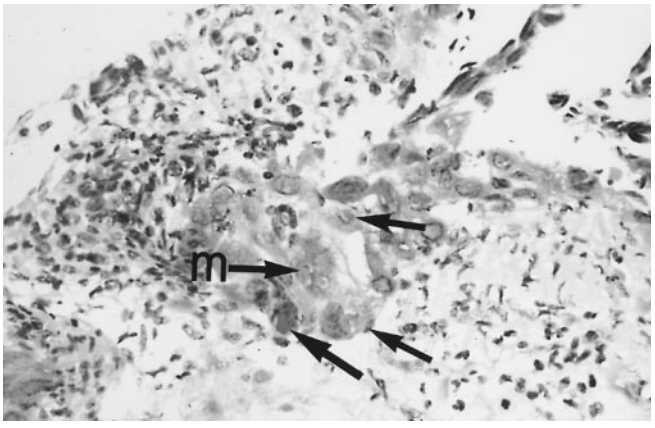

FIGURE 25-4 Herpes esophagitis with nuclear inclusions, multinucleate giant cells, and a prominent mononuclear cell infiltrate (m) (×200 original magnification).

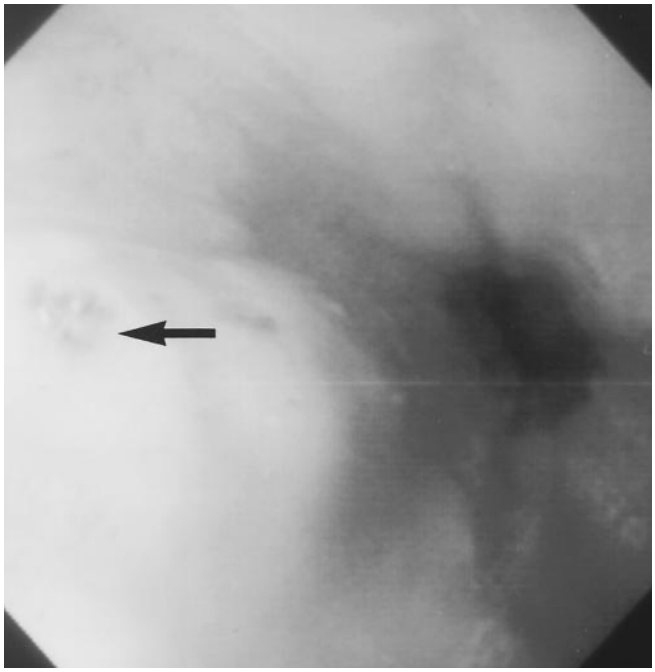

FIGURE 25-5 Macroscopic appearances of herpes esophagitis. Roundish distinct disseminated lesions with yellowish borders are seen and have been termed "volcano ulcers" (*arrow*).

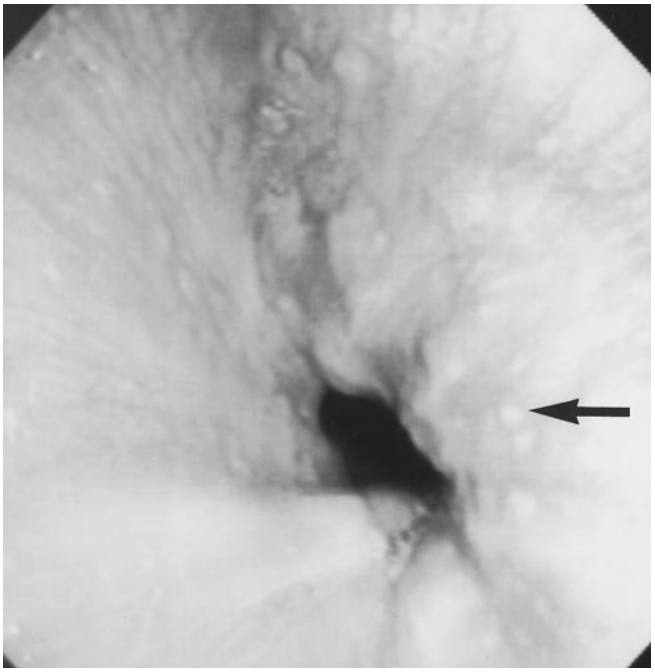

FIGURE 25-7 Candidal esophagitis may have the appearance of white focal lesions on the esophagus, which may be difficult to distinguish from allergic esophagitis.

didal esophagitis.[79] Steroid use (even poor technique with inhaled steroids for asthma) or acquired or congenital immunocompromise may be etiologic and may have the appearance of white focal lesions on the esophageal surface (Figure 25-7). This appearance may be difficult to distinguish from allergic esophagitis. Apart from the macroscopic appearances, diagnosis is confirmed by the presence of hyphae in biopsies (Figure 25-8). Culture is not helpful because coexistent oral *Candida* can confuse the assessment. Complications include fistulae, perforation, painless stricture formation, esophageal dysmotility, transient achalasia,[80] and systemic candidiasis. A 2- to 6-week course of oral nystatin can be effective in those with normal immune function, but it is more convenient to give fluconazole. Fluconazole or liposomal amphotericin is required, and both are effective in the immunocompromised child. Esophageal resection and diversion for necrotizing candidal esophagitis have been successful in a 10 year old.[81]

Eradication of *H. pylori* in adults has been associated with increased acid production and hence more noxious gastroesophageal refluxate. However, there does not seem to be any increased incidence of esophagitis in the presence of or following the eradication of *H. pylori* in children.[82] Because *H. pylori* affects gastric epithelium, it is not surprising that it has been identified on Barrett epithelium in a child, in whom symptoms resolved only with addition of amoxicillin to antireflux therapy.[83] Primary bacterial esophagitis is described in immunocompromised patients.[84]

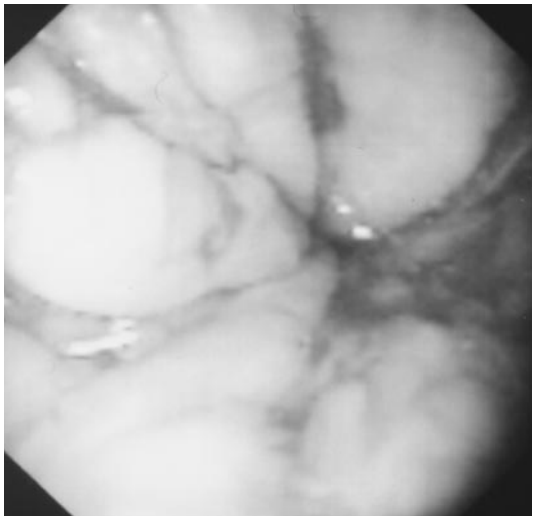

FIGURE 25-6 Candidal esophagitis has the classic appearance of white plaques on the mucosa that cannot be washed or brushed off.

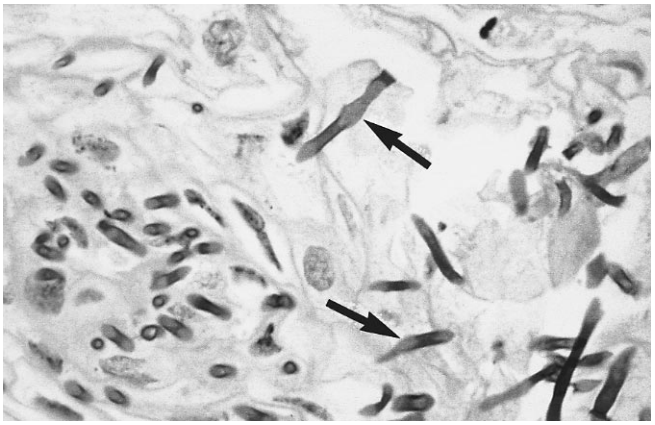

FIGURE 25-8 Candidal hyphae (*arrows*) (×200 original magnification).

Other opportunistic organisms causing esophagitis, such as *Cryptosporidium* and *Acremonium*, have been reported.[85,86]

Traumatic

Trauma causing esophageal pathology could, of course, be accidental, intentional, or iatrogenic. The presence of a nasogastric tube may be associated with abrasive esophagitis, and it has been postulated that the severe esophagitis found in newborn infants in one study, in the absence of other etiologic factors, may have been secondary to enthusiastic upper GI suction at birth.[7] Of particular note was the severity of the esophagitis in the face of relatively minimal symptomatology, such as feeding refusal. Radiation-induced esophageal strictures are described in children receiving mediastinal irradiation (usually greater than 4,000 cGy) and doxorubicin, occurring between 1 and 10 years post-therapy.[87] Radiation-associated esophagitis following bone marrow transplant conditioning is known to occur in the subsequent 1 to 2 weeks but is usually amenable to medical therapy.

Systemic Disease Manifestation

GER occurs more commonly in diverse conditions such as cystic fibrosis, severe combined immunodeficiency, cerebral palsy, raised intracranial pressure, celiac disease, and conditions associated with impaired gastric emptying.[88,89] Certain diseases are, however, associated with esophagitis, which is not via the pathogenetic pathway of reflux. Crohn disease is a prime example, and Crohn lesions in the esophagus are usually distinct rounded ulcers, although diffuse disease may also occur. (Figure 25-9). Endoscopic examination with biopsy of the upper GI tract should be part of the diagnostic workup of a child with suspected Crohn disease.[90] Relapse of the disease may be associated with recurrence of esophageal manifestations.[91] Type 1B glycogen storage disease may present with similar phenotype to Crohn disease, and severe esophageal involvement has been noted in children in this condition.[92] Inflammation and stricturing of the esophagus can occur in chronic granulomatous disease and can involve most of its length, making balloon dilation difficult.[93] Scleroderma and vasculitic conditions such as polyarteritis nodosa have significant esophageal pathology in adults but are very rare in pediatric populations.

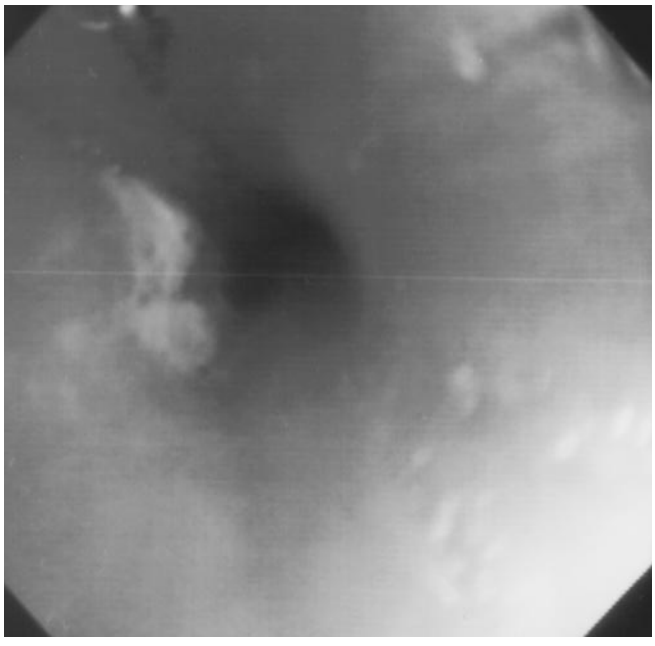

FIGURE 25-9 Distinct round ulcers of Crohn esophagitis.

Miscellaneous

Passive smoking has a strong association with esophagitis in childhood. The reasons behind this are not completely understood, but nicotine is known to relax the LES and may decrease mucosal blood flow. The nicotine levels in swallowed saliva may directly injure the esophagus or render it more susceptible to injury from acid exposure. Also, free radicals present in tobacco smoke may reduce antioxidant defenses.[94]

Munchausen syndrome by proxy (dealt with in more detail in Chapter 20, "Munchausen Syndrome by Proxy: Factitious Disorder by Proxy") can be at the root of esophagitis in children, but this is usually due to the deliberate introduction into the esophagus by the perpetrator of caustic or irritative substances.[95]

Idiopathic

IEE is characterized by a dense eosinophilic infiltrate in the absence of GER, parasitic infection, or other recognized causes of eosinophilic inflammation.[53,96] The importance of IL-5 and eotaxin, both potent eosinophilic chemokines in the mucosal recruitment of the eosinophilic infiltrate, has recently been recognized.[97] It is an unusual entity and may encompass a wide range of symptoms and histology. Dysphagia, odynophagia, and chest pain have been described.[89] It is important to diagnose IEE definitively because it may result in narrowing or stricturing of the proximal or midesophagus. Macroscopically, it appears as either concentric indentations for most of the length of the esophagus, with the suggestion of background mucosal edema and inferred inflammation, or longitudinal furrows (Figure 25-10).[54,98] Indeed, the suggestion of inflammation has been confirmed by one endosonographic study identifying an increase in the diameter of the submucosa and muscularis layers in children with this rare pathology (Figure 25-11).[54] In conjunction with this, it is becoming clear that a distinction can be made between IEE and simple allergic esophagitis on histology. IEE will have more than 20 to 40 eosinophils per HPF, whereas allergic esophagitis will have less than 10 to 15 eosinophils per HPF (Figure 25-12). Interestingly, in contradistinction to reflux esophagitis, the distal esophagus may be spared, and proximal esophageal biopsies are always recommended if IEE or allergic esophagitis is suspected. Allergy testing does not usually help to identify a responsible allergen because IEE, as the name suggests, is idiopathic, but this can sometimes be helpful in allergic esophagitis. Treatment with topical aerosol-delivered steroid (fluticasone propionate 50 to 200 µg sprayed into the back of the throat and then swallowed twice a day), systemic steroids, or even azathioprine may be effective,[53,96] but an elimination diet and dietary

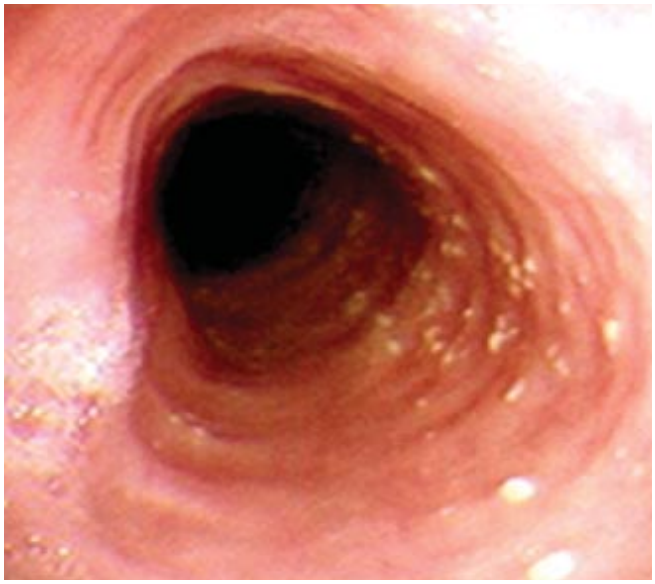

FIGURE 25-10 Macroscopic appearances of idiopathic eosinophilic esophagitis: concentric ring indentations and inference of edema and inflammation.

reintroduction, which are useful in allergic esophagitis, are not usually therapeutic in IEE.

SYMPTOMS

Comparatively little has been validated regarding the appearance, prevalence, or specificity of symptoms of esophagitis.

In the infant, parents and the clinician may have differing opinions on what constitutes excessive crying, irritability, and regurgitation, but parents have often learnt to distinguish what is normal and abnormal crying for their infant. It must be remembered, however, that crying varies with age and often with the time of day, peaking in frequency between 6 weeks and 3 months, with the majority occurring in the evening.[99] Excessive crying or irritability is likely to be associated with pathologic GER or esophagitis over, but not under, 3 months of age,[100] and feed refusal may occur if the infant learns to associate this with pain on swallowing.[101] Excessive crying and irritability causing maternal distress leading to child abuse have been reported in three cases.[102] Visceral hyperalgesia, in which prior painful GER leads to sensory nerve changes, which, in turn, lead to pain with subsequent innocuous stimuli, may be important and may explain in part the lack of a clear correlation of symptoms and esophageal pathology in some cases.[2,102–104] Paroxysmal head posturing, often with torticollis or neck extension, is known as Sandifer-Sutcliffe syndrome (Figure 25-13).[105] Refractory wheezing as an association of GER rather than esophagitis is well recognized and may be secondary to vagal stimulation at the distal esophagus.[106] GER airway–associated sequelae are noted in Table 25-1 and dealt with more fully in Chapter 24.

Anemia is uncommonly due to esophagitis in an infant, but hematemesis merits same-day endoscopy if feasible. Fecal occult blood has been noted in only 15% of infants and toddlers with esophagitis, although all patients with pH study evidence of GER had esophagitis when endoscopy was performed for hematemesis.[103] Even prenatal GI bleeding has been reported secondary to esophagitis.[5]

The term "colic" is defined as paroxysms of irritability, fussing, or crying lasting more than 3 hours per day for 3 days per week and has been estimated to occur in up to 25% of infants (see Chapter 13, "Colic and Gas"). It probably represents a variant of normal infant development. Pediatricians have a difficult decision to make to determine what is abnormal in this situation, but it would be wise to assume a low threshold of suspicion for reflux esophagitis if the irritability is excessive, according to their judgment or that of the parents,[107] bearing in mind that there is a significant overlap between maternal perceptions of "colic" and what is termed "normal infant distress."[108]

In 34 patients with an endoscopic diagnosis of esophagitis (median age of 6.5 months), Ryan and colleagues recognized the following symptoms: repeated regurgitation (100%), excessive crying and irritability (85%), significant sleep disturbance (79%), failure to thrive (41% below 10th percentile for weight/age), and hematemesis (29%). Maternal distress was a common finding in infants less than 6 months. These were compared with a group of 28 infants with no or minimal esophagitis in whom the respective percentages were 100%, 58%, 21%, 11%, and 3%. Hence, regurgitation was not predictive of esophagitis.[102]

Tables 25-1 and 25-2 outline the common symptom characteristics seen in infancy and in older children.

In the group of children between 1 and 5 years who are still not able to verbalize and describe their symptoms accurately, there may be a mixture of both constellations of symptoms, but they may remain nonspecific, with feeding disorders and food refusal, sleeping disorders, and more generalized behavioral problems predominating. In the younger age groups, it is important to realize that there is no clear relationship between symptoms and the severity

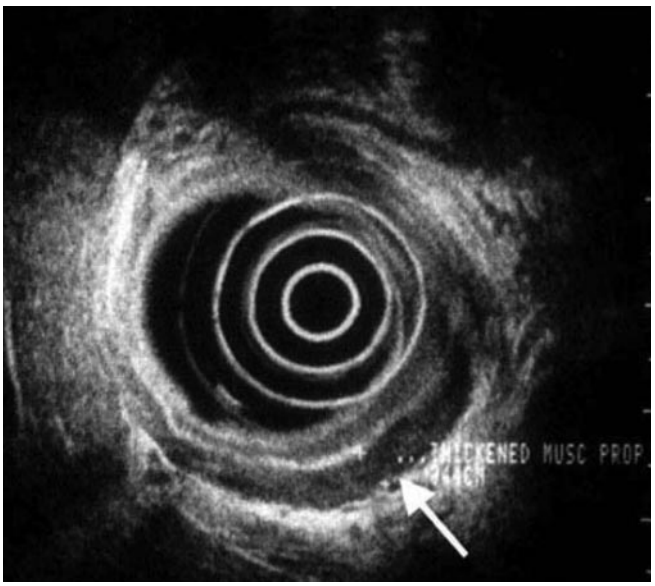

FIGURE 25-11 Endosonographic appearances of idiopathic eosinophilic esophagitis: increase in thickness of submucosa and muscularis layers (*arrow*).

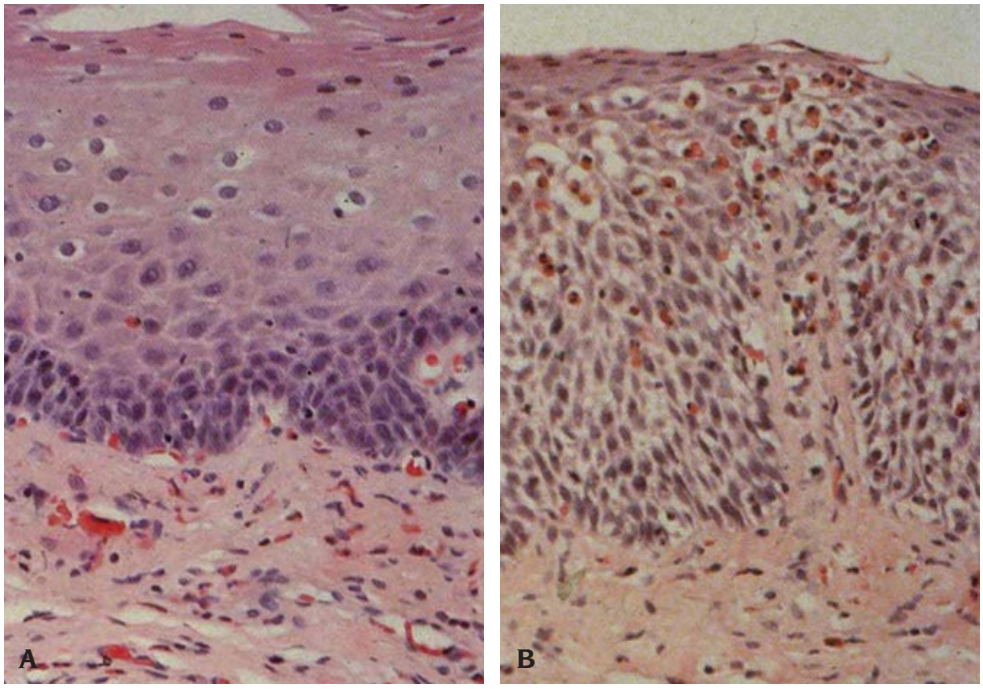

FIGURE 25-12 Density of eosinophilic infiltrate differs between *A*, allergic esophagitis (< 10–15 eosinophils/high-power field) and *B*, idiopathic eosinophilic esophagitis (> 20–40 eosinophils/high-power field).

of the esophagitis. The extent of such symptoms as irritability, crying, failure to thrive, or wheezing does not predict the severity of esophagitis.[1,102,103] It is also important to be aware that GER and associated esophagitis may be secondary phenomena to other pathology outside the GI tract, such as urinary tract infections, raised intracranial pressure, deliberate poisoning, and metabolic conditions.

Older children exhibit symptoms similar to adults and are less of a diagnostic conundrum. Conjecture exists regarding the role of esophagitis in recurrent abdominal pain, and in one series, 38% of such children had esophagitis on endoscopy.[109] However, although this may be true for recurrent epigastric pain, it is not generally thought to account for such a large proportion of classic periumbilical recurrent abdominal pain.

It is reasonable to include endoscopy and esophageal manometry in the diagnostic workup of children with chest pain, as Glassman and colleagues demonstrated esophagitis in 28%, and esophageal spasm and dysmotility in 25% of consecutive children complaining of chest pain.[110] Eleven of 16 children with asthma and chest pain had endoscopic and histologic evidence of esophagitis in a study by Berezin and colleagues, and all 16 had significant GER on pH study.[111] Rarely, hypertrophic osteoarthropathy has been reported with esophagitis in childhood.[112]

DIAGNOSIS

In this context, one is clearly concerned with determining a number of important issues, namely, the presence, severity, extent, etiology, and potential complications of esophagitis. Hence, investigations must be tailored to the question being asked. Indeed, in uncomplicated cases of GER, no investigation may be indicated, and simple therapeutic measures or even a trial of a first-line antireflux medication such as ranitidine may be a first-line diagnostic and therapeutic maneuver.[113,114] Ambulant esophageal pH analysis will give an indication of the nature and severity of acid or alkali reflux, whereas endoscopy with biopsy reveals the nature and severity of the esophagitis and other pathology in the upper GI tract, and investigations such as an upper GI barium series will tell us only about anatomic abnormalities and are clearly an inadequate method for looking at esophagitis.

FIGURE 25-13 Sandifer-Sutcliffe syndrome, which usually manifests as torticollis, in this case as neck hyperextension that resolved on adequate acid suppression.

TABLE 25-1 COMMON SYMPTOMS/ASSOCIATIONS WITH ESOPHAGITIS (USUALLY DUE TO REFLUX) IN INFANTS

GENERAL	SPECIFIC
Excessive crying	Hematemesis/melena/fecal occult blood
Irritability	Anemia
"Colic"	Sandifer syndrome (torticollis)
Feeding refusal	Aspiration
Failure to thrive	Wheezing
Excessive regurgitation	Apnea, stridor
Vomiting	Apparent life-threatening events
	Sudden infant death syndrome

Endoscopy with Biopsy

Endoscopy of the whole upper GI tract (esophagus, stomach, and duodenum) with multiple biopsies is the investigation of choice in evaluation of infants and children with symptoms suggestive of esophagitis.[1,2] This should be performed only by experienced and qualified pediatric endoscopists trained in endoscopy in infants and children. Technology now allows us to perform esophagogastroduodenoscopy in even the smallest infants.[115,116] It is, however, useful only if it will lead to alteration in diagnosis, treatment, or prognosis, and position papers for the North American and European Pediatric Gastroenterology Societies have recently been published.[2,110,113,117,118] Short general anesthetic is preferable to sedation for the procedure for reasons of safety, ease, and success of a complete and comprehensive study.[119]

Macroscopic appearances of the esophagus revealing, for instance, erythema, erosions, or ulceration will guide biopsy acquisition from the areas and lesions most likely to yield highest diagnostic return. A normal endoscopy or an absence of macroscopic lesions does not exclude the presence of histologic esophagitis,[120] and with our increased understanding of the variety of etiologies for esophagitis, biopsies have an enhanced role in altering management; the counterargument to this was previously advanced to defend endoscopy without esophageal biopsy in cases in which no macroscopic lesions existed,[1,3,4] and these authors also suggested that the increase in the cost of endoscopy, when combined with biopsy, may mitigate against the latter in some countries. This is generally held to be an outdated philosophy. No conjecture exists when performing biopsies for detection or surveillance of Barrett esophagus in which four-quadrant biopsies between 2 and 5 cm from the GEJ can be most helpful—the so-called Seattle protocol, using jumbo biopsy forceps.[121]

TABLE 25-2 COMMON SYMPTOMS/ASSOCIATIONS WITH ESOPHAGITIS IN OLDER CHILDREN

Epigastric pain, especially peri-/postprandial and nocturnal

TABLE 25-3 PROPOSED ENDOSCOPIC CLASSIFICATION OF ESOPHAGITIS

GRADE	FEATURES
0	Normal mucosa
1	Nonconfluent erosions appearing as red patches or striae just above the Z line*
	Erythema or loss of vascular pattern
2	Longitudinal noncircumferent erosions with a hemorrhagic tendency of the mucosa
2a	1 plus bleeding to light touch (friability)
2b	1 plus spontaneous bleeding
3	Circumferent tendency; no strictures
4a	Ulcerations with stricture or metaplasia
4b	Stricture without erosions or ulcerations

Adapted from Savary M and Miller G.[122]
*Z line defined as junction between columnar gastric fungal mucosa and stratified esophageal mucosa.

Classifications and scoring systems are employed in an attempt to semiquantify the appearances suggestive of esophagitis, which helps to remove interobserver error. The most widely used of these are the modified Savary-Miller criteria (Table 25-3, Figure 25-14).[122] The classification of Hetzel and colleagues has also been employed (Table 25-4); however, a criticism of this is that distinction between grades 0 and 1 is relatively subjective.[118] These classification systems have uses other than introducing objectivity, that is, the pretreatment grade of esophagitis is of value in predicting the pattern and severity of acid reflux and healing rates,[123] and improvement to grade 0 or 1 would be the usual aim, in either classification, of treatment. The specific macroscopic appearances of conditions other than GER esophagitis are noted in the relevant sections on pathogenesis above. Hassal suggests that erosions usually found on the tops of esophageal folds are specific for reflux disease, often with a rim of erythema around the white erosions[3]; however, these may mimic, for instance, Crohn disease (see Figure 25-9). Gupta and colleagues suggest that vertical lines in the distal esophageal mucosa are a true endoscopic manifestation of reflux esophagitis in children (Figure 25-15).[124] In severe ulcerated esophagitis, objective proof of recovery following treatment is important, and repeat endoscopy between 3 and 12 weeks later is generally recommended.

Generally, it is held that although the majority of esophagitis is due to reflux, the esophageal appearances themselves do not reliably differentiate between reflux and other causative pathologies. This is perfectly demonstrated in the diagnosis and management of esophagitis in children with cancer, in whom esophagitis is a common occurrence but whose etiology is not predicted accurately by clinical observations (eg, oral candidiasis does not predict for candidal esophagitis) or by macroscopic endoscopic appearances[125]—hence, the requirement for confirmatory biopsy and histology.

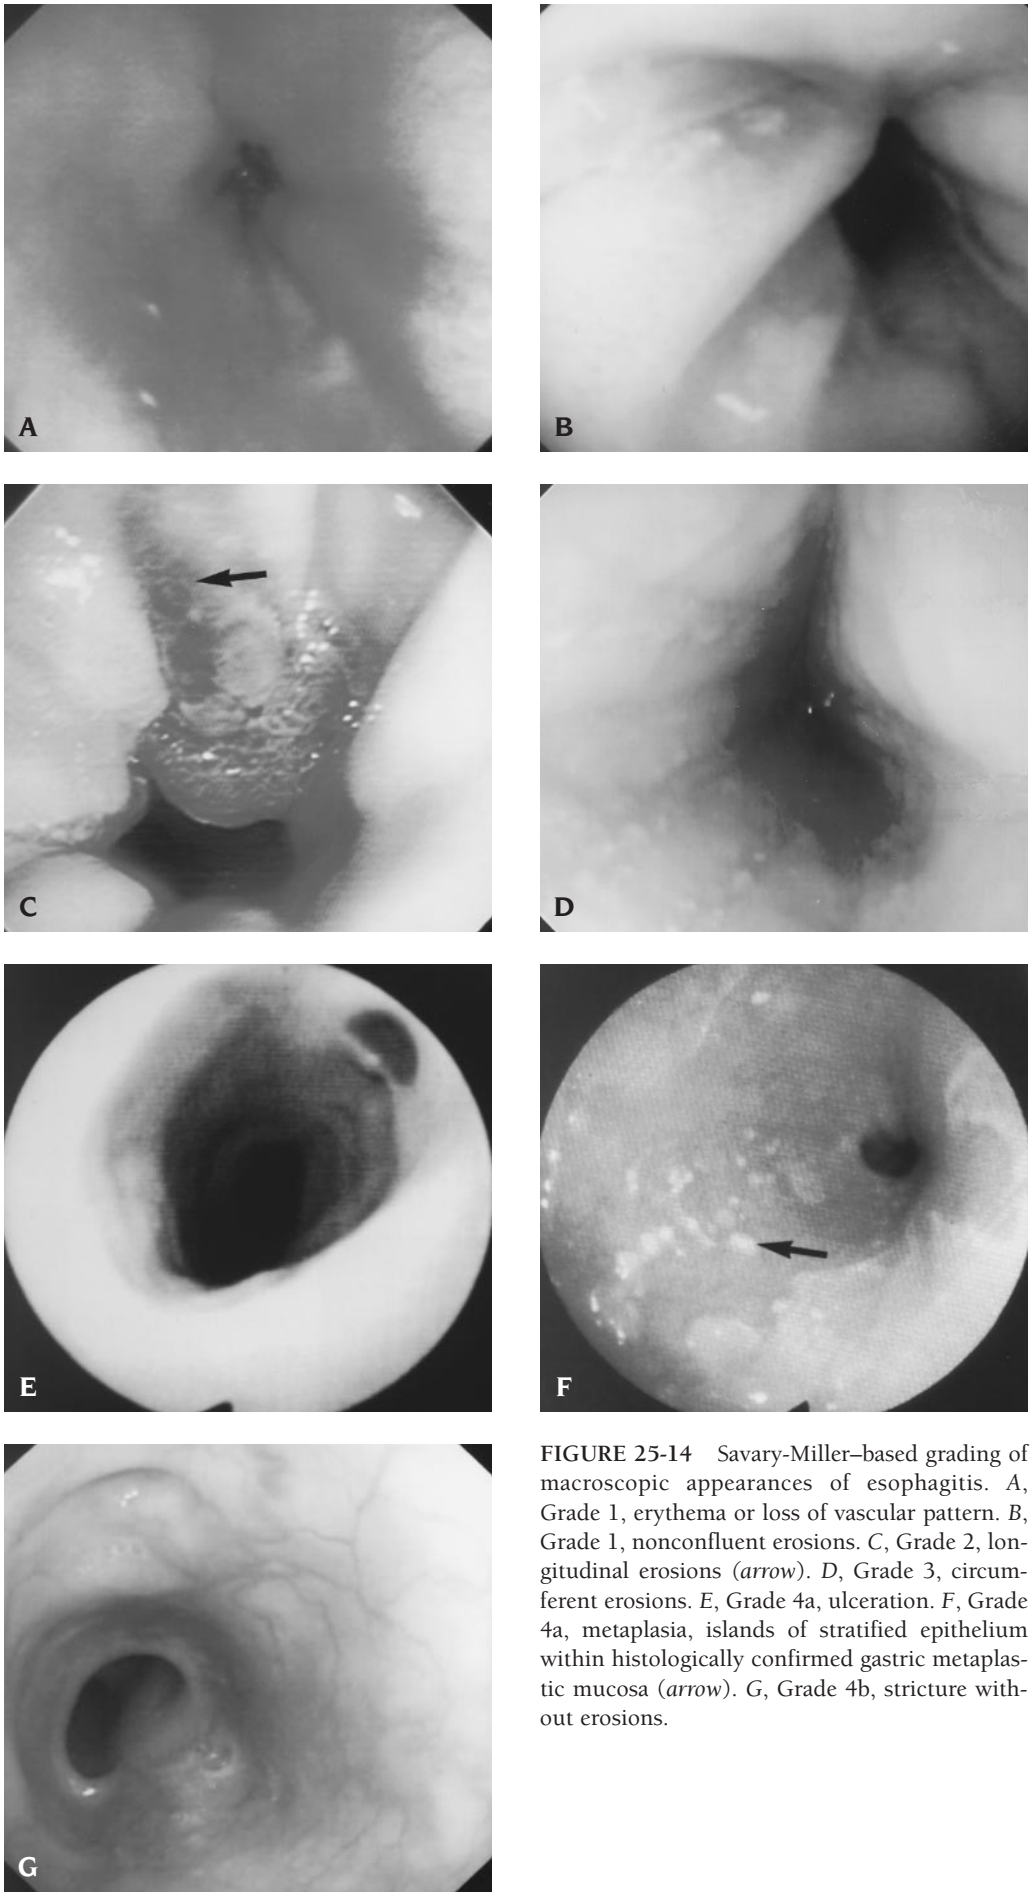

FIGURE 25-14 Savary-Miller–based grading of macroscopic appearances of esophagitis. *A*, Grade 1, erythema or loss of vascular pattern. *B*, Grade 1, nonconfluent erosions. *C*, Grade 2, longitudinal erosions (*arrow*). *D*, Grade 3, circumferent erosions. *E*, Grade 4a, ulceration. *F*, Grade 4a, metaplasia, islands of stratified epithelium within histologically confirmed gastric metaplastic mucosa (*arrow*). *G*, Grade 4b, stricture without erosions.

TABLE 25-4 ENDOSCOPIC CLASSIFICATION OF ESOPHAGITIS

GRADE	FEATURES
0	No mucosal abnormalities
1	Erythema, hyperemia, mucosal friability
2	Superficial erosions affecting < 10% of the distal 5 cm of esophageal squamous mucosa
3	Superficial erosions or ulceration of 10–50% of the mucosal surface of the distal 5 cm of esophageal squamous mucosa
4	Deep peptic ulceration anywhere in the esophagus or confluent erosion of > 50% of the mucosal surface of the distal 5 cm of the esophageal squamous mucosa

Adapted from Hetzel D et al.[118]

HISTOLOGY

A diagrammatic representation of an esophageal cross-section is shown in Figure 25-16. Nowadays, biopsies are endoscopic, but suction biopsies have been assayed in the past and probably yield a deeper, more satisfactory biopsy.[126] When suction biopsies were added to conventional grasp biopsy technique in a study by Hyams and colleagues, the histologic diagnosis of esophagitis was increased from 60 to 83% of cases, although if one takes more biopsies, one would expect a greater diagnostic yield given the patchy nature of childhood esophagitis; hence, this cannot be used to suggest that suction biopsies are superior in pediatric practice.[103] Friesen and colleagues showed no statistically significant difference in predictive value for esophagitis in infants between the two techniques.[127] Correctly oriented endoscopic biopsies (eg, immediate orientation on filter paper or nylon mesh in 10% formalin) are, however, perfectly adequate, and so-called "crocodile" biopsy forceps, which allow the operator to biopsy perpendicular to the esophageal lumen, may be preferable. Large-cup ("jumbo") biopsy forceps are increasingly used and are mandatory for the surveillance of Barrett esophagus because they yield deeper biopsies.[120] The site of biopsy should be above the distal 15% of the esophagus to avoid confusion with normal variance.[103] Biopsies should include epithelium, lamina propria, and muscularis mucosae and be oriented in a perpendicular plane to maximize diagnostic yield, such as evaluating properly the thickness of the basal zone, vascular ingrowth, and the elongation of the stromal papillae. For definitive diagnosis, the presence of two of three of these features is preferable, which will not be possible with poorly oriented tissue.[1,2] In an adult study, failure to use well-defined histologic criteria resulted in only 50% sensitivity for diagnosing esophagitis.[128] The classic histologic findings of GER esophagitis are displayed in Table 25-5

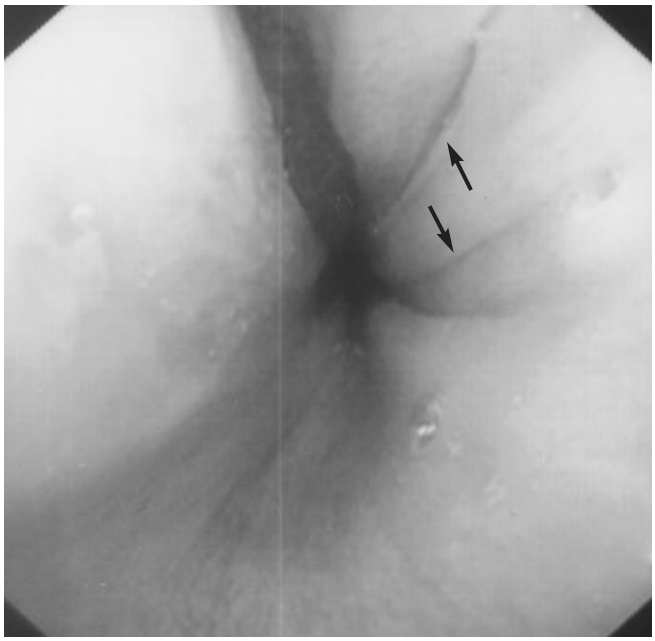

FIGURE 25-15 Vertical lines in the distal esophageal mucosa may be an endoscopic manifestation of reflux esophagitis (*arrows*).

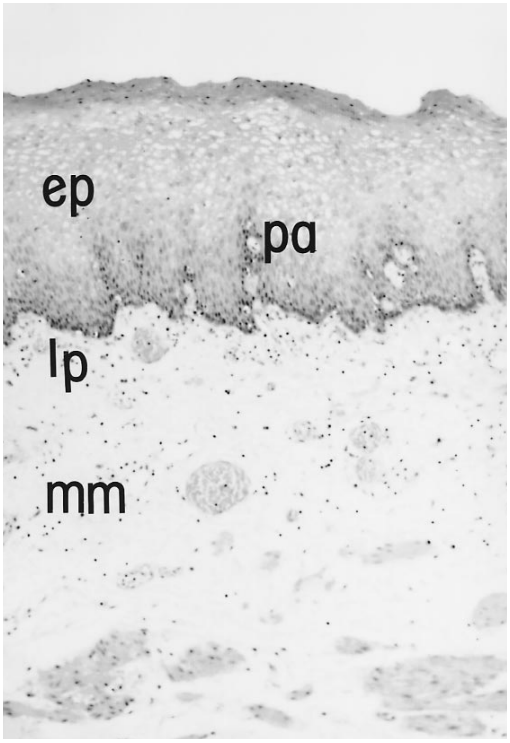

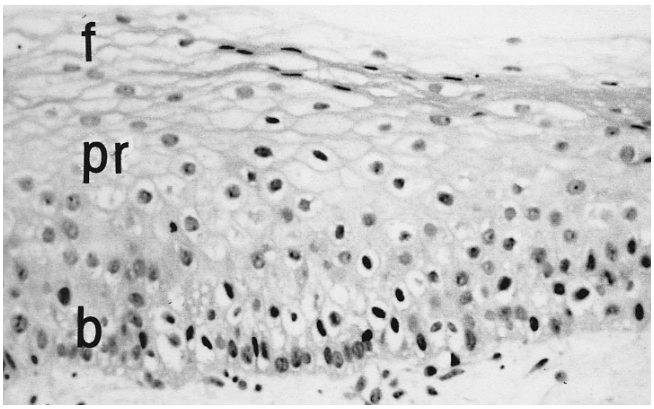

FIGURE 25-16 Diagramatic representation of an esophageal epithelial cross-section. Epithelium (ep) comprises functional (f), prickle (pr), and basal (b) layers. Papillae (pa) are contiguous with lamina propria (lp). Muscularis mucosa (mm) is deep to this but superficial to circular and longitudinal muscle layers and serosa, not shown (hematoxylin and eosin).

(Figure 25-17). Elongation of stromal papillae is a useful indicator of reflux, and basal zone hyperplasia is defined when the papillae are more than 25% of the entire thickness of the epithelium, and if more than 50%, then the papillae are considered to be elongated.[58]

Esophageal mucosal eosinophilia has been described in both suspected cow's milk–associated[46] and primary reflux esophagitis,[52] as well as in other conditions, such as primary eosinophilic esophagitis (see Figures 25-2 and 25-12).[53] The clinical significance of eosinophils and their role in the pathogenesis of mucosal injury are poorly understood and are the subject of recent debate.[3,4,55] Some have suggested an active role for eosinophils in the inflammatory process of esophagitis and have supported this with the observation of resolution of symptoms and eosinophils in the esophagus on dietary exclusion of cow's milk[46,48] or with oral steroids,[46,53] both suggesting a pathoetiologic role for eosinophils. The mucosal density of the eosinophils may be important, as noted above, in distinguishing between allergic esophagitis and IEE. In addition to eosinophils, intraepithelial T lymphocytes, known as CINC or squiggle cells, have also been implicated as markers of reflux esophagitis (Figure 25-18).[57,59] However, the degree of intraluminal esophageal acid exposure did not correlate well with the CINC count in one study in children, and the authors use this fact to question the day-to-day reliability of pH-metry in defining the extent of reflux in children.[58] In adults, such cells are of memory phenotype and display activation markers,[59] although little is known of their pediatric equivalents. The finding of mucosal mast cells may also help to differentiate GER from CMP-associated esophagitis, but there is considerable overlap with the presence of eosinophils.[56] Neutrophils also indicate a degree of inflammation,[12] and actual numbers of eosinophils and/or neutrophils per most involved HPF have been used to indicate the severity of esophagitis.[58] Minimal histologic criteria are simultaneous occurrence of elongated papillae and basal zone hyperplasia. Moderate esophagitis is diagnosed if there is ingrowth of vessels in the papillae, and 1 to 19 eosinophils and/or neutrophils are seen in the most involved HPF. Severe esophagitis is diagnosed if more than 20 eosinophils/neutrophils are seen in the most involved HPF. However, the criteria established by the European Society of Paediatric Gastroenterology Hepatology and Nutrition and displayed in Table 25-5 are probably the most robust to date.[2]

TABLE 23-5 GRADING CRITERIA FOR HISTOLOGIC APPEARANCE OF ESOPHAGUS

GRADE	HISTOLOGIC CRITERIA	CLINICAL DIAGNOSIS
0	Normal	Normal
1a	Basal zone hyperplasia	Reflux
1b	Elongated stromal papillae	Reflux
1c	Vascular ingrowth	Reflux
2	Polymorphs in the epithelium ± lamina propria	Esophagitis
3	Polymorphs with epithelial defect	Esophagitis
4	Ulceration	Esophagitis
5	Aberrant columnar epithelium	Esophagitis

Adapted from Knuff T et al[197] and Leape L.[198]

The important point to realize is that correlation between macroscopic and histologic features is generally poor, partly because the esophagitis may be a patchy lesion but also because histologic esophagitis may exist when the esophagus is macroscopically normal.[119] This is not now merely academic because it does have the potential to direct therapy appropriately, for example, in the case of CMP allergy– or intolerance–associated esophagitis when a cow's milk exclusion diet is associated with a better outcome than use of antacid therapy alone, and it is suggested that up to 40% of cases of esophagitis may have CMP intolerance as an etiologic factor.[46,48,61]

Furthermore, with the advent of more complex diagnostic techniques such as immunohistochemistry and electron microscopy, the esophagus, which is apparently normal both macroscopically and histologically, may still yield diagnostic information. Standard endoscopic biopsy and histology do not reliably distinguish between, for instance, primary reflux esophagitis and the emerging clinical entity of cow's milk–associated reflux esophagitis. Some differentiation from primary reflux has been suggested on the basis of esophageal pH testing pattern and β-lactoglobulin antibody response, although the former has not been substantiated by more than one center.[48,49]

Barrett esophagus and premalignant or malignant esophageal pathology are dealt with in Chapter 24. Cytologic esophageal brushings may be helpful in such situations, as they are in candidal esophagitis.[129]

Immunohistochemistry

A variety of immunohistochemical markers have been used to examine the esophageal mucosa. An increase in Ki-67, a proliferation marker, has been shown in the longer papillae seen in GER, suggesting increased cell turnover (Figure 25-19). Basal focal distribution of CD4 lymphocytes showing expression of the activation markers CD25 and HLA-DR, together with up-regulated epithelial HLA-DR expression, has also been reported.[61] Eotaxin is a recently described eosinophil-specific chemokine,[60] and, despite the mild histologic abnormality in CMP-associated esophagitis, an increased expression of eotaxin colocalized with activated T lymphocytes to the basal and papillary epithelium has been shown, distinguishing this from primary reflux esophagitis (see Figure 25-3).[61] Inhibitory neurotransmitter production is integral to LES relaxation, and the nonadrenergic, noncholinergic neurotransmitter NO has received recent attention in human studies.[16,17] Increased esophageal expression of iNOS has also been noted,[23,25] although in another study, it was not up-regulated in the inflamed pediatric esophagus.[24] Because NO is a powerful smooth muscle relaxant, it is interesting to speculate whether inflammation-induced iNOS may play a role in LES relaxation, leading to more reflux and hence worse inflammation, and so on.

Hence, techniques such as immunohistochemistry will allow better comprehension of the pathophysiology of esophageal pathology in the near future and already allow a diagnostic distinction to be drawn between etiologies.

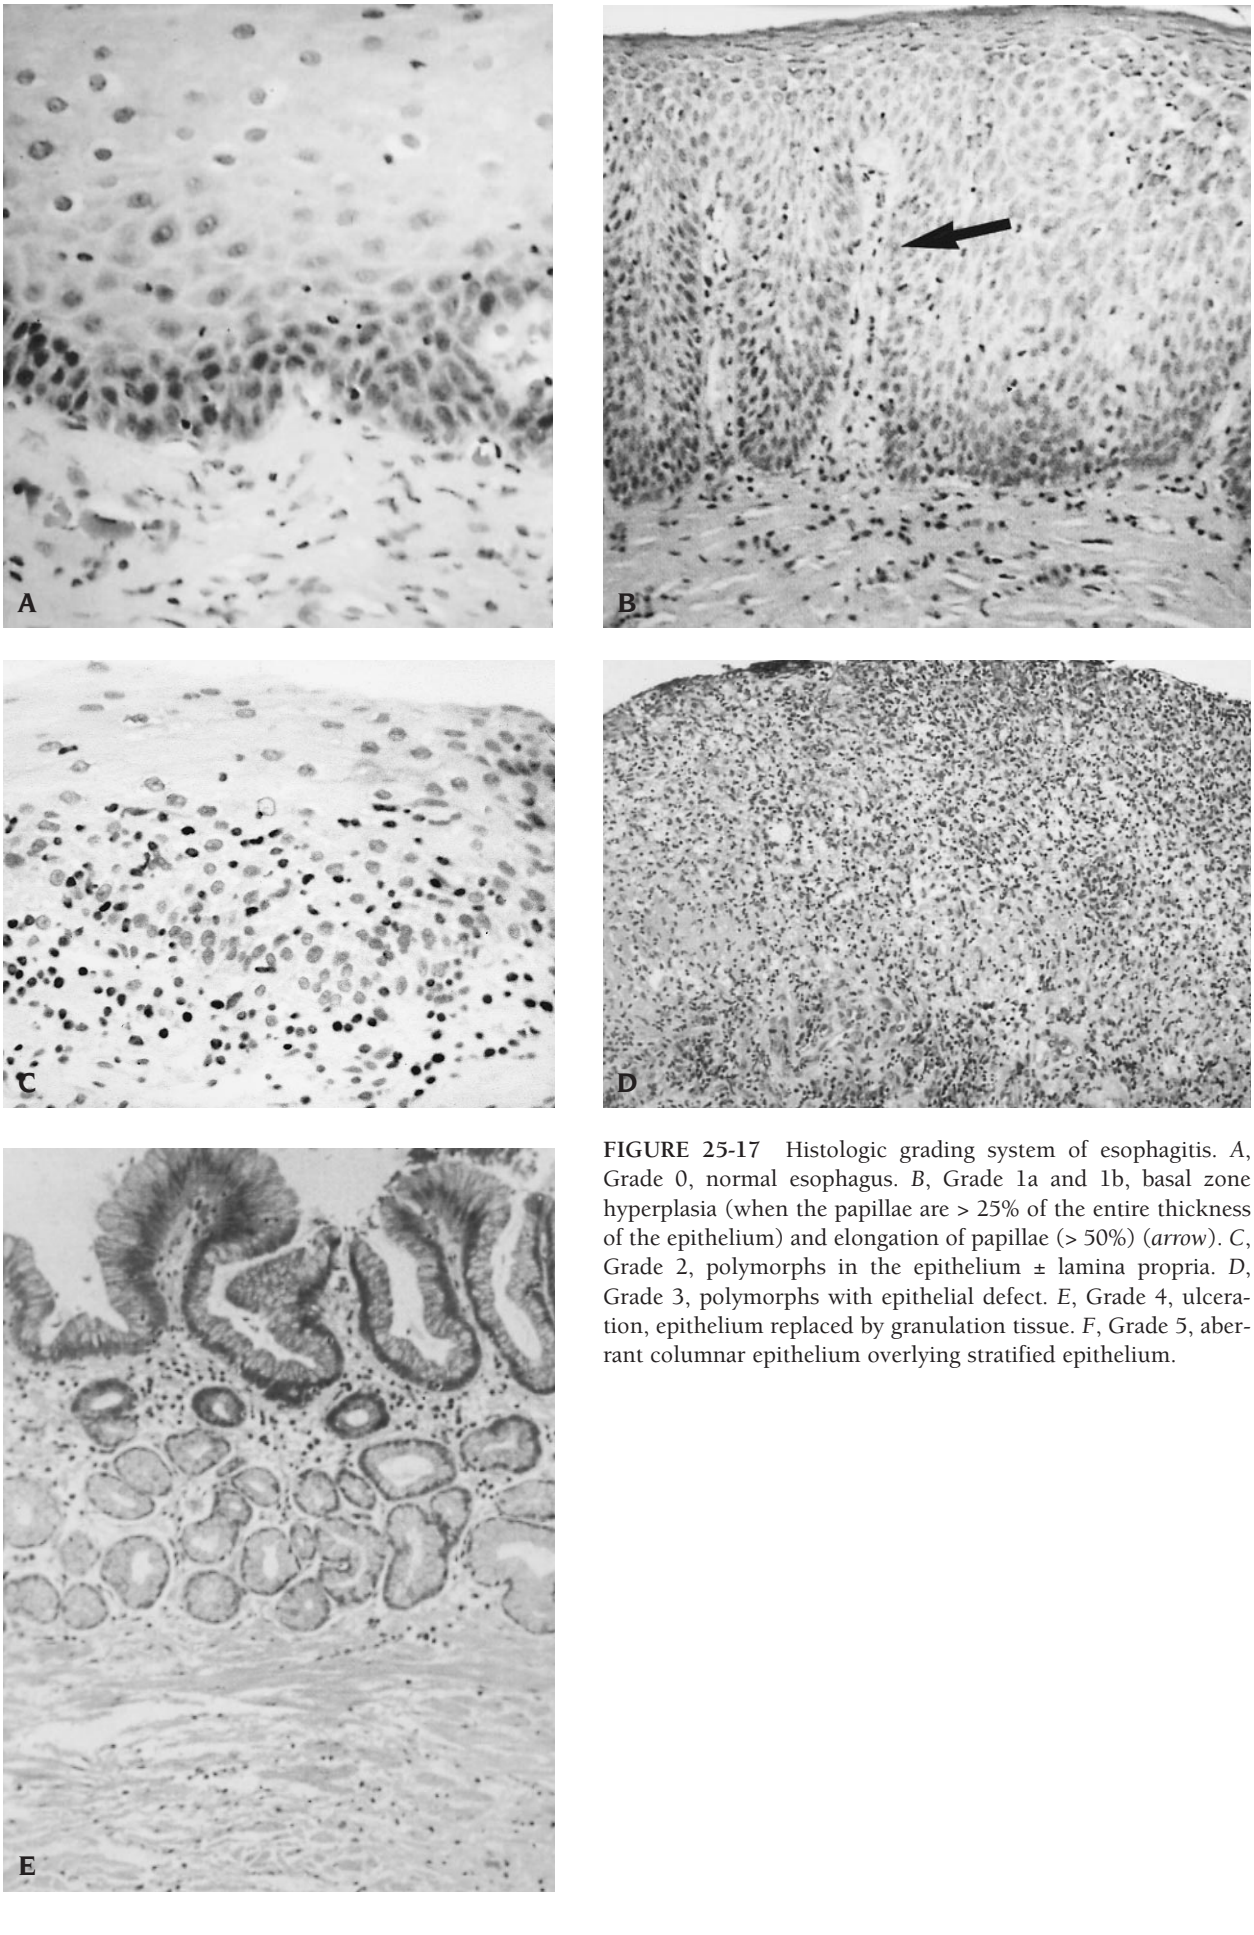

FIGURE 25-17 Histologic grading system of esophagitis. *A*, Grade 0, normal esophagus. *B*, Grade 1a and 1b, basal zone hyperplasia (when the papillae are > 25% of the entire thickness of the epithelium) and elongation of papillae (> 50%) (*arrow*). *C*, Grade 2, polymorphs in the epithelium ± lamina propria. *D*, Grade 3, polymorphs with epithelial defect. *E*, Grade 4, ulceration, epithelium replaced by granulation tissue. *F*, Grade 5, aberrant columnar epithelium overlying stratified epithelium.

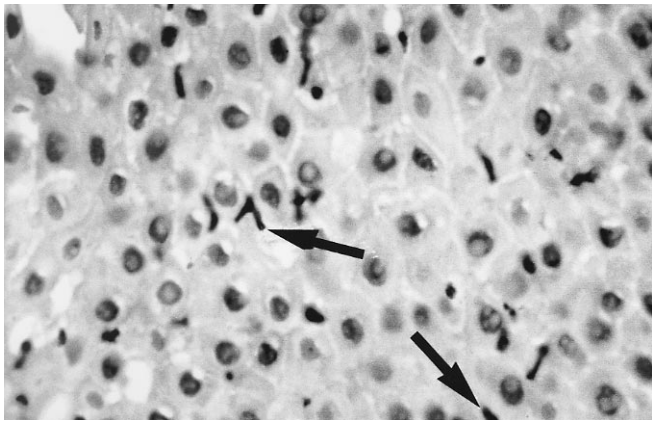

FIGURE 25-18 Intraepithelial T lymphocytes, known as cells with irregular nuclear contours or squiggle cells (*arrows*).

Electron Microscopy

Electron microscopy has demonstrated the ultrastructural changes associated with esophagitis, adding to our comprehension of the lesion. Stratified squamous nonkeratinizing epithelium line the mucosa, and the surface is composed of large flat cells displaying a regular pattern of parallel microridges 200 nm in thickness. Three layers are visible by transmission electron microscopy: (1) the basal layer, composed of polygonal cells with a high nucleus-to-cytoplasm ratio; (2) the intermediate layer, composed of large prickle cells; and (3) the superficial layer, composed of flattened cells. Three grades of ultrastructural changes in esophagitis in children have been identified: grade I, irregular microridges and reduced intercellular junctions; grade II, of the superficial epithelium only, microvilli instead of microridges that, when present, are distorted, and extruding cells with degeneration and interruptions of the cell membrane; lymphocytes and monocytes occupy the large intercellular spaces in the intermediate layer, and the basal layer is thickened; and grade III, microerosive cytopathy, loss of superficial layer microridges with crater-like erosions and abundant cell debris. Degenerating cells are seen in all three layers (Figure 25-20). Reduced numbers of desmosomes and large intercellular spaces containing lymphomonocytes are seen. Ultrastructural damage to nuclei, nucleoli, Golgi complex, and endoplasmic reticulum is seen. Activation of eosinophils by electron microscopic criteria has helped in the distinction of GER and CMP-associated esophagitis.[56] Hence, a more compelling case can be made for biopsy than previously.

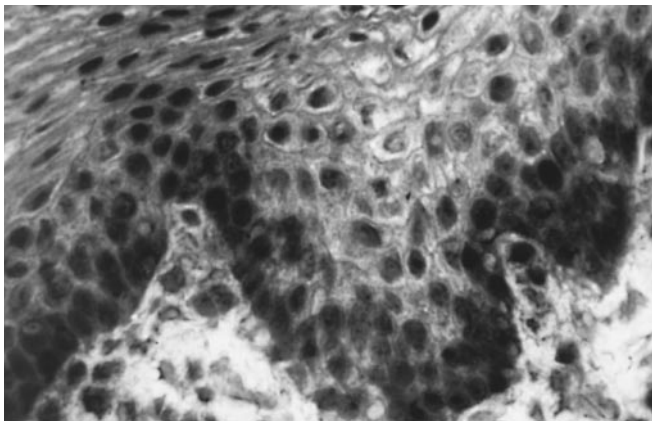

FIGURE 25-19 Increase in Ki-67, a proliferation marker, has been shown in the longer papillae seen in gastroesophageal reflux, suggesting increased cell turnover.

pH Studies

Esophageal pH monitoring has gained general acceptance as the method for assessment of GER in children and until recently has been regarded as the investigation technique of first choice in infants and children with unusual presentations of GER disease, such as apnea and recurrent respiratory disease.[130–132] However, pH measurements cannot detect GER in the pH range of 4.0 to 7.0 owing to the proximity to the normal esophageal pH.[133,134] Consequently, pH-metry misses many episodes of postprandial reflux in young infants because of neutralization of gastric contents by milk formula for 1 to 2 hours after a meal. Therefore, the term acid, neutral, or alkaline GER should be preferred over the blanket term GER. A poor correlation exists between morphometry and histology and classic parameters used in pH studies[3,135]; however, this correlation is improved by analysis of esophageal acid exposure using the parameter area under pH 4.0.[136] Indeed, pH-metry does not detect GER directly but measures the H^+ ion concentration at the sensor site.[137]

Hyams and colleagues found no correlation between any pH parameter (except the acid reflux in the 2 to 4 hours following a clear liquid feed) and the severity of esophagitis or macroscopic appearances suggesting esophagitis and histologic changes, and this has been seen by other groups.[103,119] Ambulant esophageal pH-metry is dealt with in greater detail in Chapter 24.

Currently available techniques for the study of reflux that are pH-independent include ultrasonography,[138] aspiration,[139] scintigraphy,[140] fluoroscopy,[141] bilirubin monitoring,[142] and pH monitoring. However, the disadvantages of these methods include short-term applicability, a high incidence of artefact caused by body movement, and the requirement for unphysiologic, nonambulant body positioning. These methods fall far short of the ideal because they measure only a short time window and do not allow for symptom or event temporal correlation.

Intraluminal Impedance

A new pH-dependent, intraluminal esophageal impedance technique, which relies on the higher conductivity of a liquid bolus compared with esophageal muscular wall or air, has been validated in adults. When used in infants with GER who had simultaneous pH measurement for prolonged periods, intraluminal esophageal impedance showed that 73% of all GER occurs during or in the first 2 hours after feeding. Furthermore, this is pH neutral and, therefore, will be missed by pH-metry. Indeed, 75% of GER extends proximally as far as the pharyngeal space,[143] and this has broad implications for the study of GER-associated respiratory phenomena and symptoms caused by gastrolaryngopharyngeal reflux. Wenzl and colleagues

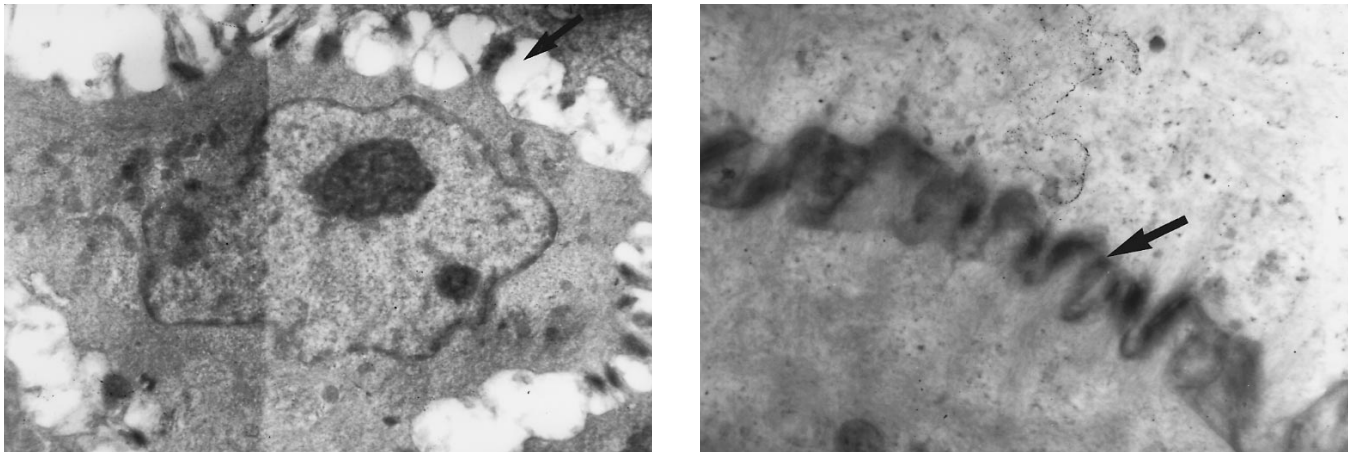

FIGURE 25-20 Transmission electromicrograph of ultrastructural changes in esophagitis in children. Grade I, irregular desmosomes and reduced intercellular junctions (*arrow*).

re-examined the temporal association between infant apnea and reflux in a recent study and found, on the basis of impedance, a marked association between these two phenomena.[143] Approximately one-third of all documented apneas occurred in the 30 seconds before or after an impedance-identified reflux event, of which only 23% were acidic reflux events—hence, the hypothesis that GER may stimulate laryngeal receptors. Conversely, they suggest that forced respiratory effort with increased abdominothoracic pressure, as occurs during episodes of obstructive apnea, can overcome LES pressure and cause a reflux episode.

Multichannel intraluminal impedance measurements have allowed new insight into the physiology and pathophysiology of gastrointestinal function in health and disease.[144] Patterns of antegrade and retrograde bolus movement, length of the swallowed or refluxed bolus, and direction and velocity of bolus movement can be described precisely.[145] Episodes of GER can be characterized by their height in the esophagus and by their duration.[146] This is especially useful in the postprandial period and in clinical situations of gastric hypoacidity.[147] Simultaneous pH monitoring and intraluminal impedance (IMP) allow further categorization of GER episodes.[148] Multichannel IMP measurement is also a valuable tool for describing the process of GER clearance and swallowing, allowing a distinction to be drawn between the protective events of volume clearance and acid clearance (primarily by swallowing of saliva) in the prevention of GER-associated lower esophageal reflux pathology and associated symptoms. Although normative values for various pediatric age groups remain to be defined, this technique already allows time-related associations to be made for GER and symptoms and allows interventional therapeutic studies to be conducted for the first time on a physiologically appropriate basis. With increasing clinical use of the IMP in children, normative data will soon be available. Until then, IMP can be performed in studies with a crossover design so that individual subjects may act as their own controls.

To document symptom association,[149] IMP can be incorporated into other diagnostic systems, for example, manometry[150–152] and sleep studies. Technical effort has now developed a portable recording device for mobile, outpatient impedance studies in all age groups.[153] Semiautomated and soon fully automated software will allow this to emerge from application on a research basis to have clinical day-to-day applicability, and software for IMP has now been developed and improved to aid in detecting characteristic patterns and eliminating artefact, thereby making it more practical for routine clinical use.[154] The importance of independent, long-term assessment of the esophageal and gastric motility is increasingly recognized, especially for pediatric patients. Impedance monitoring is indeed very promising in revolutionizing this aspect of GER investigation. In the next few years, a combination of pH and IMP will be adopted as the new gold standard for investigating reflux events in pediatric settings. Future studies will verify and improve the technique and will broaden our understanding of esophageal motility and its disorders and associated supraesophageal phenomena.

Other techniques, such as IMP, may offer advantages over pH-metry for assessing nonacid or neutral reflux, which is the predominant type in the postprandial 1 to 2 hours when most GER occurs, and a variety of studies now point clearly to the inadequacy of assessment of simple acid exposure of the esophagus in determining the role of reflux in the genesis of GER.[155] More recently, Tasker and colleagues suggested that reflux of gastric juice could be a major cause of glue ear in children by analyzing middle ear effusion fluid at the time of grommet insertion for the presence of pepsin (which can only have come from the stomach by reflux) and found it to be present in 83% of cases. This elegant study further supports the association of GER with tubotympanal disorders and also suggests that nonacid reflux may be just as important as acid reflux.[156]

Manometry

This is useful in limited circumstances in the evaluation of esophagitis per se, although it has a role in the assessment of GER etiology. Berezin and colleagues studied 31 children with mild to moderate esophagitis and concluded that there were no differences compared with 48 normal controls in LES pressure and the amplitude, duration, and velocity of

esophageal contractions.[157] Combined pH/impedance/micromanometry catheters are now available and expose the possibility of a more profound comprehension of all of the issues that contribute to the complex process of a reflux event in an infant or child.

Upper GI Barium Series

Barium studies of the upper GI tract are not helpful in assessment of esophagitis except in detecting the presence or absence of anatomic abnormalities, for example, esophageal strictures, gastric outlet obstruction, and small bowel malrotation, for which they are indispensable. Some authors report specific radiologic abnormalities associated with pathologies such as candidal esophagitis,[125] but the technique of choice is obviously endoscopy in such situations.

Blood Tests

Obviously, hemoglobin estimation will allow anemia to be excluded as a complication of esophagitis. Specific etiologies can be elucidated and distinguished by specific blood tests. Examples include a high anti-β-lactoglobulin in CMP-associated esophagitis; radioallergosorbent tests for specific allergens; low-quartile immunoglobulin (Ig)A, high IgE, high IgG, and specifically high IgG1 and IgG4 subclasses, all suggestive of CMP-associated GER; herpes or CMV serology; and raised inflammatory markers such as C-reactive protein, erythrocyte sedimentation rate, and platelet count suggestive of more widespread GI inflammation such as occurs in Crohn disease.

MANAGEMENT AND PROGNOSIS

Management of esophagitis must, of course, be dictated by its etiology, which further underlines the vital nature of obtaining an accurate diagnosis based on upper endoscopy and histologic assessment.

Because the vast majority of cases of esophagitis in infants and children will be due to GER, then treatment of GER and treatment of GER-related esophagitis will be very closely linked. Treatment of GER is also dealt with in Chapter 24, and the emphasis of this section is toward the rationale for treatment of esophagitis but inevitably touches on anti-GER measures also. Other specific treatments for specific pathologies are also dealt with.

It must be borne in mind that spontaneous resolution of reflux esophagitis may occur. The early studies of Carre indicated in infants that if no active therapy is initiated, approximately 60% will be symptom free by 18 months of age, with the greatest improvement by 8 to 10 months, when the child starts to sit upright; 30% will continue to have symptoms during childhood; approximately 5% develop strictures; and 5% will die of pneumonia or malnutrition.[9] In another, more up-to-date study on the outcome of infant GER esophagitis with accurate recognition and treatment (at that stage, only a histamine$_2$ [H_2] antagonist), 82% had responded satisfactorily to medical management by 18 months of age, with 51% being able to cease treatment with spontaneous improvement by 8 to 10 months, a proportion similar to Carre's.[10,102] With the advent of effective antireflux therapies, one would expect the figure of 18% who required antireflux surgery in the latter study to be much less. Shepherd and colleagues advocate the early use of endoscopy to detect the degree of esophagitis because the constellation and severity of symptoms do not always reflect the degree of esophagitis.[10] It is important to know the degree of esophagitis (see Tables 25-3 and 25-4) because this may allow one to tailor therapy appropriately and, indeed, prognosticate on outcome. One group suggested that more than 7 eosinophils per HPF made the success of treatment with ranitidine and cisapride unlikely, although the confounding factor of allergic esophagitis certainly has importance in this situation.[125] Individualized treatment is the goal, but generalizations may be made based on the severity of the esophagitis and, to an extent, the severity of the symptom constellation. In adult studies, the pretreatment severity of esophagitis is of some help in predicting healing rates on antisecretory therapy.[158,159] It also correlates with the duration and pattern of acid reflux in adults,[160] although a poor correlation exists between morphometry/histology/endoscopic appearances and classic parameters used in pH studies in pediatrics[3,103,120,135]—except, perhaps, area under pH 4.0.[136] Hence, the presence of histologic esophagitis alone may not allow prediction of outcome. It is clear also in adult studies that erosive esophagitis is a chronic problem that has an attendant worse prognosis and will tend to relapse off treatment.[161] This is probably the case in pediatrics also, but this question is very difficult to answer because long-term follow-up studies with treated and untreated patients would be required to provide viable answers.[2]

Figure 25-21 outlines an algorithm for the treatment of GER esophagitis in infants and children. It is generally agreed that for treatment purposes, infants and children with GER esophagitis can be regarded as falling into two main groups: those with normal (grade 0) or mildly erythematous (grade 1) mucosa and only histologic esophagitis and those with esophagitis, which is erosive or worse (grade 2 or more) (see Figure 25-14). The milder group will generally receive so-called simple measures, which are particularly applicable in infancy, such as positioning with the head elevated to 30° in the left lateral Trendelenburg position, which may be effective in up to 25% of infants with simple regurgitation[2]; advice to increase the frequency and decrease the volume of each feed; use of milk-thickening agents (eg, Nestargel, Carobel) or prethickened milks (eg, Enfamil AR); and the use of antacids (eg, Infant Gaviscon), which may be effective in mild, simple GER.[162,163]

For uncomplicated reflux unresponsive to these measures, a case can be made for the use of an H_2 antagonist before further investigation. Unfortunately, cisapride, the noncholinergic prokinetic drug with 5-hydroxytryptamine$_4$ agonist properties that improves pH-metric variables[164] and was the drug of first choice in GER, is no longer widely available owing to concerns, rightly or wrongly, regarding prolongation of the Q–T_c interval and cardiac dysrhythmias in childhood. It is metabolized by the cytochrome P-450 3A4 isoenzyme, as are "azole" antifungal agents and the macrolide antibiotics erythromycin and clar-

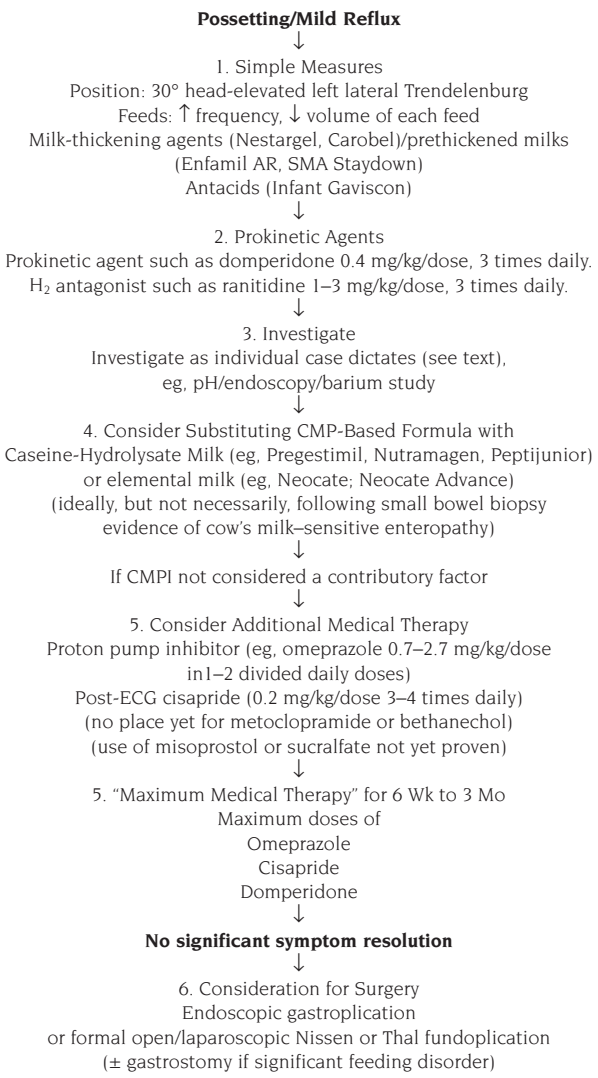

FIGURE 25-21 Gastroesophageal reflux treatment algorithm in infants and young children. CMP = cow's milk protein; CMPI = cow's milk protein intolerance; ECG = electrocardiography.

ithromycin, and combinations of these drugs with cisapride have produced cardiac dysrhythmias and prolonged Q–Tc syndrome in some patients. In a major article purporting to show a prolongation of the Q–T_c interval, there was no statistical difference between the cisapride group and the control group with regard to Q–T_c interval or J–T_c interval. However, 16 of the 35 patients reported have had a prolongation of Q–T_c.[165] There have been recent reports of prolonged Q–Tc syndrome in neonates with cisapride alone,[166] but Levine and colleagues published a report on the use of cisapride in 30 children, 12 of whom were premature neonates, and no effect on the Q–T_c interval was seen.[167] At present, some pediatric gastroenterologists would not recommend the use of cisapride in those infants born prematurely (less than 36 weeks gestation) in the first 3 months of life. In Canada, a survey of use in over 11,000 such neonates who received cisapride revealed three nonfatal arrhythmias, two with 10-fold dosage errors and one with cotreatment with erythromycin.[168] A useful and rational summary of risk and benefit has recently been published.[169] Its active component, termed nor-cisapride, which is purported to have no effect on the Q–T_c interval, may be available soon. Tegaserod may also be available in the near future to treat GER in childhood, but its major market focus has been in adult irritable bowel syndrome.

H_2 blockers can improve esophagitis, but the effect on GER cannot be assessed by pH because they neutralize gastric acid. High-dose ranitidine (6–7 mg/kg/dose 3 times per day) has been shown to be as effective as omeprazole in refractory reflux esophagitis in those children with[170] and without[171] developmental disabilities. A rebound nocturnal acid secretion has been reported.[172]

For the second group of infants and children who have documented erosive esophagitis or whose symptoms are refractory to the use of cisapride and ranitidine (grade 2 or more), the treatment must entail a more aggressive approach.[3] Occasionally, this will pertain to a young child without a proreflux condition, but, more usually, this will be in an older child with a predisposing condition such as neurologic compromise, cystic fibrosis, and repaired esophageal atresia. Medical treatment of the latter has an effect on the duration of reflux and could decrease the rate of subsequent stricture formation.[173] Ongoing trials and recent work with proton pump inhibitors in infants and children suggest that they are a useful therapeutic strategy in refractory reflux esophagitis, producing symptom improvement in all and histologic improvement in 40% in a recent study.[174] It has been proposed as the therapy of choice in children with neurologic compromise.[175] Symptomatic relapse is an issue on cessation of therapy, however, and this may be because the underlying lower esophageal dysmotility is unaltered by omeprazole therapy.[176] Definitive dose-finding studies remain to be carried out, and a higher dose/kg may be required than is observed in adults, for example, 0.7 to 2.0 mg/kg/d of omeprazole.[118,177,178] Lansoprazole has not been studied for GOR/dyspepsia in childhood to date.

Domperidone acts similarly to metoclopramide but has less dystonic reactions or other side effects and may be helpful for a limited period.[179,180]

The role of surgery is as a last-line therapy after maximal medical therapy has failed and significant complications of GER esophagitis remain. Most fundoplications to date have been open Nissen procedures, which involve a full wrap-around of the gastric fundus on the distal esophagus. Thal procedures are performed less commonly and involve an approximately 80% circumferential wrap. Fundoplication probably works because it prevents full LES relaxation and a reduction in the number of transient LES relaxations.[181] A large retrospective (20 years) multicenter study of over 7,000 children showed that so-called good to excellent results were achieved in 96% and 85% of normal and neurologically impaired children, respectively. Mortality was 0.1% and 0.8%, respectively. Recurrent reflux occurred in 7%, gas bloat in 3.6%, and obstruction in 2.6%. Reoperation was required in 3.6% and 11.8%, respectively.[182] Failed fundoplication is reported in those with IEE.[53] Laparoscopic

fundoplication is becoming more widespread. The results now compare favorably with the open procedure,[183] and it is associated with a faster recovery.[184,185]

Of particular interest recently is the advent of endoscopic antireflux procedures whose efficacy is well documented in the adult literature but whose use in pediatrics is still in only a few centers. One such procedure makes use of an Endocinch (C. R. Bard Inc., Murray Hill, NJ, USA) sewing machine attached to the endoscope, which was used to place three pairs of stitches below the GEJ to create three internal plications of the stomach (Figure 25-22).[186,187] Two plications are placed circumferentially 1.5 cm below the GEJ and one is placed 0.5 cm below the GEJ, which differs slightly from the reported adult studies in which various combinations of plications have been employed (eg, two circumferential, two or three longitudinal).

The initial results from a pilot study of 17 children suggest that endoluminal gastroplication is safe and effective in terms of improved quality of life assessed with two validated quality of life scoring tools, in terms of symptom scores, and objectively with improvement of all analyzed pH parameters in 16 of 16 patients and return to normal values in 14 of 16 patients who underwent pH studies subsequent to endoluminal gastroplication (Figure 25-23).[188]

Questions have been asked regarding the way in which the procedure actually improves the degree of reflux. It may be that the plications help to alter the angle of His, addressing the defective LES, and thereby decrease the amount of refluxate entering the esophagus. Swain and colleagues demonstrated an increase in the length and pressure of the LES.[189] However, other groups have not shown similar findings using esophageal manometry. It may be that the angle of the GEJ is improved or that the number of transient LES relaxations is decreased, and it is known that these are a major contributor to GER disease.

The alternative endoluminal techniques that have been promoted are endoluminal delivery of radiofrequency energy (Figure 25-24)[190] and endoluminal injection of inert biopolymers (Figure 25-25)[191]; however, neither of these techniques are reversible and are hence not desirable for application in the pediatric patient. As with any new technique, concerns remain about the learning curve of the endoscopist. However, a previous multicenter study in adults does not show a significant difference in the learning curve of endoscopists in different centers.[191]

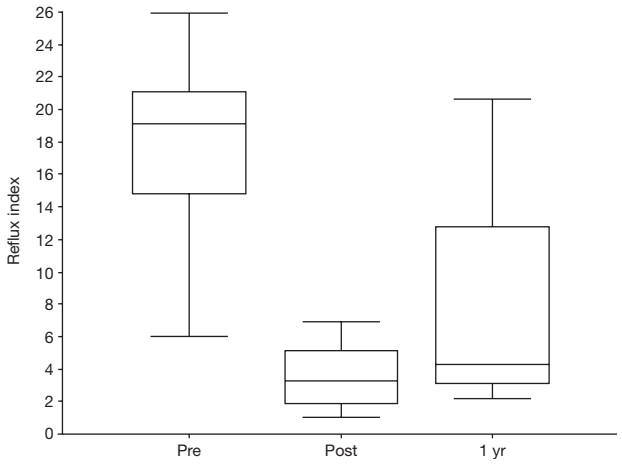

FIGURE 25-23 Reflux index of pH pre–, 6 weeks post–, and 12 months post–endoscopic gastroplication showing medium-term sustained response. (Wilcoxon rank sum test, and data presented as box and whisker plots with interquartile ranges).

Removal of CMP from the diet needs to be complete in a case of CMP-associated esophagitis and may occur even in the breastfed infant whose mother is taking dairy produce in her own diet, in which case, these should be excluded from mother's intake, and breastfeeding can continue. CMP-associated symptoms in exclusively breastfed infants have been reported with a prevalence of 0.37% in a population in which CMP allergy amounts to 1.9%.[192] In those on formula milk, a substitute is required. It is not appropriate to use soy milks because up to 30 to 40% or so of CMP-intolerant infants will also have an intolerance to

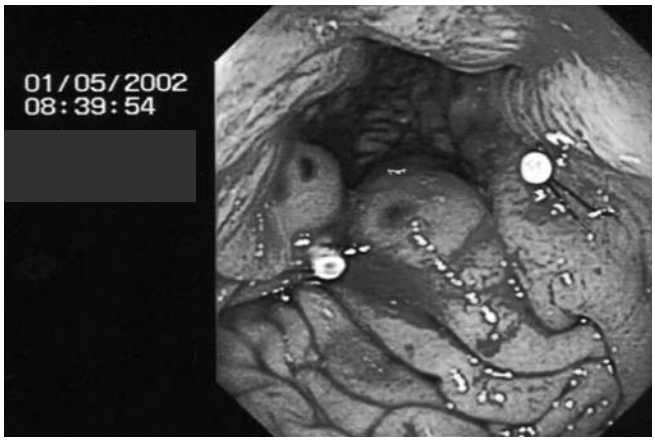

FIGURE 25-22 Endoscopic gastroplication (Endocinch) creating three pairs of sutures (plications): either longitudinally 0.5 cm, 1 cm, and 1.5 cm distal to the gastroesophageal junction (GEJ) and on the lesser curvature; or one each on the greater and lesser curvatures 1.5 cm distal to the GEJ and one on the lesser curvature 0.5 cm distal to the GEJ.

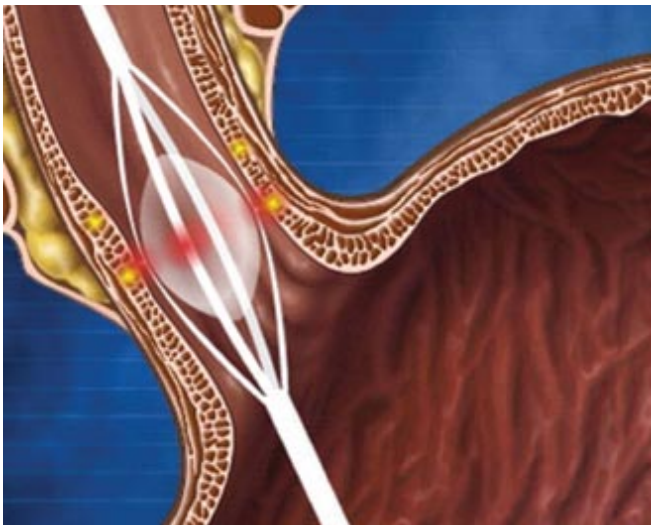

FIGURE 25-24 Delivery of radiofrequency energy to the gastroesophageal junction as an antireflux endoscopic procedure: not performed in children to date.

soy.[48] Classically, an infant will initially improve on the soy formula, and then symptoms similar to those experienced with CMP will ensue some 4 to 6 weeks later. More preferable, and to be recommended as a first-line substitute in this situation, is a casein hydrolysate milk (eg, Pregestimil, Nutramagen, Alimentum) or a whey hydrolysate (eg, Pepti-Junior, Alfa-Ré, Profylac, Hypolac, Nutrilon-Pepti).[193] However, these still contain peptides greater than 15 amino acids in length, which are still capable of precipitating a major histocompatibility complex–mediated immunoreaction. In some instances, it is necessary therefore to go one step further and put the infant exclusively on an elemental milk (eg, Neocate, Neocate Advance, Nutri Junior) containing amino acids, glucose polymer, and long-chain fatty acids. An improvement may be seen within 1 week, but Kelly and colleagues, and other groups, recommend a 6-week trial.[46,194,195] The glucose polymer is used to prevent the osmolality of the milk becoming too high and precipitating osmotic diarrhea. The only drawback of such milks is their unpalatability, but with persistence, infants usually get used to them, especially if introduction occurs early in life. Certain milks may require the addition of calcium to the diet, and involvement of a dietitian is advised. It is normal practice to reintroduce CMP around 12 to 18 months, but some children require dairy exclusion until 3, 4, or more years. Multiple food-associated esophagitis can occur,[47] and in such situations, a few-foods diet starting with hypoallergenic components such as rice, potato, green beans, and chicken with stepwise reintroduction may be necessary. A proportion of these infants are also helped by oral sodium cromoglycate.

IEE has been effectively treated with oral or inhaled corticosteroids,[96] and it is possible that the latter route may be preferable given that multiple courses of systemic corticosteroids are often required.

Infective causes of esophagitis in pediatrics require specific therapies. Viral esophagitis is usually due to herpes simplex, CMV, and, occasionally, varicella zoster.[65–67] Although the inflammation can resolve spontaneously in the immunocompetent, in those with poor immune function, acyclovir and a high index of suspicion are recommended.[72] Use of prophylactic acyclovir is conjectural but may be of some benefit post-transplant. Resistance to acyclovir has been described, in which case, foscarnet is the agent of choice.[73] CMV esophagitis is predominantly found in immunocompromised individuals, and treatment is with ganciclovir or foscarnet.[67] Hemorrhage, fistulae, and esophageal perforation in adults with viral esophagitis have been described.[74,75]

Acute HIV infection can also cause esophagitis, and antiretroviral regimens are needed.[76]

Candida is the most common infectious cause of esophagitis. A 2- to 6-week course of oral nystatin can be effective in those with normal immune function, but it is more convenient to give fluconazole. Fluconazole and liposomal amphotericin are both effective and are necessary in the immunocompromised child. Esophageal resection and diversion for necrotizing candidal esophagitis have been successful in a 10 year old.[81]

Eradication of *H. pylori* is not likely to improve coexistent esophagitis, and, indeed, in adults, eradication has been associated with increased acid production and hence more noxious gastroesophageal refluxate. However, there does not seem to be any increased incidence of esophagitis in the presence of or following the eradication of *H. pylori* in children.[82] Primary bacterial esophagitis is described in immunocompromised patients and requires appropriate antibiotics dictated by sensitivity testing.[84] Other opportunistic organisms causing esophagitis, such as *Cryptosporidium* and *Acremonium*, have been reported and require appropriate therapy.[85,86]

Treatment of caustic esophagitis is initially conservative, with barium swallow at 4 to 6 weeks postingestion, endoscopic assessment, and, if necessary, stricture dilation. The place of steroids in stricture prevention is controversial and not routine in many centers. Recently, the use of an antifibrotic, mitomycin C, applied topically to the mucosa poststricture dilation has been used successfully in patients who have required multiple stricture dilations, with prevention of restenosis.[41] Antibiotic therapy for mediastinitis and judicious use of surgery may be employed; these are dealt with in Chapter 24.

Older children whose esophageal stratified epithelium is exposed to long-term acid may, as with adults, develop gastric metaplasia, eponymously termed Barrett esophagus.[196–198] This increases the risk for esophageal adenocarcinoma 30 to 40 times. Debate surrounds the relative merits and success rates of antireflux surgery or long-term proton pump inhibitor use, and this is dealt with in greater detail in Chapter 24.

Prognostication in infant and childhood esophagitis is wholly dependent on etiology; however, fortunately, the most common causes, reflux and allergy, are relatively self-

limiting, with a natural improvement and recovery by 18 months to 2 years in the vast majority. This is dealt with in greater detail at the beginning of the section on treatment. It is the responsibility of the pediatrician to prevent avoidable complications such as peptic strictures occurring during the period of vulnerability until such an age has been reached. A low threshold for diagnosis and intervention is therefore sensible in this population.

CHAPTER 26

OTHER MOTOR DISORDERS

Rachel Rosen, MD
Samuel Nurko, MD, MPH

Abnormalities of esophageal function occur frequently and can be primarily confined to the esophagus or can be secondary to systemic illnesses (Tables 26-1, 26-2, and 26-3). By interfering with the normal progression of food transit from the mouth into the stomach or by failing to provide adequate protection from gastric acid, esophageal motor disorders can be debilitating and even life threatening. Because the major esophageal functions are to transport food from the mouth to the stomach and to prevent reflux of gastric contents, the main manifestations of disease in this organ are either feeding difficulties or regurgitation. Chapter 23, "Disorders of Deglutition," and Chapter 24, "Gastroesophageal Reflux," discuss normal esophageal function and development and present a general approach to the patient in whom an esophageal motor disorder is suspected. This chapter provides an in-depth discussion of the clinical manifestations of specific disorders in esophageal motility from the perspective of pathophysiology, diagnosis, and management. Because disorders of the oral and pharyngeal phase of swallowing have been described elsewhere in this volume, the following discussion relates mainly to clinical problems of the esophagus and the esophageal phase of swallowing (see Table 26-1). It first focuses on the disorders that affect the upper esophagus (see Table 26-2) and then on those that affect the rest of the esophageal body and the lower esophageal sphincter (LES) (see Table 26-3).

DISORDERS OF THE CRICOPHARYNGEAL MUSCLE

Problems with the cricopharyngeal muscle usually present like those of the pharyngeal phase and are therefore difficult to differentiate. Normal deglutition depends on precise coordination between relaxation of the upper esophageal sphincter (UES) and the pharyngeal contractions that propel the food bolus through the sphincter into the esophagus. When UES relaxation is incomplete or uncoordinated with respect to pharyngeal activity, the bolus is mishandled.[1]

When there is cricopharyngeal dysfunction, the symptoms usually appear shortly after birth or during the first 2 months of life. Repeated aspirations and choking are usual symptoms and can be life threatening. Evaluation usually includes radiographic studies to assess the anatomy and the coordination of the swallow. Cricopharyngeal dysfunction should be suspected in children with pooling of saliva at the back of the pharynx, holding up of barium at the UES, and a shellfire impression at the cricopharyngeal level.[2]

The usefulness of UES manometry in the diagnosis of cricopharyngeal dysfunction is not clear. Malhi-Chowla and colleagues explored this issue in adults. They found that 80 (17.7%) of 435 of their routine manometries revealed an abnormality of the UES or the pharynx, but these findings changed management in only 6 patients. Therefore, only 1.4% of the total number of UES manometries done resulted in a management change. As a result, the authors argue that unless there is a strong clinical suspicion or an abnormality on a barium swallow that needs further evaluation, routine testing of the UES has a low yield.[3]

Evaluation of motor dysfunction of the pharyngoesophageal junction suggests two main defects of UES motility: abnormalities in the sphincter resting pressure and abnormalities in the UES relaxation.[2,4]

Abnormalities of Resting UES Pressure

Cricopharyngeal Hypertension. The term "cricopharyngeal spasm" was initially introduced after prominent cricopharyngeal impressions were seen by barium swal-

low.[4] Later it was found that clinically or radiographically diagnosed "esophageal spasm" did not correlate with elevated UES pressure measured by manometry.[4] It has been reported that a horizontal esophageal bar can be found in up to 5% of adult patients undergoing a barium swallow for all indications[2] and is a frequent radiologic sign in infants.[2] There are, however, reports in which the resting pressure of the UES was found to be elevated in patients with globus sensation in the pharynx, although this finding has not been replicated in all patients.[4]

Cricopharyngeal Hypotension. Because tonic closure of the cricopharyngeus is due to tonic myoneural activity, a variety of myoneural disorders may lead to a decreased pressure in the UES. These include amyotrophic lateral sclerosis, myasthenia gravis, oculopharyngeal muscular dystrophy, dystrophia myotonica, and polymyositis.[5] This hypotension can be diagnosed manometrically but will not be seen by radiography unless the UES weakness is extreme.[4] The clinical significance of UES hypotension is not clearly defined. It is possible that it allows air to enter the gastrointestinal (GI) tract during respiration and also predisposes the patient to tracheobronchial aspiration of the esophageal contents.

ABNORMALITIES OF CRICOPHARYNGEAL RELAXATION

Three types of abnormalities of cricopharyngeal relaxation have been described: incomplete relaxation, premature closure, and delayed relaxation.[4,6] All of these abnormalities may result in dysphagia and will be considered separately.

Incomplete Cricopharyngeal Relaxation. Patients with cricopharyngeal achalasia show incomplete UES relaxation after the majority of swallows.[7] Radiographically, cricopharyngeal achalasia is characterized by a horizontal indentation on the posterior esophageal wall, with the barium passing the muscle very slowly and the cricopharyngeal muscle appearing to relax poorly.[8] At times, there is complete functional obstruction, and no barium passes into the esophagus.[7] Manometric studies have confirmed this incomplete cricopharyngeal relaxation in some patients,[1,7,9,10] whereas in others, the UES has been shown to relax normally.[2,4] The reason for this discrepancy between radiologic and mano-

metric findings is not clear, although it may relate to the difficulty in studying this region.[7] In children, most studies have documented abnormal relaxation by cinefluoroscopy,[7,8,11] although manometric abnormalities have also been described.[7,12] Symptoms usually include food regurgitation, choking, nasal reflux, coughing, recurrent aspiration pneumonia, and failure to thrive. Symptoms usually begin at birth or shortly thereafter.[1,7,9,13] It is crucial to evaluate children with recurrent respiratory symptoms for cricopharyngeal achalasia because the diagnosis is often missed, resulting in unnecessary fundoplications because the children are given the diagnosis of reflux.

One of the largest series in children described the findings in 15 children.[12] Because of a lack of suspicion, the diagnosis was usually made at the end of the first year. All patients were diagnosed radiographically, and esophageal motility studies were performed in 5 patients, documenting the lack of cricopharyngeal relaxation in all. Abnormal esophageal motility was also noted. It is interesting to note that 10 of 15 patients had an associated disease: four myelomeningoceles and six congenital anomalies associated with central nervous system (CNS) involvement. Cricopharyngeal achalasia has also been confirmed manometrically in five other studies.[1,7,9,10,14] Dinari and colleagues, however, reported a child with cricopharyngeal achalasia in which there were radiologic abnormalities but normal manometric findings.[2] It has also been reported that cricopharyngeal achalasia may occur in children with Down syndrome[6] or with Chiari malformations.[1,7,9]

The treatment of cricopharyngeal achalasia in adults has ranged from bougienage to surgery.[1,2,4,7,9,15–17] The results with bougienage have been unsatisfactory owing to short-lasting effect,[2,4,7,17] so, for severe cases, cricopharyngeal myotomy has been advocated.[2,7,17] A decrease in cricopharyngeal pressure occurs, and most patients have relief of the dysphagia.[17] Major complications can occur because the protective mechanism of the UES is taken away, and, in fact, deaths from aspiration have been described following myotomy.[7,17] Recently, injections of botulinum toxin in the cricopharyngeal muscle have been successfully used to treat patients who are at high risk for surgery.[15,16,18,19]

There are two recent studies in adults on the use of botulinum toxin in the treatment of cricopharyngeal dysfunction. The first, by Haapaniemi and colleagues, reported on four adults with cricopharyngeal dysfunction from systemic illnesses (CNS lesions, myositis, or neuropathy) who had relief of their dysphagia for 2 weeks to 10 months after injection.[18] Shaw and Searl described their series of 12 patients who had botulinum toxin injection for cricopharyngeal dysfunction owing to CNS lesions or to dysfunction from prior otolaryngologic surgeries. They found that symptom improvement ranged from 0 to 14 months. The complications that have been reported from injection include pharyngeal tears and worsening dysphagia.[19]

Experience with the treatment of cricopharyngeal dysfunction in children is very limited.[7,14] Successful balloon dilatation has been accomplished in cases of cricopharyngeal achalasia[2,7] and incoordination.[2,7,8] Some authors make the observation that, in contrast to adults, even one dilatation in infants and children may be successful in relieving the symptoms.[7] The smallest patient reported with cricopharyngeal achalasia treated with dilatations was 5 months old at the time of the treatment, and she responded well, without any evidence of obstruction 1.5 years after the procedure. The smallest patient with cricopharyngeal incoordination treated with dilatations was 2.5 years and has remained symptom free for 6 months after the dilatation.[2]

In one of the largest pediatric series of 15 patients with cricopharyngeal achalasia, 6 were managed conservatively with nutrition and positioning, 4 with myelomeningocele had shunt revisions, with subsequent improvement in 3, 4 had gastrostomies, and 2 had tracheostomies. Only 2 patients underwent cricopharyngeal myotomy, and only moderate improvement was observed.[12]

There have been case reports of successful cricopharyngeal myotomy performed in children with cricopharyngeal achalasia.[7,10,13,20] Brooks and colleagues described their experiences with five children who had esophagomyotomy (EM) for cricopharyngeal achalasia, two of whom had manometry pre- and postmyotomy.[14] The EM reduced the UES pressures by 29% and 47% in these two patients. Most importantly, however, all five patients were free of symptoms during the follow-up period of 2 to 14 years. Esophagomyotomy has also been reported in children with cricopharyngeal incoordination,[10] with good results reported at short-term follow-up.[7]

Because of the possibility of spontaneous improvement and the good response reported after dilatation in infants and children, a conservative approach should be undertaken, with aggressive nutritional support and dilatations in those patients with severe compromise, reserving surgery for the difficult patients who do not respond to the above-mentioned conservative management.[2,7,12] Even though there is no experience with the use of botulinum toxin for cricopharyngeal disorders in children, it may play a role in the management before more invasive procedures are attempted.

Premature Cricopharyngeal Closure. It had been suggested that premature closure of the cricopharyngeal sphincter following deglutition plays a role in the pathogenesis of Zenker diverticulum.[4] Recent studies, however, have found manometric abnormalities in only some or none of the patients studied. According to manometric data, the universal acceptance of cricopharyngeal myotomy in the management of Zenker diverticulum has little justification.[21]

In a manometric study in children, two patients were found to have delayed pharyngeal contraction with respect to cricopharyngeal relaxation, two were found to have incomplete cricopharyngeal relaxation, and one had both cricopharyngeal incoordination and failure to relax.[10] All had gastroesophageal reflux (GER), and one also had incomplete UES relaxation. In all cases of incomplete relaxation, the barium swallow was reported to be abnormal; all five patients had severe swallowing difficulties, and three had an associated syndrome with mental retardation (Russell-Silver syndrome, 5p- [cri du chat] syndrome, and minimal change myopathy).

Other case reports of cricopharyngeal incoordination in children have been published.[1,2,9] Some authors have described a "transient cricopharyngeal incoordination" that may occur in the newborn period. The clinical features resemble tracheoesophageal fistula or laryngotracheoesophageal cleft, and the diagnosis has been made radiographically.[4,22] This "incoordination" is usually manifest from birth, and even though sucking is normal, infants may choke or even aspirate. The nature of the problem, however, has not been defined manometrically, although there is a case report in which the manometry was normal.[2] Recently, it has been shown that children with Arnold-Chiari malformation type I can have neurogenic dysphagia with pharyngo-UES incoordination preceding other brainstem dysfunction (see discussion below).[1,9] Repeated aspirations and choking can be life threatening. The clinical course is variable, and even though it tends to be progressive, with increasing severity in the respiratory complications and increasing nutritional problems, spontaneous improvement has been described, particularly in those in whom no associated anomalies were found.[2,8] We recently described the natural history of nine newborns who presented with isolated neonatal swallowing dysfunction.[23] We found that most children were able to eat by mouth by the age of 3 years. Four of the nine patients had associated anomalies or syndromes that became evident only through close follow-up. Because it is known that some of these infants "outgrow" their incoordination, careful attention should be paid to the nutritional state of the infants, and feedings by spoon, gavage, or gastrostomy tube may be required for a few years until symptoms disappear.[2,8] It should be mentioned, however, that fatal aspiration has been reported.[22,24] In one infant who died, the autopsy showed marked dilatation of the pharynx above the area of obstruction and hypertrophy of the pharyngeal constrictors. Aganglionosis of the proximal third but not of the distal third of the esophagus was noted, but no further information was provided.[22]

Delayed Cricopharyngeal Relaxation. If reflex cricopharyngeal relaxation is delayed, pharyngeal contents are propelled toward the upper esophagus before the UES is opened. It has been suggested that a delay in cricopharyngeal opening of more than one-third of a second[1] is associated with pulmonary aspiration. In children with familial dysautonomia (Riley-Day syndrome), the cricopharyngeal opening is delayed, but once the sphincter opens, its opening is complete (unlike patients with cricopharyngeal achalasia).[4,25] Careful radiologic studies in 11 patients with Riley-Day syndrome have also demonstrated that they have disordered esophageal motility,[25] although it was suggested that the major cause of the disability was the cricopharyngeal abnormality, and others have suggested that the impaired pharyngeal muscle coordination creates the problem. No manometric studies of these patients exist.

Delayed cricopharyngeal relaxation had not been shown manometrically until Wyllie and colleagues described two children whose drooling, observed with the administration of nitrazepam, proved to be secondary to delayed cricopharyngeal relaxation (Figure 26-1), providing direct evidence that cricopharyngeal incoordination can be secondary to drug administration.[6]

DISEASES THAT AFFECT THE STRIATED MUSCLE PORTION OF THE ESOPHAGUS

Many diseases can produce dysphagia secondary to buccopharyngeal involvement (see Table 26-2). These illnesses can produce abnormalities of the tongue, pharyngeal muscles, cricopharyngeal muscle, upper esophagus, and even, at times, the lower esophageal body. Therefore, the precise genesis of the difficulty in swallowing may be very complex, involving multiple factors rather than a single one.[1,4] Some selected diseases that cause this type of dysphagia with impact in the pediatric age group are described.

Myopathic Diseases

Muscular Dystrophies. Dysphagia is rare in most forms of muscular dystrophy, except for two relatively rare types of muscular dystrophies: myotonic muscular dystrophy and oculopharyngeal dystrophy. The former is the one that can present in the pediatric age group.

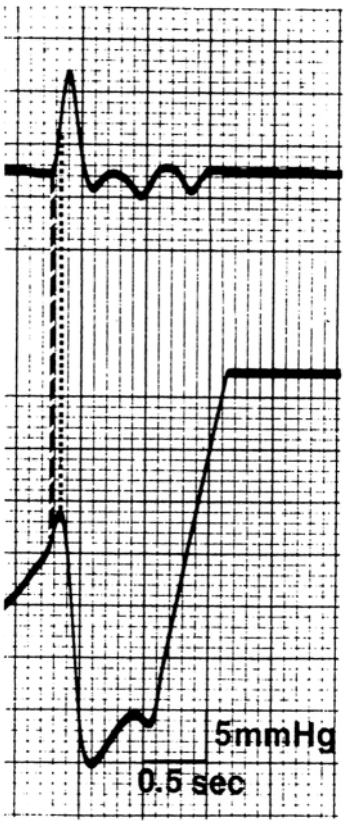

FIGURE 26-1 Delayed cricopharyngeal relaxation in a patient taking nitrazepam. The upper tracing represents hypopharyngeal contraction (onset at *broken line*); the lower tracing represents cricopharyngeal relaxation (onset at *dotted line*). Note that the hypopharyngeal contraction preceded the cricopharyngeal relaxation by 0.3 seconds. Reproduced with permission from Wyllie E et al.[6]

Even though myotonic muscular dystrophy usually has its onset in the adult, it begins in infancy or childhood with considerable frequency. It is characterized by myotonia, "myotonic facies," muscle wasting, frontal baldness, testicular atrophy, and cataracts. Pharyngeal muscle weakness is found in up to 92% of these patients,[26–29] although symptomatic involvement occurs in less than half.[26,27] Usually, however, myotonia or other evidence of disease is present for 2 to 15 years before the onset of dysphagia, and in addition to dysphagia, these patients also have involvement of the striated and the smooth esophageal muscle.[1,26] Pharyngeal weakness of contraction is the predominant finding[4] and reveals itself as barium stasis and hypomotility in the radiograph. The UES may be incompetent and is responsible for the appearance of a continuous column of barium in the pharynx and the upper esophagus.[1,26] Manometric studies reveal a reduction in the basal UES pressure, the duration of contractions in the amplitude, and amplitude progression, as well as in coordination[1,4,26,28,29] of pharyngeal and cricopharyngeal contractions.

Inflammatory Myopathies. Systemic diseases in which there is inflammation of the skeletal muscle usually also affect the striated muscle of the pharynx and esophagus. Dysphagia is a frequent symptom in these patients.[4] In a series of 152 patients, dysphagia was present in 54%,[30] and in about 2% it may be the initial symptom.[4] The dysphagia is related to pharyngeal muscle weakness. In one study of six patients with polymyositis and dysphagia, barium appeared to pass the oropharynx with difficulty, and all patients showed retained barium in the vallecula and piriform sinuses. Transport seemed to be affected only by gravity.[31] Manometric studies have revealed decreased cricopharyngeal pressure, with normal relaxation of the sphincter and poor amplitude of contractions in the pharynx and upper third of the esophagus.[31] It has been suggested that these abnormalities respond to the administration of steroids.[30] Recently, it has been reported that these patients may also have abnormalities in the distal esophagus.[32]

Neurologic Diseases

Arnold-Chiari Malformation. The Chiari malformation has been associated with dysphagia and radiographic evidence of UES dysfunction. Type II is usually associated with myelodysplasia, whereas type I is not. It has been suggested that up to 5% of patients with a Chiari malformation will develop symptoms as a result of brainstem dysfunction.[1,9]

Putnam evaluated the dysphagia in five children with Chiari malformation using esophageal manometry and barium esophagography.[1] The studies were done before and after craniocervical decompression. Preoperatively, three patients had failure of compete UES relaxation, one had pharyngo-UES incoordination, and the other had both. All patients had clinical and manometric resolution of the symptoms after surgery, suggesting that surgical decompression of Chiari malformations may lead to complete clinical and manometric resolution of the dysphagia owing to UES dysfunction. It is interesting to note that the dysphagia was the first symptom in two of the patients and was the only evidence for cranial nerve dysfunction in one, indicating that patients with unexplained cricopharyngeal dysfunction should be evaluated for Chiari malformations.

In another series of 46 patients who underwent craniectomy and laminectomy for Chiari malformations, 15 patients presented with symptoms of neurogenic dysphagia.[9] All patients had normal swallowing before the development of the dysphagia, and the symptom was progressive in all and in eight preceded other signs of brainstem involvement. Patients had widespread dysfunction of the swallowing mechanism, with a combination of pharyngoesophageal dysmotility, cricopharyngeal achalasia, nasal regurgitation, tracheal aspiration, and GER. Outcome after surgery varied according to the severity of the preoperative symptoms, with those patients with other signs of brainstem involvement having a poor result, whereas those with mild symptoms showed an excellent response. This finding suggests that early recognition of neurogenic dysphagia and expeditious intervention are crucial to ensure a favorable neurologic outcome.

In children with Arnold-Chiari malformation and neurogenic dysphagia, the treatment needs to be directed to improve the brainstem function, usually with craniectomy and cervical laminectomy.[1,9]

Motoneuron Disease. This is characterized by degeneration of the upper and/or lower motoneurons. Involvement of the bulbar neurons leads to paralysis of the tongue and the pharynx, which produces abnormalities in the buccal and pharyngeal phases of swallowing.[4] A recent survey in adults found that 73% of patients with motoneuron disease had difficulty in chewing and swallowing, with most problems being related to solid food rather than to liquids.[33] Cricopharyngeal abnormalities have also been found in adults with motoneuron disease.[33]

Bulbar palsy can occur in children. In the infant, this is usually supranuclear, with difficulty in sucking or swallowing and prominent drooling being the frequent symptoms.[22] The jaw jerk tends to be exaggerated, which is a diagnostic clue, and usually a picture of diffuse cerebral palsy and spasticity develops. In the lower motoneuron form of bulbar palsy, there are usually poor suck and nasal regurgitation of the formula. If facial bulbar paralysis is associated with facial diplegia, it constitutes Möbius syndrome.

Selective paralysis of the laryngeal nerve has been reported. Dysphagia and altered esophageal motility have been reported, and recovery usually occurs at the end of the first year.[22] Other processes that may induce motoneuron disease, with secondary problems in the pharyngeal and esophageal phases of swallowing, include neurosurgical procedures and tumors that involve the brainstem.[8]

Other Neurologic and Neuromuscular or Muscular Diseases

Myasthenia Gravis. This disease affects the motor end plate of the striated muscle, including the one situated in

the esophagus. In children, it can present in three clinical forms: transient neonatal myasthenia gravis, persistent neonatal myasthenia gravis, and juvenile myasthenia gravis, which is the most common form.[4,22] Dysphagia, choking, and aspiration of food are frequent clinical manifestations of the disease.[4] The description of the swallowing difficulty is characteristic: the patient is able to swallow normally at the beginning of the meal, but progressive difficulty appears with each swallow. Manometrically, these patients have been shown to have a decrease in the amplitude of peristaltic contractions, mainly in the upper esophagus, with the amount of decrease dependent on how severely each particular patient is affected.[34] At times, the proximal esophageal weakness may be apparent only with repetitive swallows, and cricopharyngeal dysfunction almost never occurs in these patients.[4] The distinguishing feature of this disease is the recovery of the manometric and clinical abnormalities with rest or the administration of anticholinesterase drugs. The intravenous administration of edrophonium chloride (Tensilon) in a dose of 0.2 mg/kg, up to 10 mg, produces prompt but transient relief in symptoms and radiographic and manometric abnormalities,[4] and it has been suggested that this diagnostic test should be employed in patients who show pharyngeal weakness without any obvious cause, particularly when ptosis is present.[4]

Other Neurologic Diseases. Swallowing difficulties are common in patients with multiple sclerosis.[4] In one study, they were reported to occur in 55% of the patients, and cricopharyngeal dysfunction can also occur. Even though cerebrovascular accidents are rare conditions in childhood, transient or persistent dysphagia is a frequent manifestation.[4] These problems occur when the lesions involve the swallowing center or the motor nuclei that control the hypopharynx, and dysphagia may be one of the predominant symptoms.

Poliomyelitis. Bulbar poliomyelitis may cause dysphagia, which is thought to be due to pharyngeal paralysis.[35–38] There are manometric and radiographic studies in which cricopharyngeal function has been reported to be normal,[36] although other studies, relying mainly on radiographic observations, have reported cricopharyngeal abnormalities and cricopharyngeal achalasia in some of these patients.[4,35,36,38] The swallowing problems of these patients have been treated with prolonged nasogastric intubation, cricopharyngeal dilatations, cricopharyngeal myotomy, and even cricopharyngeal denervation, all with good results.[4,35,36,38]

Poliomyelitis is a disease that has been eradicated from many parts of the developed world, but late postpolio sequelae have been reported recently in patients who suffered from the disease many years ago.[38] These late sequelae may occur more than 30 years after the original illness, and new symptoms include unaccustomed fatigue, new joint or muscle pain, new weakness in muscles affected and unaffected by polio, and new respiratory difficulties. Recently, dysphagia has been noted in nearly 18% of polio survivors.[35–38] This new dysphagia is worse for solids, and, radiographically, it seems to be related to decreased pharyngeal peristalsis. The dysphagia may be progressive, and it may be produced by a slow deterioration of the bulbar neurons.[38] A thorough evaluation is necessary to determine optimal feeding management and to search for treatable contributing factors.[37,38]

Botulism. The syndrome of infant botulism is characterized by peripheral muscle weakness, hypotonia, respiratory depression, and diminished suck and swallow.[39,40] Although descending flaccid paralysis of striated muscles is the most striking clinical feature of the syndrome, difficulty in swallowing and delayed evacuation of stool are often initial findings and are often overlooked.[39] The symptoms in this disease result from the irreversible binding of the botulinum toxin to peripheral cholinergic terminals, with the subsequent prevention of the release of acetylcholine at the neuromuscular junctions, as well as preganglionic and postganglionic synapses.[39] In a study of four infants with this disease, Cannon reported the results of esophageal motility in these infants.[40] The major effect of the toxin of esophageal motility was the disruption of the UES function and peristalsis in the proximal esophagus. There was a reduction in UES pressure and a marked reduction in the percentage of UES relaxation after swallowing (1–20% in patients compared with 80–100% in controls). The hypopharyngeal and proximal esophageal contractions were of low amplitude and poorly coordinated. Gradual return of esophageal motor function accompanied improvement in peripheral muscle strength and return of the gag and suck reflexes. Interestingly, the botulinum toxin had no significant effect on the LES and the distal esophagus.[40]

Drug Administration

Since the original report by Wyllie and colleagues, which described two children with delayed cricopharyngeal relaxation after nitrazepam administration,[6] Lim and colleagues performed a prospective study in 38 patients and found that 3 had delayed cricopharyngeal relaxation and high-peaked esophageal peristaltic waves.[41] They were also able to show in one patient that the manometric abnormalities disappeared after the drug was stopped. They postulated a CNS effect of nitrazepam promoting parasympathetic overactivity. These findings are important because they indicate that cricopharyngeal dysfunction may be responsible for the respiratory compromise seen in some of those patients and suggest that esophageal manometry should be considered in the evaluation of patients taking nitrazepam who have eating difficulties or aspiration pneumonia. If abnormalities of cricopharyngeal function are detected, the patient may be at greater risk for major complications, including sudden death.

Dysphagia has been described as being frequently associated with the administration of neuroleptics or other psychotropic medications.[42–44] The problem can be life threatening and is usually reversible once the medications are stopped.[42,43]

DISORDERS THAT AFFECT THE SMOOTH MUSCLE OF THE ESOPHAGUS

Primary Esophageal Motor Disorders

Achalasia. Achalasia is a motor disorder of the esophagus that presents as a functional obstruction at the esophagogastric junction (see Table 26-3).[45,46] It is characterized by the following abnormalities: a lack of esophageal peristalsis, increased LES pressure, and partial or incomplete LES relaxation.[45,47–49]

The illness is uncommon, with an estimated incidence of 1 case per 10,000 people.[47,50] Data suggest a worldwide incidence at between 0.03 and 1.1 of 10^5/yr.[47] It has been estimated that from all patients with achalasia, fewer than 5% manifest symptoms before the age of 15 years.[45,51,52] Moersch reported that of 690 cases seen in the Mayo Clinic, only 12 (1.7%) presented in the pediatric age group.[52] Olsen and colleagues reported that only 17 children (2.8%) of 601 patients were treated by them.[53] In a recent epidemiologic study of achalasia in children, Mayberry and Mayell, based on a study of 129 children, determined that in Ireland, the incidence was 0.31 cases per 105 children per year, and in England, it was 0.11 per 105 children per year.[51] No such epidemiologic information is currently available about children in the United States.

Etiopathogenesis. In idiopathic cases of achalasia, the incomplete relaxation of the LES is believed to be secondary to the fact that the postganglionic inhibitory nerves are absent, reduced in number, functionally impaired, or lacking in central connections.[54–56] The disease seems to involve the Auerbach plexus,[57] and absence of ganglion cells from the myenteric plexus in the involved portion of the esophagus with normal ganglion cells in the noninvolved segment has been described.[58–60] Ganglion cell degeneration appears to be prominent in the early years of the disorder, with progressive loss of neurons detected after a decade or more.[61] This progressive lesion of the plexus is accompanied by progression of the disease. Even though the most consistent neuropathologic lesion has been the ganglion cell degeneration or loss in the esophageal myenteric plexus, these findings are not a constant feature, and multiple instances of normal ganglion cells have been described.[62,63]

Many reports in children have found absent ganglion cells in the distal esophagus.[58–60,64] However, some other authors have described normal histology in some children with achalasia[62,65,66] or adequate numbers of ganglion cells but extensive perineural fibrosis. The presence or absence of ganglion cells may depend on the duration of the disease.[65]

Other neuropathologic findings that are frequently although inconstantly described include chronic inflammatory infiltrates in the myenteric plexus and degenerative changes in the smooth muscle or nerve fibers.[61] These findings could be secondary to neuronal degeneration and loss or to confounding variables.[61]

Most studies have noted no changes at the light microscopic level in the vagus nerves,[61] although some authors show evidence of nerve fiber degeneration at the electron microscopic level in the vagus nerve and its dorsal motor nuclei.[57,65] Electron microscopic studies on the muscle wall of achalasic LES have confirmed the specific nerve tissue damage, which light and electron microscopic studies on the intrinsic and vagal innervation of the LES had previously demonstrated.[67,68] The evidence of histopathologic studies points then to a primary neurogenic abnormality in patients with achalasia.[56,57,68]

The end result of all of those abnormal histologic findings is a decrease in the postganglionic cells, which mediate LES relaxation via the release of vasoactive intestinal polypeptide (VIP) and nitric oxide (NO).[69–71]

NO is an important mediator for the nonadrenergic, noncholinergic nerve effects in the human esophagus and LES.[70,72] Recent studies have demonstrated an absence of NO synthase in the myenteric plexus at the gastroesophageal junction of patients with achalasia, suggesting that NO deficiency may also be responsible for the lack of LES relaxation,[70,73] as it has been shown in other GI diseases that also involve a lack of inhibitory neurons, particularly in Hirschsprung disease.[74]

The evidence that suggests that VIP may also be important comes from the observation that it has been found to be reduced or completely lacking in patients with achalasia.[69,71,75] It has also been shown that the nerve endings in patients with achalasia are rare, contain few synaptic vesicles, and are particularly lacking in the large granular ones, which are those considered to contain VIP.[68] Furthermore, a study of six patients with achalasia, in which VIP was administered intravenously, showed that whereas normal controls did not show any changes in LES pressure after the VIP infusion, in patients with achalasia, there was a significant decrease in a dose-dependent manner. There was also a significant increase in the percentage of LES relaxation after swallowing. These findings suggest that there is a supersensitive response to VIP in the smooth muscle of patients with achalasia.[69]

Indirect evidence for the lack of inhibitory innervation in patients with achalasia has also been provided by hormonal studies. It was initially shown that in the cat, the effect of cholecystokinin-octapeptide (CCK-OP) on the LES involves two different opposing mechanisms: on the one hand, it elicits an indirect inhibitory effect by stimulating inhibitory nerves that mediate physiologic LES relaxation; on the other hand, it also has a direct excitatory effect by stimulating excitatory receptors located on the LES smooth muscle.[76] In cats, the net effect of CCK-OP administration is LES relaxation, but after pharmacologic denervation with tetrodotoxin, CCK-OP produced LES contraction. In normal human volunteers, the administration of CCK-OP results in LES relaxation.[76–78] Holloway and colleagues and others showed that when CCK-OP is administered to patients with achalasia, there is a paradoxic LES contraction in 90%, in contrast to the normal LES relaxation obtained in normal people, suggesting that this LES contraction in the patient with achalasia may be the result of the postganglionic inhibitory denervation of the LES that has been described in the cat.[54,55,68]

Even though the main problem seems to be neurogenic in origin, minor changes in the smooth muscle of the esophagus have also been noted.[57,79] It has recently been suggested that the interstitial cells of Cajal could also be involved in the pathogenesis of achalasia.[67] These authors found that the interstitial cells of Cajal present in patients with achalasia are fewer in number and more highly modified than those in normal patients or patients with other esophageal disorders. Other studies have found that there is a disruption in the contact between the nerves and the interstitial cells of Cajal, which may result in diminished conduction and resultant atrophy.[80,81] Because their function is not known, it is difficult to know which role they play, if any, in the pathogenesis of achalasia.

Although the denervation is mainly confined to the esophagus, abnormalities in other organs have been described. It has been shown that whereas 91% of achalasic patients studied had absent ganglia in the distal esophagus, 20% had no ganglia in the middle third of the stomach.[63] Also, in some patients, degenerative changes have also been found in extraesophageal vagal fibers and in the brainstem vagal motor nuclei, so it is expected that achalasic patients may have functional derangement of other alimentary tract organs under vagal control.[57,82,83] The exact nature of gastric involvement has been controversial. Different results have been found in gastric emptying studies, with some authors finding alterations with delayed solid emptying and increased liquid emptying, suggesting vagal dysfunction,[84] whereas others found normal patterns.[63] Other authors have found a decreased postprandial fundus relaxation, suggesting autonomic neural damage,[85] whereas others have described abnormalities in acid secretion although gastric emptying is normal, raising the possibility that the alterations observed are probably secondary only to intrinsic abnormalities in the myenteric plexus. Finally, some authors have reported abnormal gastric secretory responses to insulin stimulation and also an abnormal response in pancreatic polypeptide release after sham feeding, suggesting some denervation, but it was not clear if the problem was intrinsic to the stomach or secondary to vagal dysfunction.[57]

Other GI organs can also be affected. Abnormal gallbladder emptying has been described.[82] In a study of ambulatory jejunal motility in 13 patients, it was shown that they all exhibited abnormal findings that ranged from loss of cyclic activity, abnormal migration of phase III, abnormal fed patterns, and giant migrating contractions or retrograde contractions.[83]

Numerous theories exist regarding the pathogenesis of achalasia. Theories suggesting that the defect is genetic, neurogenic, myogenic, hormonal, or infectious have been postulated.[56,62] In the United States, the great majority of cases have no known cause,[57] although in certain parts of the world, Chagas disease of the esophagus can produce achalasia,[86] and achalasia has also been diagnosed in certain cases of carcinoma.[87,88] In one study, it was found by using deoxyribonucleic acid (DNA) hybridization that there was a significantly higher presence of varicella-zoster virus in tissue obtained at cardiomyotomy in three patients with achalasia, raising the possibility that this virus could be of etiologic importance.[89] This finding has not been replicated by others. Recently, myenteric neuronal antibodies have been isolated in some patients with achalasia, suggesting that there may be an autoimmune mechansim,[90] but the etiology is still unknown.

Genetics. The influence of genetic factors remains to be assessed. The clustering of esophageal motor disorders in families and the occurrence of achalasia in certain syndromes have led to the suggestion that genetic factors may play an important role in the etiology of the disease.[66] Many cases of achalasia in siblings have been reported, including in monozygotic twins,[91] and inheritance as an autosomal recessive trait has been suggested because of the lack of consistent vertical transmission, the clustering of cases in families, and the occurrence of the disease in father and son.[91–93] On the other hand, there is one report in which there was a lack of concordance of achalasia in monozygotic twins,[94] and the role of genetic predisposition seemed minimal when two large community-based studies failed to identify any family clusters.[47]

It has also been suggested that familial achalasia may be different from the nonfamilial variety, being either congenital in origin or more virulent.[66] Other arguments in favor of a possible congenital origin in subpopulations of patients are the occurrence of achalasia in the first 2 months of life[66] and a marked difference in sex ratio, with male preponderance among the familial cases. Also, a third of published familial cases are the product of consanguineous parents, a figure that again suggests a congenital disease caused by a rare recessive gene. It should therefore be recommended that all siblings of children with confirmed achalasia be studied, particularly if they are the product of consanguineous parents.

Others have proposed that there is an association of different human leukocyte antigen (HLA) types with idiopathic achalasia. Wong and colleagues found an association between HLA-DQW1 and patients with idiopathic achalasia,[95] whereas Verne and colleagues did not find an association with HLA-DQ1, although they did find an association between whites with achalasia and those with the DQB1*0602 allele.[96] Because the numbers are small in these studies, subgroup analysis is difficult, but it does provide hypotheses for future studies.

Associated Conditions. Achalasia has been associated with adrenocorticotropic hormone insensitivity and alacrima (triple-A or Allgrove syndrome).[97–99] The disorder seems to be inherited in an autosomal recessive manner and has been linked in some patients to markers on chromosome 12 q13.[100–102] In an article by Handschug and colleagues, all 47 families studied had a mutation in a 6 cM region on chromosome 12q13.[101] Usually, the alacrima has been present since birth, but hypoglycemia, usually associated with addisonian skin pigmentation, is the presenting symptom, starting before the age of 5 years. The achalasia is usually diagnosed either at the same time or after the cortisol deficiency, but its diagnosis may precede that of cortisol deficiency by 1 to 4 years. Investigation for glucocorticoid deficiency should therefore be undertaken in

cases of achalasia when parents are consanguineous, if the age at onset of symptoms is very young, and if the patient is male. In a study of 20 patients, neurologic abnormalities were also found, including hyperreflexia, muscle weakness, dysarthria, and ataxia, together with impaired intelligence and abnormal autonomic function, particularly postural hypotension.[97] These abnormalities indicate alterations in both central and peripheral neurons. Because there are many known similarities between the enteric and central nervous systems, it seems very likely that the alacrima, autonomic dysfunction, and abnormalities of the CNS have an origin in common with achalasia, and it is possible that there is a primary abnormality in parasympathetic function.[97–99] Achalasia has also been associated with an autosomal recessive syndrome consisting of deafness, vitiligo, short stature, and muscle weakness, as well as with familial dysautonomia with hypophosphatemic rickets (Rozychi syndrome).[97]

It has also been suggested that achalasia may be more frequent in patients with Down syndrome.[103,104] This has been studied prospectively by Zarate and colleagues, who found a high incidence of esophageal dysmotility in children and adults with Down syndrome. They found that in their 58 patients, 2 had achalasia by manometry, whereas a high proportion of other patients had other types of dysmotility diagnosed by manometry, nuclear medicine esophagography, or barium swallow.[105] A wide variety of esophageal abnormalities have been found in children with Pierre Robin syndrome; in a case series of 35 patients by Baujat and colleagues, 94% had abnormal manometries, of which 43% had LES hypertonia and 46% had an LES that did not relax. These children also had significant esophageal dyskinesia and UES dysfunction.[106] It may also be associated with pyloric stenosis, Hodgkin disease, and Hirschsprung disease. However, in a survey of 126 patients with achalasia and their first-degree relatives, it was found that there was no increased incidence of these conditions in either the patients or their relatives.[107]

Clinical Presentation. The usual age of presentation in adults is during the third and fourth decades of life. In a literature review of 167 patients, 57% were older than 6 years, with only 22% between 1 and 5 years, 15% between 30 days and 1 year, and 5.3% less than 30 days.[45] Even though it is a rare occurrence, the condition can present in the neonatal period,[60,62,108,109] with the youngest patient reported being a 900 g, 14-day-old premature infant.[93,110] The mean age at the time of diagnosis in the pediatric patients, taken from a recompilation of all of the pediatric series available (Tables 26-4 and 26-5),[45,52,53,58,59,62,64,65,92,98,110–148] was 8.8 years (range neonate to 17 years). The mean duration of symptoms prior to diagnosis was 23 months (range 1 month to 8 years). It has been suggested that in adults, there is a female preponderance, although in children, there is conflicting information, with authors describing a preponderance of males,[51,112] no difference,[111] and a female preponderance.[45] From the review, the female-to-male ratio was 1.1 to 1.

TABLE 26-4 CLINICAL SYMPTOMS IN 528 PATIENTS WITH ACHALASIA

SYMPTOMS	% OF CHILDREN
Vomiting	80
Dysphagia	75
Weight loss	64
Respiratory symptoms	44
Chest pain/odynophagia	45
Failure to thrive	31
Nocturnal regurgitation	21

This table is a recompilation of 23 pediatric series in which symptoms were reported.[45,58,59,62,64,65,92,111–124,146,148]

Table 26-4 presents the symptoms of presentation of achalasia in children, taking the pediatric series in which symptoms were reported.[45,58,59,62,64,65,92,111–24,146,148] The table summarizes the presentation of 528 children. Younger children tend to have symptoms of refusal to eat, although some may present as if they have GER. Respiratory symptoms predominate, with choking, recurrent pneumonias, and nocturnal cough. Older children have symptoms that are similar to adults, with dysphagia, regurgitation, and retrosternal pain being the most prominent.

As can be seen in Table 26-4, the most prominent symptoms on presentation are vomiting (80%) and dysphagia (75%). The dysphagia occurs initially with solids, but as the disease progresses, it occurs also with liquids.[149] Patients describe the sensation of food getting caught in the middle to lower chest,[45,112] and the children are usually noted to be very slow eaters and to swallow repeatedly to get food passed into the stomach.[59,112] Vomiting may manifest initially as food remnants on the child's pillow and progresses to severe vomiting and an inability to eat, with consequent weight loss.[112,117–119] The regurgitated food usually looks much as it did when it was swallowed and is not mixed with gastric juice.[117]

In contrast to adults, retrosternal pain does not seem to be a common complaint in children, having been reported in 1 to 50% of cases. From the 528 patients reported in Table 26-4, chest pain was present in 45%. When present, it is described as sharp and retrosternal and can be aggravated by the passage of food. Weight loss can be severe,[45] and, particularly in younger children, failure to thrive, aspiration, and recurrent pneumonia dominate the clinical history.[59,92,117,121,149] Sudden death from aspiration of esophageal contents has been reported,[109,149] and, overall, the respiratory complications in children are more prominent than those in adults.[45,149] The diagnosis in young infants can be difficult. The primary manifestations tend to be regurgitation and respiratory problems, so there is an overlap with infants who have other more common conditions such as GER.[150]

Methods of Diagnosis. R*adiography*. A plain chest radiograph may show a widened mediastinum and an air-fluid level and should be a clue to the diagnosis. Another feature that may be present is a lack of air in the stomach.[45] Radiographic features in a barium swallow include variable degrees of esophageal dilatation with tapering at the esophageal junction, which is sometimes referred to as beaking (Figure 26-2).[45,92,119] The esophageal dilata-

*This represents a recompilation of all of the pediatric series. See the summary at the bottom.
GER = gastroesophageal reflux; NR = not reported; PD = pneumatic dilatation; UGI = upper gastrointestinal series.

tion may be severe, with the esophagus occupying the whole mediastinum, and it may assume an S shape, a form that some authors have called the sigmoid esophagus.[149] There may also be absence of peristalsis, tertiary contractions, and failure of LES relaxation.[119,151] Occasionally, an epiphrenic diverticulum may be observed. The barium swallow has been shown to be useful for the evaluation of patients after treatment.[151] Parkman and colleagues prospectively studied 96 adult patients referred for dysphagia. All of the patients received manometry, a barium swallow, and esophageal transit scintigraphy.[152] They found that, using manometry as the gold standard for the diagnosis of achalasia, the positive predictive value of a barium swallow to make the diagnosis of achalasia was 96%. The sensitivity was 100%, and the specificity was 98%.[152] Interestingly, although the barium swallow is good for diagnosis, the correlation of severity of disease assessed by barium swallow and the patients' symptoms is very poor.[153]

Endoscopy. The main clinical use of upper endoscopy in these patients is to exclude a malignancy or another cause of secondary achalasia, so the esophagogastric junction needs to be carefully examined. Berquist and colleagues and others reported that all of the children with achalasia who underwent endoscopy had esophageal dilatation and that the gastroesophageal junction did not distend with air insufflation.[45,148] Despite the achalasia, the endoscopists in Berquist and colleagues' study were able to get into the stomach in all patients.[45] Endoscopy also provides information about the esophageal mucosa before treatment is undertaken, particularly to assess the presence of inflammation or infection. It is also helpful to remove retained food particles.[148] Endoscopic ultrasonography can be used to evaluate the muscle thickness of the LES, but there is overlap between the thickness in patients with achalasia and control patients, so the technique is primarily used to rule out infiltrative disorders that may be causing the achalasia.[154]

Esophageal Motility. Esophageal motility remains the study of choice to make the diagnosis and provides quantitative information about the severity of the condition and the response to treatment (Figure 26-3).[117,155] Four manometric findings are characteristic of achalasia[48,49,117,137,155]:

Absence of Esophageal Peristalsis. This lack of esophageal peristalsis is the hallmark of the disease (see Figure 26-3).[48,49] Usually, the aperistalsis involves the entire length of the esophagus, and tertiary waves of low amplitude have been described.[48,49] If the amplitude of these tertiary contractions is greater than 50 or 60 mm Hg or if three or more pressure waves appear in response to a single swallow, the condition is usually known as vigorous achalasia.[48,49]

Increased LES Pressure. LES pressure has been described as being elevated, usually twice normal, in the majority of patients.[49,155,156] It is important to point out that even though, as a group, patients with achalasia have higher LES pressure, there is enough overlap with normal people that normal LES pressure does not exclude the diagnosis. Van Herwaarden and colleagues performed 24-hour pH/manometry recordings on adult patients and

FIGURE 26-2 Barium swallow in a child with achalasia. Note esophageal dilatation and beaking.

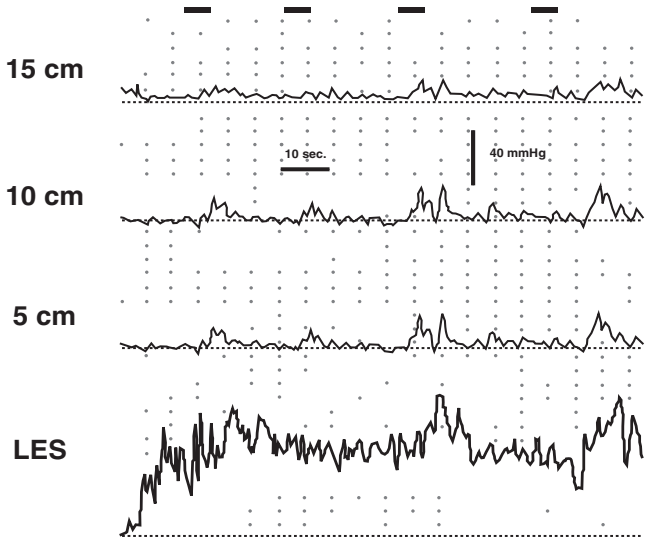

FIGURE 26-3 Esophageal manometry in a patient with achalasia. Note the high lower esophageal sphincter (LES) pressure, the lack of LES relaxation, and the lack of peristalsis after wet swallows. The distance above the LES is indicated in cm.

found that LES pressures were lower after meals and during sleep compared with preprandial recordings.[157] Hussain and colleagues reported in their series of 33 children with achalasia that 95.5% had increased LES pressures.[148]

Incomplete or Abnormal LES Relaxation. In normal individuals, LES relaxation is usually 100%, but in patients with achalasia, it usually represents less than 30% (see Figure 26-3).[48,49] However, the LES may also show complete relaxation. In a study of 23 adult patients with clinical and radiologic manifestations of achalasia, 30% had aperistalsis but complete LES relaxation.[158] Van Herwaarden and colleagues, using 24-hour manometry recording, showed that in 63.6% of their patients, there were at least occasional complete LES relaxations.[157] Katz and colleagues found that the relaxations were of shorter duration than the duration in normal controls, and esophageal emptying in these patients was delayed.[158] This study and others have shown that the relaxation was of shorter duration than the duration in normal controls, and esophageal emptying in these patients was delayed.[159]

Morera and colleagues examined the manometric tracings of 29 children who had achalasia diagnosed by barium swallow and absense of peristalsis by manometry. Fifty-seven percent of these patients had normal LES pressure. Additionally, 13.8% of children had no LES relaxation, whereas 87% of patients had some LES relaxation.[160]

It was suggested that incomplete LES relaxation may represent early stages of the disease, and one patient had progression from complete LES relaxation to incomplete relaxation over a period of 2 years. In another study of 135 adult patients without peristalsis, Vantrappen and colleagues noted that 81% had incomplete LES relaxation and 19% had intermittent normal LES relaxation.[48]

Elevated Intraesophageal Pressure Compared with Intragastric Pressure. This is the result of the functional obstruction at the level of the LES, and it is usually a useful clue to the diagnosis. In a study of 50 patients with achalasia, the esophageal pressure was 6.1 ± 0.7 mm Hg higher than the fundic pressure in 45 patients.[156] There was also no correlation between LES pressure and intraesophageal pressure.[156]

It has become apparent that to make the diagnosis of achalasia, absence of esophageal body peristalsis is necessary; other criteria are often fulfilled but are not required. Manometric abnormalities have been found in even the youngest patients. Asch and colleagues reported an infant who became symptomatic at 2 weeks of age in whom there was no esophageal peristalsis, and the LES pressure ranged between 25 and 40 mm Hg.[108] Some patients may initially present with nonspecific manometric findings but may progress manometrically to achalasia.[161]

Little information is available on UES function in patients with achalasia. Recent reports of cases have drawn attention to an association between acute airway obstruction and achalasia and prompted speculation that abnormalities of the pharynx and the UES may be present.[162,163] A study of 19 patients with achalasia found abnormalities in UES function. The major manometric finding was increased residual pressure. The researchers also found a reduction in the duration of UES relaxation with swallowing and a more rapid onset of pharyngeal contraction after relaxation.[163] They found that mean UES residual pressure was increased in patients and that the duration of UES relaxation was shorter. There was no correlation between the degree and duration of symptoms with the manometric abnormalities. Whether all of these abnormalities lead to impaired pharyngeal function is not known, and the clinical significance of these findings remains uncertain. Recently, it has been shown that the UES abnormal residual pressure observed in patients with achalasia decreases significantly after successful pneumatic dilatation (PD), suggesting that it is a secondary phenomenon.[162]

Repeat manometry is usually not necessary after therapy provided that the symptoms disappear. If manometry is done after treatment, the following changes can be expected: the LES pressure is lower, and the LES relaxation remains incomplete, although it is possible to see complete relaxation following a swallow.[137,164,165] It has been suggested that manometric findings after PD correlate with clinical response. In a study of 43 patients, it was found that a decrease of the LES pressure below 17 mm Hg or more than 40% of the pretreatment manometry was associated with a successful outcome.[166] It is still controversial whether peristalsis returns after successful treatment. Because treatment fails to correct the underlying motility disorder, it has always been assumed that the therapy is palliative at best and that the peristaltic defect is a permanent one.[167] There are case reports in which the return of peristalsis has been documented after PD.[48,167–169] In one study, it was found that aboral peristalsis returned in 22 of 69 patients with achalasia after PD.[48] In another study of 34 patients treated successfully with PD, it was found that in 20%, there was a return of distally progressive contraction waves following therapy.[167] There are also reports of return of peristalsis after successful myotomy,[168] and there is one report of a 14-month-old child with achalasia in whom esophageal peristalsis returned 6 months after she underwent a Heller myotomy.[169] These studies have found that there was no correlation between the return of peristalsis and clinical status, the decrease in LES pressure, or the radiographically measured diameter of the esophagus. This "return of peristalsis" has been explained as secondary to a reduction in the diameter of the esophagus (allowing the perfusion catheter to detect the pressure waves) as a result of dilatation or surgery rather than to a reversal of the degenerative process of the esophageal neurogenic structures.[48,137,168] As expected, not all studies have shown a return in peristalsis. In a study of 14 children who underwent stationary and ambulatory esophageal manometry before and after treatment, it was reported that there was no change in the abnormal peristalsis seen, even after long periods of follow-up.[137]

Radionuclide Tests. Recently, radionuclide tests have been used as a screening tool to assess esophageal emptying, particularly before and after therapy. The most commonly used method involves the ingestion of a solid meal labeled with technetium 99m sulfur colloid,[170–172] although it can also be done with the ingestion of liquid. They have also been useful in the differential diagnosis of achalasia and other conditions, such as scleroderma, because the pattern of retention is different, with the patients with achalasia retaining the tracer even in the upright position.[170,171] It is becoming clear that esophageal emptying studies using radionuclide techniques are a simple and noninvasive way to evaluate these patients and the result of the therapy.[170] Parkman and colleagues found that the positive predictive value of esophageal transit scintigraphy for the diagnosis of achalasia was 95%, the sensitivity was 91%, and the specificity was 98% using manometry as the gold standard for diagnosis.[152] The value of radionuclide esophageal emptying studies in the clinical follow-up of these patients remains to be determined. They do not, however, provide a way to predict accurately eventual success in individual patients, and they do not seem to be better than the symptom scores.[170,173] They do remain a useful, objective way to study esophageal function and may have an important future role in the objective outcome when comparing different treatments.

Provocative Tests. Two provocative tests have been used in the past to diagnose achalasia: the Mecholyl test and the administration of CCK-OP. The administration of acetyl-p-methacholine (Mecholyl) in patients with achalasia produces a rise in esophageal baseline pressure and the occurrence of high-amplitude, repetitive contractions in the esophageal body. The test is considered abnormal if there is a rise in esophageal pressure of greater than 25 mm Hg lasting for at least 30 seconds within 8 minutes after methacholine chloride (5 to 10 mg subcutaneously).[54] It is contraindicated in patients with asthma or heart disease, and the unpleasant cholinergic side effects and pain do not justify its routine use.

The administration of CCK-OP has been shown to produce paradoxical contraction in 90% of patients with achalasia.[54] In a study of 24 patients, CCK-OP produced paradoxical contraction in 21 patients and LES relaxation in 6 of 7 controls. These results were compared with those obtained after the Mecholyl test, and both gave a similar percentage of positive responses (90% of patients with achalasia had an abnormal contraction). If both tests are combined, in 94% of patients, either one or the other was abnormal.[54] The CCK-OP paradoxical response is not specific for achalasia because it might be expected to induce LES contraction in any condition in which the innervation to the LES is impaired, as in Chagas disease, diabetic neuropathy, and the neuronal form of pseudo-obstruction. This test has not been used in children, and the exact clinical role of both provocative tests in children remains to be determined, so their routine use should be avoided.

Differential Diagnosis. Achalasia has to be differentiated from other organic causes of esophageal obstruction, particularly infections[174] or benign or malignant neoplasms and benign strictures.[49] Payne and colleagues mention two children with a clinical diagnosis of achalasia who underwent surgical exploration and were found to have leiomyomas of the distal esophagus.[120] Usually, endoscopy and biopsy are the methods of choice to exclude this condition. In adults, a condition mimicking manometrically proven achalasia secondary to carcinoma has been described,[48,175] but this has not been found in children. Even though adenocarcinoma of the stomach is the most common tumor presenting as achalasia, even extraintestinal tumors such as oat cell carcinoma of the lung and pancreatic carcinoma have been reported.[175]

Chagas disease has to be part of the differential diagnosis in areas where it is endemic, particularly in South America.[86] The disease occurs from neuronal damage by the parasite *Trypanosoma cruzi*. The pathologic description of the megaesophagus seen in Chagas disease consists of neuronal destruction of Auerbach plexus, and this can also be seen in

other parts of the GI tract and can also manifest as megacolon. The LES of patients with Chagas disease has been studied by EM. The denervation has been attributed to direct infection by the trypanosoma, and the changes observed in the smooth muscle nerve endings are very similar to those reported in patients with idiopathic achalasia.[67,86] Usually, the damage to the neural plexus of the esophagus occurs late in the disease, and there seems to be a correlation between the severity of the ganglion cell destruction and the symptoms. Dantas and colleagues compared the manometries of patients with Chagas disease with those of patients with idiopathic achalasia. They found that patients with Chagas disease have lower LES pressures, fewer simultaneous contractions, shorter contraction duration, and higher numbers of ineffective contractions compared with patients with idiopathic achalasia.[176]

Patients originally diagnosed as having anorexia nervosa have also been shown manometrically to have achalasia.[64,112,177] In one study, esophageal motor activity was investigated in 30 consecutive patients meeting the standard criteria for the definition of anorexia nervosa, and it was found that 7 patients had achalasia instead of primary anorexia nervosa.[177] Analysis of their data shows that dysphagia for solids and liquids, as well as spontaneous vomiting and regurgitation, was more common among patients with abnormal esophageal motor function. Of interest is the fact that four of the seven patients with achalasia underwent mechanical dilatation, with subsequent disappearance of the symptoms. Two other patients with achalasia were successfully treated with nifedipine. It is important to emphasize that the evaluation of the patients suspected of having primary anorexia nervosa should always include careful assessment of upper GI function and, when clinically indicated, of esophageal motor activity.

Treatment. Because the etiology of achalasia is not well defined, treatment is generally directed at symptomatic relief of the functional obstruction at the level of the LES.[46,155] Multiple treatments aimed at reducing the resistance of the LES pressure have been tried,[178,179] but only invasive techniques have provided long-term benefit.[155,180] PD and surgical EM are still considered the best available options,[155,178–181] but the optimal treatment is still debated.[46,155,180] Because the complications after dilatation or EM may be significant, alternative therapies, such as botulinum toxin, are being sought.[16,164,178–183]

Table 26-5 shows the published reports of treatment of achalasia in children. Diet has no role in the primary treatment of the disease,[59] although a soft diet encourages more rapid esophageal emptying, and elevation of the head of the bed helps prevent nocturnal regurgitation.[155] Nutritional rehabilitation, on the other hand, has to be an important part of the overall management of the patient .

Pharmacologic Treatment. Anticholinergic drugs have been found to be of no value.[49,155] The manipulation of esophageal motility disorders using pharmacologic therapy was unsuccessful until reports on the use of isosorbide dinitrate (long-acting nitrate) and nifedipine (calcium channel blocker) appeared.[56,155,184–186]

Nitrates have the effect of relaxing the smooth muscle.[155,187] Isosorbide dinitrate (5–10 mg) has been shown to cause significant LES relaxation in patients with achalasia and has allowed most patients to eat normal meals. It usually decreases LES pressure by 30 to 65%, resulting in symptom improvement in 53 to 87%.[155] This improvement has been confirmed manometrically and with radionuclide esophageal transit measurements.[187] Long-term use of the drug is associated with a high incidence of either side effects, particularly headache in up to one-third, or early or late failure to respond, raising to 50% the number of patients who have some problems with this drug.[187] In a report of 15 adult patients, 5 patients received isosorbide dinitrate therapy successfully for 8 to 15 months.[187] There is one report of the successful short use of an isosorbide dinitrate patch in an 8 year old.[188]

Calcium channel blockers have been used. Because calcium is directly responsible for the activity of the myofibrils and, consequently, the tension generated, the idea that their use may produce a reduction in LES pressure seems logical. Their usefulness, however, remains limited.[186] Overall, calcium channel blockers decrease LES pressure by 13 to 49% and improve smptoms by varying amounts, which range from 0 to 75%.[56,155] Nifedipine has been shown to decrease LES pressure and the amplitude of the esophageal contractions in normal volunteers.[184] Studies in patients with achalasia have shown that nifedipine (10–20 mg) significantly decreases LES pressure and improves esophageal emptying.[184–186] Nifedipine also decreases the amplitude of esophageal contractions. A report of long-term use of nifedipine from 6 to 18 months showed an excellent response in two-thirds of the patients and rare side effects that included venous dilatation, ankle swelling, heat, and systemic hypotension in one case, all appearing soon after ingestion of the drug. In all cases, with continued use, the side effects either disappeared or decreased in severity. In a double-blind study, nifedipine significantly reduced LES pressure (28% reduction) and had no effect on esophageal emptying. Side effects were common.[184] A comparison between isosorbide dinitrate and nifedipine[187] in adults showed that isosorbide had a more pronounced effect on symptomatic relief, early LES pressure fall (63.5% versus 46.7%), and improvement of esophageal emptying compared with nifedipine. These aspects, however, become blunted because of the higher incidence of side effects and of failure to respond with isosorbide. In one study, it was suggested that patients with slight esophageal dilatation (< 5 cm) on radiography and a good manometric response to nifedipine may be good candidates for its long-term use. The drug was given as 10 to 20 mg sublingually 30 to 45 minutes before each meal. Of 56 patients, 17 did not achieve a response or developed side effects; of the 39 who continued, 13 were still on therapy and 26 stopped after an average of 2.8 years: 17 had PD or EM, 4 for unknown reasons, and 5 recovered.[186]

The experience with nifedipine in children is limited, consisting mainly of case reports.[62,185,189] In the largest report, four adolescents were administered 10 mg of nifedipine 15 minutes before each meal and before

esophageal manometry.[185] In all cases, there was a good clinical response and a manometrically proven fall in LES pressure. Two children developed mild transient headaches, and it was noted that they all experienced a recurrence of their symptoms if the medication was not taken.

Recently, sildenafil has been used to decrease LES pressure, initially in healthy volunteers and then in patients with achalasia.[190,191] Sildenafil blocks phosphodiesterase type 5, an enzyme that is responsible for the destruction of cyclic guanosine monophosphate. When this enzyme is not destroyed because of sildenafil, there is resulting inhibition of smooth muscle. Bortolotti and colleagues, in a double-blind study, gave 14 patients, ages 21 to 64 years old, with idiopathic achalasia either sildenafil or placebo. They found a decrease in LES tone, pressure wave amplitude, and residual pressure compared with baseline in the treatment group. More studies must be done to determine the clinical utility of this class of drugs.[190]

The exact role of long-term pharmacologic therapy remains to be determined. The clinical response appears to be short acting, with prominent side effects and partial remission of symptoms.[155] Long-term pharmacologic therapy may therefore have a role for patients who are very early in their disease with a nondilated esophagus, who are not candidates for PD or EM,[46,155] and who refuse invasive treatment, or who need to achieve some weight gain before more aggressive therapy,[187] as well as for various reasons when definitive therapy has to be postponed, such as to wait for school vacation.[185]

Botulinum Toxin. It has recently been suggested that the intrasphincteric injection of botulinum toxin may be a simple and effective treatment.[46,133,155,179,180,182,192] Botulinum toxin is a neurotoxin that binds to presynaptic cholinergic terminals, thereby inhibiting the release of acetylcholine at the neuromuscular junction and creating a chemical denervation.[193,194] It has been used therapeutically in humans, including children, for a variety of other medical conditions since 1980[193,194] and has been found to be of therapeutic value in the treatment of a variety of neurologic and ophthalmologic disorders. The clinical effect is due primarily to its action at the neuromuscular effective junction, but it can be transported to the spinal cord or brainstem by retrograde delivery.[193,195]

Although the innervation of GI smooth muscle is different from that of striated muscle,[196] the local injection of this neurotoxin in the abnormal LES of patients with achalasia has some theoretical basis.[46,179,180,182] The esophageal abnormalities seen in achalasia result from a loss of inhibitory neurons in the myenteric plexus, resulting in unopposed excitation of the smooth muscle of the LES.[196] This excitatory effect is probably mediated by acetylcholine because the pressure in the LES can be reduced by anticholinergic drugs and increased by drugs that inhibit cholinesterase activity.[54] Botulinum toxin has been shown to reduce LES pressure in patients with achalasia,[164,182] and it does so by decreasing the excitatory cholinergic innervation to the sphincter.[16,197]

Experience with botulinum toxin for the treatment of achalasia is growing.[46,133,155,179,180,182,192] Initially, an open-label study and, later, a double-blind placebo-controlled trial showed that it is an effective, safe, and simple method for the treatment of achalasia in adults.[182,192] The long-term follow-up of the first 31 patients treated has been reported.[196] A good initial response was observed in 28 patients, but during the first 2 to 3 months after injection, 11 patients reported a relapse of their symptoms and required a second injection. Only 20 patients had sustained responses beyond 3 months, 17 after a single injection (54.8%). Nineteen of those 20 patients relapsed and 15 received a second injection, with satisfactory results in only 60%. This experience indicates that frequent injections are necessary and that the response to subsequent treatments may diminish. This need for repeated treatments and loss of effectiveness with each treatment in some patients are also well documented when botulinum toxin is used in patients with skeletal muscle disorders.[193,195]

Since those initial reports, many other uncontrolled[198] and controlled studies have duplicated the effectiveness of botulinum toxin.[155,164] Annese and colleagues completed a randomized controlled trial of botulinum toxin in 118 adult patients.[199] The patients were randomized to receive one of three doses of botulinum toxin (50, 100, and 200 U). The patients who received 100 U were given a second injection 30 days after the first one. The authors found that a much higher percentage of patients who received two doses of 100 U remained in remission compared with those who received a single dose of either 50 or 200 U (68% versus 29% of patients receiving 50 U and 27% of patients receiving 200 U). The severity of the disease prior to injection did not predict who would respond to therapy. These researchers also found that there was no difference in the percentage of patients who were asymptomatic in the group receiving 50 U compared with those receiving 200 U. They found that the only predictor of response to botulinum toxin is the presence of vigorous achalasia.

The information on children appears only in case series.[133,138,140,141] Khoshoo and colleagues reported the first experience with botulinum toxin for the treatment of achalasia in three children.[133] Since then, there have been two larger case series of children with achalasia who received botulinum toxin. The first series by Hurwitz and colleagues examined the efficacy of botulinum toxin in 23 children using data pooled from multiple institutions.[140] They found that 83% of patients had an improvement or resolution of symptoms. Of the 19 patients, approximately 16% required subsequent balloon dilatation, 58% required or were scheduled for surgery at the time of publication, and 16% had balloon dilatation and then surgery. The mean duration of effect for the botulinum toxin was 4.2 ± 4.0 months. Sixty-three percent of patients required more than one injection.

Ip and colleagues published a series of seven children.[141] All patients had an improvement in their symptoms and all patients required repeat injections. In this series, the median length of response was 4 months. The authors reported that the patients who had higher LES pressures at the time of the first injection had a shorter duration of response to botulinum toxin compared with those children with lower initial LES pressures.

With such a limited number of patients, however, it is difficult to know if the response to treatment in children will be similar to the adult experience. It has been noted that younger adults and adults with classic achalasia do not respond as well,[196] raising the possibility that the response rate in children may be even lower. Even though in the adult studies there was no relationship between the response to botulinum toxin and a history of previous dilatations,[182] the only child with a sustained response in the present series had initially undergone one pneumatic dilatation and relapsed. This observation needs to be replicated in controlled studies because it raises the possibility that botulinum toxin in children may have a role in those who failed previous dilatations.[46]

Botulinum toxin has been used in thousands of patients with ocular and spastic muscle disorders, at various doses and without serious reactions,[193,200] and no major morbidity or mortality has been reported with its use for achalasia or other disorders.[193] Occasional chest pain or transient skin rashes have been reported.[193,200] Retrograde axonal transport of trace amounts of botulinum toxin to spinal cord segments has been detected in animals, but the implication that this has for patients, in particular children, is not known but is probably insignificant.[46,193,200] It has also been noticed that in some patients, botulinum toxin stimulates the formation of antibodies, which may neutralize the physiologic effect.[46,193,200]

One concern is that botulinum toxin injections as an initial therapy may affect any future surgical outcomes should these injections fail to provide symptom relief.[183,201] Patti and colleagues began to address this concern.[201] They looked at the outcomes of Heller EM and Dor fundoplication in adults who received no therapy, PD, and botulinum toxin injection prior to surgery. They found that in those patients who received botulinum toxin injections and had symptom improvement for at least 4 months, the surgery was significantly more difficult owing to periesophageal inflammation and fibrosis of the LES. The surgical complication rate in this population was much higher than that of the other study groups and the rates of dysphagia postoperatively were higher in the botulinum toxin responders. These results are very interesting, but, because the numbers in this study are small, a future study would be crucial to help clarify the role of preoperative botulinum toxin. Most authors agree that even though it is useful, it is limited by its short-term efficacy and need for repeated treatments.[180,200,202] Botulinum toxin may have a role in the management of those patients who, for medical reasons, are poor candidates for surgery.[183] It has been suggested that because of its short-term duration of action, it may be useful in guiding therapy before considering more invasive treatments.[202] Candidates for this approach may be patients with symptoms compatible with achalasia but insufficient manometric criteria to establish the diagnosis, complex situations in which there are factors in addition to achalasia contributing to the symptoms that may require a different treatment, atypical manifestations of achalasia, and advanced achalasia in which it is unclear that sphincter-directed therapy (versus esophagectomy) would be of benefit, as well as after Heller myotomy.[202] In a description of this approach, 11 patients with the above characteristics received botulinum toxin, and 10 showed a good response.

In children, botulinum toxin may have the advantage that, depending on the age, it may be administered without general anesthesia and is relatively noninvasive.[46] The main disadvantages include the fact the duration of treatment is short-lived, with the need for multiple treatments over time[46,180,183] and the possibility that surgical therapy may be more difficult.[183]

Before this therapy can be recommended as a first-line treatment for children, more information needs to be gathered. For now it may be a good alternative in those places in which performing PD is not possible, for those children who refuse more invasive therapies, in those in whom the diagnosis is not clear, for those children who may be at high risk for the other procedures or their complications, or for those who have failed other therapies.

Nonpharmacologic Treatment. There have been two main successful modalities to decrease the pressure of the LES and to relieve the functional obstruction. One is surgical, with an EM, and the other involves forceful PD.[155,203] In a simple way, they can be thought of as an approach that tries to relieve the obstruction from the exterior of the esophagus (surgery) and as an approach to do it from within the lumen (PD).

Pneumatic Dilatation. The use of bougienage has been uniformly disappointing,[45,111,119,155,203] and in one series, an incidence of 6% of esophageal perforation was described.[204] Payne and colleagues reported the use of bougienage in eight children, in whom it rarely provided more than very temporary relief.[120] Because of the short-term benefits and the complication rate, this type of therapy is no longer advocated.

PD tries to produce a controlled tear of the LES, resulting in relief of the distal esophageal obstruction and clinical improvement.[155,205] It consists of positioning a dilating device at the level of the LES, with the purpose of inflating it to apply direct pressure on the esophageal muscle to the muscle fibers of the LES.[45,62,121,155] Even though the purpose is to tear the LES fibers, it is interesting that in experimental animals, there is no evidence that the muscle fibers actually tear and do not just stretch. Vantrappen and Janssen have subjected dogs and monkeys to balloon dilatation of the LES, and histologic examination failed to distinguish the sphincter segments of treated animals from those of controls.[206]

The initial experience was reported with the Mosher bag, the Browne-McHardy dilator, and others.[155,206] In general, these are no longer used, and at this point, PD is performed most commonly with Rigiflex dilators (Microvasive, Boston Scientific Corp, Boston, MA).[155] They have been successful, showing high success rates from 70 to 93% and low complications.[164,181,207,208] This is also the most common method of PD currently employed in children. These balloons have a predetermined size and are made of a modified polyethylene polymer mounted on a flexible polyethylene catheter. In children, the most common range used goes from 20 to 30 mm Hg. If necessary, 35 and 40 mm Hg are also available. To

introduce the dilator, a guidewire is placed through the biopsy channel of the endoscope into the stomach. The endoscope is then removed, leaving the guidewire across the esophageal junction. The dilating balloon is introduced over the guidewire and placed so that it is across the LES. The position is then checked fluoroscopically. The balloon is then inflated rapidly in an attempt to obliterate the waste.[155,205] In most centers, it is then maintained inflated for 1 minute and then deflated. The procedure is repeated up to three times with each diameter, and the dilator is removed. The dilation is followed by the administration of contrast to exclude esophageal perforation.

Despite its widespread use, the practice of PD has not been standardized. Recent studies compared the use of different balloon sizes (30–35 mm), number of balloon inflations (one or two), and duration of the inflations (15, 20, 40 or 60 seconds) and found that the outcome did not depend on the technique used.[209–211] In another prospective study, balloon inflations of either 60 or 6 seconds were compared. Significant and sustained improvement was observed in both groups, and there were no perforations.[210] The higher-size balloons have been associated with perforations more frequently.[155]

In adults,[155,212] and in many pediatric centers, PD[112,119] is performed under intravenous sedation, whereas general anesthesia is routinely used in others. In younger children, it is difficult to ensure that movement will be restricted, so general anesthesia may be safer.

The results of PD in adults have been satisfactory, with an overall response rate that varies from 60 to 95% depending on the technique used.[132,155,213] The cumulative experience with the old dilatation methods (Mosher bag, Browne-McHardy dilator, and others) was recently reported as showing symptom improvement in 72% of 2,418 treated patients. The perforation rate was 2.5%.[155] With the use of the Rigiflex, symptomatic relief was reported to be 67 to 93% of patients after a mean follow-up of 0.3 to 4 years.[155]

In a report of their experience with 455 dilatations, Vantrappen and Hellemans found that 77% of patients had excellent results, 8.7% had moderate results, and 14.4% had poor results.[165] There was an overall improvement in 93% of the patients. In 41 of the patients, symptoms recurred and another series of dilatations had to be performed, and approximately 50% of those had a good or an excellent result.

To assess long-term success with PD, Katz and colleagues reviewed their cases of PD between 1971 and 1996.[214] All patients who had a PD were sent a questionnaire to evaluate for persistent symptoms. The mean time from dilatation to follow-up was 6.5 years. Eighty-five percent of the patients had a successful dilatation, which was defined as no further therapy required after two dilatations. Fifteen percent of patients required further therapy such as surgery or botulinum toxin injection. In long-term follow-up, there was no difference in the dysphagia scores between those who had successful PDs compared with those who had dilations followed by surgery or botulinum toxin injections. The authors found no difference in the long-term success across ages, gender, duration of symptoms prior to dilatation, or duration of follow-up.

In a prospective study of 54 adult patients, it was reported that outcome was worse in younger patients and that postdilatation LES pressure was the most valuable factor for predicting the long-term clinical response.[215] In some series, successful long-term results after PD[216] with symptomatic improvement have been lower, around 40%.[216] It has also been shown in another series that 40% of patients treated by a single dilatation required a second dilatation after 5 years.[213] Patients who have undergone a second and a third dilatation required subsequent dilatations in 40 to 75% of cases, respectively.[213] It has also been reported that if the first dilatation is unsuccessful, 38% and 19% improve after a second or third dilatation,[155] suggesting that patients who have poor results originally or a rapid recurrence of their symptoms respond less to subsequent dilatations.

The results of dilatation in children have been variable and are difficult to compare because of the different techniques used. PD has been used successfully in children for a variety of conditions other than achalasia, particularly for peptic strictures, anastomotic strictures, and restrictive Nissen repairs.[217] The use of PD for achalasia in children was first reported by Moersch in 1929.[52] As can be seen in Table 26-5, many authors have used PD with varying results. Overall, there are approximately 107 children reported, in whom there was an overall improvement rate of 56% (60 patients). Perforations were the most frequent complication. Long-term dysphagia persisted in 29% and GER in 2.8%, and 37.4% required a myotomy. Of course, it is difficult to compare different studies and techniques, and the rate of improvement after PD among the different series varies from only 35%[111] to 100%.[52] Moreover, like adults, many children require more than one dilatation to respond. Nakayama and colleagues reported that of their 15 patients, 7 responded to one dilatation, 7 required two, and 1 required four, and in the patients who failed, the duration of symptom relief was much shorter than in the patients with a good response (6 weeks versus 18 months).[119] It has also been suggested that if symptoms recur after PD in the first 6 months, the patient is likely to require a second dilatation[45] or eventually surgery.[127] Some authors have suggested that children who respond to PD are older than 9 years,[111] although many reports of successful PD in children younger than 5 years have appeared.[45,132,218]

Originally, it was also suggested that after a failed myotomy, PD had a prohibitive risk. This, however, has not been the recent experience even in children,[45] five of whom underwent successful PD without complications after EM. Although both PD and EM are safe procedures with very low complication rates, both are potentially dangerous.[46,119]

Complications after PD. Esophageal perforation after pneumatic dilatation has been described in 1 to 12% of cases.[155,164,165,213,219] It has been suggested that older age; the presence of a hiatal hernia, epiphrenic diverticulum, esophagitis, malnutrition, or high-amplitude esophageal contractions; and one or more previous dilatations may increase the risk.[219] Balloon instability or inflating the dilation balloon to 11 psi or higher may also increase the risk.[219,220] Perforation rates also seem to be greater when the larger balloon sizes are used and to be lower if the smaller

balloons are used; only the large sizes are used when the patient does not respond to initial dilatation.[207] In a compilation of adult series, there were 7 perforations in 345 patients treated with Rigiflex balloons.[155] Sixty percent occurred after a 4.0 cm balloon was used, whereas a 3.5 cm balloon was responsible for the other 40%.[155] Perforation, however, also occurred after the 3.0 cm balloon.[155,221]

Okike and colleagues, in their study of 899 patients with achalasia, found that the rate of esophageal perforation following PD was 4%, and following EM, it was 1%.[222] Reviewing their own experience, Vantrappen and Hellemans reported an incidence of 2.6% of esophageal perforation and 4.3% of other complications (fever, pain, or pleural effusion) in a total of 537 patients with three or four dilatations each.[165] A survey of 1,224 instances of PD for achalasia completed by the American Society of Gastrointestinal Endoscopy noted a 1.8% incidence of esophageal perforation.[223] The perforation usually occurs at the anterolateral esophageal wall.

The exact incidence of this complication in children is not known, although a recent study reported perforation in 3 of 50 procedures (6%).[221] Two occurred after the 3.5 cm dilator was used and one occurred after the 3.0 cm dilator was used. As can be seen in Table 26-5, there was a reported incidence of perforation of 5.3%. The symptoms after perforation include severe and persistent chest pain (longer than 4 hours), usually fever, and unexplained tachycardia. Dysphagia and subcutaneous emphysema may also be seen.[155] A plain chest radiograph may reveal subcutaneous or mediastinal emphysema or a left-sided pleural effusion. A definitive diagnosis is made with the use of a water-soluble contrast esophagogram.[155] Some centers recommend the routine use of a postdilatation esophagogram[224] because there are case reports of an esophageal perforation that was missed because of the paucity of symptoms, resulting in the patient's death.[222] In a prospective series of 41 patients undergoing PD and an early postprocedure esophagogram, it was found that there were two immediate and two delayed esophageal perforations, for a perforation rate of 9.5%.[224] This illustrates the fact that delayed perforations of the esophagus can occur and may not be present after the first study, emphasizing the need to closely observe all patients and to obtain or repeat contrast studies if symptoms develop. By performing early contrast studies, these researchers also found six intramural hematomas, one of which progressed to a free perforation, whereas the other five resolved spontaneously. They also showed that there is no correlation between the postdilatation appearance of the esophagus and the clinical outcome, suggesting that the esophagogram should be performed only to exclude complications and not to assess the adequacy of the forceful dilatation or to predict clinical outcome. Prior PD and the use of more than 11 psi with a Browne-McHardy dilator were found as risk factors for perforation.[220] Also, patients with a tortuous esophagus, esophageal diverticula, or previous surgery at the gastroesophageal junction may have a higher risk for perforation.[155,225]

The mortality after a perforation has been reported to range from 0 to 50%.[165,219,222] It is now recognized that if the perforation is diagnosed and treated promptly, the outcome is similar to that of patients who undergo elective myotomy.[221,226] Some authors prefer a nonoperative management of esophageal perforations,[165,221] but others continue to advocate aggressive surgical management.[227] Miller and Tiszenkel described their surgical management of six patients with esophageal perforation after PD. They advocated suturing the perforation followed by a modified Heller procedure, reporting excellent results.[227] Vantrappen and Hellemans reported that 10 of 13 patients with esophageal perforation healed with total parenteral nutrition and broad-spectrum antibiotics for 2 weeks.[165] In 4 patients, a pleural effusion was evacuated by puncture or drainage under local anesthesia. Two other patients needed surgical drainage, and the last patient died. In a summary of the literature, Wong and Johnson found 53 perforations reported, with only 17 patients having undergone surgery.[228] A mortality of 4% was noted, and, overall, 68% of the patients were treated conservatively. In the only series in children, perforation was successfully managed with the use of total parenteral nutrition and intravenous antibiotics.[221] These children were again eating by mouth 7 to 10 days after the perforation. It is now suggested by some that medical therapy may be appropriate for small perforations without significant mediastinal contamination, when the cavity drains back into the esophagus, and when there is an absence of communication with the pleural space and no evidence of sepsis.[221,229] Medical therapy needs to include measures to avoid mediastinal contamination (by giving nothing by mouth), neutralization of gastric acid, and administration of intravenous antibiotics.[221,226,227]

GER can also be a late complication of PD. This complication has been described in adults to range from 1 to 9%.[155,165] Disabling reflux in children has also been described,[111] and some other reports show an incidence of 12% compared with 36% after myotomy.[127] In a prospective study comparing pH measurements before and after PD, the percent pH < 4 increased from 2.9 ± 4.9 to 10.2 ± 15.9% after PD.[230] As can be seen in Table 26-5, GER in children was reported to occur in close to 2% of the patients.

Another complication that has been rarely reported after PD is bleeding. In a review of 1,261 cases, there was an incidence of 1.1% of moderate hemorrhages.[165]

Surgery. The surgical treatment varies, but it involves performing a myotomy, with or without an antireflux procedure.[155] The most common EM employed is the Heller myotomy and its variants, which consist of either a thoracic or an abdominal approach and a vertical incision of the esophagus extending along the serosal surface of the distal esophagus and transecting the circular muscle fibers that make up the LES.[56,231] The recent advent of minimally invasive surgery is changing the surgical approach, resulting in shorter patient hospital stay, reduced morbidity, and quick return to activities.[56,155]

Good to excellent results have been obtained after EM in 64 to 94% of adult patients.[17,56,222,231–234] In their report of 468 patients with achalasia who underwent myotomy, Okike and colleagues reported excellent to good long-term results in 85% of the surgically treated patients compared with 65%

of a group of 431 patients treated by PD.[222] In a recent review of the literature, Vaezi and Richter reported an overall good to excellent symptom improvement in 83% of 2,660 patients undergoing EM through the abdominal approach and in 83% of 1,210 patients who had a transthoracic EM.[155] LES pressure was reduced by a similar degree (74% versus 79%), and the operative mortality from both procedures was low (0.2% versus 1%).[56,155] When surgery has been performed after failed PD, the results have also been satisfactory, and previous dilatation does not seem to alter the response to surgery. Furthermore, the literature shows that after a failed dilatation, surgery is usually successful.[119,222]

As can be seen in Table 26-5, from 526 children evaluated after surgery, 77.5% had excellent to good results. The improvement rate varies among series, going from as low as 10%[45] to as high as l00%.[64,98,110,125,126] The youngest successful patient reported was 6 weeks of age,[60] and there are numerous reports of successful EM in infants less than 6 months.[98,117] The results after surgery are not uniformly good. In the series of Berquist and colleagues, of five patients who underwent an EM as primary therapy, four had recurrence of symptoms 1 month to 5 years following surgery, and either repeat dilatation or surgical intervention was necessary to relieve the symptoms.[45] Most series, however, report excellent results, and it is interesting to note that most of the recently reported series of achalasia in children have used an EM as a primary treatment.[98,114,116,123,124,145] In the largest published series from one institution with 35 patients, the primary treatment was myotomy.[98] In their first four patients, it was performed without an antireflux procedure and later with a fundoplication. The long-term results were excellent, with 34 of 35 remaining without dysphagia. In six patients, GER developed and was particularly severe in those patients without fundoplication.

The most common Heller myotomy is done using a transabdominal approach.[56] In a worldwide survey of pediatric surgeons that compiled 164 patients treated surgically with different methods, a fair clinical response to open transthoracic EM and a good to excellent result from open transabdominal EM were reported.[117] Even though most of the experience has been with using the transabdominal approach, some authors have also reported good long-term experience in children after the transthoracic Heller myotomy. In a series of 19 children, 17 had excellent and 2 good long-term results after a mean follow-up of 9 years.[115]

The surgical approach has changed recently with the advent of minimally invasive surgery.[46,56,130,233] The results obtained with the use of minimally invasive surgery have been very encouraging, with a reduction in the duration of hospitalization and a more rapid recovery of the patients.[56,130,235–237] The EM can be performed thoracoscopically or laparoscopically. Simultaneous endoscopy provides insufflation and light, which allow the surgeon a better visualization of the esophageal wall during EM. The endoscopist can also determine if a complete EM has been accomplished and can alert the surgeon if there has been a violation of the esophageal or gastric lumen. The experience with thoracoscopic myotomy is limited,[56,155,236,237] with good to excellent symptomatic improvement reported cumulatively in 84% of 82 treated patients.[155] There has been, however, a high incidence of dysphagia (up to 18%) and GER (50%), which has suggested that the laparoscopic approach may be more effective.[56,155] The results after laparoscopic myotomy have shown a cumulative good to excellent clinical response rate in 94% of 254 treated patients (range 83–100%).[56,155] Reviews have shown that it reduces LES pressure by 59% (range 42–72%); GER was reported in 11%, and there was no mortality.[155] However, the long-term outcome is still not known.

The first case reports in children have started to appear; within the last 2 years, there have been three case series published about pediatric laparoscopic and thoracoscopic myotomies.[143–145] These series report good to excellent results in 90.9% of their pediatric patients.[143–145] Because the results after EM in children have been very good, some authors have recently suggested that the primary treatment for children with achalasia should be surgical.[98,114,117]

Complications after Surgery. Esophageal perforation can also be a complication of myotomy. Most commonly, it is secondary to inadvertent perforation of the mucosa at the time of the myotomy, which occurred in 14% of 502 collected cases.[165] Such a perforation can be closed with one or two sutures. Nevertheless, in 2% of those 502 patients and 1.7% of other series, it resulted in a fistula formation.[155,165,206,222]

Other rare complications include phrenic nerve paralysis, massive hemorrhage, and necrosis of the stomach and esophagus owing to herniation.[165] The overall rate of severe complications after EM is said to be 3 to 4%.[56,165]

As can be seen in Table 26-5, there was an incidence of 10.5% of complications after EM. There were seven perforations (1.5%) and other children with lung empyema, atelectasis, intussusception, adhesions, bleeding, paraesophageal hernia, wound infections, epiphrenic diverticulum, pneumothorax, and subphrenic abscess. Three patients died, 4 children required esophageal resection (0.8%), and 21 required reoperation (4.6%).

There are two main long-term complications after EM[56,165]: failure to relieve the obstructive symptoms and GER. Failure to relieve the obstruction is usually secondary to an inadequate myotomy, usually owing to failure to carry the muscle division distally enough to divide all of the obstructing circular muscle fibers.[56,238]

This has made some authors recommend that the EM should include the entire length of the gastroesophageal junction, thus requiring extension onto the stomach cardia for about 1 to 1.5 cm,[56] although different authors recommend different distances because excessive distal extension of the EM onto the stomach contributes to the major long-term complication of myotomy, which is GER.[165]

Significant dysphagia after the operation has been reported in 1 to 9% of patients, although mild dysphagia may be found in up to 20%.[56] This dysphagia represents the most frequent indication for reoperation in up to 58% of patients.[56,165,238] In the evaluation of those patients, manometry and endoscopy are important to permit the differentiation between an inadequate myotomy (high LES pressure still present) and a complication from the operation (eg, severe esophagitis and a stricture).[56,165,238] In children, the

incidence of postoperative dysphagia varies. As Table 26-5 shows, it was reported as a long-term complication in 4.6%, being equally distributed between those children who did and those who did not have a concomitant fundoplication.

The true incidence of GER is unknown. Most authors' estimates vary from 3 to 21% (mean 10%) of the cases.[56,155,165,222] In a long-term study, it was estimated that 52% of patients suffered from it.[239] This latter report is important because of the long follow-up, with an average of 7 years. They also reported that the incidence of reflux increases with the passage of time, 24% after 1 year and 48% after 10 years, and becomes stable only after 13 years. In another study of 70 patients after EM, asymptomatic GER was detected in 14.3%, symptomatic GER in 8.6%, peptic strictures in 5.7%, and Barrett esophagus in 4.5%.[240] In a recent prospective study in which a pH probe was used, it was estimated that 35 to 40% of patients having undergone PD or thoracic myotomy without a fundoplication may develop significant reflux.[230] In the myotomy group, the total percentage of time of pH < 4 rose from 3.7 ± 4.4 to 8.6 ± 9.2%.[230]

It is thought that the incidence of GER is related to the surgical technique.[232] The authors with the largest experience have suggested that the anterior myotomy should not extend more than a few millimeters beyond the gastroesophageal junction because further dissection into the anterior wall of the stomach results in an incompetent gastroesophageal junction.[222,232] In general, less GER is noted in studies that specified that the anterior myotomy extended up to or less than 1 cm from the gastroesophageal junction.[222,232]

The scope of this problem in the pediatric patient is unknown. In a pediatric series of 10 patients studied by pH monitoring, it was reported that GER was present in 36% of children postmyotomy compared with 12% after PD,[127] and other series have reported severe and disabling reflux after EM (see Table 26-5).[62,119,120] As can be seen in the table, GER was reported in 5% of patients after a myotomy without fundoplication, and 80% of those required a fundoplication.

Peptic strictures can develop as a complication of GER in 3 to 6% of patients.[165,240] Ellis, in a 22-year follow-up, stated that GER was a problem in nine patients, six of whom developed a stricture, with three eventually requiring a colonic interposition.[232] Barrett esophagus has also been described as a complication of the GER that can occur after myotomy.[240] In two series totaling 70 patients treated with EM, three cases of Barrett esophagus (4.3%) were found 5, 8, and 15 years after the procedure.[240,241] In one case, an adenocarcinoma was reported to have developed in a Barrett esophagus many years after a Heller myotomy,[241] and in another two cases, dysplastic changes were found.[240] Peptic strictures secondary to disabling GER after EM have also been described in the pediatric literature.[116,119,127]

Because of the development of postoperative GER and the severe sequelae that can accompany it, the need to perform an antireflux procedure at the time of the EM has been argued by some. This is also controversial and depends on the experience and results of the different surgeons.[56,165] The point merits careful consideration, particularly if one considers that, overall, the results from surgical therapy tend to be better, but the long-term outcome can be dramatically affected by GER complications.

One side of the discussion claims that a precise EM carried just onto the stomach relieves dysphagia effectively and does not cause reflux.[222] These researchers also mentioned that the additional dissection necessary to do an antireflux repair is meddlesome, and the fundoplication runs the additional risk of causing a distal obstruction, thereby defeating the purpose of the myotomy. They suggested that the only indication for an antireflux procedure is the presence of a hiatal hernia. In their long-term follow-up from the Mayo Clinic, Okike and colleagues reported a 3% incidence of GER-related complications and suggested that an antireflux procedure is not routinely necessary.[222] It has been suggested that an antireflux procedure should be performed only in certain circumstances: presence of hiatal hernia, presence of pretreatment esophagitis and GER, or when the integrity of the esophageal mucosa is compromised (excision of diverticulum or perforation).[56,165,203]

Skinner recommended the routine use of a fundoplication, arguing that to perform an adequate myotomy, a greater area of exposure is necessary and that the use of fundoplication does not change the long-term effectiveness of the surgery but avoids the GER complications.[242] Nissen fundoplications, Belsey and Collins repairs, and anterior gastropexy or a Dor procedure have been reported with varying degrees of success.[114,165]

It has been suggested that if pathologic GER is documented preoperatively, an antireflux procedure should be done at the time of the myotomy. In a prospective study of five patients, it was found that in two patients, reflux occurred 16.8% and 53.3% of the total time, with prolonged episodes in the supine position. Smart and colleagues cautioned that the use of preoperative 24-hour pH monitoring may be altered by the presence of food residue. In a prospective study of 17 patients with achalasia before PD, they found that 1 patient had evidence of typical episodes of GER by 24-hour pH monitoring and 9 patients had increased times of acid exposure.[243] They showed that this increased exposure was secondary to lactic acid from food residue and not from refluxed acid, so they concluded that preoperative esophageal pH studies do not offer a valid means for the selection of patients in whom an antireflux procedure should be combined with the cardiomyotomy.

It is difficult to draw conclusions because it is usually difficult to compare one surgical technique with another. However, in one adult series that compared patients after EM with or without a Nissen fundoplication, symptoms of GER were present in 10 of 12 patients after EM alone and in none of the Nissen patients, suggesting that an antireflux procedure should have been done.[244] Recently, however, 24-hour pH determinations were done in a prospective study of five patients who underwent a successful myotomy for achalasia, and even though in two of five patients there was more GER while they were supine, there was no difference between the patients and the controls in the total amount of reflux or total number of reflux episodes, supporting again the notion that a fundoplication is not routinely necessary.[245] Things may be different

after laparoscopic myotomy, where the LES is freed from its surrounding ligamentous attachments.[56] Therefore, many authors consider the performance of an antireflux procedure as necessary after laparoscopic myotomy.[236,237] It has been suggested that a Toupet fundoplication may control reflux more effectively in those patients.[56,155,246]

Some authors have not considered fundoplication necessary when children undergo an EM.[65,111,120,122] In some series, however, GER has developed when an EM was performed without a fundoplication,[62,98] and some have suggested that there is an increased risk for the appearance of reflux with the passage of time.[113]

Nihoul-Fekete and colleagues reported that they initially performed only EMs, but after their first patients developed severe GER, a His reconstruction was added in the next 10 patients. GER continued to be problematic and 3 patients needed a Nissen fundoplication, so it was added in the subsequent 21 patients, with only 1 patient developing dysphagia, but none with GER. Similar good results after adding a Nissen fundoplication were reported by Emblem and colleagues.[116] Myers and colleagues reported in their worldwide survey that the best surgical results were observed in those children who had a transabdominal myotomy with a fundoplication.[117]

It is clear, then, that the argument for the need for antireflux surgery following EM centers on the small percentage of patients who develop complications from GER. Because this percentage is small and because it is not possible to predict reliably who those patients are going to be, it is probably not necessary to subject all patients to a longer and more difficult procedure to prevent the few cases of troublesome reflux; this is also the latest recommendation from most of the adult series.[232] By reviewing the available literature in children, it can be noted in Table 26-5 that 329 children have had an EM alone and 175 had an EM with fundoplication. In the group without an antireflux procedure, there were 4.6% with GER and 4.9% with dysphagia, and 4.6% required esophageal dilatation, 3.6% a fundoplication, 0.9% a repeat myotomy, and 0.9% an esophageal resection. These compare with an incidence of 5.7% with dysphagia, 2.3% with GER, a 2.3% reoperation rate, and 0.6% requiring esophageal resection who had a myotomy and a fundoplication.

Dysphagia also occurs from 10 to 28% after a fundoplication is made during laparoscopic myotomy.[56,155,236,237]

Zaninotto and colleagues looked at adult patients who had Heller EMs and anterior partial fundoplications who developed symptoms of dysphagia or chest pain after the surgery.[247] In their series of 113 adults, 8.7% of patients had these syptoms. When they performed manometries on those who had the surgery and were asymptomatic compared with those patients who were symptomatic, they found that the syptomatic patients had a longer LES postoperatively compared with preoperatively, had a longer LES overall compared with that of the asymptomatic patients, and had higher pressures in the esophagus proximal to the surgery.

In a second series of 102 adults who underwent Heller myotomies and Dor fundoplications by Patti and colleagues, 11 patients had persistent or recurrent dysphagia. The etiologies for this dysphagia were myotomies that were too short (36%), fundoplications that were too tight (36%), and stricturing of the esophagus owing to prior dilatations or botulinum toxin injections (27%) that was not recognized prior to surgery.[234]

Obstructive symptoms are also common in children after fundoplication.[45,98,111,128] This potential complication has led to the recommendation of a partial fundoplication.[62,114] Interestingly, in children, dysphagia has been reported in around 5% (see Table 26-5) and, as can be seen in the table, in an equal percentage when comparing those with or without a fundoplication. One problem with surgery is the fact that if it fails and multiple operations are needed, eventually, it may be necessary to perform an esophageal resection (0.9%; see Table 26-5).

Medical versus Surgical Therapy. The choice of initial therapy is still controversial.[46,56,155]

PD versus EM. The results obtained with any of the main treatments vary from center to center, and the most extensive experience comes from the adult literature. In one of the largest adult series, the Mayo Clinic reported the results on 899 patients and compared the late results of treatment with dilatation and EM.[222] They concluded that EM was more successful and safer than dilatation, with poor results being obtained twice as often with dilatation as with EM. As mentioned before, the adult experience reports a success rate of 65 to 75% after PD and of 85 to 90% after EM.[222]

In the only large prospective randomized study, Csendes and others randomized patients to EM or Mosher bag dilatation.[212] A total of 81 patients were included, and after a follow-up of 5 years, 95% of the operated patients were asymptomatic and two had mild heartburn, whereas only 65% of the dilated patients were asymptomatic. Positive acid reflux tests were noted in 28% of the postoperative patients versus 8% after dilatation. They also found a lower LES (less than 10 mm Hg) in the surgical group. They concluded that surgery is more efficacious. This study has been criticized on the grounds that the technique of dilatation may have been suboptimal and that the study may have been biased against the dilated patients because of their more pronounced dysphagia.[248] In the only study that compared EM with the Rigiflex dilators, the authors found equal effectiveness (88% versus 89%) in symptom improvement in 45 patients.[249]

Most authors still recommend PD as the initial therapy in adults.[155,203,248] Also, in a retrospective analysis based on the treatment and follow-up of 123 patients, Parkman and colleagues estimated that the cost of EM was five times greater than the first PD and still two to four times greater, adding to the PD the cost incurred by all of the patients who required multiple dilatations.[213] In another recent cost-effective analysis comparing PD, laparoscopic surgery, and botulinum toxin, it was found that PD was the most cost-effective approach.[155,225]

As can be seen in Table 26-5, the experience in children also varies from center to center. Grouping all of the studies, with an understanding of the problems inherent in

doing so, both treatments look similar, although the long-term results may be slightly better after EM. The percentage of improvement was higher after EM than after PD (up to 82.8% with fundoplication versus 56%), and the complication rate was similar (7.5% after dilatation and up to 12.6% after myotomy). It has also been noted that in long-term follow-up, 29% of patients had dysphagia and 2.8% had GER after PD, whereas in the surgical group, 5.7% had dysphagia and 4.6% had GER. Also, 37.4% of the children who had PD required a myotomy, whereas of those who had a myotomy, 3.4% required a second operation, 3.6% required fundoplication, and 0.8% required an esophageal resection, and there was a mortality of 0.6%.

Both medical and surgical therapies are effective.[203] On the one hand, PD is safe, effective, and cheaper unless repeated dilatations are necessary and is usually an outpatient procedure. The risk of perforation is always present, and improvement of the dysphagia varies among studies but is probably not as great as that occurring after EM. On the other hand, EM generally results in a more complete and longer duration relief of the dysphagia, and GER is a major complication. The cost and morbidity associated with the surgery are significant.

PD versus Botulinum Toxin. Recent randomized studies comparing botulinum toxin with PD have appeared.[164,208,250,251] When comparing botulinum toxin with PD done with Witzel dilators, there was a 6-month clinical remission of 89% following PD compared with 50% after botulinum toxin.[250] In another trial, there was a symptomatic response rate of 80% at 12 months after two injections of botulinum toxin, although the effectiveness was only 13% after one injection. The response to PD was reported as 100% initially.[208] Muehldorfer and colleagues found that dysphagia improved in 75% of patients who received botulinum toxin and in 83% of patients who had PD. Long term, however, the patients who received botulinum toxin had significantly higher rates of regurgitation and dysphagia than did the PD group.[251] In the largest prospective study, 42 patients were randomized to either PD or botulinum toxin.[164] Both therapies were equally effective at 1 month. PD resulted in a significant higher cumulative remission rate. At 12 months, 14 of 20 patients (70%) after PD and 7 of 22 patients (32%) after botulinum toxin were in symptomatic remission. PD also resulted in significant reductions in symptom scores, as well as objective parameters (LES pressue, esophageal diameter, barium swallow), whereas botulinum toxin decreased symptom scores but did not change objective parameters. Also, the failure rates were similar initially, but failure over time was higher after botulinum toxin.[164] In another comparative study of 42 patients receiving botulinum toxin compared with 26 receiving PD, it was shown that retreatment was necessary in 50% of botulinum toxin patients after 265 days compared with < 40% after 2 and 5 years of follow-up after PD. However, if repeated injections are compared, the benefits approximated those obtained by a single PD.[252]

The information published so far indicates that despite the initial enthusiasm for botulinum toxin, it seems to be inferior to PD or myotomy, and recent data indicate that it is less cost-effective.[225,253] Therefore, botulinum toxin therapy needs to be reserved only for those patients who represent a poor risk for the other invasive therapies, for those who refuse other therapies, or for those in whom it may help clarify an indication for definitive therapy.[46,155,202]

Therapy in Children. The therapy of choice for esophageal achalasia in children has not been established and will still depend in large part on the expertise present at each institution. Some centers advocate PD,[45,46,111,119,139,142] whereas others advocate surgical treatment.[62,92,98,113,122] As can be seen in Table 26-5, the results obtained with different modalities vary from center to center, and there are no comparative studies. Although surgery may provide better results and a longer duration of remission in children, it is costly and may be associated with serious short- and long-term complications. Because PD is less invasive, is effective in more than 50% of patients (range 35–100%),[46] and has a low rate of short- and long-term complications, with nearly absent mortality, many feel that a trial of PD should be a first-line therapy. If repeated dilatations become increasingly necessary, with short periods without symptoms between them, a surgical procedure should be done.[46,119,164] If surgery is necessary, the modified transabdominal Heller EM without a fundoplication has been the procedure of choice.[56,98,235] Recently, however, the successful advent of laparoscopic EM has provided a new, effective, and less invasive alternative.[56,130,134,136,143–145,203] In some centers, laparoscopic myotomy is now being offered as the initial treatment,[56,134,155] but long-term studies are needed, and experience in children is still very limited.[46,130,134,136]

Pharmacologic therapy with nifedipine is not a good long-term option and can be used to buy time to prepare for the definitive treatment and to adjust to the child's school schedule. Botulinum toxin should be reserved for those children who are high-risk candidates for invasive procedures or for those in whom the nature of the problem is not clear, and before undertaking a definitive procedure, the response to an intervention that is self-limited needs to be evaluated.[46,202]

Long-Term Follow-up. After successful therapy, a recurrence of symptomatic achalasia may develop, even after a symptom-free period of many years.[165] This may occur after either PD or EM without any evidence of peptic or stenosing esophagitis. The reason for this is unknown. It may be due to slow progression of the degenerative process of the myenteric plexus and other nervous structures. Some patients seem to be resistant to therapy, and it has been noted that some patients who fail PD respond poorly to EM and that forceful dilatations are less successful in patients with previous PD or EM.[165]

Esophageal cancer, particularly squamous cell carcinoma, has been considered by some authors to be a late complication of achalasia.[254] Numerous case reports and retrospective reviews have appeared to substantiate the association between achalasia and esophageal carcinoma,[255] with most series estimating an incidence of 5% of esophageal carcinoma in these patients.[255] Esophageal cancer arises at a younger age in these patients, with a mean of 48 years, and the mean time from diagnosis of the achalasia to the occurrence of the malignancy is 17 years.[255] In a

population-based study, it was estimated that the prevalence of this complication was 1%,[256] and an autopsy study reported a prevalence of 1.5%.[257] A follow-up study of 147 patients treated with EM (mean 23.2 years, range 6–41 years) found that 10 of 23 patients who died of cancer had a malignant tumor in the esophagus, with an overall mortality rate of 66.1% and with 11.9% of the deaths caused by esophageal cancer, concluding that achalasia is a risk factor.[255] It has been suggested that this complication is more likely in patients who have had a long course without treatment or have failed therapy, raising the possibility that mucosal irritation from stasis of different substances may be an important factor. A recent report found a prevalence of 9.21%, using endoscopy with Lugol staining. They found a higher incidence in patients with more than 20 years of evolution, enlarged esophagus with knees, and marked retention.[254] Because of this possibility, some authors have advocated frequent endoscopy with cytology and biopsy or with Lugol staining every 3 to 5 years,[254] particularly because any warning symptoms are more likely to occur late as a result of the dilated esophagus. It is also not known what role other risk factors (eg, alcohol, tobacco) play in the development of this complication.[254]

Brucher and colleagues published one of the most recent series of patients with achalasia and their experience with the development of esophageal cancer.[258] They found that esophageal cancer was diagnosed 17.8 to 42.5 years after the diagnosis of primary achalasia in 3.2% of patients. Conversely, when they examined all of the patients who presented at their institution for the treatment of esophageal squamous cell carcinoma, 1.5% had a preceding history of primary achalasia; the average length of time between the diagnosis of achalasia and carcinoma in these patients was 32 years. When they examined all of the patients at their institution who had adenocarcinoma of the esophagus, 0.2% (one patient) had preceding primary achalasia diagnosed 22 years previously.[258]

There is currently no information about the incidence of this complication in patients who developed achalasia as children, although, as far as we can tell, no cases of esophageal carcinoma have arisen in adults who had achalasia as children. At this time, with our current knowledge, it is believed that a surveillance program in adults would not be cost-effective, not only for the amount of psychological trauma that would be inflicted but also because there are no data showing that such an approach can alter the outcome.[259] It is recommended that diagnostic tests in treated achalasia patients rely on clinical criteria, with particular attention paid to recurrence of symptoms or newly developed dysphagia or pain. Because there is no information about the long-term prognosis of children with achalasia, these children should be followed closely, and the threshold for initiating an evaluation should be low.

OTHER PRIMARY MOTILITY DISORDERS

Advances in esophageal manometry and more widespread use of this technique in the evaluation of patients with noncardiac chest pain or dysphagia have shown that patients with primary esophageal motor disorders do not fit into the simple classification of achalasia and diffuse esophageal spasm.[165] A variety of motor alterations have been described in the adult literature, and even though some distinct clinical entities, such as diffuse esophageal spasm (DES) and nutcracker esophagus, have been identified, a larger proportion of patients remain in the category of nonspecific esophageal motility disorders.[260,261]

Diffuse Esophageal Spasm and Nutcracker Esophagus

DES is a primary disorder of the motor activity in the smooth muscle portion of the esophagus.[260–262] It represents a group of disorders in which there are high-amplitude, repetitive, nonperistaltic esophageal contractions. DES is a distinct clinical entity in adults, but its incidence in children is unknown, and there are only case reports.[263] The pathophysiology is still unknown, although it has been suggested that it is the result of damage to the inhibitory esophageal nerves and the consequent increase in excitatory input. In adults, this syndrome is characterized by chest pain and/or dysphagia that is usually not progressive or associated with weight loss.[260,262] Because of the predominance of the chest pain, these patients are usually evaluated first for coronary artery disease.[260] The pain may be initiated by the ingestion of very cold or very hot meals, dysphagia is usually present in 30 to 60% of the patients, and in contrast to the pain in achalasia, it is not constant. The barium swallow may show frequent nonpropulsive contractions indenting the barium column, usually only in the lower third. There may also be delayed transit documented either by radiography or emptying scans. The diagnosis, however, is established manometrically using the following criteria: (1) repetitive, simultaneous (nonperistaltic) contractions, at least 10% of wet swallows; (2) periods of normal peristaltic sequences; (3) alterations in the contraction waves (increased duration and amplitude), although there are patients who can have normal amplitude; and (4) a normal LES in most patients, although incomplete LES relaxation or a hypertensive sphincter has been described.[260–262] This alteration in the LES and some long-term follow-up of patients with DES confirming the rare evolution of some cases of DES into achalasia suggest that the two disorders may represent points on a continuum of esophageal motility dysfunction.[48,260] It has been suggested that compared with stationary motility, 24-hour ambulatory motility is more sensitive and specific for diagnosing DES.[261] When high-frequency intraluminal ultrasonography is done during the manometry, patients with DES (and nutcracker esophagus) have thicker muscles in the area of the LES and throughout the esophagus compared with normal subjects. Both the circular and longitudinal muscles are thicker than those of controls.[264]

In children, this is an extremely rare entity.[263,265] In infants, the presentation is usually with apnea and bradycardia; in young children, it is aspiration pneumonia; and in older children, the presentation is similar to that in adults. There is a particularly well-documented case

reported by Fontan and colleagues in which a newborn was found to have bradycardia, obstructive apnea, and central apnea, all of which were consistently associated with manometric findings typical of DES.[263] They suggested that the symptoms in this infant were secondary to vagally induced responses because the infant showed an immediate decrease in heart rate after esophageal spasms, with a lack of a temporal relationship between the apnea and bradycardia and subsequent good clinical response to the use of anticholinergic medication. Glassman and colleagues reported a retrospective study in 83 children with chest pain who underwent esophageal manometry and endoscopy.[265] They found that 47 had normal studies, 15 had esophagitis with normal motility, 13 had dysmotility and normal histology, and 8 had abnormalities in both esophageal motility and esophagitis. In the group with motility disorders, they identified 7 patients with achalasia and 4 with DES, indicating that children with unexplained chest pain should have an evaluation to exclude primary motility disorders.

Using the above-mentioned criteria, it is estimated that only 10% of adult patients referred for esophageal motility because of chest pain have DES.[260,266] The most frequent finding is what is now called nutcracker esophagus. This is a clinical entity presenting as noncardiac chest pain and occasionally dysphagia. The barium swallow and radionuclide emptying scans are usually normal, and the diagnosis is made manometrically, with high-amplitude peristaltic waves being the hallmark of the disease.[260,266] This is in contrast to DES, in which the high-amplitude contractions do not result in peristalsis. The mean peristaltic amplitude with nutcracker esophagus is usually greater than 120 mm Hg, and there is usually an increased duration of esophageal waves.

A large number of patients with noncardiac chest pain have been shown to have manometric abnormalities that cannot be classified as one of the above disorders. These patients are now classified as having nonspecific esophageal motility disorders, and the manometric findings can vary from a "hypertensive LES" with normal relaxation and peristalsis to minor abnormalities in the peristaltic sequences with repetitive contractions or isolated prolonged contractions.[260,266] Patients with these nonspecific abnormalities also show a delay in esophageal emptying for solids, indicating that the manometric findings are not only a laboratory curiosity.[267]

Esophageal dysmotility in infants has also been linked to the "near-miss" sudden infant death syndrome in a report of four infants with radiographically proven esophageal dysmotility.[268] The alterations consisted of distal esophageal spasm and esophageal strictures. No manometric studies were performed, so it is difficult to know the type of motor alterations. They were all born prematurely, the symptoms occurred after feeding, and they all had esophageal strictures, suggesting that they all had long-term GER. Of interest is the fact that two patients developed apnea during the barium study in relation to esophageal dysmotility and that they all improved after aggressive antireflux treatment was undertaken.

The therapeutic armamentarium for the primary motility disorders, with the exception of achalasia, is greatly limited.[269] Treatment is directed toward symptom reduction. Calcium channel blockers and nitrates have been shown in uncontrolled trials to improve the symptoms of patients with spastic disorders.[270,271] Peppermint oil may also be helpful in reducing the simultaneous contraction seen with esophageal spasm.[272] Of particular interest is the recent observation that different antidepressants produce improvement and reduce distress from esophageal symptoms.[262,273] In some studies, this improvement was not related to manometric changes, emphasizing that manometric abnormalities may not be solely responsible for the symptoms.[273] The fact that antidepressants have such a marked influence over these disorders raises the issue of the importance of psychiatric alterations in these patients and their relationship to esophageal motor disorders. Previous studies have revealed that a psychiatric disorder at some point in the patient's lifetime is present in approximately 80% of patients with esophageal contraction abnormalities.[262]

If conservative treatment fails, the use of PD, surgery, or, recently, botulinum toxin has been advocated to treat patients with spastic esophageal disorders.[17,269,274,275] PD has been reported to improve the dysphagia of 40% of the patients with severe manometric abnormalities, particularly if there is incomplete LES relaxation.[269,276] In a series of 20 patients treated with PD, good results were obtained in 14 and poor results, including an esophageal perforation, in 6.[276] Botulinum toxin injection of the LES was used in 15 patients, and there was a significant improvement in chest pain, dysphagia, and regurgitation. One month after treatment, 73% had a good to excellent response. At a mean follow-up of 10 months, 33% continued to have good to excellent results, whereas 67% required additional treatment with botulinum toxin or PD.[274]

Surgery should be the last resort; a long EM is generally advocated for intractable cases, and good results have been reported,[17] although, in general, the results are poorer than those of surgery for achalasia.[17]

SECONDARY ESOPHAGEAL MOTOR DISORDERS

Motor Disorders in Esophageal Atresia and Tracheoesophageal Fistula

Primary repair of esophageal atresia permits the restoration of GI continuity but does not ensure normal esophageal function. Even though a complete consideration of esophageal atresia is beyond the scope of this chapter, we briefly discuss some of the important aspects that relate to esophageal motor function.

Early surgical intervention allows the neonate to survive, but it has become clear that many children surviving the repair of esophageal atresia frequently have symptoms related to esophageal motor dysfunction, including regurgitation, vomiting, heartburn, dysphagia, and chronic respiratory symptoms, such as nocturnal wheezing and recurrent pneumonias.[277–280] Up to a third of patients followed long term report impaired quality of life.[280] Some patients also develop strictures near the anastigmatic site, which have been attributed by some authors to reflux esophagi-

tis.[277] Long-term follow-up of these children with esophageal atresia repair has revealed disordered esophageal motility in almost all of the children studied.[277,279–283] Manometric tests and long-term pH monitoring have proved to be the most sensitive indicators of esophageal abnormalities in these patients,[277,279,282] although barium esophagrams[284] and radionuclide scans have been used as well.[283] Most series have shown almost universal alterations in the peristalsis of the esophagus, with rare reports of normal esophageal function.[282] The alterations described have been a low LES pressure and a lack of peristalsis, with esophageal contractions that tend to be simultaneous and weak, although at times of normal amplitude, especially in the lower esophagus.[279,282,283] It has been suggested that a low LES pressure in these patients correlates with the development of worse reflux[283] or aspiration pneumonia,[283] although two studies found no correlation between abnormalities in pulmonary function tests in these patients and the presence of GER, esophagitis, or esophageal dysfunction.[285,286]

Long-term esophageal function has been described by Biller and colleagues, who studied 12 adult patients who had their original repair in the first week of life.[286] The mean age was 26 at the time of the evaluation. During manometry, they found a mean LES pressure of 21.3 ± 2.8 mm Hg, with only two patients having LES pressure less than 15 mm Hg (both had esophagitis). Ten had complete LES relaxation after swallowing, and the amplitude of the contraction was also low throughout the esophagus, although the duration was normal. All patients had at least one portion of aperistalsis, with most patients showing a diffuse abnormality. The UES pressure and function were normal. The peristaltic function of 22 adolescents and adults with tracheoesophageal fistula repairs was described with the use of ambulatory 24-hour pH manometry.[281] All had diminished contractile activity, disorganized propulsive activity, and abnormal and ineffective peristalsis. This indicates a poor capacity for acid clearance and may explain the frequent dysphagia and GER-related problems experienced by these patients.

The etiology of abnormal esophageal motor dysfunction is unclear.[287] Some authors have suggested that there is damage to the esophageal branches of the vagus during the surgical repair.[282,288,289] Shono and colleagues described two patients with a long gap esophageal atresia without tracheoesophageal fistula in which manometry was performed before the operation.[288,289] Both patients showed peristaltic contractions in the proximal esophagus, which was always followed by coordinated contractions of the distal esophagus and a normal LES relaxation. After the operation, the repaired esophagus demonstrated abnormal motility and LES relaxation, suggesting that the alterations were secondary to intraoperative mobilization and probable denervation.[288,289] Experimental evidence in dogs in which the esophagus was divided and the vagus nerve was damaged in half gives support to this observation. Motility studies showed that normal peristalsis was preserved only in those in which the nerves were not affected.[288,289] Also, it has been shown in dogs that even though cervical vagotomy produces low LES pressure, thoracic procedures, including vagotomy, resection of the esophageal branches of the vagus, phrenic nerve resection, and midesophageal resection, have no significant effects on the LES.[290]

The fact, however, that there is dysmotility not only in patients who have had surgery but also in those with a fistula without atresia who have not had surgery, or in the different segments before the operation, has led others to believe there may be a congenital abnormality.[279,287] To further support the theory that the esophageal motility alterations are present since birth, before the operation, Romeo and colleagues reported esophageal motility studies of both the proximal and the distal segments in 20 newborns with esophageal atresia before surgical repair.[291] They found that the LES length varied from 8 to 14 mm, and the pressure was between 22 and 35 mm Hg in 84%. The LES pressure was low in 16.7% of the patients, and there was incomplete relaxation in 8.4%. There was also incomplete relaxation of the UES in 12.5% of the patients. The esophageal body in the proximal and distal segments showed a positive basal tone with total motor incoordination. Nakazato and colleagues demonstrated preoperatively abnormalities of the myenteric plexus, suggesting that there is abnormal development of neural tissue in these children.[292] Experimental evidence in a rat model of esophageal atresia has also shown abnormalities not only in the course and branching of the vagus nerve but also of the intrinsic esophageal innervation (both excitatory and inhibitory).[287] These studies suggest that there may be intrinsic abnormalities and that the esophageal motor incoordination is an intrinsic part of the congenital malformation, although it may be exacerbated by damage to the extrinsic inervation during surgery.[287]

Chronic Idiopathic Intestinal Pseudo-obstruction

This syndrome is characterized by intermittent symptoms and signs of intestinal obstruction without evidence of actual mechanical blockage and is discussed in Chapter 46.4, "Chronic Intestinal Pseudo-obstruction Syndrome." Various motility abnormalities throughout the body have been described; besides the small bowel, the esophagus is frequently involved.[293–295] At least 85% of patients have abnormal esophageal motility. Most patients exhibit aperistalsis and often decreased or absent LES. In the recent national survey reported by Vargas and colleagues, esophageal motility studies were performed in 14 children.[294] All patients had low LES, with failure to relax with swallowing. Low-amplitude waves occurred in the esophageal body, with lack of propagation and the presence of tertiary contractions in all 14 patients. Because none of the patients had histologic studies done to correlate whether they had a myopathic or a neuropathic form, no further conclusions can be reached. In another report of 20 children, 18 had abnormal esophageal peristalsis, consisting mainly of simultaneous contractions, short-lasting, or low-amplitude waves.[293] It can therefore be concluded that because of the high incidence of esophageal motor abnormalities in these patients, esophageal motility can be used as an initial

screening test, particularly if small bowel motility studies are not available where the patient is located.[293,295]

Caustic Ingestion

Ingestion of harmful household compounds is a frequent accident in toddlers and can lead to severe esophagitis and life-threatening acute complications.[296,297] In the subacute and chronic stages, strictures of the esophagus and dysphagia are common, and it is known that the severity of the symptoms does not correlate with the degree of esophageal stenosis. Long-term follow-up has shown motility abnormalities.[297,298] Cadranel and colleagues have shown that the severity of symptoms correlates with impairment of esophageal motor function and delayed esophageal transit. The basis of the motor abnormalities seems to be damage to the deep muscle esophageal layers with fibrosis, with subsequent loss of normal motility. Manometrically, they found signs of segmental hypoperistalsis, usually with normal UES and LES function. Esophageal transit was altered, with abnormalities observed in the middle and lower esophagus.[297]

Endoscopic Injection Sclerotherapy and Band Ligation

Endoscopic variceal sclerotherapy (EVS) of esophageal varices and, recently, endoscopic variceal ligation (EVL) are effective treatment modalities for patients who have had variceal hemorrhage.[299] They have also been successfully used in children. Following EVS, the histologic changes in the esophageal wall include thrombosis of the submucosal vessels, esophagitis, ulceration, and, subsequently, fibrosis. Persistent dysphagia after EVS has been uncommon despite extensive damage to the esophageal mucosa, although there are reports of esophageal strictures following the procedure.[300] The results of esophageal motility studies in patients undergoing EVS have varied. A recent review of the literaure concluded that esophageal varices reduce the mean amplitude of contractions, particularly in the lower third, and increase the mean duration of peristaltic waves but have little effect on LES function.[299] Nonpropagating simultaneous contractions may appear and may result in chest pain and/or dysphagia in the absence of stricture. Pathogenesis of the abnormal motility remains poorly understood, and no correlations were demonstrated between esophageal motor parameters and doses of sclerosant.[301] In some studies, the abnormalities have been reversible, suggesting that sclerotherapy injections acutely impair the motility of the esophagus and indicate that the motor function is partially restored 4 weeks after their completion.[301]

The information after EVL is limited, but it appears to have little impact on esophageal motility.[299,302] In one study comparing EVS and EVL, the LES pressure did not change, but the amplitude of contractions changed significantly after either two sessions of EVS or EVL variceal therapy. There was also an increase in nonperistaltic waves, but there was no correlation between the presence of ulcers and dysmotility and there was no difference in the changes between the EVS and EVL groups, suggesting that both affect esophageal motility.[302]

Collagen Vascular Disorders

Of all of the collagen vascular disorders, scleroderma shows the most marked esophageal abnormalities.[303,304] Scleroderma is a systemic disease of unknown etiology characterized by excessive deposition of collagen and other connective tissue components in skin and other target organs, most notably the GI tract.[303,304] Esophageal abnormalities are present in half to three-fourths of patients with scleroderma, a much higher frequency than in patients with other collagen vascular disorders.[303,304] Prominent digestive symptoms in these patients are dysphagia, weight loss, and diarrhea alternating with constipation. In advanced cases, the esophageal involvement can be easily diagnosed by cinefluoroscopy, whereas at an early stage, it can be detected by esophageal manometry.[303,304] The manometric findings are quite suggestive of the diagnosis, although not pathognomonic, because severe reflux esophagitis can have the same manometric appearance.[303–305] The characteristic esophageal manometric findings are (1) incompetent LES, (2) low-amplitude esophageal contractions in the smooth portion of the esophagus, and (3) later alterations in the striated muscle section.[303,304,306,307] The incompetent LES fails to provide an effective barrier against the gastric acid, and the abnormal peristalsis provides an inadequate acid clearance, predisposing the patients to severe complications from GER.[305] It is not surprising then that patients with scleroderma may have heartburn as a prominent symptom.[303,304,307]

Ling and Johnston looked at the yield of various GI tests in the evaluation of the esophagus in connective tissue disease in adults.[308] Their patient population included 47 patients with scleroderma; calcinosis cutis, Raynaud phenomenon, esophageal dysmotility, sclerodactyly, and telangiectasia (CREST); mixed connective tissue; and other connective tissue diseases (lupus, rheumatoid arthritis, dermatomyositis, myasthenia gravis, Still disease). These patients all had manometry and some combination of an upper GI series, endoscopy, and/or a pH probe. Of all of the tests, endoscopy had the lowest diagnostic yield, with only 33% of patients with positive findings on the test. Sixty-six percent of patients had abnormal manometry, 56% of patients had an abnormal upper GI series, and 100% had an abnormal pH probe, although only 3 of the 47 patients underwent a pH probe in the study.[308]

The severity of the esophageal motor dysfunction in scleroderma varies.[304] It has been suggested that alterations are more severe in patients with progressive systemic sclerosis (PSS) than in those with localized scleroderma (LS). By studying the relationship between the severity and extent of esophageal acid exposure and manometric abnormalities in patients with systemic sclerosis, it was concluded that the severity and extent of GER are closely related to the integrity of the distal peristalsis. It has also been reported that Raynaud phenomenon is closely associated with the loss of esophageal peristalsis and that there is a significant association of esophageal dysmotility with

reduced lung volumes.[304] It is possible that the pulmonary damage is due to GER or to simultaneous involvement of the esophagus and the lungs in the disease process.[304]

In a study of children with scleroderma, Flick and colleagues studied seven children with PSS and two with LS.[307] The most frequent symptoms in patients with PSS were regurgitations, heartburn, and dysphagia. They showed that in 72% of the patients with PSS (mean age 15 years; range 10 to 18 years), there was a decreased LES pressure, tertiary waves, or feeble contractions. They found a strong correlation between the presence of Raynaud phenomenon and esophageal symptoms but no correlation with disease duration. There was a correlation between dysphagia and the presence of esophageal motor abnormalities. In contrast to adults, they also did not find any correlation between the presence of esophageal motor abnormalities and Raynaud phenomenon. Both patients with LS had no esophageal symptoms and minimal nonspecific alterations in the esophageal motility (tertiary waves and variability in amplitude). Of interest is the fact that after 4 years of follow-up, none of the patients with LS had either progression of their motor abnormalities or the appearance of symptoms, challenging the suggestion that nonspecific esophageal abnormalities may indicate which patients will develop a more progressive illness.

Because of the link between motor disturbances and reflux disease, Weber and colleagues examined 14 children with scleroderma for evidence of reflux disease using pH probes.[309] They found that 64.3% of the children had pathologic reflux, defined as reflux for greater than 4.5% of the day. They also found that 85.7% of the patients had more frequent episodes of reflux and 50% had longer episodes of reflux than normal standards.

The pathogenesis of the esophageal motor disorder in these patients remains unknown. In some pharmacologic studies, Cohen and colleagues showed that the LES pressure in patients with intact peristalsis is higher and demonstrates an increase in sphincter pressure after the administration of methacholine (a cholinergic agonist) or edrophonium (a cholinesterase inhibitor).[305] In patients with reduced or absent peristalsis, the sphincter responds to methacholine but shows a diminished response after the administration of edrophonium. Some patients with absence of peristalsis did not show any response to methacholine, suggesting extensive muscle atrophy. All patients with scleroderma showed a diminished response of the LES to gastrin injection. They suggested that patients with scleroderma have an early abnormality in cholinergic neuronal function, which later is compounded by smooth muscle atrophy. It has also been shown that scleroderma patients with autonomic dysfunction also have esophageal dysmotility, also supporting the hypothesis that there is a neurogenic defect.[310] It is possible that a neural lesion occurs early in scleroderma and disrupts esophageal motor function before the development of significant smooth muscle disease.[305] Studies of motility abnormalities in the small bowel, colon, and anorectal area seem to support this hypothesis.[305,311] Other authors suggest that the LES hypotension is secondary only to a primary muscle defect, although the finding of abnormal motor function in areas of normal muscle in several studies suggests that atrophy is a later stage of the disorder.[307]

At present, there is no specific treatment for the esophageal alterations secondary to scleroderma. The treatment is symptomatic, trying to prevent the complications from GER.[304,305,307] Cimetidine, metoclopramide, cisapride, and, recently, omeprazole have been shown to cause symptomatic improvement.[304,305,307,312]

Even though the esophageal motor abnormalities of scleroderma have been well characterized, other connective tissue diseases also have motor alterations,[306,313] particularly in patients with systemic lupus erythematosus (SLE) and those with mixed connective tissue diseases (MCTDs). In a study of 150 patients with different rheumatic disorders who underwent esophageal motility studies, it was common to find functional involvement of the esophagus.[306] The frequency differed by disease: in scleroderma patients, abnormalities were found more frequently in the LES (81.8%) and in the esophageal body (84.8%), whereas patients with dermatomyositis and MCTD overlapped. In SLE, there did not seem to be abnormalities of the LES, and the most specific problem was an isolated abnormal peristalsis. The authors concluded that the simultaneous involvement of the esophageal body and the LES is discriminant between nonlupus connective tissue disease and SLE.[306] Other studies have suggested that esophageal symptoms and aperistalsis are not prominent manifestations of SLE. Patients with SLE can also have esophageal motor abnormalities (approximately 50%). In a series of 14 patients, 3 had low LES, 1 had aperistalsis, 2 had changes similar to PSS, and 4 had minor esophageal abnormalities.[237] Even though heartburn was a very common symptom, no correlation between motility abnormalities and symptoms could be established.

In a study of 17 adults with MCTD, Gutierrez and colleagues showed that 82% of patients had abnormal esophageal motility.[314] The mean LES and UES pressures were lower than in controls, and the amplitude of esophageal contractions was significantly decreased. In 53% of patients, there was total aperistalsis of the esophagus, including the upper third, reflecting involvement of the striated muscle. They suggest that the diagnosis of MCTD should be entertained when total aperistalsis in the esophageal body is found, although this pattern can be seen occasionally in patients with PSS and SLE.[314] In a recent study of four children with MCTD, three had low LES pressure, two had tertiary waves, and two had feeble contractions. They found no evidence of aperistalsis, in contrast to the findings in the above-mentioned study.[307] The question of whether steroids will improve the esophageal motility problems remains unanswered. It has been suggested that the abnormal peristalsis in MCTD returns to normal after steroid treatment, although in the study by Gutierrez and colleagues, 14 patients had been receiving steroids for a mean of 6.9 years, and all had abnormal peristalsis.[314] This question needs to be addressed with a prospective study.

Sjögren syndrome, which is characterized by xerostomia and keratoconjunctivitis, can have involvement of

other organs, including the GI tract.[313] Esophageal function has been studied in these patients, and it was shown that they have minor motor differences compared with controls (shorter peristaltic contraction time and faster peristaltic velocity in the distal part of the esophagus). Webs were found in 10%, and it was concluded that the dysphagia that was reported by 73% of the patients is probably related to the lack of saliva, making the solid bolus passage difficult. In a study of esophageal manometry in 21 patients with Sjögren syndrome, abnormalities were present in 33%, and these did not correlate with the dysphagia or the extraglandular involvement.[313] The esophageal motor abnormalities included a high LES pressure in seven, aperistalsis in two, and nonspecific motor problems in one.

There has been controversy around the possibility that women with silicone breast implants may have an increased incidence of rheumatologic problems.[315] Even though this is a problem that is not encountered in the pediatric population, it has been suggested that breastfed children of mothers with silicone breast implants may be at risk of having esophageal motor problems with absent distal peristalsis and decreased LES pressure.[316,317] The initial reports described 11 children with chronic GI symptoms, including abdominal pain, vomiting, and poor weight. Eight children had been breastfed (mean age 6.1 years; range 1.5 to 9 years) and three bottle-fed, and they compared their esophageal manometry with a control group of 20 children. Six of eight breastfed infants studied demonstrated significant esophageal motor abnormalities, which are typical of those seen in both children and adults with scleroderma. The changes included abnormal peristalsis in the lower third and decreased LES pressure, findings that persisted over time in at least three children who had repeated manometric studies done a mean of 10 months later. They found that only 21% of swallows propagated to the lower third of the esophagus. The mean LES was 13.1 ± 5.9 mm Hg in breastfed children compared with 24.8 ± 11.9 mm Hg in controls. UES pressure and function were normal. Endoscopic biopsies failed to reveal either granulomas or silicone crystals,[316] and a search for a variety of autoantibodies yielded no differences.[318] These children were followed prospectively, and 7 of 11 had subjective clinical improvement on prokinetics. In 8 of 10 children, the esophageal biopsies were normal or showed mild esophagitis. LES and UES pressures and percent propagation were not significantly different at follow-up, whereas the wave amplitude significantly increased.[317]

The physiopathology of this problem is not clear. The fact that bottle-fed infants were unaffected suggested that the exposure was postnatal. It is unclear if the passage of silicone itself, other by-products released by the implants, or immunologic factors may have contributed to the esophageal dysmotility. In a case-control study in which urinary NO metabolites and neopterin were compared between 38 infants breastfed by mothers with silicone implants and controls, it was found that the breastfed infants had increased urinary NO metabolites and neopterin, as well as in vitro macrophage activation after silicone exposure.[319] Also, there was a significant inverse relationship between urinary neopterin excretion and the severity of the esophageal dysmotility. These findings suggest that in those breastfed children, there is evidence of macrophage activation, and this may be associated with esophageal dysmotility.[319] After long-term follow-up, the urinary levels of neopterin decreased significantly, whereas the urinary nitrates were unchanged.[319] The implications of the above-mentioned findings are not clear. More data are needed to confirm these findings, particularly if one takes into account that the population studied was a very self-selected sample and that the benefits of breastfeeding are well established, so that it may be premature to state that women with silicone breast implants should not breastfeed.[320]

Hirschsprung Disease

Patients with short segments of Hirschsprung disease usually do not have any problems related to esophageal function. However, it has recently been stated that they have minor abnormalities in esophageal motility, including abnormal tertiary and double-peaked contractions that persisted after surgery.[321] Isolated case reports of an association between Hirschsprung disease and achalasia have also been published.[322]

Patients with total colonic aganglionosis usually have feeding difficulties, and a recent study described abnormalities in both duodenal and esophageal motility in 11 children.[323] They found normal UES and LES function and abnormalities in the lower third of the esophagus, with abnormal and double-peaked waves and absence of propagation in more than 20% of swallows, as well as abnormalities in small bowel function, suggesting that patients with Hirschsprung disease have diffuse digestive dysmotility.[323] It is not clear if this dysmotility is related to antenatal chronic obstruction, the surgical repair itself, or a primary motor disorder. Clearly, more studies will be necessary to further define the nature of the esophageal dysmotility in these patients.

Graft-versus-Host Disease

Dysphagia, painful swallowing, and severe retrosternal pain can develop in patients with chronic graft-versus-host disease (GVHD). In one series, 8 of 63 patients developed this problem, including a 12-year-old and a 19-year-old patient.[324] No infectious pathogens were identified, and in all patients, an endoscopy showed desquamative esophagitis in the upper and middle esophageal third and, frequently, webs. The distal esophagus was described as normal in all but two patients. Seven underwent esophageal manometry and five had abnormalities, including two with aperistalsis, one with simultaneous contractions and aperistalsis after swallowing, and two with high-amplitude, long-duration peristaltic contractions. They suggested that reflux esophagitis was present in at least three patients, including two with distal strictures; that the esophageal motor disorder is secondary to the immunologic response to GVHD; and that, as a result of delayed acid clearance, these patients are prone to develop complications from acid reflux. It is interesting that the

pathologic description of the esophagus of those symptomatic patients who died did not indicate any abnormalities of the myenteric plexus or the smooth muscle, with only severe mucosal abnormalities, further reinforcing the impression that the motility disorder is secondary to the mucosal lesion. Whether the abnormal motility is secondary to the mucosal lesion that occurs with GVHD, to reflux esophagitis, or to both is not known, but these esophageal motor alterations are of interest because they seem to be secondary to immunologic phenomena.

SUMMARY

This discussion is the clinical extension of that in Chapter 25, "Esophagitis." In this chapter, the pathophysiology and clinical manifestations of specific motor disorders of the esophagus, including achalasia, were discussed. In addition, a detailed approach to the treatment of these conditions affecting the esophagus was provided.

CHAPTER 27

INJURIES OF THE ESOPHAGUS

Jean-Pierre Olives, MD

Injuries of the esophagus in children are most often due to ingestions and to traumatic lesions secondary to thoracic contusion, crush syndrome, blunt trauma, or iatrogenic perforations occurring during investigational procedures or surgery.[1,2] Ingestions of foreign bodies, coins, disk batteries, corrosive substances, and drugs are accidental in the majority of cases,[3–6] but child abuse, poisoning, or Munchausen syndrome by proxy should be considered.[2] Retrosternal pain, dysphagia, hypersalivation, and emesis are typical symptoms of esophageal lesions,[3–6] but in the young and nonverbal or retarded child and sometimes in older children, esophageal symptoms are not always obvious.[2] For example, large esophageal blunt objects might predominantly cause respiratory symptoms[7–9] and be misdiagnosed as tracheobronchitis, bronchopneumonia, or asthma.[8] Moreover, small impacted foreign bodies and even intramural perforations or infections can be, in infants and toddlers, completely asymptomatic.[3,10–13]

The management of esophageal injuries has changed significantly over the last two decades with the improvement of diagnostic procedures; 30 years ago, only radiologic studies (chest radiographs, barium swallow, or conventional tomography) were performed. Nowadays, sophisticated procedures are available in the majority of pediatric hospitals: ultrasonography, computed tomography (CT) (if necessary with three-dimensional reconstruction), nuclear magnetic resonance imaging, and, of course, fiberoptic endoscopy, which allows a thorough examination of the esophagus lumen but also provides the opportunity to perform interventional procedures.[1,2,14]

INGESTED FOREIGN BODIES

Foreign object ingestions in children occur commonly. The management of these patients remains controversial; each team probably has its own protocol; therefore, the type of intervention and the risk of complication vary with the site of initial health care contact.[5] The majority of foreign bodies will progress through the gastrointestinal tract without any problem and will be excreted by the feces. Although deaths caused by foreign body ingestion have rarely been reported, mortality rates have been extremely low, with recent large series reporting no deaths among 852 adults and 1 death among 2,206 children.[10,11,14,15] Most studies showed no gender predilection[2] or a slight prevalence of male ingesters[3]; surprisingly, the prospective study from Paul and colleagues reported that 60% of the patients were female.[5]

Infants and young children explore their environment by placing objects in their mouth; around 10% of the children seem to be recidivists.[5] Childhood curiosity and carelessness appear to be the major risk factors for accidental ingestion. Because it appears that foreign bodies are often easy for children to reach, parents need to place more emphasis on environmental safety than on their own vigilance. In only 51% of the cases reported by Paul and colleagues, the ingestion was witnessed.[5] This might suggest that the true incidence of accidental swallowing is, in general, underestimated because the majority of ingested foreign bodies do not cause symptoms. As a consequence, it can be supposed that the caretakers of the child are not aware of accidental ingestion in an important number of cases.[11]

Esophageal foreign body impactions should be removed as soon as possible because of the increased risks of perforation and aspiration, especially when they are lodged in the upper third of the esophagus.[2,6] Foreign objects that arrive in the stomach are likely to be eliminated between 2 and 30 days. Nevertheless, a high incidence of complications has been reported with large objects (> 5 cm in length and > 2.5 cm in diameter), sharpended foreign bodies, and batteries located in the stomach or duodenum.[2,3] In considering the outcome of foreign bodies located in the gastrointestinal tract, the composition, size, shape, and number of ingested objects should be taken into account but also the existence of a number of specific anatomic barriers. The transit is most likely to be retarded or blocked at the cricopharyngeal ring, aortic arch, lower esophageal sphincter, pylorus, duodenal curve, ligament of Treitz, Meckel diverticulum, ileocecal valve, appendix, and rectosigmoid junction.[2,3,14] There exist as well possible associated conditions, such as esophageal stenosis, achalasia, or previous abdominal surgery, that may alter spontaneous passage.

The evaluation of children with an ingested foreign body should include a careful clinical history, including age, previous digestive symptoms, the type of ingested object, and the interval from ingestion to consultation.

Pharyngeal and Cricopharyngeal Foreign Bodies

Foreign bodies that lodge in the pharynx or at the level of the cricopharyngeal ring are often coins, tokens, toy

parts, or fish bones. Standard fluoroscopy is useful to detect metallic objects; plain films of the neck should be taken in both posteroanterior and lateral views. Flat objects, such as coins or tokens, that lodge in the hypopharynx are seen on edge on the lateral film of the neck, whereas those lodged in the upper airway are seen on edge on the frontal film. The accuracy of radiologic examination to locate fish bones has been validated for nine species when taped to the neck of a control patient[2] and for 14 fish bones embedded in a tissue phantom.[16] Coins and flat objects are easily removed using a Magill forceps, a Foley catheter,[17,18] or a magnet[3,11] or by suction retrieval.[19] Fish bones can usually be extracted with a curved forceps or with long tweezers.

Esophageal Foreign Bodies

Children can put inedible things in their mouth. Sometimes the object is swallowed and consequently becomes a foreign body when it enters into the gastrointestinal tract. Impaction, obstruction, and perforation most often occur at areas of physiologic narrowing.[14] The esophagus is a natural "filter": the majority of foreign bodies pass spontaneously if they are less than 2 cm in diameter.[2,3,6,20,21] Blunt, long, or sharp-pointed objects are most likely to be retained in the cervical esophagus (Figure 27-1), at the level of the aortic arch or just above the lower esophageal sphincter. The type of ingested foreign body varies with age: in young children, they are largely coins, toy parts, crayons, jewelry, and ballpoint pen caps, whereas older children and adults commonly tend to have problems with meat and bones (Table 27-1).[2–6,10,11,14,15,20–28]

Small coins (15–20 mm) are less likely to get stuck in the esophagus than are larger coins (20–35 mm), which lodge at the cricopharyngeal ring in 60 to 65% of cases (Figure 27-2), at the level of the aortic arch in 10 to 15% of cases, or above the lower esophageal sphincter in 20 to 25% of cases.[2] Radiologic investigations reported by Gryboski in a review showed that the coins passed from the esophagus to the stomach between 1 and 20.5 hours in two studies, whereas another prospective study showed that 62% of the coins were in the stomach 6 hours after ingestion.[2]

*More frequently ingested by teenagers and adults.

Symptoms

Older children are able to identity the object swallowed and point to the location of discomfort. In young or noncommunicative (mentally impaired or psychiatrically deranged) children, the sudden onset of dysphagia, wheezing, or respiratory distress should suggest ingestion of a foreign body. The most common symptoms of an impacted foreign body are choking, hoarseness, refusal to eat, vomiting, drooling, bloodstained saliva, or respiratory distress. Less common complaints are pain on swallowing, chest pain, and local-

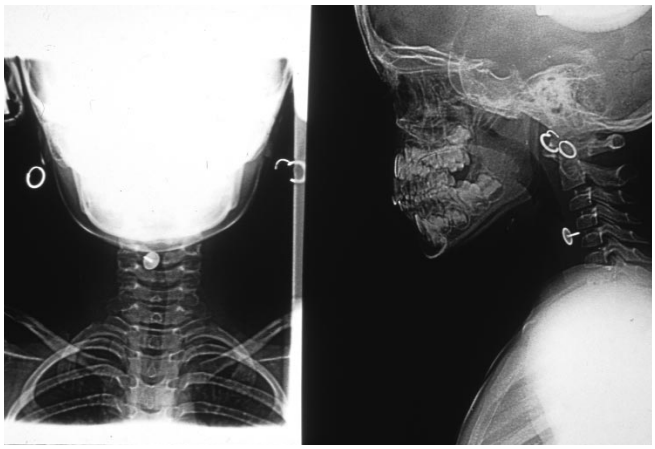

FIGURE 27-1 Ingested thumbtack at the level of the cricopharyngeus.

FIGURE 27-2 Anteroposterior film showing the flat surface of an ingested coin within the cervical esophagus. Lateral film showing the edge of the coin.

ization of the level of impaction within the chest, which is usually not reliable. Long-standing esophageal foreign bodies can present as a neck mass, chronic cough or stridor, and dysphagia. Swelling, erythema, tenderness, or crepitus in the neck region may be present with oropharyngeal or proximal esophageal perforation.[2]

Diagnosis

Radiographs usually identify most true foreign objects, bones, and the majority of complications secondary to perforation such as pneumomediastinum, pneumothorax, mediastinitis, and pneumoperitoneum.[2,14] Plain films of the neck, chest, and abdomen are generally recommended and should be taken in both posteroanterior and lateral views.[2,3,20,21] The lateral projection confirms location in the esophagus and may reveal the presence of more than one disk-shaped object (coins, button batteries, tokens).[10]

Handheld metal detectors are useful to spot the majority of swallowed metallic objects and may be of use as a screening tool in pediatric patients.[23–28] Nevertheless, it depends on the location of the foreign body: in an emergency room study, in 14 children, the presence or absence of coins was correctly identified by a metal detector in 13; when compared with radiologic studies, the remaining child had a coin lodged in the rectum. The same results were published by Saccheti and colleagues; of 20 coins, 1 was missed in the right iliac fossa.[24] More recently, in a large prospective study, radiopaque metallic foreign bodies were detected by use of a metal detector in 79% of the cases (183 of 231) when only 181 were identified by radiologic studies. In the remaining 45 children, in whom ingestion was suspected but not definitive, both a metal detector and radiology confirmed the presence of a foreign body in only 4.[26]

If symptoms are not clear or specific, a cautious contrast study may be appropriate to clarify the presence of a foreign body or its location (Figure 27-3).[27,28] CT may be necessary in some cases but may be negative with radiolucent objects; the yield may be improved with the use of three-dimensional reconstruction.[14,29] Drug packings have been studied by radiography, CT, and ultrasonography. Cannabis and cocaine packages were easily detected by plain radiographs and CT scans showing a high-density shadow surrounded by a gas halo. Heroin packages are difficult to localize, but on sonograms, they appear as round, echogenic structures.[29]

Treatment

The management of an esophageal foreign body is influenced by the child's age, body weight, some clinical criteria (ie, the size, shape, number, and classification of ingested objects), the anatomic location in which the object is lodged, and, finally, the armamentarium, skilfulness, and technical capacities of the endoscopist.

For coin ingestions, in many circumstances, noninternational protocols are applied. For instance, in a home-based study, 52 of 61 children having swallowed a coin were managed at home without calling a physician.[2] Two studies proposed a management based on location.[30,31] Radiologic study documented the site of the coin. If it is in the upper third of the esophagus (including the cricopharyngeus region), it should be removed urgently. If it lies in the middle of the lower esophagus, a repeat film should be taken in 12 to 24 hours if the child has remained asymptomatic because most coins pass into the stomach within 24 hours.[30] For Maksimak and colleagues, children without symptoms were treated conservatively with observation and sips of water or clear liquid to promote passage of the coin. This protocol was successful in 83% of the cases (18 of 21 children).[31] If the coin is still in the esophagus after 24 hours, it should be retrieved. If the coin is located below the diaphragm or not visible, the family may be reassured; the child is discharged, and the stools are examined and strained to identify the coin's passage. If, after a week's time, the child has not passed the coin, an abdominal film should be obtained. If the coin remains in the stomach after a delay of 4 to 6 weeks, it should be removed endoscopically.[2,3,30] In removing a foreign body from the esophagus, the most important point of treatment is the maintenance of an airway at all times.[2,21] For that, endotracheal anesthesia, coupled with endoscopy, is the safest method. Rat-tooth and alligator-jaws forceps are very efficient to ensure coin retrieval if the child is correctly sedated. If the patient does not have an endotracheal tube, the Trendelenburg position should be used to keep the coin out of the trachea.[21]

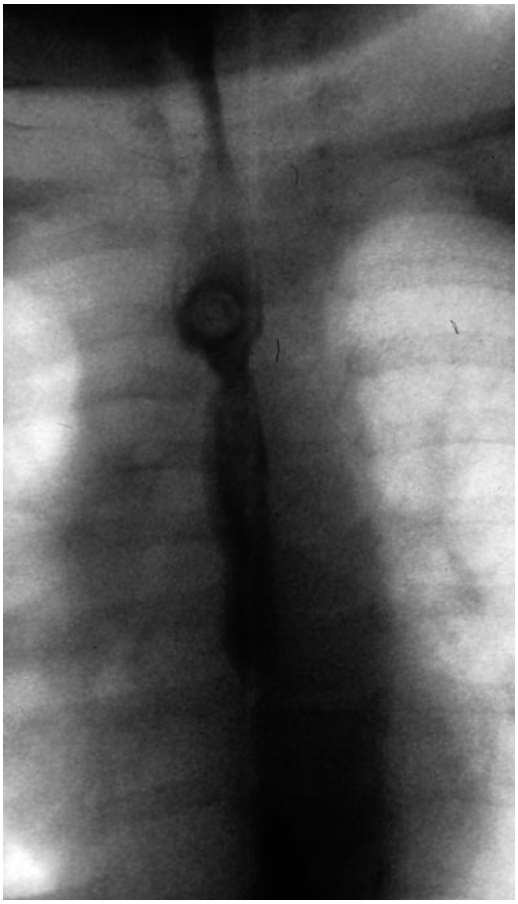

FIGURE 27-3 A 9-month-old boy who had an esophageal atresia repair has a plastic pearl impacted at the level of the anastomosis.

The "through-the-scope" balloon can also be used to extract a coin, but this is rarely necessary. However, blunt foreign bodies, such as marbles, that cannot be grasped with instruments can be removed easily under direct vision by using through-the-scope esophageal dilating balloons.[21] The Roth retrieval net, which is a polypectomy snare with a net, can be used to capture round or oval foreign bodies with ease.[2,20,21] It should be stressed that if one is having difficulty retrieving a foreign body from the esophagus and it is less than 2.0 cm in diameter and 5.0 cm in length, it can be gently pushed into the stomach and should pass through the gastrointestinal tract without difficulty.[2,3,14]

An alternative method for removing coins and blunt foreign bodies from the esophagus is the use of the Foley catheter.[32–34] Campbell and colleagues successfully removed blunt foreign bodies from 98 of 100 infants and children by this method.[32] In a survey of pediatric radiologists, 2,500 successful removals were recorded, with only one reversible complication.[33] This procedure is performed in the radiology department under fluoroscopy, with the catheter being placed orally, rather than nasally, to keep the foreign body out of the nasopharynx. The radiograph table is placed in a deep Trendelenburg position to minimize the chance that the foreign body will enter the larynx.[21] The Foley catheter technique provides no control of the foreign body as it is removed.[2,21] Another disadvantage is that the pathology, if present, cannot be assessed. If the foreign body has been present for longer than 24 hours, or if edema is present, this technique should not be used. The Foley catheter technique is recommended only if endoscopy is not available. The magnet can be used for removal of metallic objects, but the disadvantages are identical to those observed with the Foley catheter. Paulson and Jaffe, however, have reported successfully removing metallic foreign bodies in 34 of 36 cases using this technique.[35]

Sharp and pointed foreign bodies, as well as elongated foreign bodies, can be difficult to manage; fortunately, they are not common. When considering sharp and pointed foreign bodies as a separate group, morbidity and mortality figures are higher.[2,4,6,10,15,21] The most common foreign bodies in this group are toothpicks, nails, needles, bones, razor blades, and safety pins. The open safety pin represents a major problem (Figure 27-4). If a safety pin is in the esophagus with the open end proximal, it is best managed with the flexible endoscope by pushing the pin into the stomach, turning it, and then grasping the hinged end and pulling it out first. An alternative is to close the pin using a polypectomy snare. The closed safety pin, once in the stomach, will pass without difficulty. An overtube or a rigid esophagoscope may be necessary with large, open safety pins.

The ingested razor blade is a challenging experience for both the patient and the endoscopist. This foreign body can be managed with the rigid esophagoscope in both the child and adult by pulling the blade into the instrument. One also can use a rubber hood or a piece of rubber glove on the end of the endoscope to protect the esophagus from sharp or pointed foreign bodies.[2,20,21]

The straight pin ingested by infants and children is an exception. Those longer than 5 cm may fail to pass through the duodenal loops and may perforate with the risk of hepatic hemorrhage or infection.[2,6] The use of an overtube or an endoscopic end protector hood will prevent laceration during removal. Crack tubes or body bags of heroin or cannabis must be retrieved very cautiously using a basket or a net because forceps grasping carries the danger of tearing the bag, with intraluminal release of the narcotic substance.[2]

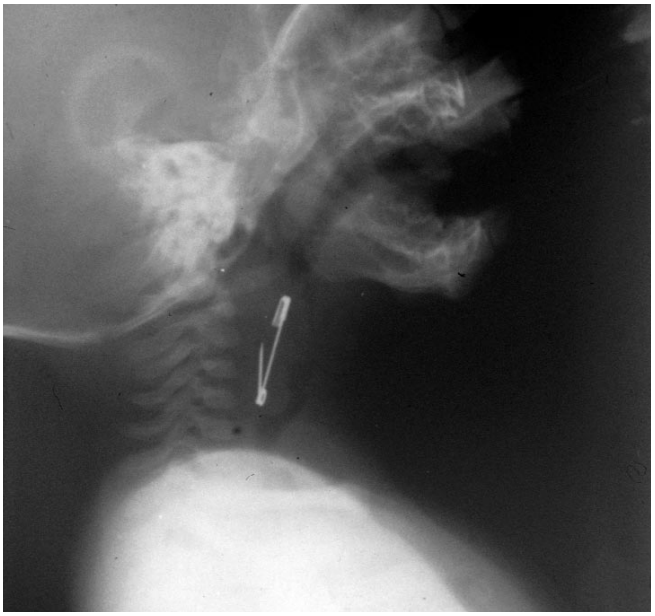

FIGURE 27-4 Open safety pin at the level of the cricopharyngeal ring.

Radiolucent objects such as pieces of glass, bone fragments, aluminum (eg, canned drink pop tabs), plastic, and pieces of wood can often be difficult to see in the hypopharynx and cervical esophagus on routine radiographs.[21] It the patient has complained of swallowing a foreign body and it is not seen on routine radiographs, thin barium is used to try to outline the object.[2] If the foreign body is identified radiographically, endoscopy is performed. If no foreign body is seen radiographically but the patient remains symptomatic, endoscopy is also performed (Figure 27-5). If no foreign body is seen radiographically and the patient has become asymptomatic, the endoscopy is not mandatory.[21]

Complications

Esophageal examination in children with coin ingestions of less than 24 hours duration may show normal mucosa in the majority or minimal erythema or abrasion in some cases.[36] Complications increase with the length of time the foreign body remains in the esophagus, with perforations, particularly from sharp bodies, occurring after 24 hours.[2,31] Fewer than 1% of esophageal foreign bodies cannot be retrieved by endoscopy, and esophagotomy must be employed. Perforation of the esophagus after foreign body and coin ingestions may be either acutely symptomatic or asymptomatic.[37] Aspiration pneumonia, lobar atelectasia, hemoptysis, perforation with neck abscess, mediastinitis with lung abscess, acquired esophageal pouch, pseudodiverticula, tracheoesophageal fistula, esophageal-aortic fistula, perforation of the heart by an

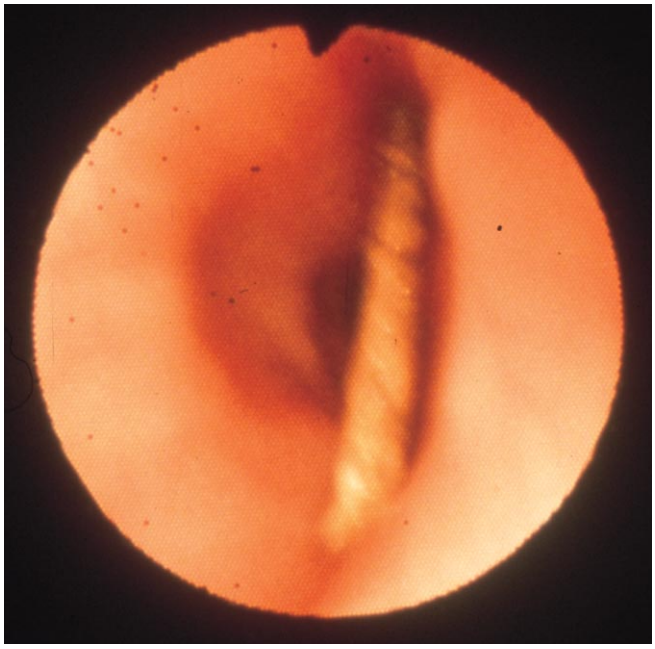

FIGURE 27-5 Endoscopic view of a rabbit bone stuck in the esophagus.

open safety pin, and aortic pseudoaneurysm are less common complications, occurring months to years after impaction of the foreign body.[2]

The CT scan is useful in confirming the location of impacted fish bones and radiolucent foreign bodies, as well as identifying inflammatory changes in adjacent structures.[29,38] Indications for thoracotomy for removal of a long-retained foreign body are poor endoscopic visualization of the foreign body because of inflammatory tissue and herald bleeding during endoscopy.[2]

Nickel dermatitis and associated gastritis and copper and zinc toxicity have been reported after coin ingestion, usually by retarded or schizophrenic adults.[2,39]

Food Impaction

Food bolus obstruction might occur in children with an esophageal stricture or with digestive motility disorders. Children who are in severe distress or unable to swallow oral secretions require immediate intervention. If the patient is not uncomfortable, not at risk for aspiration, and able to handle his or her secretions, then intervention need not be emergent and can be postponed to a reasonably convenient time because food impactions will often pass spontaneously.[21] However, endoscopic intervention should not be delayed beyond 24 hours from presentation because the risk of complication may increase.[6,15,20]

The initial endoscopic examination should verify and locate the site of the impaction. The food bolus can usually be removed en bloc or in a piecemeal fashion.[14]

An overtube may facilitate multiple passes of the endoscope, protect the esophageal mucosa, and minimize the risk of aspiration. Nevertheless, in small children, this technique is difficult to use because of the risk of esophageal injury during the overtube insertion. Once reduced in size, the bolus can often be passed under endoscopic visualization and direction. The high incidence of underlying esophageal pathology in this setting increases the risk associated with the practice of blindly pushing an impacted food bolus with the endoscope or a dilator.[14] The application of a cautery current applied to a bipolar snare to cut into, grasp, and retrieve an impacted food bolus in the esophagus has been reported in two articles.[40,41]

Enzymatic digestion with papain should not be used because it has been associated with hypernatremia, erosion, and esophageal perforation.[20,21] The administration of glucagon 0.5 to 1.0 mg intravenously, in an attempt to relax the esophagus, is generally safe and may promote spontaneous passage of an impacted food bolus while definitive endoscopic therapy is being coordinated. However, its use should not delay definitive endoscopic removal.[14] The use of Coca-Cola has even been suggested to "digest" a food bolus trapped in an esophageal stricture to avoid endoscopy.[42]

Food-Related Esophageal Trauma

Food-related trauma of the esophagus in children is rare. In adults, esophageal hematoma or laceration has followed swallowing or impaction of tortilla chips, taco shells, bagels, or bay leaves. Ingestion of hot pepper sauce can cause esophageal burns; inflammation of the mucosa is associated with a significant increase of esophageal peristalsis.[2]

Disk Battery Ingestion

The disk button battery is a single cell usually used to power digital watches, photographic equipment, toys, hearing aids, car electronic keys, handheld calculators, and even musical greeting cards.[2,43] Although these cells are sealed, they contain corrosive and toxic chemicals. Lodgment in the esophagus can lead to mucosal damage, and exposure to gastric acid is associated with a remote risk of leakage of the cell contents.[44,45]

There are four main types of button cell: mercury, silver, alkaline manganese, and lithium. Lithium cells are mostly used in watches in which replacement is normally by a specialist, thereby limiting access to children. Lithium cells exhibit a potential of 3 V against the 1.5 V of the other systems but are more resistant to corrosion than other button cells. Used batteries are potentially far less toxic than new ones. Discharged cells are less liable to leak or cause tissue injury, and in discharged mercury cells, the mercuric oxide will be largely converted to elemental mercury, which is not absorbed.[43,45] Finally, the mechanisms that corrode the cell container also discharge the cell, so the contents of a discharged cell are the most relevant.[43]

Because of a then estimated 510 to 850 ingestions yearly, a National Button Battery Ingestion Study was established in 1982 in the United States to provide guidelines to therapy. A 1995 review of 119 ingestions during an 11-month period determined that the majority of buttons contained silver or mercuric oxide.[46] Less common were those of magnesium dioxide, zinc or air, or lithium content, with all containing a 20 to 45% solution of potassium or sodium hydroxide. Those most frequently ingested were the 7.9 and the 11.6 mm batteries. Ingesters were primarily young, with

71.2% less than 5 years, and with 1 to 2 year olds at greatest risk. Sixteen percent were between 6 and 12 years and 4.5% were between 13 and 17 years, all with a male preponderance. Nearly half of the children found the battery loose or discarded, and a surprising source (39%) was from hearing aids belonging to the children or to others. More than one battery was ingested by 8.5% of patients. Older children or adults, while testing the viability of the battery by touching it to the tongue, have inadvertently swallowed it. A 1992 update from the Registry described 2,382 cases with similar findings.[47] The authors estimate a minimum of 2,100 battery ingestions per year based on their figures of 2.1 to 8.5 ingestions per million population in different states. The battery removed from a child's own hearing aid was the most common (44%) of ingested batteries. Lithium batteries with larger diameters and greater voltage cause the more severe injuries. Mercuric oxide cells were more likely to fragment.[2,47]

Although 89.9% of batteries passed spontaneously between 12 hours and 14 days, with 31% requiring more than 48 hours, those lodged in the esophagus (4.2%) required early removal. Most of the batteries that lodged in the esophagus were 20 to 23 mm. Esophageal injury is attributable to electrolyte leakage from the battery, alkali produced from external flow of current causing liquefaction necrosis (it is estimated that when lodged in the esophagus, 26 to 45% will leak sodium or potassium hydroxide), mercury toxicity, pressure necrosis, and direct flow of 1.5 or 3.0 V current to cause low-voltage burns.[2] Although most batteries show corrosion, they do not disassemble, although 2% in the series of Litovitz and Schmitz did fragment, and 11% had severe crimp dissolution or extensive perforations.[47]

Esophageal damage occurs rapidly, and burns are noted as early as 1 hour after ingestion. Within 4 hours, there may be involvement of all layers of the esophagus. In experimental studies in dogs in whom batteries were placed within the esophagus, by 8 hours, there was mucosal abrasion or necrosis under the muscular layer without evidence of battery leakage.[2] In rabbits, esophageal injury was created by placing a 3 V battery in the esophagus for 9 hours. Injury was more severe on the alkaline side when the battery was placed with the cathode directed toward the trachea. More severe damage is produced by a lithium battery than a button alkali one, with damage occurring within 15 minutes.[2]

Symptoms

Usually, children are asymptomatic after button battery ingestion.[44,46] Nevertheless, the immediate symptoms might be coughing, gagging, nausea, vomiting, and chest or abdominal pain.[2]

Diagnosis

The battery must be identified and distinguished from a coin radiologically. In the anterior projection, it shows a double-density shadow owing to its bilamellar structure (Figure 27-6). On lateral films, the edges are round and show a step-off at the junction of anode and cathode.

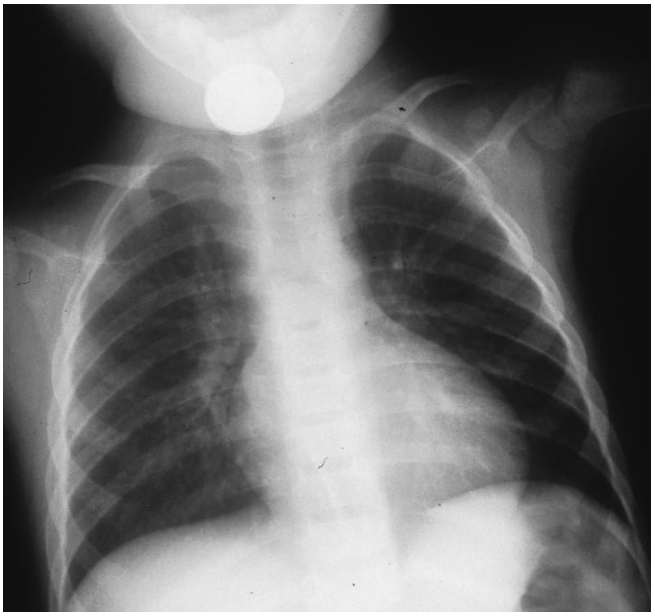

FIGURE 27-6 Anteroposterior film of a large disk battery (20 mm) with the halo sign (double-density shadow).

Treatment

Ipecac is not recommended to induce vomiting because it may lead to aspiration and impaction of the disk in the respiratory tree or to retrograde advancement from the stomach to the esophagus. Its use further carries the risk of perforation of the stomach or esophagus if the battery has caused a significant mucosal burn.[2] Administration of neutralizing solutions or charcoal has not been helpful. The treatment protocol recommended by the Button Battery Study advocates nothing by mouth and an initial radiologic study to determine the location of the battery.[47] If the battery is lodged within the esophagus, it should be removed immediately.[2,44,47] Endoscopic retrieval rates are 33 to 100%, and in children, endoscopic removal is performed using general anesthesia (to avoid aspiration) and may include the use of a polyp snare, a Roth retrieval net, a basket, or a through-the-endoscope balloon.[2] Endoscopy may also assess the degree of esophageal trauma. If there is evidence of tissue damage, a follow-up barium study should be performed 10 to 14 days later to rule out stricture or fistula formation.[47]

Success to remove disk batteries lodged in the esophagus has also been reported with the use of a Foley catheter, a balloon, or a magnetized catheter (Figure 27-7). In this author's experience, button batteries located in the esophageal and gastric areas can easily be extracted with a magnet attached to an orogastric tube in 88% of cases. My colleagues and I reported the management of 64 cases of accidental ingestion of button batteries in which magnetic removal proved to be successful in 49 of 56 attempts (14 of 14 cells lodged in the esophagus).[44] Failure of extraction occurred for 6 batteries located in the duodenum and solely for 1 in the stomach. This type of device is very cheap (50 dollars) and can be used by all pediatricians under fragmentary fluoroscopy. Because magnetic removal of disk batteries is very easy, and leakage, although extremely rare,

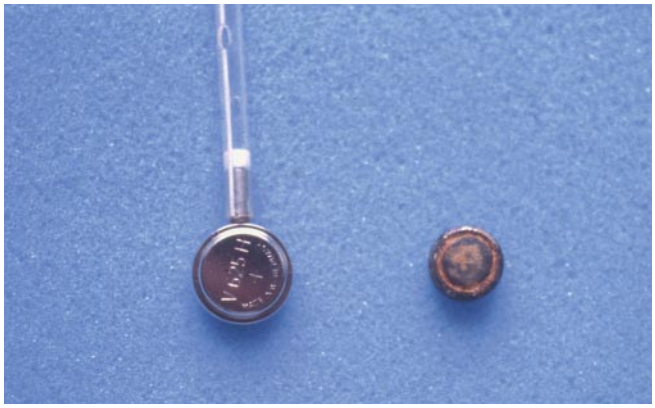

FIGURE 27-7 The new battery on the left is attracted with the magnet tube. The battery on the right shows severe corrosion after 6 hours in the upper gastrointestinal tract.

would result in life-threatening complications, especially when lodged in the esophagus, we recommend extracting emergently batteries if they are in the esophagus or still in the stomach at the first health care contact.[44] Management of a battery lying in the stomach remains controversial; for several authors, the child can be discharged home with normal eating and activity, with the parents instructed to strain the stool for retrieval of the battery and to report any pain, fever, or vomiting.[43,45,48] A prokinetic agent such as metoclopromide or a laxative may hasten battery transit through the stomach and small intestine. If the battery remains within the stomach after 1 week, it should be retrieved by endoscopy. If the battery fails to move through the intestine or if the child develops pain or peritoneal symptoms, it should be removed surgically.[2]

Complications

Reported complications of esophageal lesions are tracheoesophageal fistula, perforation, stricture, and even death.[2,49,50,51] A battery may lodge in a Meckel diverticulum and cause perforation.[2] Mercury toxicity is possible but rare, with only one mild case having been reported. Elemental mercury is produced by the action of gastric acid and iron from the casing, and this, in contrast to mercuric oxide, is readily absorbed. Elevated mercury levels have been reported in some patients after battery ingestion, but there were no signs of mercury toxicity.[48] The highest levels were found in children in whom the batteries split before or after passage and who had evidence of radiopaque droplets within the gastrointestinal tract. Rashes owing to presumed nickel hypersensitivity occur in approximately 2% of children.[2]

CAUSTIC INGESTIONS

Esophageal injuries caused by ingestion of caustic agents occur frequently in young children. The peak incidence is below the age of 5 years. The estimated frequency of admissions for caustic ingestion ranges from 1,000 to 20,000 per year in industrialized countries; the majority of cases are children.[52] Severe caustic injuries have been reported from developing countries, especially in northern Africa, with a very high incidence.[53] The male-to-female ratio is 1.2 to 1.4:1, although a female preponderance has also been reported, mainly owing to occupational habits. After a rise in frequency in the 1960s, there has been a decreasing incidence owing to legislation and because of an increasing awareness of the hazards of storing caustic products in an inappropriate way, such as within the reach of young children or in food and drink containers.[52] Inappropriate storage occurred in 10 to 15% of the accidental ingestions.[54]

Etiology

In the majority of cases, ingestion of caustic agents in children is accidental.[2,52–54] Only a minority of cases are intentional as an attempt at suicide or, rarely, as an attempt at homicide.[52]

Caustic products ingested by children most often are strong alkaline or acidic agents. Liquid forms cause more significant injuries than solid products, which are more irritating and difficult to swallow.[2,55] Strong alkali are used in the household as cleaning agents for the dishwasher (sodium metasilicate, sodium tripolyphosphate), oven, drain, or toilet bowl or as a declogging agent (sodium hydroxide, potassium hydroxide). Sodium hydroxide tablets are used for medical (Clinitest tablets) and sometimes pseudomedical purposes (a homemade mixture to predict gender during pregnancy) and cause caustic as well as thermic injury, leading to devastatingly deep burns.[55] Ammonia causes not only caustic esophageal injury but also chemical pneumonitis and pulmonary edema. Less frequently, caustic esophagitis is caused by ingestion of strong acids (eg, hydrochloric, sulfuric, formic, or phosphoric acid used in the household as cleaner for coffee makers, irons, and toilet bowls but also used as soldering fixes, antirust compounds, battery liquids, cleaners for swimming pools, milking machines, and slate). Detergents and bleach are reported to be ingested most commonly by children. This is not confirmed by many reports. Household bleach (Na hypochlorite, pH 6.0) is considered an esophageal irritant but does not cause tissue necrosis because of its low concentration (5%) and seldom causes clinically significant esophageal injury.[2,52,54]

Pathophysiology

The physical form and pH of the corrosive agent play a significant role in the location and type of resultant injuries. Crystalline drain cleaners (lye) tend to adhere to the oropharynx or become lodged in the upper esophagus, where they cause most of their damage.[55,56] High-density liquid drain cleaners usually pass rapidly through the oropharynx and upper esophagus and cause more significant problems in the lower esophagus and stomach. Strong acids usually pass rapidly through the esophagus and cause their most significant damage in the stomach and duodenum.[56]

Because corrosive substance ingestions are rarely fatal and the injured part is seldom removed surgically during the immediate postinjury phase, little histopathologic information is derived from human specimens. Much of what is known is derived from studies in experimental ani-

mals. Acid burns cause a coagulation necrosis that usually limits acid penetration and results in damage limited to the mucosa.[2,56] Both cats and dogs have been used to study the effects of sodium hydroxide on the esophagus. Initially, there is liquefaction necrosis with destruction of the epithelium and the submucosal layer. Hemorrhage, thrombosis, and a marked inflammatory response with significant edema are seen within the first 24 hours of injury (early acute phase). Depending on the extent of the burn, inflammation may extend through the muscle layer, and perforation may occur. After several days, the necrotic tissue is sloughed, edema decreases, and neovascularization begins. This early reparative or subacute phase extends from the end of the first week through the second week after injury, and if the insult has been relatively minor, function begins to return. The cicatrization phase begins in the third week when fibroblast proliferation replaces the submucosa and muscularis mucosa; there stricture formation begins. During this time, adhesions form, and narrowing or obliteration of the esophageal lumen may occur. If there has been a significant penetrating injury, adhesions to surrounding mediastinal tissues may also occur. Re-epithelialization begins during the third week and is usually complete by the sixth week after injury.[56]

Household bleach, which is moderately alkaline, has been, for a long time, a matter of debate regarding its potentiality to induce caustic lesions.[2,52,53,56] To clarify the conflicting observations that sodium hypochlorite bleaches cause significant burns identifiable at endoscopy and that serious long-term morbidity and stricture formation are exceedingly unusual, Yarrington studied the effect of sodium hypochlorite bleach on the canine esophagus.[57] Large volumes of bleach and prolonged contact time (longer than 2 minutes) were necessary to induce injuries detectable by endoscopy. Animals were killed 1 week after injury, and significant histologic changes were identifiable only in animals subjected to a large volume (30 mL) or significant exposure time (5–10 minutes). None of the dogs had penetrating injury or involvement of the muscularis. Yarrington concluded that although ingestion of household bleach may induce mucosal burns and edema, extensive necrosis and stricture formation do not occur.[57]

Symptoms

The clinical presentation of caustic esophageal injury shows a wide spectrum: in many cases, the child will have no complaints, and the physical examination may be normal. At the other end of the spectrum, the child can present with shock or severe respiratory distress.[58–60]

Respiratory distress and stridor following laryngeal injury occur more frequently in children below the age of 2 years and are not related to the nature of the caustic. Vomiting, dysphagia, drooling, epigastric pain, abdominal pain, and refusal to drink may inaccurately predict the presence or the severity of esophageal injury.[52] A close inspection of the patient will show irritation or frank burns periorally, on the lips, but also on other parts of the body, for example, the thorax and/or the extremities if the caustic agent has been vomited. Inspection of the mouth and pharynx can show edema, ulceration, or white, fragile, easily bleeding membranes over the buccal mucosa, tongue, uvula, and tonsils. Laryngoscopy can reveal laryngeal edema or more severe lesions. Fever may occur, and in 30%, slight leukocytosis is present.[52]

Serious esophageal burn, even perforation, can occur in the absence of oropharyngeal burns or abdominal complaints. On the other hand, burns to the mouth do not provide evidence of an esophageal burn.[2,52,54,59,60]

Diagnosis

Ingestion of caustic agents by children is often unwitnessed. The first element in diagnosing esophageal burn is a good history taking. Every effort should be made to document the possible agent, its physical and chemical characteristics, and its volume to estimate not only the caustic properties but also the noncaustic toxicity.[2,52] However, adequate information often is not available. The simplest way to obtain the information is to have the product itself.

If there is any suspicion of ingestion of a caustic agent, the child needs immediate evaluation by a physician. Burns of the mouth or pharynx are inaccurate as indicators of esophageal injury or its extent and mandate endoscopy. Conversely, the absence of oropharyngeal burn does not eliminate the need for endoscopy.[2,52,54,59,60]

Esophagoscopy with a flexible fiberoptic pediatric endoscope, allowing complete examination of both the esophagus and the stomach, is accepted as the single most accurate method of assessing esophageal injury. It should be performed within 12 to 36 hours after ingestion or suspicion of ingestion.[2,52] Because there is no correlation between esophageal and peribuccal or oropharyngeal burns, esophagoscopy should be done under general anesthesia. Not all authors agree with the need for systematic endoscopy.[2,52,54,55] Two recent studies concluded that endoscopy is not mandatory for children living in developed countries who are asymptomatic after nonintentional caustic ingestion.[61,62]

Caustic esophageal lesions are graded endoscopically as grade 0, normal; grade I, erythema and edema; grade II-A, noncircumferential superficial mucosal ulcerations with necrotic tissue and white plaques extending over less than one-third of the esophageal length; grade II-B, the same as grade II, with deep or circumferential ulcerations extending over more than one-third of the esophagus; grade III-A, mucosal ulcerations and area of necrosis in a circumferential pattern extending over less than one-third of the esophagus length; and grade III-B, extensive necrosis over more than one-third of the esophagus.[63] Some authors include a grade IV, that is, with signs of transmural necrosis: shock, coagulopathy, and metabolic acidosis. Some others do not take into account the circumferential appearance of the lesions. Distinguishing grade II from grade III then can be difficult because there is no clear definition of how the depth of an injury is determined (Figure 27-8).[52]

The opinion that endoscopy is the most accurate way to diagnose caustic esophageal lesions is not shared by all, and esophagography, in an early stage as well as during follow-up, is believed to provide better information.

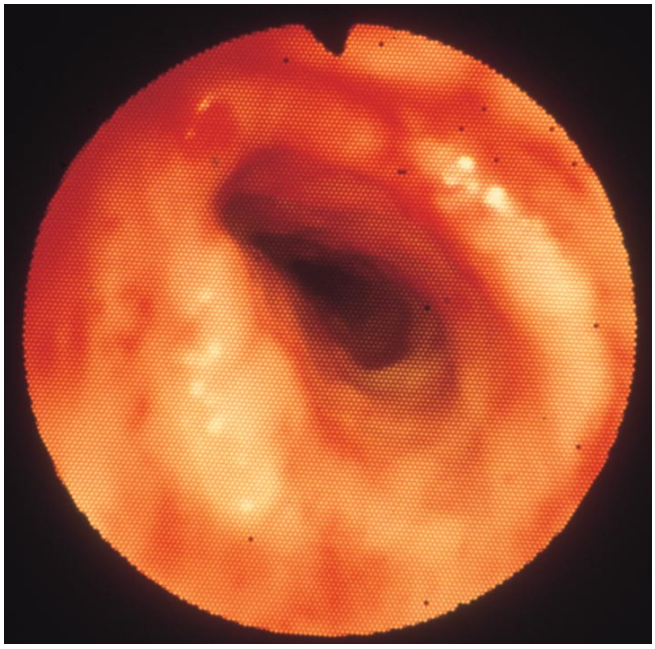

FIGURE 27-8 Endoscopic view of a grade III caustic esophagitis.

Indeed, radiology is adequate in the management of caustic esophageal injury.[52,64] Barium swallow, when performed early, is useful in assessing perforation in patients with suggestive symptoms; however, it is rarely sensitive enough to detect early mucosal injury or to allow therapeutic or prognostic decisions. When performed 2 to 3 weeks after ingestion, assessment of stricture formation can be made.[65] Cine-esophagography has been recommended as the examination of choice in assessing esophageal damage sufficient to provoke stricture formation. Mucosal and submucosal injuries are then seen as irregularities along the contact margin. Alterations in esophageal motility, resulting from injury to the myenteric nerve plexuxes, are indications of severe burn and accurately show evolution to stricture formation.

Outcome

Sequelae of caustic injuries of the esophagus are stricture formation, development of achalasia, brachyesophagus, gastroesophageal reflux, and, as a late complication, development of malignancy.[2,52] Esophageal motor function is disordered for days to years after lye ingestion and shows weak to absent peristaltic contractions, nonpropulsive contractions, gastroesophageal reflux, and dysphagia. Studies with pH monitoring, esophageal manometry, radiology, and esophageal transit scintigraphy with technetium 99m or krypton Kr 81m showed that the severity of the dysphagia was not correlated to the importance of the residual stenosis but rather to specific patterns of esophageal motility.[66,67] Pyloric stenosis can occur after gastric lesions, mainly owing to acidic agents.[52,54] The incidence of esophageal strictures in children is reported to be up to 15%, but figures range from 9 to 18%.[52,59,60,65] Most strictures result from grade III lesions and to a lesser degree from grade II-B and, rarely, from grade II-A. However, management is not consensual; many authors agree that grade I lesions heal without stricture, regardless of treatment, and that grade III lesions progress to stricture, regardless of treatment.[52,54] Acute inflammatory strictures appear at about 21 days (or earlier); complete stricture formation can take 30 to 45 days (Figure 27-9).[54,56]

Treatment

Some suggest that patients who are asymptomatic after unintentional ingestions are not at risk for complications and do not necessarily have to undergo endoscopy.[61,62] Many, however, agree that all children suspected of caustic ingestion should be admitted to the hospital for observation.[2,52,54,56,60] Intravenous fluids are administered, and the child is not permitted to drink until the decision for endoscopy.[2,52,54,55,65]

If there is a reasonable suspicion of caustic ingestion, regardless of the symptomatology, the child should be brought immediately to the emergency department, even if there is doubt that ingestion has occurred.[52] If medical advice is asked via the telephone, the first treatment that should be recommended is not to make the child vomit or give any acid or alkali to neutralize the agent ingested, as is sometimes recommended on the package of caustic agents. The latter can cause marked exothermal reactions and additional injury. Water can be used to wash away residual caustic from the buccal mucosa and face.[52,56] There is no role for diluents, emetics, lavage, smectite, aluminum phosphate, or charcoal. The use of a nasogastric

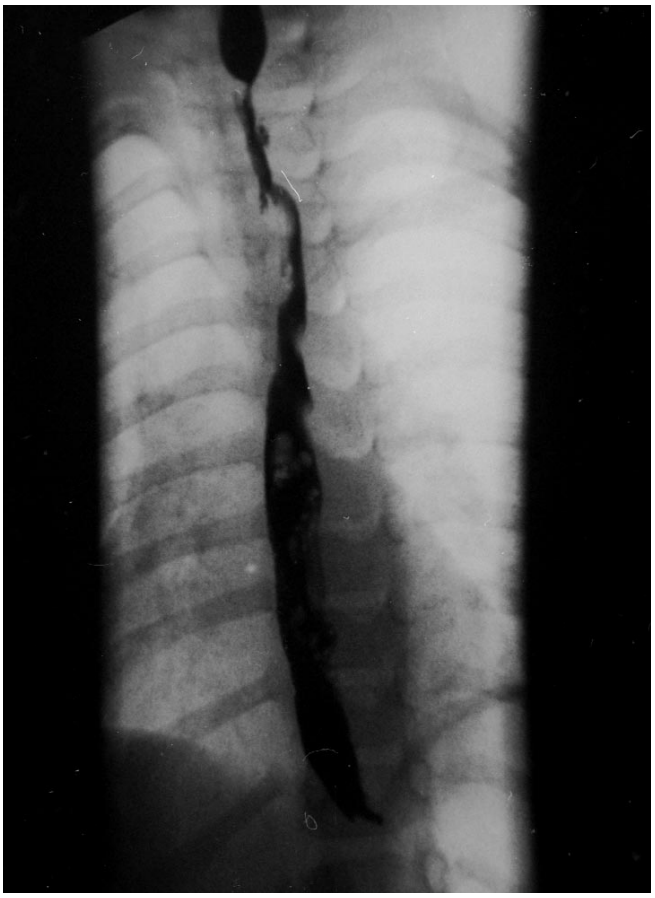

FIGURE 27-9 Severe irregular stricture of the upper third of the esophagus.

tube for gastric lavage is contraindicated because of the risk of aggravation or esophageal perforation. For suspicion of ingestion of bleach or mild household detergents, endoscopy is not mandatory, except when signs or symptoms suggest mucosal injury.[2,52,57,61,62]

After admission to the hospital, when severe general symptoms are present in cases of perforation, laryngeal obstruction, or pulmonary edema, immediate treatment consists of resuscitation, airway control, administration of fluid, plasma expanders, or blood. Physicians agree on the necessity of keeping children with severe lesions under strict surveillance in an intensive care unit during the first week after the accident. Early surgical treatment in cases of esophageal or gastric perforation or laryngeal edema, or for feeding gastrostomy in cases of very severe injury, is rarely indicated.[65] Emergency esophagectomy is indicated only if massive quantities of a strong caustic agent are ingested with esophageal necrosis, occurring almost exclusively in intentional ingestion. Gastric resection, if indicated, must be sparse and limited to the antrum if possible.[52]

When no burns or grade I lesions are present on endoscopy, no treatment is indicated, and the patient is discharged. Children with grade II-A lesions can be observed for 1 to 3 days in the hospital. In some centers, they receive no treatment, but in others, they are given an oral broad-spectrum antibiotic and, in some cases, antacids or histamine$_2$ (H_2) blockers.[2]

Once definitive evidence of grade II-B or grade III lesions is established, treatment of esophageal lesions is directed toward the prevention of stricture formation. Optimal nutrition is imperative during the acute healing phase.[2,52,54,56] Liquids are given by mouth as soon as the child is able to swallow. Oral intake, if possible, is started with antacids and dairy products. The diet is progressively increased as tolerated. If the patient is unable to eat, feeding gastrostomy or parenteral nutrition is indicated. Total parenteral nutrition is sometimes given systematically in grade II and III lesions for at least 3 weeks and continued if there is still no healing of the lesions.[68]

The treatment regimen of significant caustic esophagitis seems to have less influence on the development of stricture formation than the degree of injury immediately after ingestion. Several treatment regimens have been recommended. Since the early 1950s, evidence from animal experiments has shown that systemic or locally injected steroids prevent stricture formation, although a high mortality resulted from infections.[52,56,66] Steroid treatment, prednisone 2 mg/kg or its equivalent, has since been widely used but also rejected as a therapy because of lack of proof of efficiency or because of the risk of bacterial infection, serious varicella infection, or suppression of the hypothalamic-pituitary function.[2,52,54–56] In a review of 14 clinical studies,[69] in which over 2,000 patients were involved, and in a more recent controlled study,[64] no significant difference could be shown in the incidence of stricture formation between the patients treated with steroids and those not treated. Following the beneficial results of early treatment with high-dose steroids in spinal cord injury, a study was conducted in which patients with severe caustic esophageal lesions were treated with dexamethasone 1 mg/kg/d.[70] Compared with those treated with prednisone 2 mg/kg, the patients receiving high doses of dexamethasone developed less esophageal stricture. However, patients in this group had less severe lesions than the patients in the other groups. On the other hand, there was a marked reduction in the number of dilatations needed to treat stricture formation when the high-dose dexamethasone was given immediately after the dilatation. In continuation of this experimental protocol, Cadranel coordinated a study reported by Beddabi in three pediatric gastroenterology centers (two in Tunisia and one in Belgium) in which only grade 3 caustic esophagitis was considered[71]; the children were treated either following classic management without steroids (n = 15) or with daily intravenous shots of 1,000 mg/1.73 m^2 of methylprednisolone (n = 21) for 6 to 12 days, depending on the results of the endoscopic follow-up after 1 week. Of those children managed classically, 14 of 15 developed a secondary stricture; on the other hand, a prevention of secondary stricture was observed in 15 of 21 children managed with early high doses of steroids. This protocol has been enlarged to a working group of the French Speaking Society of Pediatric Hepatology, Gastroenterology, and Nutrition; at the present time, more than 40 children with severe corrosive esophagitis were treated, with a 75% success rate in prevention of stricture formation (J. P. Olives, unpublished data, 2003).

The use of antibiotics is also controversial.[65] In all cases in which steroids are included in the therapy, antibiotics are associated with the prevention of infection.[2,52] In some reports, antibiotics without steroid treatment are used, whether systematically or if indicated.[52,58,68] However, bacteremia does not occur even in severe reflux esophagitis, and it is very rare in caustic lesions, except in cases of perforation. It can occur, although rarely, after esophageal dilatation. If antibiotics are used, mostly ampicillin 50 to 100 mg/kg/d is given.[2,52] Because caustic injury causes esophageal dysmotility and gastroesophageal reflux, antacids and H_2-blocking agents are indicated.[52,54]

The use of an esophageal stent to prevent stricture formation was tried in cats and later in a clinical setting in the 1970s.[52,72] It has since then been widely used with variable degrees of success in preventing stricture formation.[2,52,54] The rationale is that stenting inhibits synechial formation in ulcerated zones, inhibits excessive granuloma formation and retraction of fibrous tissue, and facilitates epithelialization. It is believed to give a continuous, atraumatic, and early dilatation; it permits gastric feeding, facilitates later dilatation if necessary, and can avoid gastrostomy. Stenting was performed in the past with a silicone rubber nasogastric tube. Poor tolerance of the stent has been reported.[52] More recently, expending stent devices inserted through the endoscope have been tried with success. The stent must be kept in situ for 3 to 4 weeks, although durations of up to 3 months have been reported.[52] Stenting is also used in combination with steroids. Possible disadvantages of stenting are its enhancing gastroesophageal reflux and inflammatory reaction, thus provoking stenosis or delaying healing. Furthermore, there is a risk of perforation when placed blind.[52]

Gastrostomy, whether or not in combination with a stent, is performed in severe burns to allow feeding and to facilitate dilatation. Additionally, it allows superficial exploration of the stomach.

Endoscopic or radiographic evaluation after 2 to 3 weeks establishes healing of the lesions or development to stricture formation. If no healing of the lesions occurred, the treatment has to be continued. If stricture formation is developing, dilatation is initiated. This should not be started before 1 to 2 months after ingestion. If performed at high enough a frequency, it can avoid major surgery. Dilatations have been performed in an antegrade way with Eder-Puestow dilators, Savary bougies, and mercury-filled Hurst-Maloney bougies or in a retrograde way with Tucker dilators using an endless guidewire via a gastrostomy.[2,52,54,55] Recent studies have shown no difference between bougienage or balloon dilatation regarding the risk of esophageal perforation, although the balloon technique seems less hazardous and more efficient.[2,52] Septicemia, brain abscess, and meningitis have been reported in children after dilatation of the esophagus for stenosis after caustic ingestion.[72] Dilatation is performed under general anesthesia; it is repeated every 2 or 3 weeks, if possible, starting at every new session with the size that was used when the last session was stopped.[52,72] When the dilatation progresses, the frequency is reduced and, according to the result, is eventually stopped. The goal of the treatment is to dilate so that the child is able to take a normal diet by mouth. However, dysphagia, a common symptom in esophageal stricture, does not correlate with the esophageal caliber but with the esophageal transit time, as measured by scintigraphy, and with the esophageal function, as measured by manometry.[66,67] Complications of esophageal dilatations are traumatic perforation and tracheoesophageal fistula. When serious complications occur, the dilatations should be interrupted.[52,72] Dilatation is not indicated in patients showing clear evidence of developing severe extended stenosis, even early after ingestion, or in patients not able to swallow saliva. Some patients need ongoing dilatations. Failure of dilatation is defined as the need for continuous dilatation after completion of a 12- to 18-month dilatation program or as the psychological burden on the child has become too important.[2,52] Recently, very promising results have been reported by Afsal's group in London using topical mitomycin C for the prevention of restenosis after dilatation in the management of intransigent esophageal strictures.[73] Alternative ways of stricture treatment are resection of the stenosis, which proved to be inefficient, and parietal fibrosis resection. Failure to obtain a sufficient dilatation is considered an indication for esophageal replacement.[52]

Esophageal replacement should not be performed within 6 months after conservative treatment.[2,52] Colonic interposition is the most frequent therapeutic procedure, but other techniques (eg, gastric interposition or gastric tube formation) are also used. Gastric tube formation can be performed only if there is no gastric lesion. The colon transversum and the left or right hemicolon are anastomosed in an isoperistaltic or an antiperistaltic way.[2,52] The antiperistaltic anastomosis is preferred by some because it inhibits gastroesophageal reflux, although it appears to make very little functional difference. Additionally, pyloroplasty, Nissen fundoplication, or an anterior cologastric anastomosis can be performed to prevent reflux.[52] Perioperative or early postoperative complications are perforation or torsion of the colonic transplant, ischemia of the colon, tracheal tear, pneumothorax, cervical hematoma, and redundancy of the colon. The most frequent late complications are anastomotic leak or fistula, cervical anastomotic stenosis, anastomotic bleeding, and gastroesophageal reflux but also pyloric stenosis, transient dumping syndrome, eventration, and mediastinitis. There is some discussion as to whether esophagectomy should be performed simultaneously with the esophageal replacement.[2,52] Because patients with severe esophageal stricture are at risk for malnutrition, adequate nutrition during the pre- and postoperative period is crucial.[52]

Risks of Cancer

Carcinoma of the esophagus occurs in a thousandfold increased incidence in patients with a history of caustic lesion.[54] According to different series, the percentage of caustic esophageal lesions in which carcinoma eventually develops is 1 to 2%, up to 5%, but figures as high as 20 to 30% have been cited.[2,52] In a large series of 846 patients with esophageal squamous cell carcinoma registered between 1941 and 1981, 12 (1.4%) had previously ingested a caustic agent.[74] In another series of 2,414 patients with carcinoma of the esophagus, aged 28 to 79 years and registered between 1945 and 1970, 63 had ingested lye at the age of 0 to 56 years.[75] The time interval between the ingestion and the diagnosis of carcinoma was 13 to 71 years. The latent time between the corrosive accident and the diagnosis inversely correlated with the age at the time of ingestion. Carcinoma can also develop in the isolated strictured esophagus, left in situ after replacement therapy.[52] The risk of malignancy has led some authors to strongly advocate early surgery in severe caustic esophageal injury, even in children.[2,52] A major contributory factor in the evolution to malignancy after caustic esophageal injury possibly is repeated stricture dilatation. It is therefore recommended to limit the duration of dilatation therapy.

THERMIC AND ELECTRIC BURNS

Burns may follow the drinking of hot beverages. In infants, intensive warming up of bottles may induce acute burns of the throat or esophagus. Because microwave ovens rapidly cook through to the center of heated foods, children may suffer esophageal burns, not appreciating that the interior of a heated dish is intensely hot, although the outer covering is only moderately warm.[76]

Electrical burns of the esophagus in adults have been reported in situations of esophageal temperature monitoring during general anesthesia. Experimentally, they have been produced during pill electrode transesophageal pacing when current levels above 75 mA are applied over a period of less than 30 minutes. A deliberate electrical burn

followed by stricture was reported in a suicide attempt by ingestion of an active electrical wire.[2] Electrical burns of the esophagus in children are extremely rare. Charged disk-shaped or cylindrical batteries may produce a direct flow of 1.5 to 3.0 V current. Low-voltage burns have been described with batteries lodged in the esophagus; endoscopy showed lesions ranging from mucosal edema to necrotic or hemorrhagic deep ulcerations.[2,45] In experimental studies in animals, esophageal damage occurs rapidly, and burns are noted 1 hour after contact with the mucosa; lesions of the submucosa and the muscle layers were noticed after 8 hours.[2]

RADIATION-INDUCED INJURY

Because some children need radiation therapy for thoracic tumors, the risk of esophageal damage is important, although the esophagus has been considered relatively radioresistant for a long time. Deleterious effect is enhanced by the combined effect of chemotherapeutic agents.

Pathologic examination of samples of irradiated esophagus shows early degenerative changes: inhibition of mitosis in the germinal cells of the squamous epithelium and dilation of the capillaries with edema and leukocytic infiltration. Epithelial cells may slough, and some glandular cells are distended with secretions, whereas others are atrophic. Endothelial cells proliferate. Regeneration begins at the end of therapy and continues for 3 or more months. Late effects are dependent on the dose, length of irradiation, and length of the esophagus exposed to it. Injury results from damage to capillaries and disturbances of microcirculation in the tissues, causing tissue hypoxia, "oxidative stress," and loss of parenchymal cells.[2] The most frequent complications are altered motility, ulcerations, pseudodiverticula, and stricture owing to fibrosis of the lamina propria and submucosa.[77–79] Secondary changes such as altered motility and stricture may occur 10 to 15 years later.[79,80] These chronic lesions are secondary to subepithelial and arteriolar-capillary fibrosis, causing epithelial atrophy and ulcerations. Chronic ulceration, fistula, and stenosis may be late complications. Esophageal squamous cell carcinoma is a late complication and, in one instance, developed 30 years after mediastinal irradiation.[81]

SYMPTOMS

Acute manifestations of radiation-induced damage are mucositis, dysphagia, and odynophagia, which can appear 10 to 12 days after the beginning of therapy. Some patients experience occasional sharp chest pains that radiate to the back and may be lessened by interruption of treatment for 2 or up to 7 to 10 days. Radiologic examination of the esophagus at this time may show fine mucosal serrations and absence of primary peristalsis. Radiologic double-contrast studies, which are more sensitive than single-contrast ones, performed 13 to 87 days after the initiation of therapy showed multiple, small, discrete ulcers and a granular appearance of the mucosa; in 13 asymptomatic patients investigated at the end of this period, 3 developed significant strictures.[82]

TREATMENT

Treatment during irradiation with sucralfate alone has been of limited efficacy in the treatment of esophagitis, particularly if used after the onset of symptoms. The combination of sucralfate given all along the therapy with fluconazole initiated during the fourth week of treatment seems to diminish oral discomfort and pain.[2] Treatment for acute esophagitis consists of viscous xylocaine, diphenhydramine for topical anesthesia, and the use of an antacid containing metoclopromide, bethanechol, or nifedipine. Experimentally, indomethacin and aspirin have proven protective in preventing esophagitis in pretreated experimental animals, presumably through the release of prostaglandin leukotriene and cytokines. Strictures are treated by stenting, bougienage, or balloon dilatation.

PILL-INDUCED ESOPHAGEAL INJURY

Esophageal injury caused directly by prolonged mucosal contact with tablets or capsules ingested in therapeutic dosage was first reported in adults in 1970.[83] Since that time, a variety of drugs have been identified as causing esophagitis or obstruction (Table 27-2).[84] Many cases of pill-induced esophageal injury probably remain unrecognized and unreported because most patients fully recover. Medication-induced esophageal injury is obviously rare in children, first, because the presence of an underlying systemic disease or esophageal transit abnormalities is not frequent and, second, because dosage forms and formulation forms are different from those for adults. Pills and gelatin or cellulose capsules have a great tendency to adhere to the esophageal mucosa; on the contrary, aqueous suspensions, syrups, or powders are less likely to stick to the mucosa and to induce esophageal injury.[85] Nevertheless, some cases of drug-induced esophageal damage have been reported in children.[86–88]

In adults, the most common site of esophageal injury has been near the level of the aortic arch, an area characterized by external compression from the arch itself, a tran-

sition from skeletal to smooth muscle, and by physiologic reduction in amplitude of the esophageal peristaltic wave, all of which might contribute to pill retention.

The sharp demarcation of esophageal injury seen in most cases suggests that this injury results from mucosal contact with a potentially caustic agent. This premise is supported first by the fact that 25% of reported patients sensed that the swallowed pill had stuck in the chest and, second, by the occasional observation of pill fragments within a region of injury.[83,84]

About 40% of patients take their pills with little or no fluid, and the primary cause of injury is adherence of the pill to the esophageal mucosa. Further predisposition to injury is decreased salivation and decreased swallowing if the pill is taken at night and if the patient lies down shortly after its ingestion.[2]

Symptoms

Continuous retrosternal pain and dysphagia occur shortly after pill ingestion. Less common are abdominal pain, weight loss, hematemesis, and dehydration. Lesions of the lower esophagus are less frequent, and their symptoms may be erroneously attributed to gastroesophageal reflux. Doxycycline, ferrous sulfate, and emepronium bromide produce an acid pH (less than 3) even when dissolved in water and may injure the buccal mucosa if held in the mouth for a protacted time. Doxycycline further accumulates in the buccal layer of squamous epithelium. Stricture may be an eventual complication of this type of esophageal burn.[2,83]

Endoscopy shows circumferential lesions, well-delineated ulcers, or longitudinal exudate with necrotic epithelial shreds covering linear ulcerations. Histologically, changes vary from intense inflammatory reaction to erosion or necrosis.

Conventional barium studies are positive only in cases with deep ulcerations or strictures. Double-contrast studies may show the discrete, clustered, ovoid ulcerations and subtle mucosal abnormalities of edema and irregularity.

Treatment

To avoid esophageal injury, pills should be taken when upright rather than supine, with adequate water, and not at bedtime when saliva production and swallowing are decreased.[2,83,84] The offending drug should be either discontinued or given in liquid or parenteral form. In patients with severe symptoms, and in a few truly severe cases, intravenous fluids and nutrition may be required. Strictures that develop require dilation.[2]

TRAUMATIC RUPTURE AND PERFORATION OF THE ESOPHAGUS

Esophageal perforation is a rare occurrence in children that can cause considerable diagnostic difficulty. Two etiologic types of rupture can be defined: traumatic and spontaneous.

Traumatic

Children. In children, perforation may occur as a complication of operative procedures, for example, during the process of immobilizing the esophagus to effect hiatal hernia repair or vagotomy, impaction of a sharp foreign body when perforation may occur at the time of its attempted removal, external penetrating injuries, gunshot and stab wounds, indirect trauma to chest and abdomen (automobile injuries), corrosive damage, and compressed air injuries (Figure 27-10).[89] Cardiac massage, neonatal resuscitation, the Heimlich maneuver, improperly positioned seat belts (even in minor accidents), boxing blows to the stomach, and even vomiting sometimes associated with anorexia have led to rupture of the esophagus.[2] Traumatic perforation of the esophagus in children is most commonly a complication of instrumentation: endotracheal intubation, nasogastric tubes, biopsy, dilating procedures, variceal sclerosis, and esophagoscopy.[90] Complications arise during a procedure by blind advancement of the fiberoptic endoscope with failure to maintain the tip of the instrument in the midline, particularly when passing it through the cricopharyngeal lumen.[2] The perforation is usually located on the posterior wall of the esophagus. Balloons used for variceal tamponade or for dilating procedures for stricture or achalasia are less frequent causes of perforation.[91] Sclerosing of esophageal varices has been associated with both hematoma and perforation, with the latter often related to frequent procedures. Perforation occurs in 2 to 6% of patients with pneumatic dilation of the esophagus.[89,91] In a review of esophageal damage after pneumatic esophageal dilation for achalasia, Molina and colleagues reported an incidence of transmural perforation in 4% and of linear mucosal tears in 8% of patients.[91] In a review of perforations encountered after dilations for caustic strictures in 195 patients, Gershman and colleagues found that 75% of perforations occurred during antegrade

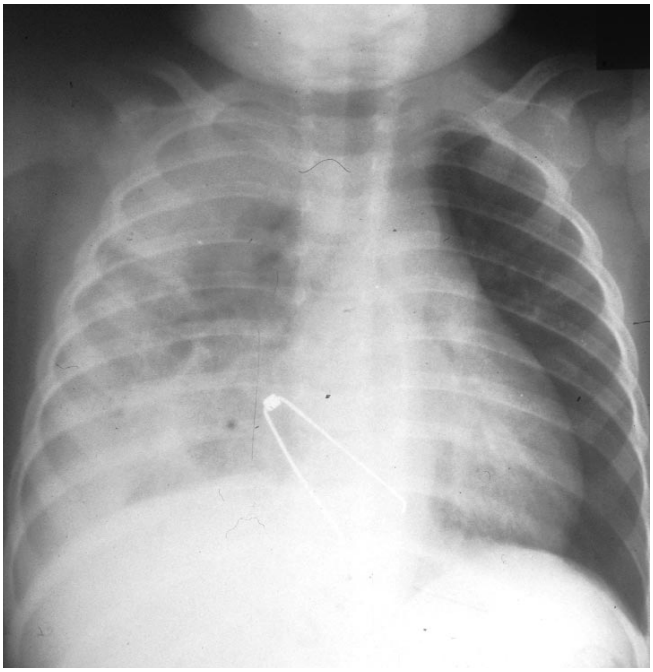

FIGURE 27-10 Perforation of the lower esophagus by a large open safety pin ingested 6 weeks ago. Note the enlargement of the mediastinum and the empyema of the right pleura.

dilations with a stiff woven dilator, and most occurred in the first, second, or third dilations.[92]

Newborns. Although very uncommon, instances of iatrogenic esophageal perforation in the newborn, particularly preterm, have been increasingly reported since the introduction of more intensive resuscitative procedures for low birth weight babies.[93] The injury is usually located in the area of the pharyngoesophageal junction and may be either transmural or intramural (submucosal).

Transmural Perforation. This complication should be suspected in any newborn who develops rapidly increasing respiratory distress. Subcutaneous crepitus of the neck and clinical signs of a pneumothorax may be demonstrable, although they will mostly be difficult to elicit because the patient is likely to be an ill preterm infant under intensive care for respiratory distress syndrome. The esophagus may be torn or perforated by too vigorous suctioning of the neonate in which nonregulated wall suction has been implicated.[2,94] Other causes of neonatal perforation have been stiff suction catheters, nasogastric tubes, traumatic laryngoscopy, or endotracheal intubation.[94] In a review of 12 cases of neonatal pharyngoesophageal perforation, 10 of whom were in premature infants, Bonnard and colleagues noted that repeated attempts at postpartum suctioning, airway intubation, or gastric aspiration preceded perforation.[93] Esophageal atresia was the initial erroneous diagnosis in five cases. Six were treated nonoperatively, five underwent thoracotomy, and one had a gastrostomy. One infant developed an esophageal stricture, and two infants died. A case of esophageal rupture in a 5-month-old child followed inadvertent placement of a Foley gastrostomy tube into the esophagus at the time of tube change. One infant had cervical esophageal rupture as a result of abusive blunt trauma. The esophageal obturator used in cardiopulmonary resuscitation has been the source of perforation owing to distention of the occlusive balloon at the level of the tracheal bifurcation. Similarly, compression of the esophagus by a tracheostomy tube cuff may result in perforation and creation of a tracheoesophageal fistula.

Intramural (Submucosal) Perforation. In some newborns, the esophageal rupture may be incomplete and result in a pseudodiverticulum. Following a mucosal breach, there occurs extensive dissection along the submucosal layer, separating the mucosa from the muscle wall.[2] This separation may extend for a considerable distance along the esophagus. On radiologic examination with contrast medium, both the esophageal lumen and false track may fill, giving the appearance of a double-barreled esophagus or a pseudodiverticulum. There is no pneumothorax.

Clinical presentation can simulate that of esophageal atresia. Affected infants present with excessive outpouring of oral mucus and saliva with immediate choking and cyanosis whenever feeding is attempted; aspiration pneumonia is a common complication. It is usually impossible to pass a nasogastric catheter into the stomach. The differential diagnosis from esophageal atresia is important because treatment is nonsurgical.

Spontaneous

Spontaneous rupture of the esophagus (Boerhaave syndrome) is a well-established entity in adults. In children, the condition is uncommon, but instances of this catastrophe have been reported.[95] All have occurred in the newborn.

The usual story is of a full-term infant who, after appearing well at birth, develops increasing respiratory distress and cyanosis within the first 48 hours owing to the development of a tension pneumothorax.[2] There is typically no preceding history of intubation or other resuscitatory procedures. An initial chest radiograph taken with the infant held upright will reveal a hydropneumothorax or tension pneumothorax; a pneumomediastinum is an unusual finding. Contrast radiography of the esophagus will show extraluminal extravasation of contrast material and will enable the site of rupture to be localized. This is almost always located in the lower esophagus just above the hiatus.

Rupture almost always occurs into the right pleural cavity.[2,95] On chest aspiration, serosanguineous fluid is obtained that may be contaminated with either amniotic fluid or orally administered feed, for example, milk or glucose water.

Early diagnosis and immediate relief of the tension pneumothorax by intercostal drainage and underwater seal are essential to a successful outcome. These measures need to be followed by prompt surgical closure of the esophageal deficit supplemented by broad-spectrum antibiotic, appropriate intravenous fluid therapy, and parenteral nutrition.

In adults, spontaneous rupture usually follows a bout of forceful retching and vomiting. This has led to the theory that in these patients, the cricopharyngeus fails to relax during the act of vomiting, resulting in a sudden, steep rise in intraluminal pressure sufficient to split the relaxed esophageal wall at its lowest and weakest point, that is, the left posterolateral aspect just above the diaphragm.[2] Infants differ in that spontaneous rupture usually occurs into the right pleural cavity, and there is characteristically no preceding history of vomiting.[95] Greater pressures are needed to rupture an infant's esophagus than that of an adult. It is likely, therefore, that in newborn infants, factors other than esophageal overdistention are operative, and the area of esophagus adjacent to a perforation is avascular and friable and shows changes of necrotizing esophagitis. Some form of local devitalizing lesion may thus be an important predisposing factor. It has also been suggested that the cause may be a localized congenital defect in the wall of the esophagus by analogy with cases of spontaneous perforation of the stomach.[95]

Symptoms

The symptoms related to trauma are immediate, whereas those attributable to iatrogenic causes may not be obvious for an hour or more. With endoscopic perforation of the piriform sinus or the cervical esophagus, there is direct extension into the mediastinum. The symptoms are pain and tenderness in the neck, tenderness under the neck, swallowing, tachycardia, and fever. Crepitus usually does not appear for several hours, after fever is evident. Cold water polydipsia is frequent in patients with cervical perforation as an effort to relieve throat discomfort. Perfora-

tions associated with procedures may occur anywhere in the esophagus and are accompanied by pain, fever, and tachycardia. If the thoracic esophagus is perforated, there is chest pain worsened by inspiration or swallowing or on motion, back pain, fever, dyspnea, and tachycardia.[2]

Diagnosis

The diagnosis is made by plain cervical and chest films, which show mediastinal widening[13] or air in the paracervical region or near the esophagus. An esophagogram using a water-soluble contrast will identify the site of perforation in most patients but in only 62% of those with cervical perforation.[2] A barium study may reveal perforation when studies with water-soluble contrast are unremarkable. CT is helpful in demonstrating extraluminal air, periesophageal fluid, esophageal thickening, extraluminal contrast, and mediastinal fluid and air. Endoscopy is the diagnostic procedure of choice to localize precisely a linear mucosal tear or a bluish submucosal mass bulging in the lumen in case of intramural hematoma.

Treatment

The type of treatment varies with the type and location of the perforation and with the condition of the patient and the time elapsed after injury.[2,93] Pharyngoesophageal perforations can be treated successfully with broad-spectrum intravenous antibiotic therapy, peripheral or parenteral nutrition, and no oral feeds. Patients with a penetrating injury of the hypopharynx below the arytenoids or of the cervical esophagus should have neck exploration and drainage.[89] Those with a small esophageal tear and minimal contamination can be treated conservatively. If there is mediastinal air, neck drainage may be necessary, and some feel that mediastinal drainage can be avoided. For large perforations and extensive contamination of the mediastinum and pleura, as from gunshot wounds where there is extensive tissue damage, esophageal exclusion through ligation of the distal esophagus gastrostomy and cervical esophagostomy with parenteral nutrition are the treatment of choice. High gastric fundoplication has also been used effectively to cover a lower esophageal perforation. Perforations of the intrathoracic esophagus that are confined to the mediastinum are treated conservatively, and those of the intra-abdominal esophagus should be treated by closure or diversion, even if this requires esophageal resection.[2,89]

Complications

Fulminant mediastinitis is the major threat in esophageal perforation.[12] Although most often attributable to rupture of the thoracic esophagus, it may also occur in cervical rupture if drainage is delayed and the infection spreads along the periesophageal planes into the mediastinum. Delayed complications are tracheoesophageal, esophagocutaneous, and carotid-esophageal fistula, which may cause important hemorrhage.

Mortality rates for penetrating perforation of the cervical esophagus range from 9 to 15% for those treated immediately to 25% for those in whom treatment was delayed. Patients with perforation after sclerotherapy for esophageal varices are at particularly high risk owing to their underlying liver disease, and in those, mortality may reach 83%. In children, most cases can be closed primarily and the esophagus salvaged, despite late presentation, with a mortality rate of 4%, significantly less than in adults (25–50%). There is little difference in the mortality between iatrogenic perforation and Boerhaave syndrome as long as the diagnosis is made early and the treatment is prompt.[2,95]

MALLORY-WEISS SYNDROME

Although this syndrome of laceration of the esophagus has been reported in few children, its frequency is probably underestimated[2,96] because the diagnosis is confirmed only by endoscopy.

The fissuration of the mucosa results from forceful or prolonged vomiting. The laceration is located at the esophagogastric junction and cardia of the stomach. The tear is sometimes double, extending only through the mucosa along the longitudinal axis of the organ. There is little inflammatory reaction or fibrosis, but some granulation tissue is apparent with healing. Bleeding is most intense when the gastric and the esophageal mucosa are involved.[2]

Symptoms

There is a history of vomiting, either of several episodes or of a duration of several days. Suddenly, the vomitus contains small or large amounts of blood. Dark blood may alternate with bright red blood. In some patients, there is a history of achalasia or hiatus hernia.

Diagnosis

This tear is not detected by radiologic examination. At endoscopy, fresh lesions appear as longitudinal cracks in the mucosa with little inflammatory reaction. They may be so thin as to be missed by the endoscopist so that several passages of the endoscope are often needed to identify them. After 24 hours, the tear will appear as a white, raised streak with some erythema and granulation tissue. If through and through perforation does occur, it involves the distal esophagus.[2]

Treatment

In the majority of children, bleeding stops spontaneously and only rarely does the patient require transfusion, unless there is an underlying coagulopathy. The stomach should be lavaged to prevent gastric distention, and many patients are treated with H_2 antagonists. If hemostasis does not occur, aggressive treatment must be undertaken using vasopressin infusion, balloon tamponade, sclerotherapy ligation, clipping, injection of drugs such as epinephrine or thrombin, bipolar electrocoagulation, neodymium-yttrium-aluminum-garnet laser, or angiographic embolization of the left gastric artery. Endoscopic sclerotherapy using 1:10,000 adrenaline + 1% polydocanol is often successful in achieving hemostasis.[97]

In children, management of bleeding is effective with medical treatment; in contrast, 25% of adults require surgical control of hemorrhage.[2]

ESOPHAGEAL LESIONS IN EPIDERMOLYSIS BULLOSA

Epidermolysis bullosa describes a group of genetically determined mechanobullous disorders that vary in course and severity, ranging from relatively minor disability to death in early infancy. They are characterized by the excessive susceptibility of the skin and mucosa to separate from the underlying tissues following minimal mechanical trauma to form bullae. The affected areas can be considerable in size because the bullae enlarge by expanding and tracking along the natural tissue planes. Like all blisters, they can be extremely painful. A painful cycle of repeated trauma, secondary infection, and subsequent healing, which results in scarring and deformity in those with the dystrophic type of epidermolysis bullosa, leads to a host of complications.[98]

Children with severe forms of epidermolysis bullosa lead very disrupted lives. Those worst affected are disabled and excluded from normal physical activities; they may be unable to attend school regularly, are frequently in pain, and are often admitted to hospital.

Health care professionals who come into contact with children with epidermolysis bullosa should be aware of the general management of the condition and of the necessary techniques to minimize bullae formation and further complications.[2,98]

There are over 20 types of epidermolysis bullosa described, with three major subtypes, dystrophic, simplex, and junctional, with each broad category of epidermolysis bullosa containing several subtypes. Each type of epidermolysis bullosa is distinguished on the basis of the skin level in which the characteristic blistering occurs.[98]

Oral, pharyngeal, and esophageal blistering is common in epidermolysis bullosa. The recurrent blistering leads to progressive contraction of the mouth (causing limited opening) and fixation of the tongue. The associated pain and resulting dysphagia lead to a reduction of nutritional intake because eating is a painful, slow, and exhausting experience. Gastroesophageal reflux is common in patients with epidermolysis bullosa, and esophageal scarring leads to dysmotility and the formation of strictures or webs,[99,100] which contributes to the dysphagia by aggravating oral, pharyngeal, and esophageal ulceration and also by increasing dental decay.[98]

Epidermolysis bullosa sufferers are prone to dental caries owing to oral infection and compounded by poor dental hygiene owing to the pain of teeth brushing. Chronic intraoral infection and gum disease, plus the absence of the normal physical cleansing effect of food owing to a more or less liquid diet often high in sucrose, also contribute. Fixation and shrinkage of the tongue also lead to a loss of normal teeth cleansing.[97]

Diagnosis

Radiologic study is the safest diagnostic procedure, but because strictures may be multiple and often associated with a web, care must be taken in interpreting the data because visualization below a web or stricture is poor. During the phase of active mucosal erosion, there are ulcer niches and detectable edema. Strictures vary from less than 3 mm to several centimeters in length and appear either smooth or irregular.[2]

Treatment

To overcome dysphagia and nutritional problems, bottle-fed infants need the softest available teats. Vitamin and mineral supplements are often required. A nasogastric tube may be used as a short-term measure in severe dysphagia. Gastrostomy (open rather than percutaneous because the endoscope causes significant shearing damage to the oropharynx and esophagus) may be necessary if nutrition cannot be maintained. Good dental hygiene must be encouraged. A conservative approach to dental treatment is taken rather than widespread extraction, but postoperative dysphagia is common, especially after conservation treatment owing to the prolonged duration of the procedure and damage to the throat on removal of the throat pack.[98]

Treatment in the acute bullous stage is aimed at decreasing bullous formation, and nutrition is of primary concern. Corticosteroid therapy is given as large doses of prednisone, 2 mg/kg/d, or the intravenous equivalent of hydrocortisone and usually results in a decrease in dysphagia within 3 to 14 days. Nevertheless, systematic use of corticosteroids should not be recommended. Peripheral parenteral hyperalimentation should be used while treatment is ongoing. After cessation of symptoms, steroids are tapered over 6 to 8 weeks, and oral hyperalimentation is initiated. Antacids and oral antibiotic suspensions also help to minimize symptoms and prevent superinfection.[2]

Dilation of strictures must be performed carefully because mouth injury and esophageal trauma are ever-present hazards. Balloon dilation is now the recommended procedure,[99,100] but perforation is likely to occur. The best results of dilation are in patients whose blistering is minimal because of either quiescence of the disease or of treatment. In those with long strictures, esophagectomy or bypass using right colon interposition or gastric tube replacement has been therapeutic for esophageal symptoms.[2]

CHAPTER 28

CONGENITAL ANOMALIES

Nikhil Thapar, BSc(Hons), BM(Hons), MRCP(UK), MRCPCH
Drucilla J. Roberts, MD

Congenital anomalies of the stomach are very rare as opposed to those of the duodenum or, indeed, the intestine as a whole. Most gastric or duodenal defects are sporadic, isolated, and of unknown etiology, but some are inherited or form part of recognized syndromes. Notable associations include duodenal atresia and trisomy 21. A careful examination looking for associated defects must therefore be carried out and appropriate management instituted. Clinical presentation is variable and depends on the anomaly. In general, given the proximal position in the gastrointestinal tract, feed-associated symptoms predominate and invariably include vomiting and reflux with or without compromise of the respiratory tract. Presentation may be more subtle and diagnosis delayed even to adult life if anomalies are less conspicuous (eg, gastric diaphragm or diverticulum).

Broadly, congenital anomalies can be divided into the following:

- *Atresia and stenosis*. Atresia refers to complete obstruction of the gut either by a membrane or fibrous band or complete separation of the adjacent sections. Stenosis refers to incomplete obstruction caused by intrinsic narrowing of the internal lumen of the gut.
- *Duplications and cysts*. Duplications are cystic or tubular malformations of the gut. They may be multiple and often communicate with and share the blood supply of the adjacent gut. Usually, they are composed of intestinal or ectopic gastric mucosa, submucosa, and smooth muscle coats. Presentation may be delayed until enlargement causes compression of adjacent structures or may be revealed following volvulus, intussusception, or investigation of gastrointestinal hemorrhage or perforation. All duplications should be surgically excised to prevent complications.
- *Abnormal rotation and fixation*. The entire gut assumes its normal postnatal position within the abdominal cavity following a carefully sequenced process of physiologic herniation out of the abdominal cavity in the sixth week of embryonic life. This is followed by elongation, counterclockwise rotation, return into the abdomen in week 10, and fixation of the duodenum and ascending colon to the posterior abdominal wall. Obstruction and volvulus tend to occur when such rotation and fixation are incomplete or abnormal (malrotation) and can lead to ischemia and infarction of the bowel. Total nonrotation results in the duodenojejunal loop on the right and cecocolic loop on the left side of the abdomen. Symptoms and signs at presentation are variable from those of acute obstruction or compromise (eg, volvulus to vague chronic gastrointestinal symptoms).

GENERAL MANAGEMENT

As for most intestinal malformations, surgery is the definitive management. This may be done electively or as an emergency within hours of presentation. Early recognition and diagnosis not only of the defect but of the clinical state of the child, resuscitation, and stabilization of the child are vital. Valuable time is often lost in stabilizing a child for surgery in whom initial resuscitation has been overlooked or inadequate in the eagerness to diagnose and transfer the child. Intravenous fluid, keeping patients nil by mouth, drainage of gastric or intestinal contents by passage of a nasogastric tube, and careful monitoring are the initial management of almost all children presenting with intestinal malformations. Sepsis must always be considered in an unwell baby or child, appropriate microbiologic cultures taken, and antibiotics commenced. Intestinal perforation or intraoperative spillage of contents may occur, and broad-

spectrum antibiotics to cover sepsis from gut organisms are usual during the perioperative period. Postoperative care involves close monitoring and the maintenance of various drains and vascular lines. Recommencement of feeding will depend on the operative procedure undertaken, healing, and clinical signs of recovery of bowel function.

NORMAL EMBRYOLOGIC DEVELOPMENT OF THE STOMACH AND DUODENUM (PATTERN FORMATION AT THE PYLORIC SPHINCTER)

The gastrointestinal tract (or gut) is formed very similarly in all vertebrate species early in embryogenesis. The gut starts out as a simple tube of mesodermal tissue surrounding an endodermal core. Later differentiation results in smooth muscle and epithelial development. Neural tissue in the gut comes from colonization of specialized neural crest cells, which form the enteric nervous system. While these tissues are differentiating, the gut tube develops regional specification both in anatomy (gross and microscopic) and physiology (function). All of these events must occur in proper spatial and temporal order to complete a normal (nonanomalous) gut. Although many of these events are understood at the molecular level, much work needs to be done to understand the coordination of these processes to ensure normal development. In this section, we review what is known about the molecular controls of gut development, focusing on the development of the stomach and duodenum. Our assumption is that the misregulation of these molecular controls results in anomalous development. Although there is no known specific genetic cause of the congenital anomalies we discuss, inferences into their etiology can be derived by understanding the normal genetic controls of stomach and duodenal development.

Early gut tube development is choreographed in synchrony with the turning and folding movements of the embryo during and immediately following gastrulation. Critical in early gut formation is the invagination of the definitive endoderm and the subsequent growth and differentiation of the subjacent splanchnic mesenchyme. A sequence of two invaginations, one at the anterior end (anterior intestinal portal [AIP]) followed temporally closely by a posterior invagination (caudal intestinal portal [CIP]), forms the two ends and begins the internalization of the gut. The endoderm of early gut tube stages is remarkably uniform in its morphology along the length of the primitive gut tube. There are no morphologic differences between the portions of tube formed by elongation of the AIP or by the CIP. The primitive gut tube is lined by a single layer of a cuboidal/columnar endoderm/epithelium and encircled by a thin layer of splanchnic mesoderm. As the mesoderm grows and differentiates into smooth muscle, the gut tube alters its gross morphology, resulting in clear demarcations that have been categorized as the foregut, midgut, and hindgut. These regions can be defined by embryologic, anatomic, vascular, functional, and molecular criteria. Each of the three major gut regions is composed of subregions: esophagus and stomach from foregut, small intestines (duodenum, jejunum, and ileum) from midgut, and colon from hindgut. Boundaries between these regions typically include valves or sphincters (the pyloric sphincter [PS] at the foregut-midgut boundary and the ileocecal valve at the midgut-hindgut boundary). The gross phenotype and the overall "gut plan" along the anteroposterior axis is quite well conserved among all animal species and remarkably so among vertebrates.

Embryologically, the stomach is one of the first structures that differentiates grossly, in nearly all vertebrates, by a left-right axis asymmetry and a hypertrophy or dilatation of the otherwise straight gut tube. The region just caudal to the stomach appears to be clearly demarcated anatomically and molecularly. The small intestines begin distal or posterior to this boundary. The rostral and caudal boundaries of the small intestines are defined in this chapter based on functional and anatomic boundaries that correlate well with molecular expression boundaries[1] and therefore are used as the boundaries for this chapter.

Because much of the work deciphering the molecular controls of gut development has used the chick embryo as a model system, we briefly review the chick gut anatomy. The avian species has a specific adaptation in the stomach region. Avian stomachs are composed of two structures, the proventriculus and the gizzard (Figure 28-1). The anterior chamber, the proventriculus, is the glandular stomach that expresses stomach-specific enzymes such as pepsinogen[2–4] and is therefore most homologous to the human stomach. Posterior to the proventriculus is the gizzard, a specialized avian adaptation to replace mastication that may act as a sphincter as well owing to its muscular anatomy. The gizzard is characterized by thick muscle and a specialized stratified keratinizing squamous epithelium covered by a thick keratin layer.[5] The gizzard at its posteriormost boundary has a specialized region homologous to the human PS. The chick PS can be discerned histologically, anatomically, and molecularly.

The luminal epithelial morphology lags significantly behind the gross gut pattern in its regionally specific differentiation. In some vertebrates, the gut epithelium continues to be plastic, often undergoing functional differentiation after birth before forming the adult phenotype.[6] The gut has the remarkable ability to continue epithelial growth and differentiation throughout the life of the organism along its radial axis. It is this axis in which the regionalization of the gut is often distinguished because morphologic differences are easily discernable.

The PS lies at the caudal end of the foregut at the foregut-midgut boundary (see above). This structure acts as a valve to control the flow of food from the stomach to the small intestines, thereby ensuring proper gastric digestion. The anatomic phenotype and physiologic functional importance of this structure vary considerably among species, but the development of this boundary appears to be remarkably conserved.[7] The molecular boundary (expression limits) of developmentally important factors shows a "hot spot," of sorts, at the PS (Figure 28-2). Many candidate control genes are expressed limited caudally, cranially, or at the PS. Examples include factors with expres-

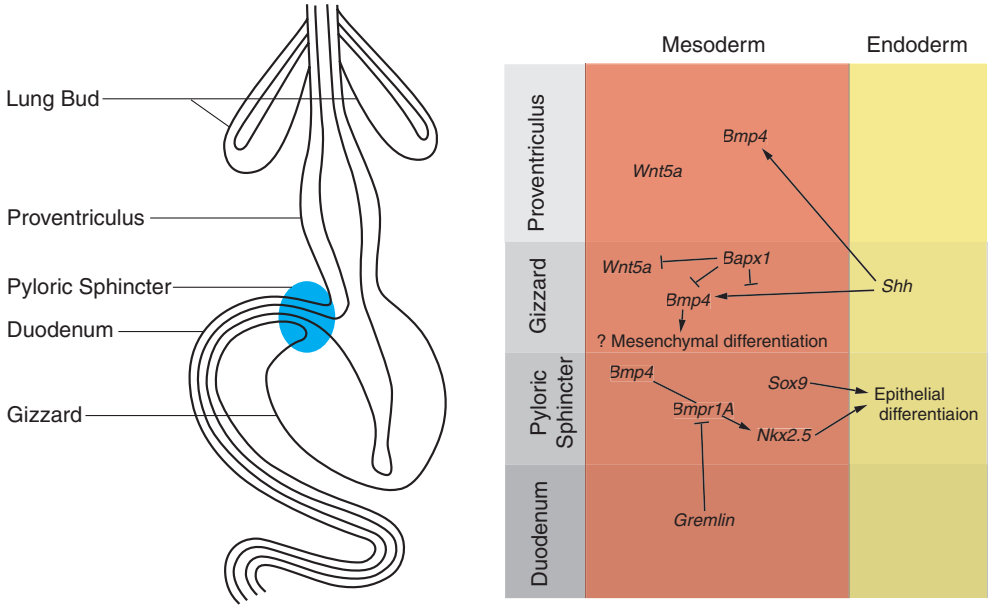

FIGURE 28-1 Cartoon of E7 chick foregut-midgut showing the major structures, with the pyloric sphincter highlighted in blue. Mesodermal (red) and endodermal (yellow) gene expression and proposed model are on the right (see CD-ROM for color image).

sion restricted to the mesoderm anterior to the PS in the stomach (or gizzard), *Bapx1/Nkx3.2*; those restricted to the mesoderm posterior in the small intestine, *Wnt5a* and *Bmp4*; and that crossing the PS, *Nkx2.5*. Additionally, some factors are expressed in the endoderm at this region (those restricted to the PS and posterior, *CdxA* and *Pdx1*; those

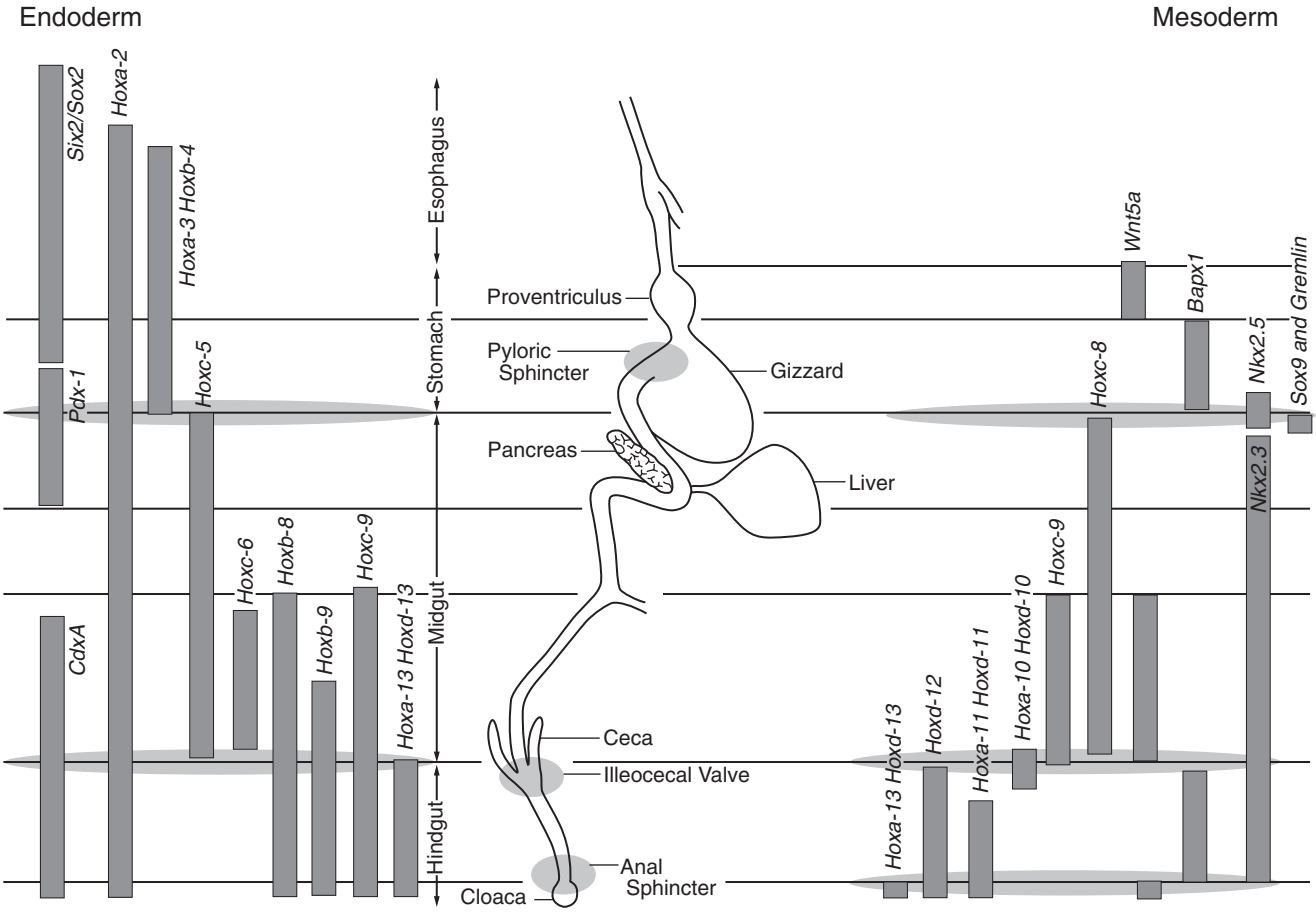

FIGURE 28-2 Cartoon outline of an E10 chick gastrointestinal tract showing major structures. Gene expression boundaries are demarcated by black bars on the right (mesodermal expression) and left (endodermal expression). Adapted from Roberts DJ.[1]

restricted to the PS and anterior, *Sox2* and *Six2*).[1,5,8–11] Other factors are apparently expressed just at the PS: gremlin and Sox9 (data not published).[12]

These expression boundaries appear to be important in ensuring proper development and placement of the PS.[5,8,9] When these expression boundaries are disturbed, the gut develops with malformations in the PS and adjoining structures. These are discussed below, but first a general overview of gut development is necessary.

It has been known for decades that the gut cannot develop normally without an interaction between the endoderm and the mesoderm.[13–15] The direction of these endoderm-mesoderm interactions has been the focus of much investigation. Cultures of primitive foregut endoderm cannot differentiate without coculture with mesodermal tissues.[3] There is a developmental window after which the primitive gut endoderm, although still morphologically undifferentiated, is committed and develops into its regionally specified epithelium when cultured with a variety of tissues, including the vitelline membrane.[16] However, at an earlier developmental time, the ultimate differentiation of primitive endoderm will depend on the anteroposterior region of its adjacent mesoderm. For example, early gizzard endoderm can differentiate as proventricular epithelium if cocultured with proventricular mesoderm.[3] Many studies have confirmed that the mesoderm directs the ultimate epithelial pattern in the gut,[14,17–19] but the endoderm also has inductive capacities. Definitive endoderm cocultured with somitic mesoderm stimulates smooth muscle (splanchnic or visceral) rather than skeletal muscle development as assayed by histology and by induction of visceral mesodermal proteins (eg, tenascin[20] and smooth muscle actin[21,22]). Other factors clearly modulate this interaction, including hormonal and basement membrane proteins.[23,24]

The mesodermal influence on endoderm patterning involves primarily specification of morphology that may not include all of the epithelial cytodifferentiation. Most of the endodermal gut regions studied appear plastic to influence from mesoderm in both morphologic and cytologic differentiation, except for the midgut region. Some midgut-specific epithelial cytodifferentiation appears to have cell-autonomous or cell-specific features. Specific midgut epithelial expression of digestive enzymes is maintained even when influenced by heterologous mesoderm.[2,11,25–27] This difference between the ability of the midgut and foregut endoderm to undergo complete heterologous differentiation may be an endogenous characteristic of the endoderm.

Some of the molecular controls of early endodermal-mesodermal events have been described. *Sonic hedgehog* (*Shh*), a vertebrate homolog of *Drosophila hedgehog* (*hh*), encodes a signaling molecule implicated in mediating patterns in several regions of the embryo.[28–32] *Shh* is expressed in the endoderm of the gut and its derivatives[11,33–38] and is a candidate for an early endodermally derived inductive signal in gut morphogenesis because its earliest endodermal expression is restricted to the endoderm of the AIP and CIP before invagination occurs.[39] *Shh* is not the signal that initiates the invagination of the AIP or CIP because murine null mutants for *Shh* develop a gut, although severe foregut abnormalities are present.[40] These mutants have malformed esophagi with enlarged lumens and disorganized or absent subjacent mesoderm.[34,41] This finding suggests that the endodermally derived signal from *Shh* is involved with mesodermal development, recruitment, or other aspects of mesodermal foregut patterning. Indeed, *Shh* must act as a signal from the endoderm to the mesoderm because its receptor is present only in the gut mesoderm,[11,35,37] and overexpression of *Shh* in the early primitive gut leads to a mesodermal (not endodermal) phenotype.[11]

In each organ in which the endoderm-derived tissue expresses *Shh*, there is closely associated mesenchymal mesoderm that expresses a homolog of *Drosophila's dpp*.[38,39,42] Of the vertebrate homologs of *dpp* expressed in the gut, only *Bmp4* is expressed at the earliest stages of gut development. In the primitive hindgut, at the earliest time *Shh* expression can be detected in the CIP region (even before invagination is apparent), *Bmp4* is expressed in the subjacent mesenchymal mesoderm.[39] In misexpression studies, *Shh* induces *Bmp4* in the splanchnic mesoderm of the developing gut.[11,35,39] An endodermal role of *Shh* is to induce *Bmp4* expression in the splanchnic mesoderm, which then controls aspects of smooth muscle development in the gut.[8,11,35,39] These aspects of patterning also play a key role in the development of the PS and the foregut-midgut boundary.

At early patterning stages (< E7 in the chick), *Bmp4* is expressed in the mesoderm of all regions of the developing gut mesoderm but is excluded from expression in the primitive gizzard.[5,9,11,42] Several bone morphogenetic protein (BMP) receptors are expressed in the intestinal mesoderm in a position to mediate Bmp signaling in this portion of the gut. The type I receptor, *BMPR1B*, is specifically expressed in the gizzard mesoderm from E2.5,[5] despite the fact that no *Bmp* is expressed in the early gizzard mesoderm. With ectopic expression of *Bmp4* early in primitive gizzard development, a thinning of the smooth muscle layer results.[9,11] *Bmp4* may affect the mesoderm by negatively regulating growth and hypertrophy or facilitating differentiation to smooth muscle.[8,9] The factor inhibiting *Bmp4* expression in the gizzard is *Bapx1*, an NK-2 class transcription factor also known as *Nkx3.2*.[9] *Bapx1* has the inverse expression pattern of *Bmp4* in early gut development, expressed only in the gizzard mesoderm from the earliest stages examined.[9] Misexpression of *Bapx1* either anteriorly into the proventriculus or posteriorly into the duodenum results in a gizzard homeosis of these structures (Figure 28-3).[9] The resulting pattern includes transformation of the normally thin-walled muscular proventriculus or duodenum into a thick-walled mesoderm (such as the gizzard), as well as an epithelial transformation from glandular (as in the proventriculus) or villous (as in the duodenum) into gizzard-like stratified squamous epithelium (see Figure 28-3). At the posteriormost boundary of *Bmp4* expressing versus nonexpressing mesoderm, it has been shown that this role of the Bmp signaling system is to pattern the foregut midgut boundary, the PS.[5,8] Signaling by

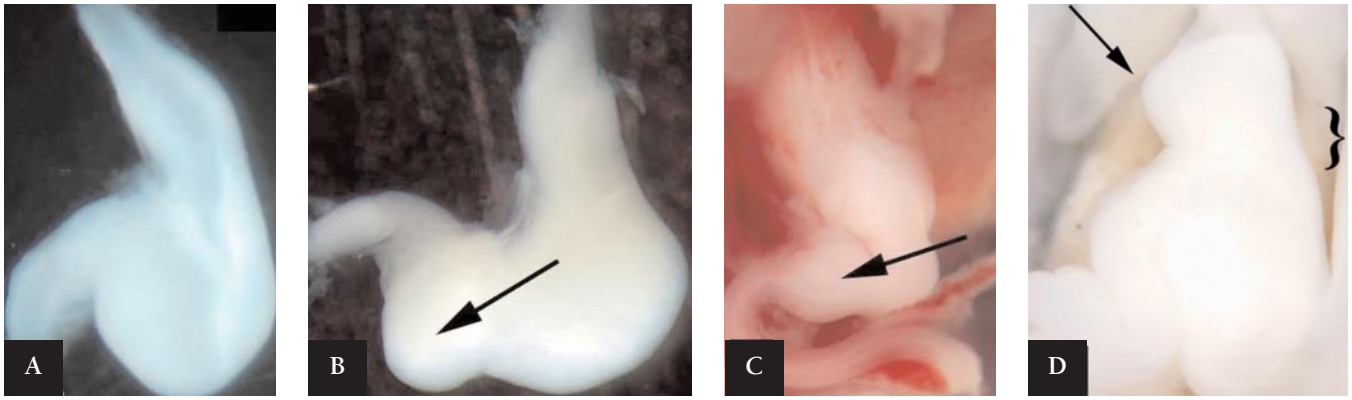

FIGURE 28-3 Panel of E7 chick stomach complexes. *A* is wild type. *B* to *D* are *Bapx1* ectopically expressing regions; *B* and *C* are ectopically expressing *Bapx1* in the duodenum (*arrows* point to enlarged gizzard-like duodena). *D* shows *Bapx1* ectopically expressed in the proventriculus with gizzard-like hypertrophy (*arrow*). The bracket indicates the proventriculus gizzard boundary. Adapted from Nielsen C et al[9] and de Santa Barbara P et al.[90]

Bmp from the avian midgut induces the cells of the adjacent gizzard primordium to form a sphincter,[5] and Bmp signaling is important in the phenotype at this boundary.[9] One of the roles of the Bmp signaling is mediated by induction of a transcription factor necessary for PS formation.

Nkx2.5 is a specific marker for the mesoderm of the pyloric sphincter in the chick embryo (see Figure 28-2). In the early stages, it is expressed adjacent to the *Bmp4*-expressing area and overlaps with the posterior expression domain of *BMPR1B*. By misexpressing *Bmp4* into the primitive chick gizzard using a retrovirus containing the *mBMP-4* complementary deoxyribonucleic acid (DNA), expression of Nkx2.5 was induced, and the PS border was anteriorly shifted.[5] If PS mesodermal *Bmp4* expression was inhibited using a *Noggin* (encoding a specific Bmp antagonist) retrovirus, Nkx2.5 was down-regulated at the border of the gizzard and the small intestine.[5] Because the Noggin-infected embryos did not survive long enough to allow morphologic analysis, the presence or absence of the PS could not be determined.[5]

Using the same retroviral misexpression system to extend the expression of *Nkx2.5*, the same alteration of the PS placement resulted if *Nkx2.5* was expanded anteriorly. With posterior infection, no alteration in gut patterning was observed.[8] This suggests that other factors are important in regulating PS patterning or responsiveness to *Nkx2.5*. Because there are other known factors expressed differentially at this boundary (see Figure 28-2), one or more of these factors must play a role in PS patterning. Although none of these factors has been *directly* implicated in development of the PS in the avian misexpression studies or in murine null transgenics, midgut malformations have been described in mice in which the anterior limit of expression of *Hoxc-8* is shifted cranially: a portion of foregut epithelium misdifferentiates as midgut.[43] This can be interpreted as shifting the foregut-midgut boundary anteriorly, although in this study, the PS as an anatomic structure was not described.

Other factors expressed in a spatially temporally mediated manner at or near the PS likely also play a role in the development of this structure. Mutations in any of them may play a role in the development of PS malformations, as discussed above.

CONGENITAL ANOMALIES OF THE STOMACH

Gastric Atresia or Stenosis

This most commonly affects the pylorus or antrum of the stomach and occurs either as a true atresia of the stomach or secondary to complete or partial occlusion of the lumen by a circumferential mucosal membrane or diaphragm. Overall, these conditions are extremely rare, accounting for approximately 1% of intestinal atresias, with an incidence of 1 in 100,000 newborns.[44,45] Embryologic events leading to these defects are not clear. Most cases are sporadic, but some may be inherited as autosomal recessive. Although a specific genetic cause of this anomaly has yet to be described, one can hypothesize that misregulation of the BMP signaling pathway may play a role because experimental inhibition of signaling results in a hypertrophied muscle at this region.[5,8,9] Defects can be isolated or occur in association with other genetic defects (eg, junctional epidermolysis bullosa, multiple intestinal atresias, Down syndrome, or aplasia cutis congenita).[46,47] Obstruction of the gastric outlet may be caused by extrinsic pressure from annular pancreatic tissue or congenital peritoneal bands.

Clinical Presentation. Onset of symptoms will depend on the degree of gastric outlet obstruction. Complete obstruction results in persistent nonbilious vomiting within a few hours of birth, whereas in cases of partial obstruction (eg, secondary to membranes, stenosis, or duplication cysts), symptoms may not appear until childhood or even adulthood. Upper abdominal distention may be present, and recurrent vomiting may result in metabolic derangement similar to hypertrophic pyloric stenosis. In incomplete obstruction, failure to thrive and upper abdominal discomfort may also occur. In association with multiple atresias of the small and large bowel or with epidermolysis bullosa letalis, the outcome is usually fatal.

Diagnosis. In cases of complete obstruction, plain abdominal radiography reveals a "single bubble" appearance with a large distended stomach and absence of distal intestinal gas.

Together with the symptoms, this is very suggestive of gastric atresia, and contrast studies are often unnecessary. In partial obstruction, additional studies using contrast and/or ultrasonography are valuable. An incomplete prepyloric membrane is seen as a thin, linear filling defect on contrast studies. On a sonogram, this appears as an echogenic band extending centrally from the lesser and greater curvatures in the prepyloric region.[48] Endoscopy may be used to directly visualize the defect, and gastric emptying studies may aid diagnosis.

Management. If the defect is a thin membrane, excision along with pyloroplasty is the treatment of choice. More complex atresias may require resection and formation of a gastroduodenostomy, pyloroplasty, or, less commonly, gastrojejunostomy. The stomach is kept decompressed postsurgery, and enteral nutrition is commenced in the first week in the absence of complications. If there is little delay of gastric emptying, conservative management consisting of low-residue feeds and gastric emptying drugs may be successful, although careful long-term follow-up is essential. Surgery involves complete excision, or endoscopic transection, of the web. Balloon dilatation and laser ablation are newer therapies. Complications are minimal. Other bowel atresias should be excluded

Gastric Duplication

Foregut duplications (esophagus, stomach, and duodenum) account for approximately one-third of all congenital duplications of the gastrointestinal tract,[49] with gastric duplications accounting for between approximately 4 and 8%.[50,51] They are more common in females. Gastric duplications occur most commonly along the greater curvature but can arise from the posterior or anterior wall or pylorus. They usually share a common blood supply and outer smooth muscle coat with the stomach, although most do not communicate with the gastric lumen. Duplication cysts are most commonly lined with gastric or other alimentary-type epithelium, but respiratory-type epithelial lining has been described.[52] Associated anomalies are common and reported in approximately 50% of patients.[53] These include other intestinal tract duplications, most commonly esophageal and vertebral anomalies, and aberrant pancreatic development.[54,55] Although the exact embryologic mechanism is not known, various theories have been proposed, including the "split notochord theory."[53]

Clinical Presentation. Presentation classically occurs in infancy, although presentation at any age is possible. Symptoms depend on the size and location of the cyst and any communication. Common symptoms are vomiting (classically nonbilious), weight loss, failure to thrive, and abdominal pain and distention. An abdominal mass may be palpable on examination. Pyloric duplication may be mistakenly diagnosed as hypertrophic pyloric stenosis. Enlargement of the cysts can present with obstruction of gastric emptying or compression of adjacent structures. Ulceration, bleeding, or inflammation of the mucosa within the cyst or of the adjacent gut results in either local complications, overt gastrointestinal hemorrhage, or perforation with peritonitis or fistula formation. Ectopic pancreatic tissue is common in gastric duplications and may be associated with raised amylase levels and pancreatitis.

Diagnosis. Duplications are often difficult to diagnose preoperatively. Plain abdominal radiography may reveal a soft tissue mass, and ultrasonography is useful to reveal the cystic nature of the duplication. Contrast studies may reveal the presence of a mass with displacement of adjacent bowel and is useful if a communication exists with the lumen of the gastrointestinal tract. Direct visualization of the mass by endoscopy has also been used.[56] Computed tomography is often used to define the nature and location of duplication cysts, but endoscopic ultrasonography and magnetic resonance imaging are becoming increasingly popular.[57] The presence of an echogenic inner rim and hypoechoic outer muscle layers is very suggestive of a duplication.[58] Prenatal diagnosis of gastric duplications by ultrasonography or magnetic resonance imaging has been reported.[59,60]

Management. Excision of the duplication cyst is the treatment of choice and can be done with minimal loss of adjacent normal stomach, although the common vasculature and wall often complicate this. A communication can be created between the cyst and gastric lumen. In complete or tubular duplications, the normal stomach can be preserved by stripping the mucosal lining, along with variable excision of the cyst. Resection of aberrant or ectopic pancreatic tissue may also be required. Laparoscopic resection of gastric duplication cysts has been reported.[61] The outcome following surgery is usually excellent.

Gastric Volvulus

Gastric volvulus was first described by Berti in 1866 and is thought to be relatively rare in the newborn period and in infancy,[62,63] although in its chronic form, it is likely to be underdiagnosed.[64] Recognition is essential, however, because it constitutes a surgical emergency. In normality, the stomach is resistant to abnormal rotation, being fixed at the gastroesophageal junction and pylorus, in addition to four gastric ligaments. As a result, congenital gastric volvulus is associated with disruption of one or more of these, although in a proportion, no cause is identified.[65] Gastric volvulus results in abnormal rotation of one part of the stomach around another, with resulting obstruction at the pylorus or cardia and possible ischemia. This rotation is either organoaxial (around the longitudinal esophagogastric-pyloric axis), mesentroaxial (around a transverse axis through the greater and lesser curvatures), or combined.[63,66] The majority of congenital gastric volvuli are secondary to gastric malfixation, especially at the gastroesophageal junction, diaphragmatic complications (eg, congenital diaphragmatic hernia), and absence or laxity of gastric ligaments.[63,67,68] Splenic anomalies are common.

Clinical Presentation. Gastric volvulus in childhood tends to present within the first few months of life, with symptoms depending on the degree of rotation and obstruc-

tion.[64,69] Classic symptoms of Borchardt triad (unproductive retching, localized epigastric distention, inability to pass a nasogastric tube) may be difficult to elicit in younger children, and Borchardt triad should be considered in the presence of other chronic symptoms (eg, gastroesophageal reflux, recurrent vomiting, failure to thrive).

Diagnosis. Radiographic features are most reliable for diagnosis, showing abnormalities in the position and contour of the stomach in the abdomen or chest and position of the pylorus in relation to the gastroesophageal junction.[63,70,71] Contrast studies may be more informative.

Management. Acute gastric volvulus, especially intrathoracic, is a surgical emergency to prevent gastric ischemia, necrosis, and perforation and to prevent cardiorespiratory compromise. At surgery, the volvulus is reduced, and the viability of the stomach is assessed. If the stomach is viable, it is fixed by gastropexy to the abdominal wall, or a gastrostomy is fashioned. Repair of any associated defects (eg, diaphragmatic defects) is undertaken. Successful laparoscopic surgery has been reported in acute gastric volvulus.[72] The treatment of chronic cases remains controversial, although surgery is indicated in persistently symptomatic individuals. Gradual improvement over time has been reported in conjunction with conservative treatment (eg, positioning infants in the prone or upright position after meals) in less affected children.[71]

Microgastria

Microgastria results from a failure of gastric enlargement during embryogenesis, resulting in a tubular stomach of reduced capacity. It is extremely rare, with approximately 45 cases described in the literature since its first description in 1842.[73] It appears to occur sporadically, with a slight female preponderance,[73] and is almost always associated with other congenital anomalies. In a review of the literature, Kroes and Festen could identify only 2 of 39 cases in which microgastria appeared to occur as an isolated defect.[74] The associated malformations include intestinal (84%), cardiovascular (43%), pulmonary (33%), skeletal (31%), urogenital (28%), and neuronal (12%) pathologies,[73] many of which share a mesodermal origin. The predominant anomalies include intestinal malrotation, asplenia, transverse liver, tracheoesophageal anomalies, atrioventricular septal defects, upper limb and spinal deformities, micrognathia (including Pierre Robin sequence), renal dysplasia or aplasia, corpus callosum agenesis, and anophthalmia. Microgastria should be excluded in patients presenting with VACTERL (vertebral, anal, cardiac, tracheal, esophageal, renal, and limb) association and midline defects. The genetic cause of microgastria is unknown, but the BMP signaling pathway may play a role. Overexpression of *Bmp4* results in a microgastria phenotype in the chick.[5,8,9]

Clinical Presentation. Symptoms are mainly related to the markedly reduced capacity of the stomach to retain contents. Thus, postprandial vomiting and gastroesophageal reflux are common, with aspiration leading to recurrent chest infections. Rapid gastric emptying can lead to diarrhea. Nutrition is compromised, and malnutrition, failure to thrive, and growth retardation are very common. Developmental delay is often evident.

Diagnosis. The diagnosis is usually made on the basis of an upper gastrointestinal contrast study, which shows a small, tubular stomach in an abnormal position, usually midline. A dilated, poorly peristaltic esophagus and gastroesophageal reflux are frequently evident. Attention should be given to excluding associated anomalies with appropriate investigations.

Management. Management is designed to ensure adequate nutrition and prevention of aspiration and, if possible, to create an adequate gastric reservoir. Failure to thrive and gastroesophageal reflux are the greatest problems. Surgery is usually attempted only if a feeding strategy of frequent small-volume, high-calorie feeds fails to achieve adequate growth or symptoms of reflux are prominent. Nasojejunal or jejunostomy feeding has also been used, with variable success.[75] The aim of surgery is to increase the capacity and drainage of the stomach and prevent or resolve dilatation of the esophagus as a compensatory reservoir. This can be achieved by attaching a jejunal pouch to the stomach and forming a distal Roux-en-Y jejunojejunostomy (Hunt-Lawrence pouch).[76] Outcome is variable.[74] Associated gastrointestinal anomalies may need correction concurrently.

Gastric Diverticulum

Congenital gastric diverticulae are very uncommon. They occur most commonly in the posterior wall, antrum, and pylorus, usually comprising all layers of the stomach wall. They may be associated with hiatus herniae and aberrant pancreatic tissue.[77] Presentation is usually in adult life, although children may present with recurrent abdominal pain and vomiting.[78] Upper gastrointestinal endoscopy or contrast studies revealing the outpouching are usually sufficient to make the diagnosis. It should be differentiated from ulcers and malignancy. Treatment is by surgical excision.

Complete or Partial Absence of Gastric Muscle

This is a rare condition characterized by complete or partial absence of gastric muscle coats. The body of the stomach is most commonly affected. Muscular agenesis likely has many genetic causes, but it is known that in the gut, the hedgehog-bone morphogenetic protein signaling pathway plays a critical role and may be one of the causes of this rare disorder. Gastric perforation is the main complication, often occurring soon after birth. The clinical presentation is of intestinal perforation, often with cardiovascular collapse. Abdominal distention may be marked and may lead to respiratory compromise. Radiography reveals free intraperitoneal air. Fluid resuscitation with or without emergency decompression of intraperitoneal air may be required prior to surgery.

CONGENITAL ANOMALIES OF THE DUODENUM

Congenital duodenal obstruction most commonly results from duodenal atresia. Other causes include extrinsic compression from annular pancreas, Ladd bands or preduodenal portal vein, midgut volvulus, and duodenal webs.

Duodenal Atresia and Stenosis

The duodenum represents one of the most common sites for atresia in the gastrointestinal tract. The reported incidence for duodenal atresia is approximately 1 in 10,000 to 30,000 live births. Most atresias occur at the level of the ampulla of Vater and the obstruction owing to either a complete mucosal membrane or diaphragm without discontinuity of the muscle coats (type 1) or blind-ending proximal and distal segments of duodenum. These segments are either connected by a fibrous band (type 2) or separated by a gap (type 3). Duodenal stenosis is again the most common of gastrointestinal stenoses and occurs when a hole is present through the mucosal diaphragm.

Embryologically, the cause is thought to be a failure of canalization of the duodenum, which normally occurs after the seventh week of gestation. Although gut atresias are thought to be related to ischemic events early in gut development,[79] genetic causes may also play a role. Associated anomalies are common and occur in about 50% of cases of atresia. The most common is Down syndrome, which is present in one-third of affected infants. Other anomalies include esophageal atresia, midgut malrotation, annular pancreas, and biliary tract, anorectal, cardiac, genitourinary, and vertebral anomalies. Prematurity, intrauterine growth retardation, and polyhydramnios are more common.[80]

Clinical Presentation. Presentation of atresia is within the first few days of life and usually follows the first feed. The major symptom is vomiting, most commonly bile stained, given that most atresias occur distal to the ampulla of Vater. Gastric distention with visible peristalsis may be present, with the former easily reducible by nasogastric aspiration. Abdominal distention is not usual. There is an increased incidence of jaundice. In duodenal stenosis, presentation may be delayed, and recurrent vomiting and failure to thrive are more common symptoms.

Diagnosis. In atresia, the classic radiographic sign is the "double bubble" sign on abdominal radiography, denoting the higher, larger, left-sided stomach bubble together with the lower, smaller, right-sided bubble of the dilated proximal duodenum. No gas is visible throughout the distal intestine. With such an appearance, there is no need for an upper gastrointestinal series, especially because these contrast studies carry the additional risk of gastrointestinal perforation and aspiration of contrast.[48,81,82] Frequent vomiting may result in an absence of air in the stomach and duodenum, making the diagnosis difficult. To confirm the diagnosis in such cases, a small amount of air can be injected into the stomach via a nasogastric tube prior to radiography.[81] Prenatal diagnosis is possible with the use of ultrasonography to demonstrate the presence of a fluid-filled double bubble in the fetal abdomen in association with polyhydramnios.[83] In such cases, the fetal karyotype and a careful search for other anomalies should be instigated. Direct visualization of defects by endoscopy may be useful in the diagnosis of duodenal stenosis, although contrast studies are most useful. A "windsock" sign on contrast studies may be produced when peristalsis and movement of gut content protrude the membrane distally into the lumen of the third or fourth part of the duodenum or even proximal jejunum. The presence of gastric emphysema or duodenal pneumatosis may suggest a diagnosis of duodenal obstruction.[84,85]

Management. Following resuscitation, surgery is performed by laparotomy, although, more recently, laparoscopic surgery, including resection of a duodenal membrane, has been described.[86,87] At surgery, the usual approach is via a supraumbilical transverse abdominal incision. The entire duodenum is visualized by mobilizing the right colon. This allows identification of the obstruction and exclusion of associated malrotation. In malrotation, peritoneal (Ladd) bands extending from the cecum to the right upper quadrant may obstruct the duodenum. A side to side or end to side duodenoduodenostomy or duodenojejunostomy is carried out. Resection of any obstructing membranes is likely to damage the bile duct or pancreatic duct and is therefore usually avoided. The presence of other small bowel atresias is excluded at operation. The stomach and bowel are kept decompressed postoperatively using nasogastric or nasojejunal tubes, which can also be used for feeding. Survival rates are above 90% in the absence of chromosomal or cardiac defects. Long-term follow-up is needed to monitor development of complications such as ulceration and duodenal stasis.

Duodenal Duplication

Duplications of the duodenum are rare. They tend to occur on the mesenteric border of the first two parts of the duodenum. Presenting symptoms usually relate to duodenal obstruction. Ulceration, hemorrhage within the cyst, pancreatitis, and biliary obstruction may also occur. On contrast studies, the duodenum may appear to be compressed by a mass in the concavity of the duodenal C loop.[48] Ultrasonography, computed tomography, and magnetic resonance imaging are useful to further characterize the mass and determine its location. Surgery to excise the duplication may be complicated by its close proximity to the pancreatic and biliary tree.

Gut duplications are fascinating malformations because they are nearly always mesenteric and often have gastric epithelial differentiation.[88] This suggests that the gastric phenotype may be the "default" gut phenotype and occurs when gut development occurs out of the normal spatiotemporal and anatomic controls of development. If this is true, then the molecular controls of stomach development (see Figure 28-2) may be "ectopically" expressed in duplicated regions of gut. Gastric epithelial differentia-

tion does express embryologic factors when present in adults, as in Barrett esophagus and Meckel diverticulum.[89] Investigation of the expression of these factors in duplications of the gut may help in deciphering their etiology.

CHAPTER 29

GASTRITIS

1. Helicobacter pylori *and* Peptic Ulcer Disease

Marion Rowland, MB, MPH
Billy Bourke, MD, FRCPI
Brendan Drumm, MD, FRCPC, FRCPI

GASTRITIS AND PEPTIC ULCER DISEASE

The surface of the gastric mucosa is lined by a simple mucus-secreting columnar epithelium punctuated by gastric pits within which the gastric glands are situated. From a functional and histologic point of view, the stomach can be divided into three areas: cardiac, fundus or oxyntic, and antral, according to the predominant gland type within each zone (Table 29.1-1). In the normal gastric mucosa, the glands are separated by little or no extracellular matrix, and few or no mononuclear cells are present.[1] Gastritis is defined as microscopic evidence of inflammation affecting the gastric mucosa. The intensity of the inflammatory response is variable. Mild mucosal inflammation may be difficult to distinguish from normal mucosa and often requires review by an experienced pathologist.[2,3]

Duodenitis is characterized by the presence of neutrophils in the lamina propria, crypts, or surface epithelium, in addition to an increase in the number of mononuclear cells. There may be associated villous blunting. Duodenitis is graded from mild to severe, depending on the number of neutrophils present. Histologic assessment of the mucosa bordering primary duodenal ulcers usually reveals active duodenitis, and this histologic appearance may also be seen in symptomatic patients without overt ulceration. Therefore, duodenitis and duodenal ulceration likely represent different manifestations of a disease spectrum sharing a common underlying pathogenesis.

Peptic ulcers, by definition, are deep mucosal lesions that disrupt the muscularis mucosa coat of the gastric or duodenal wall.[4] Peptic erosions, on the other hand, are superficial mucosal lesions that do not penetrate the muscularis mucosae. Most gastric ulcers are located on the lesser curvature of the stomach. More than 90% of duodenal ulcers are found within the duodenal bulb.

Gastritis and peptic ulcer disease can be divided into two major categories, primary and secondary, on the basis of the underlying etiology.[5] This division is relevant because the natural history of primary gastroduodenal inflammation or ulceration is different from that of the secondary type.[5] Most cases of primary or unexplained gastritis are now known to be caused by gastric infection with the organism *Helicobacter pylori*.[6–11] Secondary gastritis and secondary ulceration are clinically and often histologically distinct from primary peptic disease.[6] Secondary ulcers may be gastric or duodenal in location and are discussed in Chapter 29.2, "Other Causes."

Gastritis and peptic ulcer disease were previously considered distinct entities. Over the past 20 years, it has come to be understood that these two conditions are closely related. In 1983, Warren and Marshall reported an association between the presence of spiral organisms on the gas-

TABLE 29.1-1 ANATOMY AND PHYSIOLOGY OF THE STOMACH

ANATOMIC/ GLAND AREA	CELL TYPE*	SECRETORY PRODUCTS†
Cardiac	Mucous	Mucus, pepsinogen
	Endocrine	—
Fundus/oxyntic	Parietal	Hydrochloric acid
	Chief	Pepsinogen
	Enterochromaffin	Histamine, serotonin
	G	Gastrin
Antral/pyloric	G	Gastrin
	D	Somatostatin
	Enterochromaffin	Histamine, serotonin

Adapted from Soll AH.[4]
*All three anatomic areas contain mucus-secreting cells in addition to endocrine cells.
†Endocrine cells in the stomach produce a variety of different products. For cells such as enterochromaffin cells and D cells, the secretory product has been identified, whereas the function of others is not as well defined.

tric mucosa and antral gastritis in adults.[12] Subsequent studies in adults and children have confirmed the etiologic role of *H. pylori* in primary antral gastritis and have demonstrated a strong association between *H. pylori*–associated gastritis and duodenal ulcer disease.[6–11]

Duodenal ulcer disease is reported as one of the more common chronic diseases in adults, occurring in 5 to 10% of the population. However, the prevalence of peptic ulcer disease in all age groups is changing. Duodenal ulcer disease, unusual prior to the turn of the twentieth century, increased steadily in the 1900s, reaching a peak in the 1950s.[13,14] Since then, the incidence of gastric and duodenal ulcers has decreased.[13–15] Nonmalignant primary gastric ulcers are now uncommon in adults.

There are no accurate figures on the incidence of peptic ulcer disease in children. Primary duodenal ulcer disease is very rare in children under 10 years of age, but prevalence increases in adolescence.[6] Large medical centers for children typically diagnose only four to six cases of peptic ulcer disease per year. As the prevalence of *H. pylori* infection decreases, the relative number of non–*H. pylori*–associated duodenal ulcers will increase, but, to date, very few non–*H. pylori*–associated duodenal ulcers have been reported in children.[7,16,17] Primary gastric ulcers rarely, if ever, occur in children.[5]

HISTOLOGIC DIAGNOSIS OF HELIOBACTER PYLORI GASTRITIS

In the past, there has been considerable confusion surrounding the histologic terminology used to classify gastritis. This is due to the use of such terms as "acute," "chronic," and "chronic active" to describe gastritis. The Sydney classification of gastritis aims to incorporate topographic, morphologic, and etiologic information into a clinically relevant scheme.[18,19] This classification and grading, which now incorporates the use of a visual analogue scale,[20] is accepted as the standard method by which all gastric biopsies from adult patients should be assessed. Classification is based on the location (antrum or corpus) and presence of a number of histologic parameters that are graded semiquantitatively as mild, moderate, or marked. These parameters are inflammation, activity, atrophy, intestinal metaplasia, and *H. pylori* infection.

When the Sydney system is used, it is recommended that two antral biopsies from within 2 to 3 cm of the pylorus, two corpus biopsies, and one biopsy from the incisura be obtained at endoscopy. The usefulness of the updated Sydney classification in a pediatric setting has not been formally assessed, but the underlying principles can be applied.

Inflammation and Activity

A precise definition for chronic gastric inflammation is difficult owing to a lack of agreement on the number of mononuclear cells present in the normal gastric mucosa of adults or children.[18] However, chronic inflammation is generally considered to be present if there are more than two to five lymphocytes, plasma cells, and/or macrophages per high-power field.[18] In children with *H. pylori* infection, substantial numbers of plasma cells and lymphocytes are present in mucosal biopsy sections. The inflammatory cell infiltrate is usually superficial in location, with panmucosal inflammation present in a small number of cases.[6,21]

The term "activity" is used to characterize the presence of neutrophils in the gastric biopsy. Neutrophil activity is almost always present in adults in association with *H. pylori* infection, and the density of the intraepithelial neutrophils has been correlated with the extent of mucosal damage.[18] Neutrophils have been identified as early as day 5 in an adult with acute infection,[22] but in children and in animal models, the active or neutrophil component of the histologic response is less than that reported in adults.[6–8,21,23]

Atrophy

Atrophy of the gastric mucosa, defined as loss of glandular tissue, is extremely rare in children.[21,24] When damage to the gastric glands is such that they lose their ability to regenerate, a repair process consisting of fibroblast recruitment and deposition of extracellular matrix occurs. The space previously occupied by the glands becomes replaced by fibrosis.[1] However, the presence of an inflammatory infiltrate and lymphoid follicles in the lamina propria may alter the architecture of the gastric mucosa, particularly in the antrum, where the glands are tortuous. Therefore, it may be difficult to distinguish loss of gastric glands from mere displacement secondary to increased numbers of inflammatory cells. For these reasons, inter- and intraobserver agreement among pathologists for the diagnosis of atrophy is poor.[25,26]

Intestinal Metaplasia and Lymphoid Follicles

Intestinal metaplasia is common in adults with chronic gastritis attributable to any cause and increases in prevalence with disease duration.[20] Intestinal metaplasia is an independent process, and although it is often present with atrophy, these conditions may occur independently. Intestinal metaplasia is rarely, if ever, found in children.

Lymphoid follicles with germinal centers are very suggestive of *H. pylori* infection in adults and children. If specifically sought, they are found in 100% of adult patients with *H. pylori*.[20] However, sampling error may occur unless sufficient biopsy specimens are taken. If lymphoid follicles and inflammation are present in the absence of *H. pylori*, it is likely that the organism has been missed.[20]

Helicobacter pylori

Colonization of the gastric antrum by *H. pylori* is graded as mild, moderate, or marked. In children, the number of bacteria present on the gastric mucosa is usually less than that in adults. Identification of *H. pylori* is facilitated by the use of special staining techniques (see below).

Successful treatment for *H. pylori* is accompanied by rapid and complete disappearance of bacteria and neutrophils. The presence of even a small number of neutrophils after treatment is very suggestive of treatment failure even if *H. pylori* is not identified.[27] Assessment of biopsy specimens for the presence of small numbers of *H. pylori* is

more difficult following treatment.[27] Chronic inflammatory changes may take a year or more to resolve.[27] Lymphoid follicles decrease very slowly and are still present 1 year after treatment. Lymphoid follicles, in the absence of active inflammation in the adjacent mucosa, are strongly suggestive of *H. pylori* eradication.[27]

DISEASES ASSOCIATED WITH HELICOBACTER PYLORI

Gastritis

H. pylori is a gram-negative spiral flagellated bacterium. It is found within and beneath the mucous layer on the gastric epithelium.[6–11] Infection of gastric epithelium has been reported not only in the stomach but also in areas of gastric metaplasia in the duodenum,[28] esophagus (Barrett esophagus),[29,30] and ectopic gastric mucosa at various sites in the gastrointestinal tract, including Meckel diverticulum[31] and the rectum.[32] However, *H. pylori* does not colonize tissue of nongastric origin.

There is strong evidence implicating *H. pylori* as a cause of chronic gastritis in children.[6–9]All children colonized with *H. pylori* have chronic gastritis. *H. pylori* is not an opportunistic colonizer of inflamed gastric tissue[33,34] because children with secondary gastritis owing to Crohn disease or eosinophilic gastritis are not consistently colonized with *H. pylori*. Eradication of *H. pylori* from the gastric mucosa results in healing of gastritis in children[6–8,35] and adults.[36] Further evidence implicating *H. pylori* as a gastric pathogen has come from volunteer studies. Two adult volunteers who ingested the organism developed gastritis, and gastric colonization was demonstrated.[37–39]

Despite the universal presence of chronic gastritis in infected individuals, the majority remain asymptomatic; however, up to 15% of infected individuals will develop peptic ulcer disease, and a further 1 to 5% may develop gastric cancer.[40–42]

Duodenal Ulcer Disease

H. pylori is found on the antral mucosa of almost 90% of children with duodenal ulcer disease.[34] Studies on adult patients have similarly indicated that 80% of individuals with duodenal ulcer disease are colonized with *H. pylori*.[10] Eradication of *H. pylori* from the gastric mucosa leads to long-term healing of duodenal ulcer disease in both adults[43,44] and children.[6–8,35] It is not known why a bacterial infection of the antral mucosa is critical in the pathogenesis of duodenal ulcers or why only a minority of those colonized with *H. pylori* develop ulcers. It has been hypothesized that *H. pylori* colonizes areas of ectopic gastric tissue (gastric metaplasia) in the duodenum, with the subsequent development of duodenal inflammation and possibly ulceration. In children, *H. pylori* infection of the antral mucosa and gastric metaplasia in the duodenum were each found to be significant risk factors for duodenal ulceration.[24,45] The presence of both *H. pylori* in the antrum and gastric metaplasia in the duodenum greatly increases the risk of duodenal disease.[24]

Gastric Ulcer Disease

There is also an association between *H. pylori* antral gastritis and gastric ulcer disease in adults.[10] The organism is found in approximately 60% of adults with gastric ulceration. This lower correlation may be due to the fact that a significant number of gastric ulcers are secondary, being related to drug and other ingestions. Gastric ulceration is extremely rare in children; when it occurs, it is usually secondary.[5,6] Therefore, there are no studies on any possible association between gastric ulceration and the presence of *H. pylori* on the gastric mucosa in children.

Gastric Cancer

Gastric cancer is the second most frequent cancer worldwide and the second leading cause of death from cancer.[46–48] Based on data from seroepidemiologic studies that suggested a two- to sixfold increase in risk for gastric cancer among infected individuals,[49–51] *H. pylori* was classified as a group 1 carcinogen in 1994 by the World Health Organization.[52] Early studies may have underestimated the risk of gastric cancer associated with *H. pylori* infection because later studies using immunoblotting or biopsy-based tests to diagnose infection suggest that the risk of gastric carcinoma may be greater.[53–55] A recent report from Japan, where the prevalence of gastric cancer is extremely high, suggests that up to 5% of *H. pylori*–infected individuals will develop gastric cancer in contrast to noninfected controls.[41] The risk of gastric cancer was highest in patients with corpus-predominant gastritis, gastric atrophy, and intestinal metaplasia. Uemura and colleagues also confirmed the previous findings of Hansson and colleagues[56] that patients with duodenal ulcer disease (who have antral-predominant gastritis rather than pangastritis) do not develop gastric cancer.

There is some evidence that genetic factors have a role in the development of gastric cancer, including a family history in 10 to 15% of cases, an elevated risk among first-degree relatives of gastric cancer patients, and reports of clustering of cases across several generations of the same family.[57–61] Furthermore, there is an increased prevalence of gastric atrophy in the relatives of gastric cancer patients.[62,63] Studies have also demonstrated an association between proinflammatory interleukin (IL)-1 genotypes and gastric cancer,[64–69] which suggests that host genetic factors are important in determining the outcome of infection with *H. pylori*.

Much attention is now focused on the possibility that treatment of *H. pylori* infection will prevent the development of gastric cancer. In a Japanese study, Uemura and colleagues suggest that patients who were not infected or who received treatment for *H. pylori* did not develop gastric cancer.[41] However, the duration of follow-up was much shorter in this group of patients compared with the patients who did develop gastric cancer.[41] Whereas a number of studies have suggested that eradication of infection can reverse atrophy and intestinal metalpasia,[70–72] others suggest that if eradication is to be successful, it must be prior to the development of atrophy because, by definition, atropy is irreversible.[73,74] Randomized trials in adults of

H. pylori eradication for the prevention of gastric cancer are currently in progress worldwide. Although a pilot study in Japan suggests that such studies are feasible, in practice, the Japanese group found that patients infected with *H. pylori* are unwilling to participate in a randomized placebo-controlled trial of cancer prevention.[75]

Mucosa-Associated Lymphoid Tissue Lymphoma

H. pylori has been implicated as an etiologic factor in mucosa-associated lymphoid tissue (MALT) lymphomas of the stomach.[76–78] Normal gastric mucosa is devoid of organized lymphoid tissue. For lymphoma to develop, the gastric wall must first acquire organized lymphoid tissue, which occurs as a reaction to infection with *H. pylori*.[79] Gastric MALT lymphoma is often multifocal, and most tumors are located in the antrum or distal body of the stomach. Eradication of *H. pylori* leads to complete resolution of 75% of gastric MALT lymphomas.[79,80] Staging of the tumor may help to determine the response to anti–*H. pylori* treatment because only those in the early stages respond to treatment.[79] Liu and colleagues demonstrated that MALT lymphomas, regardless of stage of disease, with the translocation t(11;18)(q21;q21) do not respond to *H. pylori* eradication and require conventional chemotherapy.[81] Less commonly, *Helicobacter heilmannii* has been implicated as a cause of MALT lymphoma.[79,82] There have been a number of case reports of MALT lymphoma in children.[83–86]

EPIDEMIOLOGY

It is accepted that *H. pylori*, in common with most enteric infections, is generally acquired in childhood and usually before the age of 5 years.[87–90] In the absence of treatment, infection is usually lifelong.[91–93] Adults rarely become infected with *H. pylori*, with seroconversion rates varying between 0.33 and 0.5% per person-year.[92–94]

Whereas most studies have reported no difference in infection rates between men and women, a large cross-sectional study from Bristol suggests that infection is more prevalent among men than women (29% vs 26%), and this remained statistically significant after controlling for other risk factors of infection.[95] Diseases associated with *H. pylori* infection are historically more common in men.

The major risk factor for infection is poor socioeconomic conditions in childhood.[96–98] In developing countries, the prevalence of infection is as high as 80% in children under 10 years of age.[99] In developed countries, although the overall prevalence of infection in young children is less than 10%, up to 50% of those children living in poor socioeconomic conditions may be infected.[96] Other markers of poverty, such as bed sharing and large sibships, are additional risk factors for infection.

The prevalence of infection increases with age, from 10% at age 10 years to 60% at age 60 years in developed countries.[99] The high prevalence seen in adults is consistent with a birth cohort effect, whereby adults acquired the infection as children because they lived in much poorer socioeconomic circumstances in the last century.[100] As socioeconomic conditions have improved in successive generations in the developed world, the prevalence of *H. pylori* has declined.

The exact age at which infection is acquired has not been determined. Cross-sectional studies in both developed and developing countries indicate that young children are the group that becomes infected. Ethiopian children appear to become infected between 2 and 4 years of age, with 60% of 4-year-old children being infected.[101] In a study from the United Kingdom, 23% of 5-year-old children were infected, and there was only a small increase in the prevalence of infection among 8-year-old children, suggesting that infection was acquired prior to school entry.[87] The rate of infection in children over 5 years of age in a large Chinese study was 1% per year, similar to the rate of infection in adults.[89] A cohort study from the United States again confirmed that most children became infected before the age of 4 years.[90] Malaty and colleagues also suggested that 9 of 58 (15%) children seroreverted during the study period.[90] This would suggest that infection with *H. pylori* may be transient in young children. However, the reproducibility of serologic assays limits their usefulness in longitudinal studies.[102] This would suggest that the seroreversion rates in children and adults are much lower than previously considered. Spontaneous clearance followed by subsequent reacquisition of infection in young children also has been reported using repeat ^{13}C urea breath tests (UBTs). However, it is now accepted that the UBT is not accurate in young children.[103]

There have been a number of individual case reports of *H. pylori* infection in very young children.[104,105] However, under 1 year of age, children rarely become infected with *H. pylori* even when they are exposed to infected mothers.[106] Many groups have reported a high prevalence of *H. pylori*–specific immunoglobulin (Ig)G antibodies in the first few months of life, with subsequent decline by 6 to 12 months.[107,108] Elevated *H. pylori*–specific IgG titers in these children reflect maternal transfer of *H. pylori*–specific antibodies to the fetus.

TRANSMISSION

The mode of transmission of *H. pylori* is poorly understood. A clear understanding of the most common route of *H. pylori* transmission would help elucidate the epidemiology of this infection and is essential for the prevention of infection.

The only known reservoir for *H. pylori* is the human stomach. Person-to-person spread currently appears to be the most likely mode of transmission. Evidence for person-to-person transmission includes clustering of *H. pylori* in families[33] and in institutions for the mentally handicapped.[109] Whether infection is spread from adult to child or from child to child is unknown. In some studies, strain identification using deoxyribonucleic acid (DNA) digest patterns has shown the same strain infecting different members of the same family, suggesting a common source of infection, whereas others have reported colonization by different strains.[110–112] Indirect evidence from a number of studies has suggested that transmission may be from mother to child,[113, 114] whereas other studies have sug-

gested that transmission is more likely from father to child.[115,116] Goodman and Correa suggested that transmission of infection is from older to younger siblings.[117] However, in this study from Columbia, 61% of firstborn children were also infected, which suggests that older siblings are not the only source of infection. In contrast, Tindberg and colleagues suggested that the prevalence of infection among mothers is the most important determinant of infection in children and that day care and school are unlikely sources of infection.[114] They also suggested that socioeconomic status and family size are risk factors for infection only when the mother was infected.

If transmission is from person to person, then the possible routes of transmission are fecal-oral, oral-oral, or gastric-oral. The fastidious growth requirements of *H. pylori* have hindered attempts to establish the relative importance of these potential routes of transmission. Polymerase chain reaction (PCR) is a very sensitive technique for detecting microbial DNA in clinical samples, but the use of PCR on feces, saliva, and dental plaque for the identification of *H. pylori* has limitations. Although a PCR diagnosis confirms the presence of DNA, it does not confirm the presence of viable organisms. Inhibitors present in fecal samples, such as acidic polysaccharides and metabolic products, can interfere with the PCR reaction.[118,119] False-positive reactions can occur because of the presence of unidentified *Helicobacter* species or other urease-producing organisms.

Using a novel approach for stool culture, Thomas and colleagues were the first to report the successful culture of *H. pylori* from feces in 9 of 23 Gambian children under 30 months of age and in 1 adult.[120] Hypochlorhydria occurs in association with acute infection.[22,38,121] It has been speculated that successful culture in these children may have been possible because of gastric hypochlorhydria. In animal studies, Fox and colleagues found that *Helicobacter mustelae* could be detected in the feces of infected ferrets when gastric pH was increased using omeprazole but not when acid secretion was normal.[121]

Using the same technique as Thomas, Kelly and colleagues cultured feces of 12 dyspeptic adults in the United Kingdom.[122] However, *H. pylori* was identified in only 3 of the 12 cultures using PCR. Others have not succeeded in culturing *H. pylori* from the feces of adults by this method.[123,124]

Parsonnet and colleagues failed to culture *H. pylori* from normal stool but cultured *H. pylori* from 7 of 14 infected volunteers following administration of a cathartic.[125] Stools passed late in the catharsis were more likely than early stools to grow *H. pylori*, but the number of organisms present was very low. This further supports the finding of Graham and Osato that *H. pylori* may not survive normal transit through the gastrointestinal tract owing to interference from bile acids.[126]

Oral-oral transmission has also been postulated. *H. pylori* has been cultured on one occasion from saliva,[127] and there are a number of reports of culture from dental plaque.[128–130] The complexity of oral flora is a major drawback in attempting to isolate *H. pylori* from the oral cavity. Evidence against oral-oral transmission is that there is no increased prevalence in teenagers and that *H. pylori* does not appear to be spread between couples.[131,132] Furthermore, although gastroenterologists have a higher prevalence of infection than expected,[133] dentists do not,[134,135] suggesting that exposure to oral secretions is not a risk factor for infection.

Gastric oral transmission has been postulated in young children in whom reflux and regurgitation are common occurrences. Recently, Leung and colleagues have reported isolation of *H. pylori* from vomitus on one occasion in a 6-year-old child.[136] Parsonnet and colleagues cultured *H. pylori* from all 16 infected adult volunteers with organism growths of greater that 1,000 colony-forming units (CFU)/mL of vomitus.[125] *H. pylori* was also cultured from saliva (9 of 16) and from air sampled close to the patient (6 of 16) in this study.[125]

Waterborne transmission has also been investigated. *H. pylori* has been cultured from waste water in Mexico,[137] and there have been a number of reports of PCR identification of *H. pylori* DNA in water from Peru, Sweden, Mexico, and Japan.[138–141] Water as a source of infection is a possibility where drinking water is untreated. It is unlikely that *H. pylori* can persist in treated drinking water systems under normal disinfectant concentrations.[142] However, in developing countries, the possibility of transmission through contaminated water must be considered.

Evidence for vector transmission is based on reports that laboratory houseflies can harbor viable *H. pylori* on their bodies and in their intestinal tracts.[143] *H. pylori* has also been detected in wild houseflies using a PCR assay to detect *H. pylori*–specific isocitrate dehydrogenase.[144] Vector transmission has some biologic plausibility because the midgut of the housefly (*Musca domestica*) has a pH of 3.1 and may be able to provide an ecologic niche for *H. pylori*.[143]

REINFECTION

Adults in developed countries rarely become reinfected with *H. pylori* following successful treatment, with reinfection rates being less than 1% per year.[43,44,145] This low rate of reinfection is not surprising because primary infection in adults is also uncommon. However, a recent study from Bangladesh suggests that reinfection in adults in developing countries may be as high as 13% per annum.[146] Reinfection in children in developed countries is also uncommon.[147–149] In children over 5 years of age, the rate of reinfection was only 2%.[147] This low rate of reinfection prevailed despite continued exposure of the children to *H. pylori*–infected family members (with 65% of siblings and 85% of parents infected).[147] Further studies are required to determine if this low rate also applies to children under 5 years of age.

MECHANISMS OF DISEASE

The mechanisms involved in the spectrum of diseases associated with *H. pylori* infection are not understood. The recent characterization and deposition in the public domain of the complete genomic sequences of two

H. pylori isolates undoubtedly will further the understanding of this organism.[150] The pathogenicity of *H. pylori* appears to result from its ability to (1) synthesize products that directly or indirectly damage the gastric mucosa, (2) cause a persistent inflammatory response, and (3) alter the regulation of acid secretion.[151] The specific bacterial virulence factors and/or host responses that determine the clinical outcome remain largely uncharacterized.

Bacterial Virulence Factors

There are many potential virulence factors that may contribute to the ability of *H. pylori* to induce gastric inflammation and ulcer disease. These include motility, adherence of the organism to the gastric mucosa, urease activity, toxin production, and subversion of host cell signal transduction.[9,152] The potent urease activity of *H. pylori* is an important virulence factor for this organism.[153] Urease-negative *H. pylori* mutants are incapable of colonizing the gastric mucosa in animal models.[153] Urease appears to play a vital role in protecting the bacteria against gastric acid.[154] The UreI protein, expressed from a gene of the urease gene cluster, has been identified as a pH-sensitive urea channel.[155] As the external pH falls, UreI increases urea transport to the bacterial cytoplasmic urease complex, providing the organism with a mechanism to maintain a neutral and viable intracellular pH despite its variable and often highly acidic milieu in the stomach.

Flagella are also important for the virulence of *H. pylori*. Flagella confer motility on the organism, allowing it to move through the gastric mucus.[152] Isogenic mutants that do not express flagella are incapable of colonizing gnotobiotic piglets.[156]

The cytotoxin-associated gene *CagA* has been identified as a possible marker for more virulent *H. pylori* strains.[157] The gene is part of a pathogenicity island (*cag* PAI) on the *H. pylori* genome encoding a so-called type IV secretion apparatus that serves to translocate bacterial products, notably CagA, into host cells.[151] Subversion of host cell processes is an emerging paradigm among bacterial enteric pathogens. In the case of *H. pylori*, it appears that within the host cytoplasm CagA is tyrosine phosphorylated and causes cytoskeletal reorganization in models of infection in vitro.[158]

The precise relevence of CagA translocation to the pathogenesis of *H. pylori*–associated diseases in vivo remains to be defined. The prevalence of CagA-positive strains varies in different parts of the world.[159] In many Western countries, CagA-positive strains are more commonly found in association with peptic ulcer disease than are CagA-negative strains.[160] However, ulcer disease can occur in association with CagA-negative strains. Furthermore, in some parts of the world, almost all strains are CagA positive, but the prevalence of peptic ulcer disease is not increased in these countries. In children, CagA is not a marker for specific disease development.[161–163]

H. pylori strains also differ in their ability to produce vacuolating cytotoxin (VacA). In some studies, toxin-producing strains also have been more commonly associated with ulcer disease.[164,165] However, as with CagA, ulcer disease may occur in association with VacA-negative strains.

H. pylori adheres only to gastric epithelium.[152] This strict tissue tropism suggests the importance of specific adhesion-receptor interaction for the maintenance of bacterial adhesion to the gastric epithelium. Several epithelial structures are potential receptors for *H. pylori*, including lipids, gangliosides, and sulfated carbohydrates.[152] A number of potential adhesins on the bacterial surface have been identified, but there is no convincing evidence to date that any of these potential adhesins or receptors are important in *H. pylori* colonization of the gastric epithelium in vivo.[152]

Host Inflammatory Response

Following infection with *H. pylori*, the human host mounts a strong local and systemic immune response. Despite this immune response, infection persists for life.[91,92] Although how *H. pylori* evades eradication is unknown, evidence is accumulating for a complex interaction between the organism and host defense mechanisms.[151] For example, some strains of *H. pylori* may be able to subvert the normal phagocytic mechanisms of the innate immune system.[166,167] *H. pylori* also has been associated with increased apoptosis and altered proliferation in epithelial cells[168] and may induce inappropriate effector T-cell responses.[151]

IL-8 recruits neutrophils and leukocytes by chemotaxis and then activates them.[169] The severity of the mucosal injury in *H. pylori* gastritis is directly correlated with the extent of neutrophil infiltration,[20] and *H. pylori* has been shown to stimulate IL-8 production in vitro and in gastric epithelial cells in vivo.[170] IL-8 production is enhanced by *cag* PAI *H. pylori* strains and by the presence of *cagE* in particular. In children, *cagE*-positive *H. pylori* strains have been associated with the development of ulcer disease.[171] However, non–*cag*-related bacterial factors also may influence IL-8 production.[172] The exact role of these bacteria-induced inflammatory changes in affecting disease outcome in *H. pylori* infection in vivo is unknown.

Gastric Acid Secretion

Acute infection with *H. pylori* is associated with a transient hypochlorhydria that may last for several months, as demonstrated by volunteer studies[37–39] and by reports of accidental infection.[22] Hypochlorhydria following acute infection has also been demonstrated in animal models.[170,173,174] The mechanism for this hypochlorhydria and its importance in determining colonization of the gastric mucosa are not understood. This acute hypochlorhydria is thought to facilitate transmission of infection.[175] More recently, it has been suggested that hypochlorhydria may become chronic in some people and may not respond to eradication of *H. pylori*.[176]

The gastric antrum plays an important role in the regulation of normal gastric acid secretion (see Table 29.1-1). G cells located within the gastric mucosa and duodenum produce gastrin, which, in turn, stimulates parietal cells to produce acid.[177,178] D cells are found within the antral mucosa in close proximity to G cells and also in the fundal mucosa close to parietal cells. D cells secrete somatostatin, a hormone that inhibits gastrin release and, therefore, acid secretion.[177,178] The factors that control acid secretion are

regulated through complex pathways. Gastrin release is stimulated by cholinergic innervation, gastrin-releasing peptide, and cytokines. If excessive amounts of acid are produced, then somatostatin is released in response to a low intraluminal pH.

H. pylori gastritis causes an increase in gastrin release, which returns to normal following treatment.[177] There is evidence that the increased release of gastrin caused by *H. pylori* is secondary to the infection depleting somatostatin-producing D cells in both adults[179] and children.[180] Eradication of *H. pylori* is associated with an increase in D-cell density and an increase in mucosal somatostatin baseline concentrations in children.[181] Changes in D-cell density and somatostatin levels are characteristic of all children with *H. pylori* gastritis and not just duodenal ulcer patients.[180]

The relationship between chronic *H. pylori* infection and acid secretion is not straightforward.[182,183] There is a large overlap in the levels of acid production between normal noninfected individuals, individuals with *H. pylori* gastritis alone, and individuals with *H. pylori*–associated peptic ulcer disease.[184] Most researchers now accept the fact that basal acid output does not differ markedly between infected and noninfected healthy controls.[177] However, patients with *H. pylori*–associated duodenal ulcer disease have an increased basal and maximal acid output when compared with infected healthy volunteers.[177] This increase in acid output may be due to the increased parietal cell mass seen in duodenal ulcer patients rather than to any direct effect of *H. pylori* on hydrochloric acid production.[183]

Pepsinogen

Oderda and colleagues were the first to report that serum pepsinogen 1 was elevated in children who were infected with *H. pylori* and that following treatment of infection, there was a significant fall in pepsinogen 1 levels.[185] This finding has since been confirmed in adult studies.[186] Earlier reports of a genetic predisposition to hyperpepsinogenemia are probably erroneous and reflect increased pepsinogen levels in several members of the same family owing to clustering of *H. pylori* infection in the family.

SYMPTOMS

Gastritis

There is no evidence that *H. pylori* gastritis in the absence of duodenal ulcer disease causes symptoms in children. *H. pylori* infection occurs frequently in asymptomatic children both in the developed and the developing world, and its eradication is consistently associated with improved symptoms only in children who have duodenal ulcer disease and not in those with gastritis alone.[187] In a large non–hospital-based epidemiologic study, Bode and colleagues have shown that abdominal pain is more common in children who are not infected with *H. pylori* than in those who are infected.[188]

There is no evidence for an association between *H. pylori* infection and recurrent abdominal pain (RAP) in children. RAP is a common condition of childhood, affecting 15% of children between 4 and 16 years of age.[189] In the search for a possible relationship between RAP and *H. pylori*, it is important that there is a clear definition of RAP, as stated by Apley and Naish,[190] and that both the patient and the researcher are unaware of the *H. pylori* status of the child when symptoms are assessed. In a meta-analysis, MacArthur and colleagues found that RAP is not associated with an increased prevalence of *H. pylori*–associated gastritis.[191]

Duodenal Ulcer Disease

Primary duodenal ulcer disease is associated with chronic or recurrent symptoms.[5,35,192,193] Most children present with episodic epigastric pain that is frequently associated with vomiting and nocturnal awakening.[5,35,192,193] When only patients with ulcer disease diagnosed at endoscopy are evaluated, up to 90% of children have abdominal pain, and in 55% of these children, abdominal pain is the sole presenting symptom.[5] However, this pain is often not typical of ulcer-associated pain, as described in adults. For example, a temporal association with mealtimes is present in only 50[194] to 75%[35] of children with duodenal ulcers.

Nocturnal awakening, which should be differentiated from difficulty in falling asleep, is an important feature in distinguishing abdominal pain associated with peptic ulcer disease from RAP.[187] Similarly, recurrent vomiting in association with upper abdominal pain should be considered suggestive of ulcer disease.

An acute episode of hematemesis may indicate primary or secondary ulceration. In such patients, a history of recent nonsteroidal anti-inflammatory drug ingestion should be sought. However, hematemesis occurring with a history of chronic abdominal pain is highly suggestive of primary duodenal ulcer disease.

In the past, up to 80% of children with primary peptic ulcer disease had symptoms that persisted into adult life.[192,193] The discovery of *H. pylori* has dramatically altered the prognosis of such patients. Successful treatment of *H. pylori*–infected children who have duodenal ulceration results in long-term healing of the ulcer and complete resolution of symptoms.[35,195]

Nongastrointestinal Manifestations

There have been a number of case reports describing children with refractory sideropenic anemia that responded to treatment only after the eradication of *H. pylori*.[196–202] A trial of *H. pylori* eradication therapy for iron deficiency anemia has been reported from Korea.[203] The numbers in the different groups in this study were very small, and although there was an increase in ferritin levels among those who were treated for *H. pylori* infection, serum ferritin levels at the end of the trial still suggest clinically depleted iron stores. A number of studies on adults also suggest that *H. pylori* may interfere with iron metabolism, with serum ferritin levels reduced in *H. pylori*–infected adults.[204–207] The mechanisms postulated include an increased demand for iron because *H. pylori* requires iron for growth, *H. pylori* may sequester iron, or *H. pylori* infection may result in hypochlorhydia, which would inhibit the reduction of iron to its ferrous state for absorption.[208] Because only 5 to 20% of ingested iron is absorbed, it is

unlikely that insufficient iron is available from dietary sources for *H. pylori*. Capurso and colleagues found that 51% of patients with *H. pylori*–associated iron deficiency anemia had a pangastritis compared with 20% of *H. pylori*–infected controls.[209] They suggest that this pangastritis may be responsible for changes in intragastric pH, which results in suboptimal iron absorption. Although pangastritis does occur in adults, there are no reports in the pediatric literature of pangastritis. Care must be used in interpreting studies of *H. pylori* and iron deficiency anemia because poor socioeconomic status is an important risk factor for both conditions. Furthermore, many of these studies use different ferritin levels to define anemia, and the duration of iron therapy is variable. Of the 21 pediatric cases reported with *H. pylori*–associated anemia,[196–202] 16 (75%) were male. Infant boys have a significantly higher risk of iron deficiency anemia than infant girls have.[210] Because children have lower iron stores than adults, *H. pylori* may contribute to the development of anemia rather than cause the anemia.

DIAGNOSIS OF H. PYLORI GASTRITIS AND ULCER DISEASE

Upper gastrointestinal endoscopy is the investigation of choice for the diagnosis of gastritis and peptic ulcer disease.[211] It has been shown to be both safe and effective, even in small infants.[212] The detection of ulcers using radiographic studies is often difficult in children. Single-contrast barium examinations correctly identified only 1 of 7 (14%) endoscopically proven duodenal ulcers in children.[5] Furthermore, the risk of false-positive diagnoses with barium studies is especially high in children. Miller and Doig failed to demonstrate any abnormality at endoscopy in 56 of 89 children with abdominal pain who had peptic ulcers diagnosed by barium meal.[213] Double-contrast barium techniques are more sensitive, but even in adults, this procedure failed to demonstrate 55% of gastric ulcers and 30% of duodenal ulcers.[214] In children, double-contrast barium studies are more difficult to perform, particularly in young children, and such studies involve increased radiation to the patient.

The endoscopic appearance of a peptic ulcer depends on the stage of the disease. Florid, active ulcers are usually round or oval, with a white base composed of debris and fibrin. The ulcer border may be hyperemic and elevated. Duodenal ulcers are often associated with spasm of the pylorus and a deformed pyloric outlet (Figure 29.1-1).

The endoscopic appearance of the stomach often correlates poorly with the presence or absence of gastritis.[2,3,6–8] Histologic evidence of mucosal inflammation is essential to establish a diagnosis of gastritis, and it frequently aids in the differential diagnosis of gastritis. Therefore, biopsies of the antrum and corpus, as well as the duodenum, should be obtained from children who undergo endoscopy.

A nodularity of the antral mucosa has been described in association with *H. pylori* gastritis in children.[6–8] These nodules give the antrum a cobblestone appearance (Figure 29.1-2). Hassall and Dimmick reported that nodularity of the antrum was present in their study in all 23 children with *H. pylori*–associated duodenal ulcers.[7] Nodularity of the antral mucosa is also seen in the majority of children with *H. pylori*–associated gastritis who do not have duodenal ulceration. The reason for this appearance of the gastric mucosa in association with *H. pylori* in children is unknown.

HISTOLOGY

The characteristic appearance and unique location of *H. pylori* allow a presumptive diagnosis of *H. pylori* colonization in children to be made by identifying spiral organ-

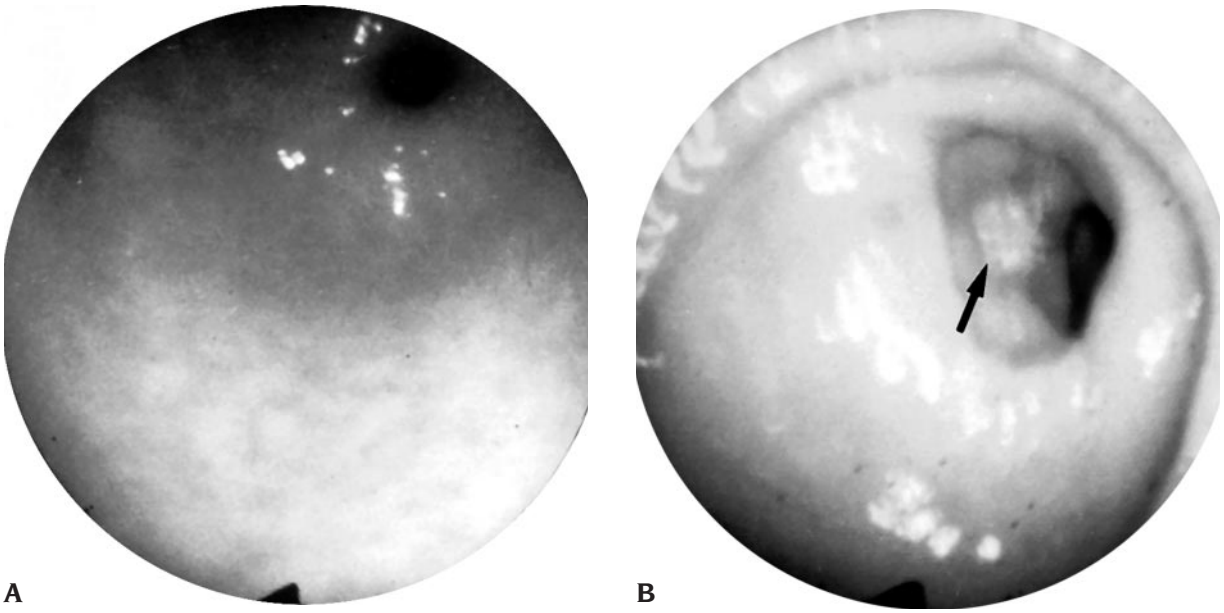

FIGURE 29.1-1 *A*, Endoscopic photograph showing normal-appearing antral mucosa: histologic examination of an antral biopsy, however, revealed evidence of acute gastritis and colonization with *Helicobacter pylori*. *B*, A duodenal ulcer (*arrow*) is visible through a patent but irregular pyloric channel.

isms on histologic sections of the gastric mucosa. Historically, the organism has been identified using a Warthin-Starry silver stain (Figure 29.1-3).[12,34] Silver stains are usually very sensitive and specific for identifying the presence of *H. pylori* in children, but they are expensive and difficult to perform. A modified Giemsa stain or a cresyl violet stain is both sensitive and specific for the organism and is much easier to perform than silver staining.[6] The Genta stain allows simultaneous visualization of the bacteria and the histologic features of gastritis.[215] Ultrastructural studies show the spiral morphology of organisms present on gastric epithelium (Figures 29.1-4 and 29.1-5).

Culture

Because *H. pylori* is extremely fastidious in its growth requirements, routine culture is difficult in a clinical practice. A more practical "gold standard" for the diagnosis of *H. pylori* is either a positive culture or the identification of *H. pylori* on both histology and urease testing.

Culturing of *H. pylori* is performed by inoculating minced biopsy specimens into blood agar plates that are held under microaerophilic conditions at 37°C. Media that contain nalidixic acid or vancomycin (ie, Skirrow medium) are frequently used to minimize overgrowth of organisms from the oropharyngeal flora. Visible colonies usually require 5 to 7 days of culture. The long incubation period is particularly important in children because the number of organisms present on their gastric mucosa is often very low. The organism is identified as *H. pylori* if it is positive for urease, catalase, and oxidase and produces a negative reaction for hippurate hydrolysis and nitrate reduction.

For optimal recovery rates of *H. pylori* from gastric biopsy specimens, the viability of the organism must be maintained during transportation to the laboratory. It was

previously considered necessary for biopsy specimens to be delivered to the microbiology laboratory within 1 hour, but successful culture is possible even after 24 hours when a suitable transport medium is used.[216] It is essential that the biopsy specimens are placed directly into the transport medium and not exposed to room air. When carefully performed, culture of the organism is successful in almost 100% of specimens.[33,34]

Urease Test

Because *H. pylori* produces high levels of the enzyme urease, this property can be exploited to detect the presence of bacteria in antral biopsy specimens and also in UBTs. To rapidly identify *H. pylori* on the gastric mucosal specimens, a specimen is placed on urea medium; hydrolysis of urea leads to a color change of the medium, from tan to pink. The color change may occur as soon as 30 minutes after inoculation, but if the number of bacteria is small, the color reaction may take up to 24 hours to develop. Urease tests in children occasionally have not been as sensitive as in adults,[34,217] perhaps reflecting the lower number of bacteria present on biopsy specimens from children. When a full biopsy specimen (rather than a fragment of the specimen) is placed in the urea medium, the sensitivity of this test increases and is close to 100%.[218] Commercial kits based on similar principles are available for use in the endoscopy suite.

Urea Breath Tests

The ^{13}C UBT is a safe and noninvasive method for the diagnosis of *H. pylori* infection in adults and children.[219–225] Isotopic urea (^{13}C) is ingested by the patient; if *H. pylori* is present in the stomach, breakdown of the labeled urea by *H. pylori* urease results in the production of labeled carbon dioxide, which is measured in the expired air. In contrast to ^{14}C (a radioactive label), ^{13}C urea is labeled with a naturally occurring stable isotope of carbon. Tests using stable isotopes are ideal for use in children, but they are more expensive because they require the use of a mass spectrometer.

The UBT for use in adults involves an overnight fast and the administration of a test meal to slow gastric emptying.[219,221,222] The use of a prolonged fast and a test meal makes the test difficult to perform in children and limits its usefulness in both research and clinical practice.

We have shown that a simplified test protocol is very successful in children over 2 years of age.[223] After the patient fasts for 2 hours, the UBT is performed by collecting a baseline sample of expired air, followed by ingestion of ^{13}C urea (50 mg for children < 50 kg or 75 mg for children > 50 kg) with 50 mg of a glucose polymer in 5 to 10 mL of water. It is important that the solution of urea is swallowed quickly and not held in the mouth. This is not a problem in the older child but may present difficulties for younger children. A second breath sample is collected 30 minutes later. In older children, as in adults, samples may be collected by blowing directly with a straw into a glass

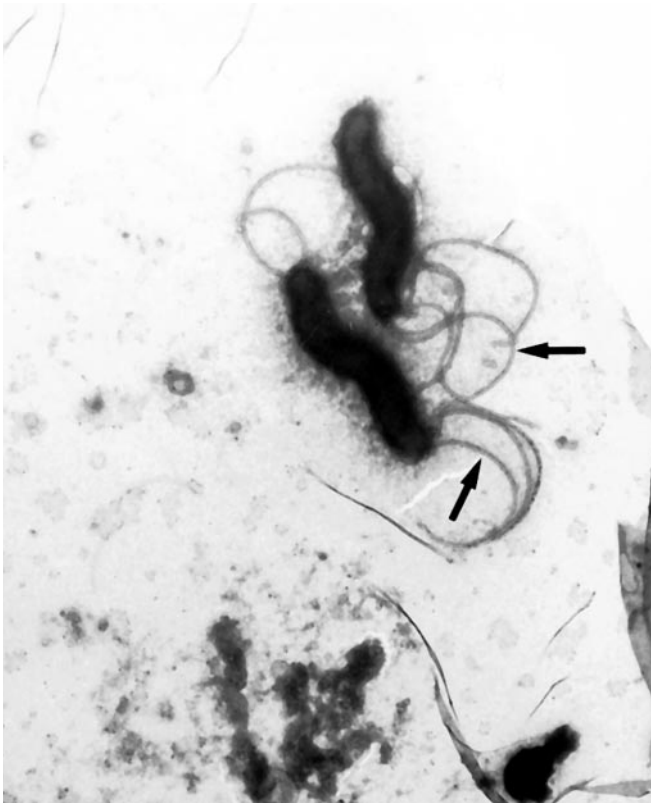

FIGURE 29.1-5 Transmission electron photomicrograph after negative staining of *Helicobacter pylori*. Note the spiral shape of the organism (comparable to intestinal *Campylobacter*) and the presence of flagellae (*arrows*).

tube that can be sealed. For younger children, a closed system such as a rebreathing bag with tap (Childerhouse Medical, London) is required, and the expired air is transferred into an evacuated glass tube. The ratio of ^{12}C to ^{13}C is measured in both the baseline and the 30-minute sample, and the difference between the samples is calculated by subtraction. This value is referred to as excess delta or delta over baseline. In children, an excess delta of 5.0 is indicative of *H. pylori* infection.[103]

The UBT was shown to be 100% sensitive and 92% specific for the diagnosis of *H. pylori* infection in older children.[223] The sensitivity and specificity were achieved after a 2-hour fast and without the use of a test meal or drink. This test has an excellent capacity to distinguish infected from noninfected children, with a clear separation of excess delta values between the two groups.[224] In children under 2 years of age, the UBT may have a reduced specificity.[103,226] Children in this age group have more borderline and false-positive results than older children. Urease-producing organisms in the mouth may interfere with the test in very young children.[103,227] When the test was carried out using a nasogastric tube (in situ for clinical indications), there were no false-positive results in children under 2 years of age.[103]

Samples collected at 15 or 20 minutes often give false-positive results, perhaps because of interference from oral urease-producing organisms.[223] Therefore, the second breath sample should be collected 30 minutes after ingestion of substrate. Because the UBT measures the ratio of ^{12}C to ^{13}C, the volume of expired breath collected is not critical. However, the effect of crying or dead space on the test in young children has not been determined. Breath samples from children are stable for up to at least 7 months; therefore, transport and storage of specimens for analysis at a later time are possible.[224] Following treatment, the UBT is 100% sensitive and specific in assessing *H. pylori* status.[223] It has replaced endoscopy as the investigation of choice for assessing treatment success in children. Breath tests should not be carried out for at least 1 month after the completion of treatment.

Isotope ratio mass spectrometry is an expensive technique for the analysis of ^{13}C. Nondispersive infrared mass spectrometry has been shown to be equally accurate and less expensive.[225] However, much larger volumes of breath are required, making this method more difficult for young children.

Serology

Infection with *H. pylori* provokes a specific serum IgG response. The initial antibody response in children is to low-molecular-weight antigens in the 15 to 30 kD range and may take up to 60 days to develop.[228,229] The mean antibody levels in young children are significantly lower than in older children and adults.[230–232] Antibody titers in children may not reach their maximum levels until the age of 7 years.[233]

Serologic tests in children must therefore be standardized using children's sera.[233] If the assay is based on adult antibody levels, less than 50% of children will be correctly diagnosed because the cutoff point is higher for adults than for children. Commercially available serologic tests do not have the sensitivity or specificity to accurately diagnose *H. pylori* infection in children under 12 years of age,[232] with second-generation serologic tests failing to diagnose up to 20% of children under the age of 10 years.[234]

Everhart and colleagues have shown that even using adult sera, the reliability of serology on repeat analysis of the same sample is poor and could easily explain the 1 to 2% seroreversion and seroconversion rates reported from adult seroepidemiologic studies.[102] Therefore, in all seroepidemiologic studies, there is a need for caution in interpreting results.

Measurement of *H. pylori*–specific serum IgA antibodies in children is not a sensitive indicator of gastric colonization. Czinn and colleagues found that only 45% of children with *H. pylori* colonization of the gastric mucosa had increased *H. pylori*–specific serum IgA antibodies.[235] Also, *H. pylori*–specific serum IgM antibodies are not consistently elevated in children with *H. pylori*–associated gastritis.[235]

Measurement of Salivary IgG Antibodies

The *H. pylori*–specific antibody response can also be detected in saliva. In adults, varying sensitivities and specificities have been reported, depending on the assay used.[236,237] In children, Luzza and colleagues have reported a sensitivity of 93% and a specificity of 82% with an in-house enzyme-linked immunosorbent assay.[238]

Stool Antigen Enzyme Immunoassay

The detection of *H. pylori* antigens in stool using polyclonal and, more recently, monoclonal antibodies provides a noninvasive method for identifying infected adults and children. The *H. pylori* stool antigen test (HpSA) (Premier Platinum HpSA test, Meridian Diagnostics Inc, Cincinnati, OH) is based on a polyclonal antibody and in adults is 91 to 98% sensitive and 83 to 100% specific for the diagnosis of infection.[239] Initial results also suggested the HpSA to be very sensitive and specific following treatment of *H. pylori* in adults,[240–242] but more recent studies would have called into question the overall accuracy of the test in this situation.[239,243,244]

Preliminary reports suggest that in children, the HpSA test is less accurate and that the cutoff values may have to be adjusted for each population studied, rendering the test of little use in a routine clinical setting.[245–249] The HpSA has a specificity of only 70% following treatment for *H. pylori* in children.[249]

The development of a monoclonal antibody has provided much greater accuracy in stool antigen testing.[250–252] This is particularly so in children in whom the sensitivity, specificity, positive predictive values, and negative predictive values were 98%, 99%, 98%, and 99%, respectively, in a large multicenter European study involving 302 previously untreated children using a monoclonal stool antigen test (*H. pylori* CnX, FentoLab, Martinsreid, Germany).[253] Although the accuracy of the monoclonal stool antigen test has not yet been evaluated in children following treatment for *H. pylori* or in the diagnosis of infection in children under 2 years of age, this approach appears to hold particular promise as a diagnostic tool in childhood *H. pylori* infection.

TREATMENT OF PEPTIC ULCER DISEASE

In adults, both the National Institutes of Health consensus statement[254] and the Maastricht consensus report[255] recommended that *H. pylori* should be eradicated in adults who have *H. pylori*–associated peptic ulcer. More recently, the Maastricht 2-2000 consensus report suggested treatment of *H. pylori* infection in first-degree relatives of gastric cancer patients.[256]

Children with peptic ulcer disease who are infected with *H. pylori* should receive treatment to eradicate the infection.[257] However, the majority of children infected with *H. pylori* do not have peptic ulcer disease and are not symptomatic.[6] The diagnosis of *H. pylori* infection is often an incidental finding at endoscopy, and the management of these children is therefore controversial. Recently, two pediatric consensus conferences on *H. pylori* have stated that there is no evidence demonstrating a link between *H. pylori* gastritis and abdominal pain except in those children in whom an ulcer is present.[257–259] If infection is incidentally diagnosed, it should be treated, but there is currently no indication to screen children for *H. pylori* infection except at endoscopy, when peptic ulcer disease is investigated.

Specific Treatment Regimens

Several regimens used to treat *H. pylori* in children are listed in Table 29.1-2.[187,260–266] Because peptic ulcer disease is much less prevalent in the pediatric age group, treatment studies in children are usually open trials with small numbers of participants. Treatment regimens have evolved from using a single antibiotic with a bismuth preparation for 4 to 6 weeks to 1-week treatment regimens using two antibiotics and either bismuth or a proton pump inhibitor for 1 week. The most frequently used antibiotics in children and adults are amoxicillin, metronidazole, tinidazole, and clarithromycin. Selection of optimal antibiotic combinations should be based on known antibiotic sensitivities for *H. pylori* in the local population. Following treatment, children should have a UBT carried out to determine if the treatment has been successful.

Currently, there is only one reported multicenter prospective randomized controlled trial of *H. pylori* treatment in children.[266] In this study, a combination of omeprazole, amoxicillin, and clarithromycin for 1 week was compared with dual therapy of amoxicillin and clarithromycin. On an intention-to-treat analysis, 74% of children were successfully treated with omeprazole, amoxicillin, and clarithromycin compared with 9% of those treated with antibiotics alone. Although this study clearly demonstrates that triple therapy is more effective than dual therapy, it also suggests that the combination of omeprazole, amoxicillin, and clarithromycin is less than optimal in children. Adult guidelines suggest that treatment regimens with less than an 80% success rate are unacceptable for use in clinical practice.[255] The reason for a much

TABLE 29.1-2 TREATMENT OF *HELICOBACTER PYLORI* INFECTION IN CHILDREN

lower success rate for the combination of omeprazole, amoxicillin, and clarithromycin compared with other open trials of treatment in children (see Table 29.1-2) or with similar studies in the adult literature is unclear.[267–269] In children, clarithromycin resistance is usually much higher than that reported in adults, yet in this study, resistance to clarithromycin was low at 7.7% and did not account for treatment failures. However, the antibiotic dosages reported in this study are lower than in many other pediatric studies (Table 29.1-2) and may account for the reported differences in efficacy.

Bismuth. Bismuth formulations have been used in the management of peptic ulcer disease for over 100 years. Their precise mechanism of action in eradicating *H. pylori* from the gastric mucosa is not known. Bismuth compounds have some antibacterial properties, and bismuth monotherapy clears *H. pylori* from the gastric mucosa in about 50% of cases. The rate of ulcer relapse after bismuth therapy alone is significantly lower than that after treatment with histamine$_2$ receptor antagonists.

In Europe, colloidal bismuth subcitrate is the bismuth preparation most commonly used to treat *H. pylori* infection, whereas bismuth subsalicylate is used in North America. There has been concern about the use of bismuth salts in children because of potential toxic effects. However, bismuth does not appear to have any toxic effects in children other than those already well described in adults. Encephalopathy and acute renal impairment after chronic use of high-dose bismuth are reported, but these side effects, which are reversible, have not been reported in children treated for *H. pylori*–associated gastritis or ulcer disease.[6] Serum bismuth levels remain within the normal range for children when colloidal bismuth subcitrate is prescribed as either 480 mg/1.73 m^2 of body surface area per day or 120 mg twice daily (240 mg twice daily for children over the age of 10 years). There is a concern about the presence of salicylate and therefore the risk of Reye syndrome with bismuth subsalicylate. A 30 mL dose of bismuth subsalicylate contains 230 mg of salicylate.

Proton Pump Inhibitors. Proton pump inhibitors inhibit the gastric acid pump (hydrogen-potassium–exchanging adenosine triphosphatase) in a dose-dependent manner.[270–272] Proton pump inhibitors are rapidly absorbed, with peak concentrations occurring 2 to 4 hours after oral administration.[273] The precise mechanism of action of a proton pump inhibitor in inhibiting *H. pylori* is unknown.[273] Proton pump inhibitors have some antibacterial activity in vivo. More important, by inhibiting gastric acid secretion, these drugs may promote the increased effectiveness of acid-sensitive antibiotics, such as clarithromycin, in triple-therapy regimens.

The side effects of omeprazole, which include headache, diarrhea, abdominal pain, and nausea, are self-limiting. Bacterial overgrowth in the stomach and small intestine by oral and colonic flora has been reported.[274,275] Proton pump inhibitors are metabolized completely by the polymorphic cytochrome P-450 system. Although drug interactions with warfarin, diazepam, and phenytoin theoretically could occur, none have been reported to date.[273]

Treatment Failure

Numerous factors are responsible for treatment failure, but the most important are poor patient compliance, inadequate drug delivery, and antimicrobial resistance. Ingestion of less than 75% of the prescribed medication results in decreased eradication rates.[276] Walsh and colleagues achieved excellent compliance in children, using special boxes in which the drugs for each dose were compartmentalized.[260] This level of compliance, although desirable, is unlikely in clinical practice.

In treating children, the availability of suitable drug preparations is very important. Although bismuth has been widely used in children and comes as a liquid preparation, the strong taste of ammonia from liquid bismuth may reduce compliance in children. In clinical practice, therefore, the treatment regimen with the simplest dosing requirement and fewest side effects is to be preferred, assuming similar eradication rates.

Antibiotic Resistance

The development of antibiotic resistance by *H. pylori* is an important variable in the success of treatment regimens. Resistance to antibiotics may be primary, or it may develop during the course of treatment. The development of secondary resistance is usually associated with suboptimal treatment regimens. Agar dilution is considered the method of choice for resistance testing.[277] Disk diffusion techniques are simple and less expensive but, although less suitable for slow-growing bacteria such as *H. pylori*, are a more realistic option for everyday laboratory use.[277] The E-test is a semiquantitative variant of disk diffusion, and although there is excellent correlation between the different methods when testing for clarithromycin resistance, discrepancies have been reported for metronidazole resistance between E-test and disk diffusion, with rates of metronidazole resistance being higher for E-tests.[256,278,279] In determining antibiotic sensitivities, it is recommended that isolates of *H. pylori* should be recovered during the active phase of growth within 3 days and that the inoculum size of 10^8 CFU/mL (equivelant to McFarland 4) is used.[277] The conditions (anaerobic vs microaerophilic) under which resistance is determined may also influence the outcome of resistance testing.

Metronidazole resistance greatly reduces the efficacy of metronidazole-based regimens in both adults and children.[268,280,281] Primary resistance to metronidazole may be a nonstable phenomenon[282] and may explain why treatment is more successful than anticipated in a number of studies in which metronidazole was used.[283] Goodwin and colleagues were the first to demonstrate that metronidazole resistance in *H. pylori* arose from mutations within the *rdxA* gene.[284] It has also been suggested that other reductase-encoding genes, including *frxA* and *fdxB*, are associated with metronidazole resistance.[285–287]

Rates of metronidazole resistance vary from 33% in Europe[278,288,289] to 20 to 50% in the United States[290] and Aus-

tralia[291] to up to 70% in developing countries.[283] Women are more likely to harbor resistant strains, as are migrants from developing countries.[288,289] The higher resistance among women and in developing countries may be explained by the use of metronidazole for gynecologic and diarrheal diseases in these groups. The rate of metronidazole resistance in adults appears to be relatively constant over time.[291,292]

The presence of metronidazole-resistant strains has been reported as 26 to 37% in French children,[266,281] a finding similar to that seen in French adults.[202] Metronidazole resistance rates are 18% in Belgian children[293] and 24% in Japanese children.[294]

The mechanism of action of clarithromycin is to bind ribosomes and disrupt protein synthesis. The development of resistance is attributed to various point mutations in the two 23S ribosomal ribonucleic acid (rRNA) genes of *H. pylori*. It is thought that clarithromycin needs effective acid control to achieve high eradication rates. Primary clarithromycin resistance is less common in adults than metronidazole resistance and ranges from 10 to 15% of strains in adults. There is concern that clarithromycin resistance rates may be increasing, particularly among children. In 1998, Raymond and colleagues reported a 4% rate of clarithromycin resistance in children,[295] and a more recent report from Kalach and colleagues suggests that the prevalence of clarithromycin resistance has increased to 18%.[296] Similarly, in Belgian children, the prevalence of clarithromycin resistance increased from 6.0% prior to 1995 to 16% in the following 5 years.[293] In this same period, metronidazole resistance remained stable at around 18% in children.[293] In Japan, clarithromycin resistance has been reported as 30% in children, with 92% of strains having an A2144G mutation in the 23S rRNA gene. Clarithromycin resistance may be becoming more common in children because of the widespread use of clarithromycin in pediatric practice. With this increasing prevalence of resistance to clarithromycin, careful consideration should be given to its inclusion as a first-line treatment in children.

Until recently, it was thought that *H. pylori* did not develop resistance to amoxicillin. Stable amoxicillin resistance has been reported from the Netherlands in an 82-year-old man. Previous reports of amoxicillin-tolerant strains have come from Italy and the United States. The major concern in the study by van Zwet and colleagues is that amoxicillin resistance could be transferred to susceptible strains, suggesting the possibility of the spreading of amoxicillin resistance. To date, amoxicillin resistance has not been reported in children.

Resistance to tetracycline has also been reported, which may greatly hinder its use as a low-cost first- or second-line treatment.[297] Mutations of the 16S rRNA genes are thought to be responsible for resistance,[297–300] but a number of mutations may be necessary to confer clinically significant resistance.[299]

Second-Line Treatment

Current treatment regimens fail to eradicate *H. pylori* infection in 5 to 30% of children. Therefore, an important question that needs to be considered is the management of children in whom *H. pylori* treatment has been unsuccessful. Currently, there are no published data or guidelines for children. The Maastricht 2 guidelines suggest that treatment for adult patients infected with *H. pylori* should adopt a planned approach, with a therapeutically effective second-line treatment regimen available if the first-line treatment fails. They suggest that first-line therapy should include a proton pump inhibitor or ranitidine bismuth citrate with amoxicillin, metronidazole, or clarithromycin, whereas second-line therapy should include a proton pump inhibitor, bismuth, metronidazole, and tetracycline (quadruple therapy). A number of recent adult studies report excellent eradication rates with quadruple therapy when prescribed twice daily for 7 days as a first- or second-line treatment.[301–306] Well-conducted randomized controlled trials remain to be conducted for second-line treatment regimens in adults.

The use of tetracycline is contraindicated in children before the age of 12 years at least. This and the increasing problem of clarithromycin resistance limit the choices available for the treatment of *H. pylori* in children. Optimal treatment protocols for *H. pylori* infection in children should be developed for individual pediatric units based on local antibiotic resistance rates and the age of children who require treatment.

H. heilmannii Gastritis

H. heilmannii (formerly *Gastrospirillum hominis*) is known to cause gastritis in humans. It can be distinguished morphologically from *H. pylori* on histologic sections by its larger size and its characteristic shape with five to seven regular spirals.[307,308] The frequency of gastric infection with *H. heilmannii* varies from 0.08 to 1% of adults undergoing routine endoscopy[307]and has been reported as 0.3% in one pediatric series.[309] There also have been a number of individual reports of *H. heilmannii* in children.[309–311] *H. heilmannii* gastritis is similar to *H. pylori* gastritis in that it mainly involves the antrum, but the mononuclear inflammatory response is described as mild, and there is no neutrophil activity. The bacteria do not adhere to the gastric epithelium but are usually seen within the mucus layer.[307] The importance of *H. heilmannii* as a gastric pathogen in children is not yet clear.

CONCLUSION

The discovery of *H. pylori* over 30 years ago has revolutionized our knowledge of peptic ulcer disease and gastric cancer. However, there are still many areas of great uncertainty in relation to the pathogenesis and epidemiology of this infection. *H. pylori* displays marked trophism for gastric tissue, yet we do not understand the mechanism of adherence or the role of the host in adherence of the organism to the gastric mucosa and the development of disease. There is now a substantial body of indirect evidence that suggests that infection is mainly acquired in preschool children. However, the mode of transmission of infection in children is unknown. This is a very important question, especially for children living in poor socioeconomic condi-

tions, if we want to develop strategies that will prevent infection. Further work on the optimal treatment regimens is required for infected children because resistance to clarithromycin is increasing and because some of the adult treatment regimens are not licensed for use in children.

2. *Other Causes*

Ranjan Dohil, MBBCh, MRCP(UK)
Eric Hassall, MBChB, FRCPC, FACG

The term *gastritis* is often used somewhat loosely. Not infrequently, clinicians will refer to a patient with epigastric pain or dyspepsia as having "gastritis," whereas radiologists may diagnose "gastritis" on the basis of nonspecific radiologic changes, such as mucosal irregularity or swelling.

However, gastritis is neither a clinical nor a radiologic diagnosis. Most often it is a purely histologic diagnosis, made by the use of random or targeted endoscopic biopsies.

Whereas some conditions that injure the gastric mucosa may result in inflammation, others do not. Thus, gastritis, as the suffix *-itis* implies, is characterized by the presence of inflammatory cells. In contrast, the term *gastropathy* is used to refer to conditions in which inflammation is not a prominent feature, although there may be epithelial damage and regeneration. In gastropathies, there are almost always visible abnormalities of the mucosa at endoscopy, with or without histologic changes; sometimes the mucosal appearance at endoscopy is typical or diagnostic of a particular condition. Therefore, in the case of gastritis, the diagnosis is always based on biopsy, whereas with few exceptions, gastropathy is usually an endoscopic diagnosis. Strictly speaking, the term *gastropathy* refers to any and all disorders of the stomach, but in this chapter, we use its more recent application.

The categorization of entities into gastritides and gastropathies is an important concept and helps narrow the diagnostic possibilities in a given case. However, for the sake of simplicity, in this chapter, the term *gastritis* is often used generically to refer to both gastritides and gastropathies.

Although gastritis and gastropathy are often clinically important in and of themselves, they are sometimes part of a continuum that includes ulcer disease.[1]

In this chapter, we propose a classification of pediatric gastritis and an approach that is pertinent to practicing pediatric endoscopists. Attention to key elements will facilitate consistency of communication between endoscopists and between endoscopists and pathologists, hopefully resulting in increased diagnostic accuracy in the area, that is, "high-yield gastroscopy." The key elements are endoscopic landmarks, terminology, and acquisition of biopsies and are discussed in detail below.

HIGH-YIELD GASTROSCOPY

Once a child is scheduled for diagnostic upper gastrointestinal (GI) endoscopy, the endoscopist has an obligation to maximize the diagnostic potential of the procedure. Central to this must come the recognition that the ability to make a diagnosis based on macroscopic appearances alone is limited.[1–7] For example, gastric mucosa that appears normal at endoscopy may harbor marked inflammation on microscopy. The converse is also true, that is, a markedly red mucosa at endoscopy may be normal or may result from contact with the endoscope; redness may reflect underlying microvascular congestion without the presence of inflammatory cells. In other words, there is often poor correlation between endoscopic and histologic findings. It follows, therefore, that targeted gastric biopsies must be an integral part of a proper examination of the gastric mucosa. In children, gastritis remains underrecognized and poorly characterized largely because of the flawed tendency to rely on macroscopic appearances at endoscopy and an evident reluctance by pediatric endoscopists to pay attention to the quantity and quality of tissue obtained at endoscopy.

A high yield of accurate diagnoses, including the definitive ruling out of mucosal disease, largely depends on the endoscopist's care and attention to detail in the following areas.

Clinical Status and Drug Therapy

Endoscopy with biopsy is no substitute for a thorough history and physical examination. Too often endoscopy is used as a means to "rule out acid peptic disease" when a history of lower abdominal pain is present and constipation is the cause or when upper GI symptoms are relatively mild, and a trial of a low-level therapy might be appropriate. Although a definitive diagnosis can often be made with endoscopy, many endoscopic and histologic findings are nonspecific and require interpretation in light of the patient's presenting complaint and overall clinical condition.

Close communication with a pathologist well versed in GI pathology is essential to do the patient and procedure justice. Drug therapy may cause disease in the stomach, change the nature and pattern of the disease, or mask the disease. Therefore, for interpretation of endoscopic and biopsy findings, the clinical context is key, and this includes what drugs the patient is taking or has recently taken. It is the responsibility of the endoscopist to communicate this information to the pathologist; this is best done in writing, on the pathology form that accompanies tissue to the laboratory. Drugs such as bismuth (PeptoBismol, DeNol), antibiotics, acid-suppressing drugs, and nonsteroidal anti-inflammatory drugs (NSAIDs) all may significantly change endoscopic and histologic findings. In patients with suspected acid-peptic disease, it is advisable to have the patient off acid-suppressing drugs for at least 2 weeks prior to endoscopy.

Endoscopic and Histologic Zones

In reporting endoscopic appearances, the endoscopist is describing the gross pathology of disease, and different disorders have predilections to involve different zones of the stomach. Familiarity with the gross and histologic zones is important (Figure 29.2-1) to avoid poor targeting of biopsies and therefore erroneous or missed diagnoses.

The largest region of the stomach is the gastric body or corpus, characterized at endoscopy by thick mucosal folds or rugae; the body or corpus extends distally to the incisura or angulus on the lesser curvature. The fundus is the dome-shaped area immediately above the gastric body and abutting the diaphragm; both the corpus and the fundus are composed of oxyntic mucosa. This consists of tightly packed glands, with little lamina propria between. The foveolae, or gastric pits, occupy the upper 20 to 25% of the mucosa, with the glands comprising the rest. The glands contain parietal cells that secrete acid and intrinsic factor and chief cells that secrete pepsinogen. The parietal cell zone occupies approximately half of the upper gland mass, with chief cells occupying the basal half. Most of the endocrine cells present are enterochromaffin-like cells that secrete histamine; some D cells that secrete somatostatin are present, as are some enterochromaffin cells that secrete serotonin. The endocrine cells are small and are present in the lower one-third or so of the glands, squashed between the basement membrane and the bases of the parietal and chief cells. The mucosal thickness is around 0.5 to 1.5 mm, thicker than other zones of the stomach. The greater curve at midbody is the thickest zone and thus the best zone to assess for atrophy.

The gastric antrum occupies the lower quarter or third of the stomach; when the stomach is distended with air to allow visualization, the antrum is seen to begin on the greater curvature where folds of the gastric body end. The antrum ends at the pylorus and consists of clear-staining mucus glands and endocrine cells. The antral mucosa is 200 to 1,000 μm thick. The foveolae or pits are deeper than those in the body, occupying about half of the mucosal thickness. The glands are clear staining, coiled, and mucus producing. The antral mucosa is also referred to as "pyloric-type" mucosa. The predominant endocrine cell is the G (gastrin producing) cell, with fewer numbers of D cells (somatostatin) and enterochromaffin cells (serotonin). These cells are primarily present at the junction of foveolae and glands.

The gastric cardia comprises a short zone of mucosa, immediately distal to and abutting the normally located Z line. Although the cardia is variously defined in different adult studies, we regard the cardia as the anatomic 0.5 to 1 cm below the Z line.[7] The anatomic cardia may be composed of purely clear-staining mucous glands (the same as those of the antrum) or clear-staining glands with occasional parietal cells; the latter is a transitional mucosa, betweeen purely fundic and purely cardiac-type mucosa. Much less commonly, pure fundic mucosa may directly abut the Z line. The cardia does not contain endocrine cells.

Although the different histologic zones of the stomach correspond to the different gross anatomic zones thereof, there is always some overlap and interdigitation of histologic zones at areas of transition—hence the term *transitional mucosa* for these. Examples of transitional zones are the antrum-body interface, especially the region of the incisura, and the cardia.

More detailed descriptions of normal gastric anatomy and histology are available elsewhere.[8,9] One of the difficulties in pediatric gastric histology is establishing what is "normal" because there are no pediatric data on "normal volunteers." Pediatric patients come to endoscopy because they have upper GI symptoms or a suspected systemic disorder in which upper endoscopy is performed to look for gastroduodenal pathology. Where "normal values" for cellularity of the lamina propria are described,[10] they are "retrospectively normal."

Terminology: Reporting of Endoscopic Findings

The endoscopy report is, in fact, a description of gross anatomic pathology or normality. Precision in description

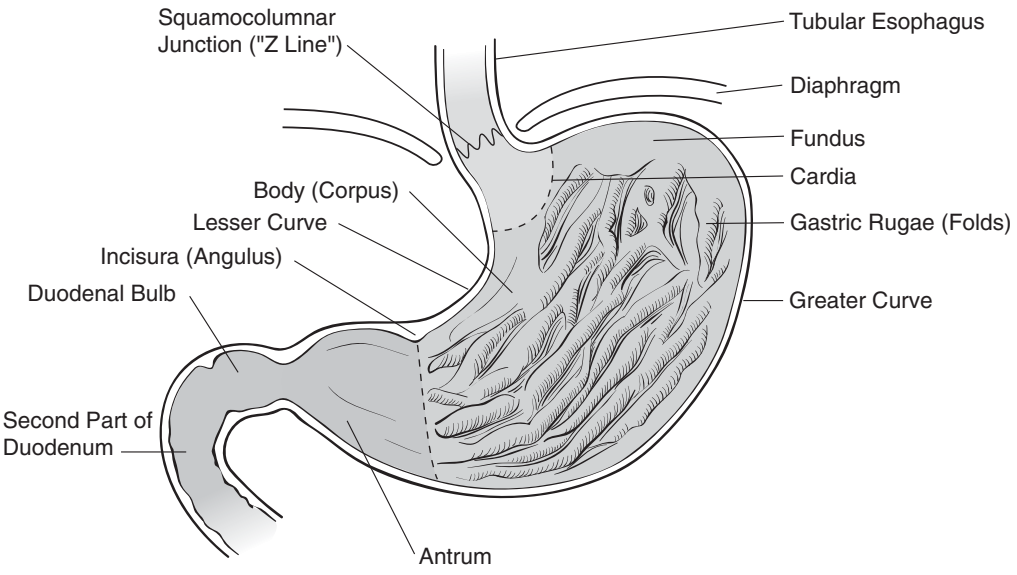

FIGURE 29.2-1 Anatomic regions of the stomach. Adapted with permission from Anatomy and histology: stomach. Rudolph CD, Rudolph AM, Hostetter M, editors. Rudolph's pediatrics. 21st ed. New York: McGraw Hill; 2003. p. 1306.

is therefore important; even when endoscopic photographs are available, words complement the images. The endoscopist should report only what he or she sees using terminology that is standard, factual, and unambiguous; the report should be descriptive rather than interpretive. Jargon, or *-itis* terms, should be avoided in the objective part of the endoscopy report. For example, use of the term *gastritis* could mean anything from erythema to distinct erosions; if the mucosa is red, it should be documented as "red" or "erythematous" (mild/moderate/intense or hemorrhagic) and not as antritis or gastritis because inflammation may not be present.[2,3] Another example is that of antral nodularity. This may indicate *Helicobacter pylori* gastritis, past or present; the nodules may persist for months or years after eradication of *H. pylori* and resolution of gastritis, and inflammation may not be present on biopsy. Therefore, the term *nodular gastritis* is to be avoided. After all, the endoscope is not a microscope; we cannot "see" inflammation at endoscopy.

An erosion is a mucosal break that does not penetrate the muscularis mucosae, whereas an ulcer extends through the muscularis into the submucosa. Endoscopists cannot accurately determine depth of lesions, but there are some clues; erosions are often multiple and usually have white bases, and each erosion is usually surrounded by a ring of erythema. When erosions have recently bled, their bases may be black. *Hemorrhage* refers to the bright, shiny red appearance of the mucosa in patches, streaks, or discrete petechiae, not associated with a visible mucosal break. Although the term *submucosal hemorrhage* is sometimes used, endoscopists cannot see through the muscularis mucosae; therefore, the term *subepithelial hemorrhage* is preferable to allow for varying depths of hemorrhage. Other confusing terms used for subepithelial hemorrhage and best avoided are *acute gastritis*, *hemorrhagic gastritis* (inflammation is usually absent from hemorrhagic lesions), or *hemorrhagic erosion* (usually no erosion present).

If gastric rugae are large, accurate terms of description are thick folds or swollen folds, not edematous folds or hypertrophic folds, because edema and hypertrophy are histologic not endoscopic findings; the swelling might be due to infiltrative disease, edema, or hypertrophy.[3,9,10] The folds remain thick in appearance despite adequate insufflation of air into the stomach at endoscopy. Causes of swollen folds are shown in Table 29.2-1.

It is also important to carefully and accurately describe nodules in the stomach because the different types and distributions have different implications. For example, a nodule or patch of nodules may be seen occasionally, especially at the antral-body junction; these may represent a prominent areae gastricae[11] and are usually unimpressive. In contrast, when a continuous diffuse carpet of nodules is present throughout the antrum, this has a high positive predictive value for *H. pylori* infection, past or present.[12,13] Absence of nodules, however, does not have a high negative predictive value for *H. pylori* infection or ulcer disease. When *H. pylori* gastritis is associated with duodenal ulcer in children, a striking diffuse nodularity of the antrum is always present; however, when *H. pylori* causes gastritis alone (primary gastritis), this nodularity is seen only in some 50 to 60% of cases.[12] We have not seen this nodularity in cases of true non–*H. pylori* duodenal ulcer disease[14] or in any of the some 8,000 upper GI endoscopies at our institution at which neither ulcer disease nor *H. pylori* was present over the last 18 years. Nodularity is sometimes not visible at first examination of the antrum, but once biopsies have been taken, oozing blood acts as a vital stain, making visible a confluent carpet of nodules. The term *hematochromoendoscopy* has been applied to use of blood as a vital stain in this circumstance.[1]

The nodules of chronic varioliform gastritis (CVG) are again different; they are larger in diameter and more raised than *H. pylori*–related nodules in the antrum and discrete, not in a continuous carpet. They often have an umbilicated central erosion or shallow ulcer, which predominates along the folds of the gastric fundus and body (Figure 29.2-2).[15–17] Large discrete nodules, more like blebs, may occur in the proximal stomach with cytomegalovirus (CMV) gastritis[3]; similar nodules in the antrum (and to a lesser degree in the body) may occur in eosinophilic gastritis and in Henoch-Schönlein disease.[18,19] In these three conditions, the mucosa is often hemorrhagic appearing, with erosions or ulcers, whereas in *H. pylori* disease, the

mucosa is often just nodular, with or without erosions, but otherwise usually looks quiescent.

Some children with the rare systemic disorder cystinosis may have a unique *H. pylori*–negative diffuse fine "reptile-skin" nodularity throughout the stomach on gastroscopy (Figure 29.2-3).[20]

Nodules are different from polyps or pseudopolyps. Polyps may occur in a variety of conditions and are mentioned below. Pseudopolyps in the stomach may occur in inflammatory conditions such as allergic gastroenteroenteritis and Crohn disease. In these conditions, the lesions, although still sessile, are generally quite a bit larger than the nodules of the above conditions; they are blebs—areas of swollen mucosa. They are usually localized to the antrum and are discrete, not continuous.

Multizone Biopsy Sampling

Different disorders often have a predilection for one topographic zone or another of the stomach. However, the same agent may cause different patterns of injury in different populations (eg, *H. pylori*). Sometimes there may be disease in more than one zone of the stomach (eg, *H. pylori*, Crohn disease, eosinophilic gastritis, atrophic gastritis, CMV), as indicated below. In addition, distribution of disease may be influenced by treatment. Thus, the topology of endoscopic or histologic findings may give important clues to the etiology. Although the antrum is the major repository of histologic abnormalities for many pathologies that occur in children, biopsies should be taken from different topographic zones of the stomach.[1,7,21–37]

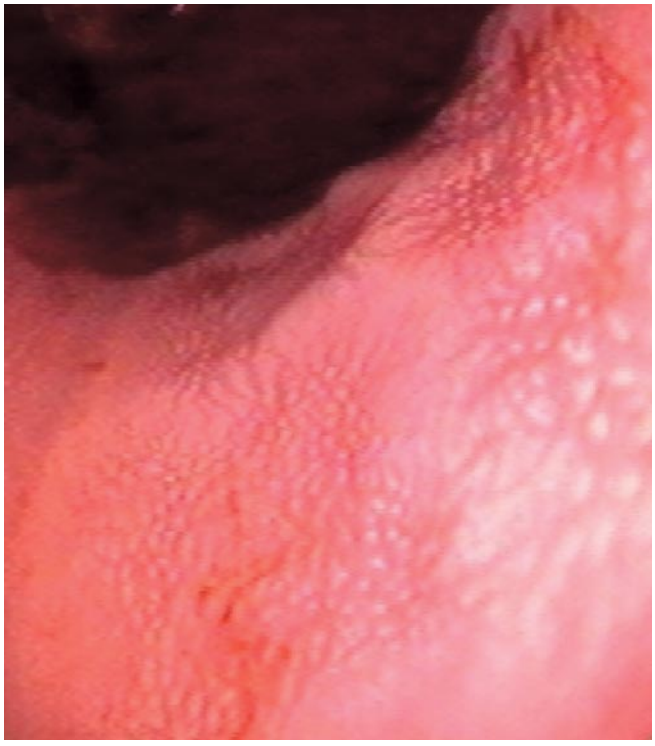

FIGURE 29.2-3 Cystinosis. Pangastric confluent finely nodular appearance in the stomach of a 3-year-old girl with cystinosis. She presented with severe abdominal pain, nausea, and vomiting and was unable to tolerate oral cysteamine.

The absence of histologic abnormalities is also helpful. For example, it is now well recognized that a significant percentage of duodenal ulcer disease in adults and children that is not due to NSAIDs, Crohn disease, or hypersecretory syndromes is truly non–*H. pylori* related.[14,38,39] In these cases, a major factor in children distinguishing the etiology of the ulcer disease from *H. pylori* is that there is an absence of gastritis.[14]

Even with careful handling of biopsies by trained personnel, endoscopic biopsies may sustain crush or other artifacts; thus, when biopsy is indicated, at least two biopsies should be taken from a particular lesion or zone of the stomach. Although the optimum number of biopsies has yet to be determined, when mucosa appears normal, our practice is to take at least two biopsies from the prepyloric or midantrum and two from the greater curve of the midbody. Others advocate taking two from the antrum-body transition zone of the lesser curve (a zone in which inflammation and metaplasia occur in adults).[9,21–27] In addition, biopsies should be taken from the gastric cardia when *H. pylori* infection, gastroesophageal reflux disease (GERD), or mucosa-associated lymphoid tissue (MALT) lymphoma[34] may be present. When the Z line is "prominent"or particularly asymmetric, that is, has one or more tongues that extend beyond most of the circumference into the tubular esophagus, this should be biopsied to determine whether this mucosa is stomach or Barrett specialized metaplasia. Whether an "extension" or "prominence" of the Z line is a variant of normal stomach with gastric cardiac or transitional mucosa or short-segment Barrett esophagus can be determined only by biopsy.[33,40–42]

Inflammation of the gastric cardia is an area of considerable interest because of the increasing incidence of cancer of the cardia and the esophagus and the potential for detecting preneoplastic changes (ie, intestinal metaplasia). Whereas some studies in adults have indicated that carditis and intestinal metaplasia are due to *H. pylori* infection as part of a pangastritis,[28,29,43,44] others indicate that the cause is GERD.[30,31] Yet others suggest that both may be etiologies[32,33]; the difference may lie in the definition of cardia and where the biopsies are taken. A study in children indicates that the most important cause of carditis is *H. pylori* infection (although GERD may also be a cause) and that the cardia may be the most sensitive area to detect *H. pylori*.[7]

When endoscopic findings are puzzling or a lesion is present, more biopsies should be taken randomly and from the lesion or its edge. The size of biopsies is also important. Biopsies taken with "pediatric" forceps are often of little value; they are tiny and difficult to mount, and the amount of useful interpretable tissue is very limited. In most children over 2 or 3 months of age, an endoscope with a 2.8 mm biopsy channel can usually be used, and biopsies with these forceps are often quite adequate if several specimens are taken. In contrast, each biopsy taken with "jumbo" or large-cup forceps offers at least two or three times the amount of mucosa for diagnosis, and these can often be obtained in older children. Issues regarding mucosal biopsy in children are dealt with in more detail elsewhere.[36]

On occasion, usually with rare disorders, even large endoscopic biopsies may be insufficient to make a diagnosis, and endoscopic mucosal resection or full-thickness surgical biopsies are required. This may be the case in infiltrative disorders, which can present with thick folds, a mass, or an ulceration, such as cancer, lymphoma, plasmacytoma,[45] or leiomyoma or leiomyosarcoma, or with certain gastric polyposes.[46] These disorders are not discussed in this chapter.

CLASSIFICATION

Previously, a scoring system was described to quantify the severity of gastritis in children,[12] but only recently has a classification of gastritis in children been proposed.[47] By placing specific pediatric conditions into a conceptual framework and describing the entities and their differential diagnosis, a system was created to facilitate understanding and diagnosis of gastric mucosal disorders.

No classification of gastritis can satisfy everyone because the published classifications have different objectives. Some are a glossary of appearances[21]; others list clinical disorders.[3] Another approach is that of the Sydney system, which essentially is a checklist of histologic findings to aid the pathologist to review biopsies and uniformly report findings by use of a visual analogue scale[22–25]; thus, it is aptly named a system rather than a classification. Although the general principles of this system can be applied to gastritis in children, its major focus is histologic grading of the severity of chronic gastritis, atrophy, and intestinal metaplasia. Although atrophy and intestinal metaplasia do occur in children occasionally, their occurrence is uncommon; therefore, the Sydney system is of limited usefulness in the pediatric age group. Although an early version of the Sydney system had an endoscopic component, this is no longer used, and it remains a purely histologic system. In addition, it does not integrate histopathology with endoscopic appearance and does not address noninflammatory conditions. Atrophy and metaplasia are addressed in Chapter 29.1, "*Helicobacter pylori* and Peptic Ulcer Disease."

We have classified mucosal disorders of the stomach in children primarily by their endoscopic appearances. In this system, gastritis is classified into two groups: erosive and/or hemorrhagic gastritis or gastropathy and nonerosive gastritis or gastropathy (Table 29.2-2). Although some disorders can present as either erosive or nonerosive, each is classified by its most common presentation. The disorders in each group are placed in approximate sequence of their prevalence in the practice of the authors. Each disorder is then described by etiology and any distinctive clinical, endoscopic, and histologic features. We believe that the advantages of this approach are simplicity and ease of use for the practicing pediatric endoscopist. Based on this approach, a diagnosis or differential diagnosis may be made with some certainty at the time of endoscopy, given the clinical context; however, for the majority of disorders, confirmation of the initial impression or definitive diagnosis is still dependent on biopsies and therefore on an active dialogue and close collaboration with a pathologist.

EROSIVE AND HEMORRHAGIC GASTRITIS OR GASTROPATHY

Most of these entities are diagnosed endoscopically, usually in patients presenting with GI bleeding. Because inflammation is not a feature of most hemorrhagic lesions, most conditions in this category are gastropathies. Biopsies are usually not required from erosive or hemorrhagic lesions. However, there are gastritides not in the erosive or hemorrhagic category that may present with erosions or hemorrhagic lesions; in these cases, biopsies are essential for the diagnosis (eg, *H. pylori*, Crohn disease, CMV, allergic gastritis).

"Stress" Gastropathy

This usually occurs within 24 hours of the onset of critical illness in which physiologic stress is present, such as shock, hypoxemia, acidosis, sepsis, burns, major surgery, multiorgan system failure, or head injury. These stressors cause reduction of gastric blood flow with subsequent mucosal ischemia[48] and breakdown of mucosal defenses.[49] Gastric acid is important in the pathogenesis of stress erosions, but actual hypersecretion is seen only in cases of

*Although some disorders can present as either erosive or nonerosive, each is classified by its most common presentation.

sepsis and central nervous system trauma. Risk factors for hemorrhage include gastric hypersecretion, mechanical ventilation, and use of corticosteroids.[49,50]

Stress erosions are typically asymptomatic and multiple and do not perforate, but when they do present, they do so with overt upper GI hemorrhage. Newborns and infants appear to be more prone to perforations.[51] Early lesions predominate in the fundus and proximal body, later spreading to the antrum to produce a diffuse erosive and hemorrhagic appearance. Antral involvement alone is uncommon.

Neonatal Gastropathies

Most neonatal gastropathies are due to physiologic stress, including prematurity, hypoxemia, prolonged ventilatory support, sepsis, and acid-base imbalance. Fatal hemorrhagic gastropathy has been reported in neonates treated with sulindac for patent ductus arteriosus[52] and dexamethasone for bronchopulmonary dysplasia.[53] A high prevalence of hemorrhagic gastropathy has been reported in sick neonates in the intensive care unit who had no upper GI symptoms or signs and underwent endoscopy under a research protocol.[54] Of note is that newborns without[54] and those with[55,56] upper GI symptoms or signs seem to have a high prevalence of hemorrhagic lesions described as esophagitis associated with gastropathy. These lesions are probably due to mechanical suctioning at the time of delivery or later. A retrospective study of 107 neonates who underwent upper GI endoscopy for irritability during feeds and hematemesis showed that 95% of those with hematemesis had endoscopically identifiable lesions.[56] However, in view of the known risk factors for upper GI bleeding and reflux in neonates and the usual good response to medical therapy, upper GI endoscopy is seldom likely to reveal specific lesions that alter the infant's supportive management or prognosis. In addition, endoscopy in sick, small infants is not without risk. More often than not, a conservative approach will better serve the patient.

Hemorrhagic gastropathy has also been reported in otherwise healthy full-term infants[57] presenting with severe upper GI hemorrhage and in one case as antenatal hemorrhage.[58] Endoscopy may be helpful in the rare instances of nonresponse to medical therapy, such as an actively or recurrently bleeding ulcer that may be amenable to endoscopic hemostasis,[59] to guide surgery, or for diagnosis and hemostasis in the extremely rare case of a gastric Dieulafoy lesion.[60]

An unusual gastropathy may occur in infants with congenital heart disease receiving prolonged infusions of prostaglandin E to maintain the patency of the ductus arteriosus. This appears as antral mucosal thickening or a focal mass consisting of foveolar cell hyperplasia, and it may present as gastric outlet obstruction.[61] This entity has also been described in a 6-week-old infant who received no medications.[62]

Traumatic Gastropathy

Forceful retching or vomiting produces typical subepithelial hemorrhages in the fundus and proximal body of the stomach. It is due to "knuckling" or trapping of the proximal stomach into the distal esophagus, resulting in vascular congestion, and is also known as prolapse gastropathy.[63,64] Mallory-Weiss tears immediately above or below the gastroesophageal junction also may occur. Although both prolapse gastropathy and tears tend to resolve quickly, they can result in significant blood loss. By a similar mechanism of trauma, linear erosions may occur in the herniated gastric mucosa of patients with large hiatal hernia, resulting in chronic blood loss anemia.[65] Suction through nasogastric tubes, especially in children who are receiving anticoagulants, can cause severe subepithelial hemorrhage and bleeding. Ingestion of foreign bodies, inflatable gastrostomy feeding devices, and endoscopic procedures such as diathermy[66–68] are also common causes of subepithelial hemorrhages, erosions, and ulcers.

Aspirin and Other NSAIDs

NSAIDs are the most commonly prescribed drugs in the world.[69,70] Although invaluable for treatment of many disorders, the usefulness of NSAIDs is limited largely by their adverse effects on the GI tract. They cause mucosal damage primarily in the stomach (gastropathy) but also in the duodenum, in a spectrum from only histologic changes to subepithelial hemorrhages, erosions, and ulcers. Gastroduodenal NSAID injury may be asymptomatic or result in life-threatening ulcer bleeding or perforation. Less frequent but well-recognized effects occur in the small and large bowel and esophagus.

NSAIDs exert their effects via inhibition of the cyclooxygenase (COX)-catalyzed conversion of arachidonic acid to prostaglandins.[71] Prostaglandins produced by the COX-1 pathway are largely constitutive, that is, responsible for mucosal integrity and hemostasis. Inhibition of COX-1 compromises mechanisms of mucosal protection, such as mucus and bicarbonate production, epithelial integrity and regenerative capacity, and microvascular supply. In contrast, prostaglandins produced by the COX-2 (inducible) pathway mediate pain, inflammation, and fever. There is overlap, however, and dual suppression of COX-1 and COX-2 is necessary for gastrointestinal mucosal damage to occur. Aspirin and other NSAIDS such as ibuprofen, naproxen, sulindac, diclofenac, indomethacin, mefenamic acid, and meloxicam are nonselective COX inhibitors, that is, they inhibit both pathways. Even a single low dose of an NSAID may cause petechial hemorrhages and ulceration within hours, and although early lesions may, on occasion, cause active bleeding, they are often asymptomatic and per se are not predictive of clinically significant ulcer formation.[72,73] Aspirin has an additional effect, that being the inhibition of thromboxane production by platelets.[74,75] Because platelets are anuclear, the effect is permanent for the life of the platelets. Although this property is of benefit in primary or secondary cardiovascular prophylaxis, it does enhance bleeding from the GI tract.

Although some adverse effects may result from topical action of ingested NSAID on the gastroduodenal mucosa, the systemic presence alone of an NSAID compromises mucosal integrity and may produce severe ulceration of the

mucosa. Although many patients report that enteric-coated (buffered) aspirin is associated with fewer symptoms, enteric coating of aspirin does not prevent complications.[71] Factors that place patients at higher risk for severe gastroduodenal ulceration and complications include a history of an ulcer complication, a history of an uncomplicated ulcer, drug dose, comcomitant use of aspirin and another NSAID, use of a corticosteroid, age over 65, use of an anticoagulant, and, possibly, *H. pylori* infection.[69,70,75,76] Although gastric acid does not appear to be a primary causative factor in NSAID mucosal injury, acid suppression with proton pump inhibitors (PPIs) does reduce the risk of gastroduodenal ulceration and bleeding. This suggests that some acid appears to be required for lesions to develop, but not much because NSAID lesions do occur in achlorhydric subjects.[71]

The newer (selective) COX-2 inhibitors or "coxibs," such as celecoxib, rofecoxib, and valdecoxib, produce fewer GI adverse effects in adults, but these drugs are expensive and not free of such effects. The rates of upper GI symptoms (dyspepsia) are only slightly lower on these drugs than on traditional nonselective NSAIDs. Combination of a coxib with aspirin—even at a low dose—substantially detracts from their otherwise improved GI safety profile.[77]

Although there are few data on the adverse GI effects of NSAIDs in children, these do occur.[78–84] As in adults, erosions and ulcers caused by NSAIDs may be single or multiple (Figure 29.2-4), and although the gastric antrum tends to be involved more than the body, they may involve any or all regions of the stomach. In young children, ulceration of the incisura presenting with upper GI bleeding is a typical NSAID lesion, and bleeding may occur after just one or two doses of drug or with more chronic use. The characteristic histologic NSAID lesion in adults and children is a reactive gastropathy, that is, epithelial hyperplasia, mucin depletion, enlarged (reactive) nuclei, fibromuscular (smooth muscle) hyperplasia, vascular ectasia, and edema (Table 29.2-3).[85] Less often, NSAIDs may cause a reactive gastritis. Reactive gastropathy or gastritis may be present at the edge of an erosion or ulcer or in endoscopically normal mucosa distant from such lesions, but it may also be absent even in the presence of severe NSAID lesions. Reactive gastropathy is not specific to NSAID injury; rather, it is a nonspecific feature of chemical injury of gastric mucosa (Table 29.2-4).[3,85]

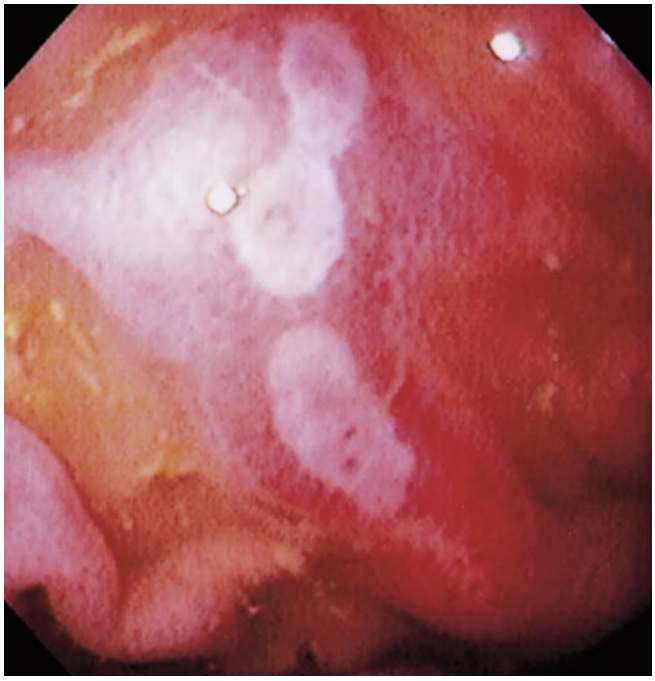

FIGURE 29.2-4 Gastric body erosions owing to a nonsteroidal anti-inflammatory drug in a 14-year-old girl presenting with hematemesis, epigastric pain, and anemia (8 g/dL). She took ibuprofen 400 mg three times daily for 2 days for severe menstrual discomfort. The endoscopic differential diagnosis includes Crohn disease and cytomegalovirus.

In children presenting with abdominal pain, blood loss, anemia, or upper GI lesions at endoscopy, it is particularly important to actively solicit a history of use of over-the-counter NSAIDs because parents and children often fail to mention nonprescription drugs in the medication history. For this reason, adverse effects of NSAIDs in children are likely underrecognized. Use of NSAIDs has increased among children (eg, for management of fever in infants). In a recent prospective randomized short-term clinical trial in children under 2 years of age treated for fever,[82] there was no significant difference in acute GI bleeding between ibuprofen (n = 17,938) and acetaminophen (n = 9,127). Only 7 of the children receiving ibuprofen (5 mg and 10 mg/kg/dose, 6 to 10 doses over 3 days) had symptoms of vomiting or hematemesis; bleeding occurred in 3 and was minor in all, not requiring transfusion, and related to forceful vomiting in some. Based on this study, short-term use in this age group appears to be relatively benign, but more data are required.

However, the main area of concern is long-term use of NSAIDs. Upper GI bleeding following NSAID ingestion in children has been well documented.[78–81] Naproxen is the most commonly used NSAID in pediatric rheumatologic practice.[84] In one study, 75% of children with juvenile rheumatoid arthritis who had taken one or more NSAIDs for over 2 months had endoscopic evidence of gastropathy, antral erosions, or ulcers[80]; of these, 64% had anemia and abdominal pain. Another study indicated that children taking NSAIDs were 4.8 times as likely to develop gastroduodenal injury as those not taking NSAIDs.[81] In that study, abdominal pain was present in 28% of patients taking NSAIDs versus 15% in those not taking them.

Because NSAIDs are protein bound, and hypoalbuminemia may occur in systemic juvenile rheumatoid

arthritis, with higher levels of free drug there is potential for greater NSAID toxicity.[84] This specific aspect has not been studied in children.

Strategies for minimization of risk in NSAID use include use of selective COX-2 inhibitors and/or concurrent use of PPIs or misoprostol.[70,71,75,76] Although both PPIs and misoprostol are very effective in prevention of morbidity, the adverse effects (abdominal cramps, diarrhea) of misoprostol limit its use, and PPI use is likely to be much better accepted in children, as it is in adults. At present, however, there are no data on this indication in children.

Risk reduction also involves consideration of *H. pylori* status. Although gastropathy induced by NSAIDs does not require the presence of *H. pylori* for its development,[86] there are conflicting and confusing data regarding the role and timing of *H. pylori* eradication in healing NSAID ulcers in adults. For example, the studies on omeprazole healing of NSAID ulcers showed higher healing rates with PPIs in *H. pylori*–positive than in *H. pylori*–negative patients.[87,88] Similar results were obtained from an analysis combining both of the US Food and Drug Administration pivotal trials for lansoprazole and NSAID ulcers.[89] This has led some to argue that *H. pylori* infection should not be treated until after the PPI has healed the ulcer; however, there is no consensus on this.

In *H. pylori*–infected adults with no ulcer disease, evidence for the effectiveness of *H. pylori* eradication as ulcer prophylaxis in chronic NSAID users is also contradictory.[90–92] Nevertheless, the weight of evidence suggests that when there is a history of *H. pylori* ulcer disease, eradication of *H. pylori* is indicated before instituting NSAID use.[75,90,92] Until data indicate otherwise, in general, it seems prudent to eradicate *H. pylori* in children requiring high-dose or long-term NSAIDs.

Use of NSAIDs in children will likely continue to increase, following the trends in adults, with the availability of the newer coxibs and for use in special groups such as those with premalignant intestinal polyposis syndromes and perhaps premalignant conditions such as chronic inflammatory bowel disease and Barrett esophagus. Data on NSAID use in children are very much needed.

Other Drugs

Although many drugs may cause nonulcer dyspepsia, erosive or hemorrhagic gastropathies have been described with valproic acid, dexamethasone, chemotherapeutic agents, alcohol, potassium chloride, and cysteamine.[53,93–101]

Portal Hypertensive Gastropathy

This congestive gastropathy occurs frequently in children with intra- or extrahepatic causes of portal hypertension.[102] The endoscopic findings vary from a mild gastropathy with a mosaic pattern of 2 to 5 mm erythematous patches separated by a fine white lattice to a severe gastropathy typified by the presence of cherry red spots or even a confluent hemorrhagic appearance.[102–104] The mosaic pattern is specific for portal hypertensive gastropathy (PHG) and was not found in any of 500 children without liver disease at endoscopy.[102] In adults, congestive gastropathy is more frequently associated with large gastroesophageal varices than with esophageal varices alone,[104,105] and sclerotherapy of esophageal varices may exacerbate PHG and gastric varices. In contrast, PHG, which has been reported to occur only after variceal obliteration therapy and not before, is more likely to be transient and less severe.[105,106] The histologic findings in PHG are ectasia of mucosal capillaries and venules and submucosal venous dilatation.[104] However, PHG is an endoscopic diagnosis; biopsy is not indicated and is potentially dangerous.

Uremic Gastropathy

In acute renal failure, gastropathy may be due to physiologic stress rather than to renal failure itself. When gastrointestinal bleeding occurs in acute renal failure, it is associated with erosions and/or ulcers in 71% of cases and with an increased risk of death and duration of hospital stay; additional factors that predispose the patient to bleeding are use of corticosteroids and other disease such as liver cirrhosis.[107]

Chronic renal failure (CRF) is associated with increased densities of parietal, chief, and gastrin-producing cells.[108] Despite this, gastric pH may be less acid than expected; this may reflect neutralization of gastric acid with ammonia, a breakdown product of urea that is very high in gastric juice in patients with CRF.[108,109] This may explain why patients are more likely to suffer acid-peptic complications after treatment for CRF, that is, lowering of the urea or gastric nitrogen levels may remove their neutralizing effect on gastric acid. Hypergastrinemia associated with CRF is likely to be secondary to the gastric acid neutralization as well as reduced gastrin clearance.[108–110]

There are few data on the effects of CRF on the stomach in children. In adults, whereas active peptic ulcer disease does not seem to be more common in CRF, hemorrhagic gastropathy is quite prevalent in patients receiving chronic hemodialysis.[109] In such patients, gastroduodenal lesions occur in up to 67%, the predominant lesion being antral gastropathy in some 50%.[110] When peptic ulcers do occur in CRF, their presentation is somewhat atypical; they are more often multiple, *H. pylori* negative, and less likely to present with pain; rather, they tend to be symptom free or present with bleeding.[110–112] Although angiodysplastic lesions in the stomach may account for some 13% of cases of upper GI bleeding in CRF, it is unclear whether they are more common in this population or simply more likely to bleed because of uremic platelet dysfunction or hemodialysis.[113,114] Endoscopic "gastritis"

was reported in 10 of 17 children with CRF, with only 4 having findings localized to the gastric antrum,[115] but the gastritis was not defined endoscopically or histologically.

Chronic Varioliform Gastritis

Also known as chronic erosive gastritis, CVG is an uncommon disorder of unknown etiology, described more commonly in Europe than in North America. Although CVG largely occurs in middle-aged and elderly men,[15,116–118] it has been reported in a few children presenting with variable combinations of upper GI symptoms, anemia, protein-losing enteropathy, peripheral eosinophilia, and elevated serum immunoglobulin (Ig)E levels.[16,17,119,120] Symptoms arise insidiously and often become subacute or chronic. Most striking endoscopically are the innumerable prominent nodules in the fundus and proximal body of the stomach (see Figure 29.2-2); in children, the antrum is less often involved. Typically, the gastric rugae are irregularly thickened, with nodules located on the crests of the folds. The nodules sometimes have an umbilicated central crater or erosion; the lesions are said to resemble the skin lesions of chickenpox—hence the name. Histologic features include edema, foveolar hyperplasia, active chronic inflammation, and eosinophilic infiltrates. Focal superficial subepithelial collagen deposition may represent fibrosis at points of previous surface erosions. We have observed variable degrees of collagen deposition with active inflammation and gland atrophy in three adolescents (see "Collagenous Gastritis" below). In adults, CVG is one cause of a "lymphocytic gastritis" in which the surface and foveolar epithelium is infiltrated with dark-staining T cells, as in celiac disease.[37,117,118] For other causes of lymphocytic gastritis, see Table 29.2-5. If the diminishing number of reports of CVG in the adult literature reflects prevalence, this disorder appears to be getting less common.

Bile Gastropathy

This is also known as alkaline gastropathy or duodenogastroesophageal reflux (DGER). Although it is well documented in the postoperative stomach,[121] reports of DGER in the intact stomach are confined mainly to the adult literature.[122,123] The mere finding of bile in the stomach at endoscopy is common and unlikely to be of any significance. Typical endoscopic features of DGER include "beefy" redness or erythema and, occasionally, erosions. Despite this, there is very little or no increase of cellular infiltrate in the lamina propria, the main histologic features being epithelial (ie, foveolar hyperplasia), occasionally with a corkscrew appearance, lamina propria edema, and venous congestion. These changes constitute the entity of a so-called reactive gastropathy.[9,85] Postoperatively, they are found more commonly in the stomach than at the stoma. Other features include stomal erosions, lipid islands, and mucosal cysts; the latter are sometimes grossly visible and are known as gastritis cystica profunda or polyposa. Some studies report a high prevalence of intestinal metaplasia, although this may reflect sampling from the stomal region, which normally reflects a mosaic of gastric and intestinal mucosa.

Fortunately, nowadays, there are hardly any indications for partial gastrectomy in children, and pyloroplasty in children[124] is seldom recognized to be attended by the above problems.

Helicobacter pylori
Idiopathic

Henoch-Schönlein Gastritis

Henoch-Schönlein purpura (HSP), or Henoch-Schönlein disease, is a frequently recognized multisystem disorder attributable to an immune complex–mediated vasculitis. The systems involved are usually skin, the GI tract, kidneys, and joints. It manifests as a clinical syndrome of nonthrombocytopenic skin lesions, arthralgias and arthritis, renal disease, and colicky abdominal pain. GI symptoms and signs include abdominal pain, nausea and vomiting, and GI tract bleeding. Less common serious abdominal complications include intramural hematomas, intussusception, bowel infarction, bowel perforation, pancreatitis, appendicitis, and cholecystitis. In HSP, endoscopic findings in the stomach include erythematous or hemorrhagic swollen mucosa with erosions or ulcers. Raised blebs may be seen with punctate hemorrhages and often central erosions or ulcer with a yellow base.[18,19] The findings may be patchy, antral predominant, or diffuse.[125] Similar lesions are often present in the duodenum and jejunum. Although gastric mucosal biopsies are usually too superficial to show typical histologic changes, they may show a leukoclastic vasculitis similar to that seen in the skin.[18] Patients may have an elevated serum IgA and reduced factor XIII levels.[18,19] Endoscopy is seldom required for the diagnosis of this condition; however, it may be helpful in those children with persistent abdominal pain or vomiting who have not yet demonstrated the typical nonthrombocytopenic rash of HSP. A few may never develop the rash.[126–128] All children with hematemesis, even those with the HSP rash, should undergo endoscopy to diagnose complications or other causes of upper GI bleeding, such as duodenal ulcer disease.[125]

Corrosive Gastropathy

The most common ingestants affecting the stomach are acids, iron, and strong alkalis; the latter predominantly involve the esophagus but occasionally involve the stomach. When gastric injury does occur, the prepyloric area is particularly vulnerable,[129,130] probably because of pylorospasm and pooling of secretions. The presence of food may limit the degree of injury. Endoscopic findings range from mild friability and erythema to necrosis, ulcers, exudates, and hemorrhage, with rare perforation. Chronic cicatrization is relatively rare and may take several months to become apparent—hence the need for serial imaging studies. Transabdominal ultrasonography may prove useful in localizing injury, determining its

depth and the presence of peristalsis, and thereby reducing repeated radiation exposure.[131] Iron poisoning, especially with ferrous sulfate, is common in children in some areas of the world and may cause a corrosive gastropathy with stricture.[132] Therapeutic administration of oral ferrous sulfate may cause mild endoscopic abnormalities in the stomach, which are of uncertain clinical significance.[133] Pine oil cleaner ingestion may also cause gastric injury.[134]

Exercise-Induced Gastropathy or Gastritis

This is well recognized in long-distance runners. The condition usually presents with blood loss anemia with or without upper GI symptoms. Symptoms often occur post-exercise and include abdominal cramps or epigastric pain, nausea, and vomiting.[135] Both erosive gastropathy and nonerosive gastritis have been described, with mucosal lesions occurring almost equally in the gastric antrum, body, and fundus.[136,137] Gastritis is usually acute, with hemorrhagic inflammation on biopsy. Postulated mechanisms include splanchnic ischemia, with reports of up to 80% reduction in visceral blood flow compared with pre-exercise levels reported.[138] Strenuous exercise does not appreciably affect postprandial gastric secretion or gastric emptying.[139]

Cystinosis

This is an inherited lysosomal storage disorder characterized by the deposition of massive amounts of cystine within macrophages. To reduce the rate of development of renal deterioration with the need for transplant and also improve life expectancy, patients are required to take the drug cysteamine every day.[140] This drug is extremely ulcerogenic and has been used to induce duodenal ulcers in laboratory animals.[100] Cysteamine is a potent secretagogue, causing hypergastrinemia and gastric acid hypersecretion that occur for 1 to 2 hours after drug ingestion.[20,140] The additional ulcerogenic effects of cystinosis are due to delayed gastric emptying and inhibition of gastric bicarbonate and mucus production. At endoscopy, 2 of 11 children had a distinctive, sometimes erosive, diffuse fine nodular appearance throughout the stomach.[20] In contrast to the gastric nodularity seen in *H. pylori* gastritis, the nodules of cystinosis are much finer, and their distribution is pangastric. In some cases, crystalline structures are seen within lysosomes of macrophages of the lamina propria of gastric, duodenal, and esophageal biopsies.

Radiation Gastropathy

This condition, associated with abdominal irradiation given to patients with malignancy, causes erosions or ulcers particularly in the gastric antrum and prepyloric regions,[141] as well as severe diffuse hemorrhagic gastritis or gastropathy. Fibrosis and stricture formation may occur and lead to gastric outlet obstruction. A high total radiation dose and, perhaps more importantly, a high daily fraction appear to be the main risk factors, but onset of gastritis may not always be dose dependent.[142,143] Treatment may be difficult and sometimes includes surgical resection.[144,145] Radiation is often given together with chemotherapy, but the combined effects are similar to those of radiation alone.

NONEROSIVE GASTRITIS OR GASTROPATHY

In nonerosive gastritis, there is usually a poor correlation between endoscopic appearance and histologic findings, that is, the diagnosis is usually purely histologic. An exception is the nodular antrum of *H. pylori*–associated ulcer disease in children; however, nodularity persists even after eradication of *H. pylori*, so, in this case, the diagnosis is endoscopic and histologic. Furthermore, nodularity is not always present, so the diagnosis still ultimately depends on histology. Some of the entities in this section may also present as an erosive gastropathy or gastritis but are included here because they more commonly present without erosions.

Lymphocytic gastritis is a type of gastritis deserving of special mention; this may be seen in disorders as apparently diverse as celiac disease, CMV gastritis, Ménétrier disease, *H. pylori* infection, and CVG. Because ours is an endoscopic classification, lymphocytic gastritis is mentioned under each of those disease entities.

Nonspecific Gastritis

In our experience, a significant number of children have chronic gastritis for which no cause can be identified.[8] In these cases, the inflammation is chronic, lymphoplasma cellular, more focal than diffuse within the biopsy, and usually superficial. Although it appears to be more prevalent in the antrum than in the corpus, this may reflect sampling bias.

H. pylori Gastritis

This is addressed in Chapter 29.1.

Inflammatory Bowel Disease

Gastroduodenal involvement is relatively common, and in children, Crohn disease is the most common cause of granulomatous gastritis.[10] Such symptoms as may occur are similar to those of acid-peptic disease and of delayed gastric emptying, with hematemesis and melena occurring less frequently.[146–149] Macroscopic and/or histologic abnormalities are present in the esophagus, stomach, or duodenum in up to 80% of children with Crohn disease.[10,150] However, some of these changes are nonspecific. The figure becomes 30% if features specific to Crohn disease, such as giant cells and noncaseating granulomas, are considered[146]; if focal deep gastritis is included, the figure becomes about 50 to 100%.[10,151,152] As would be expected, the figures quoted for these studies will largely depend on the number of biopsy specimens taken and whether serial sections of those specimens are carefully examined. In one study of *H. pylori–negative* adults,[142] the focal gastritis in 80% of patients with Crohn disease was characterized by perifoveolar or periglandular accumulation of CD3+ lymphocytes and CD68+ and CD68R+ histiocytes, together with granulocytes. This characteristic gastritis was found in the antrum in 48% (36 of 75 patients) and in the body in 24% of cases.[142]

In the appropriate clinical context, the identification of noncaseating granuloma is diagnostic of Crohn disease, but differentiation from other granulomatous gastritides (Table 29.2-6) is important.[3,10] Endoscopic and/or histo-

logic evidence of Crohn disease of the stomach may occur in the absence of upper GI symptoms and sometimes precedes diagnostic features in the colon.

In our own experience, 67 of 229 (29%) patients with Crohn disease who underwent upper GI endoscopy had histologic evidence of gastritis[10,150]; only one-third of these had endoscopic features of loss of vascular pattern, mucosal swelling, aphthous ulcers, or luminal narrowing (Figure 29.2-5). Deep ulceration in the duodenum can also occur, and this can mimic primary peptic ulcer disease. Histologic features range from focal chronic active inflammation to more typical non-necrotizing granulomas. For both the endoscopic and histologic findings, the antrum is the most common repository of disease, but granulomas are also present in the corpus and the cardia. In our experience, gastric Crohn disease is second overall to *H. pylori* as an identifiable cause of gastritis in children.[150]

Not infrequently, histologic findings of chronic antral gastritis will result in a change of diagnosis from ulcerative colitis to Crohn disease, even in the absence of granuloma. However, mild chronic gastric inflammation is also seen in ulcerative colitis. Whether this represents a greater prevalence than in normal children is still unclear. In two reports in which 5 and 14 children, respectively, were said to have ulcerative colitis, gastric inflammation was typically chronic active and mild.[153,154] In the larger of the two studies, although none of the patients had moderate to severe gastritis, 69% of the patients did have mild antral gastritis. This, however, did not reach statistical significance when compared with "control" patients who were endoscoped for possible reflux esophagitis.[154] In another retrospective study, antral focal gastritis was reported in 60% (28 of 43) of children with Crohn disease, in 20.8% (5 of 24) with ulcerative colitis, and in 2.3% (3 of 129) of patients without inflammatory bowel disease. In this study, focal antral gastritis was not considered reliable in differentiating between the two conditions.[155]

Allergic Gastritis

This is the gastric component of allergic gastroenteritis. This condition usually presents in infancy but may be seen even in preterm infants.[156,157] Although allergic gastritis and eosinophilic gastritis (discussed below) have some features in common, in allergic gastroenteritis, the disease is always mucosal and not deeper, the endoscopic changes are milder, and it is a more benign disease, of limited duration. For the gastroenterologist, this condition is usually diagnosed through clinical suspicion, histologic findings, and the response to elimination diets. A temporal relationship between characteristic symptoms and the ingestion of certain foods is particularly helpful in establishing the diagnosis. Allergic gastritis is usually associated with a specific allergen; in children, cow's or soy milk protein, egg, and wheat are the most frequently identified antigens, usually causing symptoms such as irritability, vomiting, and growth failure within the first 6 to 12 months of life.[158] Vomiting may be due to allergen-induced gastric dysrhythmia and delayed gastric emptying in sensitized infants.[159] Unlike eosinophilic gastroenteropathy, in which some patients remain symptomatic into later childhood and even adulthood, in allergic gastritis, reintroduction of the antigen is almost always possible by 24 months of age and often earlier. The histologic features include an eosinophilic infiltrate in the lamina propria and the surface and foveolar epithelium, and, occasionally, lymphocytes, plasma cells, and neutrophils are present. Endoscopy may show normal mucosa or changes similar to those of eosinophilic gastritis but usually not as marked. However, erosions have been described in children.[160] Peripheral eosinophilia, elevated serum IgE levels, and positive radioallergosorbent testing for specific allergens may be detected.

TABLE 29.2-6 CAUSES OF GASTRIC GRANULOMAS

NONINFECTIOUS CAUSES
Crohn disease
Chronic granulomatous disease
Vasculitis associated
Sarcoidosis
INFECTIOUS CAUSES
Tuberculosis
Syphilis
Histoplasmosis
Parasites
Isolated granulomatous gastritis
Foreign body granulomas
Idiopathic

Adapted from Dohil R et al.[47]

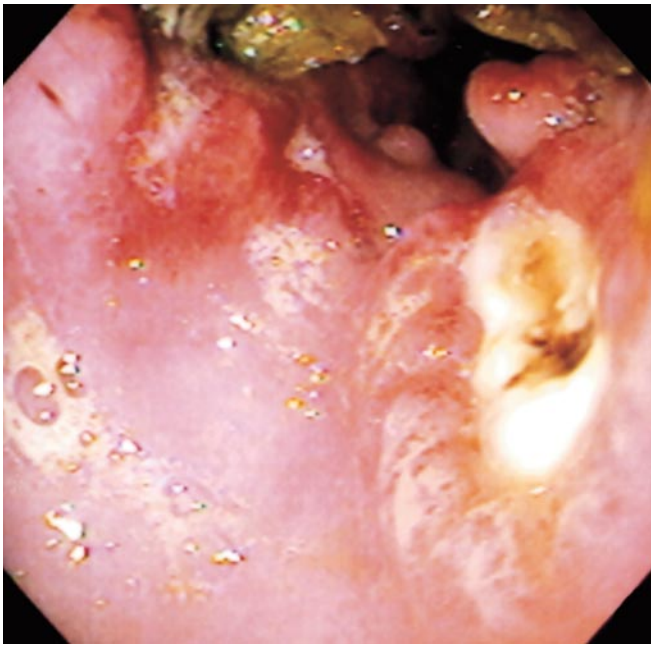

FIGURE 29.2-5 Crohn disease of the gastric antrum. Gastric erosions, ulcers, and pseudopolyps in a 16-year-old boy presenting with epigastric pain and early satiety; no other symptoms were present. Granulomas were present on biopsy.

PPI Gastropathy and Gastric Polyps

Long-term or high-dose PPI therapy often causes a characteristic hyperplasia of parietal cells, with a thickened parietal cell zone, and lingular pseudohypertrophy of individual parietal cells. Cystic changes often occur in the glands. In

some cases, benign fundic gland polyps may be present. The parietal cell changes regress to normal some weeks after cessation of acid suppression therapy.[161–165] In a study of patients on long-term (mean 7.9 years) PPI therapy, enterochromaffin-like cell hyperplasia was reported in over 50% of patients and was thought to be a trophic effect of the associated hypergastrinemia; no evidence of dysplasia was reported even after 10 years of therapy.[166]

Gastric polyps unrelated to PPI therapy are also uncommon in pediatrics.[46]

Celiac Gastritis

A lymphocytic gastritis has been described relatively recently in celiac disease.[167–171] In celiac disease and in *H. pylori*, it occurs in the presence of a usually normal gastroscopy. The gastritis in celiac disease is typified by the intraepithelial location of the lymphocytic infiltrate.

In one study, this gastritis was present in 10 of 22 (45%) adults with celiac sprue.[169] It was characterized by a striking mononuclear infiltrate (primarily T cells) mainly in the surface and pit epithelium of the antrum and body, with sparing of the deeper glandular epithelium; the lamina propria was expanded by an infiltrate of plasma cells, lymphocytes, and rare neutrophils. Children and adults with this pattern of gastritis have a mean of some 40 to 46 lymphocytes per 100 epithelial cells, compared with means of 3 to 5 in normal controls or those with the lymphocytic form of *H. pylori* gastritis.[169,170] In the latter, the infiltrate is predominantly in the lamina propria.[168] A milder lymphocytic gastritis was seen in another pediatric study.[171] The pattern of gastric lymphocytic inflammation in celiac disease resembles that seen in the small bowel and in the colon in that disease; this gastritis is associated with increased gastric permeability[172] and resolves in some patients following treatment of celiac disease.

In one pediatric study, 15 of 25 children with celiac disease had chronic gastritis; 9 of these had lymphocytic gastritis, and 6 had mild nonspecific inflammation.[170] A more recent study in children reported intraepithelial lymphocytic gastritis (more marked in antrum than body) in 29 of 33 children with untreated celiac disease; 15 of these 29 also had evidence of focal or diffuse chronic gastritis within the lamina propria.[171] Mucin depletion was often seen when increased intraepithelial lymphocytes were associated with chronic gastritis. None of the patients had endoscopic evidence of varioliform gastritis, mucosal swelling, or ulceration. The number of intraepithelial lymphocytes returned to normal on a gluten-free diet.[171] The variation in severity and prevalence of lymphocytic gastritis between studies may reflect varying amounts of dietary gluten intake as well as the lack of uniformity in the targeting of biopsies.[173] In one study, dyspeptic symptoms, such as epigastric pain and vomiting, were significantly more frequent in those celiac children with lymphocytic gastritis than without[170]; however, no such correlation was found in another study.[171] We have seen two childhood cases of celiac disease with multiple duodenal erosions, and a case of severe bleeding from multiple gastric ulcers has been described in an adult with celiac disease and lymphocytic gastritis.[174] It has been suggested that patients with *H. pylori*–negative antral-predominant lymphocytic gastritis should be evaluated for celiac disease.[173]

Chronic Granulomatous Disease

Chronic granulomatous disease is a rare X-linked recessive immunodeficiency disorder of boys in which granulomatous gastric wall involvement is common. When present, symptoms of delayed gastric emptying occur, with a narrowed, poorly mobile antrum on contrast radiography.[175,176] There are no specific endoscopic findings, but often the antral mucosa is pale, lustreless, and swollen. Histologic findings include focal, chronic, active inflammation in the antrum with granulomata or multinuclear giant cells. In our own experience of six cases, the diagnostic lipochrome-pigmented histiocytes were absent in gastric biopsies but were found in the lower gastrointestinal tract.[10]

Cytomegalovirus Gastritis

On those rare occasions when CMV infection occurs in immunocompetent children, it manifests as Ménétrier disease (see below); it is so uncommon in apparently immunocompetent adults[177] that its finding suggests an occult malignancy or early immunodeficiency.[178] Conversely, CMV infection is so common in immunosuppressed patients (such as those with acquired immune deficiency syndrome [AIDS] or following solid organ or bone marrow transplant[179]) that, in some cases, it is difficult to know whether it is a pathogen or a commensal. In such patients, this compounds the diagnostic difficulty in distinguishing between gross or histologic lesions caused by infection, graft-versus-host disease (GVHD), physiologic stress, or chemotherapy. However, if the highly distinctive pattern of injury is present, it is more likely that CMV is the cause. The infection tends to occur in the gastric fundus and body and may cause wall thickening, ulceration, hemorrhage, and perforation.[180,181] Histologic findings include active acute and chronic inflammation with edema, necrosis, and cytomegalic inclusion bodies in epithelial and endothelial cells, as well as in ulcer bases and mucosa adjacent to ulcers.[182] In contrast to herpes virus infection, which tends to be superficial, CMV usually affects deeper portions of the mucosa, and the active inflammation may be focal or panmucosal. The diagnostic yield is increased by viral culture of mucosal biopsies and by immunohistochemical detection of CMV early antigen. Treatment with ganciclovir may be beneficial in immunosuppressed patients, but, otherwise, spontaneous recovery usually occurs within 1 to 2 months.

Eosinophilic Gastritis

This is the gastric component of eosinophilic gastroenteritis; the term *gastroenteritis* is somewhat misleading because, in addition to the stomach and small bowel, the colon and esophagus may also be involved in this disorder. This condition usually presents in infancy but has also been reported in preterm infants.[156] It is a chronic, severe disease, of unknown etiology, characterized by the presence of upper GI symptoms and signs, as well as poor

growth, gastrointestinal bleeding, and, often, diarrhea. Iron deficiency anemia and hypoproteinemia with protein-losing enteropathy are commonly present.[157,183–185] In most, but not all, patients, serum IgE is elevated, and peripheral eosinophilia is present.[184] All layers of the gastric wall may be involved; the eosinophilic infiltrate may be patchy, and there may be selective predominance of eosinophilic infiltrates in the mucosa, muscle layer, or subserosa.[183] Therefore, diagnosis by endoscopy with biopsies may not always be possible; sometimes, surgical full-thickness biopsy is necessary. When present, gastroscopic features are nonspecific and include friability and erythema, erosions, swollen mucosal folds, and scattered mucosal blebs or nodular lesions, particularly in the gastric antrum. When present, these nodules differ from those associated with *H. pylori* gastritis in that they are scattered, few in number, and not of uniform size. Even when the mucosa is normal at endoscopy, biopsies often reveal a striking eosinophilic infiltrate through the lamina propria into the epithelium; occasionally, small numbers of lymphocytes and plasma cells are present. Eosinophilic gastritis has also been described as a manifestation of collagen vascular disease such as scleroderma[186] and also with acute infections with the parasite *Anisakis*. The latter is most likely due to an allergic reaction occurring in sensitized individuals.[187]

Collagenous Gastritis

This rare entity, which is characterized by subepithelial collagen deposition and an associated gastritis, may not itself comprise a distinct disorder but, rather, a consequence of inflammation or a local immune response in the stomach or as one histologic feature of a more diffuse disease process. For example, it has been described in association with the histologically similar conditions of collagenous sprue and collagenous colitis, lymphocytic colitis, and celiac disease.[188–193] In some of these reports, it appears to be a "stand-alone" disorder. It has also been described as a prominent histologic feature in some children with the typical endoscopic features of CVG, including diffuse gastric erythema, erosions, and hemorrhage.[17,194] The pattern of mucosal fibrosis in collagenous gastritis, colitis, or sprue is subepithelial in the lamina propria and quite different from the much deeper (usually circular muscle) involvement seen in scleroderma.[195] In children, collagenous gastritis most often presents with upper abdominal pain, gastrointestinal bleeding, and anemia.[17,194,196,197] None of these children had endoscopic or histologic improvement at follow-up, although symptoms may resolve with acid suppression treatment. Adults more often present with diarrhea, and this most likely represents associated lymphocytic or collagenous colitis or even celiac disease. Symptomatic improvement has been reported with therapies including gluten-free diet, corticosteroids, and acetylsalicylic acid preparations.[190–192]

Graft-versus-Host Disease

Acute GVHD occurs 3 to 4 weeks after transplant, with varying degrees of mucositis, dermatitis, enteritis, and hepatic dysfunction.[141] Upper GI symptoms are also commonly seen. More recently, the stomach has been shown to be an important area for the histologic diagnosis of gastrointestinal GVHD, even when diarrhea is the main symptom[198,199]; the gastric endoscopic and histologic findings may underestimate the severity of GVHD elsewhere in the gut. Endoscopy with biopsies is not routinely required for the diagnosis of GVHD, but when performed for investigation of abdominal pain, for bleeding, or to exclude opportunistic infection, the findings vary considerably. These range from normal or subtle changes, even when most or all of the epithelium is lost, to patchy erythema with erosions, to extensive mucosal sloughing; the early biopsy findings are unique to GVHD, consisting of crypt epithelial cell apoptosis and dropout. In more severe cases, whole crypts may drop out. There is variable lymphocytic infiltration of the epithelium and lamina propria. In advanced cases, there may be ulceration, edema, fibrosis, and perforation. When acute GVHD is suspected, the duodenum and esophagus should be biopsied, in addition to the proximal and distal stomach, but with recognition that duodenal biopsy carries higher risk in these patients.[198–200] Histologic distinction between GVHD, CMV infection, human immunodeficiency virus (HIV), and other immunodeficiencies may be difficult.[201] Chronic GVHD rarely involves the stomach.

Ménétrier Disease

Ménétrier disease (hypoproteinemic hypertrophic gastropathy) is a rare, acquired disorder of the stomach that is premalignant or may even present with malignancy in adults but is generally a clinically benign, self-resolving disorder in children. It is characterized by large folds that most often involve the fundus, excess mucus secretion, decreased acid secretion (hypochlorhydria), and hypoproteinemia secondary to selective loss of serum proteins across the gastric mucosa.

The childhood form of this rare disorder may follow a viral prodrome and includes epigastric pain, anorexia, vomiting, edema, hypoproteinemia, and raised IgE levels in some.[202] Full-thickness gastric biopsy at laparotomy or even partial gastric resection for diagnosis has become obsolete in children with the advent of pediatric endoscopy, although other "thick fold" diseases are in the differential diagnosis and may require this approach (see "Multizone Biopsy Sampling" above). The combination of endoscopic and histologic findings is diagnostic. Endoscopy shows swollen convoluted rugae sometimes with polypoid or nodular configuration. The histology typically shows elongated, tortuous foveolae, with reduction of chief and parietal cell glands and often with cystic dilatations that may extend into the muscularis mucosae and submucosa. The lamina propria is edematous with increased eosinophils, lymphocytes, and round cells, and the muscularis mucosa may be hyperplastic with extensions into the mucosa. Gastric wall thickening as determined by ultrasonography is not diagnostic of Ménétrier disease, but serial studies may be helpful in monitoring the course of the disease.[203] Endoscopic ultrasonography has also been used to diagnose hypertrophic gastric folds,

which may reach up to 20 mm in diameter in adults.[204] Ménétrier disease has been strongly associated with CMV infection in immunocompetent children, and elevated CMV IgM levels, positive CMV testing by polymerase chain reaction, or positive culture of gastric tissue may be helpful in confirming the diagnosis.[202,205] The cause of adult Ménétrier disease is unknown. Reports of CMV-associated gastric fold thickening in adults are rare.[206] A genetic predisposition was suggested in a report of three affected generations in one family,[207] and cure of *H. pylori* infection has resulted in resolution of adult Ménétrier disease.[208] Increased signaling of the epidermal growth factor receptor has been implicated in the pathogenesis of adult Ménétrier disease.[209]

Although this condition is reported from the neonatal period onward, the mean age at onset in children is 4.7 years.[210] In children, the natural history is of self-resolution within weeks or months.[202,210,211] In contrast, the adult disease is usually chronic, and evidence of the benefits of anticholinergic drugs, acid suppression, octreotide, and eradication of *H. pylori* is inconsistent; occasionally, partial gastrectomy has been required to alleviate persistent abdominal symptoms, hypoproteinemia, and blood loss. Dramatic resolution of many manifestations in adults has been reported with the use of antiepidermal growth factor receptor antibody.[212] A lymphocytic gastritis has been described in the adult form.[213]

Pernicious Anemia

Although megaloblastic anemia may result from dietary, malabsorptive, or other causes of vitamin B_{12} (or folate) deficiency, the term *pernicious anemia* (PA) is applied to the anemia and condition that result from a deficiency of intrinsic factor.[214] The classic or adult form of PA occurs also in children and is due to an autoimmune process with autoantibodies to parietal cell components, including the proton pump and intrinsic factor. This results in absolute achlorhydria and megaloblastic anemia secondary to vitamin B_{12} deficiency. Conditions associated with PA include endocrinopathies such as autoimmune thyroid disease and diabetes mellitus, vitiligo, selective IgA deficiency, abnormal cellular immunity, chronic candidiasis, and collagen vascular disease.[215–217] The typical finding at endoscopy is thin rugae of the gastric body, sometimes with blood vessels visible through the mucosa. Histology shows severe atrophic fundic gland gastritis with absence of parietal cells. Adenocarcinoma of the stomach occurs as a complication of PA. Although gastric adenocarcinoma is very rare in children, it does occur,[218–220] and endoscopic surveillance of PA is indicated.

A separate category entirely is so-called childhood or juvenile PA. This is a heterogeneous group of conditions that can be considered as metabolic rather than autoimmune. There is no gastric atrophy, but megaloblastic anemia and hypo- or achlorhydria are present.[221] Recently, secretion of abnormal intrinsic factor or abnormalities of secretion of intrinsic factor have been found as the cause of juvenile PA.[222] A congenital anomaly of vitamin B_{12} metabolism (cobalamin *C* disease) occurs very rarely; it is accompanied by striking cystic dysplastic changes in gastric mucosa and total absence of parietal and chief cells.[223]

Gastritis Associated with Autoimmune Diseases

Gastritis with and without atrophy has been seen in children with autoimmune thyroiditis and nongoitrous juvenile hypothyroidism, some with achlorhydria and gastric parietal cell antibodies.[215] Autoimmune atrophic gastritis has also been described in 15% of adults with vitiligo.[216]

In children and adults with connective tissue diseases, a mast cell gastritis and a combination of mast cell and eosinophilic gastritis has been described.[186,224] We have seen atrophic gastritis in a teenage girl with scleroderma. Gastrointestinal bleeding in patients with systemic sclerosis and CREST syndrome has been reported and is most often due to mucosal telangiectasia, although peptic ulcers and erosive gastritis are also described.[225]

In a large group of children with insulin-dependent diabetes mellitus, 7% had upper GI symptoms for which endoscopy was performed[226]; 48% had evidence of erosions and ulcers, and 35% had evidence of delayed gastric emptying. Histologic gastritis was reported in 25 of 27 children in whom biopsies were taken; all were negative for *H. pylori*.

Other Granulomatous Gastritides

Granulomatous gastritis other than that attributable to Crohn disease is rare. The differential diagnosis includes foreign body reaction, tuberculosis, histoplasmosis, and Wegener disease, among other disorders (see Table 29.2-6).[227–229]

Idiopathic isolated granulomatous gastritis is a rare condition of a chronic granulomatous reaction limited to the stomach and a diagnosis of exclusion. Primarily reported in adults, it has also been reported in a 14-year-old who responded to steroids.[227] However, in most cases of idiopathic granulomatous gastritis, an etiology of Crohn disease or sarcoidosis can be established.[228]

Langerhans cell histiocytosis (histiocytosis X), a rare condition in which organs are infiltrated by proliferating histiocytes, can cause granulomatous gastritis[230] and gastric polyps.[231] Sarcoidosis is very rarely encountered in the gastrointestinal tract, and reported cases are confined to the adult literature.[232–234]

Phlegmonous Gastritis and Emphysematous Gastritis

Phlegmonous gastritis is a rare, life-threatening condition in which a rapidly progressive bacterial inflammation of the gastric submucosa results in necrosis and gangrene.[235] Most cases are due to α-hemolytic streptococci, *Staphylococcus aureus*, *Escherichia coli*, and *Clostridium welchii*, but other organisms, such as *Candida albicans* and *Mucor*, may be involved.[236] Patients may have infections elsewhere in the body or be immunocompromised.

Acute emphysematous gastritis is a complication of phlegmonous gastritis in which gastric wall infection is due to gas-forming bacteria.[237–240] This often fatal condition is characterized by severe abdominal pain and systemic toxic-

ity, with radiologic evidence of gas bubbles and thickening of the gastric wall. Predisposing factors include ingestion of caustic agents and abdominal surgery. It has also been reported in a leukemic child,[239] in a child with a phytobezoar,[237] in a patient who ingested large volumes of a carbonated beverage,[240] and in hepatic cirrhosis owing to chronic alcoholism, Indian childhood cirrhosis, and Budd-Chiari syndrome.[241] Treatment should be prompt if mortality is to be avoided and may involve gastrectomy, drainage of localized intramural collections that can be identified by computed tomography or endoscopic ultrasonography, and the use of broad-spectrum antibiotics.[242] Emphysematous gastritis must be distinguished from two other entities that cause gas to be present in the gastric wall, gastric emphysema and cystic pneumatosis. These usually follow instrumentation or gastric outlet obstruction and in and of themselves are not clinically significant.[239,240]

Other Infectious Gastritides

Giardia lamblia is said to be the most common of all gastrointestinal parasites and occurs worldwide.[243] It is characteristically a small bowel parasite. Gastric colonization with *Giardia* has been reported in 41 (0.37%) of some 11,000 patients who underwent gastroscopy and biopsies over a 5-year period at one institution.[244] All 41 had chronic atrophic gastritis, and most had intestinal metaplasia with or without *H. pylori* infection. *Giardia* trophozoites were found on the surface epithelium and at the base of pits; they were always present in the antrum, never in association with fundic-type mucosa. They had presented with symptoms including dyspepsia, epigastric pain, and abdominal distention. Some patients had received acid-suppressing drugs for peptic ulcer disease or partial gastrectomy. Hypochlorhydria was a likely prerequisite for the organisms to infect the stomach. In all 9 of the 41 who had concurrent duodenal biopsies, *Giardia* was present. In larger numbers of patients with duodenal *Giardia*, none who had normal or near-normal gastric mucosa had gastric *Giardia*. In another study of 252 *Giardia*-positive cases, trophozoites were found within the gastric antrum in about 9% of those who had gastric biopsies taken, and non–*H. pylori* chronic active gastritis was reported in only 2.9%.[245] This study also showed that *Giardia* does not cause atrophic gastritis. Given the evidence, *Giardia* may be a pathogen in the stomach in some patients and may be a regurgitant contaminant from the duodenum in others.

Helicobacter heilmanii (previously *Gastrospirillum hominis*) is probably transmitted from cats and dogs[246,247] and may cause chronic active gastritis similar to that of *H. pylori* but with less severe inflammation, which is focal and usually restricted to the antrum.[247–250] Gastric ulceration has been reported in one teenager and antral nodularity in another.[246,248] However, as yet, a definite association between *H. heilmanii* infection and ulcer disease has not been established.[250] Associated gastritis responds to therapy.[251]

Herpes simplex is a rare cause of gastritis and erosions in immunosuppressed patients, with biopsy showing the characteristic intranuclear inclusion bodies.[251,252] Evidence of herpes simplex virus type 1 was identified in 4 of 22 gastric or duodenal ulcers using immunohistochemistry and molecular probes.[253] The herpes varicella-zoster virus is a rare cause of gastritis in adults and possibly children.[254,255]

Influenza A is a rare cause of bleeding from hemorrhagic gastropathy in children and is sometimes fatal.[256] Serology was positive in all cases, but gastric biopsies were negative for virus. This may have been a stress gastropathy owing to a severe systemic illness rather than directly attributable to virus.

A gastropathy with hypertrophic gastric folds and protein-losing enteropathy has been described in a 3-year-old with a rising titer of IgM to *Mycoplasma pneumoniae* and no evidence of recent CMV infection.[257]

Mycobacterium tuberculosis involvement of the stomach is very rare and usually associated with tuberculosis elsewhere or with immunodeficiency.[258–260] Syphilis involving the stomach is very rare.[261]

Fungal infections of the stomach, such as *C. albicans*, histoplasmosis, and mucormycosis, may occur, especially in sick neonates, malnourished children, and those with burns or immunodeficiencies.[262–267] If gastric ulceration is seen in immunodeficient patients, fungal infection should be sought and, if present, should be treated, along with peptic ulcer therapy.

Infection with fungi of the Mucoraceae family (*Rhizopus*, *Mucor*, and *Absidia*) can cause the systemic disease mucormycosis, which is fatal in malnourished or immunosuppressed children and preterm neonates.[268,269] Mucoracea are ubiquitous organisms occurring in bread, fruit, and decaying material. Bleeding, gastric ulcers, and perforation may occur in the rare involvement of the stomach .

Fungal infection of the stomach with histoplasmosis and aspergillosis or the parasite *Strongyloides stercoralis* occurs rarely.[270]

Acute gastric anisakiasis simplex infection occurs frequently in Japan and in areas of high consumption of raw fish. Gastric symptoms may occur within 3 hours of ingestion, and in sensitized people, systemic allergic symptoms may arise within 5 hours of ingestion. Peripheral leukocytosis and eosinophilia may also occur. Endoscopy shows one or more worms protruding into the lumen a couple of millimeters off the gastric mucosa, surrounded by a ring of intense erythema, mucosal swelling, and sometimes gastric erosions. They can be in the antrum or body but tend to favor the greater curvature of the stomach. Early endoscopy is diagnostic and therapeutic, allowing for removal of the worm and relief of symptoms.[187,271–273]

CHAPTER 30

ESOPHAGEAL AND GASTRIC NEOPLASMS

Fiona Graeme-Cook, MB, FRCP
Gregory Y. Lauwers, MD

ESOPHAGUS

Three tumor types occur with any frequency in the esophagus: small benign mucosal leiomyoma, adenocarcinoma arising in Barrett esophagus, and squamous cell carcinoma. Unusual even in adulthood, all are reported in children. The latest US cancer surveillance data from the Surveillance, Epidemiology, and End Results (SEER) program show a measurable but small incidence of esophageal malignancies in the 10- to 14- and 14- to 18-year age groups. Other tumors, benign or malignant, including papillomas, granular cell tumors, and esophageal sarcomas, are unusual in adults and even more so in childhood. A specific pediatric issue related to tumors of the esophagus is the recognition of pathologies in childhood that may predispose the patient to adult malignancy. These are summarized in Table 30-1 and are discussed in the specific sections on tumor types. Childhood mediastinal malignancies treated with irradiation may result in various esophageal solid tumors in early adult life. Human papillomavirus (HPV) infections have been linked to both esophageal papilloma[1] and, less certainly, adult squamous cell carcinoma. Nutritional factors and genetic disorders may manifest as benign pediatric esophageal pathology, predisposing the patient to adult malignancy. Pediatric esophageal tumors may also occur as part of an inherited or genetic syndrome or systemic disorder (those relevant to this chapter are listed in Table 30-2).

TABLE 30-1 PEDIATRIC ESOPHAGEAL PATHOLOGY ASSOCIATED WITH ADULT MALIGNANCY

PATHOLOGY	ETIOLOGY	TUMOR
Squamous papilloma	Viral	SCC
GERD	BE	ACA
Tylosis	Genetic	SCC
Achalasia	Inflammatory	SCC
TEF	Inflammatory	SCC
Chemoradiation	Oxidative stress	Sarcoma/SCC/ACA
Lye	Corrosive	SCC
Esophagitis*	Various†	SCC

ACA = adenocarcinoma; BE = Barrett esophagus; GERD = gastroesophageal reflux disease; SCC = squamous cell carcinoma; TEF = tracheoesophageal fistula.
*In geographic areas of high squamous cell carcinoma incidence.
†Including vitamin and mineral deficiency, dietary carcinogens, and cooking methods.

Clinical Symptomatology, Diagnosis, and Therapy

Most benign tumors of the esophagus are small, more than 50% are asymptomatic, and they are discovered incidentally during upper endoscopy performed for unrelated problems. Dysphagia occurs with larger tumors. In infants, feeding and respiratory difficulty may be the presenting problem.[2] Bleeding, weight loss, and vomiting are less common and indicate a larger or malignant tumor. A mediastinal mass discovered on chest radiography is rare.[2,3] Esophageal tumors are usually investigated using upper gastrointestinal endoscopy, with or without barium esophagraphy; computed tomography, magnetic resonance imaging, and endoscopic ultrasonography help define the depth of invasion and degree of spread. Biopsy diagnosis is usually possible in most cases, and endoscopic procedures may also be curative for small lesions. Surgical resection is the treatment of choice for the remainder, but minimally invasive surgery has decreased morbidity for such resections. Data on adjuvant chemo- and radiotherapy for esophageal malignancy in children are not readily available because malignant tumors are rare.[4]

Benign Epithelial Esophageal Tumors

A summary of benign epithelial tumors of the pediatric esophagus is provided in Table 30-3.

TABLE 30-2 ESOPHAGEAL PATHOLOGY ASSOCIATED WITH EXTRAESOPHAGEAL DISEASE

ESOPHAGEAL PATHOLOGY	EXTRAESOPHAGEAL DISORDER
Cysts	Vertebral anomalies, malrotations, and TEF
Glycogen acanthosis	Cowden disease
Leiomyomatosis	Alport syndrome
Webs	Plummer-Vinson syndrome
SCC	Celiac disease
SCC	Keratodermatoses

SCC = squamous cell carcinoma; TEF = tracheoesophageal fistula.

TABLE 30-3 BENIGN TUMORS OF THE PEDIATRIC ESOPHAGUS

RELATIVELY FREQUENT	RARE	NOT REPORTED IN CHILDHOOD
Leiomyoma	Pseudodiverticulosis	Inflammatory fibroid polyp
Papilloma		
Granular cell tumor		
Duplication cysts		

Esophageal Squamous Papilloma. The esophageal squamous papilloma is a benign polypoid tumor usually found in the lower esophagus. The reported incidence rates vary, from more than 0.1 to 0.4%, based on adult autopsy studies.[5] Because this polyp is most often asymptomatic and regenerative in nature, these rates may be a large underestimate. Esophageal squamous papilloma is reported in childhood, with similar demographic distribution as in adults,[6,7] and has also been described in a case of Cowden disease.

Two main categories of etiologic factors have been implicated in the development of these tumors: physical trauma (including acid reflux, radiation, irritation from chemicals or foreign bodies) and infection with HPV infection, which remains controversial. In the lower esophagus, most papillomas are associated with acid reflux and hiatal hernia.[8] In the mid- and upper esophagus, and with multiple esophageal squamous papillomas, HPV (subtypes 16–11) is found in a variable percentage.[8,9]

At endoscopy, esophageal squamous papillomas are usually solitary mucosal protrusions without a true stalk. The overlying squamous mucosa is normal in appearance or roughened and white owing to mucosal keratinization. Most are small (< 5 mm), although "giant" esophageal squamous papilloma (as large as 23 cm in maximum dimension) has been reported, mainly within the adult population.[8]

Pathology. Esophageal squamous papilloma consists of a central fibrovascular core covered by benign mature squamous epithelium (Figure 30-1). Inflammation and reactive epithelial atypia are common. Cytoplasmic clearing and nuclear irregularity (koilocytosis), when seen, may indicate the presence of HPV.[8]

Papillomatosis, the presence of multiple esophageal squamous papillomas distributed throughout the esophagus, is rare but occurs predominantly in the pediatric age group.[10] HPV is suspected but only occasionally found.[11] A single case report links these esophageal squamous papillomas to laryngotracheal papillomatosis.[12] Multiple esophageal squamous papillomas are reported with Goltz syndrome (focal dermal hypoplasia).[13]

Malignant Transformation. Most small esophageal squamous papillomas are reactive rather than truly neoplastic and will not recur or progress. Large or multiple esophageal squamous papillomas arising in association with HPV subtypes 16 and 18 have been reported to show more aggressive behavior in some instances. Some reports of esophageal squamous papilloma with carcinoma may represent papillary carcinoma. The association between HPV and esophageal carcinoma is also debated.[14,15] No cases of malignant esophageal squamous papilloma have been reported in the pediatric literature.[5,15]

Esophageal Cysts and Reduplications. Gastrointestinal reduplication with resulting cysts and tubules occurs throughout the gastrointestinal tract. The esophagus is involved in 19% of cases, where spherical and cystic forms are more common. Resulting from a possible abnormality of the notochord, they are usually seen in the lower third and toward the right side. Usually single, they may extend the entire esophageal length or communicate with a subdiaphragmatic gastric duplication. Intramural and extramural forms occur, with associated vertebral anomalies (in the form of clefts or fusion) in the extramural form. Most cases present within the first year of life associated with respiratory difficulty; with increasing age, dysphagia or feeding problems become more common.[2,16] The mucosal lining of the cyst may be ciliated columnar (developmental form), gastric, or esophageal squamous. The wall contains

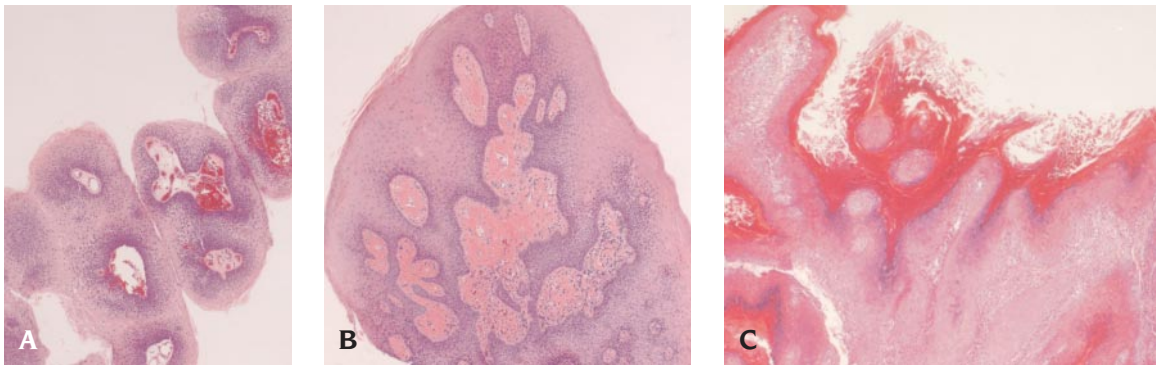

FIGURE 30-1 Esophageal squamous papillomas. *A*, The exophytic form has a branching fibrovascular core, with the "branches" covered by mature, sometimes thin squamous mucosa (hematoxylin and eosin; ×40 original magnification). *B*, Endophytic papilloma is a sessile polyp with smooth benign squamous epithelium overlying a fibrovascular core into which the deep squamous "rete" extend. It is also occasionally called a "fibroepithelial polyp" (hematoxylin and eosin; ×100 original magnification). *C*, The "spiked" exophytic esophageal squamous papilloma, least frequent, is characterized by keratohyaline granules within the superficial keratinocytes and a thick layer of orthokeratin forming hyperkeratotic "spikes" (hematoxylin and eosin; ×40 original magnification).

smooth muscle, nerves, and blood vessels forming a muscularis propria–like appearance in the wall that may be shared with the adjacent intestinal wall.[17,18] Intramural cysts without muscular components are considered esophageal cysts if lined by squamous mucosa and "bronchogenic" if the lining is ciliated columnar and there is cartilage within the cyst wall. The presence of muscularis propria indicates an intestinal reduplication (Figure 30-2). Communication with a gastric reduplication is relatively common, but only 10% of the cysts communicate with the esophageal lumen.[17]

Treatment is by surgical resection. Extramural forms separate easily from the adjacent esophageal muscularis propria; intramural forms tend to share the muscle wall with the esophagus. Complete excision is recommended, which may be possible by thoracoscopy.[19,20] There is a small risk of malignant transformation in adulthood of the epithelial lining of untreated cysts.[21,22]

Pseudodiverticulosis. In this unusual condition, the duct orifices of the esophageal submucosal glands become dilated to form multiple intramural cysts. Achalasia may be present, and esophageal dysmotility is the presumptive cause.[23] The pseudodiverticula may involve a segment, usually in the upper esophagus, or be diffuse. Endoscopically small pit-like openings may be seen on these mural protrusions, but radiologic studies may suggest a cystic neoplastic process, particularly in localized disease. Biopsy reveals a squamous lining, commonly with candidal superinfection.

Glycogen Acanthosis. Glycogen acanthosis appears as a white patch of esophageal mucosa at upper endoscopy. Glycogen acanthosis is flat and, although not neoplastic, may be confused with leukoplakia. Biopsy reveals esophageal squamous mucosa with enlarged superficial keratinocytes. The cleared-out appearance of the cytoplasm is due to the accumulation of glycogen within the cells. Glycogen acanthosis is usually sporadic, but multiple glycogen acanthoses in childhood may indicate the presence of hamartomatous polyposis (Cowden disease and Lhermitte-Duclos syndrome)[24] related to germline mutation in the *PTEN* gene and associated with thyroid and breast malignancy.

Benign Nonepithelial Esophageal Tumors

Esophageal Leiomyoma. Small mucosal leiomyomas derived from the muscularis mucosa are considered the most common benign neoplasms of the esophagus. Autopsy studies suggest a steady increase in incidence with longevity.[25] Accordingly, esophageal leiomyoma is an unusual tumor in childhood.[26]

Esophageal leiomyoma has been reported in children as young as 4 years old,[26] but most are reported in the teenage years. Unlike adults, in childhood they appear more commonly in females (female-to-male ratio 1.7:1), and diffuse or multiple forms are more common, with isolated single esophageal leiomyoma representing only 9% of cases.[26]

Esophageal leiomyomas may occur as part of Alport syndrome (nephropathy and sensorineural hearing loss).[26] Gastroesophageal reflux disease (GERD) has been reported as an association, possibly reflecting the frequency of GERD, with coincidental esophageal leiomyoma. Esophageal diverticulum has been reported with esophageal leiomyoma, an association of uncertain significance. Rare cases of congenital stricture with esophageal leiomyoma may represent the development of stromal tumors rather than esophageal leiomyoma in families with inherited mutations of the gastrointestinal stromal tumor–associated gene *KIT*.[27] Esophageal leiomyoma has also been seen in patients with multiple endocrine neoplasia type I. The characteristic gene mutation at chromosome 11q13 was demonstrable within these tumors but does not appear to be responsible for sporadic leiomyoma.[28]

Endoscopic Appearance. Esophageal leiomyomas appear as submucosal bumps or sessile polyps at endoscopy. The overlying mucosa is intact.

Pathology. Most esophageal leiomyomas are intramural (97%), with 1% presenting as polyps and 2% as extramural mediastinal tumors.[29] The most common sites are the distal esophagus and gastroesophageal junction, with decreasing numbers aborally. Esophageal leiomyomas form well-circumscribed, noninfiltrative nodules. The characteristic whorled white-yellow cut surface is due to intersecting fascicles of spindle smooth muscle cells. Calcification and cystic degeneration are common in larger forms. Rarely, lesions grow circumferentially around the esophagus, forming a stricture.[29,30] In small esophageal leiomyomas, an origin from the muscularis mucosa is often apparent. Treatment is by enucleation for single tumors and surgical resection for multiple esophageal leiomyomas.[31]

Leiomyomatosis. Multiple esophageal leiomyomas, when confluent, are sometimes referred to as "diffuse leiomyomatosis." This term has also been used to indicate diffuse hyperplasia of one of the layers of the muscularis propria. These two processes should be clearly delineated

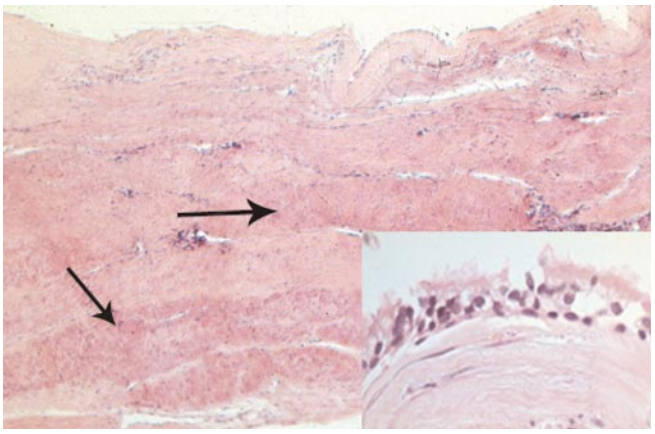

FIGURE 30-2 Esophageal reduplication cyst. The partially denuded cyst wall contains muscle layers (*arrows*) reminiscent of muscularis propria (hematoxylin and eosin; ×20 original magnification). *Inset:* Intact cyst lining has a ciliated columnar appearance (hematoxylin and eosin; ×200 original magnification).

because esophageal leiomyoma, although benign, is a neoplasm. The etiopathogenesis of the hyperplastic process is unknown.[32] The proliferative form is seen in Alport syndrome and familial leiomyomatosis that formed 22% of esophageal leiomyomas in a recent pediatric review.[26]

Alport Syndrome and Familial Leiomyomatosis. Alport syndrome, or sensorineural hearing loss with nephropathy, is reported in children as young as $2^1/_2$ to 5 years old.[26,33] The genetic basis is a mutation in genes responsible for the α_5 chain of type 4 collagen (*COL4A5*). Type 4 collagen is essential for basement membrane synthesis[34] and may play an important role in cell-matrix interactions. Similar mutations have been found in both Alport syndrome and a familial form of diffuse leiomyomatosis without Alport syndrome features.[34,35]

Granular Cell Tumor. The esophagus is the main site of occurrence of the granular cell tumor in the gastrointestinal tract. This unusual mesenchymal tumor is reported in the pediatric population[36] and even in the newborn.[37] Most are small and are found incidentally at upper endoscopy, where a sessile, yellow-white firm nodule is found. The overlying mucosa is intact, and most tumors are 2 cm or less. The lower esophagus is a more common location than the upper esophagus, and males and blacks are more likely to be affected. Occasional reports have linked granular cell tumor to neurofibromatosis.[36]

The tumor is composed of epithelioid or plump-spindled cells with abundant coarsely granular eosinophilic cytoplasm and small round nuclei without obvious nucleoli. The cytoplasm of the cells is characteristically positive with periodic acid–Schiff stain, and both cytoplasm and nucleus are S-100 positive by immunohistochemistry, consistent with schwannian differentiation.[38] Short fascicles of tumor cells diffusely infiltrate the lamina propria of the esophagus. The overlying squamous mucosa is often markedly hyperplastic, with tongues of atypical-appearing squamous epithelium extending deeply into the granular cell tumor. This pseudoepitheliomatous hyperplasia is a close mimic of invasive squamous cell carcinoma and is a trap for unwary pathologists (Figure 30-3). Small granular cell tumor has been reported to remain stable in size, but some large granular cell tumors require resection for symptoms.[39] Malignant forms, although exceedingly rare, are reported,[40] although not so far in the pediatric age group.

Vascular Tumors. Hemangioma and lymphangioma have both been reported in the esophagus of children, albeit rarely.[3,41,42] Both are composed of benign vascular channels, and the former may present with bleeding. The lesions are usually apparent at endoscopy.

Malignant Esophageal Tumors

The esophagus and proximal stomach are the sites of cancer with the largest and most rapid increase in incidence in the last two decades.[4,43] Most of these are adenocarcinoma. In the same time period, the incidence of esophageal squamous cell carcinoma has been falling. Squamous cell carcinoma is still more common than adenocarcinoma of the esophagus, but the rise in adenocarcinoma in older white males is alarming, and its cause is not understood. Given the time course of evolution from preneoplasia to overt carcinoma, many of these tumors may trace their origin to childhood esophageal pathology.

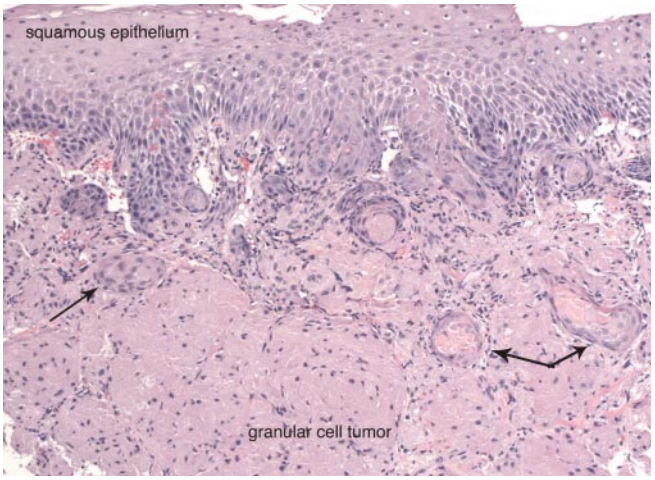

FIGURE 30-3 Granular cell tumor. Esophageal squamous epithelium overlies neoplastic cells with abundant amphophilic cytoplasm and small nuclei. Trapped by or infiltrating into the granular cells are tongues of squamous epithelium with dysmaturation (pseudoepitheliomatous hyperplasia) (*arrows*) (hematoxylin and eosin; ×200 original magnification).

Malignant Epithelial Tumors

GERD, Barrett esophagus, and adenocarcinoma arising in Barrett esophagus are the most significant causes of neoplasia of the pediatric esophagus (Table 30-4).

GERD and Barrett Esophagus. Barrett esophagus represents glandular mucosa lining the lumen of the esophagus. Barrett esophagus is an acquired defect, the result of chronic mucosal injury, usually from acid reflux, but also

TABLE 30-4 PEDIATRIC ISSUES RELATING TO BARRETT ESOPHAGUS

GERD is common in childhood and increasing in incidence.
GERD is an accepted risk factor for the development of BE in childhood (2.5–13% incidence).
BE increases the risk of adenocarcinoma of the esophagus 40- to 125-fold.
The reversibility of metaplasia is not well established.
Some reports suggest that the endoscopic appearance of pediatric BE may not be classic.
Approximately 50% of pediatric BE occurs in the setting of significant other disease, including neurologic impairment, where GERD-related symptoms may be absent.
Esophageal and proximal gastric adenocarcinoma incidence rates are rising more rapidly over the last two decades than any other carcinoma; both tumors are linked statistically to BE.
Extrapolation from adult data suggests a 30% incidence of adenocarcinoma in pediatric patients with BE if followed for 50 years.
Relatively good survival has been reported with early surgical intervention for esophageal adenocarcinoma.

BE = Barrett esophagus; GERD = gastroesophageal reflux disease.

possibly from bile, alkali (lye), and other physicochemical causes. Gastroesophageal acid reflux into the esophagus results in active chronic esophagitis; epithelial injury often results in ulceration. Healing occurs by ingrowth by epithelium from the ulcer borders. These ingrowing epithelial progenitor cells are of uncertain and disputed derivation. The possibilities include a stem cell from the basal cell region or residual mucosa, which, in dividing, rapidly becomes less differentiated. In the stem cell theory, repair after a single episode of damage may be by normal squamous epithelium. Repeated injury and repair in the continuing presence of acid, pepsinogen, or in combination with alkali may result in differentiation of the covering mucosa to a more resistant type, glandular mucosa. The second possibility, regrowth from nearby residual mucosa, requires the repairing mucosa to be glandular in type; origin from the ducts of esophageal mucosal glands has been posited for this pathway. Both of these would explain the cardiac-type nature of "columnar-lined esophagus." Barrett esophagus occurs in only 10% of patients with GERD, implying that other factors, genetic or environmental, play an undetermined role. Familial Barrett esophagus is reported, and a study of these families should elucidate associated genetic abnormalities.[44,45]

Significant comorbidity is common in childhood Barrett esophagus, and a high prevalence of neurologic disease or autism is found. This can make the medical management of these cases harder.[46] The development of intestinal metaplasia is increasingly accepted as a preneoplastic step in a sequence through dysplasia to adenocarcinoma arising in the esophagus. In the adult population, a continuum from GERD to Barrett esophagus through dysplasia to adenocarcinoma is relatively well documented, but this pathway is less clear in childhood.[47] GERD is a common phenomenon in children, but because adenocarcinoma is rare, the issue of risk for dysplasia and screening is unclear.[48–51] Management of acid reflux with medical therapy and/or surgery may not be adequate to reverse the metaplastic process.[52]

Initial reports of pediatric Barrett esophagus have little documentation of the presence of goblet cells in the mucosa and recently have been considered "columnar-lined esophagus."[51] Intestinal metaplasia in GERD or columnar-lined esophagus with the appearance of goblet cells within the mucosa increases with age and time; recent studies suggest that documentable goblet cells in columnar-lined esophagus begin to occur at the age of 7 years.[51,53] Progression from intestinal metaplasia through dysplasia to carcinoma has been documented to require approximately 20 years.[54]

The scattered case reports of adenocarcinoma in reflux-associated Barrett esophagus in children display similar pathologic features of malignancy in a setting of dysplastic and metaplastic Barrett esophagus, suggesting that the pathway of GERD to Barrett esophagus to adenocarcinoma is similar to that in adults.[55,56]

Endoscopic Appearance. The presentation of Barrett esophagus is similar to that in adults, with the exception that strictures appear more common in childhood, and malignancy is less frequent.[57] Barrett esophagus is grossly apparent at endoscopy as velvety red tongues extending up the esophagus from the proximal gastric fold at the gastroesophageal junction. Within an area of Barrett esophagus, there may be islands of residual white squamous mucosa (Figure 30-4). Other endoscopic changes include ulceration and nodularity or friability.[54,58] All of these may be related to peptic injury and regeneration but should alert the endoscopist to biopsy generously because these features also occur with dysplasia and adenocarcinoma.[51,59]

Pathology. Historically (pre-endoscopy), Barrett esophagus was recognized as glandular mucosa extending for more than 3 cm from the gastroesophageal junction. Nomenclature issues related to recognition of anatomic landmarks at endoscopy have been the source of controversy in the adult literature. Many adult pathologists will not diagnose Barrett esophagus now without the presence of goblet cells to indicate the intestinal rather than the gastric phenotype.[54] The remainder of cases are called columnar-lined esophagus. This relates to the recognition that the presence of goblet cells (indicating intestinal metaplasia) is generally indicative of progression of the pathologic process, and their presence suggests that screening for dysplasia should be instituted. The presence of intestinal metaplasia between the proximal gastric fold and 3 cm into the tubular esophagus (in the adult literature, termed short-segment Barrett esophagus) is associated with an increased risk of adenocarcinoma, although not as high as for standard or long-segment Barrett esophagus.[58]

Classic Long-Segment Barrett Esophagus. The mucosa in Barrett esophagus may show a gastric phenotype with antral or body- or fundic-type glands and foveolar surface epithelium. Rarely is the mucosa the well-organized body or fundic type. The presence of hiatal hernia should be suspected if pure body or fundic mucosa is seen. Focal goblet cells are present, resulting in incomplete intestinal metaplasia. In the absence of goblet cells, the presence of a villiform surface appearance is most suggestive of Barrett esophagus (Figure 30-5).[60,61] The presence of submucosal glands with

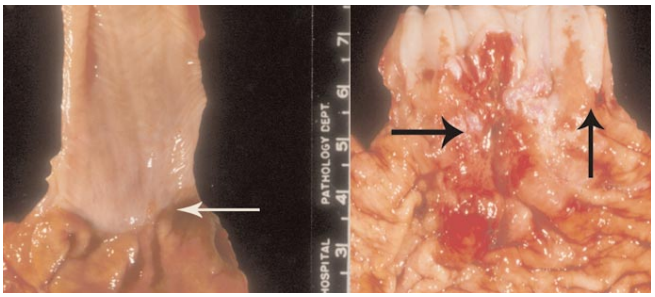

FIGURE 30-4 Normal gastroesophageal junction (GEJ) and Barrett esophagus (BE) with adenocarcinoma. The esophagogastrectomy specimen on the left shows the normal white appearance of squamous esophageal mucosa with a *white arrow* at the squamocolumnar junction. The specimen on the right shows a GEJ obscured by a carcinoma on the left (*black horizontal arrow*) with ulceration and raised edges. On the right, the normal white mucosa is partially replaced by a tongue of "salmon-pink" BE extending proximally from the GEJ (*black vertical arrow*) (see CD-ROM for color image).

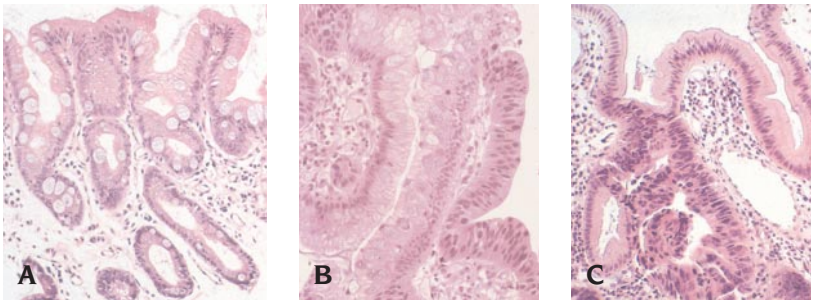

FIGURE 30-5 Barrett mucosa and dysplasia. *A*, Barrett esophagus: villiform mucosa with foveolar-type cells alternating with goblet cells in "incomplete metaplasia." *B*, Low-grade dysplasia: metaplastic mucosa is partially replaced by an abrupt focus characterized by cell crowding, pseudostratification, and nuclear hyperchromatism. *C*, High-grade dysplasia: the focal area shows increased atypia; nuclei are large with nucleoli. Individual cell necrosis or apoptosis is present. Architectural changes with back-back glands or cribriforming (like a sieve with the gland lumina as the holes) are apparent (hematoxylin and eosin; ×200 original magnification).

mucosal ducts lined by transitional-type mucosa is very good evidence for anatomic localization of the specimen from the tubular esophagus. Because goblet cells are often sporadic, and studies have shown that goblet cells "yield" increases with the number of biopsies taken[47] and that goblet cells tend to evolve after the first decade in children,[53] it is hard to be dogmatic about the pathologic definition of Barrett esophagus. Dysplasia refers to early neoplastic change in the mucosa, recognized as changes resembling colonic adenoma formation in the surface epithelium (see Figure 30-5), and is graded as low or high grade. High-grade dysplasia is associated with a high rate of invasive adenocarcinoma within 1 year. Photodynamic therapy is being used to ablate dysplastic mucosa in adult patients; no data are available in children.

Adenocarcinoma. Adenocarcinoma arising in Barrett esophagus usually occurs in the distal esophagus. The reported cases in childhood have shown the presence of surrounding areas of dysplasia and residual Barrett esophagus (Figure 30-6).[55,56] Survival is related to stage. Long-term survival is possible with mucosal carcinoma. Submucosal invasion and lymph node metastasis are associated with rapidly diminishing survival.[43]

Squamous Cell Carcinoma. Squamous cell carcinoma is a rare tumor in the esophagus in children.[4,62,63] It is more common in blacks than in whites and in males than in females (ratio 3.7:1). The major predisposing factors in the United States are alcohol and tobacco use, but in other regions, where the incidence of squamous cell carcinoma is very high, such as Linxian in Henan province in China, Northern Iran, South Africa, and areas of India, factors such as the ingestion of hot foods, vitamin-deficient diets, mineral deficiencies (zinc), and other dietary problems (foods high in nitrosamines such as pickled vegetables, diets low in fresh foods, high intake of benzo[a]pyrenes from coal smoke) are key. In these areas, investigation of children in their teens has shown the presence of chronic esophagitis in families with squamous cell carcinoma at double the rate of control families.[64] It is unclear as yet the relative importance of genetic over environmental forces in these populations. Some data suggest regression of the

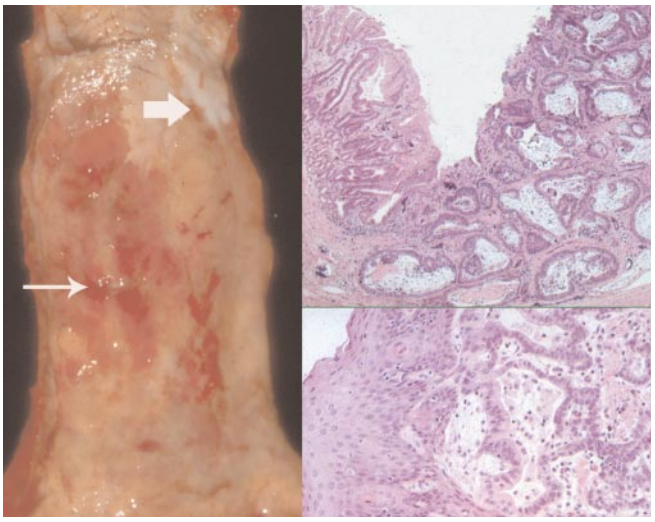

FIGURE 30-6 Barrett esophagus (BE) with early adenocarcinoma. The resection specimen shows a long segment of metaplastic mucosa with the squamocolumnar junction now in proximal esophagus (*thick arrow*). The pink BE mucosa is irregular with areas of reddening and nodularity (*thin arrow*) corresponding with dysplastic and malignant changes. The upper photomicrograph shows a benign BE on the left, with intramucosal adenocarcinoma on the right half of the figure. The malignant glands are dilated and invade into but not through the muscularis mucosa (hematoxylin and eosin; ×100 original magnification). The lower photomicrograph shows intact squamous mucosa with infiltrating adenocarcinoma within the lamina propria beneath (hematoxylin and eosin; ×100 original magnification) (see CD-ROM for color image).

inflammatory changes with vitamin A and zinc supplementation, at least in laboratory animals.[65]

Inherited or sporadic genetic disorders, mainly affecting keratin synthesis, including palmoplantar keratosis and tylosis, may be associated with very high rates of esophageal squamous cell carcinoma. These conditions often manifest in childhood, usually with cutaneous lesions. Mutations in keratin genes or linkage to the tylosis esophageal carcinoma gene (*TEC*) on 17q25.1 has been documented.[66]

Celiac disease is associated with a significant increased risk of esophageal squamous cell carcinoma. The pathogenesis is unclear, and the tumor so far has not been reported in childhood.[67]

Caustic ingestion is another pediatric problem associated with squamous cell carcinoma of the esophagus. The latency between ingestion and neoplasm is around 40 years, although cases as short as 13 years have been reported.[68–69]

The presence of stricture of the esophagus, by increasing food impaction, irritation, inflammation, ulceration, and repair, is associated with squamous cell carcinoma formation in the esophagus. Achalasia, dysmotility owing to the absence or destruction of the distal innervation of the esophagus, whether congenital or acquired, is associated with squamous dysplasia and squamous cell carcinoma. Squamous cell carcinoma has also been reported owing to postoperative strictures related to early childhood surgery. Childhood malignancies leading to mediastinal irradiation may also predispose the patient to early squamous cell carcinoma.[69]

Endoscopic Appearance. Squamous pre- and early neoplastic lesions form white plaques, nodules, and occasional polyps. Granular surface or ulceration is often associated with higher grades of dysplasia (Figure 30-7). The mid- and lower esophagus is most often affected. Lye-associated neoplasias are usually seen at the site of tracheal bifurcation, where the stricture is located. Although, occasionally, squamous cell carcinoma may be grossly papillary, benign esophageal squamous papilloma is not associated with a significant rate of malignant progression in the esophagus.

Pathology. Biopsy of a nodule or plaque may show thickened squamous mucosa with layers of keratin on the surface: benign hyperplasia (see Figure 30-7). Inflammation, both chronic within the lamina propria and acute within the epithelium, is common, and there may be prominent small blood vessels. As dysplasia occurs, maturation to the flat squamous phenotype is progressively delayed; when no maturation is seen, carcinoma in situ is present (see Figure 30-7). Ultimately, stromal invasion occurs, and early squamous cell carcinoma has developed. The lesion may still have the appearance of a plaque, but as the tumor grows, central ulceration with raised edges or annular stenosing growth may occur. Early invasion into mediastinal soft tissue occurs, with metastasis to regional nodes.

Prognosis and Therapy. The prognosis is grim for advanced tumors, regardless of age. Three-year survival with mucosal carcinoma is more than 80%. This drops with submucosal invasion to 45% and with lymph node metastasis to 17%.[70,71] Death is usually related to local disease.

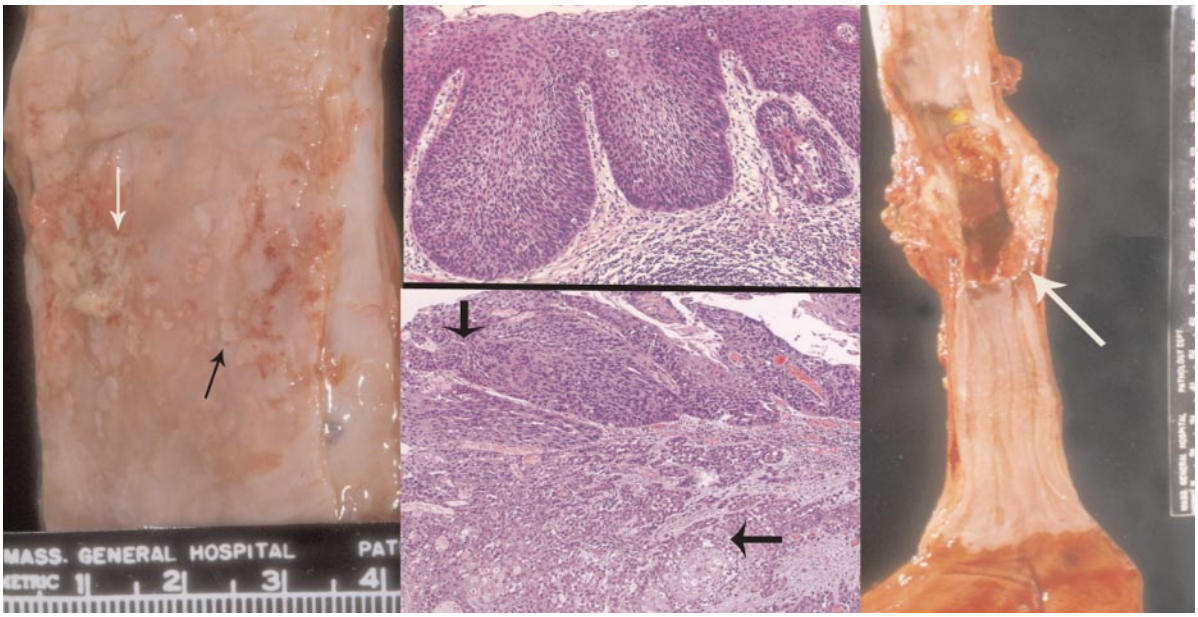

FIGURE 30-7 Squamous cell carcinoma of the esophagus. The esophagectomy specimen on the left shows esophageal squamous mucsoa with loss of the normal folds and with areas of nodularity and redness (*white arrow*) indicating areas of dysplasia and a raised irregular area (*black arrow*) of early carcinoma. The top photomicrograph shows severe squamous dysplasia with increased cellularity, nuclear enlargement, and loss of maturation (hematoxylin and eosin; ×200 original magnification). The lower photomicrograph shows intraepithelial carcinoma on the right half (*vertical arrow*), with invasive intramucosal carcinoma on the left (*horizontal arrow*) (hematoxylin and eosin; ×100 original magnification). The resection specimen on the right shows advanced squamous cell carcinoma of the midesophagus forming a deeply penetrating ulcer extending through the wall of the esophagus (*arrow* at lower margin of tumor edge) (see CD-ROM for color image).

Fistulization into the tracheobronchial tree and hemorrhage occur. Distant spread is a late phenomenon. Surgical resection is often now delayed until after chemoirradiation, although the results are inconclusive thus far.[62,72]

Malignant Melanoma. Melanocytes are normally found in small numbers in the esophagus, more numerous distally, and malignant melanoma of the esophagus is reported in young adults.[73] A single case report of malignant melanoma in an 8-year-old boy revealed an aggressive melanin-producing tumor.[74] Whether this case represented a melanoma deriving from mature melanocytes or a more primitive precursor, such as a primitive neuroectodermal tumor with melanocytic differentiation, is not entirely clear. Melanoma presents with dysphagia and usually forms a sessile polyp in the lower esophagus. The surrounding esophageal squamous mucosa may be heavily pigmented (melanosis). The tumors are often at a late stage at diagnosis, and curative therapy is rare. Metastasis from cutaneous melanoma to the esophagus must be considered, although the ileum is the most common site for secondary melanoma.

Nonepithelial Esophageal Malignant Tumors

Esophageal Sarcomas. These are very rare; most are the focus of case reports or small series, occasionally arising in the radiation field after treatment of mediastinal hematopoietic malignancy (Figure 30-8). Rhabdomyosarcoma, malignant schwannoma, leiomyosarcoma, and carcinosarcoma are reported. Most present with dysphagia, and a large submucosal mass, often with ulceration and necrosis, is found on endoscopy.[75,76]

Gastrointestinal Stromal Tumor. This tumor, arising from the interstitial cells of Cajal and uniformly expressing the KIT protein (a tyrosine kinase receptor) (CD117), has not been reported in the pediatric age group. However, germline mutations of the *KIT* gene are associated with a younger age of gastrointestinal stromal tumor; in these families, there is a theoretic risk of gastrointestinal stromal tumor in the pediatric group.[27]

Leiomyosarcoma. This tumor has not been reported in the pediatric age group. In adults, this is the rarest of the esophageal soft tissue tumors.[76] Uniformly aggressive and bulky, these tumors express smooth muscle markers (smooth muscle actin [SMA]), not CD117.[31,77]

Conclusion

Although tumors of the pediatric esophagus are rare, they are likely to increase in number if the current increase in esophageal adenocarcinoma continues. Guidelines for assessing pediatric patients with GERD for Barrett esophagus may emerge, as may consensus regarding surveillance for dysplasia. Benign tumors show different patterns than in the adult esophagus, and underlying pathophysiologic processes are more likely to be apparent.

STOMACH

Although more frequent than their esophageal counterparts, gastric neoplasms are uncommon in the pediatric population. Reviewing the charts of 4,547 pediatric cancer patients admitted over 44 years, Bethel and colleagues reported only three neoplasms arising in the stomach, making the relative incidence of primary gastric neoplasms 0.06%.[78] Although malignancies, particularly lymphomas and sarcomas, are the most frequent neoplasms, a number of benign tumors can occur, either inflammatory or malformative in nature.[78–81] Because they belong to the differential diagnosis of gastric neoplasms, these tumor-forming lesions are also reviewed in this chapter.

Benign Tumors of the Stomach

Although uncommon, benign gastric neoplasms, either epithelial or stromal in nature, can be observed in children.

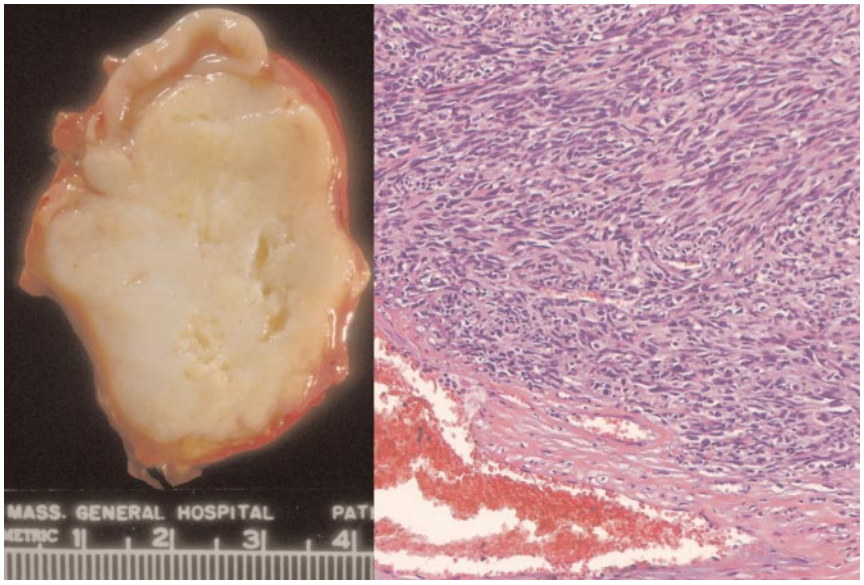

FIGURE 30-8 Esophageal sarcoma. Fibrosarcoma following irradiation forms a rubbery, well-circumscribed mass deep in the wall of the esophagus, with intact overlying mucosa. The photomicrograph shows a cellular spindle cell proliferation without anaplasia with a pushing rather than an infiltrative edge (hematoxylin and eosin; ×100 original magnification).

Gastric Polyps. Sporadic or more common manifestations of a polyposis syndrome, polyps are found less frequently in the stomach than in the lower gastrointestinal tract. They can be of several different types: adenomatous, fundic gland type, juvenile, or hamartomatous. Familial adenomatous polyposis is the most common polyposis syndrome of childhood.[82] The patients frequently develop multiple gastric polyps. Fundic gland–type polyps are found more frequently than adenomatous polyps. Fundic gland polyps have recently been shown to be neoplastic in nature, with frequent somatic mutations of the adenomatous polyposis coli (*APC*) gene.[83] However, the development of carcinoma in these lesions remains rare and usually occurs beyond the pediatric age range. However, one case of adenocarcinoma has been diagnosed in a 16-year-old familial adenomatous polyposis coli (FAPC) patient.[84–88] Gastric adenomas should be completely excised, and the entire stomach should be examined carefully. Endoscopic follow-up should be initiated because there is a relatively high risk of developing new adenomas. Compared with sporadic cases, fundic gland polyps and adenomas associated with FAPC occur at a much younger age. They increase in prevalence with increasing age. Given the risk, regular surveillance is indicated in patients with FAPC.

Peutz-Jeghers Syndrome. Forty percent of Peutz-Jeghers patients present with gastric polyps.[82] These hamartomatous polyps are usually silent, although rare presentations may occur, such as antral obstruction or, in one case, autoamputation. The polyps preferentially affect the antrum. Histologically, the polyps display an arborizing framework of smooth muscle covered by hyperplastic fundic– or antral-type mucosa with elongation and cystic change of foveolar epithelium with frequent atrophy of the underlying glands.[89] The risk of malignancy, via the development of dysplasia, is low but not nonexistent, with gastric adenocarcinomas reported as early as the second decade.[82,90,91]

Juvenile Polyposis. This type of polyposis is distinguished by its early clinical manifestations, with three-quarters of the affected patients presenting during childhood.[82,91] Among the different forms of juvenile polyposis, the stomach is involved in generalized juvenile polyposis (with a reported involvement of 13.6% of the cases) and in the usually fatal juvenile polyposis of infancy typified by the diffuse involvement of the gastrointestinal tract, with patients developing severe diarrhea, hemorrhage, and protein-losing enteropathy.[90–92] Juvenile polyposis of the stomach is limited to that site. Most sessile hamartomatous polyps measure between 5 and 40 mm. They are characterized by large cystic spaces lined by foveolar epithelium and embedded in the lamina propria with mixed inflammatory infiltrate.[89,92] The risk of malignant transformation in the stomach is lower than in the colon.[93] Dysplasia can sometimes be found. It is therefore reasonable to suggest that patients with juvenile polyposis should undergo periodic upper endoscopy. In addition to the colon and stomach, patients with juvenile polyposis have an increased risk of developing adenocarcinomas in the biliary tract and pancreas.

Gastric Teratoma. This rare tumor is composed of mesodermal, endodermal, and ectodermal elements and occurs almost exclusively in the pediatric population. The pathogenesis of gastric teratomas is unknown, but they are thought to arise from pluripotential cells. Nearly all of the patients are male, and most are either infants or neonates less than 2 years of age.[94,95] The patients usually present with large intra-abdominal masses that may lead to obstruction, whereas younger patients may present with oratory insufficiency because of the limitation of movements of the diaphragm secondary to tumor displacement.[95] Upper gastrointestinal bleeding, resulting from ulceration of the overlying mucosa, can also be observed. Characteristically, preoperative imaging studies may demonstrate calcifications corresponding to teeth or bone structures developed within the tumor. The histology demonstrates intermixed mature tissue elements such as skin, smooth muscle, bone, cartilage, and adipose and neural tissue. With the exception of a single case reported in an adult, no malignant transformation is available in the pediatric literature, and excision is curative.[94]

Malignant Tumors of the Stomach

Adenocarcinoma. Between 2 and 10% of gastric carcinomas are diagnosed in patients younger than 40 years old, and cases seen in the pediatric population are extremely rare.[96,97] Also, the marked variations in the incidence of cancer found in adults between different regions with high rates (Asia, Central and Eastern Europe, South America) and Western nations are not encountered in the pediatric population either.

In a series of 501 gastric cancers in individuals younger than 31 years of age, only 0.4% of cases occurred in children 10 years or younger, 3.4% occurred in children between 11 and 15 years, and 8% occurred in children between 16 and 20 years.[98] A study of 3,079 cases of gastric carcinoma diagnosed in British Columbia over a 10-year period revealed that only 65 cases occurred in younger individuals (under 40 years of age) and that the youngest patient was 24 years old. No pediatric cases were reported in this series. Interestingly, the younger patients exhibited more adverse clinical and pathologic features compared with older patients.[99] In fact, most publications are case reports, with a case diagnosed as early as 20 months of age.[96,97, 100]

In contrast to the adult population, the risk factors for the development of gastric cancers in childhood are not well established. Approximately 10 to 25% of young gastric cancer patients have a positive family history, suggesting the role of genetic factors.[101] To the best of our knowledge, the cases associated with the familial diffuse gastric carcinoma syndrome associated with germline mutations in the E-cadherin/*CDH1* gene have been diagnosed in young adults but not in pediatric patients.[102–105] *Helicobacter pylori* infection associated with the development of adult gastric cancer is apparently not reported in pediatric cases. Other precursor lesions, such as intestinal metaplasia, pernicious anemia, and hypertrophic gastropathy, as well as previous gastrectomy, are also rare in this population.

However, several conditions that occur in infancy and childhood have been linked with gastric cancer. These include immunoglobulin A deficiency, common variable immunodeficiency syndrome, and ataxia telangiectasia.[106–108] A rare association with Rothmund-Thomson syndrome (characterized by short stature, cataracts, pigmentation of skin, baldness, and abnormalities of bones, nails, and teeth) has also been reported.[109] Polyposis syndrome, that is, familial polyposis coli, and Peutz-Jeghers syndrome are associated with the development of adenocarcinoma, although it usually develops later in life. Finally, two cases of gastric adenocarcinoma have also been reported as a late complication in individuals previously treated (3.5 years and 10 years earlier) for abdominal lymphoma by irradiation and chemotherapy.[110]

In many instances, the presenting symptoms are not different from those of older patients.[100] The most common presenting complaints include pain and vomiting, followed by anorexia and weight loss.[101,111] Abdominal distention is also reported.[100,112] A mass can be palpated in 70% of the patients according to one series.[98] A rare association with tumor-thrombotic microangiopathy has been reported.[113]

Although the histologic pattern of gastric cancer in childhood can be similar to that in the cases reported in adults, some authors report a predominance of mucinous and signet ring cell carcinoma (Figure 30-9).

Because there are no large series of children with gastric carcinoma, it is not possible to draw significant conclusion with regard to prognosis. Despite anecdotal reports of cure, the evidence provided suggests that a delay in diagnosis usually contributes to limited patient survival.[101] Various protocols, usually based on experience in adult patients, include surgery and various chemotherapy protocols with or without radiotherapy. Lymphatic, vascular, direct extension and seeding of peritoneal surface have been reported.[81,100,101,112–114]

Hematopoietic Neoplasms. ***Gastric Lymphoma.*** In the adult population, the stomach is the most common site of gastrointestinal lymphomas, comprising about 40% of the cases, followed by the small bowel in 27% of cases.[115] Conversely, in children, the small bowel is the predominant site, accounting for 40 to 45% of cases, whereas gastric lymphoma represents between 2.5 and 17% of gastrointestinal non-Hodgkin lymphomas.[115–118] The reported increase in the annual incidence of gastrointestinal lymphoma observed in adults has not been observed in the pediatric population.[115]

Predisposing conditions for gastric lymphoma include primary immunodeficiency such as severe combined immunodeficiency, X-linked agammaglobulinemia, common variable immunodeficiency disease, Wiskott-Aldrich syndrome, and ataxia telangiectasia.[119] Also, B-cell lymphomas, which account for the most frequent neoplasias in human immunodeficiency virus (HIV)-infected patients, also frequently involve the stomach.[120]

The mode of clinical presentation may include nonspecific symptoms such as abdominal pain, a palpable abdominal mass, or gastrointestinal bleeding. Gastric outlet obstruction by a lymphoma has been reported (Figure 30-10).[121] Most gastric lymphoma tumors are cytologically high-grade malignancies, either the lymphoblastic or large cell anaplastic type.[115,116] Primary treatment includes

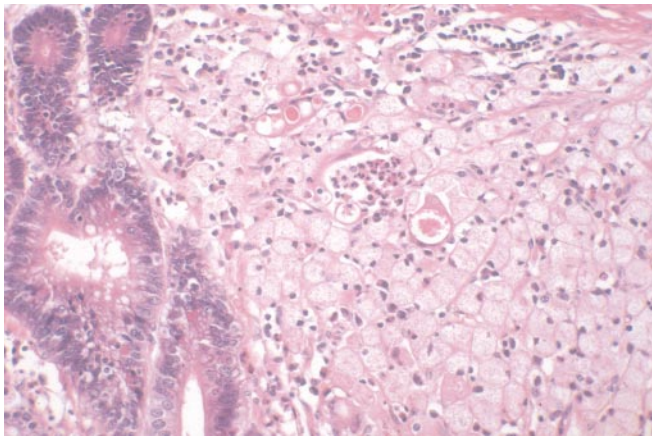

FIGURE 30-9 Diffuse-type gastric carcinoma in a 17-year-old patient. The tumor is composed of single cells expanding the lamina propria. Rare signet ring cells can be seen (hematoxylin-eosin stain; ×400 original magnification).

FIGURE 30-10 Selective view of the antrum from an upper gastrointestinal series in a 15-year-old boy who presented with hematemesis, weight loss, and right upper quadrant abdominal pain. A mass is seen encircling the antrum and almost completely obstructing it. Endoscopic biopsies revealed a large cell immunoblastic lymphoma. Courtesy of the Teaching Collection, Department of Radiology, The Children's Hospital, Boston.

resection of the tumor, followed by postoperative chemotherapy and/or radiotherapy. Careful medical and surgical management following prompt diagnosis have been shown to offer long-term survival.[116]

Langerhans Cell Histiocytosis. Langerhans cell histiocytosis of the stomach has been reported in a 14-year-old girl.[122] Besides its rarity, the diffuse antral and fundic polyposis and the granulomatous pattern displayed by the histiocytosis are noticeable.[122] To date, only a handful of cases with gastric involvement have been reported, all but one in adults.[123–125] In the case in point, the patient remained asymptomatic at 10 months after diagnosis.[122]

Mesenchymal Neoplasms. ***Gastrointestinal Stromal Tumor.*** Gastrointestinal stromal tumors are rare, accounting for less than 1% of all gastrointestinal malignancies. They are uncommon before middle age and extremely rare in children.[126,127] Nowadays, gastrointestinal stromal tumors are defined as spindle and/or epithelioid mesenchymal neoplasms that usually express CD117 and do not have diagnostic features of any other type of mesenchymal tumors.[126,128] Most neoplasms now included in this category would have been previously diagnosed as smooth muscle tumors (leiomyoma, leiomyoblastoma, leiomyosarcoma, fibromatosis, and schwannomas). However, the massive amount of information collected on gastrointestinal stromal tumors has been based on the adult experience. Whether it is true for the pediatric population is unknown. Bates and colleagues recently reported that congenital stromal tumors of the stomach in children were morphologically similar to those in adults but did not express CD117 and carried a favorable prognosis.[129] However, other cases reported in the pre-CD117 era have followed a course similar to that seen in adults.[109]

Although, in most cases, they occur sporadically, some gastrointestinal stromal tumors have been described as a component of the Carney triad (gastric epithelioid stromal sarcoma, functioning extra-adrenal paraganglioma, and pulmonary chondroma).[130] Rare myogenic tumors have been reported in acquired immune deficiency syndrome (AIDS) patients. Their pathogenesis is unknown, but the initiating role of HIV, as well as that of Epstein-Barr virus, has been entertained.[120,131]

It has been shown that gastrointestinal stromal tumors share phenotypic similarities with the interstitial cells of Cajal, including the expression of KIT and CD34.[126,132] These pacemaker cells are now considered to represent the origin of these rare neoplasms. Another important biologic breakthrough has been the demonstration that most gastrointestinal stromal tumors have oncogenic mutations of the KIT gene. This has been translated clinically by the use of an inhibitor of the tyrosine kinase activity of Kit (ST-571), which has shown significant promise in treating patients with metastatic disease.

Most gastrointestinal stromal tumors are diagnosed in the stomach (60–70% of the cases). The majority measure between 3 and 15 cm, although tumors as small as a few millimeters and as large as 30 to 40 cm can be observed. Gastrointestinal stromal tumors may present as intraluminal or subserosal masses that may compress regional adjacent organs (Figure 30-11).[128] Depending on their size, various nonspecific clinical presentations (ie, nausea, vomiting, abdominal pain, bleeding) may be observed. The most common presenting symptoms of gastrointestinal stromal tumors in children are gastrointestinal bleeding (with frank hematemesis in about 40% of patients and occult bleeding in up to 80%) and symptoms of intestinal obstruction (in about 50% of patients). Abdominal pain, weight loss, fever, and abdominal masses also are reported.[126–129,133] Gastrointestinal stromal tumors present as firm, tan, well-circumscribed masses (Figure 30-12). Hemorrhage, necrosis, and cystification are seen in large tumors. They are variably cellular and composed of spindle cells and/or epithelioid cells. The spindle cells can be organized in fascicles, storiform and herringbone arrangements, or palisading or organoid groupings (Figure 30-13).[133]

The microscopic characteristics of gastrointestinal stromal tumors are poor indicators of their clinical behavior. A recent workshop sponsored by the National Institutes of Health concluded that the benign and malignant behavior of a tumor could not be predicted on the basis of morphology alone. It is now recommended that all gastrointestinal stromal tumors be considered potentially malignant and be classified according to their risk of aggressive behavior based on the size and the number of mitoses in 50 high-power fields.[128]

Miscellaneous. ***Gastric Hemangioma.*** Visceral hemangiomas are rare outside the liver. In the stomach, although

FIGURE 30-11 Upper gastrointestinal series in a 10-year-old girl with severe anemia and tarry stools. A large nodular leiomyosarcoma is seen in the gastric antrum. Courtesy of the Teaching Collection, Department of Radiology, The Children's Hospital, Boston.

FIGURE 30-12 Gastric gastrointestinal stromal tumor. The tumor is well circumscribed but not encapsulated. Note the central necrosis, characteristic of a malignant biologic behavior.

hemangiomas can be isolated, they are frequently associated with vascular lesions of the skin and intestine.[134–136] The cases associated with gastrointestinal hemangiomatosis tend to occur at an earlier age, with cases discovered in the neonatal period.[136] Hematemesis is a frequent initial symptom. Despite their benign nature, these sometimes large hemorrhagic masses require surgical therapy, ranging from wedge excision to partial and even total gastrectomy.[136]

Gastric Lipoma. Composed of lobules of mature adipose tissue, gastric lipomas are slow-growing tumors. They frequently originate from the submucosa, whereas others are centered on the subserosa. The common antral location of these usually sessile and polypoid lesions accounts for the reports of intussusceptions into the pylorus or duodenum.[137] Mucosal ulceration with chronic blood loss but also hemorrhage has been reported.[138] On barium swallow, gastric lipomas change shape with peristalsis and show a preserved mucosal profile, both characteristics of a benign process.

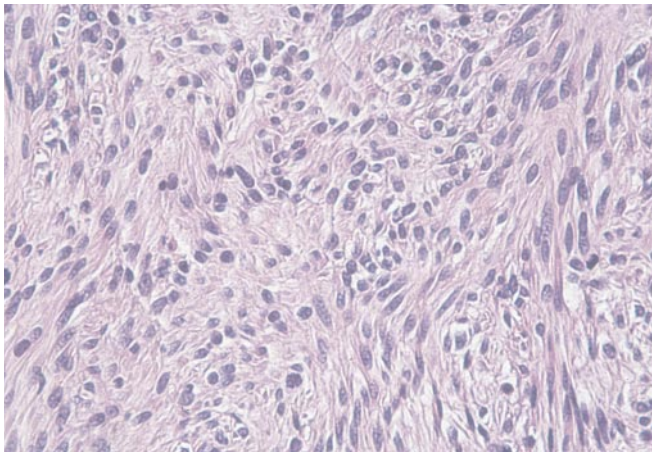

FIGURE 30-13 Gastric gastrointestinal stromal tumor. Photomicrograph with typical fascicular arrangement of spindle cells. Scattered mitoses can be seen (hematoxylin and eosin; ×400 original magnification).

Magnetic resonance imaging shows, on T_1-weighted images, a solid hyperintense lesion with a signal corresponding to fat. Finally, on endoscopy, the typical "sinking impression" is felt when the mass is poked with forceps.[137] If small, gastric lipomas can be removed by polypectomy, but larger lesions may necessitate a laparotomy.[138]

Inflammatory Myofibroblastic Tumor. Despite much interest in the pathology literature, the pathogenesis of this unusual process, also known as inflammatory pseudotumor and plasma cell granuloma, remains indeterminate.[139] It preferentially affects children and young adults, and most cases are reported in the lungs, whereas only rare cases have been seen in the stomach. Microscopically, these tumors show a mixed pattern composed of a variable number of spindle-shaped myofibroblasts embedded in a usually collagenized stroma with intermixed chronic inflammatory cells in which plasma cells may be numerous. The spindle cells are CD117 negative and usually positive for SMA.[139] Although usually benign, large-size tumors and invasion into surrounding tissues have characterized the aggressive nature of rare cases. Such cases may require several surgical resections.[140]

Gastric Hamartoma. Hamartomas of the gastric wall are benign lesions showing considerable histologic variation. They are composed of abnormal admixture of components of the gastric wall, including hypertrophied bands of muscularis mucosa branching out and dissecting through the mucosa that shows misplaced and cystically distended glands.[141] They should be differentiated from the adenomyomatous variant of ectopic pancreas, which is formed of cystic pancreatobiliary type ducts.[118,142]

Gastric Leiomyosarcoma. Leiomyomas and leiomyosarcomas have been reported in association with Alport syndrome, AIDS, pulmonary osteoarthropathy, and Carney triad.

Rare Mesenchymal Lesions of the Stomach. A distinctive malignant gastric mesenchymal tumor sharing some features with clear cell sarcoma of soft part has been reported in a 13-year-old boy.[143] This type of tumor, also found in the small bowel, displays a distinct nesting pattern formed by medium-sized tumor cells with a clear to acidophilic cytoplasm admixed with osteoclast-like multinucleated cells. Strong positive immunohistochemistry for S-100 protein and t(12;22)(q13;q12) also supports the similarities with clear sarcoma of soft part.[143] A case of gastric rhabdomyosarcoma with disseminated metastases and death within $2^1/_2$ months following diagnosis has been reported.[81] Only a few cases of hemangiopericytoma have been observed in the stomach. The younger patient was 2 days old when he developed hematemesis and had surgery at day 12. Although these uncommon vascular tumors have the potential to behave in a malignant fashion, metastasis of gastric neoplasms seems to be rare, perhaps because of the usual early diagnosis and treatment.[144] Although less frequent than in adults, Kaposi sarcoma has also been reported to affect the stomach of pediatric AIDS patients.[120]

Conclusion

Given their rarity, gastric tumors in childhood are almost always unexpected findings. Nevertheless, the differential

diagnosis of upper gastrointestinal symptoms in childhood must include these rare lesions. Their diagnosis is of obvious clinical importance because, in many cases, timely treatment is the only hope for good prognosis.

CHAPTER 31

MOTOR DISORDERS INCLUDING PYLORIC STENOSIS

Peter J. Milla, MSc, MB, BS, FRCP, FRCPCH

The movement of bowel contents from one specialized region of the gut to another occurs as a result of the coordinated contraction of the smooth muscle coats. In this chapter, the present state of knowledge of motor activity of the stomach and duodenum in the infant and child is summarized and conditions in which motor activity is disordered are discussed. Despite investigation spanning the last century, knowledge derived from systematic scientific observation in this area remains scarce, and our understanding of the pathophysiology of human gastroduodenal motility in the infant and child is far from complete. However, the practical application of such knowledge as exists is beginning to affect the practice of clinical pediatric medicine.

NORMAL MOTOR ACTIVITY OF THE STOMACH AND DUODENUM

The pattern of contractions that occurs in a particular region of the gut is related to and integrated with the function of that region of the gastrointestinal (GI) tract. In the case of the stomach, the organ can be divided into two areas. The proximal half acts as a reservoir, exhibiting mainly tonic activity, which allows for large changes in intragastric volume. The process of digestion is initiated here with the secretion of acid and pepsin. The distal region includes the lower half of the body, the antrum and the pylorus. Contraction here is phasic and organized to segment and break up food into small particles or to impart movement. To empty food from the stomach, gastric and duodenal contractions are coordinated, resulting in movement of luminal contents in an aboral direction. When digestible food has been emptied from the stomach, the digestive phase ends and the fasting or interdigestive phase begins. Any remaining gastric contents are swept into the duodenum by bursts of forceful, rhythmic contractions, phase III of the fasting state, in the antrum and the duodenum.

The process of digestion is continued in the duodenum, where pancreatic and biliary secretions are added to the chyme. Two patterns of motor activity occur: (1) when the duodenum is receiving chyme after feeding, continuous segmenting activity occurs to ensure maximal mixing of the intraluminal contents and exposure to the mucosa; (2) in the fasting or interdigestive state, when the lumen is devoid of nutrients, a band of forceful contractions is propagated in an aboral direction, sweeping exhausted chyme down the gut (Figure 31-1).

SPECIFIC PATTERNS OF GASTRODUODENAL MOTILITY

Proximal Stomach

Proximal Receptive Relaxation. Little contractile activity occurs in proximal regions of the stomach, where the predominant activity is receptive relaxation[1]; on swallowing, the proximal muscle relaxes to accommodate the ingested food. This mechanism is so efficient that the average full-term infant can accommodate 60 to 70 mL of feed with a rise in intragastric pressure of only 5 mm Hg. Receptive relaxation is mediated by a vagal reflex. A number of putative neurotransmitters have been studied, and most recent evidence favors vasoactive inhibitory polypeptide and nitric oxide (NO) as the nonadrenergic, noncholinergic inhibitory transmitters in this region of the stomach.[2]

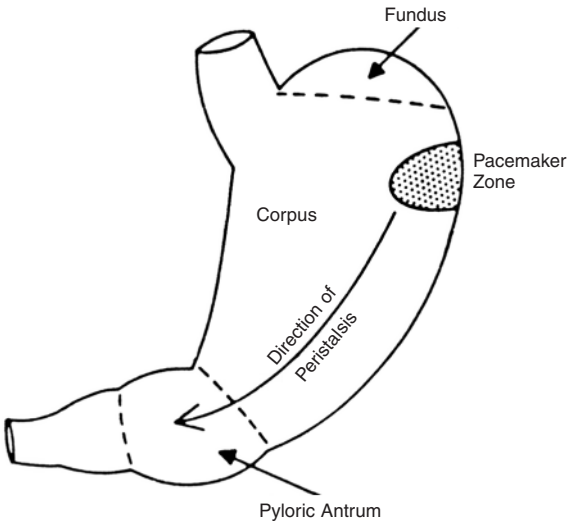

FIGURE 31-1 Regions of the stomach.

Tonic Contraction. Following ingestion of a meal, the proximal region of the stomach exhibits weak tonic contractions, which may play a role in passing intragastric contents to the antrum and pylorus. Vagal and intrinsic cholinergic factors are believed to be important in stimulating such a response.

Distal Stomach and Duodenum

Postprandial or Digestive Activity. The caudal or distal region of the stomach behaves quite differently from the proximal region, and, together with the duodenum, a separate pattern of activity occurs according to whether a meal has just been eaten or the individual is fasting. After a meal, rhythmic, phasic contractions that begin near the middle of the stomach are propagated toward the duodenum. The antral waves (about three per minute in humans) are constant in terms of frequency and propagation velocity and are determined by a pacemaker region on the greater curvature of the stomach (see Figure 31-1). The timing and spread of the contractions are regulated by the slow-wave activity of the smooth muscle cells and the pacemaking activity of the interstitial cells of Cajal.[3] Action potentials spread from the midstomach to the duodenum but not to the fundal region of the stomach, ensuring that propagation of contractions with a maximum frequency and velocity of the action potentials occurs only in the aboral direction. The occurrence, timing, amplitude, and spread of gastric contractions depend on the integrity of the gastric muscle, its innervation, the activity of the interstitial cells of Cajal, and the humoral environment of the smooth muscle cells.

These seemingly simple peristaltic contractions of the gastric body and antrum cause fairly complex movements of the intragastric contents, which result in mixing of the contents, mechanical breakdown of food particles, and gastric emptying. The antrum and pylorus are the sites of regulation for the emptying of solids. When a mixed meal is consumed, liquids empty more rapidly than solids, which are retained by antral contractile activity and passed through the pylorus only when they have been broken down into particles of approximately 1 mm.[4,5]

When contraction begins, gastric contents are propelled toward the duodenum, but only a small amount enters the duodenum. As a consequence, pressure rises in the antrum and provides a continued driving force across the pylorus. As the pressure falls, retropulsion may occur, and the consequent mixing and shearing of flows that take place cause food particles to be broken down. Gastric emptying also occurs during the contractions, but the amount emptied depends on the peristaltic contractions, tone of the proximal stomach, and contractile activity of the pylorus and duodenum. In the digestive phase, contraction of the pylorus and proximal duodenum is highly coordinated, up to 70% of antral contractions being linked to groups of one to three sequential duodenal contractions separated by periods of relative quiescence. This pattern of activity seems to be important for gastric emptying and is modulated not only by neural factors but also by nutrients via paracrine and endocrine polypeptide hormones.[1] That both the nature of a meal and polypeptide hormones influence gastric emptying seems to be beyond doubt from a number of experimental studies in animals[1] and the human infant.[6,7] In the infant, it is clear that increasing caloric density of feeds, with either carbohydrate in the form of glucose polymers versus monosaccharides or lipids in the form of long-chain triglycerides or medium-chain triglycerides, results in slower emptying.

Fasting or Interdigestive Activity. Toward the end of fed activity, contractions become more forceful and propel any remaining undigested food into the duodenum, leaving the stomach empty. The pattern of activity then changes to that seen in the fasted state in both the stomach and duodenum. In the interdigestive period, the motor activity of several regions of the GI tract has a characteristic, specific, integrated cyclic pattern. This cyclic pattern of fasting activity was first shown in dogs by Szurszewski in 1969,[8] and, for the most part, coordination of contractions between the antrum and the duodenum does not occur. The pattern is characterized by what he termed a "migrating myoelectric complex" (MMC).

It was not until 1975 that the first demonstration of the MMC in humans was published.[9] At intervals of approximately 100 minutes, brief periods (about 5 minutes) of rhythmic contraction recur at the frequency of the slow wave of 3 cycles per minute in the antrum and 11 cycles per minute in the duodenum. These episodes of rhythmic contraction, phase III activity, are preceded by a period of irregular contraction (phase II activity) in which about 10% of antral contractions are coordinated with those in the duodenum and are followed by a period of quiescence (phase I activity). Phase III activity migrates relatively slowly down the entire small intestine from the antrum and duodenum to the terminal ileum, taking about 90 to 120 minutes to migrate; a new complex usually arises proximally as one dies away distally. However, some cycles may begin distal to the duodenum, and others may fail to progress down the complete length of the small intestine. Fenton and colleagues demonstrated similar patterns in children[10]; these differ from those in adults only in the very young, in whom propagation velocity is slower and the duration of phase III activity is longer.[11] The purpose of the MMC is to prevent the aboral migration of colonic bacteria[12] and to cleanse the intestine of cellular debris, residual food, and secretions. These effects are aided by the increased gastric acid, biliary, and pancreatic secretion at the start of phase III activity. Studies in both humans and experimental animals have shown phase III activity to be highly propulsive.

Like fed activity, fasting activity requires the integrity of smooth muscle interstitial cells of Cajal, innervation, and humoral secretion. In the stomach, extrinsic innervation seems to be much more important than in the jejunum or ileum, and motilin surges are associated with phase III activity.[13]

DISORDERS OF GASTRODUODENAL MOTOR ACTIVITY

Motility disorders result in alterations of motor activity that are clinically significant and interfere with normal

receptive relaxation[14] and propulsive functions of the stomach and duodenum. These disorders, which alter the motor control mechanisms of the gut, may affect the muscle coats themselves, the intrinsic and extrinsic gut nerves, or the humoral environment of the neuromusculature. Most often no obvious anatomic abnormality is present, but hypertrophic pyloric stenosis clearly is an exception. Some disorders may be acute owing to transient metabolic changes or immunologic responses: in this chapter, only chronic conditions are considered. Motor dysfunction may be restricted to the stomach or duodenum or may be part of a more diffuse disease. Often the clinical presentation is regional (eg, recurrent vomiting), yet investigation reveals dysfunction in other regions of the gut.

Clinical Manifestations of Disordered Gastroduodenal Motility

Vomiting and epigastric discomfort are common symptoms of disordered foregut motility in children. Despite careful investigation, a diagnosis of organic disease is often not made. Table 31-1 lists the symptoms that may present, but none are very specific. In most cases, a diagnosis cannot be made on clinical history alone. The symptoms of delayed and accelerated gastric emptying have much in common, and the typical symptoms of dumping owing to hypovolemia and hypoglycemia occur in only a minority of cases. It is only when food from the previous day is vomited that seriously delayed gastric emptying is certain. Thus, gastroduodenal motor disorders often present with nonspecific clinical signs and symptoms. The obvious exception is hypertrophic pyloric stenosis, in which the character of the vomiting, the presence of visible gastric peristalsis, and a palpable pyloric tumor (see below) enable the clinician to diagnose the condition with sufficient certainty for surgery to be undertaken in a large proportion of patients.

Emesis

Surface electrogastrography has proven useful to differentiate vomiting owing to activation of the emetic reflex and that owing to gastroesophageal reflux (GER).[15–17] Activation of the emetic reflux results in an output that consists of two phases: a pre-ejection phase and an ejection phase. The pre-ejection phase is marked by a variety of autonomic responses, including nausea, skin pallor, sweating, and tachycardia. Nausea is due to a dysrhythmia of the gastric antrum and duodenum, which results in cessation of gastric emptying and bloating of the stomach. The pre-ejection phase is followed by ejection of the gastric contents by forcible contraction of the abdominal, diaphragmatic, and intercostal muscles. Activation of the emetic reflex may be initiated by a variety of different inputs to the central processing apparatus of the reflex, which includes the dorsal vagal nuclei and the chemoreceptor trigger zone in the area postema in the floor of the fourth ventricle. Inputs may be metabolic, as occurs with cytotoxic drugs, urea cycle defects, or lactic acidosis, or peripheral from the gut, such as in gastritis or enteropathies, visual flicker effects, and vestibular and auditory stimuli.[16,17] When recurrent activation of the emetic reflex occurs, the term cyclic vomiting is often used.

TABLE 31-1 SYMPTOMS OF DISORDERED GASTRODUODENAL MOTILITY

RAPID EMPTYING/DUMPING	DELAYED EMPTYING
Nausea, vomiting	Epigastric fullness
Abdominal cramps, diarrhea	Early satiety
Early satiety	Nausea, vomiting
Epigastric fullness	Pyrosis
Faintness	Belching
Pallor	
Sweating	

Rapid Gastric Emptying. Rapid emptying of liquids most frequently occurs following surgical procedures and in some patients with peptic ulcer. After both proximal and distal gastric resection, increased liquid emptying rates are seen. After proximal resection, the accommodating reservoir is lost, and after a meal, intragastric pressure rises. Following distal resection, resistance from the antropyloric region is lost. Vagotomy is rarely performed in childhood, but damage to the vagus may occur following esophageal surgery and have similar effects, which are discussed below.

Delayed Gastric Emptying. There are many causes of delayed gastric emptying, as shown in Table 31-2. Of course, it is always important to exclude anatomic causes such as hypertrophic pyloric stenosis, duodenal stenosis (both intrinsic and extrinsic), duodenal web, and malrotation of the small intestine causing duodenal obstruction. Some of these conditions are associated with disordered motor activity other than that caused by the obstruction in which either the smooth muscle or the innervation is diseased. Alternatively, the neuromusculature operates in an abnormal humoral environment usually created by an associated inflammatory process.

Duodenogastric Reflux. Bile-stained vomiting occurs in conditions in which there is obstruction beyond the second part of the duodenum and in conditions causing pseudo-obstruction of the duodenum and upper jejunum. Usually, when there is severe bilious vomiting and no anatomic obstruction is found, the pseudo-obstruction is neuropathic in origin.

DISEASES OF THE STOMACH AND DUODENUM

Hypertrophic Pyloric Stenosis

The grossly thickened circular muscle of hypertrophic pyloric stenosis results in a well-recognized clinical presentation of projectile vomiting and failure to thrive. This muscular hypertrophy is usually not present at birth but starts in the first few weeks of life.[14]

Incidence and Inheritance. This condition occurs 2.5 times more commonly in whites than in other ethnic groups. The incidence rose from 1 to 2 per 1,000 live births

TABLE 31-2 CAUSES OF DELAYED GASTRIC EMPTYING

Anatomic obstruction	Pyloric stenosis, duodenal stenosis, duodenal web
Metabolic or electrolyte disorder	Hypokalemia, acidosis, hypothyroidism
Drugs	Opioids, anticholinergics
Neuronal dysfunction	Central nervous system disease, vagotomy, intestinal pseudo-obstruction
Muscle disease	Visceral myopathy, systemic lupus erythematosus, myotonic dystrophy
Infection	Viral, microbial toxins (eg, *Rotavirus*, *Parvovirus*)
Idiopathic	Slow-wave arrhythmias

in the early 1950s to 6 to 8 per 1,000 live births some 30 years later. The cause for this increase in incidence is not clear, but in the United Kingdom, it correlates positively with a 30% increase in breastfeeding.[18] The natural history of the condition is for vomiting to continue into the third month of life, after which survivors recover. Pyloric stenosis is more common in firstborn children. Males are affected five times more frequently than females. Inheritance is polygenic, and both siblings and the offspring of affected children are at increased risk. The risk is highest (approximately 20%) in the firstborn male of a mother who herself was affected.[19]

Etiology and Pathogenesis. Although the etiology is not known and the nature of the pathologic process is not clear, it is now clear that the stenotic pylorus is not present congenitally.[20] There is an increasing body of evidence that the local enteric innervation is involved[21] and that primarily argyrophilic NO synthase–containing neurons[22,23] are affected.

Study of neuronal NO synthase knockout mice implicates the genetic control of neuronal NO synthase in the etiology of pyloric stenosis. Transcriptional control of neuronal NO synthase is complex, with nine first exons.[24] Exon 1c is particularly important in the gut,[25] and it appears that in pyloric stenosis, there is overexpression of exon 1c (H. D. Allescher, personal communication, 2003). Another study suggested that there is also profound abnormality of development of the network of interstitial cells of Cajal within the muscle layers in pyloric stenosis.[26] Stem cell factor also appears to be defective. Taken together, these findings suggest that it is more likely that the developmental abnormality of the circular muscle layer occurs as a consequence of the defective nitrergic innervation, although how this comes about is still unknown, but bone morphogenetic protein 4 appears to be involved.[27] In most cases, hypertrophic pyloric stenosis can be thought of as an isolated pseudo-obstructive lesion. In some situations, however, it is part of a more generalized pseudo-obstructive condition and is associated with bowel malrotation and short small intestine.[28] Pyloric stenosis is increasingly recognized in association with other gut anomalies, such as esophageal atresia, duodenal atresia, anorectal anomalies, Cornelia de Lange syndrome, Smith-Lemli-Opitz syndrome, and Zellweger syndrome. In about 15% of cases of pyloric stenosis, a hiatal hernia and GER are present.[29] Whether this abnormality is a consequence of the obstruction or whether the neural abnormality is not restricted to the pylorus is not clear.

Clinical Features. These patients present with vomiting, which is never bile stained but frequently contains stale milk. Vomiting usually begins in the second or third week of life, but it may present earlier or much later. The vomiting becomes increasingly forceful and copious until it is projectile. Initially, the infant is irritable and hungry, with increasing malnutrition; however, the baby becomes miserable and lethargic. Characteristically, the early part of the feed is taken eagerly, but as the stomach fills, the baby starts to become anxious and fretful, visible peristalsis may be easily seen (it is presumed that the baby perceives this prior to vomiting), and then vomiting occurs, which is often projectile in nature. A pyloric tumor is then usually easily palpable immediately before the vomiting. The other clinical features are the consequence of gastric outlet obstruction with loss of gastric secretions leading to constipation, dehydration, and metabolic alkalosis.

The profuse and continuous loss of acidic gastric contents results in the loss of protons and chloride and hypochloremic alkalosis. When proton loss becomes severe, hypokalemia may also occur. Jaundice occurs in association with pyloric stenosis in 2 to 5% of cases, and, as in some infants with neonatal bowel obstruction, there is an unconjugated hyperbilirubinemia in up to 50%.[30] This jaundice has been associated with low levels of glucuronyl transferase.[30]

When there is doubt about the diagnosis, radiologic or ultrasonographic studies should be undertaken. A plain film often shows pyloric hold-up and a dilated stomach with absent gas distal to the pylorus. Ultrasonographic studies confirm the presence of a pyloric tumor and barium studies the long, narrow pyloric canal. The presence of GER should be sought because it may influence postoperative management.

It has been suggested that ultrasonography is the diagnostic imaging of choice. Diagnostic criteria have been developed and include a muscle thickness of more than 4 mm and a pyloric length of more than 16 mm. Using these criteria, ultrasonography has a specificity of 100%, a sensitivity of 97%, and positive and negative predictive values of 100% and 98%, respectively.[31]

Management and Prognosis. Virtually all major centers advocate surgical treatment for pyloric stenosis. Pyloromyotomy is the operative intervention of choice. Most infants are referred for surgery before marked biochemical disturbances have occurred and require no special preparation other than a gastric washout 2 to 3 hours prior to operation. However, if dehydration and metabolic alkalosis are present, they must be corrected first and surgery delayed for 24

to 48 hours. Infants with moderate to severe fluid and electrolyte depletion with elevated serum bicarbonate levels should be given 5% dextrose in 0.45% saline initially as a bolus of 10 to 20 mL/kg and then at one to two times maintenance as required until serum electrolytes approach normal and dehydration is corrected. Twenty-five to 40 mmol of potassium chloride should be added to each liter of fluid once the infant is passing urine. Correction of alkalosis prior to surgery is essential to avoid postoperative apnea owing to alkalemic respiratory depression.

The surgical treatment of pyloric stenosis has a morbidity of between 1% and 5%, a recurrence rate of 1 to 3%, and a mortality of less than 0.5%.[29] There are two well-recognized postoperative problems: continued signs of pyloric obstruction owing to an incomplete myotomy and wound dehiscence.[29] The former frequently settles with conservative management, so several days should elapse before re-exploration. The latter is probably due to malnutrition rather than surgical technique. In about 15% of patients, vomiting continues owing to the associated GER; usually, only a small proportion require further surgery and fundoplication.[29]

Idiopathic Gastroparesis

Gastroparesis may develop in apparently healthy children without evidence of systemic disease. The symptoms may be acute, may be preceded by a flu-like illness, or may be part of a gastroenteric infection. The abnormality may be confined to the antrum, with impairment of emptying of solids but not liquids. There have also been several case reports of patients with arrhythmias of gastric electrical control activity (ECA) and idiopathic gastroparesis. Symptoms may be mild, with early satiety, nausea, and occasional vomiting, or severe, with uncontrollable nausea and vomiting.

Gastric Antral Dysrhythmias

Telander and colleagues and others described an unusual case of persistent vomiting in an infant associated with marked impairment of gastric emptying.[32,33] A series of elegant investigations showed marked dysfunction of antral smooth muscle owing to a disturbance of slow-wave activity.[32] The slow wave increased from its customary frequency of three cycles/min to six cycles/min. The authors coined the term "tachygastria."[32] In this patient, normal depolarization frequencies occurred in vitro when indomethacin was added to the bathing medium, suggesting that an abnormality of the local synthesis of prostaglandins was involved. In another infant, antrectomy was curative.[33] You and colleagues found that 50% of a group of patients with functional upper abdominal discomfort had abnormalities of the antral slow wave.[16] Diagnosis of these infants, however, relied on highly invasive and difficult methods for recording intraluminal myoelectric activity. More recently, attempts to measure antral slow-wave activity by surface electrodes have been more successful owing to the application of sophisticated signal processing techniques, and now a noninvasive way of investigating these patients exists. In a group of patients with intestinal pseudo-obstruction investigated using surface electrogastrography, a variety of dysrhythmias were found.[34] If the dysrhythmias were correlated with histopathologically proven enteric neuromuscular disease, those with neuropathic disease had very obvious tachygastria, as shown in Figure 31-2. In contrast, in myopathic conditions, no dominant frequency could be demonstrated.

Migraine and Nonulcer Dyspepsia

Nausea and vomiting are frequent symptoms in classic migraine and nonulcer dyspepsia. The Rome II Paediatric Working Group on Functional Gastrointestinal Disorders divided functional or nonulcer dyspepsia into three subgroups[35]: ulcer-like dyspepsia, which is predominantly pain central in the upper abdomen; dysmotility-like dyspepsia, in which nonpainful sensations, including early satiety, bloating, and nausea, occurs; and nonspecific dyspepsia in those patients whose symptoms did not fulfill the above two criteria. It should be noted that these conditions have not been rigorously defined in children. Activation of the emetic reflux results in delayed gastric emptying in both migraine and nonulcer dyspepsia. Clinically, it may be difficult to differentiate patients with migraine and nonulcer dyspepsia and idiopathic gastroparesis from those with psychogenic vomiting and bulimia nervosa.

Lesions of the Extrinsic Innervation

Central Nervous System. Local lesions of the vagal and vestibular nuclei and of the labyrinth, as well as raised intracranial pressure, may result in disordered gastroduodenal motility and vomiting. Tumors and congenital abnormalities are the most common chronic disorders and interfere either directly with the dorsal vagal nuclei or, more likely in the case of raised pressure, by stimulating the chemoreceptor trigger zone in the area postrema in the floor of the fourth ventricle.

Infectious, Metabolic, and Degenerative Disorders. A number of infectious organisms, including varicella[36] and Epstein-Barr virus,[37] have been reported to cause pseudo-obstruction. A recent study has shown that varicella zoster may be latent in the enteric nervous system, just as occurs in dorsal root ganglia of the spinal cord.[36] Automatic dysfunction also occurs in Guillain-Barré syndrome, where it may be unrelated to the degree of sensory and motor disturbances.

The common metabolic causes of gastroparesis in adults—diabetes mellitus and amyloidosis—occur only extremely rarely in childhood. However, degenerative conditions clearly occur and may be familial. The most common of these is the pandysautonomia of Riley-Day syndrome, in which there are abnormalities of both cholinergic and nonadrenergic, noncholinergic nerves.[38] Vomiting is very common and may be associated with constipation, internal ophthalmoplegia, lack of tears and sweating, and orthostatic hypotension. With the exception of orthostatic hypotension, these features were also present in four children reported to have postganglionic cholinergic dysautonomia.[39] In one of these patients with GI dysmotility, on the basis of in vitro studies of antral muscle, the authors

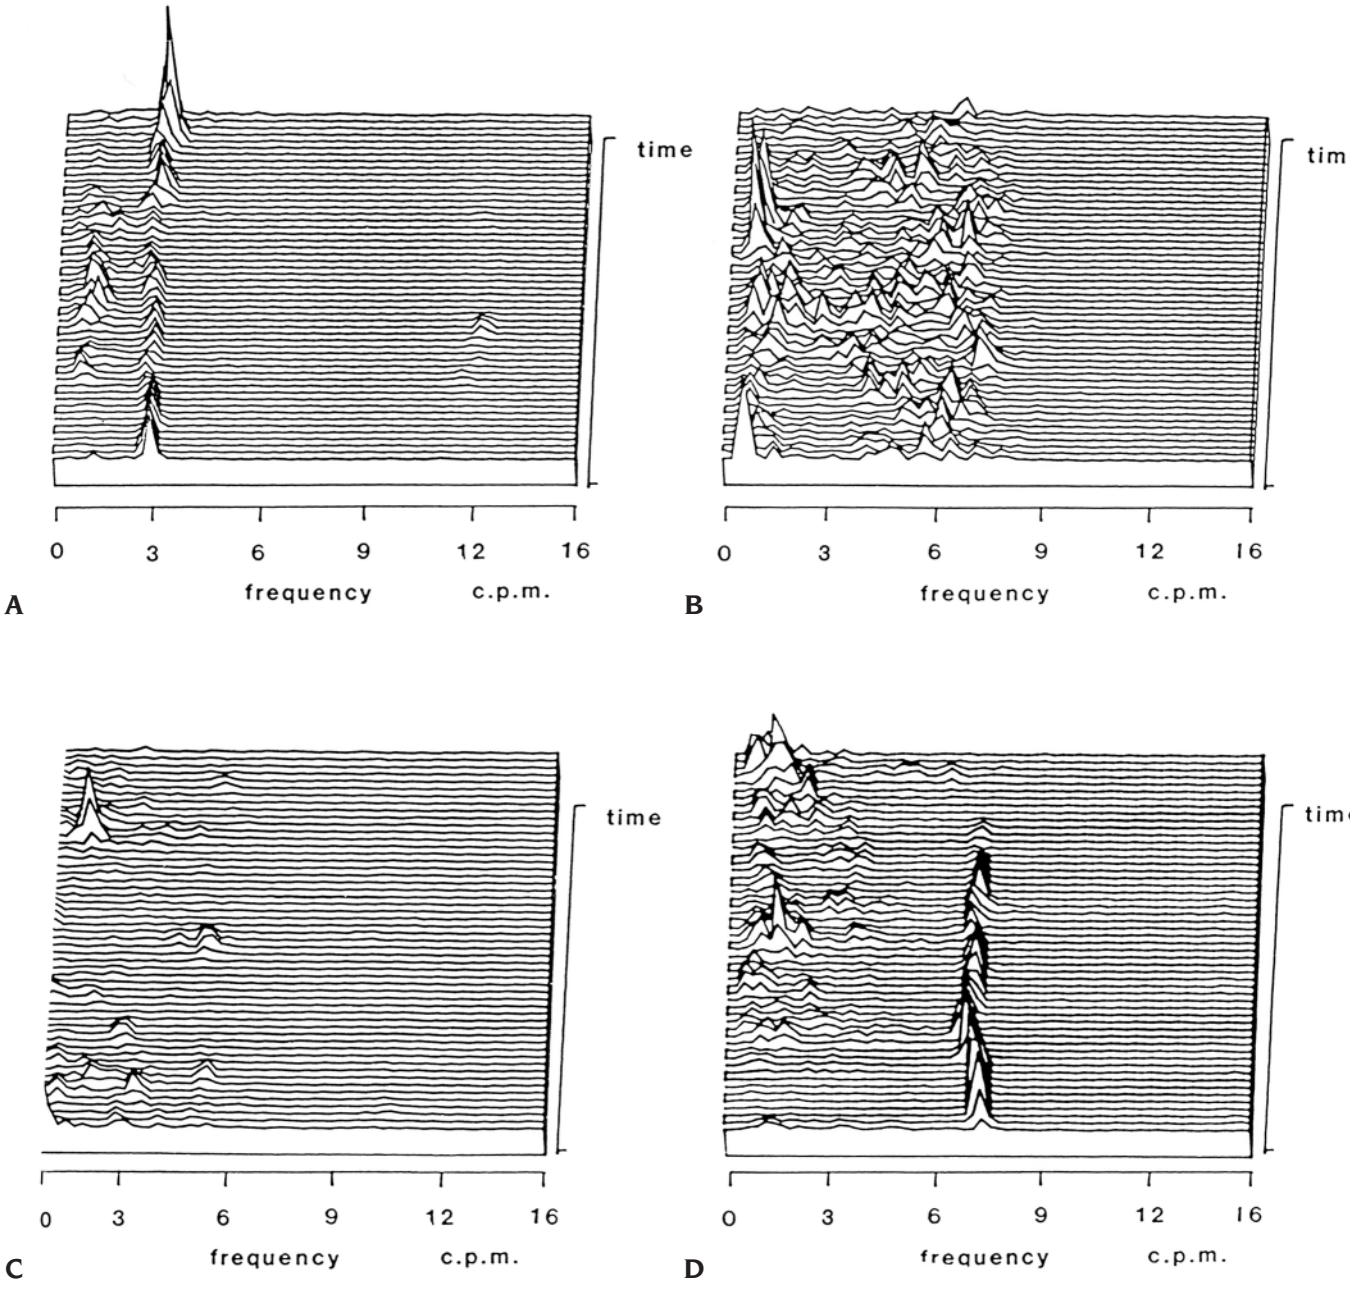

FIGURE 31-2 Pseudo–three-dimensional plots of a running spectral analysis of surface electrogastrograms of *A*, control children; *B* and *C*, myopathic pseudo-obstruction and hollow visceral myopathy; and *D*, neuronal pseudo-obstruction.

demonstrated defects proximal to smooth muscle and enteric nerves and speculated that the condition was due to a failure of nonadrenergic inhibitory innervation. It is now clear that degeneration of sensory and autonomic nerves occurs owing to mutations of the *IKBKAP* kinase gene[40] in Riley-Day syndrome.

Vagotomy. Although vagotomy is not commonly a purposeful operation in children, it has been used in the treatment of severe recurrent peptic ulcer disease and may occur as an unintended consequence of difficult surgery for congenital esophageal anomalies. After a highly selective vagotomy, relaxation of the proximal stomach is impaired.[41] As a consequence, rapid initial emptying of liquids may occur, with about 25% of patients developing symptoms of early satiety and epigastric fullness. These symptoms tend to improve with time.[41] With truncal and total vagotomy, the entire stomach loses its vagal innervation. In addition to impaired relaxation of the proximal stomach, disturbances of ECA occur more frequently after these types of interventions, and there is, thus, defective antral motility and delayed emptying of solids.[42]

Interdigestive motor complexes are less regular and less frequent, which may also contribute to the stasis of solids. The combination of very fast liquid and slow solid emptying can be extremely difficult to manage. The use of uncooked starch has been proposed to control the dumping, which is very troublesome in infants.[43] Drainage procedures such as pyloroplasty, although helpful in controlling the stasis of solids, do nothing to control the dumping and diarrhea.

Enteric Nervous System

Primary disorders of gut motor activity owing to either systemic disease or disorders of the enteric nervous system may be either diffuse or regional in their presentation. In this section, we are concerned with those disorders that result in abnormal gastroduodenal motility and present with early satiety, postprandial epigastric fullness, nausea, vomiting, and failure to thrive. The etiology of these conditions remains obscure. Some cases are congenital and may be inherited, whereas others are acquired and potentially reversible. It is likely that the so-called superior mesenteric artery syndrome, is, in fact, a duodenal pseudo-obstructive disorder rather than a mechanical obstruction.[44]

When the primary disease appears to be of the stomach and/or duodenum, the terms "idiopathic gastroparesis" and "duodenal pseudo-obstruction" are used. Such conditions are uncommon but usually present during the first few years of life. It is in this age group that there is the highest mortality rate.[44–49] In the majority, distinctive abnormalities can be found either in the smooth muscle or in the myenteric plexus.

Disease of enteric nerves may be familial and limited entirely to the gut, as in congenital absence of argyrophil nerves (which is inherited as an X-linked or perhaps an autosomal recessive trait) and familial megaduodenum,[46] or as part of a familial visceral neuropathy. Sporadic cases have also been reported with a peripheral neuropathy in which enteric nerves have been involved. The pathogenesis of the neural disease is not known.

Disorders Affecting Gastroduodenal Smooth Muscle

In adult life, most gastroduodenal muscle diseases occur secondary to a number of different conditions, including dystrophia myotonica, progressive systemic sclerosis, Ehlers-Danlos syndrome, dermatomyositis, and systemic lupus erythematosus. However, smooth muscle disease restricted to the gut is rare. The reverse is true in children; smooth muscle disease as part of a systemic disease occurs extremely rarely, and the majority suffer from two syndromes: hollow visceral myopathy[47,48] and megacystis microcolon hypoperistalsis syndrome.[49] The pathogenesis of these conditions is not understood and are described in detail in Chapter 46.2, "Dysmotilities," and Chapter 46.4, "Chronic Intestinal Pseudo-obstruction Syndrome."

Drugs Affecting Gut Motility

A variety of drugs have been found to affect gastroduodenal motility, and a number of others may be expected to do so. These include cholinergic agents, adrenergic, dopaminergic, and chemotherapeutic compounds. Opioids and Ca^{+} channel blockers may also impact on normal gut motility.[50–53]

Gastroduodenal Motility in Other Gastrointestinal Disorders

Gastroesophageal Reflux. Although the motor mechanisms of GER are relatively well described in children, the association with disease elsewhere in the GI tract is less well defined. It is clear that GER may occur with obstructive lesions (see above) such as pyloric stenosis and malrotation or may be part of a generalized pseudo-obstructive disease that also involves the stomach and duodenum. However, it is not clear whether gastric emptying is affected in those who present with GER alone.

In patients treated surgically by fundoplication, a proportion may develop acute gas-bloat syndrome or a more chronic syndrome of early satiety, bloating, nausea, recurrent retching, and vomiting.[15] These complications occur most frequently in children with severe neurologic disorders. Electrogastrographic studies show that there is increased sensitivity of the emetic reflex.[54] The nature of this is ill understood, but a study of fundoplication in an animal model suggests that inflammation and fibrosis around vagal nerve fibers induced by surgery result in abnormal vagal nerve function.[55]

Small Intestinal Malrotation. The majority of children who develop symptoms related to malrotation do so within the neonatal period with features of complete or incomplete upper intestinal obstruction. A proportion of children postoperatively have prolonged feeding difficulties and recurrent vomiting. Investigation of such children shows aberrant antroduodenal dysmotility, which is compatible with a neuropathic pseudo-obstruction.[56] It is of interest that malrotation is a common feature of pseudo-obstructive disorders. Devane and colleagues speculate that the underlying disease process is responsible for the disordered movement of the intestine around the superior mesenteric artery during embryologic development.[56]

DIAGNOSTIC TECHNIQUES

To understand the gastroparetic or pseudo-obstructive disorder and plan rational treatment, the involved areas must be defined and the physiology and pathology of the affected areas studied.

Radiology and Transit Studies

Conventional contrast radiography is used to delineate anatomic abnormalities, and, together with studies of gut transit, it provides a limited description of the disease but no clues to the underlying nature of the disorder.

Manometry

Studies of motility are helpful in delineating both the nature and extent of the disease. In patients with suspected pseudo-obstruction, at least three areas of the GI tract—the esophagus, the upper small intestine, and the rectosigmoid colon—should be studied because the disease may not be restricted to the stomach and duodenum. Swallow-induced peristalsis, fasting activity, and the gastrocolonic response to food each can be used as tests of the integrity of the enteric nervous system and of the contractility of the smooth muscle.[57] In addition, postprandial activity provides information regarding the humorally mediated response to food and whether enteroenteric reflexes are intact.

In the esophagus, swallow-induced peristalsis and the associated relaxation of the lower esophageal sphincter can be studied using a Dent sleeve assembly modified for use

in infants and younger children.[58] Particular attention should be paid to the nature of the primary peristaltic sequence, to determining whether secondary peristalsis occurs in response to reflux, and to the presence of tertiary contractions. The amplitude and form of the contractile waves are also noted.

The cyclic nature of the fasting gastric and duodenal motor activity is determined by the inherent activity of the enteric nervous system. This relationship can be used to test whether the enteric nervous system is intact and whether extrinsic nervous modulation is present. Observation of the disruption of fasting activity and the establishment of postprandial activity provide information regarding the hormonally mediated responses to food and clarify whether enteroenteric reflexes are intact. To test these motor functions, a standardized, age-appropriate meal is administered after observing three cycles of fasting activity.[57]

Manometric studies show that myopathic processes produce low-amplitude, poorly propagated contractions,[57] whereas neuropathies are associated with contractions of normal amplitude that are often bizarre in waveform, abnormally propagated, and, in phase III activity, ill formed.[59] Disturbance of the neuroendocrine environment may be signaled by increased slow-wave frequency in diseases in which catecholamines are secreted in excess (such as hyperthyroidism, pheochromocytoma, and ganglioneuroma) and decreased slow-wave frequency in preterm infants and in hypothyroidism.

Gastric Emptying

Methods used to measure gastric emptying in infants previously involved invasive intubation studies or the use of radioisotopes. Until recently, these methods have been most used: the serial test meal or a modified version of the George method.[60] The George method and its modifications[60] allow a single meal to be followed.

For those with access to a gamma camera, emptying of milk or solids[61] can be studied by labeling a test meal with indium diethylenetriamine pentaacetic acid for the fluid phase or technetium 99m attached to a number of different stable substances, such as aggregated ferrous hydroxide or tin colloid, which are neither adsorbed onto the gastric mucosa nor absorbed systemically. Successive 90-second images over a 60- to 90-minute period are then obtained, the counts in each image are computed, and emptying curves and half-empty times are calculated. This method suffers from the difficulty of relating planar changes to a three-dimensional organ; in small infants especially, superimposition of parts of the stomach over the small intestine makes separation of emptied and retained meal difficult.[61]

In more recent years, noninvasive methods using real-time ultrasonography, electrical impedance tomography, and C^{13} octanoic acid breath testing each have been developed.[62] However, scintiscanning currently remains the gold standard.[62]

Electrogastrography

Electrogastrography[63] is defined as the recording of myoelectric activity of the smooth muscle of the stomach by means of electrodes attached to the abdominal skin. The first electrogastrogram was recorded by Alvarez in 1921, but the advent of powerful personal microcomputers has revived interest in this diagnostic modality. This test has the great advantage of permitting the study of gastric myoelectric activity in both the fasted and fed state totally noninvasively; moreover, it readily detects disturbances of slow waves.[63]

Histology

Usually, when no microscopic lesion of nerve or muscle has been reported in cases of pseudo-obstruction, adequate full-thickness biopsies of an appropriate region of the gut have not been taken or have not been rigorously examined. To demonstrate disease of smooth muscle or enteric nerves in the majority of patients with pseudo-obstructive disorders, paraffin-embedded material stained with hematoxylin and eosin or a trichrome stain is inadequate. Only if there is widespread severe fibrosis can a defect of a muscle be detected in this way. Ultrastructural studies are necessary for both muscle and nerve. In addition to electron microscopy, enteric nerves must be studied by silver staining and by immunocytochemistry and histochemistry.[64,65] Such studies define the nature and the extent of the disease and, in some instances, are helpful in understanding disease etiology.

TREATMENT

Operative Management

In patients in whom there is no anatomic abnormality, it is usually not possible to treat a primary motility disorder by surgical means. This discussion should dispel the naive view that all problems of delayed gastric emptying can be resolved by cutting the pylorus.

In those patients with an isolated tachygastria, antrectomy has been successful.[32,33] However, this step should be considered only after a thorough evaluation to eliminate the diagnostic possibility of a generalized pseudo-obstructive disorder. In some children with the superior mesenteric artery syndrome or duodenal pseudo-obstruction, a gastroenterostomy has proved beneficial.

In those with generalized pseudo-obstructive disease, adhesional obstruction often occurs after laparotomy, and the risk increases with repeated laparotomy. Adhesional obstruction should be treated conservatively, with surgery being employed only when there are localizing signs, incipient peritonitis, or bowel necrosis.

Medical Management

Little can be done directly to treat these underlying disease processes, even when they are acquired, but much can be done to treat the consequence of the secondary effects of malnutrition and primary disease exacerbation. The majority of patients who die from gastroduodenal motor disorders do so from malnutrition and its consequence or serious electrolyte imbalance.

Primary Disease Exacerbation. Although the nature of the pathologic process is often not known, it is common

for exacerbation to be associated with infection, anesthetics, drugs, and procedures involving gut handling that may normally adversely affect gut motility.

Malnutrition. Many patients with motor disorders die from malnutrition. These deaths are totally avoidable with the judicious use of parenteral nutrition. Many episodes subside completely provided that nutrition is maintained. Only the most severely affected need to be considered for home parenteral nutrition. Others tolerate modern enteral formulas but not normal food.

Pharmacologic Agents. Most attempts at treatment with prokinetic agents (metoclopramide, domperidone, or cisapride) or motilin agonists (erythromycin) in patients with neuromuscular disease of the gut are unsuccessful, yet, occasionally, one of these agents is helpful. Some tachygastrias have been associated with disturbed prostaglandin metabolism.[32] In such patients, treatment with a prostaglandin synthetase inhibitor such as indomethacin may be successful. Until an understanding of the disease processes is available, drugs will provide only marginal relief at best.

PROGNOSIS

The prognosis for patients with uncomplicated pyloric stenosis or malrotation is excellent, and only a success rate approaching 100% is acceptable. However, in those patients in whom the stomach and duodenum are involved in a pseudo-obstructive disorder, either restricted to that region of the gut or as part of a more generalized disease of the GI tract, the prognosis is more uncertain. In conditions in which the extrinsic innervation is affected, the prognosis is that of the underlying condition. In those patients in whom there is intrinsic neuromuscular disease, particularly when it is part of a diffuse condition of the gut, the overall mortality rate may be as high as 25%,[45] with the highest rate in the first few years of life. The majority of these patients die from sepsis, malnutrition, electrolyte imbalance, or aspiration.

Only in the last 20 years have many of the diseases that cause gastroduodenal motor disorders been recognized. However, effective treatment for many will ensue only when a much greater understanding of the disorders is achieved.

CHAPTER 32

CONGENITAL ANOMALIES

David A. Lloyd, MChir, FRCS, FCS(SA)
Simon Edward Kenny, BSc(Hons), MB ChB(Hons), MD, FRCS(Paed Surg)

EMBRYOLOGY

The primitive gut develops during the fourth week of gestation by division of the primitive yolk sac into primitive gut and yolk sac proper. These two structures remain in continuity through the vitelline (omphalomesenteric) duct until the duct obliterates during the seventh week. Most of the epithelial attachments to the gut, including the liver and the pancreas, arise from the endoderm of the primitive gut. Connective tissue elements of the gut, such as smooth muscle, are of splanchnic mesenchymal origin. The primitive gut is divided into three parts: foregut, midgut, and hindgut.

The foregut gives rise to the pharynx, lower respiratory system, esophagus, stomach, and proximal duodenum down to the level of the bile duct, liver, pancreas, and biliary system. The foregut enteric nervous system is derived from migration of somatic neural crest cells. The blood supply is derived from the foregut artery, which later becomes the celiac artery.

The midgut gives rise to the small intestine beyond the opening of the bile duct, cecum, appendix, and ascending and proximal transverse colon. The foregut and hindgut enteric nervous systems are derived from migration of neural crest cells from the vagal region of the hindbrain into the developing esophagus and their subsequent caudal migration. This process is complete by 12 weeks gestation. The midgut blood supply is from the midgut artery, which subsequently becomes the superior mesenteric artery. Between the sixth and twelfth weeks of gestation, the midgut herniates into the umbilical cord and by a complex series of rotational movements, probably reflecting differential growth, returns into the peritoneal cavity and assumes the postnatal position.

The hindgut derivatives are the distal third of the transverse colon, descending colon, sigmoid colon, rectum, and rostral portion of the anal canal. Organs derived from the hindgut are supplied by the inferior mesenteric artery. The distal end of the hindgut ends in the cloaca. This is separated from the ectoderm of the anal canal by the cloacal membrane. As the hindgut differentiates, a sheet of mesenchyme, the urogenital septum, divides the distal hindgut into dorsal and ventral parts. When separation is complete, the ventral component forms the urogenital sinus and the dorsal component forms the anorectal canal. The epithelium of the anal canal is derived from the endoderm of the hindgut rostrally and ectoderm caudally, as demarcated by the pectinate line.

RECOGNIZING CONGENITAL ANOMALIES

Prenatal ultrasonography will identify the major abdominal wall defects, exomphalos and gastroschisis, and gastric or small bowel distention suggestive of intestinal obstruction. The distinctive "double bubble" characteristic of duodenal atresia may be seen, and associated anomalies may be present, notably cardiac. Polyhydramnios raises the possibility of esophageal atresia and upper gastrointestinal obstruction. The abdominal wall defects may be associated with elevated maternal serum α-fetoprotein levels. Fetal karyotyping may be considered in abnormalities with a high risk of chromosomal disorders, such as exomphalos. Prenatal diagnosis provides the opportunity for parental counseling and allows arrangements to be made for prompt postnatal surgical care.[1] However, prenatal diagnosis may not be accurate, and confirmation of the diagnosis after birth is important.

ABDOMINAL WALL DEFECTS

Exomphalos and Gastroschisis

Exomphalos is a midline developmental defect of the anterior abdominal wall, as a result of which some of the abdominal organs lie outside the abdominal cavity (Figure 32-1). The eviscerated abdominal organs are contained within a membranous sac derived from the amniotic membrane. Depending on the size of the lesion, the sac will contain stomach, intestine, liver, and spleen. More complex lesions include upper abdominal midline defects in which exomphalos coexists with defects of the diaphragm, sternum, pericardium, and heart (pentalogy of Cantrell) and lower midline defects associated with bladder exstrophy. Up to 75% of infants have major associated structural abnormalities, of which congenital cardiac defects are the most common, or chromosomal anomalies, notably trisomy 13, 18, or 21, which may determine the outcome.[2] In Beckwith-Wiedemann syndrome, which includes exomphalos, macroglossia, and hypoglycemia associated with pancreatic islet cell hyperplasia, early recognition is essential to prevent complications of hypoglycemia.[3]

With gastroschisis, the stomach and intestine are eviscerated through a defect to the right of the base of the umbilical cord (Figure 32-2). There is no enveloping sac, and evisceration of other organs is rare. The likely mechanism, supported by evidence from serial sonograms, is prenatal rupture of a small hernia of the base of the umbilical cord at the site of the obliterated fetal right umbilical vein.[4] Abnormalities of the intestine, notably atresia, occur in up to 10% of infants, but chromosomal and extra-abdominal anomalies are rare.[5]

Accurate diagnosis is possible with antenatal ultrasonography.[2] Amniocentesis and karyotyping may be appropriate for exomphalos, with the high risk of associated anomalies.[2] Delivery should take place in a specialist unit. Stable infants with a gastroschisis or a small exomphalos may be safely delivered per vaginam, and cesarean section is recommended for most infants with exomphalos.

Preoperative correction of hypovolemia is essential, particularly with gastroschisis, in which boluses of saline or albumin may be required to replace the protein-rich fluid losses (see the section "Intravenous Fluids"). With an intact exomphalos, there is no urgency to remove the sac if it remains intact and infection is not a concern. For gastroschisis or ruptured exomphalos, primary closure of the defect may be possible, depending on the volume of the herniated viscera relative to the abdominal cavity; postoperative ventilation is required because of the resultant abdominal distention. Alternatively, the eviscerated organs are placed in an artificial bag (silo) fashioned from a sheet of reinforced Silastic and sutured to the abdominal wall.[5] This is progressively reduced in size each day, allowing secondary closure of the abdomen by 7 to 10 days. A commercial silo has been developed that is introduced into the defect without the need for anesthesia or sutures.[6] Infection is a major cause of morbidity, and antiseptic care and prophylactic antibiotics are important. Establishment of gastrointestinal function is slow, and intravenous feeding is required. Overall survival for gastroschisis is greater than 90%; postoperative problems include adhesive obstruction and short-gut syndrome. For exomphalos, the outcome is dependent on the associated abnormalities; in the absence of these, most infants survive to lead a normal life.[7]

Umbilical Granuloma

Umbilical granuloma is a mass of pink granulation tissue at the umbilicus caused by low-grade infection of the stump of the umbilical cord. It must be distinguished from an omphalomesenteric duct mucosal remnant. Topical treatment suffices, with local cleansing and applications of either topical steroids or silver nitrate. The latter carries a risk of damage to the adjacent skin, which must be protected.

FIGURE 32-1 A large exomphalos. The sac is intact and contains intestine and liver; typically, the umbilical cord is attached to the apex of the sac.

FIGURE 32-2 Gastroschisis. The abdominal wall defect is to the right of the umbilical cord, and there is no sac. Only the stomach (lying to the left) and intestine are prolapsed, not the solid organs.

Omphalomesenteric Duct Remnants

Failure of regression of the omphalomesenteric duct[8] results in a fistula that presents with a persistent umbilical discharge, often with ectopic intestinal mucosal at the umbilicus (Figure 32-3). The diagnosis is confirmed by passing a nasogastric tube through the fistula and aspirating small bowel content or injecting radiopaque contrast. The entire fistula is resected through a subumbilical incision. The omphalomesenteric duct may obliterate but persist as a band between the umbilicus and small intestine.

The most common remnant of the omphalomesenteric duct is persistence of the enteral end as a Meckel diverticulum, which is lined by ileal mucosa but may contain ectopic gastric mucosa.[9] Complications include Meckel diverticulitis, which is clinically indistinguishable from acute appendicitis. Ectopic gastric mucosa within the diverticulum may lead to local ulceration with bleeding or perforation. Ectopic gastric tissue causing mucosal ulceration and bleeding may be identified by 99m technetium scanning (Figure 32-4), which has an 85% sensitivity and a 95% specificity.[9] Intestinal obstruction may result from intussusception of the diverticulum or small bowel volvulus around a connecting band to the umbilicus (Meckel band). In all situations, the diverticulum is resected with the adjacent segment of ileum. There is no sound evidence to support routine resection of an asymptomatic diverticulum encountered incidentally at operation.

An isolated mucosal remnant at the umbilicus must be distinguished from an umbilical granuloma and is suspected when the "granuloma" fails to respond to topical treatment. Treatment is excision of the ectopic mucosa. A limited exploration beneath the umbilicus to exclude an omphalomesenteric (Meckel) band is important; if present, it is resected.

FIGURE 32-3 A patent omphalomesenteric duct excised intact. At the top of the specimen, note the ectopic mucosa at the umbilicus. Below this, the fistula joins the small intestine.

Congenital Hernia and Hydrocele

Congenital inguinal hernia and hydrocele are common abnormalities of childhood, with a peak incidence in the neonatal period. They result from persistent patency of the processus vaginalis, an extension of the peritoneal cavity that passes through the inguinal canal within the spermatic cord in boys and along the round ligament in girls. Normally, the processus vaginalis begins to obliterate once testicular descent is complete; it follows that obliteration does not occur when the testis is undescended. It is important to distinguish between congenital hernia and hydrocele because the natural history and management of each are radically different in the newborn period.

Congenital inguinal hernia is the presence of an abdominal viscus in the processus vaginalis (hernia sac), usually the small intestine but occasionally an ovary, which presents as a firm mobile inguinal mass and may be confused with a lymph node. Spontaneous resolution does not occur, and because of the high risk of incarceration during the first months of life, prompt operation is advised (see Chapter 36, "The Surgical Abdomen").

Congenital hydrocele is associated with a narrow patent processus vaginalis that becomes distended by peritoneal fluid. Most hydroceles will spontaneously resolve in the first 6 months of life, and because there is no risk of incarceration, treatment is expectant. After 2 years of age, a hydrocele is not likely to close spontaneously, and operative closure of the processus vaginalis is recommended.

INTESTINAL OBSTRUCTION IN THE NEWBORN INFANT

Congenital intestinal abnormalities present most commonly with intestinal obstruction. The following general observations are fundamental to the diagnosis and management of these infants.

Clinical Features

Vomiting. Bile-stained (green) vomiting is a characteristic of intestinal obstruction distal to the ampulla of Vater, and, if present, obstruction must be excluded. Non–bile-stained vomiting may be due to obstruction at the pylorus or in the proximal duodenum and must be distinguished from gastroesophageal reflux.

Abdominal Distention. This will depend on the level of obstruction. It is most marked in the case of large bowel obstruction and least apparent with duodenal atresia, where the distention is confined to the epigastrium. Visible peristalsis may be apparent. Abdominal colic is not a characteristic of congenital intestinal obstruction.

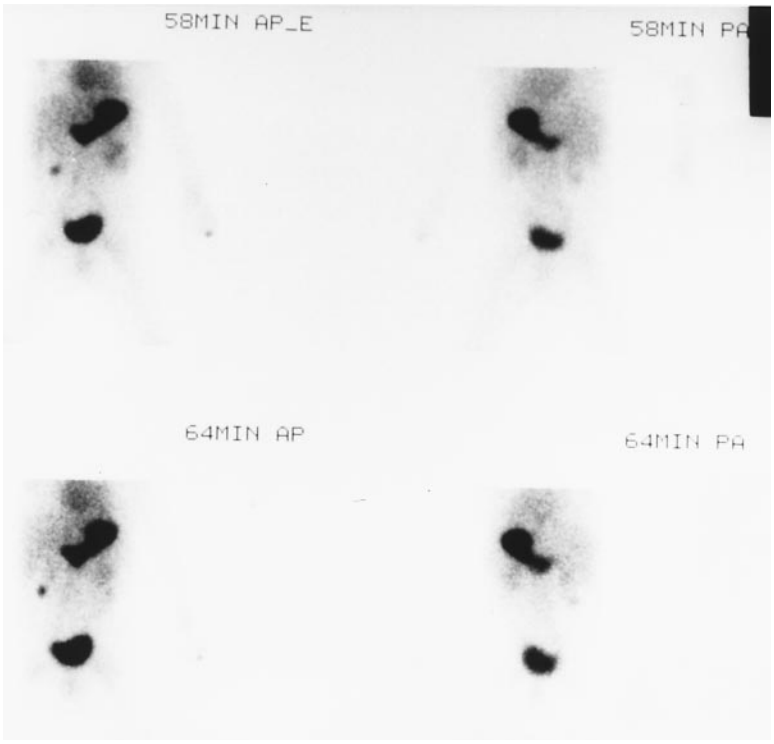

FIGURE 32-4 99m Technetium scan showing uptake by ectopic gastric mucosa in a Meckel diverticulum in the right lower abdomen. Anteroposterior images on the left, posteroanterior images on the right, at 58 minutes (above) and 54 minutes (below).

Failure to Pass Stools. The normal infant should pass meconium within 36 hours of birth. Failure to pass stool in association with abdominal distention suggests colonic, rectal, or anal obstruction. The passage of stool does not exclude a proximal congenital obstruction such as an ileal atresia because meconium already in the colon at the time that the obstruction develops will be evacuated, after which no further stools will be seen.

Diagnosis

A plain abdominal radiograph will show distended bowel loops characteristic of obstruction in most cases. This may be less obvious when the bowel is filled with fluid or meconium, as with meconium ileus. Contrast studies and ultrasonography have specific diagnostic roles.

Management

Gastric Drainage. The largest comfortable nasogastric tube, usually 8 to 10 French, is inserted to drain the stomach to prevent vomiting and aspiration and minimize gastric secretions. Ventilation will be optimized by reduced abdominal distention, which restricts diaphragmatic movement. The newborn infant is an obligate nasal breather, and although a nasogastric tube has the advantage that it can be firmly secured to the face, it does reduce the nasal airway by 50%, and in the premature infant with increased oxygen requirements, an orogastric tube may be preferred. The tube must be left on continuous drainage and regularly flushed with air or water and aspirated to confirm that it is functional.

Intravenous Fluids. The use of 10% dextrose solutions reduces the risk of hypoglycemia, but regular monitoring of the blood sugar level is important. Gastric aspirates and third-space fluid loss in the obstructed intestine will increase sodium, potassium, and chloride requirements, which cannot be accurately measured and are not fully compensated for by standard "maintenance" solutions containing 0.18% sodium chloride. In anticipation of these additional requirements, we use 0.45% sodium chloride (half normal) with potassium chloride 10 to 20 mmol/L. Fluid volume requirements are increased for the same reason, and a starting rate of 4 to 5 mL/kg/h for full-term infants and 5 to 6 mL/kg/h for premature infants is recommended, depending on the degree of dehydration of the infant. With severe hypovolemia, as occurs with gastroschisis, 10 to 20 mL/kg boluses of crystalloid or albumin may be required in addition. Measured gastric aspirates are replaced with 0.9% sodium chloride (normal saline). Hydration is monitored by clinical assessment of the peripheral circulation, skin turgor, and anterior fontanel tension and by accurately monitoring the urine volume (normal in a neonate is 2 mL/kg/h) and concentration (ideal specific gravity is 1008–1012). Serum electrolytes and acid-base balance are monitored, and urine sodium estimations are useful for interpreting renal function. Based on these findings, the volume of intravenous fluid is increased or decreased every 4 to 8 hours, the actual frequency of assessment depending on the individual clinical situation.

Vomiting in the Newborn Infant

Causes of congenital intestinal obstruction are shown in Table 32-1. Nonsurgical causes of vomiting must be excluded, including feeding difficulties (under- or overfeeding), systemic infection, urinary tract infection, raised intracranial pressure, food allergy, and adrenogenital syndrome.

TABLE 32-1 CONGENITAL CAUSES OF GASTROINTESTINAL OBSTRUCTION

VOMITING IN THE NEWBORN INFANT
Duodenal atresia
Malrotation
Jejunoileal atresia
Meconium ileus
Duplication cyst
Incarcerated inguinal hernia
FAILURE TO PASS STOOL
Anorectal malformation
Hirschsprung disease
Meconium plug syndrome
Colonic atresia

Duodenal Atresia. The site of obstruction is typically at the level of the ampulla of Vater and may take the form of complete obstruction owing to atresia or an intact membrane or partial obstruction owing to stenosis or a fenestrated membrane. The common bile duct usually opens on the membrane and is vulnerable if an attempt is made to excise the membrane. At the level of the atresia, there is a marked decrease in the caliber of the distal duodenum. Occasionally, an intact membrane will bulge distally, forming the windsock anomaly, as a result of which the site of obstruction appears to be more distal than it actually is.

The incidence of duodenal atresia ia about 1 in 5,000 live births.[10] Prematurity is common, and associated anomalies include trisomy 21 (Down syndrome), congenital cardiac disease, esophageal atresia, anorectal abnormalities, and malrotation. The cause of the anomaly is not understood; its occurrence at a complex site of development of the duodenum, pancreas, and biliary and pancreatic ducts and the association with trisomy 21 suggest a genetic origin.[11]

The diagnosis may be suspected prenatally when the fetal sonogram shows hydramnios and a distended stomach. Because of the association with trisomy 21, these findings may prompt fetal karyotyping, particularly if termination of pregnancy is a consideration.[12] Following birth, the typical presentation is with bilious vomiting and epigastric distention, but vomiting may be nonbilious if the ampulla of Vater opens distal to the atresia. A plain abdominal radiograph showing the characteristic double bubble representing the distended stomach and proximal duodenum, but no gas distal to this, is diagnostic (Figure 32-5). When there is gas distal to the dilated proximal duodenum, malrotation must be distinguished from duodenal stenosis by ultrasonography or a contrast study. Partial duodenal obstruction may not be recognized for months or years until persistent postprandial vomiting prompts a contrast study or endoscopy.

Preoperative management includes gastric decompression and correction of fluid and electrolyte abnormalities. The duodenum is approached through a supraumbilical right transverse incision. The gastric tube is pushed distally into the duodenum to define the site of obstruction and exclude a "windsock" abnormality. An annular pancreas may encircle the duodenum at the point of atresia. Because of the risk of injury to the ampulla of Vater, the preferred procedure for duodenal atresia is a duodenoduodenal anastomosis, bypassing the obstruction. The "diamond" incision described by Kimura and colleagues uses a transverse incision in the dilated upper pouch and a longitudinal incision in the narrow distal duodenum.[13] Postoperative ileus may be prolonged, and intravenous feeding is often needed; if this is not available, a transanastomotic nasoduodenal feeding tube is passed at operation under direct vision to enable early postoperative enteral feeding. For duodenal stenosis or a fenestrated diaphragm, the proximal duodenum is entered through a longitudinal incision that is then extended across the stenosis, taking care to avoid the ampulla of Vater by placing the incision anterolaterally. The incision is closed transversally. Survival rates for duodenal atresia and stenosis are over 90% and depend largely on the influence of associated anomalies.[14]

Midgut Malrotation. Malrotation describes a situation in which the intestine does not lie in a normal position. The common form is midgut malrotation in which there are two components: the third part of the duodenum lies to the right of the vertebral column instead of curving across to the left, and the cecum lies in the upper abdomen to the left of the duodenum. As a result, the mesentery of the midgut (jejunum to mid–transverse colon) is not attached across the posterior abdominal wall but is narrow and confined to the base of the superior mesenteric artery. As a result, the midgut is liable to twist around this narrow pedicle at any time. Torsion of more than 270° may lead to potentially fatal irreversible midgut ischemia (Figure 32-6). Traditionally, malrotation is attributed to failure of the intestine to

FIGURE 32-5 Abdominal radiograph showing the characteristic "double bubble" sign owing to gas in the distended stomach and duodenum proximal to a duodenal atresia.

FIGURE 32-6 Midgut malrotation with volvulus. The midgut (small bowel, cecum, and right half of the colon) has twisted in a clockwise direction around the pedicle of the superior mesenteric vessels. In this example, the intestine is still viable.

"rotate" to its normal position when it moves into the peritoneal cavity from the normal umbilical cord hernia during the first month of gestation. This is probably an oversimplication, and the true mechanism is not understood.[15]

The risk of acute volvulus is highest during the neonatal period, but the true incidence of malrotation is not known because it may remain asymptomatic throughout life. Recurrent volvulus may present at any age with a history of chronic intermittent abdominal pain with or without vomiting. A contrast radiograph will show the characteristic features of malrotation (Figure 32-7).

In the infant, acute midgut volvulus presents with bilious vomiting, abdominal pain, and progressive abdominal distention and tenderness. Stools may be passed in the early stages; the passage of blood suggests intestinal ischemia. With progressive midgut ischemia, the infant rapidly deteriorates with hypovolemia and persistent metabolic acidosis. A plain abdominal radiograph may show signs of duodenal obstruction; beyond this, the bowel may contain more fluid than air, with resultant opacification of the abdominal cavity.

Urgent laparotomy is required after rapid correction of fluid and electrolyte abnormalities and nasogastric drainage. A generous supraumbilical transverse incision is used to enable easy delivery and inspection of the small and large bowel. The volvulus is derotated, usually in an anticlockwise direction, to allow restoration of the mesenteric circulation and reveal the cecum lying adjacent to the duodenum. The peritoneal folds extending from the cecum across the duodenum (Ladd bands) are divided to enable the cecum to be mobilized toward the left, thus widening the base of the mesenteric pedicle and exposing the superior mesenteric vessels. If the intestine is viable, the cecum is replaced on the left side of the abdominal cavity and the small intestine on the right side. The appendix may be removed to avoid future diagnostic confusion. When the viability of the bowel is uncertain, obvious nonviable bowel is resected, stomas are made, and the abdomen is closed; the bowel is re-examined by laparotomy after an interval of 24 to 36 hours. If the entire volvulus clearly is not viable, resection will inevitably result in severe short-gut syndrome and the inevitable consequences of long-term intravenous feeding.[16]

Jejunoileal Atresia. Congenital obstruction of the jejunum or ileum due to atresia or stenosis develops as a result of ischemic infarction of a segment of fetal intestine. This was first demonstrated experimentally in a fetal dog model in 1955 by Louw and Barnard.[17]

Patterns of small bowel atresia are atresia in continuity (type I), atresia with connecting band and mesenteric defect (type II), atresia with adjacent mesesnteric defect (type

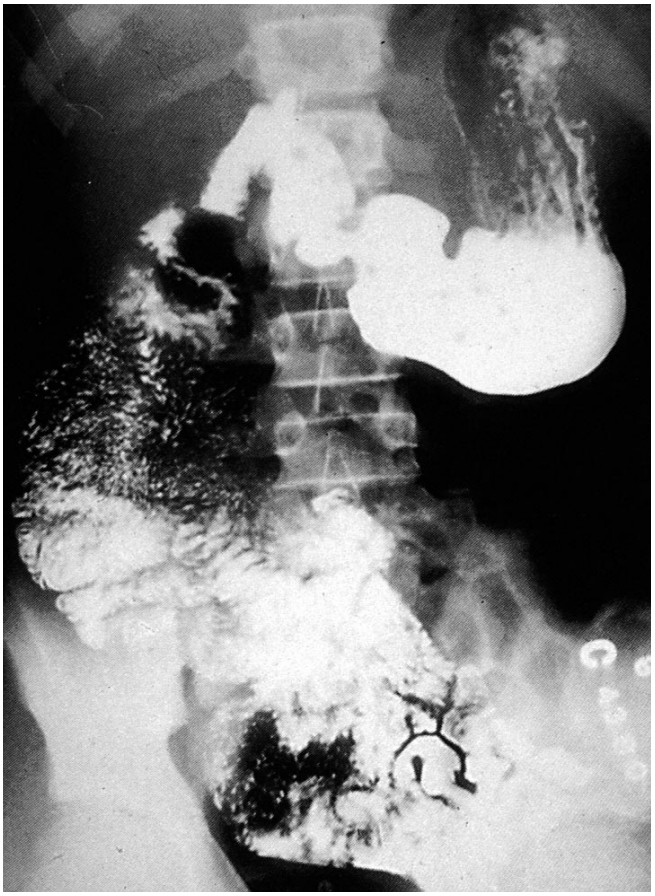

FIGURE 32-7 Midgut malrotation: an upper gastrointestinal contrast study showing the duodenum and small intestine lying to the right of the vertebral column.

IIIA) or extensive mesenteric defect and "apple peel" bowel configuration (type IIIB; Figure 32-8), and multiple atresias (type IV). Presentation is with bilious vomiting and abdominal distention. Meconium stool already in the colon may be passed, confirming that the obstruction occurs after the secretion of bile into the embryonic gastrointestinal tract. The diagnosis is confirmed by plain abdominal radiography, which shows multiple dilated loops of intestine with air fluid levels. Distal ileal atresia must be distinguished from meconium ileus and long-segment Hirschsprung disease; a contrast enema may be required.

Preoperative preparation is as described above. At operation, the site of obstruction is easily identified by the abrupt change in caliber from the dilated proximal intestine to the empty narrow distal small bowel. In type IIIA atresia, there is a defect in the adjacent mesentery. The dilated proximal bowel is resected, and continuity is restored by end-to-end or end-to-back anastomosis. In the case of multiple atresias (type IV), as many segments as possible should be salvaged to avoid short-gut syndrome. Postoperative recovery may be prolonged, and parenteral nutrition may be required. Survival rates over the past two decades have ranged from 78 to 100%.[18] Postoperative complications include anastomotic leak or stenosis and functional intestinal obstruction at the anastomosis. Extensive loss of small bowel attributable to multiple atresias (type IV) or a precarious blood supply (type IIIB) may result in short-bowel syndrome, requiring prolonged intravenous nutrition.

FIGURE 32-8 Jejunoileal atresia type IIIB: there is an extensive mesenteric defect and an "apple peel" bowel coiled around the long marginal artery. There is a risk of the bowel twisting and obstructing the tenuous mesenteric blood supply.

Where there are concerns about the safety of the anastomosis, either because of impaired vascularity or possible distal obstruction, stomas may be created but at the expense of high fluid and electrolyte loss. This may be alleviated by refeeding the effluent into the distal stoma. This also has the additional advantage of promoting growth of the distal intestine.[19] With proximal jejunal atresia, resection of the dilated bowel is not possible, and tapering by antimesenteric excision or inversion of the proximal jejunum facilitates anastomosis and may enhance postoperative transit.

Meconium Ileus. This is a misnomer because the obstruction is mechanical. As a result of pancreatic enzyme deficiency, the distal ileum is plugged by viscid and often nonpigmented meconium with a high albumin content. The deficiency of pancreatic enzymes is, with rare exceptions, associated with cystic fibrosis. Up to 20% of newborn infants with cystic fibrosis present with meconium ileus. The diagnosis is suspected when there is a family history of cystic fibrosis and is confirmed by chromosomal analysis, which in 85% of patients will demonstrate the ΔF508 mutation, a three-basepair deletion from chromosome 7.[20] Mutations result in defective chloride transport in the apical membrane of epithelial cells and an abnormally high excretion of chloride from the skin.[21] This can be measured by iontophoresis (the sweat test), an alternative diagnostic test in mature infants.

The characteristic abnormality in meconium ileus is a narrow terminal ileum obstructed by multiple pellets of meconium, with an abrupt transition proximally to dilated ileum containing meconium that is abnormally tenacious and adherent to the intestinal mucosa. The colon is empty and contracted (microcolon). Presentation is with distal ileal obstruction, which must be distinguished from ileal atresia and long-segment Hirschsprung disease. Abdominal radiographs show air-fluid levels in the proximal small bowel. The meconium-filled ileum appears opaque, whereas in the right iliac fossa, the dilated meconium-filled distal ileum contains multiple translucencies owing to entrapped fat globules, the "soap bubble" appearance. Meconium ileus may be complicated by volvulus of a dilated meconium-filled loop of distal ileum, which may result in atresia or may perforate, leading to meconium peritonitis. The latter is seen on abdominal radiography as multiple calcifications in the peritoneal cavity.

Following nasogastric decompression and correction of fluid and electrolyte abnormalities, the diagnosis is confirmed by water-soluble contrast enema, which will show the microcolon, the meconium pellets in the distal ileum, and the dilated proximal dilated ileum (Figure 32-9). Switching to Gastrografin enema, it is possible to clear the obstructing meconium in over 50% of cases.[22] Gastrografin has an osmolality of approximately 1,700 mOsm/L, and great care must be taken to anticipate and replace fluid

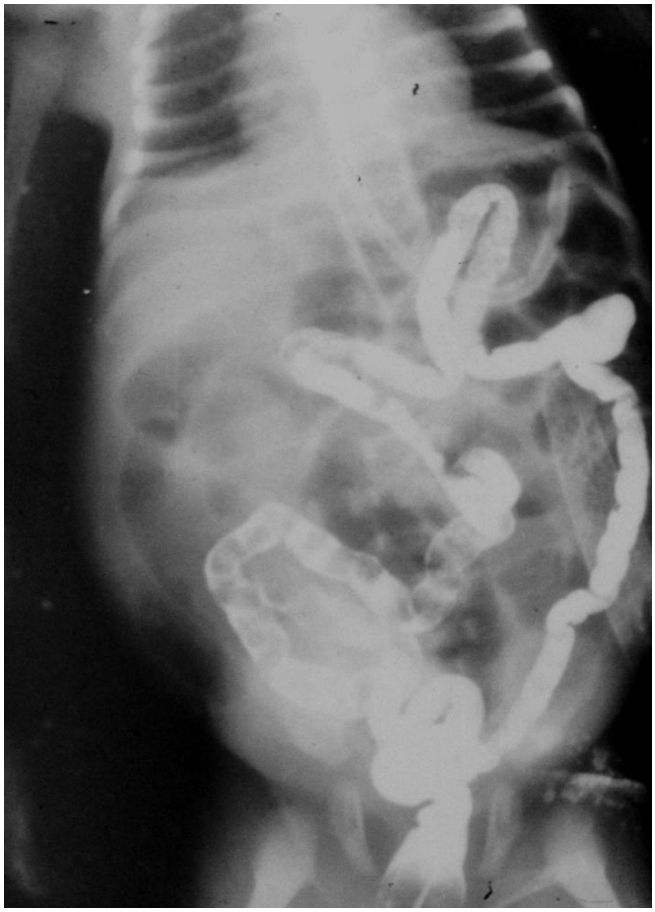

FIGURE 32-9 Meconium ileus. The contrast enema shows the typical microcolon, displaced cecum, and filling defects representing meconium pellets in the terminal ileum.

losses into the intestine. At operation for uncomplicated meconium ileus, the proximal dilated ileum is opened and the meconium is removed using saline irrigation. Simple enterostomy and resection of the dilated intestine with primary anastomosis are safe when the bowel wall is healthy and the distal obstruction can be cleared with certainty. Alternatively, proximal and distal stomas should be created.

The survival rate for meconium ileus has improved from 30% in the 1960s to over 90%.[23] This is attributable to the overall improvement in perioperative respiratory care and increasingly successful nonoperative management and avoidance of stomas. In older children, episodic obstruction due to inspissated meconium may occur (meconium ileus equivalent, distal intestinal obstruction syndrome), at times associated with underhydration and altered enzyme replacement needs. Presentation is with pain, tenderness, and possibly a mass in the right iliac fossa, which must be distinguished from an appendix mass, ovarian tumor, and inflammatory bowel disease. In most children, oral Gastrografin will relieve the obstruction.[24]

Duplication Cysts. Duplication cysts are congenital tubular or spherical cysts attached to the alimentary canal anywhere between the mouth and the anus, most commonly in the ileocecal region. The cysts have a muscle layer and an epithelial lining that usually resembles the adjacent part of the gastrointestinal tract. In the abdomen, nodules of ectopic gastric mucosa may be present. The blood supply is shared with the adjacent normal structure. Thoracic duplications may communicate through the diaphragm with the intra-abdominal gastrointestinal tract, from which the blood supply is derived (a potential pitfall for the unwary surgeon). Intestinal duplications lie on the mesenteric side of the small intestine and the antimesenteric side of the large bowel. Tubular duplications may communicate with the intestinal lumen.[25]

Presentation may be with an abdominal mass or obstruction of the adjacent intestinal lumen. In a tubular cyst, peptic ulceration secondary to acid secretion from ectopic gastric mucosa may lead to rectal bleeding or perforation. The diagnosis may be suspected on a prenatal sonogram.

For diagnosis, ultrasonography and plain or contrast radiography may be helpful, depending on the site of the lesion. Computed tomography or magnetic resonance imaging will help to distinguish the duplication from an ovarian cyst. Complete excision is the treatment of choice. Where this is not possible, partial excision and removal of mucosal lining from the residual cyst or resection of the duplication and adjacent intestinal are options.

Failure to Pass Stool in the Newborn Infant

Causes of failure to pass stool are shown in Table 32-1.

Anorectal Anomalies. Anorectal anomalies (imperforate anus) occur in approximately 1 in 2,500 live births.[10,26,27] The embryologic events surrounding hindgut development remain poorly understood. The cloaca forms at approximately 21 days gestation and is a cavity into which hindgut, tailgut, allantois, and mesonephric ducts open. By 6 weeks, a combination of programmed cell death and differential growth results in the formation of an anterior urogenital cavity and a posterior anorectal cavity. When this process is disrupted, an anorectal malformation may result. The anatomic findings in children with anorectal malformations are considerable, and a number of complex classification systems have been proposed. The simplified classification of Pena and Hong (Table 32-2) conveniently summarizes most commonly encountered variants.[28]

The cause of anorectal anomalies is unknown. Although prenatal dosing of rats with the antimitotic agent doxorubicin can cause anorectal malformations,[29] there is little evidence for environmental factors playing a major causative role in humans.

Anorectal anomalies are most often detected during routine postnatal examination, although with some anomalies, the perineum may appear relatively normal to casual inspection. Anatomically, the lesion is usually associated with a fistulous communication between the rectum and either the genitourinary tract or perineum; the spectrum of abnormalities ranges from simple anterior malposition of the anus to complex anal agenesis, in which, typically, the anus is absent or represented by a shallow pit, the infants' buttocks are flattened, and the sacrum and anorectal innervation are deficient. The degree of abdominal distention is variable, and intestinal perforation is rare.

TABLE 32-2 CLASSIFICATION OF ANORECTAL ANOMALIES

MALES	FEMALES
Cutaneous fistula, bucket handle malformation, anal stenosis, anal membrane	Cutaneous (perineal) fistula
Rectourethral fistula (bulbar or prostatic)	Vestibular fistula
Rectovesical fistula (bladder neck)	Persistent cloaca
Imperforate anus without fistula	Imperforate anus without fistula
Rectal atresia/stenosis	Rectal atresia/stenosis

About 60% of infants will have malformations affecting other organ systems, most commonly cardiac, gastrointestinal, genitourinary, or vertebral in origin.[26,27] These may coexist as the VACTERL (vertebral, anorectal, cardiac, tracheoesophageal, renal, limb) sequence of anomalies.[27] A structured approach to the assessment of these infants needs to be adopted. Thorough physical examination is essential. Echocardiography, renal tract and spinal ultrasonography, plain spinal radiography, and karyotyping all need to be performed. Neonates with multiple anomalies may require assessment by a range of specialists, including clinical geneticists, neonatologists, orthopedic surgeons, otolaryngologists, neurologists, and neurosurgeons. Children should be maintained on urinary tract antibiotic prophylaxis until micturating cystourethrography, often performed following definitive reconstructive surgery, has excluded vesicoureteric reflux.

The principles underlying the initial management of infants with imperforate anus are relief of the distal bowel obstruction and protection of the anal sphincter mechanism. Initial resuscitation should include passage of a nasogastric tube (this will also exclude esophageal atresia) and establishment of intravenous access. Surgical options are to form a colostomy or to perform definitive reconstruction. Only low lesions such as those presenting with rectocutaneous fistula in which the anomaly is distal to the anal sphincter are amenable to relatively straightforward perineal reconstructive procedures without diverting a colostomy. The rectocutaneous fistula discharges meconium and can occur anywhere in the midline anterior to the presumptive site of the anus, including the scrotum and penis (Figure 32-10). Occasionally, it is recognizable as a chain of whitish pearl-like nodules. In all other cases, or when there is doubt, it is advisable to perform a temporary diverting colostomy followed by a staged reconstructive procedure. A sigmoid colostomy is suitable for most cases of imperforate anus, but for a cloacal anomaly, a transverse colostomy is recommended.

Most anorectal anomalies are amenable to reconstruction via a posterior sagittal approach, although a laparotomy is often required in boys with rectovesical fistula and girls with cloacal anomaly. The two main steps in the reconstruction are, first, mobilization and ligation of the fistula and, second, creation of the neoanus. In girls with a cloacal anomaly, genitourinary reconstruction is also required. Meticulous surgical technique is essential to optimize the long-term outcome. More recently, laparoscopic anorectal reconstruction has been advocated, and long-term outcome data are awaited.[31] Following reconstruction, the parents are taught to dilate their infant's anus to avoid stenosis of the infant's neoanus.

The long-term outcome in children with anorectal malformations is variable and to a large extent dependent on the initial anatomy and subsequent clinical management. Children with "high" malformations tend to have a poorer outcome, with higher rates of fecal incontinence.[28] Troublesome constipation can occur in children with "low" lesions. Careful follow-up and parental support are necessary to ensure that constipation and development of a dilated megarectum are avoided. The psychological effects of incontinence and constipation in this group of children and their families as they grow up are considerable.[32] In the last decade, the antegrade continence enema procedure has been found to be useful in establishing independent continence.[33] In later life, females will need specialist obstetric assessment and advice in choosing the most appropriate form of delivery.

Hirschsprung Disease and Related Disorders. Hirschsprung disease affects 1 in 5,000 newborns and is defined as an absence of ganglion cells (aganglionosis) in a variable length of distal bowel.[34,35] In 80% of infants, the aganglionosis is confined to the rectum and sigmoid, includ-

FIGURE 32-10 Anorectal malformation: cutaneous fistula. The anus is covered by a skin cap from which meconium is tracking along the fistula anteriorly in the midline onto the scrotum.

ing the internal sphincter (short-segment disease), but it may extend to encompass the entire colon (total colonic) or rarely affect the entire intestine. Although macroscopically normal, the affected gut is unable to relax, causing a functional bowel obstruction with dilatation of the proximal intestine.

Ganglion cells of the enteric nervous system are derived from the vagal neural crest. During the first trimester, neural crest cells migrate from the vagal neural crest into the esophagus and then colonize the developing gut in a craniocaudal direction. Aganglionosis can result from a failure of migration, differentiation, or survival of these cells. Mutations in several genes can cause aganglionosis. The receptor tyrosine kinase gene *RET* is the most common gene in which a mutation may be found.[36] Significantly, mutations in *RET* have been found in multiple endocrine neoplasia syndrome types IIA and IIB and familial medullary thyroid carcinoma; a careful family history should therefore be taken and genetic counseling offered to families at risk.[37] Hirschsprung disease is also more common in children with trisomy 21 (Down syndrome).

Hirschsprung disease should be suspected in all infants who have not passed meconium within 48 hours of birth and all infants presenting with signs of bowel obstruction. Constipation and abdominal distention are the most common presenting signs, although affected children may also present with bile-stained vomiting, failure to thrive, or cardiovascular collapse owing to Hirschsprung enterocolitis. A minority of children will present later in life with chronic constipation. Plain abdominal radiographs will show distended loops of bowel, although in neonates, often it is impossible to distinguish large from small bowel obstruction. Initial management should be directed at resuscitation, establishment of intravenous access, and passage of a nasogastric tube. When the abdomen is very distended, gentle anal dilatation and rectal washouts with 0.9% saline solution can often result in dramatic decompression and improvement in the physical condition of the child.

Diagnosis is made by suction rectal biopsy of the submucosal plexus, a procedure that can be performed using custom-made biopsy forceps on the ward, with minimum discomfort and distress to the infant. Multiple biopsies should be obtained at 2 and 4 cm above the anal verge. Histopathologic examination will reveal an absence of ganglion cells and thickened nerve trunks that often extend into the lamina propria. Increased acetylcholinesterase staining is also seen and can aid diagnosis. Availability of an experienced pediatric pathologist is essential. Where there is doubt, repeat biopsies should be obtained and the need for a full-thickness biopsy that includes the myenteric plexus considered. A contrast enema may be useful in determining the extent of aganglionosis if a clear transition zone from ganglionic to aganglionic colon is seen; however, false-positives can occur, and Hirschsprung disease should not be diagnosed on the basis of a contrast enema alone. Radiologically, Hirschsprung disease must be distinguished from meconium plug syndrome, small left colon syndrome, colonic atresia, and distal ileal atresia. Anorectal manometry can also be diagnostic in older children on the basis of an absent rectoanal inhibitory reflex, but this cannot be reliably performed in neonates.

The principles of definitive surgical reconstruction are excision of the aganglionic colon and "pull-through" of ganglionic colon with a coloanal anastomosis. The traditional operative approach is to perform a colostomy in the neonatal period at the distal limit of ganglionic bowel (confirmed histologically) followed by staged surgical procedures over 3 to 9 months. Increasingly, infants are initially managed by rectal washouts until definitive surgical treatment. Initial data would suggest little difference in eventual outcome from either approach.[38] Recent advances have been adoption of a laparoscopically assisted or purely transanal approach.[39] Frozen section biopsies are used to determine the presence of ganglion cells at the level of resection.

Following definitive operation for Hirschsprung disease, fecal incontinence has been reported in about 60% of patients compared with age-matched controls,[40] and the incidence was higher when evaluation was carried out by a psychologist.[41] Most patients have constipation with soiling that appears to improve with age, but 9 to 40% are severely incontinent.[40–42] The reasons for these poor results are multifactorial. Incomplete excision of the aganglionic segment, internal sphincter dysfunction, external sphincter damage, and dysmotility of the apparently normal ganglionic bowel may all play a role, and children need careful follow-up into adulthood.

Hirschsprung enterocolitis, characterized by malaise, pyrexia, abdominal distention, constipation, or diarrhea, is a potentially life-threatening complication that can occur before or following surgery. The pathologic basis of Hirschsprung entercolitis is poorly understood and may represent alterations of bacterial flora, relative gut stasis, and impaired mucosal or neuronal immunity. Current treatment is empiric, consisting of rectal washouts, antibiotics (vancomycin or metronidazole), probiotics,[43] and sodium cromoglycate.[44] Chemical (botulinum toxin[45] or topical glyceryl trinitrate[46]) or surgical internal sphincterotomy may be of benefit. Occasionally, it is necessary to perform an urgent colostomy.

There is a further small group of children who present with symptoms of Hirschsprung disease but who have ganglion cells on rectal biopsy. Often their symptoms are transient. Some investigators have found histopathologic features such as altered numbers of ganglion cells and increased acetylcholinesterase activity and labeled this intestinal neuronal dysplasia.[47,48] Others feel that such findings are part of the spectrum of normality in infants and neonates. Other children continue to have pseudo-obstructive symptoms throughout life. It is difficult to define whether histopathologic abnormalities are responsible for the obstructive symptoms or secondary to them.

Meconium Plug Syndrome. Occasionally, when a rectal examination or contrast enema is performed in neonates with symptoms suggestive of Hirschsprung disease, a whitish "plug" of epithelial cells is expressed followed by brisk passage of meconium and flatus with relief of symptoms (Figure 32-11). This condition is called meconium plug syndrome and is common in premature infants, possibly owing to relative immaturity of their ganglion cell

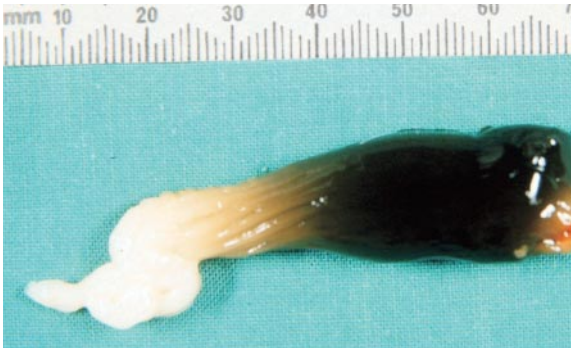

FIGURE 32-11 A meconium plug consists of thick meconium proximally and pale epithelial cells distally. Presentation is with distal colonic obstruction, which is relieved by a contrast enema.

TABLE 32-3 KEY POINTS FOR NEONATAL TRANSFER

Trained nursing and, if necessary, medical staff must accompany the patient.
Temperature control using a transport incubator to prevent hypothermia
Intubation and ventilation must be established before transfer of infants with respiratory distress.
Nasogastric drainage is essential for abdominal disorders, with the tube on open drainage and regular aspiration during transport.
Intravenous fluids appropriate for the needs of the infant
Send with patient:
Maternal blood sample for cross-matching
Documentation of medications given, notably vitamin K and antibiotics
Results of investigations and copies of radiographs
Written consent by the mother for operation where appropriate.

development. Cystic fibrosis and Hirschsprung disease should be positively excluded in children with meconium plug syndrome.

Colonic Atresia. This rare cause of distal intestinal obstruction presents with abdominal distention, failure to pass stool, and vomiting. A contrast enema will distinguish it from distal ileal atresia, with which it may coexist, and Hirschsprung disease. Management is local excision of the atretic segment.

TRANSPORTING THE SURGICAL NEWBORN INFANT

Ideally, infants known from prenatal screening to have a major surgical anomaly should be delivered in a specialist center. Postnatal transfer is safe provided that attention is paid to the key points in Table 32-3.[49]

CHAPTER 33

HERNIAS

Juan A. Tovar, MD, PhD

The term "hernia" (from the Latin) means "bud" or "bulge" and is extensively used in medical practice to address the various defects of the walls of the abdominal or other body spaces. In this chapter, an apparently heterogeneous group of hernias that may involve the gastrointestinal tract is addressed. Particular attention is paid to the digestive symptoms that may appear before and after the treatment of such conditions. These hernias are summarized in Table 33-1.

OMPHALOCELE (EXOMPHALOS)

"Omphalos" (from the Greek "ομφαλος") means "navel" and "cele" (from the Greek "κηλη") means tumor. Therefore, omphalocele means umbilical swelling. This anomaly is also referred to as "exomphalos" (in Greek "εξ," meaning "out") or prominent umbilicus. In fact, these terms describe a congenital defect of the umbilical region in which the umbilical cord is replaced by a sac, formed by Wharton jelly and peritoneum, that contains bowel loops and sometimes part of the liver and that is implanted on the rim of a more or less large parietal defect.

The prevalence of omphalocele ranges between 1 in 5,000[1] and 1 in 20,000[2] live births, but it is probably much higher if stillborns and aborted fetuses are considered. It is more frequent in boys than in girls, and there are no racial differences in incidence.

This developmental defect has an early origin during intrauterine life. Its causes are unknown, but chromosomal defects,[3] particularly trisomy 18,[4,5] are detected in these patients in proportions ranging from 10[2] to 40%.[1,6] Its association with other genetic disorders, such as Beckwith-Wiedemann syndrome, and the observation of some familial cases[7] support an embryonal origin for this malformation. However, it could be plainly derived from the arrest of the process of abdominal wall closure by growth of the ectodermal and mesodermal structures that surround the implantation of the umbilical stalk during the period in which the midgut reintegrates into the abdomen from the "physiologic" hernia into the umbilical stalk. During this phase, the bowel grows rapidly in length, and part of the jejunum, ileum, and proximal colon migrate into the umbilical stalk until the abdomen is large enough to accommodate them. During reintegration, the midgut undergoes a process of rotation in which we can distinguish two components that take place simultaneously: the duodenojejunal junction, originally located on the right side, rotates counterclockwise downward and leftward for a total of 180° passing underneath the vitelline (superior mesenteric) artery to end up on the left side to form the angle of Treitz. The cecum, in turn, rotates counterclockwise upward and rightward for another 180° in front of the artery from its original lower left position to its final right iliac position. Once rotation is completed, the bowel becomes fixed by several attachments from the bowel to the abdominal walls. When the process of intestinal repositioning is interrupted, the abdominal space remains empty, and rotation of the gut is incomplete.

Nowadays, omphalocele is generally diagnosed on prenatal ultrasonography between the second and third trimesters of pregnancy because it is very visible as a more or less enlarged umbilical stalk containing bowel loops and surrounded by amniotic fluid.[8] Cell karyotype from fluid obtained by amniocentesis is mandatory in these cases because of the rather high incidence of associated chromosomal diseases, particularly when the sac is small and the liver is intracorporeal.[3,9,10] In cases with trisomy 18, exomphalos is frequent, but there are several craniofacial, limb, and visceral malformations that are incompatible with life. The same happens with trisomy 13, and these diagnoses allow for the well-counseled parents to decide on continuation or termination of gestation.[11,12]

If pregnancy proceeds to term, patients with omphalocele often have neonatal weights appropriate for their gestational age and are immediately diagnosed because the malformation is very prominent: there is an abdominal wall defect of variable width centered at the umbilicus with herniation of bowel loops and sometimes the liver depending on the size of the defect. The viscera are covered by a gelatinous, translucent sac on top of which the umbilical cord enters the fetal body (Figure 33-1A). The umbilical arteries

run downward along the inferior wall of the sac to reach the abdominal wall. The urachal stump is located between them. The umbilical vein enters the abdomen on the superior side of the stalk. The abdomen may be remarkably small owing to the lack of content during fetal life, and this represents one of the main therapeutic problems.

The phenotype of the newborn may display the anomalies seen in either trisomy 18 or trisomy 13, but it may also be normal. Internal anomalies, particularly heart defects,[13] should be sought as soon as possible to tailor the timing of treatment to the clinical situation. Associated malformations are present in half[2] to three-quarters[1] of patients with omphalocele.

Termination of pregnancy may be indicated in fetuses with trisomy,[11,12] but it cannot be recommended in all other cases because successful treatment is possible in most of them. There is no evidence of the need for cesarean section on the basis of the incidence of neonatal infection or of the results of treatment. However, the convenience of starting the treatment as soon as possible after birth prompted many institutions to adopt a policy of induction of the labor or cesarean section.

After looking for associated anomalies that might contraindicate or delay surgery at this stage, repair of the defect is performed early after birth. This usually consists of excision of the membrane, reintegration of the viscera into the abdomen without or with stretching of the wall, and closure under bearable tension. Primary closure is possible only in some instances, and the risks of creating excessive intra-abdominal pressures capable of impairing arterial blood flow to the organs and venous return to the heart (compartment syndrome), as well as difficulties in ventilation, prompt the use of temporary coverage of the viscera with a Silastic chimney or "silo," as proposed originally by Schuster (Figure 33-1B).[14] The silo can be progessively squeezed in the ensuing few days to allow for progressive bowel reintegration without excessive intra-abdominal pressure.

The difficult bowel reduction, the prolonged contact of the bowel with the silo, and the daily manipulations usually interfere with the introduction of enteral feeding at this stage. Some surgeons advocate the use of a temporary gastrostomy for decompression and step-by-step feeding. This tube may facilitate the measurement of intra-abdominal pressure during surgery to avoid compartment syndrome.[15] The use of total parenteral nutrition for as many days as required greatly facilitates the treatment of omphalocele.

These patients may develop normally once the defect has been closed and the gastrointestinal function is resumed, but some of them may undergo gastrointestinal symptoms that should be recognized by the pediatrician or the pediatric gastroenterologist.

Early intestinal necrosis owing to closure of the abdominal defect under tension may cause short bowel and require long-term parenteral support.[16] Incomplete or abnormal rotation is not corrected in most cases during the neonatal operation because at that time, the priorities are visceral repositioning without excessive tension and secure wall closure. Malrotation does not cause problems in most cases, but it may become symptomatic as well.[17] Rarely is volvulus a problem, but this may happen with all of the risks involved. Repeated, often bilious, vomiting should direct the attention to the position of the bowel. Barium meal helps in defining the anatomic arrangement of the duodenum and the duodenojejunal angle. Barium enema is rarely necessary to depict the position of the colon if upper tract malposition is found in upper series, but it might be otherwise necessary. Surgical correction of malrotation might be eventually required for alleviation of the symptoms.[18]

Gastroesophageal reflux with esophagitis is detected in almost half of these children and may manifest itself early after abdominal wall closure.[19] The hiatus is abnormally located in them with a more or less marked anterior displacement, and the intra-abdominal pressure is increased after closure under tension. This creates an increased abdominothoracic gradient that facilitates reflux.[20] Some

patients may require fundoplication,[21] and it is obvious that gastric emptying should be assessed and malrotation ruled out prior to operation. The surgical approach to the esophagogastric region by laparoscopy or laparotomy may be difficult in these cases, and a thoracic approach has been considered advisable.[22]

If patients with chromosomal anomalies are not considered, the results in this group of patients are good in terms of survival and quality of life. Most patients live normal lives as adults, with occasional problems related to the scar or relatively mild gastrointestinal dysfunctions.[23]

CLOACAL EXSTROPHY (VESICOINTESTINAL FISSURE)

This is a major defect of the abdominal wall in which an omphalocele, a bladder exstrophy, and an ileal prolapse in the middle of a colonic plate replace the anteroinferior wall of the trunk. The anus is absent, and there are many other malformations.

Cloacal exstrophy is very rare, and its prevalence is probably below 1 in 200,000 or 1 in 400,000 live births. It may be seen in both genders, but it is slightly more frequent in males.

It has been traditionally attributed to a grossly defective closure of the abdominal wall folds, but many aspects of the malformation are not explained by this simple interpretation. In addition, there is prenatal ultrasonographic evidence in some fetuses of an intact lower abdominal wall that only secondarily ruptures.[24,25] Nevertheless, the association with other malformations suggests a profound disturbance of organogenesis that can occur only during early intrauterine life.[26]

The two halves of the exstrophied bladder are located on both sides of an intestinal mucosal surface, corresponding to the ileocecal region, in which two or more orifices can be recognized: the proximal ileal one is often prolapsed, whereas the distal colonic one ends in a blind pelvic pouch (Figure 33-2A). Other orifices corresponding to one or two appendices can eventually be seen on both sides. The external genitalia are also split below and on both sides of the exstrophied bladder halves. The genital tubercles are generally difficult to identify because the corpora of the penis or clitoris, implanted on the widely separated pubic bones, are not fused. The genital folds are also rudimentary, and their scrotal or labial nature is difficult to ascertain, particularly because the testes are usually undescended. The vagina may be absent. Gender assignment is therefore difficult at birth on visual inspection of the genitalia alone. There is an omphalocele containing intestines and liver on top of the exstrophied structures, the anus is absent, the perineum is generally flat, and the sacrum may be split by an open or covered spina bifida (Figure 33-2B). The vertebral bodies are often malformed, and ultrasonography and magnetic resonance imaging may demonstrate tethered cord, accounting for innervation deficits.[27,28] The colon ends

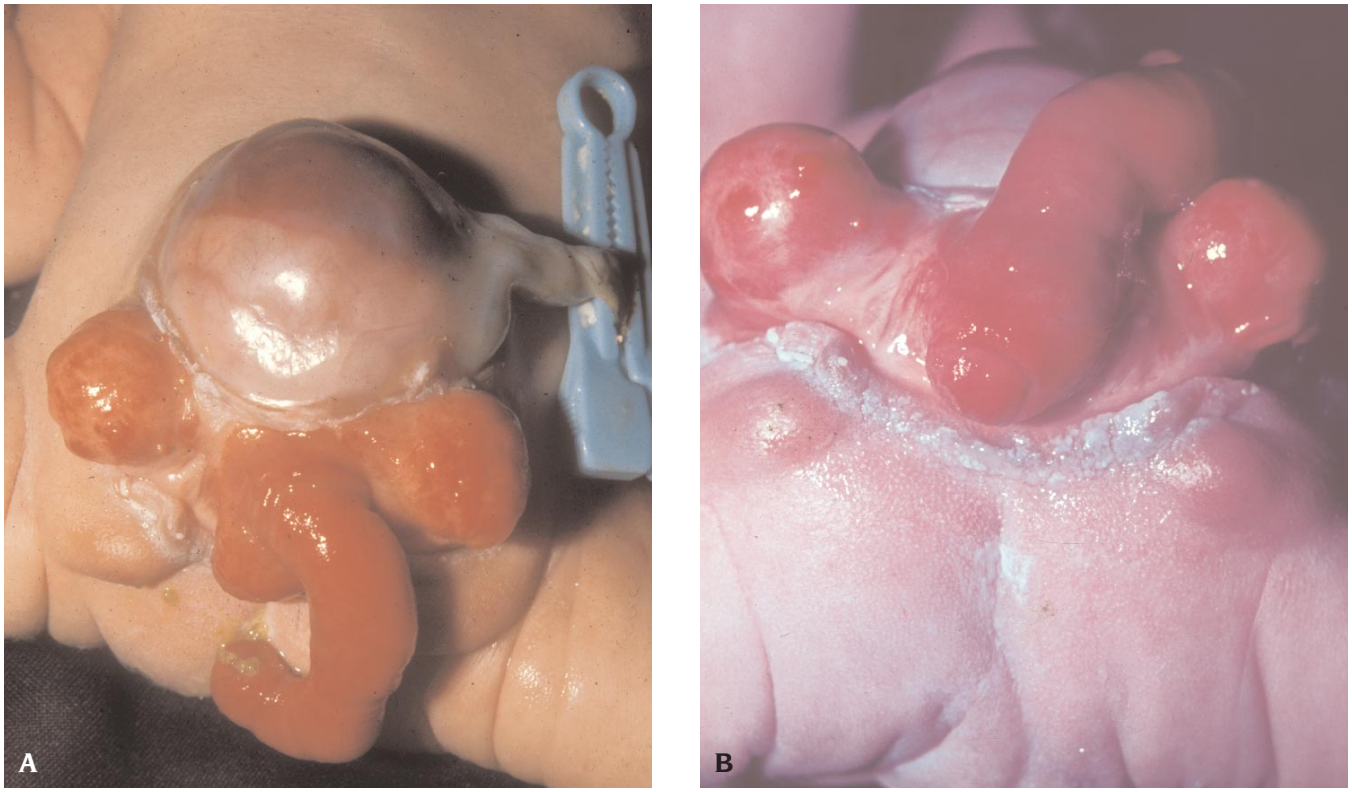

FIGURE 33-2 Cloacal exstrophy. *A*, Gross defect of the abdominal wall with a midsize omphalocele, an ileocecal plate with prolapse of the ileum, and two hemibladders on both sides of the plate. *B*, Details of the perineal region in which the anus was absent and the genitalia were uncertain in this male patient in whom the corpora were very small and the testes undescended. He also had a neural tube defect, which is not shown in the picture.

blindly, and it is generally shortened and limited to a terminal blind-ending pouch. The small bowel can also be somewhat shortened. Both ureters open at the exstrophied bladder halves and drain usually normal kidneys.

The aims of treatment will be preservation of life and renal function, to obtain continence of bladder and intestine, and maintenance of a positive self-image, allowing adequate integration into society,[28–31] and it is obvious that they are extremely difficult to reach. Gender assignment at birth must take into account the possibilities of reconstructing a functional phallus with the available material, and for this reason, some of these babies are raised as females in spite of all of the multiple problems and uncertainties that this decision involves. Closure of the omphalocele with reconstruction of the colon preserving its entire available length and diversion as a colostomy is followed by anastomosis of the two bladder halves to form a closed reservoir, which may later require augmentation with bowel. A continent urinary diversion using a Mitrofanoff appendicostomy is generally performed at a later stage. Colonic pull-through is generally possible and should be attempted[30,31] in spite of the grim expectations of continence owing to the anatomy of the region and to the neurologic impairment. A program of daily washouts may be very helpful. Neurosurgical, orthopedic, and other problems may require attention for life. Nowadays, most patients survive, but they endure multiple operations and face difficult choices and adaptative efforts.

Fecal incontinence or permanent stomas are often unavoidable in these patients. Short bowel may exist from the beginning, and it is eventually aggravated by the use of intestinal segments for reconstruction of the urinary tract, vagina, or the continent stomas.[28]

GASTROSCHISIS OR LAPAROSCHISIS

These terms are derived from the Greek ("σχισις," meaning fissure; "γαστρης," meaning stomach; and "λαπαρα," meaning abdomen) and describe an abdominal wall defect consisting of an orifice, generally quite narrow, not more than 2 or 3 cm, located on the right side of the umbilical cord insertion, that allows evisceration of part of the abdominal contents, small bowel, large bowel, stomach, and, sometimes, the gonads. These organs are matted in a more or less thick "peel" that makes anatomic boundaries difficult to define.

Gastroschisis is a condition clearly different from ruptured omphalocele with which it was confused in the past. The etiology is unknown, but the scarcity of associated malformations and the relative ease with which identical lesions can be reproduced in laboratory animals by fetal operations are consistent with the interpretation of an unknown agent acting during early fetal life as the origin of the orifice. The explanation for its almost constant location on the right side is obscure, but it has been suggested that fetal occlusion of the omphalomesenteric artery could account for it.[32] Gastroschisis is becoming relatively frequent in industrialized countries because its prevalence, which ranges from 1 in 3,000 to 1 in 20,000 gestations,[2,6,33] has increased in the last 30 years. It is certainly higher (1 in 3,000 to 1 in 6,000)[6,34] if stillborns and terminated fetuses are taken into account.[35] Gender distribution is roughly balanced. The prevalence increased almost three times in the last 30 years in developed countries,[2,33,36] in parallel with the increased use of tobacco and other drugs[2,37] by progressively younger, often primiparous mothers.[33] These gestational agents might account for the defect itself, whereas the remaining lesions are caused by prenatal evisceration. Prolonged exposure of the intestinal walls to the amniotic fluid accounts for the intestinal shortening, serosal thickening, and matting of the loops and can be reproduced in chicks,[38–40] rats,[41] rabbits,[42–44] and lambs[45–47] after fetal operations, which expose the bowel to this irritant fluid for more or less prolonged periods of time. The eviscerated bowel may undergo ischemia during gestation owing to the narrowness of the orifice, and this may cause fetal distress,[48] intestinal atresia,[49] or even fetal demise.[11] On the other hand, fluid, proteins, immunoglobulins, and electrolytes are exchanged between the fetal internal environment and the amniotic fluid,[50] causing fetal malnutrition and protein losses[51] that may impair healing or immune defense and interfere with the response of the patient to neonatal treatment.

Prenatal diagnosis is possible on ultrasonographic screening in about 60 to 80% of cases[52,53] from the twentieth week on,[52] but it can be done well before this date. The bowel loops floating into the amniotic fluid are identified on the right side of the umbilicus, and the distended loops, sometimes with thickened walls, can be seen quite early.[52] Amniocentesis is probably unnecessary in gastroschisis because of the lack of association with chromosomal diseases.[8,54] However, close ultrasound monitoring is mandatory because it allows assessment of fetal growth and wall thickness and Doppler imaging of intestinal blood flow.[55] Echographic signs of fetal distress may be helpful for deciding on early delivery.[56]

In contrast to those with omphalocele, patients with gastroschisis are usually small for gestational age because of fetal malnutrition related to the above-mentioned reasons.[37] At birth, they are generally normal, except for the narrow orifice, which is almost invariably located on the right side of the base of the umbilical cord. The root of the usually prominent mass of eviscerated bowel is more or less constricted, and its aspect ranges from quite normal to matted in a thick, reddish, inflammatory mass in which the different parts of the bowel are difficult to discern (Figure 33-3). Like in patients with exomphalos (omphalocele), the abdomen is generally small owing to its emptiness during gestation.

There is some debate about the convenience of acting "in utero" on the gastroschisis fetus. Because some of the local and general changes observed in these babies are related to the duration of the contact of the eviscerated bowel with the irritant components of the amniotic fluid, shortening this contact by preterm delivery might be beneficial. This would additionally reduce the effects of bowel constriction at the orifice and prevent loop distention and later paralysis.[57] On the other hand, there is evidence of the

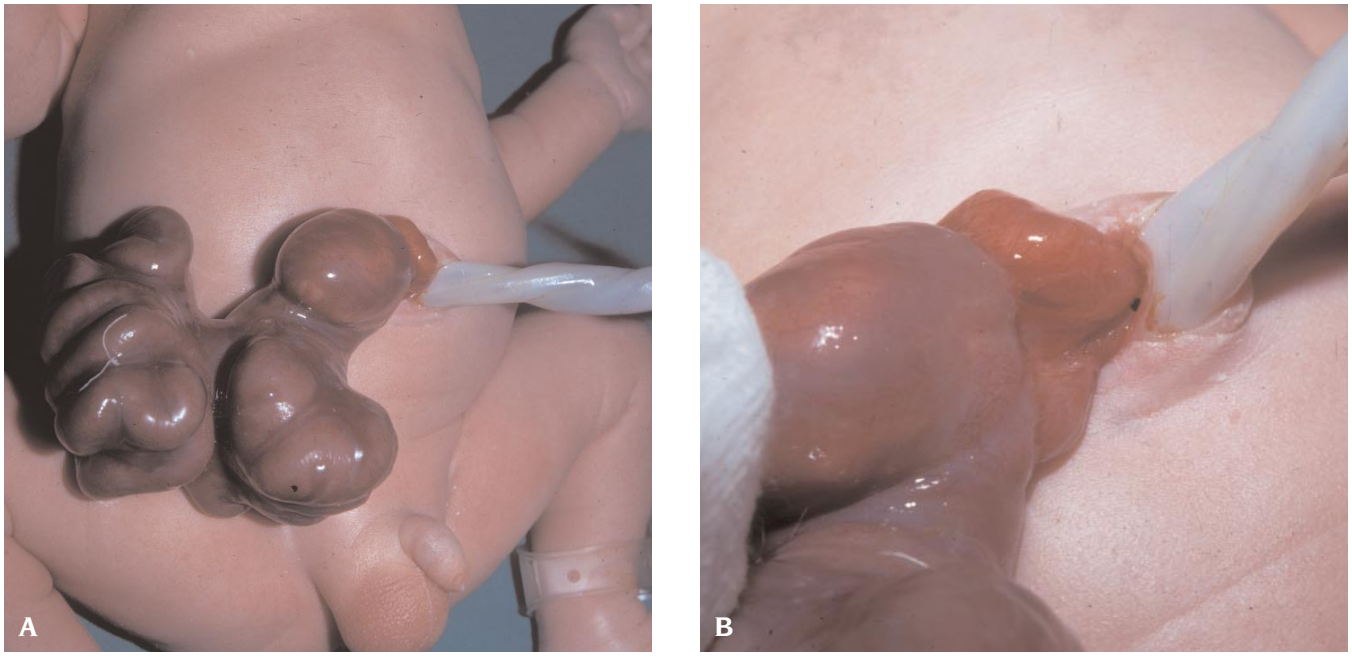

FIGURE 33-3 Gastroschisis. *A*, Massive prolapse of the intestine through a small paraumbilical orifice. The bowel loops are matted into a thick peel that makes anatomic definition of the underlying structures very difficult. *B*, Detail of the umbilicus depicting the intact cord with a right-sided and quite narrow orifice.

detrimental effect of compression on the intestinal wall during delivery, and to avoid it, premature, prelabor cesarean section has been advocated.[58] Cesarean section is indicated anyway whenever fetal distress is detected on frequent monitoring,[56,59] but, in other cases, there is not much evidence of the benefits of cesarean section over induction of labor when the rationale of prelabor delivery is not adopted.

Other prenatal approaches aimed at preventing the bowel lesions are possible: repeated amniotic fluid exchange or amnioinfusion to dilute the amount of offending solutes has been tried in the experimental[60–62] and clinical settings.[63,64] The use of prenatal anti-inflammatory agents such as dexamethasone has been shown to be beneficial in animal experiments.[65,66]

After birth, repositioning of the eviscerated bowel into the abdomen is urgently needed because excessive heat irradiation, fluid depletion, and bacterial contamination are rapidly progressive. Careful coverage of the lesions, adequate fluid and electrolyte replacement, and prompt surgery are usually performed. Some authors proposed treating these infants in the delivery room itself,[67] and it is generally accepted that referring the mothers for delivery in specialized neonatal surgical centers is beneficial. If adequate bowel coverage and intensive care are provided over an interim time period of some hours, delaying definitive treatment does not seem to decrease the chances of survival in these babies.

The rationale of surgical treatment of gastroschisis is basically similar to that of omphalocele: reintroduction of the bowel into the abdominal space after enlarging the orifice when necessary, abdominal wall stretching, meconium expression to reduce the bulk of the colon, and primary closure if possible. If the pressures into the abdomen become unbearable, silo-staged closure[68–70] or skin-only closure and late repair of the ventral hernia[71] can be lifesaving. Gastrostomy is preferred by some surgeons to facilitate postoperative handling.[72] An increasing proportion of patients can be primarily closed, and, in the last few years, careful reduction of the eviscerated bowel in the incubator by manual compression without anesthesia has allowed primary closure with excellent cosmetic results in a growing number of patients.[73]

Babies with gastroschisis may have associated intestinal atresia owing to vascular flow interruption to a segment of the bowel during gestation. The lesions may be masked by the thick peel covering the bowel loops at birth, and it is a wise policy to leave the treatment (and even the diagnosis) of this relatively rare associated condition for a second-look operation performed if the symptoms of intestinal obstruction do not subside after a few weeks.[74] The peel disappears, and the bowel lengthens when it is repositioned into the abdomen.[75] The anatomic definition of the atresia and its repair are definitely easier at that moment.

The development of abdominal "compartment" syndrome during primary repair owing to excessively increased intra-abdominal pressure and vascular compromise may lead to necrosis and dramatic amputation of the gut.[16] This can be prevented by careful assessment of the intra-abdominal pressure[15] and the use of silo whenever necessary. Even if these precautions are taken, secondary necrotizing enterocolitis may intervene in these patients,[58] with all of the additional risks of necrosis and bowel loss involved. It should be taken into account that gastroschisis is one of the leading causes of end-stage gastrointestinal failure referred for transplant.[76]

Owing to bowel wall thickening with abnormal collagen and muscle,[45–47] to focal ischemic changes,[39] or to disturbed neuromediator secretion,[77] these children almost

invariably suffer intestinal dysmotility that causes prolonged ileus and makes enteral feeding impossible for more or less prolonged periods of time. The intrinsic innervation of the bowel has been found to be intact in some experimental studies,[38,39,78] although others described reduced density of ganglia in the intermuscular or submucosal plexuses.[66] In addition to the motor dysfunction, some difficulties for absorption of nutrients that might further impair nutrition in gastroschisis have been investigated in experimental animals.[77,79,80] Total parenteral nutrition allows adequate caloric and plastic inputs for days or weeks until intestinal motility recovers, and it is one of the cornerstones of treatment.

Malrotation is almost constant in gastroschisis survivors because usually no attempt is made at correcting this malposition during the early phase of treatment. Nonrotation without obstruction is probably the more frequent situation, but incomplete, obstructing malrotation should be ruled out when prolonged ileus extends for too much time in these infants.[17,18,81,82] Volvulus is another cause of short bowel consecutive to gastroschisis and should be thought of when symptoms of strangulation are present.[73]

The other problem that may be encountered in these patients later in life, like in survivors of neonatal exomphalos repair, is gastroesophageal reflux.[18,19,83] The same anatomic factors play a role in the failure of the antireflux barrier together with prolonged intestinal obstruction. In addition, the conditions of abdominal wall closure increase the pressure gradient between the abdomen and the thorax that is one of the reflux driving forces.[20]

CONGENITAL DIAPHRAGMATIC HERNIA

Congenital diaphragmatic hernia (CDH) is a developmental defect in which intra-abdominal organs are displaced into the thorax through a posterolateral diaphragmatic orifice. Babies with CDH also bear lung hypoplasia and immaturity, as well as other associated malformations that make neonatal treatment very difficult and cause a high mortality.

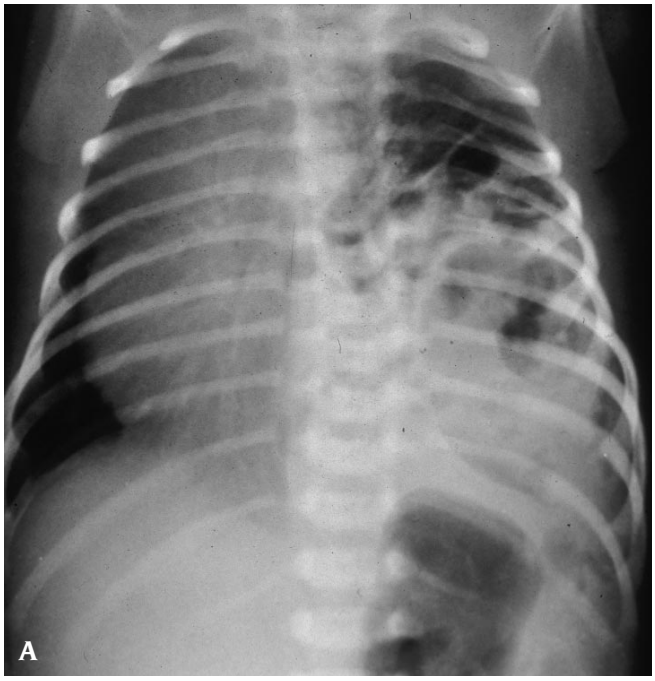
CDH is observed in 1 in 4,000 live births, without gender or racial differences, but, again, this prevalence can be much higher if stillborns and aborted fetuses are accounted for.[84] Harrison and colleagues pointed out in the past the importance of the "hidden mortality" in this particular condition,[85] and although the refinements of prenatal diagnosis have reduced the hidden proportion of fetuses with CDH, this effect still plays a role.

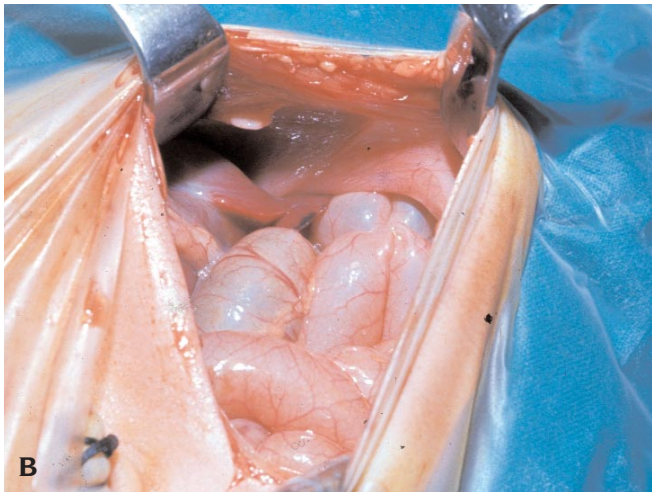
CDH is probably caused by abnormal molecular signaling in the early phases of development. This explains the multiorgan involvement and the striking similarities with animal conditions induced experimentally by genetic manipulation. The name of Bochdalek has been associated with CDH for a long time because this author was one of the first to describe it, but his report involved herniation through the lumbocostal posterolateral orifice in the diaphragm.[86] For a long time, it was thought that CDH was caused by incomplete closure of the posterolateral pleuroperitoneal canal, which communicates the pleural and the abdominal compartments of the celomic cavity. In fact, experimental studies have shown that the diaphragmatic orifice is due to incomplete growth of the posthepatic mesenchymal plate prior to pleuroperitoneal canal closure.[87] On the other hand, it has been shown that lung hypoplasia is primary because it is already present before herniation of intra-abdominal organs into the thorax.[88,89] Compression of the lungs later in gestation would play a secondary but important role in the lung lesions.[90] There is evidence of underexpression of several transcription and growth factors in the lungs of animal models of CDH, and this is interpreted as an indication of a molecular dysregulatory origin.[91–93]

The diaphragmatic orifice is usually located on the posterolateral area of the left hemidiaphragm, which may eventually be absent. In these cases, the hiatus may be practically nonexistent, and the esophagus enters the abdomen through the same orifice. The small and large bowel, spleen, and left lobe of the liver are often into the thorax in direct contact with the lung and the mediastinum because these hernias rarely have a sac. When the orifice is located on the right side, the corresponding lobe of the liver is herniated into the thorax. Very rarely are these hernias bilateral. As a consequence of compression or owing to a primary maldevelopment, there is a marked lung hypoplasia that is more severe on the side of the defect.[94] The lungs are small, with reduced bronchoalveolar ramification and excessive muscularization of the terminal arterioles.[95] Owing to their early displacement into the thorax, the intestines are not normally rotated and attached.[96] More often, they adopt the nonrotation position, but sometimes there are also Ladd bands between an upward displaced right colon and the right abdominal wall or the gallbladder.[97,98]

In addition to lung hypoplasia, the scant and small air spaces left cannot expand because of the immaturity of the surfactant system or simply because of the lack of alveolar surface for the surfactant to exert its action.[99] Some degree of heart hypoplasia, particularly of the left side, has been observed, together with several other heart malformations that may interfere with the transition from the fetal to the extrauterine patterns of circulation in these patients.[100–103] At birth, appropriate ventilation is often impossible, and hypoxia, acidosis, and the abnormal arteriolar shaping cause pulmonary hypertension without enough flow into the pulmonary vascular bed. The blood is shifted to the aorta through the ductus arteriosus and the oval orifice, perpetuating a fetal pattern of circulation that is rapidly lethal in patients in whom pulmonary hypertension persists.[104]

In some cases, polyhydramnios prompts ultrasonographic detection early during pregnancy, but the malformation may be found as well on routine screening.[105–107] At birth, these babies have a hollow abdomen with displacement of the heart bruits toward the contralateral side, and the majority of them show symptoms of severe respiratory insufficiency. Plain radiographs of the thorax depict displacement of the abdominal viscera into the thorax with major restriction of the lung space on the side of the hernial orifice and mediastinal shift toward the contralateral side (Figure 33-4A). Hypoxia, hypercapnia, and acidosis are progressive, and unless vigorous treatment is instituted, patients succumb to the disease.





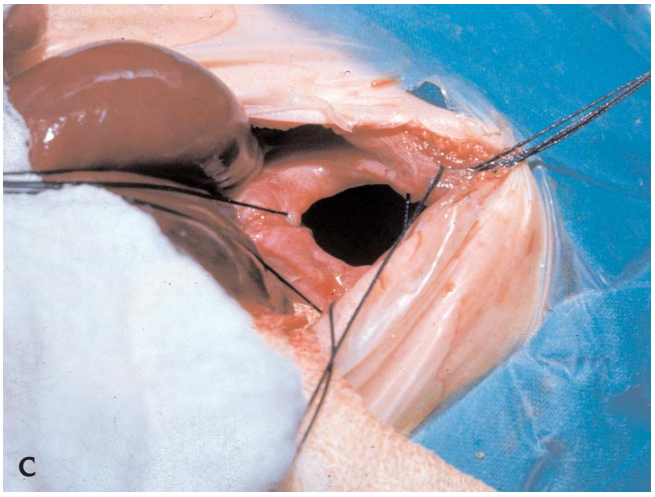


FIGURE 33-4 Left congenital diaphragmatic hernia in a newborn. *A*, Radiograph of the thorax shows herniation of intestinal contents into the left hemithorax, shifting of the mediastinum to the right, and reduction of the lung space. *B*, Detail of the left diaphragmatic orifice during operation. The bowel loops are seen entering the thorax. *C*, The orifice after extracting the bowel and the left lobe of the liver, which are now in the abdomen. The orifice will be straightforwardly closed.

Less often, the clinical picture is milder. In some cases, the disease manifests itself more subtly, and the diagnosis is delayed beyond the first days of life and may be made even much later.[97,108] These patients more often have a hernial sac, and their prognosis is good.

Nowadays, most mothers bearing fetuses with CDH are referred to specialized centers for perinatal treatment, which may even involve endoscopic fetal surgery consisting of reversible tracheal plugging,[109–112] prenatal corticosteroids,[113,114] and neonatal instillation of surfactant[115] followed after birth by a wide range of ventilatory techniques (conventional, high-frequency, oscillatory, liquid ventilation with perfluorocarbons) and extracorporeal membrane oxygenation (ECMO) in cases in which a minimally adequate gas exchange cannot be established and persistent pulmonary hypertension cannot be reverted.[116] With appropriate ventilatory support, vasodilator medication, and, eventually, ECMO, the first phase of the disease can be overcome by two-thirds to three-quarters of the patients. The abdominal viscera may then be surgically repositioned into the abdomen and the diaphragmatic orifice closed (Figure 33-4B and 33-4C). In some patients, a gastrostomy is placed at that moment to facilitate enteral feeding later. Usually, no attempt is made at correcting malrotation because the priorities at that time are the reconstruction of the diaphragm with relocation of the abdominal viscera below it and closure of the abdominal wall. This may be difficult, such as in exomphalos or gastroschisis, owing to the smallness of an abdominal space that remained partially empty during gestation.

Thanks to the vigorous efforts directed at improving the prognosis of this highly lethal disease, more patients survive in the last few years after often very sophisticated treatments. Many of them suffer chronic respiratory insufficiency, sensorineural sequelae, pectus excavatum, and gastrointestinal symptoms.[117]

Gastroesophageal reflux is particularly frequent in these children for several reasons.[118,119] First, the hiatus is mal-

formed or distorted by the repair of the hernia, which always involves some degree of tension on the left diaphragm. Second, the lung hypoplasia contributes to create very high intrathoracic negative pressures during inspiration after closure of the defect. This, together with increased intra-abdominal pressures owing to the forceful reintegration of the intestine and other organs into the abdomen, creates a very unfavorable abdominothoracic pressure gradient that facilitates reflux.[120] Third, esophageal motility in these patients is probably abnormal because the organ is often dilated and inert.[121,122] Finally, gastroduodenal emptying may be delayed owing to malrotation.[123] All of these causes create an environment favorable for reflux, and this explains why many of these patients, already burdened by a failing respiratory function, require fundoplication.[124]

Malrotation may cause other problems, such as duodenal obstruction or, more rarely, volvulus.[123] The former can be suspected at the time of withdrawing a gastrostomy tube eventually inserted during surgery when the gastric fistula, sealed spontaneously in most cases after a few days, persists. It is imperative that volvulus be ruled out whenever one of these patients suffers a clinical picture of intestinal obstruction with shock.

Necrotizing enterocolitis is another possible gastrointestinal complication of CDH.[125] Perinatal and neonatal hypoxia, formula feeding, and increased intra-abdominal pressure after intestinal reposition during hernia repair contribute to provide an environment prone to this disease.

HERNIA OF MORGAGNI

Herniation of abdominal viscera through an anterior, retrosternal orifice of the diaphragm was described by Morgani and bears his name. This type of hernia is quite rare, and its prevalence is higher in patients with trisomy 21.[126] It is due to delayed or failed closure of the anterior part on the diaphragm during septation of the celomic space. The hernia generally has a sac constituted by peritoneum, which is in close contact with the pericardium, although both spaces may communicate. This sac may contain the transverse colon or the stomach, as well as part of the liver, which adopts the shape of the inner surface of the defect. The stomach may undergo volvulus in this abnormal position.

Hernia of Morgagni is often asymptomatic, but it may sometimes induce repeated respiratory infections, abdominal pain owing to the colonic entrapment into the sac, or, eventually, vomiting because of the gastric malposition or intestinal malrotation.[127,128] Sometimes there are other associated malformations.[126]

Surgical repair of the hernia is advisable once the diagnosis is made. This consists of generally straightforward transabdominal excision of the sac with closure of the defect. The operation can be performed laparoscopically.[129]

INGUINAL HERNIA

When the fetal communication between the peritoneal and the vaginal celomic compartments remains partially patent for a part (hernial sac) or for the entire length of the peritoneovaginal canal after birth, it is possible for intestinal loops to pass from the abdominal cavity to the inguinal region or into the scrotum (Figure 33-5). This is known as inguinal hernia or "indirect" inguinal hernia, as opposed to the "direct" hernia, rare in childhood, in which a weak posterior wall in the inguinal canal permits the bulge. Hernia also occurs in females because, although extra-abdominal displacement of the gonads does not occur in them, the round ligament of the uterus has its lower insertion in the labia and exits the abdomen through the inguinal canal accompanied by an evagination of the peritoneal lining, which constitutes the sac. Inguinal hernia is, in this respect, a developmental defect rather than an acquired condition owing to weakness of the wall.

The inguinal canal contains the spermatic cord with its elements: the vas, the spermatic vessels, and the cremaster muscle in males and the round ligament in females. The canal runs obliquely between the laterally located internal inguinal orifice and the medially located external ring. In older children and adults, both orifices are separated by several centimeters, and the canal itself has a floor and clearly defined walls. In contrast, in young infants, it is so short that both orifices almost overlap, facilitating the bulging of the intestine into the hernia.

There are other varieties of the same developmental defect. A hydrocele (from the Greek "υδρος," meaning water, and "κηλη," meaning bulge) is a cystic swelling of the vaginal space of the testicle that is full of fluid and may have a large volume. Often it is the result of the persistence of a thin communication between the peritoneal and the vaginal spaces, allowing the fluid to accumulate during the day and disappearing during the night after a few hours in the recumbent position. This is a "communicating hydrocele," as opposed to the "congenital hydrocele" of the newborn, which is usually noncommunicating and generally resolves spontaneously in the first months of life. When the peritoneovaginal canal closes, leaving a fluid-filled cyst isolated midway between the abdomen and the vaginal spaces, the result is a cyst or hydrocele of the cord. The equivalent in females is the cyst of the canal of Nuck.

The hernia is "incarcerated" when a loop of intestine is blocked into the narrow sac and becomes difficult to reduce. The hernia is "strangulated" when the loop is not only blocked in the canal but also compressed to the point of having its blood flow compromised and its integrity threatened. In girls, the ovary may be incarcerated or strangulated as well, and it may undergo torsion in the sac.[130]

Inguinal hernia is extremely frequent because it is observed in 1 in 50 boys and 1 in 500 girls.[131] It is considerably more frequent in premature infants for reasons that are explained later. Two-thirds of inguinal hernias appear on the right side in boys, whereas laterality in girls is even. Bilateral hernias are less frequent in boys than in girls, in whom they may attain a proportion of 50%.[131]

The closure of the peritoneovaginal canal is a late phenomenon during intrauterine life because the descent of the gonads into the scrotum takes place in the seventh month of gestation, with the left testis arriving first to its final location. Respiratory tract disease increases intra-

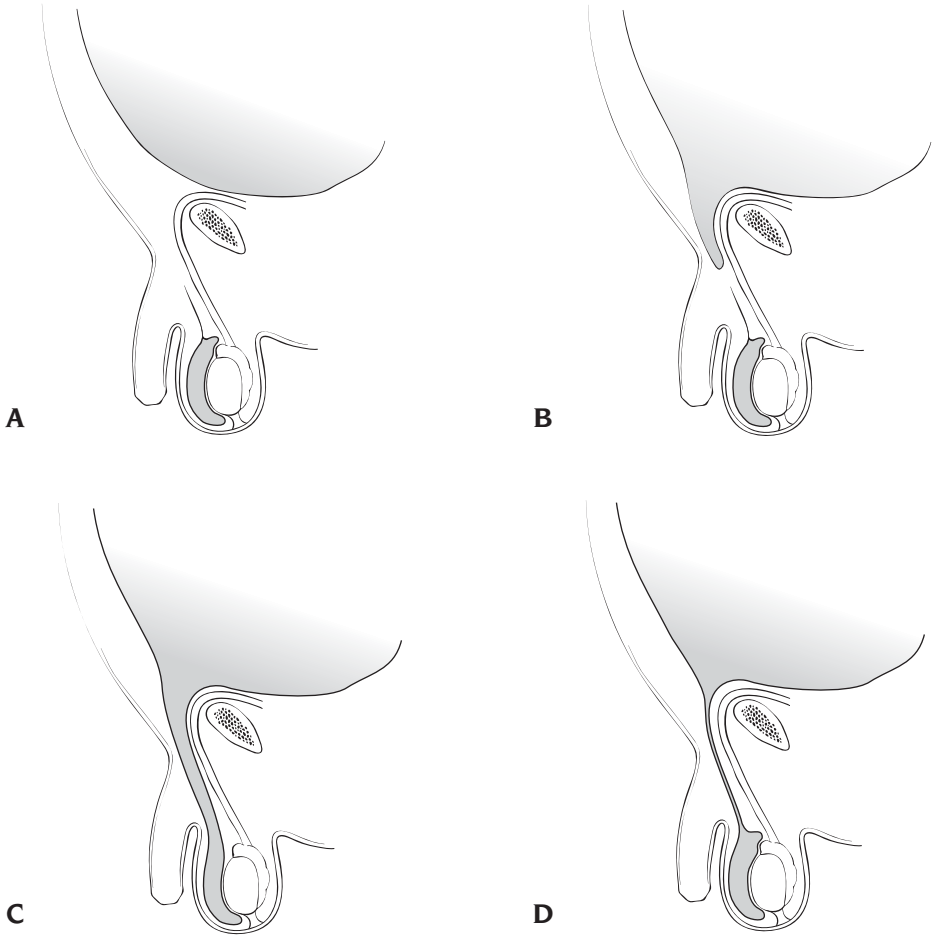

FIGURE 33-5 Schematic drawing of the inguinal region in a male baby. *A*, In a normal situation, the peritoneal and the vaginal spaces are widely separated. *B*, In inguinal hernia, the sac protrudes into the inguinal region above the pubic bone. *C*, In the inguinoscrotal hernia, the peritoneovaginal canal is widely patent, leaving ample passage into the scrotum. *D*, In the communicating hydrocele, the canal is very narrow, allowing only the passage of peritoneal fluid in both directions.

abdominal pressure, facilitating the clinical expression of hernia. This is particularly true for premature babies, but also for cystic fibrosis children and adult chronic respiratory patients (see below).[132] Closure is probably influenced by the local action of neuropeptides such as calcitonin gene–related peptide or growth factors such as hepatocyte growth factor during late gestation.[133] The different timing of gonadal descent on each side explains why hernias are more frequent on the right side than on the left.

Hernias are particularly frequent in association with diseases in which intra-abdominal pressures are increased (chronic respiratory disease,[134] cystic fibrosis[135]), in the presence of abundant peritoneal fluid (after ventriculoperitoneal shunting[132] or during peritoneal dialysis[136]), or in some diseases of the connective tissue (Ehlers-Danlos syndrome,[137] mucopolysaccharidoses[138]).

The main symptom is the appearance of a bulge in the groin that only in some cases reaches the scrotum and reduces itself spontaneously most of the time (Figure 33-6A). This swelling is not particularly painful, but it can bother young infants considerably, in whom it is frequent for the herniated bowel loop to be partially blocked, interfering with the passage of liquids or gases. The hernial bulge may be permanent or appear and disappear intermittently. It generally reduces itself or becomes inapparent during sleep. On physical examination, the inguinal canal is occupied when the bowel is herniated. If not, it is not unusual to perceive a thickened spermatic cord, and, sometimes, well-trained individuals can perceive a sensation of smooth friction, described as the "silk glove sign," on displacement of the examining finger transversely to the axis of the cord. An enlarged inguinal orifice may be palpated when exploring purposefully the inguinal region directly or invaginating the scrotal skin into the canal with the finger. In cases of communicating hydrocele, the scrotum is full of fluid, and it can be easily transilluminated with a pocket lamp. In these cases, the cord is usually not enlarged. Cysts of the cord are palpated as elastic fluid-filled masses located midway between the inguinal orifice and the scrotum.

In girls, the hernial swelling is similar to that seen in boys, although it rarely extends itself down to the inferior part of the labia (Figure 33-6B). Sometimes, particularly in young female infants in whom the pelvic space is small, an almond-shaped mass corresponding to the ovary can be palpated in the groin, and it may be difficult to reduce.

When the hernia is incarcerated, the swelling becomes painful, intestinal transit may be slowed or arrested, and patients manifest their discomfort rather explicitly. However, if the inguinal regions are not purposefully examined, the diagnosis may be missed, and ill-oriented tests may be requested.

In cases of strangulation, the clinical picture is one of intestinal obstruction with more or less marked signs of vascular suffering of the intestine. This picture rarely progresses

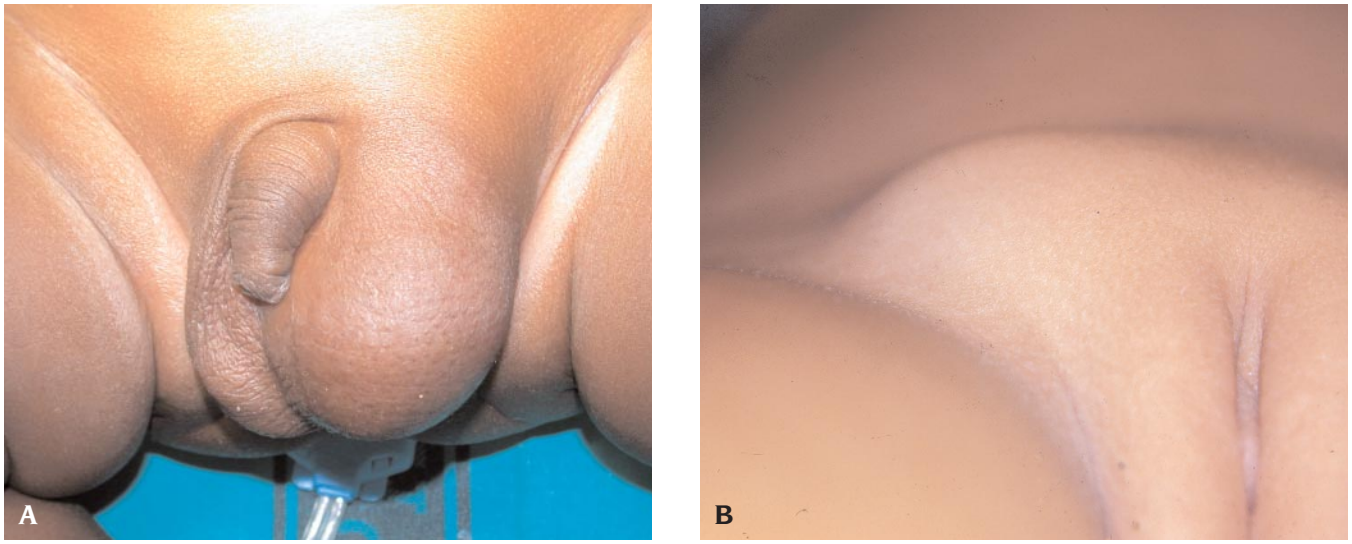

FIGURE 33-6 Inguinal hernia. *A*, Left inguinoscrotal hernia in a boy. *B*, right inguinal hernia in a girl.

to one of frank obstruction because the inguinal region is swollen and painful and because all efforts are made to reduce or treat the ailment, but it may happen that omission of groin examination interferes with prompt diagnosis and treatment. In girls, a strangulated ovary is also very painful, but the mass is less conspicuous on inspection, making diagnosis more difficult if the groins are not palpated. A rare event is strangulation of Meckel diverticulum into an inguinal hernia. This condition is known as Littre hernia, after the person who first described it.[139] In this case, the strangulation may or may not obstruct the small bowel, but it may also cause ischemia and necrosis of the diverticulum.

Treatment of inguinal hernia must be surgical and is one one of the most frequent operations of pediatric surgery. It aims at the interruption of the peritoneovaginal canal or to high ligation and excision of the hernial sac. In opposition to adults, in whom the inguinal wall weakness plays a major role, inguinal hernia in children is approached more as a developmental delay that left the sac open than as a parietal problem requiring surgical reinforcement. Therefore, simple closure of the hernial sac or peritoneovaginal canal heals the hernia, allowing the wall to reinforce itself and to regain a normal anatomy. The operation, often performed in toddlers through the external inguinal orifice without opening the inguinal canal, is usually done as day surgery and has excellent results, with a minimal risk of recurrence. However, when the same operation is performed in premature infants, it is technically more difficult owing to the thinness of the sac, and both the anesthesia and the postoperative periods may be burdened by respiratory complications, particularly in individuals who previously had lung diseases and required assisted ventilation in the neonatal intensive care unit. In this particular group of ex-premature infants, it is wise to delay the operation until the second semester of life or, if that is impossible, to admit them into the hospital to be operated on with all of the necessary precautions. The risks of damaging the vas or the spermatic vessels during surgery are smaller in the hands of trained pediatric surgeons. In girls, the rationale of the operation is similar, but the inguinal orifices can be closed safely if preferred. There are also considerable risks for the testicle when the hernia incarcerates or strangulates. Some gonads may undergo atrophy as a consequence of ischemia during strangulation, and this has to be explained to the parents after every episode.

An interesting and hotly debated issue is whether contralateral inguinal exploration of an asymptomatic hernia should be performed simultaneously at the time of surgery for a symptomatic unilateral one. The higher incidence of bilaterality in girls would make routine bilateral exploration more attractive in them, and the higher incidence of righ-sided hernias in boys could invite the same attitude when the hernia is on the left. Some surgeons have advocated routine bilateral exploration in all cases to decrease the risks of repeating anesthesia, but, on the other hand, the risks to the integrity of the vas or the spermatic vessels invite treatment of the hernia only after it is clinically patent.[140] In the past, introduction of some radiologic contrast into the peritoneum (peritoneography or herniography) allowed preoperative diagnosis of the patency of the peritoneovaginal canal,[141] but although this patency is constant in all inguinal hernias, not all patent canals involve real hernias. A high proportion of asymptomatic individuals have some degree of patency on necropsy.

Laparoscopy has modified the attitudes of some surgeons on the management of the asymptomatic contralateral side at the time of repair of a symptomatic hernia. Visual inspection of the inner inguinal ring after introducing a laparoscopic telescope through the hernial sac during an open operation is a relatively simple manipulation that allows diagnosis of otherwise inapparent contralateral hernias,[142,143] but the meaning of the patency of the canal in the absence of hernia will remain unclear in this setting. It is presently recommended to operate only in clinically manifest hernia, except perhaps in girls, in premature infants, after incarceration, or in individuals with comorbid conditions.[144]

The inguinal hernia repair itself may be performed by laparoscopy,[145,146] but this is probably hard to justify

because standard herniotomy in infants is practically as minimally invasive, brief, and painless as a two- or three-port laparoscopy. However, this approach, consisting of closure with a purse-string suture of the peritoneal orifice leading into the sac from inside, may be useful in recurrent hernias in which inguinal canal scarring makes open dissection difficult.[147–150]

Incarcerated hernia can usually be reduced by trained persons avoiding unwanted operations in an emergency setting. Sedation, bottle feeding, or a warm bath may facilitate careful manipulation (taxis) of the herniated bowel (or the ovary) back into the abdomen. Strangulated hernia is a different matter. Taxis may be successful if strangulation is very recent, but it is otherwise discouraged when it has evolved for some hours. The risks of reducing damaged bowel into the abdomen make it advisable to proceed with operation as soon as possible to assess the viability of the herniated bowel, to resect it if necessary, and subsequently to repair the hernia. This may be particularly difficult in these cases owing to the swelling, hemorrhage, and edema of the inguinal structures. Testicular atrophy happens in some patients after inguinal hernia strangulation.[151]

Irreducible ovaries should benefit from a prompt operation as well.[152]

Recurrence is rare and is more often related to comorbid conditions such as prematurity, ventriculoperitoneal shunts, peritoneal dialysis, or strangulation.[153]

FEMORAL HERNIAS

The passage of a hernial sac that may contain bowel through an enlarged femoral orifice is known as femoral or crural hernia. The femoral orifice is located underneath the inguinal ligament (and therefore below the inguinal canal) and allows passage of the femoral vein, artery, and nerve from the pelvis to the thigh. This enlargement is always medial, and the sac is therefore in close contact with the femoral vein.

Femoral hernias are rare in children. Most series collect only a few cases among hundreds of inguinal hernias. Both genders and all races are equally affected.

The diagnosis is based on the observation of a groin swelling located underneath the external inguinal orifice. However, this location is easily missed[154,155] because, unless the bulge is visible on examination, relatives and doctors will first interpret its appearance as the expression of an inguinal hernia. This explains why half of these patients are operated on for inguinal hernia and why only when the sac is not found, exploration of the femoral area allows diagnosis and repair.[156,157] Furthermore, the femoral defect can be missed even during inguinal exploration in a consistent proportion of these patients, and the correct diagnosis is made in them only when the bulge persists after the alleged inguinal hernia has been "repaired."

A well-directed operation allows excision of the sac and adequate closure of the enlarged orifice without damaging the femoral vein. This is more often performed through an inguinal approach, displacing forward the inguinal ligament to treat the femoral region from above. A mesh-plug technique has been recently adopted by some surgeons for this purpose,[158] and a laparoscopic approach might be particularly indicated in these cases of apparently "recurrent" inguinal hernia.[150,159]

UMBILICAL HERNIA

Failed closure of the fascial orifice of the umbilicus shortly after birth causes umbilical hernia in which there is a parietal defect centered at the umbilical level, covered externally by skin, and lined internally by peritoneum. It may contain bowel loops or epiploon and sometimes may attain considerable dimensions.

Umbilical hernias are frequent in newborns, particularly in premature infants, and they are observed more often in black babies. Both genders are equally affected. The natural history of the hernia is favorable at large because the fascial orifice reduces spontaneously with time and eventually closes itself. Most hernias disappear during infancy or early childhood, and only a minimal proportion of them persist beyond the fourth year. This proportion is certainly higher when the orifice is not concentric with the umbilical scar because supraumbilical hernias do not tend to heal spontaneously.[160] Umbilical hernia is particularly frequent in individuals with Ehlers-Danlos[161] or Beckwith-Wiedemann[161] syndrome, mucopolysaccharidoses,[162] hypothyroidism,[163] or trisomy 18, and the expectation of spontaneous resolution in them is certainly reduced. It is also more frequent when chronic peritoneal dialysis is used.[164,165]

During intrauterine life, the umbilical stalk houses the vessels (umbilical vein and arteries and vitelline artery) connecting the embryo and the fetus with the placenta. The process of closure of the abdominal wall, consisting of ectodermal (skin) and mesodermal (peritoneum, muscle and fascia) growth and differentiation, proceeds concentrically around the umbilical stalk, and, at birth, after the interruption of these vascular connections, it is completed by further closure, leaving the umbilical scar and a fibrous area in which the peritoneal and fascial layers fuse. This process may be incomplete, and in such cases, there is a fascial orifice leaving the peritoneum and the skin in contact with and closely related to the umbilical arteries, the round ligament derived from the umbilical vein, and the urachus. Intra-abdominal pressure pushes the hernial layers outward, creating a hernial space in which bowel loops or epiploon can be located.

Umbilical hernia is immediately visible because of the prominence of the umbilicus (Figure 33-7). It may be very huge, particularly in black infants, in whom it may adopt the shape of an elephant's trunk.[166] On palpation, the content is almost always easily reduced, and the borders of the fascial defects can be palpated through the skin. Only very rarely, umbilical hernias incarcerate[167,168] or strangulate[169]; even more rarely, they rupture.[170] The swelling may be painful, particularly when the epiploon is involved in the content or as a symptom of intra-abdominal sepsis.[171] Sometimes, particularly in young infants, the frequent presence of bowel loops in the hernia interferes with adequate feeding and intestinal transit.

FIGURE 33-7 Umbilical hernia in a young girl.

In view of the favorable natural history of umbilical hernia, surgical indications are restricted to those located slightly above the umbilicus; to those persisting beyond the age of 3 or 4 years, particularly in girls, in whom future pregnancies will enlarge the orifice; and to the above-mentioned associated conditions.

EPIGASTRIC HERNIA

Defects of the linea alba, where the fascial layers of the anterior abdominal wall fuse, may allow protrusion of the intra-abdominal contents. This condition is known as epigastric hernia. This hernia is quite frequent, but it is asymptomatic in most cases, and its prevalence is certainly underestimated. Slim individuals in whom there is a wide diastasis between the rectus muscles of the abdomen are more often affected. It is usually asymptomatic, but it may cause pain, sometimes quite disturbing, particularly when the preperitoneal fat pad and eventually the peritoneum and some of the epiploon are herniated into the defect. In these cases, intra-abdominal causes for pain may be mistakenly investigated. On physical examination, the defect can be palpated in the midline together with its small fat content.[172] Epigastric hernias are straightforwardly closed by surgical reinforcement of defect in the linea alba.

CHAPTER 34

PERITONITIS

Christophe Laplace, MD
Guillaume Podevin, MD
Hugues Piloquet, MD
Marc-David Leclair, MD
Yves Heloury, MD

Peritonitis is an inflammation of the peritoneum in reaction to contamination by microorganisms or chemical irritation by organic fluids (intestinal fluids, blood, bile, urine). Among infectious peritonitis, there is primary peritonitis and secondary peritonitis, which is caused by bowel perforation. The latter is more common. In children, the incidence, pathophysiology, and etiology of peritonitis vary according to age.

PATHOPHYSIOLOGY

The peritoneum is a functional membrane that lines the intra-abdominal wall and the viscera contained within the peritoneal cavity. Under normal circumstances, the peritoneal cavity is a sterile environment, and the peritoneum provides a smooth lubricated surface within which the intestines can move freely. It contains serous fluid, which is an ultrafiltrate of plasma and a small number of cells (less than 300 cells/mm^3). Almost half of normal peritoneal cells are macrophages, 44% are lymphocytes, 2% are dendritic cells, and a few are eosinophils and mast cells.[1–3] The basic structure of peritoneum is a smooth layer of mesothelial cells resting on a basement membrane with a deeper layer of vascularized loose connective tissue. By electron microscopy, mesothelium appears as a continuous cellular surface covered by numerous microvilli. Mesothelium is capable of extensive secretory activity, which is evident from the large nuclei present in mesothelial cells, the abundance of rough endoplasmic reticulum, and the prominence of Golgi complexes.

When bacteria reach the peritoneal cavity, a local peritoneal and systemic response is initiated to eradicate the invading pathogens. This response is characterized by hyperemia; exudation of protein-rich fluid containing fibrinogen, albumin, opsonins, and complement; and a marked influx of neutrophils into the peritoneal cavity, for example, peritonitis.[1,2] Mesothelial cells play an active role through secretion of cytokines and up-regulation of adhesion receptors that stimulate the transmigration of leukocytes across the mesothelium. Interaction between bacteria and mesothelium and its influence on inflammation, coagulation, and fibrinolysis are especially important processes that may induce permanent adhesions.

Bacterial adherence to mesothelial cells is the initial step in contact between mesothelial cells and bacteria, resulting in activation of mesothelial cells and causing peritonitis. Adherence to mesothelial cells is made possible by the presence of cell wall substances and opsonization or ingestion, resulting in sequestration of the bacteria protecting them from antibiotics and neutrophils, allowing them to persist and cause relapsing episodes of peritonitis (by *Staphylococcus aureus*).[4] Adherence of *Bacteroides fragilis* to peritoneal mesothelial cells is firm, and extended saline lavage fails to significantly reduce the mesothelial microbial population.[5]

Mesothelial cells produce cytokines after stimulation. Cytokines are proteins capable of regulating immune and inflammatory responses. Peritoneal mesothelial cells can produce several cytokines, such as interleukin (IL)-6 and IL-8 after stimulation with IL-1β or tumor necrosis factor (TNF)-α.[6]

IL-6 has the ability to stimulate T-cell, macrophage, and B-cell differentiation.[7–9] IL-8 is a chemoattractant that is highly selective for polymorphonuclear leukocytes and is secreted in a polarized way, preferentially oriented toward the apical side of the cell layer, creating a gradient.[10] *Escherichia coli* has an activating effect on IL-8 secretion by mesothelial cells, with a role for lipopolysaccharide or peptidoglycans. The latter has the same effect after interaction with gram-positive bacteria.

Neutrophil influx into the peritoneal cavity is one of the most important host defense mechanisms. The greater omentum is a source of exudative neutrophils.[11] The bacterial concentration decreases within the first 3 hours after bacterial penetration into the peritoneal cavity.

Bacteria can have synergistic activity, which increases the pathogen effect. Synergistic activity exists between *E. coli* and *B. fragilis* caused by a heat-stable factor.[12]

ETIOLOGY AND MANAGEMENT

Antenatal Peritonitis

Prenatal peritonitis is defined by the presence of meconium in the peritoneal cavity. It occurs after prenatal intestinal perforation, and the most common cause is meconium ileus associated with cystic fibrosis. The other causes are intestinal atresia, appendicular perforation associated with Hirschsprung disease, antenatal appendicitis, and intrauterine parvovirus B19 infection.[13]

Meconium peritonitis is a chemical fibroadhesive peritonitis[14] because meconium is sterile within the prenatal period. Digestive enzymes in meconium cause a peritoneal inflammatory reaction (Figure 34-1).

Diagnosis is made by prenatal ultrasonographic examination showing ascites and/or calcifications in the bowel wall and peritoneum.[15] Free ascites develops when the bowel perforation occurs just before birth. This should be distinguished from urinary ascites.

There are several types of meconium peritonitis: generalized, localized, and cystic.[16] Meconium peritonitis is localized near the intestinal perforation when atresia occurs. The generalized type is severe, and its surgical treatment is often difficult.

Prenatal diagnosis should include genetic counseling to determine if cystic fibrosis exists. A blood test is carried out in the two parents. When parents are heterozygotes, genetic tests to detect cystic fibrosis are performed on the fetus.

At birth, management depends on the clinical and radiologic presentation. When abdominal distention is extensive after birth, surgery is performed after abdominal decompression to improve the respiratory condition of the newborn. When the newborn is asymptomatic, plain abdominal radiography is performed to look for intra-abdominal (Figure 34-2) or scrotal calcifications.[17,18] When the clinical status is stable, without evidence of obstruction or pneumoperitoneum, the digestive perforation may have healed spontaneously, and surveillance is reasonable. When radiographic examination shows evidence of intestinal obstruction or perforation (pneumoperitoneum), a laparotomy should be performed.

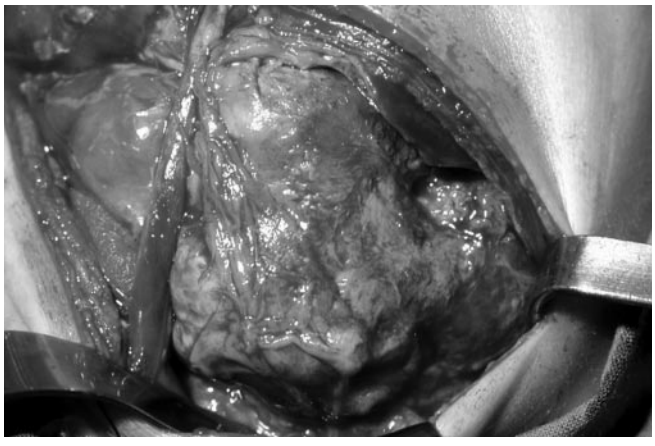

FIGURE 34-1 Meconium peritonitis, an operative view.

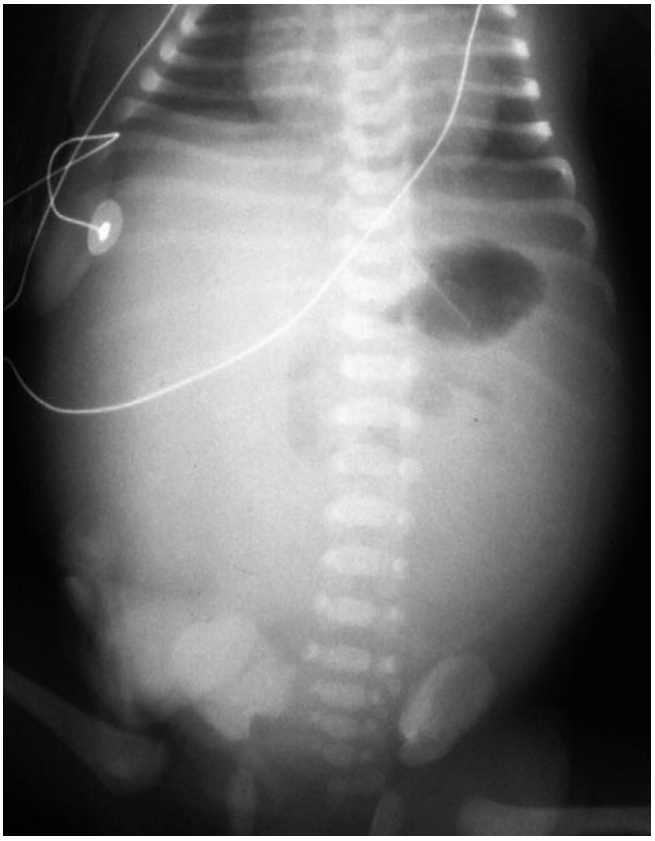

FIGURE 34-2 Meconium peritonitis, anteroposterior radiograph. Calcification on the right flank.

When surgical exploration is performed, laparotomy is done through a transverse umbilical or midline incision. The intestinal perforation is removed by segmental resection, and anastomosis is performed if the bowel wall is not inflamed. If the peritoneum is too inflamed, a stoma must be created. The appendix can be removed to be examined for ganglia cells. Surgery can be difficult, and hemorrhage can occur.

Neonatal Peritonitis

The clinical presentation of peritonitis in neonates is marked by bilious vomiting with fever. The general signs (tachycardia, oliguria, dyspnea, lethargy) can be extensive and lead to septic shock with multiorgan failure. Locally, the abdomen is tender and edematous, and the wall is glistening and marked by a venous distention pattern. The biologic assessment suggests an infectious syndrome with leukocytosis and increased C-reactive protein. Leukopenia is possible, as well as thrombocytopenia. Acidosis and hyperkalemia are suggestive of digestive failure. The radiographic assessment should include plain abdominal radiography and ultrasonography. Anteroposterior and lateral radiographs in the supine position can show an ileus and can lead to a diagnosis of pneumoperitoneum. Ultrasonography can be done at the newborn's bedside. This approach makes possible the capacity to show intraperitoneal disruption and helps contribute to the etiologic diagnosis of peritonitis. In the event of ischemic digestive failure, ultrasonography can reveal liquid in connection

with the presence of blood or pus, a peritoneal cavity filled with liquid, and a thick and aperistaltic bowel wall. Treatment consists of fluid re-equilibration and insertion of a nasogastric tube before undertaking surgery, the nature of which is determined by the etiology of the peritonitis. Surgery will be carried out with intravenous antibiotics appropriate to the diagnosed bacteria and is usually included on the administration of ceftriaxone, aminoside, and metronidazole for 10 days following surgery.

Etiology

Necrotizing Enterocolitis. Necrotizing enterocolitis is the most common surgical emergency in newborns, especially premature infants (90% of cases). Some cases are described in full-term infants with low birth weight and cardiac malformations.[19] The etiologic factors are low blood flow in the mesenteric vessels, enteral feeding, and infection.[20] Inflammatory factors such as platelet activating factor and TNF-α contribute to the development of the initial histologic lesion represented by coagulating necrosis of the digestive mucosa, which can extend the full thickness of the digestive wall. This lesion is the result of the production of metalloproteinase[21] enzymes that cause destruction of the extracellular matrix of the intestinal mucous membrane. The digestive wall is then invaded by monocytes, macrophages, and neutrophils.[22] The lesions can be located at any place in the digestive tract but are generally located in the terminal ileum, right colon, and left colonic angle. Clinically, enterocolitis occurs in the first 3 weeks of life, with a septic syndrome, abnormal gastric residues during enteral feeding, abdominal distention with tenderness, and bloody stools. Some authors ascribe importance to an increased fecal calprotectin,[23] a marker of inflammation of the digestive mucosa in newborns that is increased in necrotizing enterocolitis. Plain abdominal radiography has an important role in the diagnosis, showing a pneumatosis intestinalis (Figure 34-3) that, when localized, would be a better prognostic factor. Radiography searches for portal venous gas, which is easier to visualize on ultrasonography and is pathognomonic of necrotizing enterocolitis but associated with a poor prognosis. Radiography can visualize pneumoperitoneum when intestinal perforation occurs.[24]

The treatment is initially medical: for example, discontinuation of enteral feeding and continuous gastric aspiration, parenteral nutrition, and intravenous antibiotics with broad-spectrum medications. Surgery is limited to digestive tract perforation with pneumoperitoneum or when plastron occurs.[25] Other surgical methods are debatable, including peritoneal drainage, which is indicated for the newborn premature infant with a very low birth weight (< 1,000 g) and represents a unique treatment in 30% of cases,[26] and laparotomy with intestinal resection and ileostomy. Morbidity is estimated at 47% in connection with sepsis, digestive stenosis, short-bowel syndrome, and complications of parenteral nutrition. Mortality reaches 50% of cases when sepsis is associated with necrotizing enterocolitis.[27] See Chapter 42, "Necrotizing Enterocolitis," for a comprehensive review of this topic.

FIGURE 34-3 Anteroposterior radiograph. Necrotizing enterocolitis with pneumatosis intestinalis.

Idiopathic Gastrointestinal Perforation. Described by Siebold in 1825,[28] this perforation occurs in premature infants with a low birth weight. Perforation is located in the terminal ileum or jejunum in an antimesenteric position. Spontaneous neonatal gastric perforation is possible but rare, occurring in 1 in 2,900 live births.[29] Gastric perforation is 4 times more frequent in boys and is found in 85 to 95% of cases in the anterior part of the greater curvature. Perforation generally occurs earlier than enterocolitis (eg, in the first week of life) and has an incidence of about 6% in premature infants with a very low birth weight. It occurs at one-tenth the frequency of necrotizing enterocolitis. Many factors can contribute to this perforation: twin pregnancy, neonatal ventilation, an umbilical artery catheter,[30] administration of nonsteroidal anti-inflammatory drugs and corticosteroids, *Staphylococcus epidermidis* infection, and candidiasis.[31] Histologically, there is a discontinuous absence of the internal layer of the muscularis propria or muscularis mucosae.[32] In cases of gastric perforation, zones without Cajal cells have been found, suggesting a disorder of gastric motility.

Newborns have extensive abdominal distention with bluish discoloration of the abdomen. The general health status is otherwise preserved, except when gastric perforation occurs in relation to pneumoperitoneum. Anteroposterior and lateral abdominal radiographs reveal pneumoperitoneum (Figure 34-4).[33] Initially, pneumoperitoneum can be deflated with a needle[34] to ameliorate ventilation and to try to obtain healing of the intestine because of peritoneal

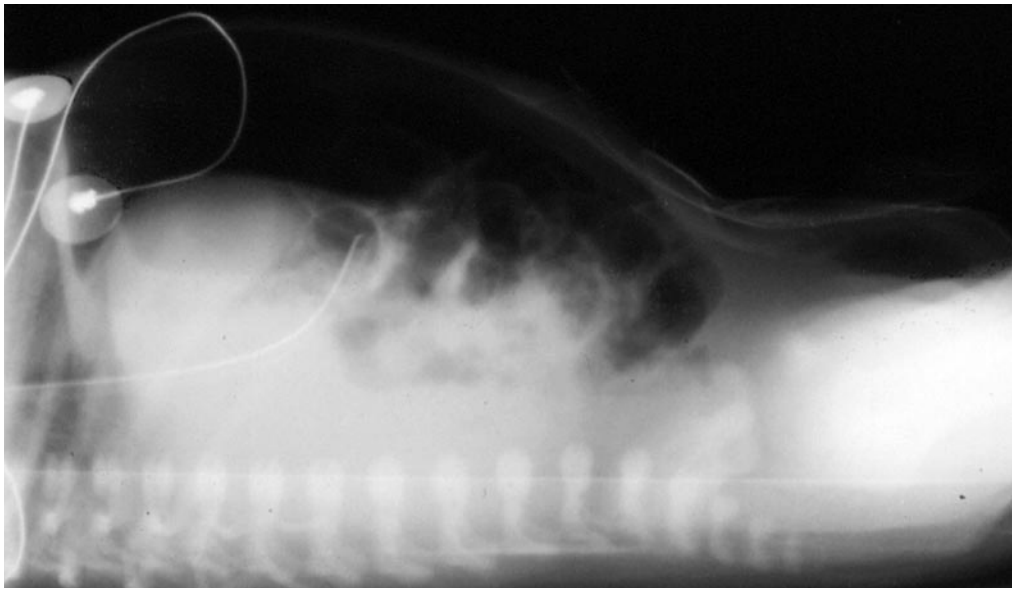

FIGURE 34-4 Idiopathic gastrointestinal perforation. Lateral abdominal radiograph. Visualization of the pneumoperitoneum.

adhesion. The effectiveness of the treatment is based on the absence of pneumoperitoneum recurrence on repeated abdominal radiographs. If pneumoperitoneum recurs after two or three punctures, laparotomy is indicated to suture the perforation or to carry out a segmental resection with concomitant anastomosis.[35] Enterostomy is rarely necessary. When gastric perforation occurs, the stomach must be explored completely because the perforations can be multiple. The prognosis is good when adapted treatment is undertaken.[36]

Diastatic Perforation in Hirschsprung Disease. Hirschsprung disease can present with an intestinal perforation in the newborn. The appendix is usually involved. It occurs with a long segment of Hirschsprung disease, and appendix perforation suggests Hirschsprung disease. With the sealing of the Bauhin valve, the appendix is likely to perforate, particularly at the level of its base.[37] During surgery, the histologic appendix is removed and examined immediately. If ganglia cells are present, a piece of sigmoid wall is then obtained for analysis. If there are ganglia cells, a stoma in the sigmoid colon is created. If the sigmoid colon does not have ganglia cells, the colonic wall is resected until ganglia cells are present to create a stoma in normal tissue. If there are no ganglia cells in the appendix, an ileostomy is performed.[38] See Chapter 46.3, "Hirschsprung Disease," for more details.

Spontaneous Biliary Perforation. Spontaneous biliary perforation is the second most common cause of jaundice in infancy after biliary atresia. The incidence occurs between the first week and 3 months of age. The etiology is unclear. In the majority of cases, perforation is localized to the junction of the cystic and common hepatic ducts and is thought to be due to embryologic mural weakness. It has been suggested that the posterolateral arterial blood supply of the bile duct has a susceptibility to ischemia of its anterior wall, which may cause a weak point that is prone to perforation. Stones or duct stenosis as a cause of distal obstruction and perforation of the bile duct are rarely encountered.[39] Antenatal perforation of the biliary system has been reported with fetal ascites on ultrasonography.[40]

Clinically, the newborn has abdominal distention, vomiting, and fever. Abdominal ultrasonography shows fluid located preferentially around the gallbladder and porta hepatis without dilatation of the bile duct.

Liver function tests may differentiate this condition from biliary atresia and neonatal hepatitis because with perforation of the bile duct, serum enzymes are not elevated significantly. The bilirubin level in the ascitic fluid is greater than the serum level.

Preoperative fluid resuscitation is mandatory because of malnutrition, dehydration, and electrolyte imbalance, especially hyponatremia. Currently, the surgical recommendation for perforation of the bile duct includes simple peritoneal drainage. Bile duct stenosis is the most common complication after simple drainage for bilomas, pseudocyst, and portal vein thrombosis. If the site of perforation is apparent, suture repair can be performed. Biliary intestinal anastomosis is needed if there is a distal biliary tract obstruction or stenosis on the operative cholangiogram. Cholecystotomy may sometimes be helpful for better decompression and for evaluation of the biliary tree.[41]

Omphalitis. Peritonitis is one of the complications of omphalitis in neonates (16% total complication with a 6% mortality rate).[42] It is a common problem in neonates in developing countries and occurs as a result of poor cord care practices in these countries. Peritonitis is the result of direct spread of infection to the peritoneal cavity. Peritonitis should be suspected if the ileus fails to respond to appropriate treatment.[43] If abdominal ultrasonography shows localized intraperitoneal abscesses, laparotomy and drainage are indicated. When the umbilical arteries contain pus, excision may be necessary to control infection.[44] Early recognition and prompt treatment of the peritonitis can avoid significant morbidity and mortality.

Perforation of the Urachal Cyst. The urachus exists generally as a fibrous cord extending from the dome of the bladder to the umbilicus. It occupies a midline space between the peritoneum and the transversalis fascia. Disorders of the urachus are usually due to its incomplete regression.[45] Urachal cysts can become infected, the most common organism being *S. aureus*. Peritonitis can occur when the urachal infected cyst perforates into the peritoneal cavity. Clinically, there is a medially located palpable inflammatory mass with peritoneal irritation. Diagnosis can be suspected during surgery because of a medially located perforated abscess with peritonitis. Abdominal ultrasonography and computed tomography (CT) are useful for a diagnosis. Treatment is surgical. The abscess must be drained first, and then it must be resected with part of the bladder dome to avoid the long-term complications of adenocarcinoma, transitional cell carcinoma, or sarcoma.[46]

PERITONITIS IN CHILDREN

Appendicular Peritonitis

Appendicular peritonitis is the most frequent form of peritonitis in children. It occurs when the appendix has perforated or when, in the absence of overt perforation, a diffusion of bacteria through an inflamed appendix wall occurs. The most common microorganisms are *E. coli*, *Enterococcus*, *Bacteroides*, and *Pseudomonas aeruginosa*, which are found in 10% of cases. Mortality is estimated at about 1%; morbidity is higher and results from deep parietal abscess and obstruction of the bowel. Adhesions increase the risk of tubar sterility by five times (personal data). The clinical diagnosis includes abdominal pain, which can initially be located in the epigastrium and then in the right iliac fossa.

Abdominal pain is associated with vomiting, fever, and deterioration of the generalized clinical status. The clinical presentation can also be intestinal obstruction with fever.

Clinical examination shows a swollen, rigid abdomen with cutaneous hyperesthesia. Palpation reveals an abdominal contracture that is painful, rigid, and continuous. A recrudescence of the pain in the right iliac fossa with a rigid abdomen suggests appendicitis as the origin of the peritonitis.

The white blood cell count reveals increased leukocytes, and C-reactive protein is increased. Abdominal radiographs can show ileus and appendiceal stercolith. Abdominal ultrasonography[47] highlights intraperitoneal masses and signs of appendicitis (eg, thickening of the appendix wall and infiltration of mesenteric fat). However, the abdominal examination can also be normal and therefore misleading. Treatment consists of appendectomy after fluid therapy and the installation of a gastric tube. The peritoneal cavity is rinsed. Drainage of the peritoneal cavity is not essential in the majority of cases. The intervention is performed by a McBurney incision when peritonitis is localized or by laparotomy if the peritonitis is diffuse. Laparoscopy plays an important role in the treatment of peritonitis; it allows sampling of intraperitoneal liquid for bacterial analysis. The peritoneal cavity should also be rinsed, and an appendectomy should be performed. However, laparoscopy is contraindicated when abdominal distention owing to intestinal obstruction occurs or when sepsis exists. However, laparoscopy's esthetic benefit is greater than that of laparotomy. The postoperative period requires parenteral antibiotics[48] for 10 days with ceftriaxone, aminoside, and metronidazole. Antibiotics are then continued for 8 days per os. See Chapter 37, "Appendicitis," for more details.

Perforation of Meckel Diverticulum

Meckel diverticulum is the result of a persisting omphalomesenteric duct. Its incidence is estimated at 2%. Complications occur in 4% of Meckel diverticula, with intestinal obstruction, gastrointestinal bleeding, or perforation. Perforation occurs in 14.5% of cases.[49] Infection of the gastric mucosa by *Helicobacter pylori* plays a minor role in this complication of Meckel diverticulum.[50] Complications occur before the age of 10 years in 89.5% of cases and before the age of 2 years in 47% of cases.[51] In newborns, nonsteroidal anti-inflammatory drugs can contribute to a Meckel perforation when neonatal ischemia is involved. Exceptional antenatal cases have been reported and discovered with surgery for inflammatory hydroceles at birth.[52] Perforation is due to ectopic gastric mucosa occurring in the small intestine. Perforation can be a complication of ileoileal intussusception. A preoperative diagnosis is very difficult also because perforation of Meckel diverticulum is usually discovered at the time of surgery (Figure 34-5). Treatment is based on surgery with segmentary resection of the intestine and an end-to-end anastomosis of the small intestine.

Gastric Ulcer Perforation

Gastric ulcer perforation is rare in children.[53] It occurs in situations of stress, such as neurosurgical intervention.

FIGURE 34-5 Perforation of a Meckel diverticulum.

Symptoms include intense abdominal pain, hemorrhage, and vomiting. Abdominal radiographs show a pneumoperitoneum. Treatment begins with installation of a nasogastric tube, and then a laparoscopy is performed if the perforation is recent.[54] Laparoscopy can be used to suture the perforation; protect the suture with a epiploic patch and wash the peritoneal cavity because chemical peritonitis predisposes the patient to infectious peritonitis. Drainage and laparotomy are justified in cases of peritonitis with abdominal distention owing to intestinal obstruction or septic shock.[55] Treatment with a proton pump inhibitor is indicated for 1 month after surgery.

Traumatic Perforation of the Intestine

Perforation of the intestine in children often has a traumatic etiology (eg, a traffic accident when the child is attached to the back seat with a two-point seat belt, a fall from a bicycle, Silverman syndrome). These intestinal lesions are associated in 30 to 60% of cases with either additional intra- or extra-abdominal lesions.[56] The mechanisms are a direct crushing of organs, a dramatic increase in the intraluminal pressure, and a shearing movement between fixed organs. Perforation occurs in 65% of post-traumatic bowel lesions. The intestinal perforation can be secondary to an initial mesenteric lesion and can thus occur secondarily. It is usually localized at the junction of a fixed and mobile bowel segment (eg, Treitz angle and ileocecal junction). The intestinal lesion can be associated with a lumbar fracture, characteristic of the "seat-belt" syndrome,[57] which is frequent with the two-point fixed belts. The diagnosis remains difficult and must be determined as soon as possible to avoid an increased morbidity and to allow early surgical intervention. A lesion of the digestive tract must always come to mind when blunt abdominal trauma in a child occurs. The diagnosis is difficult when hemoperitoneum is associated with fever and ileus. The clinical signs of perforation are the presence of abdominal tenderness, tachycardia, and fever. Abdominal radiographs rarely show pneumoperitoneum. Abdominal ultrasonography is not helpful in the diagnosis. CT, when hemodynamic status is stabilized, is the best procedure to detect intestinal lesions.[58] It can reveal the presence of pneumoperitoneum (eg, bubbles of air in an extradigestive sector). It shows a thickening of the bowel wall associated with a localized intraperitoneal effusion. Analysis of the density of an intraperitoneal effusion suggests, in some cases, a digestive origin. In case of doubt about a perforation, it can be helpful to repeat the CT scan a few hours later, or when the doubt persists (eg, when the CT scan appears normal), lavage of the peritoneum or a laparoscopy can be carried out.[59] Treatment consists of a laparotomy and suturing of a small intestinal lesion. When the lesions are more severe, a segmentary resection should be performed with anastomosis to the small intestine. The surgical procedure ends with a peritoneal washing. When the colon is perforated, a primary suture should be performed with parenteral antibiotics. However, when the lesion is seen too late, a colostomy must be done.

Neutropenic Colitis

Neutropenic colitis is an inflammatory process involving the colon, most frequently the cecum, which is associated with immunocompromised patients. The pathogenesis is most likely related to multiple factors, such as immunocompromised status, neoplastic infiltration of the bowel, intestinal ischemia, and bacterial overgrowth. The preferential location within the cecum is in connection to its distensibility, its existent high bacterial count, its predisposition to mucosal ischemia, and the relative stasis of its contents. Neutropenic colitis is most common in children who develop acute leukemia or lymphoma or are post–renal transplant. Involved bowel loops have edema, ulceration, and hemorrhage. Transmural necrosis may also occur. The prognosis is very poor because the mortality rate is between 50 and 100%.[60] Children present with diarrhea, abdominal pain, gastrointestinal hemorrhage with vomiting, and fever. They can also present with an acute abdomen if a perforation has already occurred. Abdominal radiographs can show pneumatosis intestinalis. A CT scan demonstrates bowel wall thickening and dilated loops of bowel. Pneumoperitoneum is a sign of perforation. Typically, there is also pericolonic inflammation. Therapy of neutropenic colitis usually includes high-dose intravenous antibiotics and antifungal agents, as well as complete bowel rest with parenteral nutrition. Surgery may be required if there is perforation, development of an abscess, gastrointestinal hemorrhage in spite of a correction of the neutropenia, thrombocytopenia, or hemostasis.[61] When sepsis is not controlled or worsens, the general status of the child deteriorates.[62] Surgical treatment consists of resecting all necrotic scars with a right hemicolectomy and ileostomy.[63]

Tuberculosis Peritonitis

Tuberculosis peritonitis is one of different types of abdominal tuberculosis that can involve the mesentery, the digestive tract itself, or abdominal solid organs (eg, spleen and liver). The diagnosis is difficult and has to be distinguished from lymphoma itself. Two historical elements are important to consider in the child: contact with adult pulmonary tuberculosis and documented weight loss.[64] Normal chest radiographs do not eliminate the diagnosis of tuberculosis. Approximately 40% of patients have a normal chest radiograph, and 50% have a normal abdominal radiograph.[64] Abdominal ultrasonography and CT can detect lymphadenopathy, ascites, thickening of the bowel wall, and omental masses. Paracentesis may reveal the presence of *Mycobacterium tuberculosis*, but culture may take 4 to 6 weeks. An advance in the diagnosis of tuberculosis is the determination of adenosine deaminase activity. This enzyme converts adenosine to inosine in the T cells activated by mycobacterial antigens. When the diagnosis is suspected, a laparoscopy can be performed to obtain a peritoneal biopsy.

Salpingitis

Especially in children, the mode of contamination can occur by two routes: ascending and hematogenous. It is part of the differential diagnosis of appendicular peritoni-

tis and is a perioperational discovery. Appendicular peritonitis can also drain into the female genital tract and simulate salpingitis. Diagnosis and treatment benefit from laparoscopy, which allows purulent liquid to be taken for bacterial analysis as well as washing out of the peritoneal cavity. This local treatment should be accompanied by parenteral antibiotics.

Primary Peritonitis

Primary peritonitis is defined as an infection of the peritoneal cavity without an anatomic break in the continuity of the intestinal lumen. Pathogens may reach the peritoneum from the bloodstream, from the lymphatics, or by ascension from the vagina by translocation from the intestinal lumen or through foreign bodies inserted into the peritoneal cavity.[1,65,66] Primary peritonitis characteristically develops in patients with an impaired ability to clear intraperitoneal bacteria, especially children with nephrotic syndrome. In nephrotic syndrome, the most frequent organism found is *Streptococcus pneumoniae*. In addition, a child with a level of blood albumin lower than 1.5 g/dL is more likely to develop primary peritonitis.[67]

When the diagnosis is made according to the treatment protocol, parenteral antibiotic therapy is implemented after paracentesis. When surgery is performed, a diagnosis is made operatively with the presence of purulent liquid in the peritoneal cavity in the presence of a normal bowel. Surgical intervention can be performed by laparoscopy, which allows access to the peritoneal cavity.

CONCLUSION

Peritonitis is a serious pathologic state in children. It requires early diagnosis based on the age of the child. Its treatment is surgical after fluid resuscitation, and it benefits from laparoscopy, especially in older children.

CHAPTER 35

BENIGN PERIANAL LESIONS

Sidney Johnson, MD
Tom Jaksic, MD, PhD

Perianal disease in children is common and encompasses a broad spectrum of pathologic processes, including fissures, fistulae, abscesses, hemorrhoids, rectal prolapse, pilonidal sinus, and pruritus ani. Occasionally, systemic illnesses such as inflammatory bowel disease may coexist. This chapter provides a diagnostic and therapeutic guide to perianal lesions based on an understanding of the underlying anatomy and the specific pathogenesis of each entity.

ANATOMY

The diagnosis and treatment of perianal disease can be confusing if the anatomy of the pelvic floor and sphincter muscle complex is not understood. Thus, as a preface to the discussion of perianal lesions, it is useful to review the anatomy of the rectum and anus (Figure 35-1).

The rectum is a continuation of the sigmoid colon that starts approximately at the sacral prominence. It can be distinguished from the colon by its lack of taeniae bands. In their place, it has a complete covering of longitudinal muscle fibers. The luminal pattern of the rectum also differs from the colon because it has two to three lateral curves that form mucosal folds known as the valves of Houston. The posterior rectum is free of peritoneum, and the most distal third of the rectum is devoid of peritoneum circumferentially.

The rectum terminates in the anal canal, which is composed of that portion of bowel that passes through the levator ani muscles and opens onto the anal verge. The external and internal sphincter muscles form an important continence mechanism in association with the anal canal.

The internal anal sphincter is a continuation of the circular muscle layer of the rectum. As this muscle layer enters the anal canal, it becomes thickened. Both the puborectalis muscle and external sphincter muscle then wrap the anal canal, suspending the rectum and facilitating contraction of the anus, thereby assisting with anal continence.

On examination with anoscopy, the dentate line can be visualized marking the transition from the columnar epithelium of the rectum to the squamous epithelium of the anal canal. The dentate line is 1 to 2 cm proximal to the external orifice of the anus. The longitudinal folds of mucosa at the dentate line are known as the columns of Morgagni. The internal and external hemorrhoidal plexus of veins accomplish venous drainage of the anus and rectum.

ANAL FISSURE

An anal fissure is a tear in the epithelium and superficial tissues of the anal canal. In children, the tear is usually linear, extending from just below the dentate line to the anal verge (Figure 35-2). Fissures can be classified as either acute or chronic and can be further subdivided into primary or secondary processes. When first formed, a fissure is a simple crack in the anoderm; however, with infection and poor healing, a chronic fissure can develop with a "sentinel tag" of skin, fibrotic edges, and exposure of the internal sphincter. Primary fissures are not associated with underlying systemic pathology, whereas secondary fissures are the consequence of illnesses such as Crohn disease. Although fissures occur in all age groups, they are most common in children. The majority of anal fissures are located in the posterior midline (90%),[1] with the next most frequent location being the anterior midline.

PATHOGENESIS

Anal fissures are thought to be traumatically induced by overstretching of the anoderm because most cases are asso-

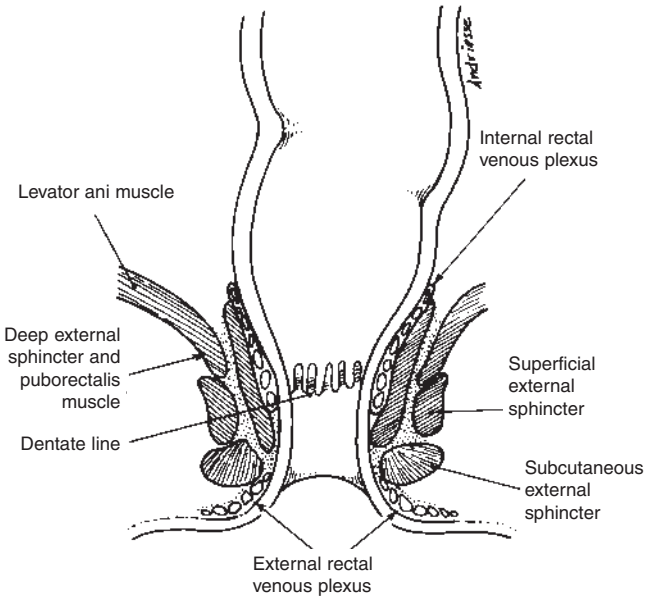

FIGURE 35-1 The anatomy of the rectum and anus is illustrated in coronal section.

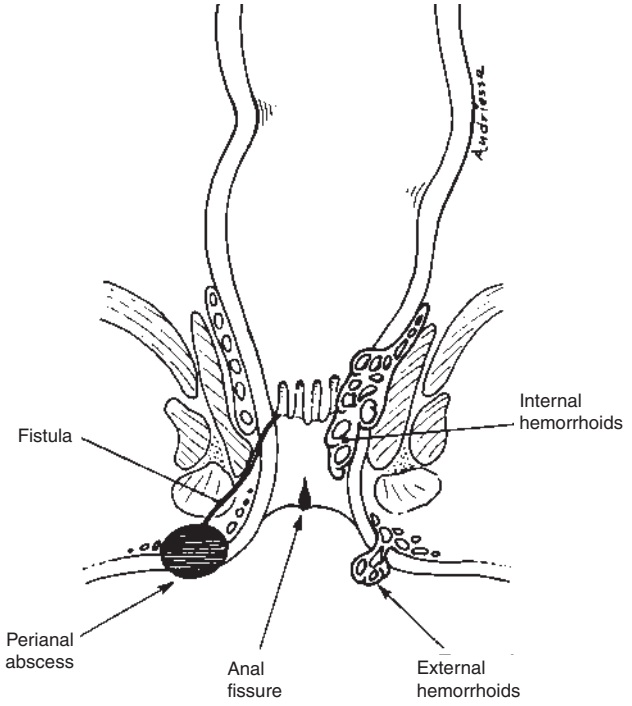

FIGURE 35-2 A diagrammatic representation of perianal lesions and their anatomic relationships is depicted in coronal section.

ciated with constipation and because the appearance of fissures is often noted after the passage of a large, hard stool.[2] Parents can, at times, describe which bowel movement resulted in the superficial tear of the anoderm because it is a painful event for the child. Pain with the next bowel movement leads to hesitancy and avoidance of bowel movements on the child's part. This fecal retention leads to more hardened stools and a persistent, cyclic problem.

In addition to the traumatic insult to the anoderm, the pathogenesis of anal fissures appears to be closely related to two predisposing factors: hypertonicity of the anal sphincter and poor perfusion of the anoderm at the posterior midline.

Angiograms show compromised blood flow through the inferior rectal artery to the posterior midline.[3] Manometric studies done in patients with chronic fissures demonstrate hypertonicity of both internal and external sphincters.[4] These higher pressures also correlate with a further decrease in perfusion.[5] The poorly perfused tissue is thus predisposed to poor wound healing.

Therefore, the etiology of anal fissures is trauma in an environment predisposed to poor wound healing. It is unclear whether constipation and anal hypertonicity are primary causal factors or a consequence of pain, but by the time a patient develops a symptomatic fissure, sphincter hypertonicity is present and is certainly a factor in the persistence of the fissure.

Clinical Presentation and Diagnosis

The initial symptom of an anal fissure is pain at defecation, which may last for minutes to hours afterwards. A small amount of red blood per rectum is common. Anal fissure is the most frequent cause of rectal bleeding in the first 2 years of life. The diagnosis can be made after inspection of the anal canal. If a fissure is not visualized on superficial examination, an anoscope can be helpful in identifying the lesion. Acute fissures are usually small, with no signs of chronicity. Chronic fissures are associated with hypertrophy of the anal papilla, fibrosis, or a distal skin tag. A large fissure associated with bruising (as well as other signs of injury) should raise the suspicion of child abuse. Crohn disease and leukemic infiltration are underlying conditions that require further investigation if a fissure persists after standard treatment.

Treatment

Given the previously described etiologic factors of anal trauma, anal hypertonicity, and poor perianal perfusion, successful therapy should accomplish one or more of the following: a decrease in trauma associated with stooling, a reduction in resting anal tone, and an increase in anal blood flow.[6,7] Initially, treatment is directed at the associated constipation by the use of stool softeners, lubricants (eg, mineral oil), or fiber supplementation. Additionally, warm baths have been shown to reduce anal tone. Results from these measures are good, with a cure in over 80% of acute fissures. Topical steroid and topical or injected anesthetic have not been shown to improve healing rates.

It is important to maintain good anal hygiene in the care of fissures. Failure to adequately clean the anus after each bowel movement may result in the continued presence of fecal matter within the fissure, consequent inhibition of healing, persistent pain, and anal hypertonicity.

The treatment of chronic fissures presents a more difficult problem. A chronic fissure is defined by symptoms that persist longer than 6 weeks after treatment and the presence of fibrosis at the base of the fissure. Fortunately, this is a relatively rare problem in children. Chronic fissures are unlikely to heal with a high-fiber diet and warm baths alone. Thus, the focus of treatment must be directed at the reduction of resting anal pressure.

Nitric oxide is an agent that will lower resting anal sphincter pressure and increase anal blood flow. A 92% cure rate of chronic anal fissures has been reported with the topical application of 0.2% glyceryl trinitrate ointment three times per day.[8] Two randomized trials using the local application of nitric oxide donor compounds in patients with chronic fissures also report good healing rates (70–90%) and no long-term complications such as incontinence.[9] Recurrence rates were 7 to 8%. Although this treatment is promising, it has not as yet been evaluated in children.

Botulinum toxin injection also reduces resting anal tone and appears to be more effective than glyceryl trinitrate. A 95% healing rate for chronic anal fissures has been reported with botulinum toxin injection.[10] However, it should be noted that in the pediatric population, botulinum toxin injection usually requires sedation or general anesthesia. As with glyceryl trinitrate application, botulinum toxin injection for chronic anal fissures has not been well studied in children.

In infants, a standard treatment for chronic fissures is gentle anal dilatation. Parents can be instructed to perform daily anal dilatations. This will help break the cycle of anal spasm and pain and thus assist wound healing. In infants

and young children, anal dilatation generally has good results, and complications such as incontinence are rare.

Very infrequently, when treatment fails despite dietary regulation, hygiene, and anal dilatation, it may be necessary to operate under general anesthesia on infants with chronic fissures. This approach allows for a satisfactory examination, possible further anal dilatation, and complete excision of the chronic anal fissure. In older children or young adults, the fissure is not removed; rather, lateral internal sphincterotomy is the procedure of choice. Lateral internal sphincterotomy achieves healing within several weeks. Studies comparing open versus closed lateral internal sphincterotomy show that both have excellent rates of healing (95%). Differences may exist, however, in long-term continence, with slightly better results achieved in patients undergoing closed lateral internal sphincterotomy.[10,11]

Special Considerations

Rarely, patients develop fissures as a consequence of systemic diseases. Fissures that result from group A β-hemolytic streptococcus infection have been reported. Patients may also evolve multiple, chronic, and difficult to manage fissures as an early manifestation of Crohn disease.

PERIRECTAL ABSCESS AND FISTULA IN ANO

A perirectal abscess is a localized, purulent fluid collection in the surrounding perirectal tissues (see Figure 35-2). Perirectal abscesses are usually classified by their location relative to the levator and sphincteric muscles of the pelvic floor. In order of frequency, abscesses are located in the perianal, ischioanal, intersphincteric, and supralevator locations. Clinical presentation and treatment interventions vary according to site.

A fistula in ano is the result of the spontaneous drainage of a perirectal abscess. This forms a chronic infected tract from the dentate line to the skin.

Pathogenesis

Perianal infections are often encountered in infants in diapers. Usually, there is no specific inciting event, but, occasionally, there is an accompanying diaper rash. In these cases, infection may be the result of an inward spread from the skin. Group A β-hemolytic streptococcal infection of the perianal tissue is also sometimes associated.

More commonly, perirectal abscesses are thought to result from abnormal columns of Morgagni. The crypts tend to trap bacteria, initiating a subsequent cryptitis that, if persistent, will become a perianal abscess. This hypothesis is supported by the presence of columnar, transitional, and stratified squamous epithelium (entrapped migratory cells from urogenital sinus development) lining the tract of a fistula in ano. In 90% of cases of perirectal abscess, the source of the abscess can be traced to an infection occurring in the crypts of Morgagni.[12]

Clinical Presentation and Diagnosis

The presentation of a perianal abscess and associated fistula may vary greatly in the pediatric population. In infants, perirectal abscess and fistula present more frequently in males.[13]

A child with a perirectal abscess will usually experience persistent rectal pain. Occasionally, diarrheal illness or anal fissure precedes the abscess. More infrequently, cryptoglandular infections are secondary to diabetes mellitus, Crohn disease, tuberculosis, or acquired immune deficiency syndrome (AIDS).

Perirectal pain is present in 98% of patients who can communicate their discomfort. The onset can be acute, and often there is no prior history of perirectal pain, inflammation, or trauma. The pain of a perirectal abscess is constant, whereas the pain associated with anal fissure is transient.

The earliest sign of perianal abscess is an indurated, tender area of the perianal skin, with or without erythema, which may occur in any location around the anus. External perianal and digital rectal examinations identify the abscess in 95% of patients.[14] In children and infants who are unable to communicate, the parent will bring the child to the clinic with complaints of crying or irritability that is worse at diaper change. Examination reveals painful perirectal swelling and possibly a fever. If the abscess ruptures and progresses to a fistula, persistent drainage and recurrent abscess formation are seen.

In children, fistula in ano usually occurs during the first year of life, when it is evident as a single cutaneous external orifice. This fistula communicates directly with the rectum at the level of the crypts of Morgagni (see Figure 35-2). It often passes through the lowest fibers of the internal sphincter. This type of fistula is thus termed "low" owing to its lack of compromise of the sphincter complex. Unlike a fistula in adults (in whom the internal opening of the fistula is usually posterior or midline in location with a circular tract following Goodsall law), the internal opening of a perianal fistula in children is usually located radially opposite to its external opening.

Treatment

Different treatment options exist depending on the age and presentation of the patient. Antibiotics have little place in the care of an established perirectal abscess. Incision and drainage with topical anesthesia are the standard of care in infants because abscesses respond poorly to antibiotics, and untreated abscesses will form chronic fistulae in ano in 40 to 60% of patients.

A nonoperative approach was reported in a group of 97 infants with perianal abscess or fistula. During their first year of life, most of these infants recovered spontaneously, but they had a high rate of recurrence. In infants, neither surgery nor antibiotics are routinely indicated. [15]

In older children, perirectal abscesses tend to extend into deeper tissues; thus, the primary treatment is surgical drainage, usually under general anesthesia. Antibiotics have no role in the primary treatment of these abscesses (although they may be useful adjuncts in complicated abscesses). In the operating room, under general anesthesia, the abscess can be drained quickly and painlessly, and a full examination is facilitated to identify concurrent abscesses or associated fistulae.

Persistence of an anal fistula is generally considered an indication for surgery. Chronic fistulae, in addition to troubling persistent drainage, are associated with recurrent abscesses. Anal fistulae are best managed with fistulectomy (excision) or fistulotomy (opening and curetting).[16] Rarely, the use of a seton loop is necessary. This loop is placed through the fistula and slowly tightened, thus allowing for division and fibrosis of higher tracts that may encompass both sphincters. The goal of treatment of a fistula is complete eradication of the fistula while preserving fecal continence.

Special Considerations

Recurrences of perirectal abscesses and fistulae are not uncommon, and treatment may be protracted.[17] Additionally, with recurrent perianal disease, one must always consider associated diseases. Older children with perianal abscess may have other undiagnosed medical problems, including drug-induced or autoimmune neutropenia, leukemia, human immunodeficiency virus (HIV), side effects from the use of immunosuppressive drugs, diabetes mellitus, and Crohn disease. For example, up to 15% of children with Crohn disease present with recurrent anal fistulae. Additionally, rare diseases, such as rectal duplication, may be mistaken for an anal fistula.[18] In general, with persistent and multiple fistulae, further investigation should be considered.[19]

HEMORRHOIDS

Hemorrhoids are generally classified into two subtypes, external and internal (see Figure 35-2). A hemorrhoid is a varicose vein from either the internal or external rectal plexus of veins. External hemorrhoids involve the skin of the anoderm external to the dentate line, and their nerve supply is cutaneously derived. Hence, newly thrombosed external hemorrhoids are associated with acute pain.

An internal hemorrhoid is also a swollen blood vessel (specifically a varicosity of the tributaries of the superior rectal vein). Internal hemorrhoids differ from external hemorrhoids in that they are located under the lining of the rectum. Patients who are suspected of having hemorrhoids should undergo a visual and digital examination to determine the type and grade of hemorrhoid. Internal hemorrhoids are graded on an ascending scale of severity from 1 to 4. With a first-degree hemorrhoid, anal cushions are present on rectal examination. Second-degree hemorrhoids may prolapse below the dentate line but reduce spontaneously. Third-degree hemorrhoids must be manually reduced. Fourth-degree hemorrhoids are irreducible.

Pathogenesis

A bout of constipation, straining, or diarrhea is often associated with a thrombosed external hemorrhoid. Chronic constipation and excessive straining are also implicated in the development of internal hemorrhoids. However, internal hemorrhoids may also be associated with chronic liver disease and portal hypertension.[20]

Clinical Presentation and Diagnosis

External hemorrhoids rarely cause symptoms. If an external hemorrhoid becomes very large, it can become difficult to clean after bowel movements. Occasionally, sudden pain occurs when a clot develops within the external hemorrhoid and becomes thrombosed. A painful, grape-like protrusion is noted on examination. This pain usually does not persist for more than a few days because the natural history of the clot is to drain spontaneously.

In children, primary internal hemorrhoids are virtually unknown. Their presence should raise questions regarding possible portal vein obstruction. Internal hemorrhoids present with either a protruding rectal mass or rectal bleeding. They are a common cause of rectal bleeding in older patients, but not in children, in whom anal fissures are much more common. Internal hemorrhoids do not cause pain. Classically, they manifest in three positions around the anus: the left lateral, right posterolateral, and right anterolateral. They can enlarge to the point that they protrude out of the rectum and may have to be pushed back in after straining. In advanced cases, they protrude enough so that they cannot be pushed back inside, resulting in chronic drainage and spotting of blood.

Treatment

Generally, an external hemorrhoid does not require surgery. External hemorrhoids are of no potential danger even if left untreated because they do not develop into cancers or other serious conditions.

The thrombosed external hemorrhoid is the only hemorrhoidal condition that is actually painful and, as such, may require surgical intervention during the acute thrombotic episode. Simple incision and drainage can promptly alleviate the pain of a thrombosed external hemorrhoid.

Treatment of internal hemorrhoids can vary from simple alterations in the diet to surgical removal. Internal hemorrhoids should first be treated with stool softeners and bulk agents (eg, psyllium). This approach is generally adequate treatment for hemorrhoids of degrees 1 to 3. Fourth-degree hemorrhoids usually require surgical intervention; banding is effective. Having said this about treatment, it must be re-emphasized that primary internal hemorrhoids are so uncommon in children that their presence should raise questions as to their etiology. A full investigation is necessary prior to treatment because hemorrhoidectomy in the face of portal hypertension can cause exsanguination.

RECTAL PROLAPSE

Rectal prolapse refers to either a mucosal or full-thickness herniation of the rectum through the anus. This diagnosis can be confused with chronic prolapsed internal hemorrhoids. Because rectal prolapse is a protrusion of the entire circumference of the rectal mucosa, concentric rings of mucosa are seen on examination. In fourth-degree hemorrhoids, the protrusion occurs only in a defined sector of the anus (usually lateral).

Pathogenesis

Rectal prolapse may be attributed to various causes and should be viewed as a sign of an underlying condition rather than a specific disease in itself. Potential etiologies include increased intra-abdominal pressure, diarrheal and neoplastic diseases, malnutrition, and conditions predisposing to pelvic floor weakness (such as prior surgery).[21] The most common cause is chronic constipation that may or may not be associated with neurologic or anatomic abnormalities. Acute diarrheal disease is the next most frequent etiology, followed by cystic fibrosis. Frequently, an extensive workup fails to elucidate any underlying factor.

Clinical Presentation and Diagnosis

Rectal prolapse is not uncommon in children, occurring more often in boys than in girls and tending to appear during the period of toilet training. The condition is usually self-limited.[22]

In infancy, there are two types of rectal prolapse.[23] The first is less pronounced and intermittent; the other is more pronounced and occurs with most bowel movements over a period of several weeks or months. Patients with rectal prolapse usually present with a history of prolonged straining at defecation. Rectal prolapse may also be associated with an acute diarrheal episode, cystic fibrosis, or a neurologic or anatomic anomaly. Although seen very rarely in developed countries, severe malnutrition or parasitosis can also cause rectal prolapse.

Children with unexplained or recurrent rectal prolapse should have a sweat chloride test to rule out cystic fibrosis. If an anatomic abnormality can be identified as a cause of rectal prolapse, a sweat chloride test is not usually indicated.[24]

Treatment

In general, the treatment of rectal prolapse is nonoperative and directed at the underlying condition predisposing the patient to prolapse. Initial management consists of manual reduction and the administration of bulk laxatives or stool softeners.

If prolapse is a persistent problem, surgical intervention may be required. Injection sclerotherapy with D50W (dextrose 50% in water) or hypertonic saline is an effective treatment with few complications.[25] Sclerotherapy can be accomplished by injecting no more than 1 cc/kg of D50W submucosally or submuscularly above the dentate line.

More aggressive surgical efforts may be needed for prolapse that fails sclerotherapy and in children with pelvic anatomic distortion caused by previous surgery. A variety of surgical procedures have been developed to treat rectal prolapse, but there is no consensus on the operation of choice. Surgery may be relatively simple, such as encircling the anus with a suture,[26] or involve complex operations such as posterior repair and suspension,[27] transsacral rectopexy,[23] transabdominal rectopexy with resection,[28] and posterior sagittal anorectoplasty.[29] Recent series advocate for the laparoscopic treatment of rectal prolapse. This minimally invasive technique allows for either a simple rectopexy or a more elaborate rectosigmoid resection for the treatment of prolapse. Regardless of the approach, the prognosis is generally good.

PILONIDAL DISEASE

A pilonidal abscess is an inflammatory cavity overlying the sacrococcygeal region in the midline and is often accompanied by multiple draining sinus tracts (Figure 35-3).

Pathogenesis

A pilonidal sinus begins in the natal cleft at the site of an ingrown hair follicle. It commonly presents 1 or 2 inches above the anus and leads into a cavity underlying the skin. The result is a pilonidal cyst that may drain spontaneously. If the superficial opening of the tract is occluded, a pilonidal abscess will form.

Clinical Presentation and Diagnosis

A pilonidal abscess presents with persistent pain in the region of the sacrum accompanied by a boil located in the midline just above the anus. The diagnosis is made on physical examination that includes a rectal examination. A pilonidal abscess that drains spontaneously often results in a chronic pilonidal sinus. A pilonidal sinus tract is usually a slightly sore spot and can be a source of bloodstained or cloudy drainage that soils the underclothes.

Treatment

If a pilonidal abscess or fistula is found, the patient should be referred for operative management. Primary treatment involves incision and drainage of any acute abscess. After resolution of the abscess, the traditional procedure of choice involves the subsequent wide excision of the underlying cyst and fistulous tracts, with the wound left to close by secondary intent. More recent experience has shown that excision of the cyst and primary closure of the wound can be attempted in most cases provided that there is careful follow-up. When successful, this latter technique allows for rapid healing and less discomfort to the patient.

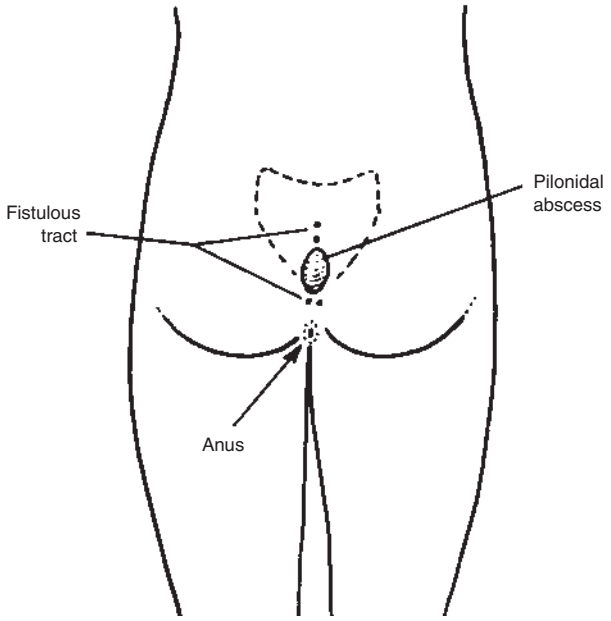

FIGURE 35-3 A pilonidal abscess and its associated tracts are shown in relation to the sacrum.

PRURITUS ANI

Pruritus ani simply implies persistent anal itching. It is a common skin condition and very frequently misdiagnosed as "hemorrhoids." Pruritus can be grouped into either primary or secondary etiologies.

Pathogenesis

Most cases of pruritus ani are secondary in nature, with primary pruritus ani being a diagnosis of exclusion. Secondary pruritus is usually the result of chronic moisture exposure, pinworm (*Enterobius vermicularis*) infection, or excessive use of soaps and detergents. Caffeine intake, which reduces anal pressure, is the most common cause of pruritus ani in older subjects. Aggressive use of soaps and detergents perpetuates the problem of pruritus ani by changing cutaneous pH and stripping the natural oils of the skin.

Pinworm is a contagious intestinal parasite infestation that is common in children. It is found throughout the United States and is especially prevalent in urban areas and day-care settings. Approximately 20% of children in the United States will develop pinworm at some point in their lives. The parasite is easily spread through a fecal-oral route. The adult parasite lives in the cecum and colon and lays its eggs outside the anus during the night.

Clinical Presentation and Diagnosis

Patients typically present with persistent anal itching that is unrelenting. Other symptoms include irritability, sleep disturbance, decreased appetite, excoriation around the anus from constant scratching, and vaginal irritation.[30] Adults and siblings exposed to children with pinworm may also note symptoms shortly after exposure. Pinworm can be easily diagnosed by applying transparent adhesive tape to the skin around the anus before bathing or using the toilet in the morning. The tape is then transferred to a slide, where the presence of pinworm eggs may be confirmed by microscopy.

Treatment

Because most causes of anal pruritus are secondary, treatment should be directed at the underlying etiology. This is not to imply that all pruritus ani is easily treated because it can be the result of a self-perpetuating cycle. A complete anal and rectal examination should be performed to look for specific causes, especially pinworm. A thorough history of dietary and hygiene habits is also helpful.

For pinworm infestation, initial treatment consists of patient and family education about hygiene and fecal-oral spread.[31] General measures, such as hand washing, keeping fingernails short and clean, laundering all bed linens twice weekly, and cleaning toilet seats daily, can usually eliminate the problem in 1 to 2 weeks. If this fails, all family members must be treated with pyrantel pamoate or mebendazole.[32] To be successful, drug therapy needs to be repeated in 2 to 3 weeks.

For pruritus ani not attributable to pinworm reassurance, patient education and follow-up are key elements of treatment. Stopping scratching, although difficult to do, can often break the itching cycle. Excessive anal hygiene habits and use of ointments, steroids, and anesthetic agents should be discouraged. Food sensitivities may exist to spices, coffee, milk, and chocolates. The aim of treatment is to achieve clean, dry, intact skin. In selected cases, some medications may also be of assistance, such as psyllium (promotes complete evacuation) and loperamide (increases resting anal pressure).

Although disturbed sphincter function has been proposed as causative (primary pruritus ani), it is an infrequent etiology. Generally, surgical intervention should be discouraged. When extensive tags or prolapsed tissue appears to contribute to poor hygiene, an operation may be considered.

CHAPTER 36

THE SURGICAL ABDOMEN

David A. Lloyd, MChir, FRCS, FCS(SA)
Simon Edward Kenny, BSc(Hons), MB ChB(Hons), MD, FRCS(Paed Surg)

The term "surgical abdomen" describes a constellation of symptoms and signs indicative of an intra-abdominal process that may require surgery. A degree of urgency is usually implied. The processes underlying the surgical abdomen include intestinal obstruction and peritonitis owing to inflammatory conditions such as appendicitis. This chapter reviews the more common causes of these processes and their differential diagnoses, some of which are addressed in greater detail in other chapters. Congenital intestinal conditions requiring surgical management are discussed in Chapter 32, "Congenital Anomalies."

INTESTINAL OBSTRUCTION

General Features and Principles of Management

The cardinal features of intestinal obstruction are bile-stained (green) vomiting, abdominal distention, failure to pass stool, and colicky abdominal pain. The clinical picture depends on the level of obstruction and the presence of complications, notably strangulation. With proximal obstruction, vomiting and colicky pains occur early, and distention is confined to the epigastrium. In more distal small bowel obstruction, the vomiting may be less frequent, and as a result of stasis and bacterial overgrowth, the vomitus becomes foul smelling and feculent. The abdomen becomes distended, and loops of bowel may be palpated. Visible peristalsis may coincide with episodes of abdominal colic. With a complete obstruction, no stools will be passed once the distal bowel has evacuated, and, typically, the rectum is empty. The finding of abdominal tenderness in a child with features of obstruction may indicate progressive intestinal ischemia. Colonic obstruction leads to marked abdominal distention, cramping pains, and cessation of stools; vomiting is a later feature.

Imaging. Plain abdominal radiography is the most commonly used imaging method for confirming the diagnosis of intestinal obstruction, and, in many cases, the level and possibly the cause of obstruction may be identified. In most cases, the supine abdominal view showing dilated proximal bowel and absence of gas distally will suffice (Figure 36-1A); erect abdominal radiographs will show air-fluid levels but are rarely needed for diagnosis and can be omitted (Figure 36-1B). Contrast x-ray examinations are useful in specific situations and should be planned in consultation with a radiologist. For example, an upper gastrointestinal study is useful for identifying duodenal malrotation with or without volvulus, whereas an air or contrast enema is helpful for suspected intussusception. In general, low-osmolality water-soluble contrast materials are used. Ultrasonography has a limited role in the diagnosis of intestinal obstruction but may be of value in malrotation by identifying the relative positions of the superior mesenteric artery and vein and in the diagnosis of intussusception.

Management. The general principles of management include nasogastric drainage, intravenous fluids, and pain control. A large nasogastric tube is passed to prevent vomiting and reduce gastric secretions and is firmly secured to the face. In small infants, an orogastric tube may be preferred. The tube is left on continuous drainage and is regularly flushed with air or water and aspirated to confirm that it is functional.

There are two phases to intravenous fluid therapy: resuscitation and maintenance. The initial fluid deficit is corrected using 0.9% (normal) saline or Ringer lactate at 3 to 6 mL/kg/h, depending on age and weight, and supplemented, if indicated, by a 20 mL/kg bolus of the same solution, repeated as required. In newborn infants, care must be taken not to overload the circulation with fluid or sodium. This is followed by maintenance infusion of Ringer lactate or 0.45% (half normal) saline with potassium chloride 10 to 20 mmol/L at 2 to 5 mL/kg/h to provide for maintenance requirements, plus anticipated ongoing hidden fluid losses into the obstructed bowel. Dextrose 5 or 10% is added to prevent hypoglycemia. Gastric aspirates are replaced with equal volumes of normal saline. Hydration is monitored by clinical assessment of the peripheral circulation and by accurate monitoring of the urine volume (normal = 1 to 2 mL/kg/h depending on age) and specific gravity (normal 1.008 to 1.012). Serum electrolytes and acid-base balance are monitored. Urine sodium estimations are useful for interpreting renal function. Based on these findings, the volume of intravenous fluid is increased or decreased every 4 to 8 hours, the frequency of assessment depending on the individual clinical situation.

With few exceptions, the definitive management of intestinal obstruction requires urgent operation. This should

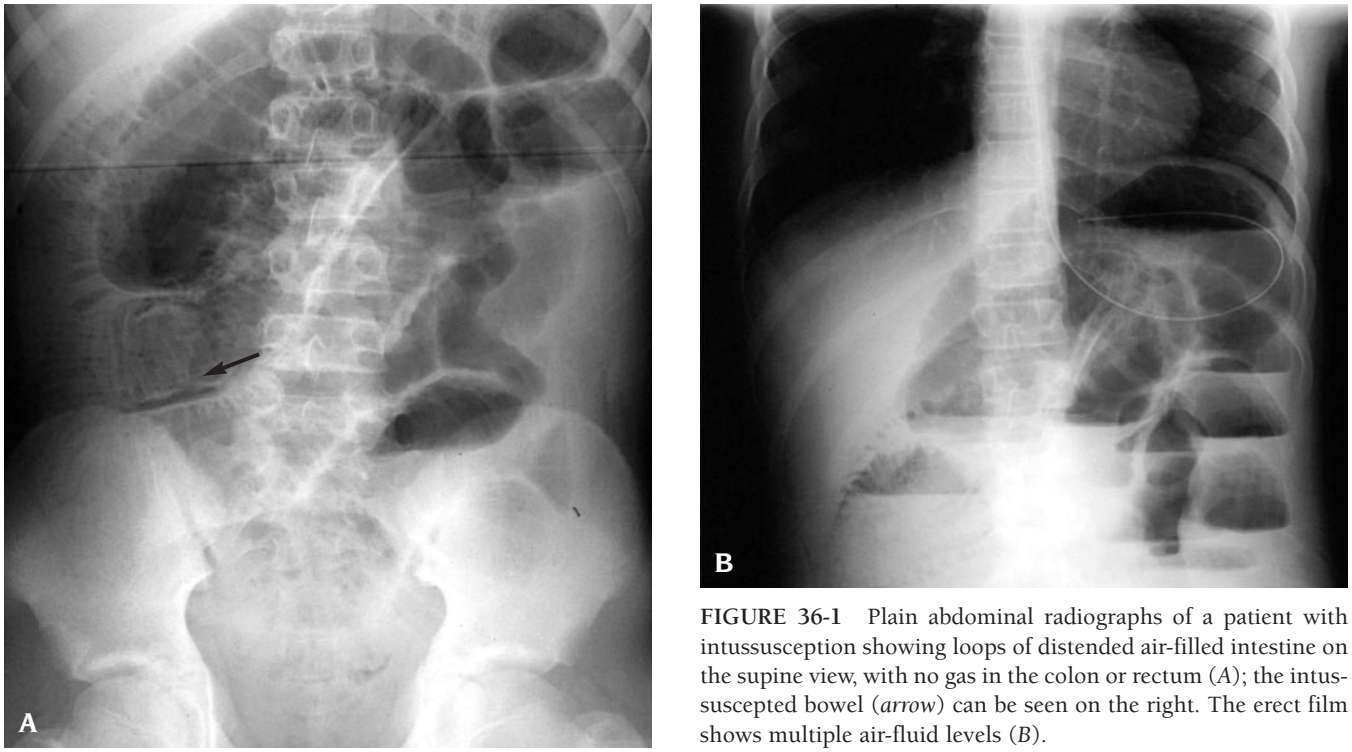

FIGURE 36-1 Plain abdominal radiographs of a patient with intussusception showing loops of distended air-filled intestine on the supine view, with no gas in the colon or rectum (*A*); the intussuscepted bowel (*arrow*) can be seen on the right. The erect film shows multiple air-fluid levels (*B*).

be undertaken only after the patient has been adequately resuscitated with correction of fluid, electrolyte, and acid-base abnormalities. The urgency for operation depends on whether there is clinical evidence that intestinal viability is being compromised, as in the case of an incarcerated hernia, complicated intussusception, or intestinal volvulus. Operation may be delayed when the diagnosis is clear and there is a possibility that the obstruction will resolve spontaneously, for example, with postoperative adhesive obstruction or intramural hematoma of the intestine.

For simple (uncomplicated) intestinal obstruction, nonoperative therapy with nasogastric drainage and intravenous fluids may be continued as long as there is evidence of progressive resolution of the symptoms. If there is no improvement by 12 to 24 hours, operative intervention generally is advisable, depending on the individual situation, including the presence of coexisting disease. Intravenous feeding should be considered in situations in which intravenous therapy and the period of enteral starvation are likely to be prolonged.

Simple obstruction may progress to complicated obstruction if the viability of the intestine becomes compromised owing to strangulation or volvulus. In this situation, there will be evidence of local or generalized peritonitis, notably abdominal distention with tenderness and guarding. There is a progessive deterioration in the condition of the patient with increasing oxygen requirement, tachycardia, hypotension, peripheral vasoconstriction, and oliguria owing to a combination of intraluminal fluid loss and septicemia caused by translocated enteric bacteria and toxins. Urgent laparotomy is required after full resuscitation and administration of broad-spectrum antibiotics with activity against aerobic and anaerobic bacteria. Causes of intestinal obstruction are summarized in Table 36-1.

Incarcerated or Strangulated Inguinal Hernia

Congenital inguinal hernia is the presence of an abdominal viscus in the processus vaginalis (hernia sac), usually the small intestine but occasionally the ovary. Spontaneous resolution does not occur, and because of the high risk (10–28%) of incarceration during the first 3 months of life, and hence strangulation, prompt operation is advised.[1] If possible, this is done within 7 days of diagnosis, provided that the infant is fit for general anesthesia.

The infant with an incarcerated hernia is admitted to hospital and sedated; the hernia is then gently reduced. The hernia is repaired after an interval of 2 days to allow tissue swelling to resolve. If reduction by taxis is not easily achieved, the attempt is abandoned, and urgent operation is undertaken to reduce and repair the hernia. When strangulation has occurred, the infant is ill and shows features of intestinal obstruction. The hernia is tender, and the overlying skin may be inflamed. Urgent resuscitation is followed by emergency repair of the hernia, potentially an extremely difficult operation. In addition to causing intestinal ischemia, a strangulated hernia may compress

the spermatic cord, resulting in testicular ischemia and, subsequently, atrophy.[2]

Meckel Band Obstruction

The primitive omphalomesenteric duct persists as a solid band between the umbilicus and a Meckel diverticulum of the small intestine (see Chapter 32). Intestinal obstruction may result from entrapment of a loop of intestine or volvulus around the band. Urgent surgery is required to prevent strangulation; at surgery, the obstruction is relieved, and the Meckel diverticulum is resected.

Peritoneal Adhesions

Adhesions within the peritoneal cavity occur most commonly following a surgical procedure but may also occur as the result of inflammatory and infectious conditions not requiring surgery or following radiotherapy. Adhesive obstruction is the result of entrapment of bowel loops and may lead to closed-loop obstruction and strangulation.

Postoperative adhesions occur to some degree in most patients following laparotomy, in particular for inflammatory conditions such as appendicitis, and in areas of serosal damage or intestinal ischemia. There is no reliable method for preventing adhesions. In the neonate, the most common associated conditions are gastroschisis and malrotation.[3] Obstruction may occur at any time after a laparotomy; in the report by Janik and colleagues, 80% of adhesive obstructions occurred within 2 years of the original operation,[4] and Wilkins and Spitz found that 75% occurred within 6 months and 90% within 12 months.[3]

The diagnosis must be suspected in any patient who presents with clinical and radiologic features of intestinal obstruction and has had previous abdominal surgery. Patients who have radiotherapy may present many years later; the possibility of recurrent tumor must also be borne in mind. Initial management is nonoperative, as discussed above, and in most patients, the obstruction will resolve within 24 to 48 hours. Because of the risk of strangulation, operation is advisable if there is no improvement within 6 to 12 hours. Urgent operation is indicated if there is unremitting abdominal pain, fever, tachycardia, abdominal tenderness, and guarding.

Hypertrophic Pyloric Stenosis

Hypertrophic pyloric stenosis (HPS) is the most common condition requiring surgery in the first 2 months of life. The incidence is approximately 2 to 3 per 1,000 live births, but there are wide geographic variations, and increasing[5,6] and decreasing[7–9] incidences over the past three decades have been reported. The underlying mechanism for HPS is not understood; in some infants, we have observed spasm of the pyloric muscle progressing to hypertrophy and evolution of the obstructive pyloric mass. Relaxation of the pyloric muscle appears to be dependent on inhibitory innervation through the nonadrenergic, noncholinergic neural system, mediators of which have been shown to be reduced or absent, notably certain neuropeptides and nitric oxide.[10] Other neural components, including the interstitial cells of Cajal,[11] neurotrophins, synapse formation, and neural supporting cells, have also been shown to be abnormal. The etiology of pyloric stenosis is not known, but a higher incidence in infants with a family history of HPS suggests a genetic predisposition.[12]

HPS is characterized by elongation and narrowing of the pyloric lumen; secondary gastritis and mucosal edema result in virtually complete obstruction. Typically, infants are well for the first 2 to 3 weeks of life. Nonbilious vomiting then begins intermittently after feeds, progressively increasing in frequency and volume, leading to dehydration, weight loss, and constipation. The vomitus may contain altered blood from secondary esophagitis or gastritis. Affected infants presenting late can be profoundly dehydrated with severe metabolic alkalosis. On examination, peristaltic waves may be seen traversing the epigastrium from left to right. Palpation of the pyloric tumor is diagnostic. Examination must be done with the stomach empty and the infant relaxed. This is achieved by aspirating the stomach through a nasogastric tube; the hungry infant is relaxed by allowing it to drink an electrolyte solution while the abdomen is palpated above and to the right of the umbilicus, the fingers probing under the liver. If the clinical findings are inconclusive, the diagnosis can be confirmed by ultrasonography (Figure 36-2) or contrast meal. HPS must be distinguished from gastroesophageal reflux, in which the vomiting is usually present from birth. Imaging studies and gastroscopy will clarify the diagnosis.

FIGURE 36-2 Idiopathic hypertrophic pyloric stenosis: sonogram showing the thickened pyloric muscle constricting the lumen (*arrow*).

Preoperative correction of fluid, electrolyte, and acid-base abnormalities, typically hypochloremic metabolic alkalosis, is essential. A nasogastric tube is passed to empty the stomach and for saline irrigations to alleviate the gastritis by removing residual feeds. Intravenous fluids are given as 0.45% saline with 10% dextrose and potassium chloride 20 mmol/L at an initial rate of approximately 5 to 6 mL/kg for 24 hours. Nasogastric aspirates are replaced with equal volumes of normal saline. Because of the risks of postoperative apnea and cardiac arrhythmia, surgery should not be undertaken until the serum electrolyte and blood gas levels have returned to normal.

Ramstedt pyloromyotomy, introduced in 1912, remains the treatment of choice. The pylorus is approached through a transverse right upper quadrant or a periumbilical incision.[13] A longitudinal incision along the pyloric tumor is deepened by blunt dissection to expose the mucosa. Laparoscopic pyloromyotomy is an established option.[14]

Postoperatively, oral feeds are given on demand, beginning with a small volume and increased progressively as tolerated. Most infants can be discharged 24 to 48 hours after operation. Postoperative complications include wound infection and dehiscence. Persistent vomiting after surgery is more common in younger infants and may reflect relative immaturity of the lower gastroesophageal sphincter[15]; rarely, it is due to unrecognized iatrogenic duodenal perforation or inadequate pyloromyotomy.

Meconium Ileus Equivalent (Distal Intestinal Obstruction Syndrome)

Patients with cystic fibrosis may develop acute intraluminal obstruction mimicking neonatal meconium ileus. This has been attributed to inadequate enzyme replacement therapy or dehydration. Oral Gastrografin may clear the obstruction; it is rare for surgery to be required.[16]

Milk Curd Inspissation

Obstruction by inspissated milk curd has been reported and is attributed to the use of concentrated formula preparations. If irrigation under radiologic control is unsuccessful, laparotomy is required to relieve the obstruction.[17]

Foreign Body Ingestion

Children frequently swallow coins, toys, and other objects, which usually impact in the esophagus. Retained esophageal foreign bodies require urgent removal, particularly button batteries and pins because these have the potential to cause esophageal ulceration or perforation, leading to mediastinal abscess or acquired tracheoesophageal fistula, and, rarely, aortoenteric fistula. Those that enter the stomach are likely to be passed per rectum but, occasionally, become impacted en route. The diagnosis is confirmed by plain radiography provided that the object is radiopaque. Commercially available metal detectors have been found to be as useful as radiographs for screening.[18] Patients who are asymptomatic are allowed a normal diet and are kept under observation as outpatients until the object has been retrieved. Special diets and laxatives are not necessary. If symptoms develop, or if the object remains in the stomach or becomes impacted in the intestine, it should be removed, particularly if it is a button battery, needle, or pin. Endoscopic removal from the stomach is often possible.

Intestinal Strictures

Pathologic narrowing of the intestine results in partial or complete obstruction. Local injury and impaired flow may result in fibrous strictures, for example, following blunt abdominal trauma or at the site of an intestinal anastomosis. Inflammatory strictures may complicate chronic diseases such as Crohn disease and intestinal tuberculosis.

Superior Mesenteric Artery Syndrome

In this rare condition, the third part of the duodenum is obstructed as it passes between the superior mesenteric artery anteriorly and the verterbral column posteriorly. Predisposing factors include rapid linear growth without weight gain, weight loss, scoliosis, spinal surgery, confinement to bed, and use of a body cast. The mechanism is not known, but absence of a cushion of retroperitoneal fat may be a factor.

The clinical features are nonspecific, with intermittent abdominal pain associated with anorexia, nausea, and bilious vomiting. Abdominal examination may reveal a succussion splash. A dilated stomach and proximal duodenum may be seen on plain abdominal radiography, and an upper intestinal contrast study will demonstrate partial obstruction in the third part of the duodenum (Figure 36-3). Management includes nasogastric drainage and intravenous fluids, depending on the severity of symptoms. Occasionally, intravenous feeding is advisable. With improved nutrition, symptoms may resolve. Occasionally, operative treatment is

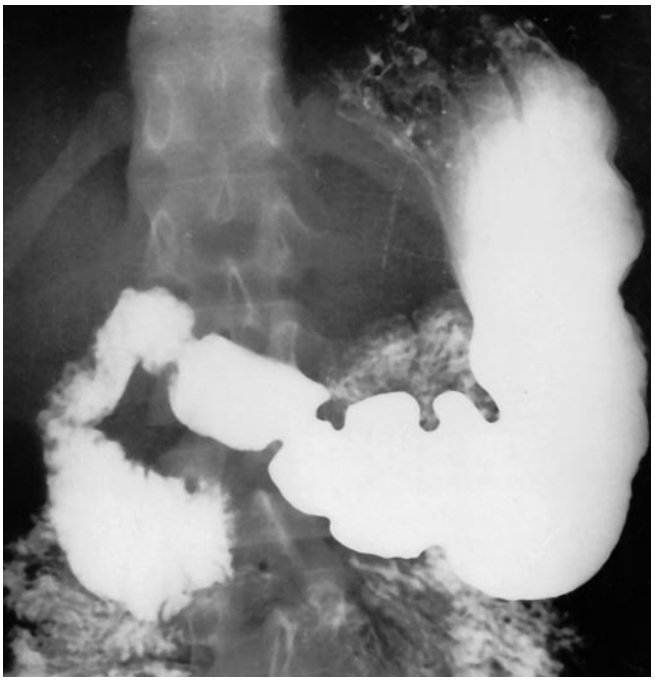

FIGURE 36-3 Superior mesenteric artery syndrome: contrast study showing partial obstruction in the third part of the duodenum by the superior mesenteric artery.

required to mobilize the ligament of Treitz and realign the duodenum; duodenojejunostomy has also been used.

Disordered Peristalsis

Paralytic Ileus. Paralytic ileus is a form of functional intestinal obstruction owing to transient loss of intestinal peristaltic activity. It is common to some degree after most abdominal operations. The causes include local factors, notably peritonitis, intestinal ischemia, surgical manipulation, retroperitoneal bleeding, or spinal surgery, and systemic factors, such as sepsis syndrome, hypokalemia, diabetic ketoacidosis, and uremia. The clinical picture resembles mechanical obstruction except for the absence of bowel sounds, an important diagnostic feature. On plain abdominal radiography, usually there is gas throughout the small and large intestine with no focal point of obstruction. Management is expectant, with nasogastric drainage and intravenous fluids.

Chronic Idiopathic Intestinal Pseudo-obstruction. Chronic idiopathic intestinal pseudo-obstruction is a rare cause of functional obstruction in children with ganglionic bowel. Acute episodes of intestinal obstruction may occur on a background of chronic peristaltic dysfunction. Treatment of these episodes is symptomatic, avoiding laparotomy if at all possible because this causes diagnostic problems for future episodes by introducing the possibility of adhesive obstruction.

CHILD WITH ACUTE ABDOMINAL PAIN

When evaluating a child with an acute abdomen, a thorough history and physical examination are essential to exclude nonsurgical and extra-abdominal conditions that may present with the clinical features of the surgical abdomen. These range from infective conditions such as acute tonsillitis and lower lobe pneumonia to vertebral discitis and metabolic conditions, including porphyria and lead poisoning.

The evaluation of the child with abdominal pain remains a challenge, and good interaction among the surgeon, child, and parents is essential. Successful evaluation requires patience and often deviates from the normal pattern of history taking and examination. General principles include addressing the child directly whenever possible and allowing time for him or her to answer questions; these should give the child several options without biasing the choice of answer: for example, "Is the pain getting better, worse, or staying the same?" "Is the pain bad all the time, or does it come and go?" As with all patients, showing an interest in the child as a person often helps build their confidence. No diagnostic information can be gleaned by attempting to examine the abdomen of a crying child who is being pinned to the examination couch. Often children pick up on the anxiety of the parents, and attempts should be made to calm their fears. In many cases, abdominal examination is best performed in an unorthodox manner; for example, the child on a parent's lap or standing up often feels safer and will relax, allowing relevant clinical signs to be detected. A useful strategy in the case of the uncooperative child is to defer examination until the child has been admitted; the fretful tearful child in the emergency room is often more cooperative when in the calm of a ward in a comfortable bed. Play specialists can also be invaluable when assessing children or if any invasive procedures need to be performed. Honesty with the child at all times is paramount; reassuring the child that a painful procedure will not hurt works only once, and all trust is then lost. This is not a minor consideration because doctor and needle phobia are real phenomena that may have lasting consequences on the future health of the individual.[19]

Some causes of abdominal pain in children are listed in Table 36-2. The clinical skills required to differentiate between them should not be underestimated. The choice of diagnostic methods will depend on the clinical picture. Ultrasonography, plain and contrast radiography studies, urine culture, serum amylase estimation, and upper and lower intestinal endoscopy all have a role.

The general principles of management for the child with acute peritonitis are similar to those for acute intestinal obstruction and include nasogastric drainage, intravenous fluids to correct hypovolemia and electrolyte and acid-base abnormalities, analgesia, and antibiotics.

Appendicitis

Appendicitis can be particularly difficult to diagnose in the very young and the neurologically impaired. Young children with appendicitis invariably present late, and perforation at the time of presentation is common in those under the age of 5 years. Abdominal signs can be subtle, and true peritonism may be absent. Abdominal distention is a common finding. Ultrasonography and/or computed tomography (CT) may provide useful diagnostic information in equivocal cases and save unnecessary surgery. Careful assessment for dehydration or shock is essential, and vigorous intravenous fluid resuscitation and intravenous antibiotics should be instituted when necessary, in addition to adequate intravenous opiate analgesia. The choice between an open or laparoscopic approach to appendicectomy in children remains controversial,

TABLE 36-2 SELECTED CAUSES OF ABDOMINAL PAIN IN CHILDHOOD

Appendicitis
Mesenteric adenitis

Ovarian cyst
Ovarian torsion
Ovulatory/perimenstrual pain
Urinary tract infection

although a recent systematic review concluded that laparoscopic appendicectomy was "likely to be beneficial" when performed by an experienced laparoscopist.[20] Robust peripheral or central venous access inserted at the time of anesthesia is important to enable administration of postoperative intravenous fluids and antibiotics, particularly in cases of perforated appendicitis.

Mesenteric Adenitis

Inflammation of the mesenteric lymph nodes, particularly in the ileocecal region, may present with acute right iliac fossa pain mimicking appendicitis. A confident diagnosis of mesenteric adenitis can be made only when a definite cause can be identified, either abdominal or extra-abdominal, for example, acute tonsillitis. In the absence of a definitive diagnosis, acute appendicitis must be assumed to be the cause of the symptoms until positively excluded by direct inspection at laparotomy or laparoscopy or by reliable imaging. Tests such as the white blood cell count and C-reactive protein levels are not sufficiently specific but may provide useful correlates to clinical assessment.[21–23] Localized right iliac fossa contrast-enhanced CT has been shown to be highly specific and sensitive in adult patients admitted following surgical appraisal,[24] but its diagnostic value in children has not been rigorously evaluated.

Intussusception

With intussusception, a segment of bowel telescopes into the adjacent distal bowel, causing intestinal obstruction and impairing blood flow through the intussuscepted bowel segment. Although not confined to children, the peak incidence of intussusception is between 4 and 14 months, when most cases of intussusception are idiopathic, although enlarged gut-associated lymphoid tissue (Peyer patches) secondary to increased exposure to novel antigens during weaning may play a role as a lead point. In older children, a pathologic lead point such as a Meckel diverticulum or small bowel lymphoma may be found. Typically, infants will experience colicky abdominal pain often associated with bilious vomiting. The passage of blood and mucus per rectum is a later sign of intussusception. Most morbidity and mortality from intussusception arise from delays in diagnosis, and a high index of suspicion should be maintained. Between bouts of colic, infants are quiet but irritable, with evidence of hypovolemia. The characteristic sausage-shaped abdominal mass may be palpated between spasms of pain. Some children present atypically with lethargy but no colic; mild abdominal tenderness and mucoid rectal blood may be the clue to the cause. Hypovolemia is invariable, and vigorous fluid resuscitation with supplemental oxygen is often required. A plain abdominal radiograph will show nonspecific features of intestinal obstruction; occasionally, the outline of the intussuscepted bowel can be identified (see Figure 36-1). The diagnosis can be confirmed by ultrasonography (Figure 36-4) or, failing this, by contrast enema. Treatment is by either pneumostatic or hydrostatic reduction through a rectal Foley catheter under controlled pressure conditions by an experienced radiologist. Possible complications of this procedure include intestinal perforation and tension pneumoperitoneum. Children must be adequately resuscitated before the reduction and monitored by staff trained in advanced life support during the procedure. Enema reduction is contraindicated in children in refractive shock or with signs of peritonitis. In a minority of patients, reduction is unsuccessful, and open surgical reduction is then required. In advanced cases, the necrotic intussusception will need to be resected. Children over 2 years of age who are successfully treated nonoperatively must be investigated subsequently to exclude underlying pathology; this may include contrast radiography and colonoscopy.

Ileoileal intussusception is a rare cause of obstruction in the early postoperative period following abdominal surgery, probably the result of uncoordinated peristaltic activity. Diagnosis is difficult because the contrast enema will not show the obstructed ileum, and ultrasonography may be compromised by distended loops of bowel. Often the diagnosis is made at laparotomy for intestinal obstruction. Ileoileal intussusception can also occur in Henoch-Schönlein purpura and rarely may be the presenting sign. Such intussusceptions may spontaneously reduce, and if the child remains stable, with no signs of vascular compromise, a period of nonoperative observation may avoid the need for laparotomy.

Midgut Malrotation

Although volvulus complicating to midgut malrotation characteristically occurs in infancy (Chapter 32), duodenal malrotation or nonfixation of the cecum may allow intermittent volvulus to occur in later years. Most episodes are self-correcting and are not associated with intestinal ischemia, but acute strangulation remains a risk. Patients present with intermittent abdominal pain with or without

FIGURE 36-4 Intussusception: transverse sonogram showing the "doughnut sign." The arrowheads indicate the intussuscepted bowel.

vomiting and a history of chronic constipation. Upper and lower intestinal contrast studies, preferably while the patent is symptomatic, may reveal the diagnosis.

Gastroenteritis

Acute gastroenteritis may present with colicky abdominal pain. The presence of vomiting and diarrhea points to the diagnosis. Sudden cessation of stools and increasing pain raise the possibility of secondary intussusception.

Constipation

Childhood constipation, defined as the infrequent painful passage of stools, with or without soiling, is extremely common in the West as a consequence of both diet and parental and societal attitudes to toileting. It can be difficult to determine the pathologic basis of constipation in a child, and careful history taking is important. Although most cases are idiopathic, constipation may be a presenting feature of a wide range of disorders. Clinical examination should include evaluation for a pelvic mass, anorectal pathology, and neurologic deficit, including examination of the lumbar-sacral spine. When constipation first develops after the first few months of life, the incidence of Hirschsprung disease and related disorders is very low. Overinvestigation by invasive measures such as rectal biopsy may only increase parental anxiety, in addition to potentially increasing aversive behavior in the child. Typically, childhood constipation is characterized by avoidance of stooling, when the child will retain feces, which become increasingly firm and bulky, making defecation painful and provoking further retentive behavior. Fecal soiling owing to paradoxical overflow incontinence is common. Therapy should be centered on clear explanation of the nature of the problem and advice on diet, toileting, and stimulant and osmotic laxative use. Enemas are rarely required but can be of use where there is considerable fecal loading. Manual evacuation is occasionally useful in children who refuse enema treatments. The key to successful treatment of childhood constipation is a good relationship and clear communication among the clinician, the child, and the parents.

Parasitic Infestation: Ascariasis

The roundworm *Ascaris lumbricoides* is one of the most common human parasites. Infestation occurs as a result of ingesting larvae, which mature in the small intestine to reach 20 to 30 cm in length. Congregation of a large number of worms may obstruct the intestine, resulting in colicky abdominal pain mimicking intussusception (Figure 36-5). The diagnosis is suspected when there is a history of passing worms in the stool and more than one abdominal mass is palpated. The worm bolus may be visible on a plain abdominal radiograph (Figure 36-6). When in doubt, intussusception is excluded by sonogram or contrast enema. Management of *Ascaris* obstruction includes intravenous fluid replacement, with nasogastric drainage if there is significant vomiting. An intravenous antispasmodic (scopolamine butylbromide [Buscopan]) and an analgesic may be required for the colic. When the acute symptoms have abated, usually after 24 to 48 hours, an antihelminthic, for example, piperazine or mebendazole, is administered orally.[25] Dead worms may precipitate local intestinal inflammation, necrosis, and perforation, and antihelminthic therapy therefore should be avoided in the presence of acute bolus obstruction. Intestinal ascariasis may be complicated by intussusception, small bowel volvulus, or appendicitis.

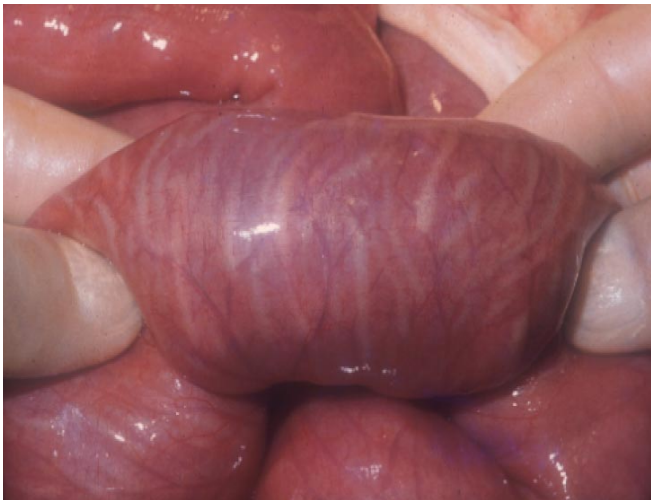

FIGURE 36-5 A bolus of *Ascaris lumbricoides* obstructing the small intestine.

Intestinal ascarids may enter the biliary tree, causing biliary colic and acute pancreatitis. Infestation of the intrahepatic ducts may lead to secondary abscess formation

FIGURE 36-6 Plain abdominal radiograph of a child with *Ascaris* obstruction. Note the large mass of intraluminal worms.

(Figure 36-7).[26] Biliary ascariasis is initially treated with intravenous fluids, an antispasmodic, and analgesia, and, in most instances, the worm will evacuate the common duct. As soon as the symptoms have resolved, an oral antihelminthic is administered. If the biliary symptoms do not resolve within 24 to 48 hours, the worm may be removed endoscopically or by open operation. Intrahepatic worms are removed by direct exploration. Late complications include biliary and pancreatic duct strictures.

Intestinal Polyps

Intestinal polyps commonly present with colicky abdominal pain, which may be accompanied by the passage of blood in the stools. The "juvenile" polyp encountered in the rectum or colon and Peutz-Jeghers polyps are benign hamartomatous lesions; true adenomatous polyps may occur in isolation or as a manifestation of familial adenomatous polyposis. The initial investigation of choice is endoscopic biopsy or excision.

Pancreatitis

Pancreatitis is uncommon during childhood and may present as acute pancreatitis, as chronic relapsing pancreatitis, or in association with trauma. Acute pancreatitis may follow viral illness such as mumps, or in children with predisposing factors such as hyperlipidemia, cystic fibrosis, and polyarteritis nodosa. Gallstone pancreatitis is rare. Pancreatitis may complicate intestinal ascariasis. More usually, no predisposing factors can be identified. Chronic relapsing pancreatitis may lead to progressive irreversible changes in the pancreas; it is uncommon in childhood but should be suspected in the child with recurrent upper abdominal pain. There is a range of causes, including congenital pancreaticobiliary malunion.[27]

Diagnosis of acute pancreatitis is by detection of raised serum or urinary amylase levels (more than five times normal levels). Supportive treatment with intravenous fluids, analgesia, and antibiotics is often the only treatment required. Severe fulminant pancreatitis is fortunately rare and may follow severe systemic upset, such as burns or septicemia. Surgery in the form of necrosectomy is only rarely indicated and of no proven benefit in terms of outcome.

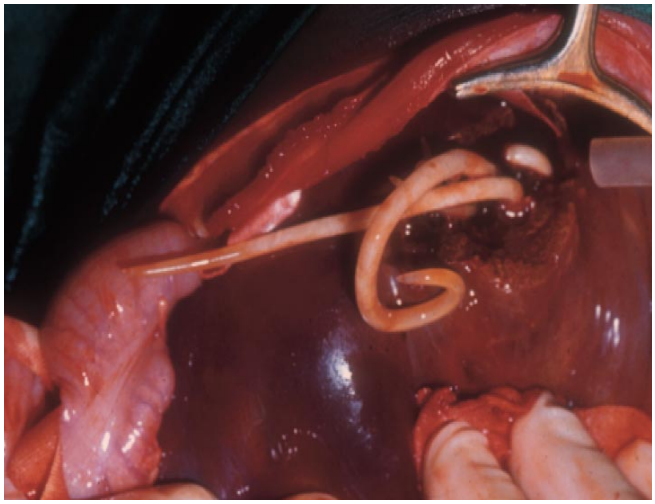

FIGURE 36-7 A nest of *Ascaris* worms being evacuated from the liver of a child with intestinal and biliary worms.

Cholecystitis

Gallstones are an uncommon cause of abdominal pain in childhood but should be considered in children with right upper quadrant pain and pyrexia. A family history of gallstones and a predisposing hemolytic condition such as sickle cell anemia or hereditary spherocytosis are important diagnostic clues. The diagnosis is also suggested by a positive Murphy sign (right upper quadrant tenderness on inspiration). Cholecystitis can be confirmed by abdominal ultrasonography, and treatment is by acute or interval cholecystectomy.

Gynecologic Causes of Acute Abdominal Pain

Adolescent girls may present with acute lower abdominal pain owing to a ruptured follicular cyst, hemorrhage into a cyst, ovarian torsion (particularly with a cyst larger than 5 cm in diameter), or premenstrual pain. Pelvic inflammatory disease may present with acute or chronic abdominal pain. When localized to the right iliac fossa, the clinical findings may mimic acute appendicitis. Ultrasonography has an important role in identifying or excluding ovarian and uterine abnormalities.[28] Urgent laparoscopy or laparotomy is indicated where acute appendicitis or ovarian torsion cannot be excluded.

Urinary Tract Infection

Urinary tract infections (UTIs) are common in children, affecting 1.5% of boys and 5% of girls by the age of 16 years.[29] UTI commonly occurs secondary to vesicoureteric reflux but may also complicate urinary tract obstruction or calculus disease, leading to suppurative pyelonephritis. Typical symptoms are pain in the lower abdomen or loin, pyrexia, and vomiting. The diagnosis is made by demonstrating bacteria on microscopy of a fresh urine specimen or pure culture of more than 10^7 bacteria/mL. The urine white cell count can be misleading because false-positives and -negatives can occur.

UTI associated with vesicoureteric reflux may lead to renal scarring and, ultimately, to hypertension or end-stage renal failure, and all children presenting with a UTI should therefore be screened with renal tract ultrasonography and technetium 99m dimercaptosuccinic acid scans regardless of age.[30] The diagnostic test for vesicoureteric reflux is a micturating cystourethrogram. Urinary tract obstruction and calculus disease are identified by ultrasonography, with specific imaging as indicated. Suppurative infection is a surgical emergency. Treatment includes oral or intravenous antibiotics and fluids and surgery as appropriate.

INFLAMMATORY CONDITIONS

Neonatal Necrotizing Enterocolitis

Necrotizing enterocolitis, a disease almost exclusively affecting premature infants, is characterized by multifocal progressive ischemic necrosis of the intestine. Predisposing factors include low birth weight, coexistent disease such as

congenital heart disease, umbilical vein catheterization, sepsis, or hypoglycemia. Necrotizing enterocolitis typically presents with the passage of blood per rectum and refusal to feed, and as the disease progresses, bilious vomiting, abdominal distention, and signs of generalized sepsis develop. Pneumatosis intestinalis and portal venous gas are the principal diagnostic radiologic features; in advanced cases, a pneumoperitoneum secondary to intestinal perforation may be seen. Most infants will respond to treatment consisting of withholding feeds, parenteral nutrition, and broad-spectrum intravenous antibiotics. Operation is indicated for complications, notably intestinal perforation or full-thickness necrosis with persistent sepsis. Percutaneous peritoneal drainage is a useful adjunct to resuscitating the low birth weight infant with perforation.[31] Subsequent surgical options will depend on the individual situation and include resection of nonviable bowel with stoma formation or primary anastomosis or stoma alone if there is extensive ischemia.

Hirschprung Enterocolitis

Hirschsprung disease may be complicated by enterocolitis, characterized by malaise, pyrexia, abdominal distention, constipation, or diarrhea. This potentially life-threatening complication can occur before or following surgery. The pathologic basis of Hirschsprung entercolitis is poorly understood and may be related to relative gut stasis, alterations of bacterial flora, and impaired mucosal or neuronal immunity. Current treatment is empiric, consisting of rectal washouts, antibiotics (vancomycin or metronidazole), probiotics,[32] and sodium cromoglycate.[33] Chemical (botulinum toxin[34] or topical glyceryl trinitrate)[35] or surgical internal sphincterotomy may be of benefit. Occasionally, it is necessary to perform an urgent colostomy.

Inflammatory Bowel Disease

Urgent operative intervention may be required for acute complications of ulcerative colitis (see Chapter 41.2, "Ulcerative Colitis") and Crohn disease (see Chapter 41.1, "Crohn Disease").

TRAUMA

Accidental injury is the most common cause of death in children over the age of 1 year. Most morbidity and mortality result from injuries to the head, but abdominal injuries account for approximately 7% of acute trauma admissions.[36]

Blunt Trauma

Falls are the most frequent cause of blunt injury, accounting for over 50% of acute trauma admissions. In Europe, motor vehicle accidents account for up to 15% of blunt injuries but are the major cause of death and disability. Motor vehicle–related trauma is also the most frequent cause of multiple injuries.

Patients with abdominal injury must be fully assessed according to Advanced Trauma Life Support guidelines.[37] The primary survey is followed by a thorough secondary survey to exclude associated injuries, particularly of the head. Surface injuries such as bruising from a seat belt or a bicycle handlebar are a clue to underlying organ injury. Management includes appropriate intravenous fluids and insertion of a nasogastric tube and urethral catheter if clinically indicated. Initial investigations include serum amylase estimation as a baseline for evolving pancreatitis and radiographs of the cervical spine, chest, and pelvis. In children, the abdomen is included with the pelvic radiograph and may reveal acute gastric distention requiring urgent decompression or pneumoperitoneum. The urine is examined for the presence of blood.

It is essential to remember that children have a considerable physiologic reserve in response to hypovolemia. Increasing heart rate, prolonged capillary return, and widening core-periphery temperature differences are early signs of significant blood loss, and changes in blood pressure and conscious state are late indicators of hypovolemic shock. Vascular access can be difficult in the child in hypovolemic shock, and an intraosseous needle may be invaluable.

Urgent laparotomy is indicated for patients who are hemodynamically unstable owing to ongoing intra-abdominal bleeding or who have evidence of peritonitis or pneumoperitoneum. For hemodynamically stable patients with clinical evidence of intra-abdominal injury, a CT scan with intravenous enhancement is the most sensitive modality for evaluating the solid intra-abdominal organs and retroperitoneum. CT is also indicated for patients with a head injury who are at high risk of abdominal injury but who cannot be evaluated clinically. Imaging is not reliable for identifying injuries to the intestine or bladder, and repeated clinical examination is essential to identify evolving peritonitis. Injuries to retroperitoneal organs, notably the duodenum and pancreas, are particularly difficult to recognize in the early phase after injury, and additional imaging may be helpful (Figures 36-8 and 36-9). Most injuries to the solid abdominal organs will heal without operative intervention. Indications for operation in stable

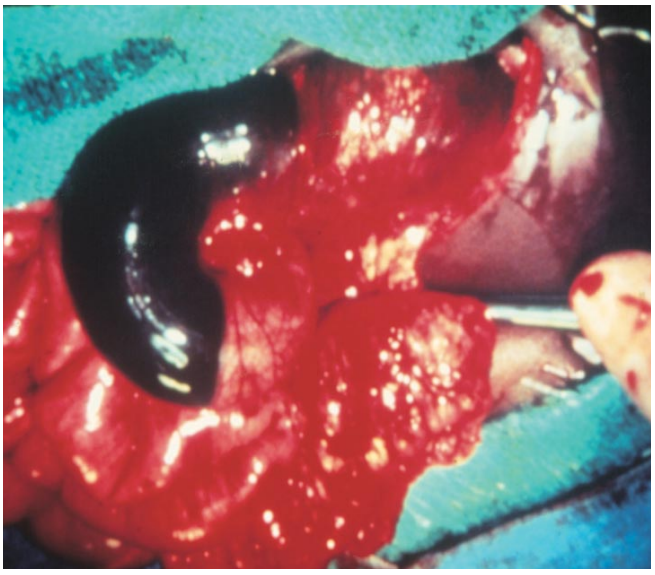

FIGURE 36-8 Operative appearance of a duodenal intramural hematoma caused by blunt abdominal trauma, in which the duodenum was crushed against the vertebral column.

FIGURE 36-9 Contrast study in a child with traumatic duodenal hematoma showing partial obstruction.

patients include ongoing bleeding exceeding 40 mL/kg (50% of the circulatory volume), clinical evidence of peritonitis, and a rising serum amylase level indicating major pancreatic duct disruption.

Penetrating Injury

The incidence of penetrating injuries owing to stabbing or shooting varies regionally and nationally according to the availability of weapons. In European countries, penetrating injuries usually result from falling onto a sharp object such as a railing fence. In a patient with an entry wound between the level of the nipples and the symphysis pubis, the possibility of an intra-abdominal injury must be considered. Unlike blunt trauma, there is a high risk of multiple intestinal injuries. If there is suspicion that the peritoneum has been penetrated, the safest approach is a laparotomy to exclude organ injury. If laparoscopy is available, this may be used to examine the integrity of the peritoneum.

Nonaccidental (Intentional) Injury

The possibility of nonaccidental injury must be borne in mind at all times, in particular with injured children under the age of 1 year. Risk factors are a delay in seeking medical attention and inconsistencies in the explanation for the injury and the circumstances surrounding it. Careful examination is essential for bruising or other marks; these may be relevant to the current injury or may indicate previous injuries. Recognition of nonaccidental abdominal injury may be difficult because of a confusing history or subtle clinical findings, and an initial misdiagnosis may lead to delayed recognition of the intra-abdominal injuries.

A team approach is important, with early involvement of social services and other child protection experts. Thorough documentation of all injuries with photographic and physical evidence when appropriate is essential. In the case of young children with perineal injury, examination under anesthesia should be considered to minimize the trauma of examinations. Any such examination must be carried out in the presence of a child protection clinician or other expert.

CHAPTER 37

APPENDICITIS

Dennis P. Lund, MD
Judah Folkman, MD

Acute appendicitis, one of the most common surgical diseases in children, is also one of the most frequently misdiagnosed. The "Holy Grail" for appendicitis, that is, a simple and fail-safe test, is constantly being sought by diagnosticians but without success. More than 115 years after the description of the pathophysiology of this disease, it frequently continues to be inaccurately diagnosed and remains a continued source of considerable morbidity and occasional mortality.

Appendicitis is the most common cause of emergency abdominal operation in children. Over 250,000 cases of acute appendicitis occur each year in the United States, and almost one-third of these occur in children. Males develop appendicitis more commonly than females (incidence ratio 1.4 to1), and the peak age of appendicitis is between 10 and 14 years in boys and 15–19 years in girls. Roughly one-quarter of cases of acute appendicitis are perforated at the time of presentation. There remains a small but definite mortality associated with acute appendicitis, and this is usually related to delayed diagnosis or concomitant diseases. It is estimated that the lifetime risk of developing appendicitis is 8.6% for males and 6.7% for females.[1]

Accurate diagnosis of appendicitis may be very difficult. It is frequently underdiagnosed, which contributes in part to a high perforation rate. However, this disease is also frequently overdiagnosed. Most institutions will report a 10 to 20% incidence of normal, or "white," appendices having been removed when patients are explored for acute appendicitis. In fact, in most training programs, it is taught that if the incidence of normal appendices is less than 10%, the rate of perforation will be unacceptably high.

Reginald Fitz first described the clinical findings of acute appendicitis in 1886. Despite the many advances of modern medicine and improvements in diagnostic accuracy with tests such as ultrasonography (US) and computed tomography (CT), there is no single test to diagnose appendicitis short of pathologic examination. The diagnosis of appendicitis requires clinical acumen; the practitioner must make use of skills in obtaining a thorough history and a careful physical examination—which are more difficult to obtain in children—coupled with close observation of the tempo of the disease.

ANATOMY AND PATHOPHYSIOLOGY

The appendix, roughly the size and shape of one's fifth finger, is a diverticulum arising from the cecum. Its length and particularly its anatomic position can be quite variable, ranging from down in the pelvis to any place on the right side of the abdomen in patients with normal intestinal rotation. Patients in whom the appendix resides in a retrocecal location can present difficult diagnostic dilemmas because of the effect this may have on the presentation and location of signs and symptoms. In those who have abnormal intestinal rotation, the location may be highly variable, confusing the diagnosis even more (Figure 37-1).

Embryologically, the cecum is visible by the fifth gestational week as an enlargement of the hindgut, and the appendix begins to appear about the eighth week. Some villi are seen in the appendix during the fourth and fifth months, but these disappear prior to birth. Lymphatic nodules will be present by the seventh month. This lymph tissue continues to increase until puberty and then slowly recedes.[2] Despite much speculation based on comparative anatomy with other mammals, the function of the appendix remains unknown.

The pathophysiologic cause of acute appendicitis is thought to be obstruction of the lumen of the appendix either by fecal matter, such as a fecalith, or by swollen lymphoid tissue. This latter cause may explain why cases of appendicitis may follow soon after a viral illness. Multiplication of bacteria in the obstructed viscus leads to swelling and invasive infection of the wall of the appendix. This initially causes activation of stretch receptors in the wall of the intestine that is perceived in the tenth thoracic (T10) dermatome, the periumibilical region. As the infection proceeds, inflammatory fluid exudes from the organ. This fluid, which contains many inflammatory mediators, travels to the parietal peritoneum adjacent to the appendix, where it causes localized pain in the right lower quadrant owing to irritation of the sensitive nerves of the peritoneum. It is important to remember that the peritoneal pain is due to the irritating fluid, not necessarily to direct contact of the appendix with the peritoneal surface. This phenomenon may be helpful in diagnosing unusual cases of appendicitis in which the irritating fluid may travel some distance from the infected organ.

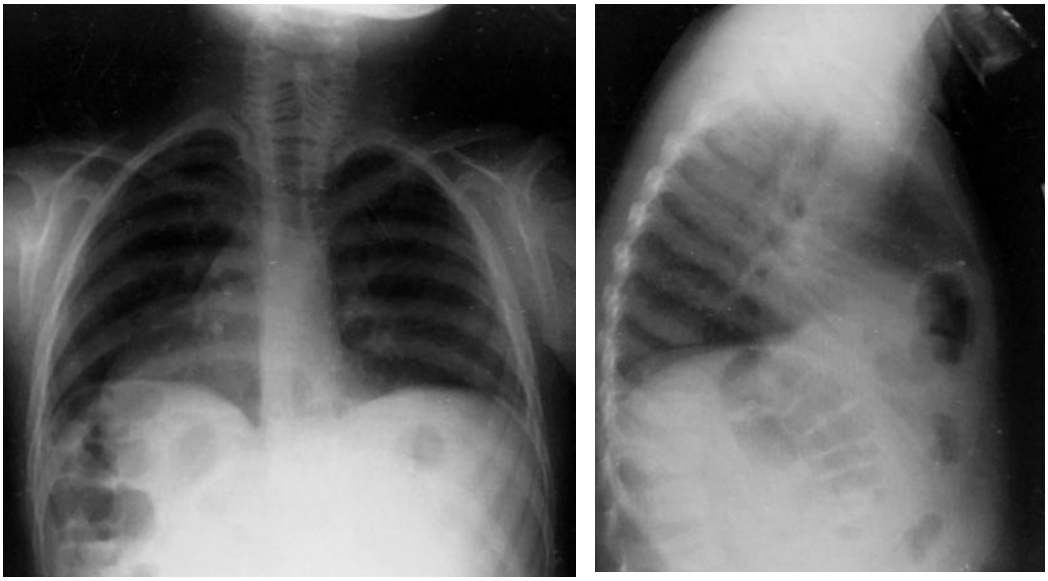

FIGURE 37-1 Posteroanterior and lateral chest radiograph from a young girl who presented with periumbilical pain that migrated to the epigastrium. She developed localized peritonitis in the epigastrium and bilious vomiting. At operation, she was found to have acute appendicitis contained within the diaphragmatic hernia of Morgagni. Note the gas-filled viscus above the diaphragm. Courtesy of R. C. Shamberger, MD.

If the inflammatory process proceeds unchecked, the appendix will usually "perforate" in about 36 hours. In children, it is estimated that 20% of cases of acute appendicitis perforate within 24 hours after the beginning of symptoms and up to 80% perforate within 48 hours. Perforation may be due to gangrene of the organ as a result of thrombosis from the invasive infection, or it may be due to direct erosion of the fecalith through the infected wall of the appendix. Alternatively, the swollen organ may begin to leak owing to high pressure from fluid and gas within the obstructed, infected lumen. If inflammatory fluid seeps throughout the abdomen, generalized peritonitis ensues. However, if the infection is confined to a local area by the body's natural defense mechanisms, such as the omentum walling off the infection, localized tenderness and a mass may be the presenting signs. When this infection is not drained in some fashion, the outcome will frequently be generalized shock and septicemia.

The bacterial flora present in acute appendicitis are those that inhabit the human colon, most of which are anaerobic. *Bacteroides fragilis*, *Escherichia coli*, *Enterococcus*, *Pseudomonas*, *Klebsiella*, and *Clostridium* species may all appear. Cultures of the peritoneum during simple appendicitis seldom yield organisms, but during the gangrenous and perforated stages of the disease, there may be a panoply of the organisms listed above.

Carcinoid tumors and parasites, particularly *Enterobius vermicularis*, or pinworm, and *Ascaris lumbricoides* may also rarely lead to obstruction of the lumen of the appendix and the development of acute appendicitis. These cases may or may not be accompanied by a history of gastrointestinal symptoms that preceded the development of the picture of appendicitis.

DIAGNOSIS

Accuracy in assessing the time of the onset of symptoms is critical in children because of the rapid tempo of the disease, that is, 36 hours to perforation from the start of the pain. The child's parents may be aware that the child awoke with pain in the night, or the child may not have eaten normally the evening before. Questioning patients and their parents about interest in the meals that immediately preceded the presentation may help pinpoint when their child first seemed unwell. Anorexia has been described as a reliable sign of appendicitis. Unfortunately, like many of the symptoms associated with appendicitis, it may or may not be present, and up to half of patients with appendicitis may say that they are hungry.

PAIN

The earliest symptom of appendicitis is usually periumbilical pain. After a few hours, the patients will frequently vomit, but the absence of vomiting does not exclude appendicitis. Many patients will progress to perforation without vomiting. Vomiting may become an important sign because it usually *follows* the periumbilical pain. In contrast, patients with gastroenteritis will vomit, but in these patients, the vomiting usually *precedes* abdominal pain. Vomiting in appendicitis is thought to be due to activation of the stretch receptors in the appendix itself; in operations done on awake, older patients under local anesthesia, traction on the bowel may induce vomiting despite complete somatic insensitivity.

After a few hours, the pain usually shifts to the right lower quadrant because of inflammatory fluid irritating the local peritoneum. This pain is stronger and overrides the

periumbilical discomfort. Thus, in the classic presentation, the pain of appendicitis starts around the umbilicus and migrates to the right lower quadrant. The pain from the inflammatory fluid is quite strong. Blood or urine in the peritoneum is less painful than inflammatory fluid or pus, whereas only bile causes consistently stronger pain than does inflammatory fluid.

McBurney first noted in 1889 that in the majority of cases, the point of maximal tenderness was localized to an area two-thirds of the way from the umbilicus to the anterior iliac spine. If the pain is due to fluid, why is this pain so localized rather than spread throughout the abdomen? The answer lies in the fact that the fluid is traveling by capillary action between the thin planes that exist among coils of intestine in the unopened abdomen, and this is commonly the point where the fluid is most concentrated. Further, the inflammatory fluid becomes gradually diluted as it moves away from the point of secretion. If the appendix lies in a retrocecal location, the peritoneal irritation may not occur, and the periumbilical pain may persist and dominate. This can go on for days and may persist even after perforation. In such cases, psoas or genitofemoral nerve irritation may be the dominant complaint, and attention is often focused on the hip or other musculoskeletal area. For this reason, retrocecal appendicitis may be very difficult to diagnose.[3]

Physical Signs

The first signs of tenderness usually appear after the pain has migrated to the right lower quadrant. This may first be mild tenderness on direct palpation. It is always wise to ask the child to localize the spot of maximal tenderness for you so that this area can be examined last (Figure 37-2). Because children are often apprehensive about examination, making the true nature of the tenderness difficult to assess, the examiner may find the stethoscope useful for "palpation" while appearing to be listening.

The most reliable diagnostic sign of acute appendicitis is localized tenderness in the right lower quadrant. As the peritoneal irritation progresses, guarding develops (voluntary stiffening of the rectus muscle), then spasm or involuntary guarding, and, finally, rebound tenderness. Stretch receptors in the peritoneum respond to the rate of stretch, not to the direction. Rebound tenderness is elicited by the examiner pressing down slowly, holding for a few seconds while the patient accommodates, and then removing the hand rapidly. If the patient suddenly winces, this is a very reliable sign of peritoneal irritation. The patient who claims the ride into the hospital caused pain with every bump in the road is describing rebound tenderness. So, too, is the patient who winces when he coughs or has pain as he jumps off the examining table. On the other hand, the patient who willingly hops up and down on one foot seldom will have appendicitis. However, we have seen patients with a gangrenous appendix walled off by omentum who performed even the hop test satisfactorily. Again, it is important for the diagnostician to remember that no single sign, symptom, or test is diagnostic of acute appendicitis aside from examining the appendix under the microscope.

The signs of peritonitis include voluntary and involuntary guarding, direct tenderness, and rebound tenderness. These signs are due only to irritation of the anterior abdominal wall. The abdomen, however, is a six-sided cavity. Each side of the cavity has physical signs unique to it. For example, retroperitoneal irritation may generate a psoas sign or an obturator sign owing to irritation of those muscles. We have seen a case of perforated appendicitis presenting with shoulder pain when the tip of the appendix perforated into the right subphrenic space. A pelvic mass or pelvic sidewall tenderness on rectal examination may be the manifestation of an inflamed or perforated appendix in the pelvis. Performing a rectal examination on a child frequently causes discomfort, making it difficult to discern true tenderness. Asking the patient to push down as if having a bowel movement and then to relax as the finger is gently inserted causes the least discomfort.

In postpubescent and especially in sexually active girls, it may be helpful to perform a pelvic examination. This should be done carefully and thoughtfully because it may be the first pelvic examination the patient has had. The patient may have localized tenderness or a mass with appendicitis. Cervical motion tenderness, however, is not usually present with appendicitis and is more suggestive of pelvic inflammatory disease.

The overall appearance of the child with abdominal pain is important in the diagnosis of appendicitis. Frequently, the child will simply "look sick"; signs and symptoms such as flushed cheeks, listlessness, low-grade fever, and unwillingness to move often accompany appendicitis even early in its course. In contrast, the child who is happy and talkative and willing to follow commands readily probably has some other cause of the abdominal pain. Fever is not a reliable sign of appendicitis. The temperature may be slightly elevated in acute appendicitis, usually by no more than one or two degrees in the child without perforation. Complicated appendicitis—perforated or gangrenous—may have high fever associated with it, however.

FIGURE 37-2 An 11-year-boy with appendicitis pointing to the area of maximal pain. Courtesy of Gary Williams, MD.

Laboratory Examination

Urinalysis is probably the only important laboratory test in the diagnosis of appendicitis, and it should be used to exclude urinary tract pathology. In a boy with symptoms that are not clearly appendicitis and a urinalysis with greater than 15 white blood cells (WBCs) per high-power field, urine should be sent for Gram stain and culture. If there is evidence of a urinary tract infection, the child may be treated with intravenous antibiotics for a few hours. However, this child should still be observed closely for response to therapy. A girl with greater than 30 WBCs per high-power field can be similarly treated, but only if the urine is obtained from a midstream specimen while the labia have been spread or by bladder catheterization. Urine obtained from a collecting bag applied to the patient may have many WBCs and squamous cells from the vagina and cannot be interpreted.

An elevated WBC count is the only laboratory test that has been shown to correlate with appendicitis.[4] Despite this, the value of the WBC count is limited. Most children who have been vomiting will have an elevated WBC count. Although there may be an increase in the polymorphonuclear leukocytes, the total WBC count does not usually exceed 20,000 cells/mm^3 in a patient with a nonperforated appendix. The WBC count is influenced by so many factors that it is not dependable in arriving at the diagnosis of appendicitis. It is not uncommon in a child without toxicity to see a WBC count below 5,000 cells/mm^3 when the appendix is not perforated. Such children may be recovering from a viral infection with leukopenia just prior to the onset of acute appendicitis. Indeed, such a viral episode may have led to swelling of the lymphoid tissue in the appendiceal wall and may have been the inciting factor in obstruction of the appendiceal lumen.

Experience has been reported using measurements of the C-reactive protein level. C-reactive protein is an acute-phase reactant, the concentration of which rises in whole blood within 12 hours of onset of an infection. It can be measured with a blood test. If patients have had symptoms for more than 12 hours and they have appendicitis, studies indicate that the C-reactive protein is elevated in over 85% of cases.[5] This test is not widely used because the result often takes time to obtain, but it may have benefit in excluding appendicitis in patients with symptoms of more than 1 day's duration[6]; however, this test is not specific, and any infectious process will have an elevated C-reactive protein level associated with it.

In an attempt to systematize the diagnosis of appendicitis, Alvarado used a combination of signs, symptoms, and laboratory values to develop an appendicitis score. In this score, eight variables were assessed: localized tenderness in the right lower quadrant, leukocytosis, migration of pain, WBC shift to the left, fever, nausea or vomiting, anorexia, and direct rebound tenderness. Each variable was assigned a score, and the scores were then added. In his scheme, Alvarado found excellent correlation with appendicitis in patients with higher scores.[7] Samuel applied a similar system based on signs and symptoms to children and found good statistical correlation with the presence of acute appendicitis.[8]

Radiologic Examination

Plain radiographs may be helpful if the diagnosis is in some doubt, but we do not routinely obtain films, except in infants. The most common finding on plain abdominal radiographs in the patient with appendicitis is curvature of the spine to the right. A dilated cecum containing an air-fluid level may be seen. A calcified fecalith can sometimes be seen if the films are well exposed and multiple films are obtained with the patient in different positions to portray the calcification unobscured by bony structures (Figure 37-3). Half of children with abdominal pain and a fecalith can be expected to have perforated appendicitis. When the appendix is perforated (especially in infants), there may be a paucity of gas in the right lower quadrant and an increase in the thickness of the lateral abdominal wall owing to soft tissue edema and evidence of free peritoneal fluid.[9] Use of routine plain radiographs is not recommended, however, because studies in adults have demonstrated no finding that correlated with appendicitis, and cost-benefit analysis showed that plain films have a very high cost-to-benefit ratio when used to diagnose this disease.[10]

In the confusing case, or if the diagnosis is in doubt, a chest radiograph may demonstrate a right lower lobe pneumonia that may be causing referred pain to the midabdomen.

FIGURE 37-3 Plain radiograph of a teenage girl with appendicitis demonstrating a large, calcified appendicolith in the right lower quadrant. Appendicoliths are rarely this large and can be difficult to differentiate from surrounding bony structures.

A large amount of experience using US has been reported in the evaluation of abdominal pain in children, but the data provided by US are operator dependent and easily misinterpreted. The normal appendix is usually not visualized on US. However, a thickened or noncompressible appendix may be seen, as well as periappendiceal fluid, a fecalith, or even a periappendiceal abscess.[11] US should be reserved for the difficult cases because it delays surgery. However, in selected cases with an experienced ultrasonographer, this test may be of value, especially in females in whom adnexal pathology may confuse the issue. In fact, in cases in which pelvic pathology is high in the differential diagnosis, US may be the most valuable test because it is better for evaluating the adnexa than is CT. Data suggest that the use of US in evaluation of difficult cases of abdominal pain changed the treatment course and increased the level of certainty of the practitioner.[12]

The data on the utility of US are quite conflicting, however. The sensitivity and specificity of US examinations for appendicitis can be quite variable. More importantly, it is not clear that use of US affects the outcome in a population of children with appendicitis, that is, it may not lower the incidence of perforation or the cost of care.[13] This test must be factored into the overall clinical picture in deciding on operative intervention, and one must remember that a negative sonogram does not exclude appendicitis.

Use of CT in the evaluation of difficult cases of abdominal pain has also been reported extensively. The CT findings suggestive of appendicitis include appendiceal wall thickening, the presence of inflammatory changes in the periappendiceal fat, or the presence of an abscess or phlegmon (Figure 37-4). An appendicolith seen on a CT scan in a patient with right lower quadrant pain is also highly suggestive of appendicitis. The best results, meaning the highest specificity and accuracy, in children have come from using limited CT scanning with a thin-cut helical technique with rectal contrast. Using this technique, the sensitivity, specificity, and accuracy of the diagnosis were all reported to be 94%. This was much better than when the same group was examined with US.[14] Some of the US and CT signs of acute appendicitis are listed in Table 37-1. Because of the low false-negative rate with CT scanning, use of this test allows patients to be discharged home rather than admitted for observation, resulting in cost savings. However, we caution that 1 of 20 cases is still misdiagnosed, and careful follow-up of these patients is warranted, especially if they are discharged from care.[14] A follow-up telephone call the next day should reveal improvement of the patient; if this is not the case, the patient must be seen and re-evaluated.

Other radiologic tests, such as barium enema and intravenous pyelogram, are of little value these days because virtually all of the information that these might reveal, such as extrinsic compression of the cecum or ureteral obstruction, can be gleaned from CT scans. These tests should be reserved for selected chronic cases that present as diagnostic dilemmas.

Once again, however, it should be emphasized that obtaining a thorough history and performing a careful physical examination will accurately make the diagnosis of appendicitis in the majority of cases without radiographic testing. Use of any of the radiographic tests discussed above is not advocated unless the presentation is confusing or the diagnosis is in question.

Perforated Appendicitis

Immediately on perforation of the appendix, the child may have a period when he feels better owing to relief of the pressure that built up within the lumen of the appendix. Soon thereafter, the child will lie still, often with the right leg drawn up, and will become tachypneic. The vomiting pattern may change: although the child with early appendicitis may vomit once or twice or not at all, vomiting after perforation is more frequent, and the vomitus may contain small bowel contents from paralytic ileus. The child will be hot and dry, with temperatures of 101°F or higher. Signs of peritoneal irritation may be diffuse or localized, and a mass may be palpable. Peritoneal findings in the patient with perforation of a retrocecal appendix are more variable, and retroperitoneal signs such as the psoas or obturator signs may be more prevalent. Rectal examination may reveal lateralizing tenderness or a mass pushing on the rectum.

Many children with perforated appendicitis have what is described as "diarrhea," which leads to the erroneous diagnosis of gastroenteritis. Diarrhea accompanying perforated appendicitis is usually low-volume, irritative fluid from inflammation of the rectosigmoid. Peristalsis is often decreased. In contrast, gastroenteritis produces high-volume (profuse) diarrhea from the rectosigmoid, abetted by increased peristalsis.

The child who has been "sick for a week" may well have a large appendiceal abscess walled off from the peritoneal cavity. When the abscess begins to leak into the free abdominal cavity, the child shows signs of extreme toxicity, oliguria, mottling of the skin, evidence of gram-negative septicemia, and a falling platelet count. Radiographs may show signs of paralytic ileus or even partial small bowel obstruction. This is the type of patient most at risk for a disastrous outcome from appendicitis.

FIGURE 37-4 Computed tomographic scan showing a large periappendiceal abscess (*arrow*) containing gas. Note the contrast enhancement of the rim, which is typical with abscesses.

TABLE 37-1 ULTRASONOGRAPHY AND COMPUTED TOMOGRAPHY CRITERIA FOR APPENDICITIS

ULTRASONOGRAPHY	COMPUTED TOMOGRAPHY
Fluid-filled, noncompressible, distended tubular structure (≥ 6 mm)	Fluid-filled tubular structure measuring > 6 mm in maximum diameter
No peristalsis in appendix	Fat stranding, abscess, or phlegmon in adjacent tissue
With or without appendicolith	With or without appendicolith
Location: anterior to psoas or retrocecal	Focal cecal apical thickening
Pericecal inflammatory changes

Diagnostic Dilemmas

Appendicitis is a common disease with many uncommon presentations. We have seen appendicitis present as an incarcerated hernia, intermittent small bowel obstruction, and diverticulitis, just to name a few. *Appendicitis must be in the differential diagnosis of any child who presents with abdominal pain*. Children under the age of 2 years and obese patients, particularly perimenarchal girls, represent the most difficult diagnostic groups in our experience. Obesity interferes with the physical examination by making it difficult to elicit direct tenderness and guarding. Very young children are unable to give a history or tell where it hurts, and their parents often cannot pinpoint when the child began to feel ill. Although only 2% of children with appendicitis will be under the age of 2 years, over 70% of very young children with appendicitis will have perforated by the time of presentation.[15] Just as it was once said that if someone understood syphilis in all of its manifestations, he understood all of internal medicine, if one understands appendicitis in all of its presentations, one understands evaluation of the acute abdomen.

DIFFERENTIAL DIAGNOSIS

Gastroenteritis

This condition is the most common cause of abdominal pain in children presenting to emergency rooms. Retrocecal appendicitis can commonly be confused with gastroenteritis. Some of the signs that may help to distinguish appendicitis from gastroenteritis are listed in Table 37-2.[16] When there is any doubt of the diagnosis, the child should be observed closely. Gastroenteritis will usually improve gradually, whereas appendicitis will continue to get worse. It must also be remembered that the dehydrated child frequently appears quite ill and may improve dramatically simply as a result of rehydration. If improvement is seen after intravenous fluids are given, the child must still be closely examined for any signs of localized tenderness.

Of the bacterial enteritides, *Yersinia*, *Salmonella*, *Shigella*, or *Campylobacter* may present with abdominal pain. Usually, there is more than the expected amount of diarrhea, but right lower quadrant pain is common, and there may even be a shift of pain from the periumbilical region to the right lower quadrant. These patients often appear quite toxic, and leukocytosis is prominent. Cramps and high fever also are frequent, and there may be occult or frank blood in the stools, which is not usually present with appendicitis. The patient with appendicitis will rarely, if ever, thrash about in bed, but crampy, intermittent pain is frequent with gastroenteritis. If an operation is undertaken, the appendix is not inflamed. Culture of lymph nodes or stool may yield *Salmonella*. *Yersinia* may be diagnosed from stool cultures or serology. With *Campylobacter* infections, there are cramps, fever, watery diarrhea, and, frequently, blood per rectum. The diagnosis is made by culture of the organism from stool, and treatment is with oral erythromycin.

Constipation

This problem is a common cause of pain in some children, particularly in older children. The right lower quadrant pain may be intermittent, crampy, or steady, but it rarely progresses, and the pain may be perceived by the patient as quite severe. Usually, it is not possible to elicit a history of constipation. Patients will state that they have moved their bowels that day or the day before, but stool may be palpable on examination of the abdomen, or the colon may appear stool-filled on the KUB (kidney, ureter, bladder) radiograph. We see this problem most often in the heat of the summer months and in the dry winter months, when household heat is being used. At both times, chronic mild dehydration probably is a contributing factor. If there is little or no evidence of peritoneal irritation in the right lower quadrant and an abdominal film shows a colon filled with feces, it is safe to give a Fleet enema. If the symptoms disappear after a large bowel movement, the patient can be allowed to go home.

Urinary Tract Pathology

When urinary tract infection is present, the fever and leukocytosis may be increased out of proportion to the abdominal signs, in contrast to the usual signs of appendicitis. When pyelonephritis is present, there is usually flank pain and tenderness and high fever as opposed to right lower quadrant pain. If there is pyuria, the urine has been collected correctly, and the signs are not clearly consistent with appendicitis, then it is permissible to treat the patient for a few hours with intravenous antibiotics. However, if the patient does not improve rapidly, or if the diagnosis is still in doubt, we proceed with appendectomy. Crampy or intermittent severe pain in the right lower quadrant may be due to a right ureteral stone. Usually, there will be hematuria. If a stone is suspected, a CT scan without any type of contrast will be diagnostic. If this study is negative, however, and appendicitis is still in the differential diagnosis, the scan should then be repeated with gastrointestinal and oral or rectal contrast.

TABLE 37-2 DIFFERENTIAL DIAGNOSIS OF APPENDICITIS AND GASTROENTERITIS

SYMPTOM	GASTROENTERITIS	APPENDICITIS
Onset of periumbilical pain	Coexistent with or after vomiting	Before vomiting
Diarrhea	High volume, frequent	Mucus or low-volume irritative type of diarrhea, infrequent
Peristalsis	High frequency, low pitch	Low frequency or absent, high pitch if paralytic ileus
Rectal tenderness	Usually absent	Usually present
Rebound tenderness or referred rebound tenderness, such as "painful ride to hospital"	Usually absent	Often present, especially in cases of perforation

Adapted from Folkman MJ.[16]

Crohn Disease

Regional enteritis usually presents with a more protracted course than appendicitis. Often the child has had bowel symptoms for months or more, including crampy abdominal pain, diarrhea, and failure to thrive. There may be a family history of inflammatory bowel disease. Occasionally, however, the presentation will be similar to that of appendicitis, and the first discovery of the disease is during appendectomy. If this is the case at operation, the bowel, usually the terminal ileum, is thickened with mesenteric fat creeping over the bowel wall. Biopsy of an ileocolic mesenteric lymph node will often show granulomas. If the cecum is uninvolved and a secure closure of the appendiceal stump can be effected, we recommend removal of the appendix. If, on the other hand, the disease involves the region of the appendix, it is safest not to proceed with appendectomy for fear of development of an enterocutaneous fistula. Primary resection of the affected bowel should not be undertaken because early disease can frequently be treated medically, and bowel resection can be delayed or avoided.

Pelvic Inflammatory Disease

Pelvic inflammatory disease in girls over 12 years is not uncommon. The onset of abdominal pain is often preceded by the menstrual period. The pain usually begins in the lower quadrants rather than in the periumbilical area, as it does in appendicitis, and frequently accompanies the onset of menses. Pain with motion of the cervix is the hallmark of pelvic inflammatory disease, and there may be bilateral adnexal tenderness. Gram stain of the purulent cervical discharge may reveal gram-negative intracellular diplococci. The sedimentation rate is greater than 15 mm/h in the majority of cases, whereas in appendicitis, the sedimentation rate is almost always normal, that is, 1 to 10 mm/h. If the differential diagnosis is in doubt or if the signs persist after initiation of treatment, it is wise to do an appendectomy. We have operated on young adolescents with appendicitis who were originally thought to have gonorrhea because the cervical smear revealed gram-negative diplococci. Culture in these patients showed that these were only the saprophytic *Neisseria* that may be present normally in the vagina.

Ovarian Cyst

Pathology in the ovary can mimic appendicitis. The most common cause is rupture of an ovarian cyst. The pain is usually quite abrupt in onset and begins in the right lower quadrant. There is frequently tenderness. If the girl is menstruating, the pain is often midcycle, but ovarian cysts are frequent at menarche as well. US may be helpful to delineate free fluid or other cysts in the ovary, or a recently ruptured follicular cyst may be seen. If the diagnosis is in doubt, laparoscopy may help define the pathology, but this test does not rule out appendicitis unless the appendix is fully visualized. If diagnostic laparoscopy is undertaken and the appendix is found to be normal, we usually remove it in any case. US may also suggest torsion of an ovary, usually associated with a cyst. Pain and vomiting are common with this disease as well. Ovarian torsion should be treated operatively.

Pneumonia

Right lower lobe pneumonia may refer pain to the abdomen through the tenth and eleventh thoracic nerves. A chest film, the presence of abnormal respiratory signs (flaring, grunting, tachypnea), and increased toxicity should help to confirm the diagnosis. These patients often have high fever and a cough. We occasionally see a child in whom the right lower lobe infiltrate and the fever do not improve after 2 days of antibiotic treatment, and the underlying process turns out to be a localized rupture of a high retrocecal appendix with a collection of fluid beneath the right diaphragm.

Mesenteric Adenitis

This entity is due to viral infection or other inflammation of the lymph nodes clustered in the mesentery of the terminal ileum. This diagnosis tends to be a diagnosis of exclusion and should probably be made only at laparotomy or laparoscopy. US or CT may demonstrate enlarged mesenteric lymph nodes. The clinician must be careful in this case because enlarged mesenteric lymph nodes may coexist with acute appendicitis. If, at exploration, the appendix is found to be normal, Meckel diverticulum and adnexal pathology are ruled out, and enlarged lymph nodes are found, we may biopsy the node for culture and pathologic evaluation.

Typhlitis

Patients who are severely leukopenic as a result of disease or cancer chemotherapy may develop a syndrome of severe right lower quadrant pain and tenderness. This is thought to be related to invasive infection of the wall of the cecum. This usually occurs at the nadir of the leukocyte counts, and it can be confused with acute appendicitis. CT scan-

ning may reveal a thickened, irregular cecum and occasional pneumatosis coli. Operation in these patients has a prohibitive morbidity and mortality and is to be avoided if possible. Most patients will respond to bowel rest and high doses of intravenous broad-spectrum antibiotics.[17]

Cost of Diagnostic Error

The sequelae of perforation are so dangerous that if the diagnosis appears to be appendicitis, even if one is not absolutely certain, it is always preferable to remove the appendix before perforation and accept the occasional "error" of removing a normal appendix rather than waiting so long that perforation occurs. Despite improved accuracy in diagnosing this disease with modern technology, 5 to 10% of cases cannot be accurately diagnosed without an operation. Therefore, it is entirely acceptable practice for the surgeon to have occasional cases in which the appendix is found to be normal. The morbidity of a negative appendectomy should be quite small, and the alternative—a missed appendicitis leading to perforation—is quite high. If the diagnosis is doubtful, we prefer to admit the child for *repeated observation by the same physician*. Sending the child home to return the next day only ensures that a different physician who cannot accurately judge whether the signs have progressed will see him. The average length of hospital stay for acute appendicitis is 1 to 2 days, whereas the child with a perforated appendix will stay for as much as 10 days or more, incur much higher costs, and have greater potential for a complication or long-term sequelae.

TREATMENT

There are many possible ways to treat appendicitis, but, in general, appendectomy on the day of diagnosis is the treatment of choice. One exception to this rule is in the case of perforated appendicitis with a well-established abscess that can be drained. Even in a sick child who must be prepared with intravenous fluids, antibiotics, correction of electrolyte imbalances, and reduction of fever, we have always been able to perform the operation on the same day.

Operative Technique

For open appendectomy, a transverse right lower quadrant muscle-splitting incision is used, more lateral than in an adult because the rectus muscle is relatively wider in a child. It is virtually always possible to remove the appendix, even in the presence of an abscess or severe perforation with peritonitis. It is safest to mobilize the cecum so that the entire appendix lies above the abdominal wall. It may be necessary to incise the lateral cecal peritoneal attachments at the white line of Toldt to do so. The mesoappendix is divided so that the appendix is completely mobilized and free at its base. A purse-string suture is placed around the base of the appendix, and the appendix is crushed and ligated with plain catgut suture near its base. The stump of the appendix is inverted while the purse-string is tied. This will give a secure closure of the stump and prevent mucocele formation because the catgut will dissolve promptly inside the lumen of the cecum. The muscle layers are closed individually, and the skin is typically closed primarily. When removing a perforated appendix, it is important not to leave behind a fecalith that may have fallen out of a perforated appendix during the procedure. This will result in later formation of an abscess.

In cases of periappendiceal abscess, we use CT- or US-guided drainage of the abscess with delayed removal of the appendix, usually about 8 weeks later. This is safe and even preferable in cases in which there is a well-defined abscess cavity. Broad-spectrum antibiotics should be given, and the patient should respond promptly to this intervention with resolution of fever and return of bowel function. This method of treatment allows the child to defervesce quickly initially without becoming too ill and has the advantage of allowing later laparoscopic appendectomy with rapid recovery. In this treatment algorithm, the appendix should be later removed because pathologic abnormalities frequently exist, and if the appendix is not removed, these patients are at risk for recurrent bouts of appendicitis.[18]

On extremely rare occasions, the appendiceal stump is so gangrenous or the cecum so edematous that the stump cannot be inverted or closed safely (Figure 37-5). In this situation, it is wisest to do a limited ileocecal resection with an end-to-end two-layer ileo-right colic anastomosis. We try to position the anastomosis away from the abscess cavity and separate the two with omentum. Another option if the appendix cannot be inverted but the cecum is not thickened or inflamed is to resect a small portion of the cecal wall and perform a two-layer closure. In either option, it is critical that the tissue that is closed be soft, well vascularized, and without significant inflammation. Failure to close healthy tissue will result in a fecal fistula, and the patient will remain ill for a long period of time.

FIGURE 37-5 Gangrene of the terminal ileum secondary to perforated appendicitis with bowel obstruction. This patient was treated with ileocecectomy and primary reanastomosis. The anastomosis was placed in the right upper quadrant well away from the abscess cavity, and the patient did well.

Considerable experience has been gained in the use of laparoscopy for appendectomy. Many surgeons now prefer laparoscopy to the open technique for their patients, and the results are comparable to those with the open technique. Appendectomy through the laparoscope may offer the benefit of faster recovery to normal activity for older patients, but the hospital stay in uncomplicated cases is equal using both techniques. To date, operative costs associated with the laparoscopic approach still exceed those of open laparotomy, and these costs are not offset by a shorter length of hospital stay, as is usually the situation when laparoscopy is used for larger abdominal procedures. One situation in which laparoscopic appendectomy may offer an advantage is in the case of a patient—usually a teenage female—in whom there is a diagnostic dilemma, and laparoscopy offers a broader view of the abdomen and pelvis to search for other pathology.

Laparoscopic appendectomy can usually be accomplished using a three-trocar technique. Most surgeons divide the mesoappendix and the appendix with a linear stapling device, although a harmonic scalpel or another similar coagulating instrument may also be used for the mesentery. As opposed to an open technique in which the mesoappendix is typically divided first, with laparoscopy, it is often easier to divide the appendix before dividing the mesoappendix. It is very important to divide the appendix close to the cecum so that the entire viscus is removed. Cases of recurrent appendicitis have been reported when a length of appendiceal stump is left after laparoscopic appendectomy.[19]

Patients with nonperforated appendicitis receive a preoperative dose of intravenous antibiotic, usually a first- or second-generation cephalosporin, to cover skin flora and possibly some gram-negative organisms. This is continued for 24 hours if the operation reveals no evidence of perforation. Routine intraoperative cultures of the abdomen are of little value in such patients.[20]

Perforated Appendicitis

Optimal management of perforated appendicitis in the era of clinical outcome studies and managed care has been a source of some controversy. The management algorithm used at Boston's Children's Hospital since 1976 is outlined in Table 37-3.[21] This protocol has been consistently associated with an extremely low rate of postappendicitis complications.[22] Recently, this protocol was modified by substituting piperacillin and tazobactam (Zosyn, Lederle Laboratories, Carolina, Puerto Rico) instead of ampicillin, gentamicin, and clindamycin. This allows simplified drug dosing and avoids the potential complications associated with gentamicin. If these children are doing clinically well, they can frequently be discharged home to finish their 10-day intravenous antibiotic course. A recent prospective study of this clinical pathway again revealed an extremely low complication rate for the treatment of perforated appendicitis.[23] The duration of antibiotic therapy is also an area of debate among surgeons, but whatever the regimen used to treat perforated appendicitis, it should result in complication rates as low as possible, preferably no more than 5%.

The use of laparoscopy in patients with complicated appendicitis is also an area of considerable controversy among pediatric surgeons. Retrospective studies have shown a significantly higher incidence of postoperative intra-abdominal abscesses in children with perforated appendicitis who were treated laparoscopically when compared with children treated by the open technique.[24,25] Other surgeons, however, argue that they see no difference between the two techniques. Clearly, a large multicenter randomized trial of open versus laparoscopic appendectomy, while holding the other parameters such as antibiotic therapy constant, is needed to answer this question.

COMPLICATIONS

Infections

The incidence of infectious complications in appendicitis varies with the severity of the infection at the time of surgery. Usually, the wound infection rate with simple appendicitis is quite low. In fact, the wound infection rate associated with removal of a noninflamed appendix is often higher than with simple appendicitis. The incidence of wound infections with primary closure of the wound without drains in perforated appendicitis has been reported to be quite significant, over 10%.[26] In our experience, however, with use of a drain brought through the wound in perforated appendicitis, this rate can be lowered to about 1%. Primary wound closure with an absorbable suture is very much preferred by children because they

TABLE 37-3 PROTOCOL FOR MANAGEMENT OF PERFORATED APPENDICITIS

1. Fluid resuscitation; control fever and administration of intravenous antibiotics (ampicillin 100 mg/kg/24 h, gentamicin 5 mg/kg/24 h, and clindamycin 30 mg/kg/24 h on admission, or piperacillin/tazobactam 240 mg/kg/24 h of piperacillin component, up to 18 g/24 h).
2. Explore peritoneal cavity via right lower quadrant incision.
3. Perform appendectomy in all cases.
4. Perform limited peritoneal débridement.
5. Irrigate peritoneal cavity with cephalothin solution (4 g/L).
6. Place Penrose drains in pelvis and right pericolic space, which exit through the lateral margin of the wound.
7. Close the muscle layers, Scarpa fascia, and skin around the drains with absorbable sutures.
8. Encourage postoperative activity and position at will.
9. Continue parenteral antibiotics for 9 days, adjusting gentamicin dosage based on serum levels.
10. Remove drains slowly from the seventh to the ninth postoperative days. If the patient has been discharged for home antibiotics, he is usually seen sometime during this period in the clinic.
11. Discharge patient generally on the tenth postoperative day.

strongly dislike dressing changes, suture removal, or delayed wound closures. Removal of a small Penrose drain, on the other hand, is well tolerated.

Similarly, the incidence of abdominal and pelvic abscesses after perforated appendicitis is real—1.3% in our series[22]—and is one of the most frequent and significant complications seen. Many abdominal or pelvic abscesses subside spontaneously under antibiotic therapy and probably represent a phlegmon or cellulitis with agglutinated loops of bowel rather than a true abscess. The progress of these masses can be followed by repeat rectal examinations or CT scans. If the collection does not resolve or the child remains toxic, it is necessary to drain such an abscess. With use of US and CT, it is frequently possible to drain it percutaneously, leaving a small drain in the cavity. This can usually be done with sedation and local anesthesia.

A very small number of patients who have had very severe perforated appendicitis may develop persistent feculent drainage through their wound—a fecal fistula. Virtually all will resolve with bowel rest, antibiotics, and total parenteral nutrition. One must be sure, however, that there is no cause of obstruction distal to the fistula that is preventing its closure.

Intestinal Obstruction

Paralytic ileus may persist for 3 to 5 days following removal of a perforated appendix. Occasionally, this ileus is followed by a few days of normal intestinal function and then by mechanical obstruction with cramping pain. Most of these cases can be managed by nasogastric tube decompression until the inflammatory adhesions subside. Repeat laparotomy at this time is meddlesome and even dangerous unless there is evidence of strangulation or closed loop obstruction. In contrast, obstructions that occur more than 4 weeks postoperatively usually require prompt operation. This complication arises in 1 to 2% of patients with perforated appendicitis. Surgeons who are not experienced with children may be uncertain about the appropriate timing for re-exploration. We saw a child who had a re-exploration for intestinal obstruction 5 days after removal of a perforated appendix. No distinct point of obstruction was found at that time, but many inflammatory adhesions were present. After a number of postsurgical wound complications, the intestine began to function, but 1 month later, there was a new episode of intestinal obstruction. This was treated by a nasogastric tube, but after a few days, the child's condition deteriorated, and at operation, a loop of gangrenous bowel was found tethered by a single strong adhesive band. The initial reoperation was too early and the second too late.

Sterility

Pelvic abscess or pelvic inflammation associated with perforated appendicitis has been thought to be associated with an increased rate of infertility in female patients,[27] but the literature on this point remains quite controversial.[28] A recent historical cohort study from Sweden found no difference in the fertility rate of women who had perforated appendicitis as young girls when compared with normal controls.[29]

Antibiotic-Associated Colitis

A few patients may develop crampy diarrhea and fever after treatment for appendicitis. A stool smear should be sent to look for leukocytes and the stool checked for *Clostridium difficile*. If the titer is positive, these patients will respond to orally administered vancomycin or metronidazole.

SUMMARY

Appendicitis is most noteworthy for the difficulty it presents in diagnosis. Despite tremendous progress in medical diagnostic imaging and laboratory testing, the incidence of perforation and missed diagnosis has not changed significantly over the years. Success in diagnosing appendicitis still requires a thorough history and physical examination and a complete understanding of the tempo of the disease, as well as the anatomy and pathophysiology of the pain. Finally, the practitioner must be willing to follow the patient closely over time, with frequent, even hourly, reexamination to observe the progress of the symptoms. One must also recognize the difficulties inherent in diagnosing unusual cases of appendicitis, such as in very young children or in those cases in which the appendix is in a retrocecal location. In the end, successful management of this process can lead to the ultimate satisfaction in medicine, that is, timely and complete cure of a child with a potentially life-threatening illness.

CHAPTER 38

INFECTIONS

1. *Bacterial Infections*

Alessio Fasano, MD

Bacterial enteric infections exact a heavy toll on human populations, particularly among children. Despite the explosion of knowledge of the pathogenesis of enteric diseases experienced during the past decade, the number of diarrheal episodes and childhood deaths reported worldwide remains of apocalyptic dimensions.[1] The recent escalation of international terrorism is raising the risk of enteric pathogen epidemics occurring beyond the boundaries of natural endemic areas. However, bacterial genome sequencing and better understanding of the pathogenic mechanisms involved in the onset of diarrhea are finally leading to preventive interventions, such as enteric vaccines, which may have a significant impact on the magnitude of this human plague. This chapter reviews the major bacterial agents of infectious diarrhea (Table 38.1-1) and their interaction with the human host.

CHOLERA

Of all enteric pathogens, *Vibrio cholerae* is responsible for the most rapidly fatal diarrheal disease in humans.[2] Although cholera is rare in developed countries, it remains a major cause of diarrheal morbidity and mortality in many parts of the developing world.[3] However, with the occurrence of both natural (eg, earthquakes) and human-generated calamities (such as ethnic wars), the spreading of cholera infection in refugee camps, where sanitary conditions resemble those in cholera-endemic areas, represents a significant threat worldwide.

MICROBIOLOGY

Vibrio (from the Greek *comma*) *cholerae* are single, short-curved, gram-negative rods with a single long polar flagellum that confers to the microorganism the characteristic rapid linear motility that forms the basis for identification by an immobilization test.[4] Currently, 34 *Vibrio* species are recognized, a third of which are pathogenic in humans.[5] *V. cholerae* is divided into 139 serotypes on the basis of the O antigen of the cell surface polysaccharide. Work in the 1930s led to the concept that *V. cholerae* strains could be divided into two groups: those that agglutinated with antisera directed against antigens present on strains isolated from cholera patients (group O1) and other "nonagglutinating" or "noncholera" vibrios (non-O1), which were regarded primarily as nonpathogenic, environmental isolates.[5,6] Group O1 is further divided into two biotypes: classic and El Tor. The El Tor strains were first isolated in 1905 from returning Mecca pilgrims at the quarantine camp of El Tor in the Sinai Peninsula in Egypt.[7]

As more attention was paid to non-O1 vibrios, it became clear that they represented a heterogeneous group that includes 11 species, which have been associated with human illness.[8,9] Until 1993, only the O1 serotype was believed to be responsible for epidemics in humans, whereas the non-O1 group was considered responsible for sporadic cases of acute enteritis and extraintestinal infections.[10] However, a strain of *V. cholerae* non-O1 (O139 Bengal) associated with epidemic cholera appeared in southern and eastern India in October 1992 (see below).[11]

EPIDEMIOLOGY

V. cholerae O1 is transmitted by the fecal-oral route and is spread primarily through contaminated food and water. Since the original observation during the cholera epidemic in London in 1854,[12] water has been considered the main

TABLE 38.1-1 IDENTIFICATION OF BACTERIAL ENTERIC PATHOGENS IN SYMPTOMATIC PATIENTS FROM DEVELOPING AND INDUSTRIALIZED COUNTRIES (PERCENTAGE)

vehicle for cholera transmission. During the outbreak in Peru, fecal contamination of public water was identified as responsible for the majority of cases.[13,14]

During the past two centuries, six pandemics spread throughout the world, starting in Asia and spreading through Europe and then to the Americas.[15] The current pandemic started in 1961 from an endemic focus in Indonesia and disseminated in southeast Asia and the Middle East, reaching Africa and Europe in 1970.[16–18] Finally, after almost a century, *V. cholerae* made its reappearance in South America in 1991, when the pandemic developed with explosive intensity in several coastal Peruvian cities.[19] Although the classic biotype of *V. cholerae* O1 caused the fifth and sixth pandemics, the seventh pandemic was caused by the El Tor biotype.

In October 1992, a new epidemic outbreak of cholera occurred in southern and eastern India[11] and spread 3 months later in Bangladesh.[20] For the first time, a non-O1 strain (named O139 Bengal) was identified as responsible for a cholera outbreak. This strain spread faster than the *V. cholerae* O1 El Tor biotype responsible for the seventh pandemic; it appeared in Thailand in April 1993[21] and as an isolated case imported from India in the United States in February 1993.[22] These observations raised the concern that the appearance of *V. cholerae* O139 may mark the beginning of the eighth cholera pandemic.[23]

Clinical Manifestations

The period of incubation of cholera ranges from a few hours to 5 days.[24–26] The vast majority of subjects infected with *V. cholerae* O1 remain asymptomatic or experience a mild disease indistinguishable from many other forms of infectious diarrhea, with a few episodes of watery stools, rare nausea or vomiting, and no significant dehydration.[27] In cholera gravis (Figure 38.1-1), the most severe form of the disease, profuse watery diarrhea and vomiting lead to massive fluid and electrolyte loss, which can occur at a rate of 1 L/h and can reach a total volume loss during illness of 100% of body weight.[28] Cholera stools are typically described as "rice water" owing to the presence of mucus in clear stools. Diarrhea is most severe during the first 48 hours of the disease, when dehydration can reach life-threatening levels, particularly in children. Diarrhea then slowly decreases, completely resolving after 4 to 6 days.[28]

Diagnosis, Treatment, and Prevention

The stools of patients affected by acute cholera contain a large number of vibrios that can be easily identified with a simple Gram stain of such stools. Direct placement of stool specimens on selective media is usually sufficient for the isolation of the microorganism. The recent spread of *V. cholerae* O139 Bengal has highlighted the need for specific tests to identify this new strain.[29]

Oral rehydration solutions are the cornerstone of cholera treatment and are typically the only necessary intervention for cholera patients. The introduction of this treatment has revolutionized the prognosis of cholera, reducing the mortality from over 50% to less than 1%.[13,30,31] If the dehydration is too severe (> 10%), the mental status of the patient is affected, or the presence of vomiting precludes the use of oral therapy, the use of intravenous solutions such as Ringer's lactate becomes the treatment of choice. The use of antibiotics for the treatment of cholera has limited indications. Antibiotics have been demonstrated to reduce the volume and duration of diarrhea by about half and to reduce the duration of *Vibrio* excretion to an average of 1 day.[32] Tetracycline (500 mg per dose four times/d) is the antibiotic most used; however, large outbreaks of tetracycline-resistant organisms have been reported.[33,34] Furazolidone (1.25 mg/kg four times/d), trimethoprim (TMP) (5 mg/kg two times/d) and sulfamethoxazole (SMX) (25 mg/kg two times/d), and erythromycin (10 mg/kg three times/d) have been suggested for children.[35]

Both killed whole-cell and live attenuated cholera vaccines have been proposed as a preventive intervention for cholera.[36] A large double-blind field trial of the killed vaccine showed 85% efficacy for a period of 4 to 6 months, dropping to 50% over 3 years of follow-up.[37] A locally produced killed vaccine in Vietnam provided 66% protection against El Tor cholera during an outbreak occurring 8 to 10 months after vaccination.[38] A genetically engineered attenuated cholera vaccine (CVD 103-HgR), obtained by deleting the active subunit of cholera toxin (see below) from a *V. cholerae* O1 classic biotype, was well tolerated when administered to volunteers. This vaccine elicited a high level of protection (82–100%) against homologous

FIGURE 38.1-1 A case of cholera gravis in a young Bangladeshi woman.

challenge with a strain of the same biotype.[39] Protection across the biotype was also observed, albeit to a lesser extent,[40] lasting for at least 6 months after a single oral dose.[41] Live attenuated *V. cholerae* O139 vaccines have been developed, with promising preliminary results.[42,43]

Non-O1 Vibrio Species

As mentioned above, non-O1 *Vibrio* species (other than O139 Bengal) that infect the intestinal tract (*V. parahaemolyticus*, *V. fluvialis*, *V. mimicus*, *V. hollisae*, *V. furnissii*, and *V. vulnificus*) are responsible for sporadic cases of enteritis. These vibrios have been isolated from surface water in multiple sites in North America, Europe, Asia, and Australia, and it is likely that they are present in coastal and estuarine areas throughout the world.[44] Virtually all infections by non-O1 *V. cholerae* acquired in the United States are associated with the eating of raw or undercooked shellfish.[45] Seafood is also the main vehicle of infection for sporadic non-O1 disease outside the United States; however, the transmission can also occur through other routes, including water[46] and a variety of other foods.[47–49] Enteritis from non-O1 *V. cholerae* can range from mild illness to a profuse, watery diarrhea comparable to that seen in epidemic cholera. Diarrhea, abdominal cramps, and fever are the most common symptoms, with nausea and vomiting occurring less frequently.[45] Bloody diarrhea has been reported in 25% of cases.[45] As with *V. cholerae* O1, the mainstay of therapy for diarrheal disease is oral rehydration. In cases of septicemia (that typically occur in immunocompromised patients), supportive care and correction of shock are essential interventions associated with antibiotic treatment (tetracycline). In countries such as the United States, non-O1 infections can be prevented by not eating raw or undercooked seafood, particularly during the warm summer months.

SALMONELLA

For more than a century, *Salmonella* has fascinated physicians, microbiologists, epidemiologists, and geneticists by virtue of its diversity and success in nature. Nontyphi salmonellae are widely dispersed in animal hosts, including the intestinal tracts of both domestic and wild mammals, as well as reptiles, birds, and insects.[50] They are effective commensals and pathogens that cause a spectrum of diseases in humans and animals.

Microbiology

Salmonella is a genus of the family of Enterobacteriaceae. These microorganisms are gram-negative, motile bacilli that can be identified on selective media because they do not ferment lactose. Based on deoxyribonucleic acid (DNA) homology and host range, *Salmonella* isolates are currently classified into two species: *S. bongor*, which includes salmonellae that infect nonhuman organisms, and *S. enterica*, which is divided into six subspecies. Most human pathogens belong to *S. enterica*, subspecies *enterica*. On the basis of somatic O-oligosaccharide cell wall antigens and flagellar H-protein antigens, over 2,300 serovars have been identified. The most commonly reported human serovar in the United States is *S. enteritidis* (formally designated *S. enterica* subspecies *enterica*, serovar enteritidis), which recently surpassed *S. typhimurium*. *S. typhi* and *S. paratyphi* A, B, and C also belong to species *S. enterica*, subspecies enterica. For clarity, only the serovar names will be used in the discussion that follows.

Epidemiology

S. *typhi* and S. *paratyphi*. *S. typhi* and *S. paratyphi* colonize only humans; therefore, disease can be acquired only through close contact with a person who has had typhoid fever or is a chronic carrier. Often acquisition of the organism occurs through the ingestion of water or food contaminated with human excrement. Typhoid fever continues to represent a global health problem, with an estimated 12.5 million cases occurring per year (excluding China) and an annual incidence of 0.5% of the world population.[51] Certain subequatorial countries report high typhoid fever mortality rates (12–32%) despite antibiotic treatment.[51] In these areas, typhoid fever is often endemic and typically constitutes the most important enteric disease problem among school-age children. In the United States, substantial progress has been made in the eradication of *S. typhi*. The incidence of typhoid fever decreased from 1 case per 100,000 in 1955 to 0.2 case per 100,000 in 1966 and has remained fairly stable since then.[52] These changes were clearly related to better sanitation, particularly to food-handling practices and water treatment.

Nontyphoidal S*almonella*. In contrast to *S. typhi*, the incidence of cases of nontyphoidal *Salmonella* infections reported to the Centers for Disease Control and Prevention (CDC) increased between 1970 and 1987 from 12 to 20 per 100,000 population.[53] Because only an estimated 1 to 5% of cases are reported, it is likely that the true incidence is much higher. The incidence is greatest among children younger than 5 years of age (61.8 per 100,000), with a peak at under 1 year of age. Risk of infection and severity of disease are influenced by numerous host factors, including congenital and acquired immunodeficiency,[54,55] age younger than 3 months,[56] and impaired reticuloendothelial function, as is seen in patients with hemolytic anemia. Other risk factors include alterations in intestinal defenses such as achlorhydria, antacid therapy, and in situations in which there is rapid gastric emptying (neonates, postgastrectomy, and gastroenterostomy).[57,58] Ingestion of antibiotics to which the organism was resistant was the most important risk factor identified in an Illinois outbreak that was traced to milk, presumably because of a diminished competition of *Salmonella* growth by endogenous flora.[59] A wide range of domestic and wild animals, including poultry, swine, cattle, rodents, and reptiles, represents the typical reservoirs for nontyphoidal salmonellae.

S. enteriditis is the leading reported cause of foodborne disease outbreaks in the United States.[60] Intact and disinfected grade A eggs and egg-containing foods have been incriminated in over 80% of outbreaks with an identified vehicle. The potential role of cross-contamination is exem-

plified in several outbreaks in which the pulp of surface-contaminated raw fruits and vegetables became inoculated during slicing.[61] Person-to-person transmission, including vertical transmission from mother to child (resulting in neonatal hematochezia),[62] is occasionally seen. Pets (chicks, ducklings, reptiles, cats, and dogs) can also be a source of *Salmonella* infection.[63] Approximately 80% of *Salmonella* isolates reported in the United States appear to be unrelated to outbreaks. [60,61]

Clinical Manifestations

Enteritis. The incubation period ranges between 6 hours and 10 days (usually 6–48 hours).[64] The typical clinical manifestation of nontyphoidal *Salmonella* infection is an acute, self-limited enterocolitis sometimes accompanied by bacteremia. Diarrhea is usually watery but may contain blood, mucus, and fecal leukocytes. Associated headache, abdominal pain, and vomiting may occur. Fever is present in at least 70% of cases.[65] Most patients recover in about 1 week, but diarrhea occasionally becomes persistent.[65] *Salmonella* is usually detected in the stool for about 5 weeks, although approximately 5% of patients will excrete the organism for more than 1 year.[66] The reported incidence of *Salmonella* bacteremia is highest during the first year of life, with a peak during the first 3 months.[67] Estimates of the frequency of bacteremia in infants with *Salmonella* enterocolitis (generally derived from studies of small samples of children) range from 5 to 45%.[68] In the normal host, the bacteremia is transient and usually benign.

Extraintestinal Manifestations. Severe extraintestinal infections occasionally occur, mainly in young infants or in patients with impaired immunity. These infections manifest as life-threatening sepsis or focal infections at virtually any site in the body, particularly the meninges, bones, and lungs,[69] or in areas of localized tissue pathology or anatomic abnormality. *Salmonella* is the most common cause of osteomyelitis in patients with sickle cell anemia.[70] Meningitis is associated with high mortality and neurologic sequelae, even with prolonged antibiotic therapy,[71,72] and a high relapse rate, particularly in neonates.[73] Prolonged diarrhea, weight loss, persistent or recurrent bacteremia, and disseminated infection can develop in human immunodeficiency virus (HIV)-infected patients.[74]

Enteric Fever. Human typhoid and paratyphoid fever are severe systemic illnesses characterized by fever and intestinal symptoms. Case-fatality rates range from less than 1% in the United States to 10 to 30% in Africa and Asia.[67,70] The incubation period of *S. typhi* varies between 5 and 21 days (depending on the inoculum ingested) and may be followed by enterocolitis with diarrhea lasting several days; these symptoms typically resolve before the onset of fever. Constipation is present in 10 to 38% of patients.[75] Nonspecific symptoms such as chills, headache, cough, weakness, and muscle pain are frequent prodromes of typhoid fever. Neuropsychiatric manifestations, including psychosis and confusion (the so-called coma vigil), occur in 5 to 10% of patients with typhoid fever.[76] Approximately 30% of patients experience rose spots on the trunk.[77] Most symptoms resolve by the fourth week of infection without antimicrobial treatment in approximately 90% of patients who survive. Some patients improve initially only to develop high fever and increasing abdominal pain from inflammation of Peyer patches and intestinal microperforation, followed by secondary bacteremia with normal enteric flora.

Diagnosis, Treatment, and Prevention

Nontyphoidal Salmonellosis. The diagnosis of nontyphoidal salmonellosis does not represent a major challenge because the microorganism can easily be isolated from freshly passed stools or blood culture. Antimicrobial therapy is not indicated to treat asymptomatic carriage or uncomplicated nontyphoidal *Salmonella* infections in the normal host. There is considerable evidence that antibiotics neither speed resolution of clinical symptoms nor eliminate fecal excretion; conversely, treatment may prolong excretion or induce relapse.[78] These observations apply to both oral and parenteral antibiotics. Although efficacy is unproven, it is common clinical practice to administer antibiotics to patients with suspected or proven salmonellosis who are at high risk of complications. This includes infants younger than 3 months; patients with hemolytic anemia, malignancy, immunodeficiency, or chronic colitis; and patients who appear "ill" or "toxic," have documented bacteremia, or have an extraintestinal focus of infection. Increasing resistance to commonly used antibiotics is seen in the United States and elsewhere, so the choice of regimens should be guided by susceptibility data. Suggested therapies include trimethoprim-sulfamethoxazole (TMP-SMX), ampicillin (10–20% of isolates in the United States are resistant[78]), cefotaxime, ceftriaxone, or chloramphenicol. Parenteral antibiotics should be considered for infants younger than 3 months, for children at high risk for invasive infection if they have suspected or proven sepsis, and for those who appear "ill" or "toxic" or have a focal infection. Bacteremia is generally treated for 2 weeks, osteomyelitis for 4 to 6 weeks, and meningitis for 4 weeks.

Hygienic practices for preventing foodborne transmission are the most efficient prevention for nontyphoidal *Salmonella* infections because the vast majority of outbreaks and sporadic cases result from culinary practices that allow the organisms to survive and multiply in food. Parents should be instructed to avoid serving food containing raw or undercooked eggs and meat (especially poultry). Food should be thawed in the refrigerator, in the microwave, or under cold water but not at room temperature because surface bacteria begin to multiply when the outer layers warm. Eggs should be cooked until both the yolk and white are firm, and meats must reach an internal temperature of at least 74°C (165°F). Frequent hand washing is important. High-risk pets (especially chicks, ducklings, and reptiles) are not advisable for young children.

An extremely problematic situation is the management of an infected child who is attending day care. Excretion can go on for weeks and create a hardship to working parents if the

child must be excluded from day care. Although the decision to admit such a child must be made in concert with day care and public health officials, it is generally recommended that the infected children be excluded from day care if they are symptomatic or if adequate hygiene cannot be ensured. There is no vaccine to prevent nontyphoidal salmonellosis.

Enteric Fever. The definitive diagnosis of enteric fever requires the isolation of *S. typhi* or *S. paratyphi* from the patient. Cultures of blood, stool, urine, rose spots, bone marrow, and gastric and enteric secretions may all be useful in establishing the diagnosis. Chloramphenicol has been the treatment of choice since its introduction, given its low costs and high efficiency after oral administration. Treatment with chloramphenicol reduced typhoid fever mortality from approximately 20 to 1% and reduced the duration of the fever from 14 to 28 days to 3 to 5 days.[79]

The most effective attenuated vaccine for typhoid fever currently available, Ty21a, has proved to be free of adverse reactions in large-scale efficacy field trials involving almost 600,000 pediatric subjects.[80] When administered as a liquid suspension, Ty21a protected both young (82% vaccine efficacy) and older children (69% vaccine efficacy).[80] Currently, three new-generation attenuated vaccines, genetically engineered by deleting different pathogenic factors, are undergoing extensive phase II or III trials.

SHIGELLA

Shigella dysenteriae type 1 was first isolated by Kiyoshi Shiga during a severe dysentery epidemic in Japan in 1896, when more than 90,000 cases were described with a mortality rate approaching 30%.[81] Over the subsequent 50 years, the microbiology and epidemiology of *Shigella* species were clarified, and the mechanisms whereby the microorganism causes disease have been intensively investigated.

Microbiology

Shigellae are gram-negative, non–lactose-fermenting, nonmotile bacilli of the family Enterobacteriaceae. They are classified into four species: *S. dysenteriae*, *S. flexneri*, *S. boydii*, and *S. sonnei*, also designated groups A, B, C, and D, respectively. Groups A, B, and C contain multiple serotypes, whereas group D contains only a single serotype. The predominant serogroup of *Shigella* circulating in a community appears to be related to the level of development. *S. sonnei* is the main type found in industrialized countries, whereas *S. flexneri*, followed by *S. dysenteriae*, predominates in less developed countries.

Epidemiology

Humans are the only natural hosts for *Shigella*, and transmission is predominantly by fecal-oral contact. The low infectious inoculum (as few as 10 organisms)[82] renders *Shigella* highly contagious. Symptomatic persons with diarrhea are primarily responsible for transmission. Less commonly, transmission is related to contaminated food and water; however, the organism generally survives poorly in the environment. In certain settings where the disposal of human feces is inadequate, houseflies can serve as a mechanical vector for transmission.[83] According to a CDC report, isolation rates of *Shigella* (mostly *S. sonnei*) in the United States have gradually risen since the 1960s from 5.4 to more than 10 isolations per 100,000 population.[84] Endemic foci persist, primarily among indigent persons living in inner cities and in some Native American communities.[84] An elevated risk of shigellosis is also present in settings where hygiene is difficult to maintain, such as day-care centers,[85] in which attending children play an important role in disseminating shigellosis to others in the community.[86] In households with small children, transmission rates can exceed 50%.[87] Worldwide, the incidence of shigellosis is highest among children 1 to 4 years old, a trend also reflected in CDC surveillance data.[84] Nonetheless, *Shigella* infection is uncommon in the United States and accounts for fewer than 5% of episodes of diarrhea among children younger than 5 years of age.[88]

In developing countries, *Shigella* infections, most commonly caused by *S. flexneri*, are mainly endemics. In this setting, endemic shigellosis causes approximately 10% of all diarrheal episodes among children younger than 5 years of age.[89] The Institute of Medicine estimates that *Shigella* causes 250 million cases of diarrhea and 650,000 deaths each year worldwide, mostly in developing countries.[90] One serotype of *Shigella*, *S. dysenteriae* type 1, is capable of true pandemic transmission. Pandemics of Shiga dysentery have spread across Central America, Bangladesh, South Asia, and Central and East Africa during the past 30 years[91,92] and have been particularly problematic among refugee populations.[92] In the United States, *S. dysenteriae* infection is seen exclusively among travelers returning from abroad.

Clinical Manifestations

After an incubation period of 1 to 4 days, shigellosis usually begins with systemic symptoms, including fever, headache, malaise, anorexia, and occasional vomiting. Watery diarrhea typically precedes dysentery[93] and is often the sole clinical manifestation of mild infection.[94] Progression to frank dysentery may occur within hours to days, with frequent small stools containing blood and mucus accompanied by lower abdominal cramps and rectal tenesmus. Patients with severe infection may pass more than 20 dysenteric stools in 1 day. A variety of unusual extraintestinal manifestations may occur.[95] The microangiopathic hemolytic anemia that can complicate infection with organisms that produce Shiga toxin (see "Pathogenesis") manifests itself as hemolytic uremic syndrome (HUS) in children and as thrombotic thrombocytopenic purpura in adults.[96]

Most episodes of shigellosis in otherwise healthy individuals are self-limited and resolve within 5 to 7 days without sequelae. Acute, life-threatening complications are most often seen in malnourished infants and young children living in developing countries. In the United States, *Shigella* bacteremia has been reported among HIV-infected and other immunocompromised patients.[97]

Diagnosis, Treatment, and Prevention

Shigella are extremely fastidious to culture and readily die off if the stool sample is not well handled. The best way to isolate the organism is to (1) obtain stool (and not rectal

swab), (2) rapidly inoculate the specimens onto selective culture plates, preferably at the bedside, and (3) quickly incubate them at 37°C.

Many controlled clinical trials demonstrate that appropriate antibiotics decrease the duration of fever, diarrhea, intestinal protein loss, and pathogen excretion in shigellosis. Most patients in these studies were infected with either *S. flexneri* or *S. dysenteriae*. The advantages of treating *S. sonnei*, which is usually self-limited, are less clear. Susceptible strains can be treated with ampicillin (but not amoxicillin) or TMP-SMX. With the exception of severely ill patients, therapy can be administered orally. However, since the mid-1980s, strains of *S. dysenteriae*, *S. flexneri*, and *S. sonnei* that are resistant to one or both drugs have been identified with increasing frequency in Asia, Africa, and North America,[98] dictating a more cautious approach to empiric therapy. For infections acquired in the United States and for which susceptibility is unknown, TMP-SMX is given empirically for 5 days unless resistance is suspected or proved. Fewer than 5% of domestically acquired isolates are resistant to TMP-SMX, whereas about 10% are resistant to ampicillin.[98]

Interruption of transmission by individual hygienic behavior, such as hand washing, is an effective way to control and prevent endemic transmission. One intensely pursued strategy for constructing modern attenuated oral vaccine candidates involves the generation of defined deletions in virulence wild-type *Shigella* genes or genes that affect the ability to survive or proliferate in vivo. Several promising deletion mutants have entered clinical trials.

CAMPYLOBACTER

It is surprising that *Campylobacter* enteritis, the most common bacterial form of acute infective diarrheal disease in developed countries, was not recognized until the mid-1970s.[99] Why *Campylobacter* has been overlooked by microbiologists remains a matter for debate, but the too rigid methods of cultures and the failure to pick up ideas from the field of veterinary microbiology certainly played a role.

Microbiology

Organisms of the family Campylobacteriaceae are small, nonsporing, spiral-shaped gram-negative bacteria that exhibit rapid darting motility by means of a single flagellum at one or both ends. *Campylobacter* are largely microaerophilic, that is, they tolerate only low oxygen concentrations (5–10%). Molecular techniques have shown that *Campylobacter* (13 species pathogenic for humans), *Helicobacter*, *Arcobacter*, and *Wolinella* belong to a distinct phylogenetic group far removed from other gram-negative bacteria.[99] *C. jejuni* is by far the most common species isolated from patients with diarrhea in most areas (80–90 percent of infections), followed by *C. coli*.[100]

Epidemiology

Campylobacter enjoys a widespread reservoir in the intestines of both wild and domestic animals.[101] Case-control studies indicate that the vehicle for at least half of all endemic cases is poultry,[102] whereas common-source outbreaks are usually linked to consumption of unpasteurized milk[103] or contaminated water.[104] Up to 75% of raw poultry (but less than 5% of pork and beef) on sale in the United States is contaminated with *Campylobacter*.[105] As a result of its extensive animal reservoir, virtually all surface waters are contaminated with campylobacters, even in remote regions.[106]

Although they share many epidemiologic features, there are important differences between *Campylobacter* and *Salmonella*. *Salmonella* is more likely to infect animals in large-scale husbandry operations and has thus become an important problem in industrialized countries. In contrast, *Campylobacter* spp live naturally as commensals in a wide variety of animals and cause human infections globally.[107] *Campylobacter* does not multiply in food to high concentrations like *Salmonella* does; however, the inoculum required to cause infection is lower.[108] This may explain why, unlike *Salmonella*, *Campylobacter* rarely causes explosive foodborne outbreaks.

The annual incidence of *Campylobacter* infection in the United States is about 1%, making it the most frequently identified bacterial cause of diarrhea.[109] In industrialized countries with temperate climates, the peak incidence of infection occurs during the summer, and infections are more common in rural communities.[110] There is a bimodal age-specific incidence, with a principal climax during 0 to 5 years of age (highest, < 12 months) and a secondary rise among young adults 15 to 29 years of age.[111] In less developed countries, infection is hyperendemic, found in 8 to 45% of cases of diarrhea and in an equal number of asymptomatic controls during the first 5 years of life.[107]

Clinical Manifestations

After an incubation period of 3 to 6 days, *Campylobacter* enteritis begins abruptly with abdominal cramps and diarrhea.[111] Watery diarrhea often precedes the onset of blood-containing stools and is often the sole manifestation, especially among children from developing countries. However, abdominal pain may be so intense as to mimic appendicitis.[112] Diarrhea usually lasts 4 to 5 days, but in some patients, abdominal discomfort persists and brief relapses of diarrhea occur. The mean duration of fecal excretion is about 1 month in the normal host,[113] but carriage may be prolonged in patients with immunodeficiency. Neonates frequently experience milder illness, often with hematochezia in the absence of fever and diarrhea. However, severe or systemic illness may occur; *C. fetus* causes most cases of neonatal *Campylobacter* meningitis.[114]

Diagnosis, Treatment, and Prevention

A definitive diagnosis of *Campylobacter* infection can be made only by identifying the microorganism in a patient's stools. Properly taken rectal swabs are also satisfactory. The indication of antibiotic therapy for *Campylobacter* remains controversial. In some studies, early treatment shortened the course of diarrhea,[115] whereas in other studies, no clear clinical benefit was observed.[116] It is advisable to reserve antibiotics for patients with severe illness ongoing at presentation (either dysentery or suspected *Campylobacter*

infection on the basis of specific clinical or epidemiologic evidence) or if risk factors (pregnancy, systemic infection, immunosuppression) are present. Erythromycin remains the drug of choice for *Campylobacter* enteritis.[109]

Campylobacter vaccine development has proceeded cautiously because of concerns about postexposure arthritis or Guillain-Barré syndrome. The most developed approach is to orally administer killed *Campylobacter* cells. A monovalent, formalin-inactivated *C. jejuni* whole-cell vaccine with a mucosal adjuvant has entered human trial.[117]

YERSINIA

Like *Escherichia coli* and *Salmonella*, *Yersinia* is a heterogeneous species; however, only a few pathogenic serotypes commonly cause disease in humans.

Microbiology

The genus *Yersinia*, of the family Enterobacteriaceae, contains two important human enteropathogens: *Y. enterocolitica* and *Y. pseudotuberculosis*. *Y. enterocolitica* is divided into six biotypes and more than 50 O-antigen serotypes, whereas *Y. pseudotuberculosis* contains six serotypes with four subtypes. Several other *Yersinia* species, including *Y. bercovieri*, *Y. mollaretii*, *Y. intermedia*, and *Y. rodhey*, are widespread in the environment but are rarely human pathogens. These microorganisms are non–lactose-fermenting gram-negative aerobic and facultatively anaerobic bacilli that grow better at 25°C than at 37°C.

Epidemiology

Yersinia spp are distributed widely in the environment, with swine serving as the major reservoir for human pathogenic strains. Foodborne transmission is the suspected route for most infections, but the source is usually not identified.[118] The high infectious inoculum makes person-to-person transmission by fecal-oral spread an improbable event.[119] Most episodes of *Yersinia* enteritis occur in infants and young children.[120] *Yersinia*'s preference for cool temperatures makes this pathogen more common in regions in northern latitudes, such as in northern Europe, Scandinavia, Canada, the United States, and Japan, where it is responsible for 1 to 8% of sporadic diarrhea episodes.[121]

Clinical Manifestations

The incubation period is estimated to be 3 to 7 days. *Yersinia* enterocolitis occurs most often in children younger than 5 years of age and is characterized by watery diarrhea, usually with fever and abdominal pain.[122] The stools contain blood in 25 to 30% of patients. There may be vomiting, and approximately 20% of subjects exhibit pharyngitis that can be exudative and associated with cervical adenitis.[123] The organism can frequently be isolated from the pharyngeal exudate. Diarrhea typically lasts for 14 to 22 days, but fecal excretion may persist for 6 to 7 weeks or longer.[122] Abdominal complications may include appendicitis, diffuse ulceration of the intestine and colon, intestinal perforation, peritonitis, ileocecal intussusception, toxic megacolon, cholangitis, and mesenteric venous thrombosis.[121] The pseudoappendicitis syndrome occurs primarily in older patients and adults.[124] These patients typically present with fever and abdominal pain, with tenderness localized to the right lower quadrant, with or without diarrhea. Computed tomography may be helpful in distinguishing true appendicitis from *Yersinia* infection.[125] Case-fatality rates may reach 50%. Bacteremic spread may result in abscess formation and granulomatous lesions in the liver, spleen, lungs, kidneys, and bone and may also result in mycotic aneurysm, meningitis, and septic arthritis.[121] As with the other bacterial enteropathogens, *Y. enterocolitica* infection is associated with immunopathologic sequelae, including reactive arthritis, uveitis, Reiter syndrome, and erythema nodosum.[121]

Diagnosis, Treatment, and Prevention

Y. enterocolitica may be isolated from stool on commonly used selective media and appears as gram-negative colonies after 48 hours of growth at 25° to 28°C. Detection of the microorganism in stool by polymerase chain reaction (PCR) methodology may represent a valid future alternative.

Like *Campylobacter*, most uncomplicated cases of *Yersinia* gastroenteritis and pseudoappendicitis resolve without treatment. Therapy is reserved for patients with severe or extraintestinal infections and for immunocompromised individuals. Production of β-lactamases by *Y. enterocolitica* generally renders all but third-generation cephalosporins, aztreonam, and imipenem ineffective.[126] Broad-spectrum cephalosporins, often in combination with aminoglycosides, resulted in a good clinical outcome in 85% of cases of sepsis in one retrospective review.[126] The duration of therapy is generally 2 to 6 weeks, with an initial intravenous antibiotic followed by an oral agent to which the clinical isolate is sensitive. No enteric vaccines against *Y. enterocolitica* are currently available.

ESCHERICHIA COLI

An extremely heterogeneous group of microorganisms, *E. coli* encompasses almost all features of possible interactions between intestinal microflora and the host, ranging from a role of mere harmless presence to that of a highly pathogenic organism. In fact, the *E. coli* species is made up of many strains that profoundly differ from each other in terms of biologic characteristics and virulence properties.[127]

E. coli are gram-negative, lactose-fermenting motile bacilli of the family Enterobacteriaceae. Currently, 171 somatic (O) and 56 flagellar (H) antigens are recognized. Six distinct categories of *E. coli* are currently considered enteric pathogens (based on either outbreak data or volunteer studies) (see Table 38.1-1): enteropathogenic *E. coli* (EPEC), enterotoxigenic *E. coli* (ETEC), enteroinvasive *E. coli* (EIEC), enterohemorrhagic *E. coli* (EHEC), diffusely adherent *E. coli* (DAEC), and enteroaggregative *E. coli* (EAggEC).

The diagnosis of diarrheagenic *E. coli* relies on isolation from stool and subsequent differentiation from commensal *E. coli* either by using genetic probes or by phenotypic assays. With the exception of *E. coli* O157:H7, assays for detection are not routinely available in clinical laboratories.

Enteropathogenic E. coli

This was the first group of *E. coli* species shown to be pathogens for humans and has been responsible for devastating outbreaks of nosocomial neonatal diarrhea and infant diarrhea in virtually every corner of the globe. Species of EPEC are distinguished from other *E. coli* species by their ability to induce a characteristic attaching and effacing lesion in the small intestinal enterocytes and by their inability to produce Shiga toxins.

Epidemiology. Between the 1940s and the 1960s, EPEC was associated with infant diarrhea in summertime and nursery outbreaks of diarrhea in the United States and other industrialized countries. Since then, it has become extremely uncommon in industrialized countries, although it is occasionally reported in child care settings.[128] However, EPEC persists as an important cause of infantile diarrhea in many developing countries.[129] In nursery outbreaks, transmission was thought to occur via the hands of caretakers and via fomites. In less developed countries, contaminated formula and weaning foods have been incriminated.

Clinical Manifestations. Volunteer studies and epidemiologic observations suggest that the infective dose for EPEC is high ($\approx 10^9$ colony-forming units).[130] EPEC causes a self-limited watery diarrhea with a short incubation period (6–48 hours). There may be associated fever, abdominal cramps, and vomiting. EPEC is a leading cause of persistent diarrhea (lasting 14 days or longer) in children in developing countries.[131]

Treatment and Prevention. Although few data exist to guide antibiotic therapy of EPEC diarrhea, administration of appropriate antibiotics seems to diminish morbidity and mortality. A 3-day course of oral, nonabsorbable antibiotics such as colistin or gentamicin (if available) has been shown to be effective.[132] Some clinicians also advocate the use of oral neomycin; however, this drug causes diarrhea in about 20% of people. In a placebo-controlled trial among Ethiopian infants with severe EPEC diarrhea, TMP-SMX and mecillinam resulted in significant clinical and bacteriologic cure rates by the third day compared with placebo.[133]

Strategies for the prevention of EPEC infection include efforts to improve social and economic conditions in developing countries, efforts to encourage breastfeeding, and prevention of nosocomial infections.

Enterotoxigenic E. coli

Species of ETEC are an important cause of diarrheal disease in humans and animals worldwide. The clinical importance of these microorgansims was first outlined in the 1970s by epidemiologic studies in India that identified them as a major cause of endemic diarrhea.[134] Their pathogenicity is related to the elaboration of one or more enterotoxins that are either heat stable (ST) or heat labile (LT) (see "Pathogenesis") without invading or damaging intestinal epithelial cells.

Epidemiology. Together with *Rotavirus*, ETEC is the leading cause of dehydrating diarrheal disease among weaning infants in the developing world. These children experience two to three episodes of ETEC diarrhea in each of the first 2 years of life. This represents over 25% of all diarrheal illness[135] and results in an estimated 700,000 deaths each year.[136] In industrialized countries, ETEC does not contribute to endemic disease[88] but is notorious for being the leading agent of traveler's diarrhea, accounting for about half of all episodes.[137] Transmission occurs by ingestion of contaminated food and water, with peaks during the warm, wet season.

Clinical Manifestations. Like EPEC, ETEC requires a relatively high inoculum[138] and has a short incubation period (14–30 hours). The cardinal symptom is watery diarrhea, sometimes with associated fever, abdominal cramps, and vomiting. In its most severe form, ETEC can cause cholera-like purging, even in adults. The illness is typically self-limited, lasting for less than 5 days, with few cases persisting beyond 3 weeks. Infection with ETEC has also been associated with short- and long-term adverse nutritional consequences in infants and children.

Treatment and Prevention. Most diarrheal illnesses owing to ETEC are self-limited and do not require specific antimicrobial therapy. Empiric therapy is reserved for those whose diarrhea is moderate to severe despite rehydration and supportive measures. Antibiotic regimens that have been efficacious in clinical trials, shortening the duration of illness by 1 to 2 days, include doxycycline, TMP-SMX, ciprofloxacin, quinolones, and furazolidone.[139] In the past, the drug of choice for children has been TMP-SMX; however, except in Central Mexico, a large proportion of ETEC is now resistant.[140] An alternative regimen for use in children is furazolidone.

Prevention of ETEC infection is based on avoiding contaminated vehicles. Although antibiotics are effective as prophylactic agents, their use is not recommended. Some experts advocate the use of bismuth subsalicylate to diminish the risk of traveler's diarrhea.[141] The development of vaccines against ETEC has received a great deal of attention because of the disease burden. Oral vaccines for ETEC are being developed by five different strategies, including killed whole cells, toxoids, purified fimbriae, living attenuated strains, and live carrier strains elaborating ETEC antigens. A killed whole-cell *V. cholerae* vaccine given with cholera toxin B provided 67% protection against LT-producing ETEC diarrhea for 3 months.[142] A formalin-inactivated whole-cell oral vaccine consisting of ETEC strains bearing colonization factor antigens in combination with cholera toxin B has entered field trial.[143]

Enteroinvasive E. coli

This group consists of invasive *E. coli* species that are genetically, biochemically, and clinically nearly identical to *Shigella*. This section serves only to highlight relevant characteristics that distinguish this pathogen.

Epidemiology. Species of EIEC are endemic in developing countries, where they exhibit similar epidemiology to *Shigella* and cause an estimated 1 to 5% of diarrheal episodes among patients visiting treatment centers.[144] The occurrence of EIEC in industrialized countries is limited to rare foodborne outbreaks.[145] From volunteer studies, it appears that the infectious inoculum is higher than that required to cause shigellosis.[146]

Clinical Manifestations, Treatment, and Prevention. Like *Shigella*, EIEC can produce dysentery, but watery diarrhea is more common.[147] The rare episodes for which treatment is desired are treated with antibiotics recommended for shigellosis. The same general preventive measures used for *Shigella* infections apply to EIEC-associated diarrhea.

Enterohemorrhagic E. coli

These *E. coli* species produce either one or both phage-encoded potent cytotoxins termed Shiga-like toxin (SLT) I (which is neutralized by antiserum to Shiga toxin produced by *S. dysenteriae* type I) or SLT II (which is not neutralized) and can cause diarrhea or HUS. *E. coli* O157:H7 is the prototypic (but not the exclusive) EHEC serotype because it is the predominant SLT-producing *E. coli*, the one most commonly associated with HUS in North America and the type most readily identified in stool specimens.[148]

Epidemiology. In 1982, a multistate outbreak of hemorrhagic colitis that was linked to the consumption of hamburgers at the same fast-food restaurant led to the identification of EHEC.[149] The causative organism was *E. coli* O157:H7, a serotype not previously recognized as a human pathogen. Soon after, Canadian investigators uncovered an association between O157:H7 and other SLT-producing strains of *E. coli* and HUS.[150] EHEC is now recognized as a global health problem; in 1996, an outbreak in Japan linked to eating radish sprouts affected over 6,000 persons.[151] One of the most severe EHEC outbreaks in the United States took place in New York State in 1999, with more than 1,000 ascertained cases, 2 HUS-related casualties, and 8 children on dialysis because of renal failure. Most of the infected individuals attended a fair whose underground water supply was contaminated by cow manure from a nearby cattle barn.

The predominant mode of transmission is ingestion of contaminated, undercooked ground beef. However, the spectrum of vehicles is widening to include raw fruits (including apple juice) and vegetables,[152,153] raw milk,[154] processed meats,[155] and drinking[156] or swimming[157] in contaminated water. The uncooked food vehicles are usually contaminated with manure from infected animals during growth or processing. Person-to-person transmission is the mode of spread in day-care outbreaks, for which secondary transmission rates of 22% have been reported.[158]

EHEC also causes sporadic diarrhea. Isolation from stools of unselected patients is low (< 1%), but isolation from stools of patients with bloody diarrhea may be as high as 20 to 30%.[159] A national laboratory-based study demonstrated that infection is more frequent in northern states and that it peaks from June through September.[159] The highest age-specific isolation rates are in patients 5 to 9 and 50 to 59 years of age. A population-based incidence rate based on stool samples submitted to a large health maintenance organization laboratory in the state of Washington was 8 per 100,000 person-years.[160]

Clinical Manifestations. Illness with EHEC follows 3 to 9 days after ingestion of as few as 100 organisms.[161] Crampy abdominal pain and nonbloody diarrhea are the first symptoms, sometimes associated with vomiting. By the second or third day of illness, diarrhea becomes bloody in ≈ 90% of cases, and abdominal pain worsens.[162] Bloody diarrhea lasts between 1 and 22 days (median 4 days). Unlike other infectious causes of bloody diarrhea, fever is usually absent or remains low grade. Younger children appear to excrete the organisms longer (median 3 weeks) than older children and adults.[163]

In outbreaks, approximately 25% of patients are hospitalized, 5 to 10% develop HUS, and 1% die.[164,165] Intestinal complications include rectal prolapse, appendicitis, intussusception, and pseudomembranous colitis.[148,166]

The most frightening complication of EHEC infection is HUS. It is usually diagnosed 2 to 14 days after the onset of diarrhea.[150] Risk factors include young and old age, bloody diarrhea, fever, an elevated leukocyte count, and treatment with antimotility agents.[166,167] Two-thirds of patients who develop HUS are no longer excreting the organism at presentation.[168]

Diagnosis. The most widely accepted indication for seeking a clinical diagnosis of *E. coli* O157:H7 infection is a patient with bloody diarrhea, in whom an accurate diagnosis may avoid unnecessary medical procedures because a surgical abdomen (such as appendicitis or intussusception) is suspected. A multicenter study found that when the presence of fecal blood was used as the sole criterion for culturing O157 strains, only 3% of stools would be cultured to detect 63% of infections.[159] Diagnosis may also be helpful in patients with HUS or with any type of diarrhea in a contact of a patient with HUS. *E. coli* O157:H7 is not detected by routine stool culture. A relatively inexpensive method exploits the inability of *E. coli* O157 to rapidly ferment sorbitol after 24 hours of incubation on sorbitol-MacConkey agar, in contrast to ~ 90% of commensal *E. coli*. The "sorbitol-negative" colonies can then be screened for the presence of O157 antigen, using commercially available antisera. These strains should be considered pathogenic pending the determination of the H type in a reference laboratory.

Treatment and Prevention. Although data are not available from prospective randomized double-blind trials, there is considerable evidence to suggest that patients who receive antibiotics to which the offending *E. coli* O157:H7 is sensitive have either the same or a poorer outcome when compared with untreated patients.[166,169,170] Therefore, antibiotic therapy is not recommended for EHEC infection. As mentioned above, antimotility agents have been

identified as a risk factor for the development of HUS and should be avoided.

Prevention of *E. coli* O157:H7 is a complex process. From a public health standpoint, control measures at the level of farms, slaughterhouses, and processing plants can decrease the risk of colonization of cattle and contamination of beef. Because these procedures are unlikely to achieve complete success, regulations governing proper processing and cooking of contaminated foods are also required. Advice to consumers should include recommending complete avoidance of raw foods of animal origin. Hamburger should be cooked until no pink remains and the juices are clear.

Because of the severity of the disease, there has been a recent focus on vaccine development for EHEC infection. Efforts have concentrated on three approaches: (1) parenteral toxoids and live oral carrier strains elaborating the B subunit of Shiga toxin[171]; (2) vaccines expressing the adhesin intimin, designed to prevent intestinal colonization[172]; and (3) a parenteral O157 polysaccharide protein conjugate.[173]

Diffusely Adhering E. coli

Until recently, DAEC was considered a nonpathogenic *E. coli* because early studies failed to find an association between this microorganism and diarrheal disease.[174–176] However, more recent studies have demonstrated such an association, particularly in children older than 2 years of age.

Epidemiology. A community-based, case-control study in southern Mexico revealed that DAEC was significantly associated with diarrhea in children less than 6 years of age.[177] Prospective cohort studies in Chile[178] and Bangladesh[179] also demonstrated a diarrheagenic role for DAEC that peaked in the 48- to 60-month age group.[178] This microorganism was more frequently isolated from cases of prolonged diarrhea,[179] and it showed a seasonal pattern similar to that of ETEC, occurring more frequently in the warm season.[178]

Clinical Manifestations, Diagnosis, and Treatment. The gastrointestinal symptoms that characterize DAEC infection are practically indistinguishable from those caused by ETEC, with self-limiting watery diarrhea rarely associated with vomiting and abdominal pain. The diagnosis is mainly based on DNA probe technique and on the pattern of adherence of the microorganism on Hep-2 cells. Given the technical challenge of both assays, their use is limited to epidemiologic surveys rather than the diagnosis of individuals.

Enteroaggregative E. coli

EAggEC are diarrheagenic *E. coli* defined by a characteristic aggregating pattern of adherence to Hep-2 cells and the intestinal mucosa (Figure 38.1-2). They have been particularly associated with cases of persistent diarrhea in the developing world. It has been hypothesized that the aggregating pattern of adherence may be a result of nonspecific, possibly hydrophobic, interaction; therefore, not all organisms meeting the definition of EAggEC may be pathogenic in humans. Moreover, because epidemiologic studies have not uniformly implicated EAggEC as pathogenic, some investigators have questioned the virulence of all EAggEC isolates. Volunteer studies performed to address both of these questions[180] confirmed that at least some EAggEC species are genuine human pathogens but that virulence is not uniform among isolates. More recently, EAggEC pathogenicity has also been proven in several outbreaks.

Epidemiology. From the earliest epidemiologic reports, EAggEC was most prominently associated with persistent cases of pediatric diarrhea (ie, lasting ≥ 14 days),[181] a condition that represents a disproportionate share of diarrheal mortality. On the Indian subcontinent, several independent studies have demonstrated the importance of EAggEC in pediatric diarrhea.[182] These studies include hospitalized patients with persistent diarrhea,[175] outpatients visiting health clinics,[182] and cases of sporadic diarrhea detected by household surveillance.[174] In Fortaleza, Brazil, Fang and colleagues demonstrated a consistent association between EAggEC and persistent diarrhea[183]; in this area, EAggEC accounts for more cases of persistent diarrhea than all other causes combined.[183] EAggEC have been implicated as a cause of sporadic diarrhea in other developing countries (including Mexico, Chile, Bangladesh, Congo, and Iran), as well as in industrialized countries such as Germany and England.[184] Besides being responsible for sporadic cases of diarrhea, EAggEC has also been associated with outbreaks in India,[185] Serbia,[186] Japan,[187] and England.[188]

Clinical Manifestations. The clinical features of EAggEC diarrhea are becoming increasingly well defined in outbreaks, sporadic cases, and the volunteer model. Typically, illness is manifested by a watery, mucoid, secretory diarrheal illness with low-grade fever and little or no vomiting.[174,189] However, in epidemiologic studies, grossly bloody stools have been reported in up to one-third of patients with EAggEC diarrhea.[190] This phenomenon may well be strain dependent. In volunteers infected with

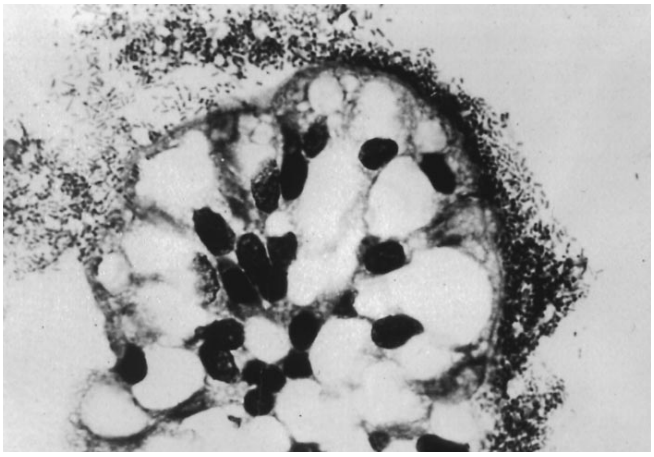

FIGURE 38.1-2 Histopathology of enteroaggregative *Escherichia coli* (EAggEC) infection in a gnotobiotic piglet ileum. The light photomicrograph shows the aggregate pattern of adherence to the intestinal mucosa that characterizes these microorganisms (hematoxylin and eosin; ×100 original magnification).

EAggEC strain 042, diarrhea was mucoid, of low volume, and, notably, without occult blood or fecal leukocytes; all patients remained afebrile. In such volunteers, the incubation period of the illness ranged from 8 to 18 hours.[180]

Perhaps even more significant than the association of EAggEC with diarrhea are the recent data from Brazil that link EAggEC with growth retardation in infants.[190] In this study, the isolation of EAggEC from the stools of infants was associated with a low z-score for height and/or weight, irrespective of the presence of diarrheal symptoms. Given the high prevalence of asymptomatic EAggEC excretion in many areas,[181,191] such an observation may imply that the contribution of EAggEC to the human disease burden is significantly greater than is currently appreciated.

Diagnosis and Treatment. Colonization of EAggEC is detected by the isolation of *E. coli* from the stools of patients and the demonstration of the aggregative pattern in the Hep-2 assay. Implication of EAggEC as the cause of the patient's disease must be done cautiously, given the high rate of asymptomatic colonization in many populations.[181,191] If no other organism is implicated in the patient's illness and EAggEC is isolated repeatedly, then EAggEC should be considered a potential cause of the patient's illness. A DNA fragment probe has proven highly specific in the detection of EAggEC strains. A PCR assay using primers derived from the aggregative probe sequence shows similar sensitivity and specificity.[192]

The optimal management of EAggEC infection has not been studied. Acute diarrhea is apparently self-limiting; however, more persistent cases may benefit from antibiotic and/or nutritional therapy. Given the high rate of antibiotic resistance among EAggEC,[193] susceptibility testing is recommended when available.

CLOSTRIDIUM DIFFICILE

Even though *Clostridium difficile* is now recognized as the single most common cause of bacterial diarrhea in hospitalized patients, its role as a pathogen had not been established as recently as the late 1970s. *C. difficile* has the ability to become established in the intestinal tract once the natural microflora have been modified by antibiotic therapy. The organism causes intestinal disease ranging from mild diarrhea to fatal pseudomembranous colitis (PMC). Although *C. difficile* is associated with almost all cases of PMC, only 25% of antibiotic-associated diarrheas are due to this pathogen.

Microbiology. *C. difficile* is a gram-positive anaerobe that forms spores, making this microorganism very difficult to remove from the hospital environment. Unlike some toxigenic clostridia, the production of spores is not associated with toxin production.

Epidemiology. *C. difficile* spreads from patient to patient[194] and tends to persist in the environment because of the formation of spores. The microorganism is not only present in the infected patient and soiled linens but can be isolated from bookshelves, curtains, and floors of rooms of infected patients, where it can persist for as long as 5 months.[194–196] The organism is spread primarily by health care workers; up to 60% of personnel attending patients infected with *C. difficile* in one study had the organism on their hands.[194] The isolation of *C. difficile* toxins from the feces of asymptomatic normal-term neonates and (in higher proportion) those admitted into neonatal intensive care units[197] further supports the concept of the nosocomial spreading of the infection.

Several outbreaks of *C. difficile* infection have been reported in the United States and throughout the world, and the incidence continues to rise. Whether this increase represents a true increment or an increased awareness of the disease is not clear at this stage.

Clinical Manifestations. Infections with *C. difficile* range in severity from asymptomatic forms to clinical syndromes, such as severe diarrhea, PMC, and toxic megacolon, and can even lead to death.[198] The onset of symptomatic forms usually begins several days after starting antibiotic therapy up to 2 months following cessation of treatment. Diarrhea and abdominal cramps are usually the first symptoms, followed by the development of fever and chills in severe cases.

Diagnosis and Treatment. Mild forms of colitis, with bloody stools and mucus, particularly if they are preceded by antibiotic treatment, should be considered suspicious for *C. difficile* infection. Clinical microbiologists face an array of methods and commercial tests when considering which procedure to use for the detection of *C. difficile* and its toxins. Culturing of the organism, latex agglutination, tissue culture assay, and enzyme-linked immunosorbent assay are all used as aids for the diagnosis of *C. difficile* infection.

In many instances, *C. difficile* disease is self-limiting, and the patient may respond simply to the withdrawal of the offending antibiotic. In more severe forms, particularly if complicated by PMC, antibiotic treatment with either oral vancomycin[199] (5–10 mg/kg, maximum 500 mg, given every 6 hours for 7 days) or metronidazole[200] (5–10/per kg, maximum 500 mg, given every 8 hours for 7 days) is recommended. Despite pharmacologic treatment, the rate of relapse is significant (up to 40–50% of cases). In these complicated patients, the use of probiotics, particularly *Lactobacillus* GG[201] and *Saccharomyces boulardii*,[202] has been associated with a significant eradication of *C. difficile* and a substantial decrease in the recurrence of the infection.

AEROMONAS, PLESIOMONAS, AND EDWARDSIELLA

This group includes microorganisms of which the existence has been known for a long time; however, only recently have they been associated with human diseases.

AEROMONAS

Aeromonads are gram-negative facultative anaerobic, motile bacilli. Although their association with enteritis is still con-

troversial, experimental, clinical, and epidemiologic data continue to support the evidence that at least certain strains are involved in diarrheal diseases.[203] The highest attack rate appears to be in young children, particularly those under 3 years of age.[204] *Aeromonas* infections occur more frequently during the warm months, with an isolation rate that varies from as little as 0.7% to peaks of 50%.[205] Despite these data, a number of troubling aspects regarding the association between *Aeromonas* and diarrhea remain unresolved. In contrast to other waterborne and foodborne pathogens, no clearly defined outbreaks of diarrheal illnesses associated with the pathogen have ever been reported, even though the microorganism is often isolated from water, food, and other environmental sources.

The intestinal diseases caused by *Aeromonas* cover the same spectrum of clinical manifestations secondary to other classic enteric pathogens. *Aeromonas* spp have been associated with several distinctive clinical syndromes, including watery diarrhea, dysentery, and prolonged or chronic diarrhea. Acute secretory diarrhea is the most commonly reported, with as many as 20 bowel movements a day. Abdominal pain, fever, nausea, and vomiting are common associated symptoms.[206,207] Although the infection is usually self-limited (< 7 days in duration), dehydration or persistent diarrhea may occur in one-third of the cases. The most common *Aeromonas* species isolated in these cases is *A. caviae*. Some children with this infection experience abdominal complications secondary to their diarrheal episodes, including failure to thrive, gram-negative sepsis, and HUS.[207]

The mainstay of therapy in *Aeromonas*-associated enteritis, as in any diarrheal disease, is rehydration, via either the oral or the intravenous route. The illness is usually self-limited, and previously healthy subjects who experience this form of enteritis who are not treated with antibiotics appear to do well, with rapid resolution of the symptoms and clearance of the microorganism from the stools. TMP-SMX is considered the drug of choice for the chronic forms that seem to benefit from antibiotic treatment.[208]

Plesiomonas

Plesiomonas, originally assigned to the family Vibrionaceae but recently reassigned to Enterobacteriaceae,[209] are gram-negative, facultative anaerobic, motile, primarily freshwater organisms, with isolation rates increasing during the warm months. Fish and shellfish, especially if associated with mud or sediment, frequently harbor plesiomonads.[210] However, the microorganism can also be isolated from the feces of asymptomatic animals, including cats and dogs.[211] Although less frequently encountered in the United States, *Plesiomonas shigelloides* is commonly isolated in other areas, particularly in Bangladesh, where this organism represents the fourth leading cause of bacterial enteritis.[212] Typical symptoms of *P. shigelloides* infection include secretory or a colitis/proctitis type of diarrhea (one-third of patients experience frank bloody diarrhea), abdominal pain, nausea, vomiting, and fever. Fatal outcomes of severe intestinal infections without apparent dissemination by *Plesiomonas* have also been described.[213] Quinolones and TMP-SMX are the best oral agents for the treatment of uncomplicated infections whose course seems to be shortened by antibiotic treatment.[214]

Edwardsiella

The genus *Edwardsiella* is composed of bacteria that are gram-negative, facultative anaerobic rods. *E. tarda*, the only species in this genus consistently associated with both intestinal and extraintestinal human illness, has been isolated from the feces of persons suffering from diarrheal diseases and from fish, freshwater ecosystems, and animals that inhabit these locales, such as reptiles and amphibia. Enteritis associated with *E. tarda* exists either as a benign secretory diarrhea or as a more invasive process resembling dysentery or enterocolitis. The most common symptoms include low-grade fever, vomiting, and watery stools.[215] Symptoms may be more severe (resembling PMC or invasive enterocolitis) and include cramping, abdominal pain, nausea, tenesmus, and up to 20 bowel movements per day. Occasionally, disseminated *E. tarda* infections (septicemia, hepatic abscess) can occur in subjects with liver dysfunction or iron overload conditions.[216] Ampicillin, TMP-SMX, and ciprofloxacin are all reasonable choices for the treatment of *E. tarda* infections.

PATHOGENESIS

The distinguishing characteristics of bacteria (small size, concise deployment of genetic information, and the ability to survive in highly varied circumstances) contribute to their acclaimed virtuosic ability to adapt and learn fast in order to survive. To be a successful enteric pathogen, a bacterium must be a good colonizer, must compete for nutrients, and must be able to interact with the target eukaryotic cell to induce secretion of water and electrolytes. Because the basic metabolism of enteric pathogens and commensals is the same, it follows that pathogens must possess highly specialized attributes that enable them to activate one of the eukaryotic intracellular pathways leading to intestinal secretion.[217] This cross-communication between enteric bacteria and the intestinal host is typically activated by the elaboration of enterotoxins (Table 38.1-2) that subvert host-cell signal transduction pathways, leading to the secretion of water and electrolytes and thus to diarrhea.

Toxins that Activate Enterocyte Signal Pathways

Intestinal cells operate through three main intracellular signal transduction pathways to regulate ion transport vectorially: (1) cyclic adenosine monophosphate (cAMP), (2) cyclic guanosine monophosphate (cGMP), and (3) calcium-dependent pathways (Figure 38.1-3). A fourth pathway involving cytoskeleton rearrangement has also been described (see Figure 38.1-3).

Cyclic Adenosine Monophosphate. Cholera toxin elaborated by *V. cholerae* represents the archetype of the family of cAMP-mediated toxins and is certainly the most extensively investigated. Cholera toxin is a protein with a relative molecular mass (M_r) of 84 kD, made up of five B subunits with

Campylobacter jejuni cytolethal distending toxin
Vibrio cholerae zonula occludens toxin (ZOT)
EAggEC plasmid-encoded protein (Pet)
Bacteroides fragilis toxin (BFT)
Vibrio parahaemolyticus thermostable direct hemolysin (TDH)

AMP = adenosine monophosphate; GMP = guanosine monophosphate.

M_r of 10.5 kD each and one A subunit with M_r of 27.2 kD. The A subunit is proteolytically cleaved to yield two polypeptide chains, a 195-residue A_1 peptide of 21.8 kD and a 45-residue A_2 peptide of 5.4 kD.[218] As with other toxins in this group, the functions of the two subunits are specific: the B subunit serves to bind the holotoxin to the eukaryotic cell receptor, and the A subunit possesses a specific enzymatic function that acts intracellularly. The single A subunit is presumably located on the axis of the pentameric B subunit ring, with the fragment A_2 extending some distance into the central hole.[219–221] The cholera toxin receptor on the surface of the enterocyte is a ganglioside GM_1 that is ubiquitous in the body, being present on such diverse cell types as ovarian and neural cells as well as intestinal cells.[219] The neuraminidase produced by *V. cholerae* can increase the number of receptors by acting on higher-order gangliosides to convert them to GM_1 gangliosides.[222] Reduction of the disulfide bond between A_1 and A_2 peptides on the external surface of the membrane is necessary for penetration of the A_1 peptide into the cell. The fate of the A_2 peptide is not known, but there is little evidence that it actually enters the cell. Once within the cell, the A_1 peptide activates adenylate cyclase at the basolateral membrane, where the enzyme is localized in intestinal epithelial cells. The A_1 peptide is thought to migrate to the basolateral membrane through the cytosol, although there is no convincing evidence that this actually occurs. An alternative model proposes that generation of the A_1 peptide and activation of adenylate cyclase are functionally linked to toxin endocytosis. The A_1 peptide acts as an enzyme to adenosine diphosphate ribosylate, the α subunit of G stimulatory (G_s) at an arginine residue. Once activated, the α subunit of G_s dissociates from the membrane-bound subunit of G_s, leaving it free to transverse the cell and attach to the catalytic subunit of adenylate cyclase in the basolateral membrane.[223] The adenylate cyclase so activated induces the formation of cAMP, which then activates the catalytic unit of cAMP-dependent protein kinase (protein kinase A). Finally, the phosphorylation of membrane proteins is responsible for the transepithelial ion transport changes induced by cholera toxin. These changes consist of the inhibition of the linked sodium and chloride absorptive process in the villous cells and the stimulation of electrogenic chloride secretion in the crypt cells.[224,225] The nature of the target protein(s) phosphorylated by protein kinase A remains uncertain. One attractive candidate is the cystic fibrosis transmembrane conductance regulator, which is a chloride channel[226] and which has multiple potential substrate sequences for protein kinase A. Unlike healthy intestinal tissue, tissues obtained from patients with cystic fibrosis do not respond to either cAMP- or Ca-mediated secretagogues.[227] Heterozygotes presumably have only half of the normal number of chloride channels responsive to kinase. After infection with *V. cholerae*, the cystic fibrosis heterozygote may have less intestinal chloride secretion and, therefore, less diarrhea, suggesting a selective advantage over "normal" homozygotes in surviving cholera.

ETEC elaborate an LT (see Table 38.1-2) that closely resembles cholera toxin in structure and biochemical mode of action. Unlike cholera toxin, LT can also bind to GM_2 and asialo-GM_1 gangliosides in addition to GM_1 ganglioside.[228] Toxin binding is followed by activation of the adenylate cyclase–cAMP system, resulting in water and electrolyte secretion into the lumen of the intestine, with a mechanism similar to that of cholera toxin.[229] However, whereas LT induces a mild diarrhea known as "traveler's diarrhea," cholera toxin is responsible for the severe, sometimes fatal, clinical condition typical of cholera. Rodighiero and colleagues have reported that the differential toxicity of cholera toxin and LT is related to a 10–amino acid segment within the A_2 fragment of cholera toxin that confers a higher stability to the cholera toxin holotoxin during uptake and transport into intestinal epithelia.[230]

In addition to its invasiveness, *S. typhimurium* elaborates an enterotoxin, whose role in inducing diarrhea remains controversial (see Table 38.1-2).[231] Cell-free lysates of *Salmonella* can cause intestinal secretion and activate intestinal epithelial cell adenylate cyclase independently of any change in inflammation.[231] How the *Salmonella* toxin activates adenylate cyclase has not been determined.

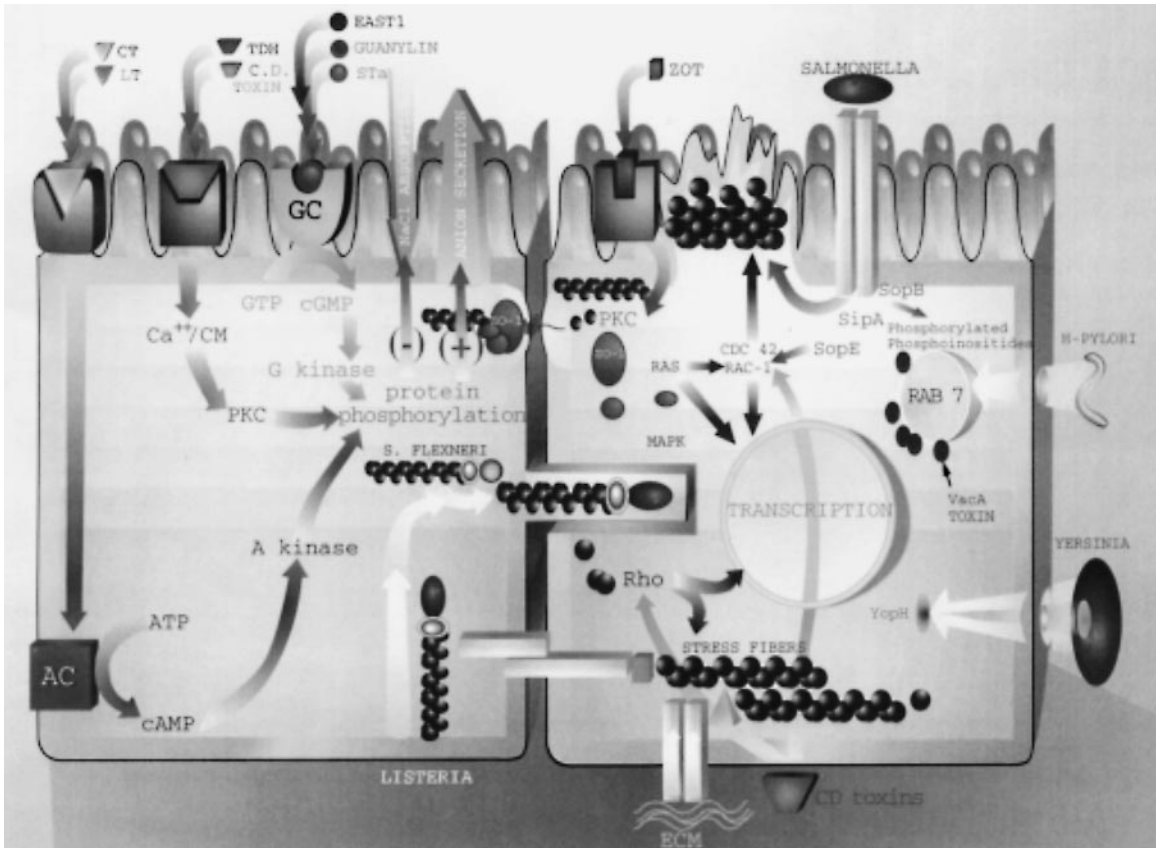

FIGURE 38.1-3 Enterocyte intracellular signaling leading to intestinal secretion. Four main pathways seem to be involved in the intestinal secretion of water and electrolytes: cyclic adenosine monophosphate (cAMP), cyclic guanosine monophosphate (cGMP), calcium (Ca), and cytoskeleton. These pathways are activated by several enteric pathogens, either directly or through the elaboration of enterotoxic products. AC = adenylate cyclase; C.D. = *Clostridium difficile*; CM = calmodulin; CT = cholera toxin; EAST1 = enteroaggregative *Escherichia coli* heat-stable toxin 1; ECM = extracellular matrix; EGF-r = epidermal growth factor receptor; GC = guanylate cyclase; LT = heat-labile enterotoxin; PKC = protein kinase C; ST_a = heat-stable toxin $_a$; TDH = thermostable direct hemolysin; ZOT = zonula occludens toxin.

Cyclic Guanosine Monophosphate. Besides LT, ETEC elaborates a family of ST enterotoxins. STIp is a small peptide that stimulates guanylate cyclase (GC), causing an increased intracellular concentration of cGMP, which evokes chloride secretion and diarrhea.[217] The STIp is a typical extracellular toxin, consisting of 18–amino acid residues synthesized as a precursor protein. The precursor translocates across the inner bacterial membrane, using the general export pathway consisting of the Sec proteins.[233] The ST_a epithelial surface receptor is distinct from the cholera toxin and LT receptor and coincides with the GC activity.[234,235] Ileal villus epithelial cells have approximately twice as many receptors as crypt cells for the enterotoxin.[236] GC exists in two major forms: soluble and particulate. These are distinct proteins encoded by separate genes. Soluble GC is a dimeric cytosolic protein that is activated by nitric oxide.[237] Particulate GC is a family of brush border membrane glycoproteins that are activated by only two classes of substances, atrial natriuretic peptides and ST_a. In the intestine, approximately 80% of total GC is particulate.[238,239] So far, three different members of the particulate GC family have been cloned.[238] GC-A and -B are atrial natriuretic peptide receptor cyclases, whereas GC-C is the specific receptor for ST_a. All three members of the GC family are proteins that span the cell membrane and contain an extracellular domain, a transmembrane domain, an intracytoplasmic domain made up of a protein kinase–like enzyme, and a catalytic domain. These proteins show minimal similarities in their extracellular domain, whereas there is a higher degree of similarity of their intracellular domains. This finding suggests that the extracellular domain represents the ligand-binding domain.[238,239] In addition to LT and ST exotoxins, ETEC also contains a lipopolysaccharide endotoxin. When orally administered to mice, lipopolysaccharide markedly increased the expression of the inducible nitric oxide synthase II and its effector enzyme-soluble GC in colonic cells.[240] This creates the pathophysiologic autocrine pathway, producing increased levels of cGMP leading to hypersecretion and diarrhea.[240] Another heat-stable enterotoxin, EAST 1, which is genetically and structurally distinct from ST, was discovered in EAggEC[241] and subsequently found in other *E. coli* belonging to several distinct diarrheagenic categories.[242] A case-control study demonstrated that 19% of children with diarrhea harbored EAST 1–positive *E. coli* in their stools compared with 3.5% of healthy individuals,[243] confirming the pathogenic role of EAST 1 in diarrheal diseases in children. The last described member of the ST fam-

ily was reported by Sulakvelidze and coworkers.[244] This toxin, elaborated by *Y. bercovieri*, elicited a secretory response in both in vitro and in vivo animal models; these results were genetically and immunologically distinct from the response to *Y. enterocolitica* STI and STII.[244]

Calcium. Several toxins, including ciguatera toxin,[245] *C. difficile* toxin,[246] *Cryptosporidium* toxin,[247] and the *Helicobacter pylori* vacuolating toxin,[248] seem to act through Ca. However, the involvement of Ca in the secretory effect of these toxins has been only indirectly demonstrated. A more definitive proof of Ca-mediated secretory effect was provided by Raimondi and colleagues.[249] Using direct intracellular ($[Ca]_i$) measurement, they demonstrated that the enterotoxic effect of the thermostable direct hemolysin elaborated by *V. parahaemolyticus* is mediated by Ca.[249] This toxin seems to interact with a polysialoganglioside GT1b surface receptor, whose physiologic function remains to be established.[249]

Pore-Forming Toxins. *Clostridium perfrigens* is a common agent of foodborne intoxication, the symptoms of which are caused by the elaboration of *C. perfrigens* enterotoxin.[250] This enterotoxin is a very hydrophobic protein that is released by bacterial lysis and subsequently binds to a brush border receptor of the host enterocyte.[250] Following binding, *C. perfrigens* enterotoxin associates with a 70 kD membrane protein, with subsequent formation of pores through which water, ions, nucleotides, and amino acids leak. *Staphylococcus aureus* α toxin also forms pores; however, its mechanism of action involves the formation of oligomers containing only toxin molecules.[250] According to Zitzer and coworkers, the *V. cholerae* cytolysin represents a novel prototype of pore-forming toxin.[251] The authors have demonstrated that the oligomerization of *V. cholerae* cytolysin yields a pentameric pore and has a dual specificity for both cholesterol and ceramides present in the mammalian brush border membrane of enterocytes.[251]

Toxins Blocking Protein Synthesis. Shiga toxin elaborated by *S. dysenteriae* represents the archetype of this family of toxins. SLTI and II are related toxins elaborated by EHEC. Shiga toxin and SLTs share the AB5 structure typical of cholera toxin and LT; however, they act through a different mechanism of action. The A_1 subunit of Shiga toxin and SLTs binds and inactivates the 60S subunit of the host cell ribosome and, consequently, completely interrupts cell protein synthesis.[252] To induce this inhibitory effect, the toxins must interact with a glycolipid surface receptor (Gb3 receptor), whose expression in different endothelial districts varies.[253] In fact, whereas endothelial cells of large blood vessels such as the umbilical and saphenous veins produce minimal amounts of Gb3,[253] human renal[253] and intestinal[254] microvascular endothelial cells constitutively express maximal quantities of the receptor. These results provide a rationale for the targeting of the glomeruli in HUS and the endothelial cells of the colon in hemorrhagic colitis. Recent epidemiologic data suggest that the elaboration of SLTs may not be sufficient in itself to induce disease in humans. By applying a multivariate logistic regression analysis, Boerlin and coworkers showed a significant association between the presence of genes for intimin (a protein involved in the intimate attachment of EHEC to the host intestinal cell) and SLT2 and isolates from cases of hemorrhagic colitis and HUS.[255] Further analysis revealed an interaction between the intimin gene and the *SLT2* gene, thus supporting the hypothesis of the synergism between the adhesin intimin and SLT2.[255]

Toxins Inducing Protein Synthesis. Up-regulation of protein synthesis, particularly of proinflammatory mediators, is one of the most recently described mechanisms through which bacterial toxins induce diarrhea. Nielsen and coworkers have demonstrated that staphylococcal enterotoxin A induces tyrosine phosphorylation of several host intracellular proteins, down-regulation of the T-cell receptor, and production of interferon-γ, a key cytokine in the pathogenesis of intestinal inflammatory and secretory processes.[256,257] Transcriptional up-regulation of proinflammatory cytokines seems also to be involved in the pathogenesis of EAggEC-associated diarrhea. It has been reported that EAggEC produces a cell-free factor that up-regulates interleukin-8 (IL-8) messenger ribonucleic acid in CaCo2 cells.[258] This up-regulation correlates with the clinical observation that increased lactoferrin (as a marker of inflammation) and IL-8 can be found in the stools of children in Brazil with EAggEC infections.[258]

Toxins Affecting the Enterocyte Actin Cytoskeleton. A growing number of toxins have been reported to act by affecting the host-cell cytoskeleton. *C. difficile* has emerged as the most important pathogen causing the syndrome of antibiotic-associated colitis.[259] The virulence of this pathogen depends on its elaboration of two related toxins, TxA and TxB. These toxins are among the largest monomeric toxins described, with molecular weights of 308,000 for TxA and 270,000 for TxB. Despite the fact that TxA has traditionally been referred to as an enterotoxin and TxB as a cytotoxin,[259] they both exert a cytotoxic effect in vitro. Both TxA and TxB are glucosyltransferases and use uridine diphosphate (UDP) glucose as a substrate to inactivate, by monoglucosylation, members of the Rho family of small guanosine triphosphatases (GTPases) at Thr,[37] an amino acid residue located within the putative effector domain of the Rho proteins.[260] Rho GTPases regulate a variety of cytoskeleton-dependent cellular functions, such as cell adhesion and motility, growth factor–mediated signaling, cellular transformation, and induction of apoptosis.[261] The dramatic effects of TxA and TxB on tissues and cells, including cytoskeletal depolymerization, increased intestinal permeability and diarrhea, cellular retraction and rounding, disruption of cell adhesion and chemotaxis, and activation of apoptosis,[262] are therefore all related to the TxA- and TxB-dependent inactivation of the Rho proteins. *Clostridium sordelli* toxin also functions as a UDP glucosyltransferase and inactivates Ras, Rap, and Rac.[259] *Clostridium botulinum* C2 and C3 toxins exert their enterotoxic effect by inactivating actin and Rho, respectively.[259]

Besides the inactivation of Rho proteins, their activation is also associated with increased intestinal permeability and diarrhea. Cytotoxic necrotizing factor 1 (CNF1), a protein of ≈ 115 kD produced by pathogenic *E. coli* strains,[263] activates Rho GTPases by deamination of Gln[62,264] and consequently induces polymerization of F actin. When tested on CaCo2 monolayers, CNF1 reduced the monolayer resistance by 40% after 4 hours of incubation,[265] suggesting that not only depolymerization but also polymerization of actin and subsequent reorganization of the actin cytoskeleton alter the barrier function of intestinal tight junctions.

A similar mechanism was previously described for zonula occludens toxin, a toxin elaborated by *V. cholerae*.[266,267] Zonula occludens toxin is a single polypeptide chain of 44.8 kD, encoded by the bacteriophage CTXϕ present in toxigenic strains of *V. cholerae*.[268] The mechanism of action of zonula occludens toxin involves the rearrangement of the epithelial cell cytoskeleton owing to protein kinase C α-dependent polymerization of actin filaments strategically located to modulate intercellular tight junctions.[269] The plasmid-encoded protein (Pet) elaborated by EAggEC is a member of the autotransporter class of secreted proteins that induces contraction of the cytoskeleton and loss of the actin stress fibers when tested on either Hep-2 cells or HT29 C-cell monolayers.[270] Both the cytopathic and enterotoxic effects of Pet seem related to the serine protease activity of the toxin that elicits cytoskeletal changes without compromising cell viability.[270]

Enterotoxigenic *Bacteroides fragilis* elaborates a 20 kD zinc-dependent metalloprotease toxin (*B. fragilis* enterotoxin) that alters tight junctions and intestinal permeability.[271] This enterotoxin specifically cleaves the extracellular domain of the zonula adherens protein E-cadherin. Its protease activity appears to be specific for E-cadherin because no proteolytic activity was detected for other cytoskeleton-associated proteins, including occludin, β_1 integrin, zonula occludens (ZO)1, or α- and β-catenins.[271]

Beside its Ca-mediated enterotoxic effect, mentioned above, the *V. parahaemolyticus* enterotoxin thermostable direct hemolysin also induces a significant (though reversible) decreased rate of progression through the cell cycle and morphologic changes related to the organization of the microtubular network, which appears to be the preferential cytoskeletal element involved in the cellular response to the toxin.[272]

ENTERIC BACTERIA GENOMIC REVOLUTION

Our knowledge of the complexity of the prokaryotic kingdom, including enteric pathogens, has been a dynamic process of learning that progressed hand in hand with the advent of cornerstone technologies. The microscope has been the first instrument that allowed us to appreciate the variety of microorganisms initially classified based on their appearance. Over time, disciplines such as cell and molecular biology and biochemistry contributed to new discoveries in microbiology. However, the full appreciation of the extent of genetic complexity and diversity among prokaryotic organisms could not be estimated until the advent of high-throughput genome sequencing and genome annotation.[273] So far, the genomes of more than 100 bacterial species have been sequenced, including enterobacteriaceae such as *V. cholerae*, EHEC, and *S. enterica*. For several of these species, the genome sequences of both pathogenic and nonpathogenic strains have been determined, thereby launching the field of comparative bacterial genomics. This information is of crucial importance in assisting us to identify pathogenic traits and, therefore, to develop alternative strategies for the treatment of enteric bacteria-associated infections.

V. cholerae represents the typical exemplification of the genomic revolution and its possible outcomes.[274] One of the most intriguing and least understood features of *V. cholerae* is its annual epidemic profile in the Bengal region of Bangladesh and India. In this region, nearly all cases occur in synchronized, massive outbreaks toward the end of the monsoon season. Between epidemics, the microorganism resides in a stable environmental reservoir, suggesting that changes in rainfall and sunlight dictate its shift from aquatic habitat host to human pathogen. The functional annotation of *V. cholerae* genomic sequence[275] shed some light on this extraordinary adaptability to two extremely different lifestyles. The *V. cholerae* genome consists of two circular chromosomes of ~ 3 million and ~ 1 million bp, respectively, that together encode almost 4,000 putative genes. The vast majority of recognizable genes for essential cell functions and pathogenicity are located on the large chromosome, whereas the small chromosome contains many genes that appear to have origins other than *V. cholerae*. This two-chromosome configuration of *V. cholerae* seems to confer to the microorganism its plasticity to adapt to climate changes and to different lifestyles. One of the most accredited hypotheses predicts that the large chromosome genes are in charge for the microorganism's adaptation to the human intestine, whereas the small chromosome genes are essential for environmental survival.[274] If this hypothesis proves correct, it will be theoretically possible to develop strategies that will prevent *V. cholerae* to switch from environmental to human host and, consequently, its survival in the human intestine.

ENTERIC BACTERIA AND BIOTERRORISM

Recent discoveries involving bacterial genomes and virulence machinery have promoted strategies to reduce the morbidity and mortality of microbial infections. Recent progress has also been made, which has resulted in effective interventions for reducing environmental risks and preventing human-to-human transmission of infectious agents. These approaches have had a huge positive impact on childhood mortality. Both the events of September 11, 2001, and the subsequent highly publicized use of the US Postal Service to spread anthrax infection have drastically changed our sense of confidence toward the prevention and treatment of infectious diseases. It has become clear that present disease control strategies are ineffective and possibly obsolete in dealing with bioterrorism. The standard goals of public health organizations—confinement of specific pathogens to endemic areas, eradication of

microorganisms, and vaccination campaigns to eliminate specific pathogens—are now undergoing a process of reprioritization in light of the new realities that we face with bioterrorism and biologic warfare. Despite the fact that hundreds of potential agents could be used in biologic warfare or bioterrorism, attention has been focused on microorganisms, including anthrax and smallpox, which have the potential for aerosol dissemination.[276] It is surprising, however, that little attention has been paid so far to enteric pathogens listed in the category B agents by the CDC. Despite the fact that these microorganisms typically cause moderate morbidity and low mortality, they pose a major risk because they are easy to produce and disseminate, they do not require complex production and stocking facilities, and they can be handled by nonprofessional personnel.[276] The threats to food and water safety represented by these agents make them an obvious choice for bioterrorism initiatives executed by terrorist groups whose level of scientific expertise may be relatively primitive. Unfortunately, deliberate contamination of food with enteric pathogens has already been perpetrated.[277] With free trade, centralized production, and wide distribution of products worldwide, the biosecurity of commercial food products is becoming a challenging task because deliberate contamination of foodstuff could present either as a slow, diffuse, and initially unremarkable increase in sporadic cases or as an explosive epidemic suddenly producing many illnesses. Among the potential enteric pathogens to be used as bioweapons, *Salmonella* serotypes need to be considered at high risk for their high rate of infectivity and their ability to survive in the environment. The bioterrorism potential of *S. typhi* was recognized in the 1970s by the World Health Organization, which assessed a potential attack on municipal water supplies with the organism.[277] *Shigella* spp, which are frequent worldwide, have a low infectious dose and cause dysentery, with severe complications and death rates of up to 20%. *S. dysenteriae* is rare in the United States, but most clinical laboratories have reference strains. *E. coli* O157:H7 causes bloody diarrhea and abdominal cramps. It is the most common cause of HUS in children, has a low infectious dose, and, therefore, is highly transmissible, and reference strains are kept by clinical laboratories.[277] The mortality rate of *V. cholerae* secondary to dehydration is limited when appropriate rehydrating therapy is enforced. However, widespread disease could overwhelm unprepared medical care facilities, and cases of severe untreated cholera have mortality rates that can reach 50%. Both cultures and purified cholera toxin are available commercially for research purposes.[277]

CONCLUSION

Despite the tremendous increase in knowledge of bacterial pathogenesis experienced during the past decade, intestinal infections remain a major cause of disease and death because they are responsible for 6 to 60 billion cases of diarrhea every year and claim the life of a child every 15 seconds. Widespread travel to developing countries and the recent events of bioterrorism have brought diseases transmitted by contaminated food and water to immunologically naive populations. These changes, along with an increased number of immunocompromised individuals and the pandemic of HIV infection, have elevated bacteria-associated diarrheal diseases to a worldwide threat. However, the widespread use of oral rehydration solutions has revolutionized the way in which this plague has being fought, and more positive results are anticipated from the development of safe enteric vaccines and a better preparedness to face possible bioterrorist attacks exploiting enteric pathogens as bioweapons.

2. *Food- and* Waterborne Infections

David W. K. Acheson, MD, FRCP
Karin Andersson, MD

Food- and waterborne illnesses typically conjure up the image of an individual who develops an infection following exposure to food. However, the definition of foodborne illness is broad and encompasses exposure to toxins, carcinogens, metals, prions, and other factors, in addition to the classic infective pathogens. Because reviewing each of these agents in detail is beyond the scope of this chapter, our focus is on food- and waterborne infections. An extensive list of foodborne pathogens is shown in Table 38.2-1; many of these are discussed individually in other chapters. This chapter discusses the current epidemiology of foodborne illness and provides an overview of the various toxins and organisms considered to be the more important foodborne agents. The clinical symptoms, treatment, and long-term consequences of various foodborne infections are also reviewed.

Everyone reading this text will likely have had a personal experience with foodborne infection. In its classic form, this illness consists of acute gastrointestinal upset with nausea, vomiting, diarrhea, and abdominal cramps. Typically, symptoms resolve spontaneously without the need for significant medical intervention and without long-term consequence. However, on occasion, foodborne infection causes severe illness or death. Unfortunately, in the early stages of illness, differentiating between a patient with an inconsequential infection and a patient who may develop life-threatening sequelae can be difficult. Some systemic consequences of infection occur several days or weeks after the initial exposure. Examples include hemolytic uremic syndrome (HUS) secondary to Shiga toxin–producing *Escherichia coli* (STEC), the development of Guillain-Barré syndrome (GBS) after *Campylobacter* infection, and the association of a number of enteric bacterial pathogens with reactive arthritis and postinfectious irritable bowel syndrome. We have much to learn about the pathogenic mechanisms of the common foodborne microbes and the illnesses they cause, but we are gradually elucidating the processes whereby pathogens such as *Listeria*, *Salmonella*, and *E. coli* subvert the host.

CURRENT EPIDEMIOLOGY OF FOOD- AND WATERBORNE ILLNESSES

The true burden of foodborne illnesses in the United States and other parts of the world is largely unknown, yet the number of suspected deaths worldwide from food- or water-related pathogen exposure is staggering. Several million children die each year worldwide from acute diarrheal disease and resulting dehydration, the majority of which is likely due to contaminated food or water. In the United States, until recently, we have had very few data on the numbers and outcomes of foodborne infection. The development of the Foodborne Diseases Active Surveillance Network (FoodNet) by the Centers for Disease Control and Prevention (CDC) has provided, for the first time, the opportunity to determine the epidemiology of foodborne disease in the US population. FoodNet is the main foodborne disease component of the CDC's Emerging Infections Program and is a collaborative venture with Emerging Infections Program sites, the US Department of Agriculture (USDA), and the US Food and Drug Administration (FDA). FoodNet performs population-based active surveillance for confirmed cases of *Campylobacter*, *E. coli* O157:H7, *Listeria*, *Salmonella*, *Shigella*, *Vibrio*, *Yersinia*, and HUS, as well as *Cryptosporidium* and *Cyclospora* infections. Currently, surveillance occurs within a defined population of 37.4 million Americans using information from clinical microbiology laboratories in nine states. FoodNet monitors only confirmed cases of diarrheal infection, missing cases that never present to medical attention. However, through additional surveys, FoodNet has the capacity to determine the frequency of diarrhea and the number of physician visits within the study population. Using FoodNet and other data, a recent publication from the CDC provides our current best estimate of the true burden of foodborne infections in the United States.[1]

Mead and his colleagues from the CDC estimate that there are 76 million illnesses, 325,000 hospitalizations, and 5,000 deaths annually owing to foodborne infections.[1] This means that, on average, somewhere between 1 in 3 and 1 in 4 Americans will have a foodborne infection each year. Although these data provide an excellent estimate of disease prevalence in the United States, they also illustrate some major gaps in our knowledge of foodborne infections. For example, in the context of sporadic infections, whether a particular case is due to consumption of contaminated food or water or is acquired through person-to-person spread is difficult to ascertain. Also, in 62 million cases, or 82% of the estimated 76 million infections each year, no specific pathogen is identified. Disease attributable to unidentified agents results in 265,000 hospitalizations and 3,200 deaths.

Our ignorance as to the cause of more than 80% of the estimated foodborne illness is a daunting problem. However, many new agents have been discovered and linked to foodborne disease in the last 20 years. Table 38.2-2 offers a list of some recently described food- and waterborne pathogens. Some are newly discovered, such as *E. coli* O157 and *Vibrio cholerae* O139. Others are agents previously rec-

TABLE 38.2-1 BACTERIAL, VIRAL, PROTOZOAL, WORM, AND TOXIC AGENTS THAT ARE ASSOCIATED WITH FOOD- AND WATERBORNE ILLNESS IN HUMANS

BACTERIAL PATHOGENS
Bacteria causing disease primarily mediated by a preformed toxin
Clostridum botulinum
Staphylococcus aureus
Bacillus cereus
Bacteria causing disease by production of toxins within the intestine
Vibrio species
Clostridum perfringens
Shiga toxin–producing *Escherichia coli*
Enterotoxigenic *E. coli*
Bacteria causing disease primarily by invading the intestinal epithelial cells
Salmonella spp
Camplylobacter spp
Yersinia spp
Listeria monocytogenes
Shigella spp
Enteroinvasive *E. coli*
Other bacterial causes of foodborne illness
Aeromonas spp
Plesiomonas shigelloides
Enteropathogenic *E. coli*
Enteroaggregative *E. coli*
Enterobacter sakazakii
VIRAL PATHOGENS
Hepatitis A virus
Hepatitis E virus
Rotavirus
Noroviruses
Enteric adenovirus
Coronaviruses
Toroviruses
Reoviruses
Saporo-like viruses
Astroviruses
Parvoviruses
Picobirnaviruses
PROTOZOAL PATHOGENS
Toxoplasma gondii
Cryptosporidium parvum
Giardia lamblia
Entamoeba histolytica
Cyclospora cayetanensis
Microsporidium (*Enterocytozon bieneusi, Septata intestinalis*)
Isospora belli
Dientamoeba fragilis
Blastocystis hominis
CESTODES AND WORMS

Taenia solium
Diphyllobothrium latum
Hymenolepis nana
Ascariasis
Trichuriasis
Trichinella spiralis
NATURAL TOXINS
Ciguatera
Scrombroid
Shellfish poisoning (neurotoxic, diarrheic, and toxic-encephalopathic)
Tetrodotoxin
Mushroom toxins
Aflatoxins

TABLE 38.2-2 FOODBORNE PATHOGENS DESCRIBED SINCE 1977

Campylobacter jejuni
Campylobacter fetus ssp fetus
Cryptosporidium parvum
Cyclospora cayentanesis
Shiga toxin–producing *Escherichia coli* (eg, O157:H7, O111:H8)
Listeria monocytogenes
Norwalk-like viruses
Salmonella enteritidis
Salmonella typhimurim DT104
Spongiform encephalopathy prions
Vibrio cholerae O139
Vibrio vulnificus
Vibrio parahaemolyticus
Yersinia enterocolitica

ognized but regarded as rare or nonpathogenic organisms. For example, *Campylobacter jejuni* was once thought to be an unusual cause of bacteremia but is now one of the most frequent bacterial causes of enteritis in the United States.

In 2002, the most recent year for which the FoodNet data have been fully tabulated, the CDC confirmed 16,580 infections from the FoodNet sites.[2] Incidence varied dramatically among the FoodNet sites. For example, *Campylobacter* affected 6.7 per 100,000 people in Maryland and 31.7 per 100,000 in California. *Salmonella* infections varied from 9.5 per 100,000 in Oregon to 22.5 per 100,000 in Georgia. Although the explanation for these geographic differences is unknown, they seem to suggest true regional variation of foodborne pathogens. Another trend observed in recent FoodNet data was the preponderance of cases in the young and elderly. Children under the age of 1 year had a much higher incidence of *Salmonella* (134.1 per 100,000) and *Campylobacter* (33.5 per 100,000) than did adults. Across all age groups, clinical outcomes differed by pathogen. Although the total number of *Listeria monocytogenes* and *E. coli* O157:H7 infections was considerably lower than some of the other pathogens, they were associated with much higher hospitalization rates and death rates than any of the other bacterial pathogens monitored (Table 38.2-3). Table 38.2-3 reflects the lack of correlation between the propensity for an organism to cause disease and its propensity to result in the death of the patient.

Since FoodNet began to operate in 1996, the accumulated data have also revealed a seasonal trend, with a spike in infection with the three major pathogens (*Salmonella*, *C. jejuni*, and *E. coli* O157:H7) during the summer months (Figure 38.2-1). The summer predominance of bacterial foodborne infections is likely multifactorial. Clearly, warmer weather allows for a more rapid bacterial growth on food that is not refrigerated. Consumer habits also change in the warmer months, with more picnics and barbecues, contributing to abuse of food. One compelling study suggests that the summer spike of bacterial pathogens goes right back to the farm. Hancock and colleagues examined *E. coli* O157 shedding in 14 cattle herds at 1-month intervals for up to 13 months. The overall prevalence was 1.0% (113 of 10,832 fecal samples), and for all herds, the highest prevalence occurred in the summer months.[3]

TABLE 38.2-3 DEATH RATES OF THE COMMON FOODBORNE BACTERIA

ORGANISM	NUMBERS OF DEATHS/INFECTIONS	PERCENT DEATHS PER INFECTION
Listeria	22/105	20.9
E. coli O157:H7	7/626	1.1
Salmonella	13/4,330	0.3
Shigella	2/2,355	0.08
Campylobacter	4/4,713	0.08
Vibrio	1/54	1.85

Adapted from FoodNet, Centers for Disease Control and Prevention/US Department of Agriculture/Food and Drug Administration.[2]

The FoodNet surveillance effectively monitors trends in the rates of infection over time. In the last several years, the rates of *Campylobacter* and *Yersinia* have declined, whereas the incidence of *Salmonella* has been stable. A change in the frequency of infection with different *Salmonella* species has occurred, however, with a decline in *S. typhimurium* and a rise in less common species such as *S. newport*. Infection with *E. coli* O157:H7, *Shigella* and HUS cases have not declined in the survey period, which may be due, in part, to increased recognition. This time period coincides with the implementation of several control measures designed to limit the occurrence of bacterial food contamination, including in 1997 the USDA's Pathogen Reduction/Hazard Analysis and Critical Care Point (HAACP) system to regulate meat and poultry slaughter and processing plants. Similarly, the FDA has emphasized food safety education and introduced guidelines on better agricultural practices, refrigeration, and product labeling. The current challenge is to assess whether the improved surveillance system, through capturing more cases, masks the decline in infection rates resulting from the regulatory measures or whether there really is little change in the levels of some of these pathogens.

Although FoodNet produces excellent data on the epidemiology of foodborne illness overall, it has several important areas of weakness. It does not survey for many of the common foodborne pathogens, including viruses, which are thought to cause the majority of foodborne illness. Similarly, it does not address the cause of illness in patients who do not have a stool sample sent for analysis: those who either do not seek medical care or who do seek care but do not have a stool sample analyzed. In an adjunctive study reported by the CDC, 11% of 10,000 residents interviewed through random telephone consultations reported an episode of diarrhea during the previous month.[4] This translates to 1.4 episodes of diarrhea per person per year, which, if multiplied roughly by the population of the United States, represents approximately 375 million diarrheal cases per year. In this study, merely 8% of those with a diarrheal episode sought medical care, and of those, only 20% reported submitting a stool sample for culture. Thus, our best data on the causes of acute gastrointestinal disturbance from FoodNet surveillance are based on cultures of less than 2% of diarrheal episodes. Nonetheless, despite the current limitations of our evaluation of foodborne illness, the endeavors of federal authorities, including the CDC, FDA, and USDA, have been critical to improving our knowledge of disease frequency, pathogen epidemiology, and the establishment of control systems to limit food contamination. The knowledge gained from FoodNet surveillance allows for targeted efforts to improve food safety and education.

SPECIFIC FOOD- AND WATERBORNE MICROBES

As noted previously, the diversity of foodborne pathogens listed in Table 38.2-1 is too extensive to be described completely in the scope of this chapter. In the following sections, many of these microbial agents are discussed briefly, with a focus on typical modes of transmission, the foods they frequently contaminate, and the specific serious consequences that may ensue from infection. Although foodborne agents cause disease by a wide variety of mechanisms, often the mode of infection falls into one of the following three categories: (1) ingestion of preformed toxins produced by bacteria in food prior to consumption; (2) infection with pathogens present in food that, following ingestion, produce toxins in the gastrointestinal tract; and (3) infection with organisms with various virulence factors that permit the microbes to be invasive, cause local damage, or create physiologic perturbations that result in clinical disease.

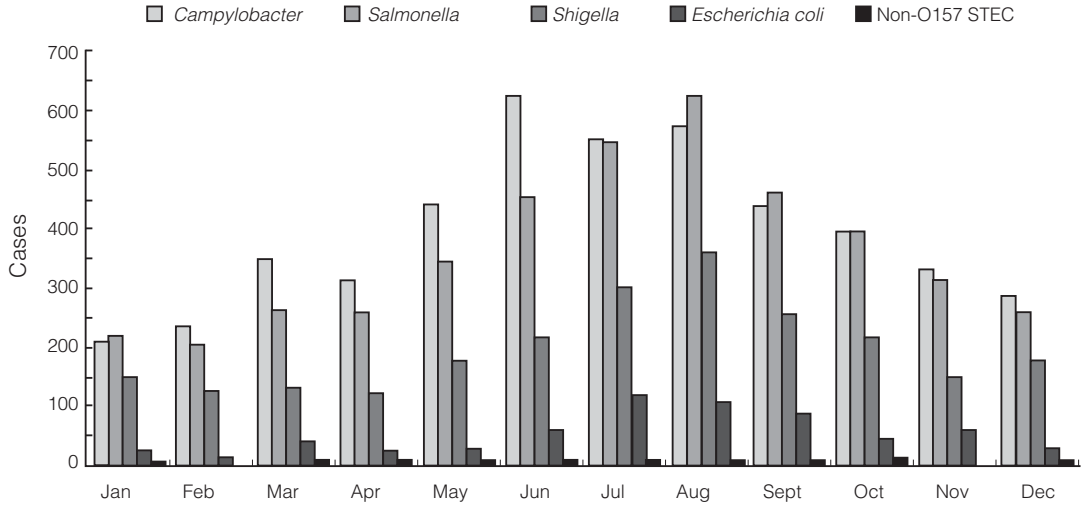

FIGURE 38.2-1 Cases of foodborne disease caused by specific pathogens, by month, FoodNet sites, 2000. Adapted from FoodNet, Centers for Disease Control and Prevention/US Department of Agriculture/Food and Drug Administration.[2] STEC = Shiga toxin–producing *Escherichia coli*.

FOODBORNE ILLNESS OWING TO PREFORMED TOXINS

Of the three mechanisms, the preformed toxin is the most consistently transmitted via food. As each toxigenic organism requires a specific environment to stimulate toxin production, each has a predilection for certain types of food. As a result, different types of foods confer different risks for toxin ingestion. The major toxins of the common foodborne pathogens are discussed in detail in the next sections and were reviewed by Sears and Kaper in 1996.[5]

Clostridium botulinum Toxins

C. botulinum produces one of the best known preformed toxins.[6] The organism is a gram-positive, spore-forming, toxin-producing, obligate anaerobe. Its natural habitat is soil; therefore, its spores frequently contaminate fresh fruits and vegetables. Commercial food sources have been occasionally incriminated, but the majority of outbreaks have been traced to home-produced canned foods, especially vegetables, fruits, fish, and condiments.[7,8] To prevent botulism, the *Clostridium* spores must be destroyed by heating food to a temperature of 120°C for 30 minutes, usually with the aid of a pressure cooker. In an anaerobic environment, any surviving spores will germinate and produce their deadly toxins.

There are seven antigenically distinct types of botulinum toxin, each of which is designated by a letter, A to G. Types A, B, E, F, and G are associated with human disease. Once ingested, the toxin is absorbed through the proximal small intestine and spreads via the bloodstream to the peripheral cholinergic nerve synapses, where it irreversibly blocks acetylcholine release. A flaccid paralysis results, with cranial nerves affected first, followed by respiratory muscle paralysis and death if left untreated.[9] Despite being a foodborne illness, the only common gastrointestinal manifestation is severe constipation. Symptoms tend to occur 18 to 36 hours after toxin ingestion but may occur as quickly as a few hours or as late as 8 days.

The diagnosis of botulism is clinical, and treatment should be initiated prior to confirmation with laboratory data because the traditional mouse bioassay for toxin detection requires approximately 4 days for final results. Samples such as food, vomitus, serum, gastrointestinal washings, and feces are all reasonable specimens to test. Newer polymerase chain reaction (PCR)- and enzyme immunoassay–based detection methods are being explored. Early in the course of the disease, treatment may include emetics or gastric lavage to remove unabsorbed toxin. A trivalent (A, B, E) horse serum antitoxin decreases the progression and duration of paralysis, but it does not reverse existing paralysis.[10] Pentavalent and heptavalent antitoxins are also being investigated. Intravenous human botulism immunoglobulin may also be beneficial.[11] Botulism carries a significant mortality rate, of up to 25%, with type A toxin. Of those who survive the acute phase of illness, most recover completely.

Staphylococcus aureus Toxin

A second well-known group of preformed toxins is those produced by *S. aureus*.[12] *S. aureus* produces a variety of enterotoxins, defined by their antigenicity as staphylococcal enterotoxin (SE)A through E. In recent years, SEG through SEO have been described, but the original strains are responsible for 95% of staphylococcal food poisoning outbreaks.[13] On rare occasions, other staphylococcal species, including coagulase-negative staphylococci, have been found to produce similar enterotoxins. The toxins are small proteins with similar tertiary structures and biologic activity, including superantigen properties.[14] Ingestion of as little as 100 to 200 ng of toxin is considered sufficient to cause disease in humans. Compared with botulinum toxin, staphylococcal toxins are not inactivated by heating or boiling, nor are they susceptible to pH extremes, proteases, or radiation. As a result, once formed in food, these toxins are almost impossible to remove.

The mechanism through which the toxin acts is not fully understood but is suspected to be via stimulation of the autonomic nervous system and gut inflammation. Because the toxin is not absorbed systemically, protective immunity is not induced following exposure. Typically, patients become symptomatic within 6 hours of ingestion, with nausea (73–90%), vomiting (82%), and abdominal cramps (64–74%). Diarrhea occurs in a large proportion of patients (41–88%), but fever is rare.[15–17] Treatment of affected individuals is supportive, and symptoms usually abate within 8 hours. There is no need to treat with antibiotics directed toward *S. aureus*.

Food is most often contaminated with *S. aureus* through the fingers or nose of a food handler. The toxin is produced when contaminated food is stored at room temperature for any length of time, thereby allowing the organism to grow and produce toxin. A number of different foods have been associated with staphylococcal food poisoning, including egg products, meat products, poultry, tuna, mayonnaise, and particularly dairy-based products such as cream-filled desserts and cakes. This disease is more frequently associated with food from the home or a service establishment rather than commercially prepared food. It has also occasionally occurred in large outbreaks with thousands of affected individuals. For example, in 2003, over 13,000 individuals in Japan became ill from a contaminated powdered milk source.[18]

Bacillus cereus Toxin

A third example of preformed toxins is that of *B. cereus*, a gram-positive, spore-forming aerobe that causes two distinct clinical syndromes: a short-incubation period emetic syndrome and a longer-incubation period diarrheal syndrome.[19] The diarrheal phase is caused by at least three enterotoxins, which are not preformed but are produced by the organism during the vegetative growth phase in the small intestine. The emetic toxin, recently named cereulide, is thought to be an enzymatically synthesized peptide produced as the organism grows in food, especially starchy foods such as rice and pasta.[20] Like staphylococcal toxin, cereulide is resistant to heat, pH variation, and proteolysis and is therefore rarely destroyed during food preparation. Its exact mechanism remains unknown, but it has been shown to stimulate the vagus afferent by binding

to the 5-hydroxytryptamine$_3$ receptor.[21] The emetic syndrome presents much like *S. aureus*–related foodborne disease, occurring 1 to 6 hours after exposure and causing nausea and vomiting. Fever is not characteristic of the illness, and full recovery usually occurs, although there has been at least one report of acute hepatic necrosis associated with exposure to emetic toxin.[22] *B. cereus* is ubiquitous in the environment, present in both soil and water, and easily spread to most raw foods; even 10 to 40% of humans are colonized with this bacterium.[23] Diagnosis can be made by finding the organism in the food or vomitus of the patient or through detection of the emetic toxin through bioassays or the enterotoxins by commercial immunoassays.

Natural Toxins

Derived from various types of food, a number of naturally occurring toxins may cause human foodborne illness. Many are associated with consumption of seafood contaminated by algae. Others are due to fungal contamination of food or inherent to certain fruits and vegetables.

Scombroid

Scombroid poisoning typically occurs after the ingestion of spoiled, dark-fleshed fish, especially tuna and mackerel.[24,25] The clinical symptoms of poisoning, including flushing, headache, palpitations, dizziness, nausea, vomiting, and diarrhea, are attributable to excess levels of histamine present in temperature-abused fish.[26] Histamine is produced by bacterial metabolism of the amino acid histidine in fish muscle. Bacterial replication and histamine production occur when fish is not frozen promptly after being caught or is stored at room temperature for several hours. A second mediator, *cis*-urocanic acid, may augment the response to histamine from spoiled fish through mast cell degranulation.[27] Symptoms of intoxication begin within minutes to several hours following ingestion. Most resolve fully within hours, but, occasionally, bronchospasm or circulatory collapse may occur. The diagnosis is clinical, and treatment consists of antihistamines. Elevated histamine levels in the contaminated fish or the patient's serum may be diagnostic, but few laboratories, other than regulatory laboratories, are equipped to undertake this analysis.

Ciguatera

Ciguatera poisoning is due to the ingestion of neurotoxins from tropical and subtropical marine fin fish, including mackerel, groupers, barracudas, snappers, amberjack, and triggerfish.[28] It affects 50,000 individuals yearly, mainly in the Caribbean and South Pacific islands.[29] The toxin is produced in reef algae, the dinoflagellates (eg, *Gambierdiscus toxicus*). It spreads through the food chain via consumption of smaller organisms and fish by larger predators, accumulating at dangerous levels in the flesh of large fish. Two groups of compounds are implicated in ciguatera fish poisoning: the lipid-soluble ciguatoxins, which activate nerve synapse sodium channels, and water-soluble maitotoxin, which induces neurotransmitter release by binding to calcium channels.[30] In humans, these toxins cause gastrointestinal symptoms 3 to 6 hours after ingestion, including nausea, vomiting, and watery diarrhea. Neurologic symptoms follow, with weakness, heat-cold temperature reversal, vertigo, ataxia, paresthesias, and dysathesias of the perioral region, palms, and soles.[31] Death and serious cardiovascular complications are uncommon. Most symptoms resolve within a week, but neurologic symptoms can persist for months. Mannitol therapy was thought to improve symptoms but did not show a significant benefit in a recent randomized controlled trial.[32] The diagnosis of ciguatera is clinical; however, the toxin can be detected in fish using a mouse bioassay or newer enzyme immunoassays.

Shellfish Poisoning

Five main types of shellfish poisoning have been described: paralytic, neurotoxic, diarrheic, amnestic, and azaspiracid.[33,34] Like ciguatera, illness is due to toxins generated by algae, usually dinoflagellates, which accumulate in the shellfish. The paralytic variant of shellfish poisoning is due to saxitoxin, an agent that blocks neuronal sodium channels and prevents propagation of the action potential. Clinically, this results in a rapid-onset, life-threatening paralysis. Brevitoxin, the agent responsible for neurotoxic shellfish poisoning, also binds sodium channels but does not cause paralysis; instead, it produces a clinical syndrome similar to but less severe than ciguatera. Symptoms of nausea, vomiting, and paresthesias occur within hours of exposure and resolve completely within 3 days. Diarrheic shellfish poisoning causes gastrointestinal disturbance with nausea, vomiting, and diarrhea. The toxin acts by increasing protein phosphorylation.[30]

Amnestic shellfish poisoning, also known as toxic-encephalopathic poisoning, causes outbreaks of disease in association with consumption of mussels.[35] Manifestations include nausea, vomiting, diarrhea, severe headache, and, occasionally, memory loss. The toxin domoic acid is a glutamate receptor agonist that causes excitatory cell death. In 1995, a new shellfish poison was discovered in Ireland, where several individuals became sick with nausea, vomiting, diarrhea, and abdominal pain after eating mussels. The illness resembled diarrheal shellfish poisoning, but chemical analysis revealed little diarrheic shellfish poisoning toxin. A new class of compound, the azaspiracids, was isolated. These are derived from a phytoplankton previously thought to be benign.[36]

Diagnosis of human illness due to shellfish toxins is clinical based on symptom profile and prompt onset of symptoms after shellfish consumption. The exception to this is amnestic poisoning, which may not cause symptoms until 24 to 48 hours after exposure. The toxins can be detected using either mouse bioassays or by high-performance liquid chromatography (HPLC), but this is done primarily for research purposes or in monitoring. Owing to the serious consequence of shellfish poisoning, large-scale surveillance systems for contamination of shellfish populations have been implemented.

Tetrodotoxin

Tetrodotoxin is present in certain organs of the puffer fish and if ingested can cause rapid paralysis and death. Symp-

toms may occur in as little as 20 minutes or after several hours. The illness progresses from gastrointestinal disturbance to almost total paralysis, cardiac arrhythmias, and death within 4 to 6 hours after ingestion of the toxin. The diagnosis is clinical and based on history of exposure. Mouse bioassays and HPLC have been used to detect tetrodotoxin in food.

Aflatoxins

Aflatoxins are produced by certain strains of fungi (eg, *Aspergillus flavus* and *Aspergillus parasiticus*) that grow in various types of food. Most human exposure occurs through mold-contaminated corn or nuts, especially tree nuts (Brazil nuts, pecans, pistachio nuts, and walnuts), peanuts, and other oilseeds. Because mycotoxins can be produced prior to or after harvest, eliminating them from food is nearly impossible.[37] Aflatoxin B1 is the most common and toxic, but there are several types of toxins (B2, G1, and G2). They are potent mutagens and carcinogens, with B1 causing deoxyribonucleic acid (DNA) damage in the *P53* tumor suppressor gene.[38] Exposure to the aflatoxin predisposes the patient to hepatocellular carcinoma, especially in conjunction with chronic hepatitis B infection.[39] With a high ingested dose of aflatoxin, a condition known as aflatoxicosis may occur, characterized by fever, jaundice, abdominal pain, and vomiting. Aflatoxin exposure is common in Asia and parts of Africa but uncommon in the United States. The diagnosis is clinical, but assays exist to detect the toxins in food. Serum and urine markers also have been developed to quantify exposure.

Other Natural Toxins

A number of other naturally occurring foodborne toxins have been reported. Grayanotoxin derives from honey produced from rhododendrons and causes self-limiting nausea, vomiting, and weakness. The Jamaican akee fruit contains hypoglycin A, resulting in vomiting and hypoglycemia. The bitter cucumber contains curcurbitacin E, which causes cramps and diarrhea 1 to 2 hours after ingestion. Hydrogen cyanide may be present in lima beans or cassava root and can lead to death within minutes. Castor beans can contain a hemagglutinin that may cause nausea and vomiting. Red kidney beans also produce a hemagglutinin known as phytohemagglutinin. Illness occurs after eating raw or undercooked red kidney beans and consists of severe nausea, vomiting, and diarrhea. The toxin is heat sensitive but requires a high temperature to be inactivated; as a result, a number of cases have been linked to beans cooked in slow cookers in which the temperature does not get high enough. Many other agents, such as toxins, chemicals, and heavy metals, may also cause foodborne illness but are not discussed further here.

FOODBORNE MICROBES THAT PRODUCE TOXINS FOLLOWING INGESTION

Vibrio

Currently, there are over 40 *Vibrio* species, a group of gram-negative marine organisms, most of which are not human pathogens. The most common and severe human illness is caused by *V. cholerae* O1, the species responsible for seven cholera pandemics. The previous six were caused by the "classic" biotype, and the seventh pandemic, which began in 1961, was caused by the "El Tor" biotype.[40,41] Because *Vibrio* species inhabit aquatic ecosystems, sporadic infection and pandemics are typically due to contaminated water. In the United States, cholera is mainly acquired through consumption of Gulf Coast seafood or through foreign travel. A clean water supply is critical to cholera prevention because the organism is resistant to washing, refrigeration, and freezing of a wide variety of seafood and fresh produce.[42] Simple water filtration for particulates greater than 20 μ reduced cholera infection by 48% in a Bangladesh study.[43]

Because stomach acidity does kill many of the organisms, more than 10^6 *V. cholerae* are usually required for infection; those with decreased gastric acidity are infected with lower doses. The incubation period is usually 1 to 3 days but may be as short as a few hours or as long as 5 days. Infection causes voluminous watery diarrhea. Hypotension and shock may result within the first 12 hours of infection. The primary virulence factor is the cholera toxin, which targets an intestinal G protein, producing cyclic adenosine monophosphate (cAMP). The increase in cAMP produces watery diarrhea by inhibiting intestinal sodium absorption and increasing chloride and bicarbonate secretion.[44] The toxin is transmitted to the organism via a bacteriophage. Indeed, in recent years, a new pathogen, *V. cholerae* O139, evolved in the Indian subcontinent. Non-O1 strains were not previously associated with human epidemics, but this pathogen appears to have acquired the cholera toxin and other virulence factors through horizontal transmission and bacteriophage infection.[45,46] Recent large epidemics of this organism in Africa and South East Asia may represent the beginnings of an eighth cholera pandemic.

Vibrio parahaemolyticus also inhabits marine environments and is acquired principally through the ingestion of shellfish. This *Vibrio* has been a major foodborne pathogen in Japan but is less common in the United States. Infection is characterized by diarrhea, abdominal cramps, nausea, and vomiting, with fever and chills present in about 25% of cases. Dysentery occurs in a minority of patients, more often in children than in adults.[47] Occasionally, wound infections and septicemia occur. Symptoms may appear in as little as 4 hours but are typically present 12 to 24 hours after exposure. Disease is attributed to a 23 kD protein called thermostable direct hemolysin.[5] Recently, studies have also located type III secretion system (TTSS) genes in the bacterial genome. TTSS is a virulence factor causing inflammatory diarrhea in other invasive bacteria such as *Shigella*, *Salmonella*, and enteropathogenic *E. coli*; significant enteric inflammation has been documented in *V. parahaemolyticus* infection.[48,49] The enteritis is usually self-limiting. Patients require fluids, and antibiotics may be useful if intestinal symptoms persist.

Vibrio vulnificus is another free-living estuarine organism that is frequently isolated from shellfish, most often acquired through raw oyster or clam consumption. It is the most

common life-threatening *Vibrio* infection in the United States. Individuals with diabetes, immunosuppressive disorders, and liver disease, including hemochromatosis and alcoholic liver disease, are especially susceptible to infection.[50,51] In these groups, the case-fatality ratio may exceed 50%. Infection presents with fevers, chills, nausea, vomiting, and diarrhea. Hypotension and sepsis ensue. Large hemorrhagic bullae erupt and progress to necrotic ulcers. *V. vulnificus* is an encapsulated organism and is therefore resistant to the bactericidal activity of normal human serum. The organisms are sensitive to the amount of transferrin-bound iron in the host, which may explain the increased susceptibility in patients with hemochromatosis. Definitive diagnosis may be made from blood, stool, or wound cultures. Owing to the severity of infection, antibiotics should be initiated promptly. *V. vulnificus* is susceptible to many antimicrobials, including tetracycline, ciprofloxacin, trimethoprim-sulfamethoxazole, ampicillin, and chloramphenicol.

Clostridia

Clostridium perfringens is an anaerobic, spore-forming, gram-positive rod associated with two main types of foodborne disease. The species has been divided into five distinct types, A to E. Type A causes the majority of human infections and is usually linked to the consumption of meat or poultry (typically high-protein foods) that have been stored between 15° and 60°C for more than 2 hours.[52,53] At this temperature, clostridial spores germinate and begin vegetative growth. At an infective dose of 10^5 vegetative cells, ingested clostridial spores transiently colonize portions of the intestine and produce enterotoxin. Ingestion of preformed toxin or nongerminated spores will not usually result in disease. The enterotoxin (CPE) is a heat-labile 35 kD protein encoded by the *cpe* gene. *C. perfringens* types A, C, and D all carry this gene, but for unclear reasons only type A is frequently associated with foodborne disease. CPE functions by a complex mechanism, inserting itself into the host cell membrane and altering membrane permeability.[5] Clinically, diarrhea and severe abdominal cramps develop 6 to 14 hours after exposure; vomiting and fever are less common. Diagnosis is complicated by the presence of *C. perfringens* in the bowel microflora of many asymptomatic individuals.[54] However, a number of tests are able to detect the enterotoxins in stool, including enzyme immunoassays or latex agglutination.[55]

C. perfringens type C causes a distinct foodborne illness, mainly in developing countries. It causes a necrotizing enterocolitis seen in the context of malnutrition. The type C strains produce enterotoxin and types "α" and "β" toxins. The β toxin appears to be responsible for the cell necrosis associated with infection. As the β toxin is inactivated by intestinal proteases, illness occurs in patients in whom these enzymes are inadequate (eg, in malnutrition) or in the presence of trypsin inhibitors found in undercooked pork or sweet potatoes.

Escherichia coli

The two main *E. coli* species associated with foodborne illness are STEC and enterotoxigenic *E. coli* (ETEC). The former are relative newcomers to the scene of foodborne pathogens. The first STEC to be associated with disease in humans was *E. coli* O157:H7 following two outbreaks of hemorrhagic colitis in 1982. Since then, at least 60 different types of STEC have been associated with clinical disease and have become recognized as the most common cause of HUS. Studies suggest that approximately 1% of samples submitted to clinical microbiology laboratories in the United States contain STEC, of which two-thirds are O157:H7 and the remainder non-O157.[56] These bacteria colonize the intestinal tracts of many mammalian species, particularly ruminants (cattle, sheep, and goats). Most human illness is due to the ingestion of contaminated bovine products, but an increasing number of reports associate infection with fecally contaminated fresh produce (lettuce, alfalfa sprouts, apple cider) and water. The main virulence factors of STEC are bacteriophage-encoded Shiga toxins (Stx). The two main types are the Stx1 and Stx2, but there are at least five subtypes of Stx2 (2c, 2d, 2e, and 2f). The infectious dose of STEC is very low, in the region of 10 to 100 organisms. Following ingestion, the bacteria colonize portions of the lower intestinal tract and produce toxin. Stx crosses the intestinal epithelial cell barrier and damages distant target sites, especially the kidney and brain, by a direct effect on endothelial cells in the microvasculature. These distant effects are responsible for HUS. Symptoms typically develop 2 to 4 days after ingestion but may occur in as little as 1 day or as long as 8 days. Nonbloody or bloody diarrhea is the primary acute manifestation.

Treatment of STEC and its major complications is currently largely supportive. Controversy exists as to the role of antibiotics, with concern that treatment of pediatric patients with certain antimicrobials (eg, fluoroquinolones and trimethoprim-sulfamethoxazole) may actually increase the likelihood of serious complications such as HUS.[57] Several recent reviews relating to foodborne *E. coli* infections have been written, and the reader is referred to them for more details.[58–60]

ETEC infection is a common cause of disease in developing countries and is frequently associated with traveler's diarrhea. Like many other *E. coli* strains, ETEC are transmitted through contaminated water and food. They have caused a number of large outbreaks in the United States; however, their importance in sporadic disease is not known. Incubation periods range from 12 hours to 2 days, and typical symptoms are abdominal discomfort and watery, nonbloody diarrhea without fever. ETEC have two significant virulence characteristics: the ability to colonize the intestine and the capacity to produce enterotoxins. A variety of colonization factor antigens and two different types of toxins, known as heat-stable and heat-labile toxins, have been found in ETEC. The heat-stable group consists of small peptides that affect intracellular concentrations of cyclic guanosine monophosphate. The heat-labile toxins are structurally and functionally much like cholera toxin. Oral rehydration is the mainstay of treatment and is often lifesaving. Antibiotic therapy is not routinely required.

FOODBORNE INFECTIONS THAT CAUSE DISEASE BY MECHANISMS OTHER THAN TOXIN PRODUCTION

An enormous diversity of microbes fall into this category, including bacterial, viral, and protozoal organisms. Many of these agents are discussed in great detail in other chapters and are addressed only briefly here.

SALMONELLA

Salmonella species are one of the most common causes of foodborne illness in humans. They can be divided into two broad categories: those that cause typhoid and those that do not. The typhoidal *Salmonella*, such as *S. typhi* and *S. paratyphi*, colonize humans and are acquired through the consumption of food or water contaminated with human fecal material. The much larger group of nontyphoidal *Salmonella* is found in the intestines of other mammals and therefore is transmitted through food or water that has been contaminated with fecal material from a wide variety of animals and poultry. More than 2,300 species of *Salmonella* are differentiated by their somatic (O) and flagellar (H) antigens. Many isolates have been named after the towns in which they were first discovered or by the individuals who first discovered them.

In the United States, most typhoid is the result of food contamination by an asymptomatic chronic carrier or from foreign travel. Typhoid fever continues to be a global health problem but is less common in the United States; only 60 outbreaks occurred between 1960 and 1999.[61] In contrast, the number of cases of nontyphoidal *Salmonella* increased steadily over the last four decades. *Salmonella enteritidis* infection owing to contamination of hen eggs is a particular problem, with an estimated contamination rate of 1 in 10,000 eggs. The bacteria penetrate intact eggs lying in fecal material or infect them transovarially before the shell is formed.[62] Other common sources of nontyphoidal salmonellosis are milk, foods prepared with raw eggs, meat, poultry, and fresh produce. To reduce contamination, the agricultural industry has implemented many safeguards. For example, Promsopone and colleagues used spray vaccination of young chicks with a combination of avian-specific probiotic and *S. typhimurium*–specific antibodies and found a significant reduction in the cecal and colonic concentration and fecal shedding of *S. typhimurium*.[63] Another study using a commercial preparation known as PREEMPT showed a similar reduction of *S. gallinarum*, with reduced mortality in the vaccinated chicks.[64]

The infectious dose of *S. typhi* is thought to be around 10^5 organisms. Typhoid infection is characterized by high fevers, abdominal discomfort, and a rose-colored macular rash. The infective dose of nontyphoidal *Salmonella* may vary from less than 100 to 10^6 depending on the host, food vehicle, and type of *Salmonella*. These species tend to cause bloody or nonbloody diarrhea, fever, nausea, vomiting, and abdominal discomfort. In all types of *Salmonella*, the most critical virulence determinant is their ability to cross the intestinal epithelium and cause invasive disease. The most concerning problem regarding *Salmonella* is the emergence of multidrug-resistant strains. For example, *S. typhimurium* phage type DT104 is resistant to ampicillin, chloramphenicol, streptomycin, sulfonamides, and tetracycline. In Europe, quinolone-resistant strains of *Salmonella* have been detected. Some of these issues are reviewed by Poppe and colleagues.[65]

CAMPYLOBACTER

Campylobacter, which was not recognized as a foodborne disease until the mid-1970s, is now one of the most common bacterial foodborne infections diagnosed in the United States.[66–68] *Campylobacter* are gram-negative, spiral, microaerophilic organisms. The two species *C. jejuni* and *C. coli* are responsible for the vast majority of human disease, with *C. jejuni* causing 90% of infections and *C. coli* nearly 10%. *C. fetus*, *C. upsaliensis*, *C. hyointestinalis*, and *C. lari* have occasionally been associated with enteritis. In human studies, infectious doses as low as 100 organisms may result in disease, and one drop of chicken juice may contain 500 infectious organisms.[69] *Campylobacter* species are more frequently associated with sporadic disease than outbreaks, and person-to-person spread does not appear to be common. *C. jejuni* and *C. coli* are intestinal commensals in many animals and birds, including domestic pets. The main vehicle for human infection is poultry, but other raw meats, milk, and water have also been implicated. Surface water can be contaminated with *Campylobacter*, and waterborne outbreaks have been reported.[70]

The pathogenicity of *Campylobacter* depends on its motility; in vitro, nonmotile strains are not capable of invading intestinal epithelial cells. Typical infection causes diffuse colonic inflammation with marked inflammatory cell infiltration of the lamina propria, which may be mistaken for inflammatory bowel disease.[71] Symptoms usually occur within 2 to 3 days after exposure but may occur as quickly as 10 hours or as late as 7 days.[72] High fevers, headache, and myalgias may precede the onset of nausea, vomiting, and diarrhea. The diarrhea may be loose and watery or grossly bloody. Abdominal cramps and pain may predominate. Interestingly, the disease is sometimes biphasic, with an apparent settling of symptoms after 4 to 5 days followed by a recrudescence. Local complications resulting from direct spread of the organisms from the intestinal tract include cholecystitis, hepatitis, acute appendicitis, pancreatitis, and focal extraintestinal infections. The case-fatality rate is low, approximately 0.5 per 1,000 infections. However, long-term complications may occur, including reactive arthritis, uveitis, HUS, and, most importantly, GBS. GBS affects 1 to 2 persons per 100,000 in the United States each year, or less than 1 person per 1,000 infected.[73] The extensive axonal injury and potentially irreversible neurologic damage following infection are likely the result of molecular mimicry of *C. jejuni* antigens and myelin proteins or peripheral nerve glycolipids.[71,74] GBS typically develops 1 to 3 weeks after infection.

Diagnosis of *Campylobacter* is confirmed by stool culture. PCR and enzyme immunoassays are now available and may become useful for species-specific antigen detection. As with *Salmonella*, a growing number of *Campylobacter* are developing antimicrobial resistance.[75]

Yersinia

Of the three members of the genus *Yersinia*, *Y. enterocolitica* and *Y. pseudotuberculosis* are considered to be foodborne pathogens, whereas *Y. pestis* is typically not.[76,77] Overall, *Yersinia* cause less foodborne illness than *Salmonella* or *Campylobacter*, and the majority of isolates in food, environmental samples, and human stool are nonpathogenic species. One of the challenges, therefore, has been how to determine the pathogenicity of an isolated organism.[78] *Y. enterocolitica* is divided into biogroups, with more than 50 "O" antigens used to designate strains. Most human disease is associated with serotypes O3, O5, O8, or O9. *Y. enterocolitica* is an invasive organism. All pathogenic strains carry a plasmid pYV, coding for the virulence proteins *Yersinia* outer proteins and adhesin A, which block phagocytosis, opsonization, and complement activation; and *Yersinia* enterotoxin, invasin, and attachment-invasion proteins, which mediate invasion and serum resistance.[79] A variety of tests can be used to determine if a strain is pathogenic, including PCR and DNA hybridization, Congo red absorption, salicin fermentation, and esculin hydrolis.

Y. enterocolitica infection results in a mesenteric lymphadenitis, enteritis, and diarrhea. Most infections are self-limited, but symptoms can be prolonged, lasting several weeks or longer. Complications such as ulceration and intestinal perforation may occur. The classic long-term complication following yersiniosis is the development of reactive arthritis, occurring most commonly in patients who are HLA-B27 positive. Although antibiotic therapy is not routinely required, many antimicrobials are effective; ceftriaxone or fluoroquinolones are recommended for serious infection. *Yersinia* infection is most frequently associated with raw or undercooked pork consumption.[80,81] Swine are the major reservoir of these organisms, although they have been found in sheep, dogs, cats, and cattle. Milk is a frequently reported source, and because *Y. enterocolitica* can survive and indeed multiply in milk at 4°C, small numbers of organisms can become a significant health threat, even if the milk is refrigerated.

Infection with *Y. pseudotuberculosis* has also been associated with consumption of contaminated water or unpasteurized milk. Six serotypes and four subtypes of *Y. pseudotuberculosis* have been described. The clinical picture is similar to that of *Y. enterocolitica*.

Listeria

Listeria monocytogenes is one of the most concerning of foodborne pathogens because of the high mortality rate associated with infection.[82,83] Of the 1,800 cases per year estimated to occur in the United States, there are over 400 deaths, giving a case-fatality rate of over 20%. Of the seven *Listeria* species, only *L. monocytogenes* is a significant human pathogen. It is common in the environment, present in soil, in water, on plants, and in the intestinal tracts of many animals. Thirty-seven different types of mammals, at least 17 species of birds, and between 1 and 10% of humans are carriers of *Listeria*. Although the organism is readily killed by heat and cooking, the fact that it is ubiquitous makes recontamination a real risk. The organism is able to grow and multiply at refrigerator temperatures, so even minor contamination of a product may result in high levels of bacteria after storage. The infectious dose is not known. The more critical determinant of *Listeria* infection is likely individual susceptibility, with the elderly, pregnant women, the immunocompromised, and newborns having higher rates of infection and higher mortality rates.[84–86]

Foods incriminated in *Listeria* infection include milk, cheese, raw vegetables, undercooked meat, and even ready-to-eat foods such as hot dogs.[87] Human infection occurs sporadically and in outbreaks. Infected individuals suffer a mild, transient enteritis 2 to 3 days after contaminated food is consumed. Most immunocompetent adults have no further symptoms. Susceptible individuals may suffer, after a period of days, fevers and mylagias, septicemia, meningitis, or encephalitis. Pregnant women have a 12-fold increased risk of infection, and transplacental transmission may cause spontaneous abortion, premature birth, neonatal sepsis, and meningitis.[88] Once the diagnosis is established, *L. monocytogenes* is readily treated by penicillins or aminoglycosides.

L. monocytogenes has also been associated with a febrile enteritis and linked with a variety of food items. Generally, such episodes are self-limiting and do not lead to the listeriosis. It is unclear how frequent *L. monocytogenes* causes enteritis because it is not an organism that is routinely looked for in this context.[89,90]

Shigella

Shigellae are unusual in that they are not present in fecal material from animals such as poultry, beef, and pork and are therefore not transmitted in the same manner as *Salmonella*, *Campylobacter*, or *E. coli*. Instead, these bacteria are highly host adapted, infecting only humans and some nonhuman primates. Transmission occurs when a food product is contaminated by human fecal material. There are four different species of shigellae (*S. dysenteriae*, *S. flexneri*, *S. sonnei*, and *S. boydii*), and all cause human disease. In the United States and other developed countries, most infection is due to *S. sonnei*, although *S. flexneri* is also common. One of the most striking features of shigellosis is the very small inoculum of organisms required to cause disease: as few as 10 to 100 of the most virulent genus, *S. dysenteriae*, are sufficient to cause dysentery in healthy adult volunteers. This low infectious dose permits person-to-person spread, with approximately 20% of persons in a household becoming infected when an index case is identified in a family.[91] Given that these organisms are not typically present in food other than through human contamination—either directly during food preparation or indirectly from contamination with human fecal material—all shigellosis could be considered to be due to person-to-person spread.

A variety of foods have been implicated in the spread of *Shigella*, including salads (potato, tuna, shrimp, macaroni, and chicken), raw vegetables, dairy products, poultry, and common-source water supplies. In 1998, eight restaurant-associated outbreaks of shigellosis revealed contamination of parsley imported from a common farm in Baja, Califor-

nia.[92] At a wake in Australia, 13 of 32 people developed shigellosis: *S. sonnei* was found in 4 people and *S. dysenteriae* type 2 in 1 person. Ham was considered to be the vehicle, and the person who handled the ham had recovered earlier that week from a diarrheal illness of unknown type.[93] Twenty-four individuals in southeastern Texas were infected with *Shigella* after eating oysters. All consumed oysters in the previous 5 days from different restaurants, but all of the implicated restaurants obtained oysters from the same supplier. Indeed, all of the contaminated oysters were traced to a single boat. One of the crew was found to be an asymptomatic carrier of *S. sonnei* similar to the strain that infected the 24 people. Subsequent investigation found that the toilets on the boat were 5-gallon pails that were tipped overboard in the oyster harvesting area after use.[94]

Shigella often cause bloody diarrhea. Some species carry the Shiga toxin and may cause a HUS similar to *E. coli* O157:H7. Treatment with antibiotics shortens the duration of fever, diarrhea, and bacteremia and reduces the risk of lethal complications. It also shortens the duration of pathogen excretion in stool, thereby limiting the spread of infection. A recent concern, however, is the increasing antibiotic resistance of *Shigella* species. Antibiotic resistance occurs quickly in *Shigella*, attributed to horizontal transfer of resistance genes on integrons.[95] Multidrug-resistant isolates have been discovered in several developing countries.[96]

Other Bacterial Agents that May Be Foodborne and Waterborne

Enteroinvasive *E. coli* (EIEC) is not frequently recognized as a foodborne pathogen, but infection has been linked to water and other foods, such as cheese.[97] EIEC causes morbidity and mortality in young children in developed countries but is a more important menace in developing countries owing to poor hygiene and sanitation. A number of prominent serogroups found to be EIEC have been described, including O28, O112, O124, O136, O143, O144, O147, and O164. Clinically, EIEC produces disease similar to shigellosis, with a watery diarrhea or dysentery. Like shigellae, they invade colonocytes and cause an intense inflammatory response by means of several virulence factors encoded on a 120 to 140 MD plasmid.[98] EIEC do not, however, produce Shiga toxins. EIEC should be considered in those subjects with dysentery and substantial fecal leukocytes, in whom other invasive organisms have been ruled out.

Enteropathogenic *E. coli* (EPEC), like *Shigella* species, is transmitted mainly by the fecal-oral route from one infected individual to another.[59] EPEC has no known animal reservoir and is transmitted via food and water once contaminated by an infected person. EPEC is a major cause of infantile diarrhea worldwide but affects mostly the developing world.[98] The organisms have caused major outbreaks in various developed countries, but their role in sporadic disease is unknown because we lack routine diagnostic testing for these bacteria. Clinically, EPEC infection presents with a watery, nonbloody diarrhea. Low-grade fever and vomiting are common. In the developing world, mortality rates may be high, especially among infants.

Enteroaggregative *E. coli* (EAEC) get their name from the way in which they adhere to epithelial cells in culture, in a "stacked brick" pattern.[59] These bacteria have been associated with an acute or persistent diarrhea among immunocompromised patients and in developing countries. Currently, there is no known animal reservoir for EAEC, and fecal-oral spread from one person to another is considered to be the usual route of transmission. As with EPEC, contamination of food and water from infected individuals is probably important. In human immunodeficiency virus (HIV) patients with persistent EAEC-associated diarrhea, antibiotic treatment has resulted in clearing of the organisms and improvement in symptoms,[99,100] suggesting that these bacteria are true pathogens, but they may be more opportunistic than other foodborne bacteria.

Aeromonads are gram-negative, facultatively anaerobic, motile, oxidase-positive bacilli that have been associated with foodborne illness.[101,102] They are present in soil, freshwater, and sewage and can contaminate fresh produce, meat, and dairy products. The infection rate tends to peak during the summer months. Of the various species, *Aeromonas hydrophila*, *A. caviea*, *A. veronii*, and *A. jandaei* are most frequently associated with acute enteritis and foodborne infections. All typically cause persistent watery diarrhea. Patients often have abdominal pain, and dysenteric-like symptoms can occur, but fecal leukocytes and red cells are usually absent from stool. Nausea, vomiting, and fever may occur in up to 50% of patients.[102] Stool cultures may be unreliable in making the diagnosis because asymptomatic carriage of *Aeromonas* has been reported. Immunologic tests can confirm recent infection. However, because infection is usually self-limiting and full recovery occurs in most healthy individuals without antimicrobial therapy, making the diagnosis is often of academic interest only. The exception may be the patient with persistent diarrhea in whom no other cause has been identified.

Plesiomonas shigelloides was placed in its own genus in 1962.[102] It is primarily a freshwater organism, and, like *Aeromonas*, the isolation rates increase in warmer months. Plesiomonads are gram-negative, motile, and facultative anaerobes. Initially, these species were regarded as nonpathogenic bacteria, but studies in Asia have demonstrated an association between the consumption of contaminated food and diarrheal illness owing to *Plesiomonas*. One review suggests that this organism may cause traveler's diarrhea in Japan and that its frequency is increasing.[103] Symptoms occur 24 to 48 hours after exposure and are thought to be linked to the production of an enterotoxin. Infection is associated with abdominal cramping and occasionally with bloody stools. Nausea, vomiting, and fever are less common. Fluid resuscitation is important in treating *Plesiomonas* infection, but antimicrobials are seldom required. If antibiotics are required, most strains are sensitive to quinolones and trimethoprim-sulfamethoxazole.

Protozoal Foodborne Pathogens

A number of protozoa have been associated with consumption of contaminated food and water. *Cryptosporid-*

ium parvum is an apicomplexan protozoan parasite that causes diarrhea in both immunocompetent and immunocompromised individuals.[104,105] Its pathogenic potential in immunocompromised patients first became evident during the early acquired immune deficiency syndrome (AIDS) epidemic. Its ability to affect healthy individuals was confirmed in 1993, when more than 400,000 people in Milwaukee developed cryptosporidiosis as a result of contaminated municipal drinking water.[106] This infection is endemic in developing countries and is a common cause of persistent diarrhea in young children. Cryptosporidia are typically waterborne, but foodborne and person-to-person spread have occurred. The primary reservoirs are bovine and human. Symptoms tend to occur 5 days after ingestion of the oocysts. Once ingested, the oocysts release four sporozoites, which then attach to and invade intestinal epithelial cells, especially in the jejunum and ileum. As a result, infection may be missed by diagnostic evaluation such as endoscopy. The diagnosis is made by a modified acid-fast or Kinyoun stain for oocysts in the stool or using commercially available immunofluorescence assays.[107]

Typically, cryptosporidiosis causes watery diarrhea, abdominal cramping, nausea, and vomiting. Fever is infrequent. In the immunocompetent, infection is self-limiting, and recovery is the rule after a week or two. Immunocompromised hosts do not clear the infection, and malabsorption may become a significant and life-threatening problem. Unfortunately, there is no known treatment for *C. parvum* infection, and current methods of water purification are ineffective for removal of the organism from the public water supply.

Giardia lamblia is probably the most common enteric protozoan worldwide.[108] Although it may not cause dramatic enteric disease and has few systemic complications, giardiasis can lead to profound malabsorption and misery. Only *G. lamblia* is known to infect humans. Like other enteric protozoa, it is transmitted via the fecal-oral route and is most commonly spread through contaminated water. Disease is caused by ingestion of cysts, which excyst in the proximal small intestine and release trophozoites. The trophozoites divide by binary fission and attach intimately to the intestinal epithelium via a ventral disk. The infectious dose is as low as 10 to 100 organisms. Clinical symptoms vary greatly; infection may be asymptomatic or, at the other extreme, may result in substantial abdominal discomfort, chronic diarrhea, protein-losing enteropathy, and intestinal malabsorption. *G. lamblia* can be diagnosed by fecal microscopy looking for either cysts or trophozoites. Currently, many laboratories use commercially available kits using either fluorescence microscopy with specific antibodies or enzyme immunoassays. Metronidazole is the drug of choice for treatment.

Entamoeba histolytica is the second leading cause of parasitic death in the world, with more than 40,000 deaths annually.[109] It is spread through fecal contamination of food and water or by person-to-person contact. Amebic cysts are the infectious agent. They may survive for weeks in an appropriate environment. Following ingestion, they pass unharmed through the stomach, travel to the small intestine, and excyst to form trophozoites. The trophozoites then colonize the large bowel and either multiply or encyst, depending on local conditions. The trophozoites invade the colonic epithelium, resulting in ulceration of the mucosa and amebic dysentery. They may also spread hematogenously to the portal circulation, causing parenchymal liver damage and amebic abscesses. The onset of symptoms in amebic dysentery may be gradual, initially presenting with mucoid stools and constitutional symptoms before progressing to bloody stools, abdominal pain, and fever. Amebic abscesses may develop months to years after exposure.

There are two types of *Entamoeba*: *E. histolytica*, which is pathogenic, and *E. dispar*, which is a commensal. Microscopic examination of the stool has been the standard technique used to diagnose amebic dysentery, but this technique cannot distinguish between the two species. In the patient with classic symptoms of amebic dysentery, this distinction may not be important. However, enzyme-linked immunosorbent assay and stool PCR techniques are now commercially available and allow specific identification of *E. histolytica*. Once the diagnosis is made, in the United States, metronidazole is the only drug available for treatment. In fulminant amebic colitis, luminal agents such as paromomycin or iodoquinol should be used to eliminate bowel colonization. Amebic abscesses can be eliminated with antiparasitic agents alone; percutaneous drainage should be reserved for those who do not improve with metronizadole therapy or those with large left-lobe abscesses.[109]

Cyclospora cayetanensis is a recently described apicomplexan parasite that has been found in food. Most recently, it has caused a number of outbreaks in North America; in 1996 to 1999 associated with consumption of imported raspberries. *Cyclospora* has also been associated with other fresh produce, undercooked meat and poultry, and contaminated drinking and swimming water. In immunocompetent patients, *Cyclospora* infection results in a self-limiting diarrhea with nausea, vomiting, and abdominal pain. In immunocompromised patients, there can be a chronic cycle of diarrhea with anorexia, malaise, nausea, and abdominal discomfort followed by transient remissions. Both *Cyclospora* and *Cryptosporidium* infections have been linked to a number of postinfectious complications, including GBS, reactive arthritis, and acalculous cholecystitis.[110] Infection is diagnosed through detection of oocysts in stool by direct stool microscopy and oocyst autofluorescence. The infection can be treated successfully with trimethoprim-sulfamethoxazole.

A number of other protozoa have been associated with food- and waterborne infections in humans. *Microsporidium* causes watery diarrhea and malabsorption in the immunocompromised host. Various microsporidia species, including *Enterocytozoon bieneusi* and *Septata intestinalis*, cause human disease. The apicomplexan protozoan *Isospora belli* also causes diarrhea in the immunocompromised host. Sarcocystosis is a rare zoonotic infection that, on occasion, causes a necrotizing enteritis in humans. Although *Dientamoeba fragilis* was originally thought to be a commensal, there are increasing data to indicate that it is pathogenic, causing abdominal pain, nausea, diarrhea, and anorexia. *Balantidium coli* is the only ciliate known to par-

asitize humans. Most infections are asymptomatic, but dysentery can occur. *Blastocystis hominis* is a strict anaerobic protozoan that infects both immunocompetent and immunocompromised hosts and results in a variety of gastrointestinal symptoms, including diarrhea, abdominal pain, nausea, vomiting, anorexia, and malaise.

Cestodes and Worms

A variety of cestodes and worms may be transmitted in food.[111–114] The beef tapeworm *Taenia saginata* is highly endemic in parts of South America, Africa, and Asia. These worms may live as long as 20 years and grow up to 25 meters in length. Humans are their definitive host, whereas cattle represent an intermediate host. In the cow, hexacanth embryos emerge from eggs and pass by blood or lymph to muscle, subcutaneous tissue, or viscera. When humans consume raw or undercooked beef, they are infected with the living larval forms, and the life cycle is completed. In the human intestine, the worms are remarkably quiescent, typically causing nausea or a sense of fullness. However, vomiting and diarrhea may occur. Worms can be eradicated with praziquantel or albendazole. The diagnosis is made by detecting the proglottids in stool.

The pork tapeworm *Taenia solium* is distributed worldwide and is acquired by ingesting pork containing the infectious cysts cysticerci. The adult worm in humans sheds proglottids, which are then eaten by pigs. In the pig, the hexacanth embryos emerge, penetrate the intestinal wall, and migrate to the muscle and other tissues. With consumption of raw or undercooked pork, humans acquire the larval forms. These larval forms, unlike those of *T. saginata*, are capable of migrating to the human nervous system. In the brain, the larvae encyst, become calcified, and may cause seizures. However, in a recent study of a hyperendemic region of Mexico, 9% of the population had calcified lesions on computed tomographic scan and were asymptomatic.[115] *T. solium* is smaller than *T. saginata*, and gastrointestinal symptoms are even less remarkable. Infected individuals often make the diagnosis by noticing proglottids in their stool. The diagnosis is confirmed by identifying the proglottids, and treatment consists of either praziquantel or albendazole.

Diphyllobothrium latum is a fish tapeworm, most commonly found in Northern Europe and Scandinavia. Eating raw fish is the primary mode of infection, and, as a result, the incidence in the United States has increased with the rise in sushi consumption.[116] The worm's life cycle is complex: the eggs are passed in human feces, hatch in freshwater, and are eaten by copepods, which are freshwater crustaceans. In the copepod, they develop into larval forms and are eaten by fish. The procecoids then invade the stomach wall of the fish and come to reside in the fish muscle. Humans become infected by eating a fish that harbors a viable plerocercoid larva. Infection is usually asymptomatic, but diarrhea and fatigue may occur. Because the worm absorbs free vitamin B_{12} in the intestine, the host may develop vitamin B_{12} deficiency and neurologic symptoms. Diagnosis is made by identifying the ova or proglottids in stool. Treatment with praziquantel or niclosamide is effective.

Ascaris lumbricoides is the most common intestinal helminth worldwide, with an estimated 1.5 billion cases globally.[117] Humans are the only host for *Ascaris* and become infected by fecally contaminated food or water. Humans ingest the mature ova, which develop into larvae in the small intestine. The larvae enter the circulation and lodge in the pulmonary alveoli, where they mature. Pulmonary infestation may cause pneumonitis and allergic manifestations. Finally, the larvae migrate up the bronchial tree and are swallowed. Although most of the life cycle is completed in humans, soil is necessary for egg development and acts as a reservoir and a contaminant. Ascariasis contributes to childhood malnutrition, growth, and cognitive delay and is an important cause of intestinal and biliary tract obstruction. Its diagnosis is made by finding adult worms, larvae, or eggs in the stool. Treatment consists of mebendazole or pyrantel pamoate.

Trichuris trichiura, commonly known as whipworm, is found in the same parts of the world as *Ascaris*. Humans are the definitive hosts. Eggs are passed in human feces and mature in warm, moist soil to become infective. They contaminate food and are ingested by a new host. The worms remain within the intestine, and their carriage may be asymptomatic or may result in chronic diarrhea. With a heavy worm burden, malnutrition or dysentery may develop. The diagnosis is made by finding adult worms or eggs in stool. Treatment with mebendazole is usually curative.

Trichinella spiralis is a nematode that infects humans following the ingestion of the first-stage larvae and its nurse cell in striated skeletal muscle tissue, typically in pork. The larvae are released from the meat in the stomach and pass to the small intestine, where they infect epithelial cells. They develop into adult worms and are shed in the stool. They may also penetrate into lymph or blood vessels, travel to the skeletal muscles, and form the nurse cell. The principal mode of transmission to humans is through the consumption of undercooked meat; outbreak sources have included pork, horse, and bear meat.[118] The major clinical features of infection relate to the cellular destruction caused by parasitic penetration of cardiac or nervous tissue. Gastrointestinal symptoms are common, including diarrhea and vomiting. The diagnosis is dependent on the histologic identification of cells containing larvae within infected muscle tissue. Serologic tests are also of value. Trichinella may be treated with thiabendazole.

Viral Foodborne Infections

According to a recent CDC report, viruses account for many more cases of foodborne infection than bacterial causes.[1] Viral syndromes range from simple enteritis to life-threatening hepatitis. Viruses contaminate both food and water, but they do not reproduce in these media, nor do they produce toxins. Several viruses, such as the noroviruses, cause large outbreaks, whereas others are associated only with sporadic disease. Noroviruses (genus *Norovirus*, family Caliciviridae) are a group of related, single-stranded RNA, nonenveloped viruses that cause acute enteritis in humans. *Norovirus* was recently approved as the official genus name for the group of viruses provision-

ally described as "Norwalk-like viruses." The difficulty in diagnosing viral illness has precluded the acquisition of large amounts of epidemiologic data. However, the advent of rapid tests such as enzyme immunoassays is beginning to change this and will eventually lead to a better understanding of the epidemiology and disease burden caused by the various foodborne viral pathogens.[119]

Noroviruses or the Norwalk-Like Viruses

Noroviruses, or Norwalk-like viruses, are the principal cause of epidemic, nonbacterial enteritis in the United States. Mead and colleagues estimate that these viruses cause 23 million infections, 50,000 hospitalizations, and 300 deaths annually.[1] Norwalk virus was first described after a large outbreak in 1972. It is a small, round, structured virus of the Caliciviridae family. Noroviruses have been associated with many large outbreaks in cruise ships, nursing homes, banquet halls, and other institutional settings. The primary source of infection is feces-contaminated drinking water, but the virus may also be spread through food that has been stored or washed in contaminated water or handled by an infected food service worker. Noroviruses are highly contagious, with fewer than 100 viral particles sufficient to cause disease, and are resistant to freezing, heating, pH extremes, and disinfection.[120] Symptoms tend to occur 48 hours after exposure and consist of vomiting and diarrhea. The diarrhea is watery, without red cells, leukocytes, or mucus. The disease is usually self-limiting, resolving in 1 to 3 days without long-term sequelae. Diagnosis can be made using transmission electron microscopy to find Norovirus particles in stool, vomitus, or food. Serologic testing, enzyme immunoassays, and PCR techniques also establish the diagnosis. The only treatment required is to prevent dehydration. Hand washing will prevent spread of the infection.

A number of other viruses have also been associated with outbreaks of acute enteritis and are suspected to be spread through the fecal-oral route. The list of potential foodborne viruses includes rotavirus, enteric adenovirus, saporo-like viruses, coronaviruses, toroviruses, reoviruses, and the smaller-sized viruses such as caliciviruses, astroviruses, parvoviruses, and picobirnaviruses.[121] All cause a similar acute illness with a self-limiting, noninflammatory, watery diarrhea.

Hepatitis A Virus

Hepatitis A is an RNA virus, belonging to the family Picornaviridae, with a worldwide distribution. It is spread via the fecal-oral route through contaminated food and water and person-to-person spread. In sporadic infections, up to 50 to 75% of susceptible household contacts of the affected individual are infected with hepatitis A.[122] Large outbreaks have been traced to contaminated water, shellfish, milk, potato salad, and fresh fruits. Symptoms develop 30 days after exposure on average, with a range of 15 to 50 days. The lengthy incubation period complicates tracing the source of infection. During the incubation period and the first week of acute illness, hepatitis A virus can usually be detected in stool. Therefore, there is a prolonged phase when an individual is asymptomatic but may transmit the disease to others—a significant concern in relation to food workers and foodborne transmission. An inactivated viral vaccine exists and is recommended for travelers to endemic regions but is not routinely recommended for food handlers. In endemic countries, childhood infection and immunity are almost universal; childhood disease tends to be asymptomatic. In the United States, disease typically occurs after foreign travel to an endemic region. It may present with fever, jaundice, fatigue, abdominal pain, nausea, and diarrhea. Diagnosis of the acute infection may be established serologically, and treatment is supportive. An immunoglobulin may also be used for pre- or postexposure prophylaxis.

Hepatitis E Virus

Hepatitis E virus was first described in 1978 after an epidemic affecting 52,000 individuals occurred in Kashmir, causing 1,650 cases of fulminant hepatic failure and 1,560 deaths.[122] It is a small RNA virus from the Caliciviridae family that is usually transmitted through contaminated drinking water. Foodborne spread has not yet been documented. Hepatitis E is endemic to India, Southeast and Central Asia, parts of Africa, and Mexico. It has an incubation period of 2 to 9 weeks, although most people develop symptoms around 40 days postexposure. Clinically, the disease is similar to hepatitis A, with constitutional symptoms followed by jaundice. Most patients recover, but mortality rates of up to 3% have been reported, with pregnant women at higher risk. The diagnosis is made serologically. Hepatitis E vaccines remain experimental.[123]

Bovine Spongiform Encephalopathy and Variant Creutzfeldt-Jakob Disease

Bovine spongiform encephalopathy or "mad cow disease" was first diagnosed in the United Kingdom in 1986. It is a member of the transmissible spongiform encephalopathies, a group of infectious neurologic diseases affecting a variety of species. Transmissible spongiform encephalopathies were recognized in the eighteenth century, when the condition scrapie was described in sheep,[124] but they did not become a public health or food safety concern until the mid-1990s, when a link was established between mad cow disease and a fatal, degenerative neurologic disease in humans known as variant Creutzfeldt-Jakob. Human infection occurs through beef consumption, with symptoms developing 10 years or more after exposure. The disease is transmitted only through nervous system tissue, included with or contaminating other meats during the slaughtering process. The disease is due to a novel infectious agent, the prion, a protein encoded on the host genome and produced as a normal cellular constituent that is altered and becomes infectious through the disease process.[125,126] In variant Creutzfeldt-Jakob, the bovine neurologic proteins are suspected to induce structural changes in the human protein PrP^c using an unknown cofactor. The epidemic of variant Creutzfeldt-Jakob is likely to have originated in changes in the rendering process, in which cattle were fed sheep and cattle remnants in a concentrated form.[127] In the United Kingdom, nearly 4.5 million asymptomatic cattle were slaughtered to prevent

disease spread. There has been one recent case in Canada, and one infected cow in the United States. A number of cattle are routinely tested for bovine spongiform encephalopathy to ensure early detection.

LONG-TERM CONSEQUENCES OF FOODBORNE INFECTIONS

As previously mentioned, most foodborne illness is characterized by rapid onset and resolution of disease. Even if the intervening hours and days result in profound illness or critical dehydration, most infected individuals recover fully. In recent years, however, we have learned that some food- and waterborne pathogens have more sinister long-term consequences. For example, osteomyelitis may result from *Salmonella* infection. Reactive arthropathy follows infection with a number of enteric bacteria, including *Salmonella*, *Shigella*, and *Yersinia*. Two of the most significant long-term consequences include *Campylobacter*-associated GBS and Shiga toxin–producing *E. coli*–associated renal failure.

In recent years, a clear association between *C. jejuni* infection and GBS has emerged.[74,128] GBS is an autoimmune disorder characterized by flaccid paralysis. The pathogenesis of injury is molecular mimicry, in which the immunologic response to the core oligosaccharides of *Campylobacter* lipopolysaccharide cross-reacts with a variety of neuronal glycosphingolipids.[129] Up to 20% of individuals affected by GBS require mechanical ventilation, and another 20% will have permanent neurologic deficits. The overall risk of developing GBS following *Campylobacter* infection is considered to be approximately 1 in 1,000.[74] The percentage of cases of GBS linked to prior infection with *Campylobacter* is estimated to be 30 to 40%.[74] At least 11 *Campylobacter* serotypes have been associated with GBS, but serotype O:19 is thought to be the most common association. The interval between infection and the development of GBS may be as short as 1 week or as long as 6 weeks. Those with a rapid onset of GBS are suspected to have had prior exposure to the critical *Campylobacter* serotypes and are therefore primed for a rapid immune response.

Another well-described example of a long-term consequence following infection with a food- and waterborne pathogen is the HUS resulting from Shiga toxin–producing *E. coli* infection. Shiga toxin crosses the intestinal epithelial cell monolayer and damages distant target sites, especially the kidney and brain, by direct and immune-mediated effects on endothelial cells in the microvasculature. Permanent renal failure may result. In the United States, 1.5% of patients will require a renal transplant following HUS.[130] In the United Kingdom and South Africa, the rate of renal transplant post-HUS is less than 5%,[131,132] whereas in Argentina, it may be as high as 20%.[133] In up to 20% of patients with HUS, the pancreas is also damaged, causing some patients to develop permanent diabetes mellitus. The majority of patients with HUS have some neurologic involvement, ranging from minor symptoms such as irritability or lethargy to major neurologic dysfunction such as seizures, coma, or stroke.[130] Of the one-third of patients who suffer major neurologic illness, a small proportion sustain permanent neurologic damage. One of the most thorough reviews of post-HUS sequelae was published by Siegler and colleagues,[134] who investigated over 100 patients with postdiarrheal HUS to evaluate outcomes. Overall, 11% had a poor outcome: death, stroke, or chronic renal failure. Approximately 50% had evidence of permanent renal damage in the form of hypertension, reduced glomerular filtration rate, or proteinuria.

SUMMARY

Over time, many new microbes and other infectious agents are discovered and associated with food- and waterborne illness. Despite this growing list of pathogens, data from the CDC suggest that over 80% of such illnesses are due to organisms that are yet to be identified.[1] We constantly have to be aware of new foodborne pathogens coming onto the horizon. One recent example is *Enterobacter sakazakii*, which has been associated with meningitis and sepsis in young infants. Several epidemiologic studies linked this infection with the presence of the organism in powdered infant formula.[135,136]

The majority of available epidemiologic data in the United States from FoodNet and other sources are based on less than 5% of enteritis cases, and many laboratories do not routinely screen for the pathogens, such as enteric viruses, that are probably causing much of the disease burden. In recent years, following a number of highly publicized outbreaks involving a variety of enteric pathogens, food and water safety has become a major public health concern. The food industry has made substantial efforts to improve the safety of food processing, and we are beginning to see the benefits of this with lower levels of bacterial pathogens in poultry and a decline in the incidence of infection with certain bacterial pathogens. Continued monitoring is necessary, both to document trends in the prevalence of pathogens and incidence of infections and to determine the outcomes of foodborne illness. We presume that the outcome is good for the vast majority of foodborne disease, but we do not know this for a fact. Clearly, the outcome is occasionally poor, with sequelae such as HUS, GBS, or reactive arthropathy following infection with enteric pathogens.

One of the primary goals in food safety is prevention through consumer education, conveying information and encouraging behaviors that reduce the risk of infection. High-risk individuals must be made aware that they have a high risk for infection. This includes the young and elderly, the immunocompromised, pregnant women, and possibly even those taking medications that markedly reduce gastric acidity. Simply paying attention to personal hygiene, hand washing, food handling, proper cooking, and food preparation and storage can go a long way in reducing the burden of foodborne illness.

3. Viral Infections

Dorsey M. Bass, MD
Mary K. Estes, PhD

Although viruses had long been suspected as pathogens in acute enteritis, the first report of reovirus-like particles in epithelial cells in small bowel biopsies from children with acute nonspecific diarrhea was made only 30 years ago.[1] That original discovery led to a cascade of clinical and laboratory studies that have established rotavirus as the leading cause of dehydrating acute pediatric diarrhea, which is responsible for 30 to 50% of episodes of acute enteritis in children in developed countries. Now 40 to 70% of cases can be attributed to one of several pathogens, compared with only 10 to 20% in the 1970s. It is now known that astroviruses account for up to 15% of cases of acute pediatric diarrhea.[2–4] Specific types of adenoviruses account for 3 to 5% of cases.[5,6] Noroviruses, such as Norwalk and Snow Mountain agents, are also emerging as significant pediatric pathogens. Norwalk agent, one such small round virus known since 1969 to cause epidemic vomiting, can cause outbreaks of vomiting and diarrhea in children at school camps,[7] as well as nosocomial infections in children's hospital wards.[8] Noroviruses are now thought to be second in frequency to rotaviruses as causative agents of acute enteritis in young children,[4] and these infections can result in children having moderately severe or severe episodes of enteritis.[9]

None of the currently recognized intestinal viruses are "new" viruses, but they are newly discovered viruses. This is illustrated by the examination of stool samples from children with acute infectious diarrhea that were stored in 1943 when Light and Hodes were searching for the elusive etiology. In 1975, after rotavirus had been discovered, Hodes tested these samples again and found rotavirus in several of them.[10] Other "novel" viruses have been described in association with acute diarrhea, but cause and effect have yet to be established for many of them. Some of these candidates are still named after the locality in which they were discovered (Breda virus) or for their appearance on electron microscopy (coronavirus) (Table 38.3-1).

Viruses also account for up to 40% of cases of severe infectious diarrhea in children in developing countries. Rotavirus is one of the single most important pathogens because of its frequency and because it is overrepresented in more severe dehydrating disease.[11] Rotavirus alone is estimated to cause 600,000 deaths per year in the developing world. Development of a rotavirus vaccine has been an objective of the World Health Organization for many years.

Enteric viruses spread mainly by contact with feces (the fecal-oral route) or person-to-person contact. The epidemiology of rotavirus closely resembles that of childhood viruses that are spread by the respiratory route.[12] There is some evidence that transmission via contaminated water supplies may be important in developing countries.[13] Excretion after infection may be more prolonged than previously thought. Polymerase chain reaction (PCR) techniques have shown excretion of rotavirus ribonucleic acid (RNA) for up to 57 days after infection.[14] If this is indicative of viable virus, there are considerable implications for the management of cross-infection in day-care centers and schools.

Discovery of these various enteric viruses was the result of the application of new technology, especially electron microscopy, to diarrheal disease. Most enteric viruses have proven difficult to grow in the laboratory; hence, they eluded recognition by traditional tissue culture techniques. Electron microscopic identification of rotavirus has been replaced by less cumbersome enzyme immunoassay (EIA) antigen detection tests, which can be undertaken on large batches of stools. EIAs have been developed for group A rotaviruses, enteric adenoviruses, and astrovirus. More recently, PCR techniques have been emerging as important diagnostic methodology.

There is a large overlap between human and veterinary medicine in this field. Knowledge of animal enteritis viruses has often preceded their discovery in humans. Animal studies have provided much of the understanding of current pathologic and pathophysiologic sequelae of viral enteritis.

PATHOPHYSIOLOGY OF VIRAL ENTERITIS

Viruses that cause diarrhea in humans and animals generally show strong tropism for epithelial cells of the small intestine. The traditional view is that these agents cause disease by selectively destroying large numbers of mature, absorptive enterocytes via lysis, and/ or apoptosis leading to inadequate absorption of fluid, electrolytes, and luminal nutrients (Figure 38.3-1). In contrast to invasive bacterial pathogens, the host inflammatory response in viral enteritis is relatively mild and is not thought to contribute much to the diarrhea. Elevations of cyclic nucleotides, such as cyclic adenosine monophosphate and cyclic guanosine monophosphate, seen with some of the toxin-producing bacterial pathogens that stimulate chloride secretion through the cystic fibrosis transmembrane regulator (CFTR) channel, are not observed during viral enteritis.

New concepts of rotaviral pathogenesis have been evoked by the demonstration that a nonstructural rotavirus protein may function as an enterotoxin.[15] Other proposed mechanisms include neuronally mediated intestinal secre-

TABLE 38.3-1 VIRAL AGENTS OF GASTROENTERITIS

AGENT	VIROLOGY	CLINICAL/EPIDEMIOLOGY	DIAGNOSTIC TESTS
Group A rotavirus	80 nm, segmented dsRNA, grow in tissue culture	Major cause of infantile dehydrating diarrhea Peak incidence in winter in temporate climate	EIA (commercial) EM PAGE RT-PCR
Astrovirus	34 nm, ssRNA, 8 human serotypes	Infant diarrhea, outbreaks in elderly, immunocompromised Peak incidence in winter in temporate climate	EIA EM RT-PCR
Calicivirus including noroviruses and sapoviruses	28 nm, ssRNA, never adapted to tissue culture	Common cause of outbreaks among adults and children, also infantile diarrhea Peak incidence in winter in temporate climate	EM RT-PCR EIA for noroviruses
Enteric adenovirus	80 nm, dsDNA, only serotypes 40 and 41 definitely associated with diarrhea	Prolonged diarrhea in infants and young children. Year-round prevalence	EIA EM
Picobirnavirus	Segmented dsRNA	? Diarrhea in immunocompromised	EM PAGE
CMV	Enveloped dsDNA	Enterocolitis in immunocompromized	Culture Serology PCR Histology
Groups B and C rotavirus	80 nm, segmented dsRNA, do not grow in tissue culture	Mostly animal pathogens with occasional human outbreaks in adults and children	EM PCR PAGE

CMV = cytomegalovirus; dsDNA = double-stranded deoxyribonucleic acid; dsRNA = double-stranded ribonucleic acid; EIA = enzyme immunoassay; EM = electron microscopy; PAGE = polyacrylamide gel electrophoresis; PCR = polymerase chain reaction; RT-PCR = reverse transcriptase polymerase chain reaction; ssRNA = single-stranded ribonucleic acid.

tion,[16] loss of tight junctions with paracellular flux of water and electrolytes (Dr. Robert Shaw, personal communication, 1999), and villus tip ischemia.[17]

These comments refer to classic agents of viral enteritis such as rotavirus, astrovirus, calicivirus, and enteric adenoviruses. Viruses such as cytomegalovirus (CMV), Epstein-Barr virus (EBV), and human immunodeficiency virus (HIV) can be associated with diarrhea that is probably due to other mechanisms, such as local or systemic inflammatory cytokines.

EFFECTS OF UNDERNUTRITION

The impact of viral enteritis has an added dimension if the child is malnourished. Although susceptibility to infection may not be greatly different, animal studies suggest that the severity of infection is greater,[18] and there is evidence from both laboratory studies[19,20] and clinical studies in malnourished children[21] that recovery is delayed.

A detailed study of the effects of chronic protein-calorie malnutrition on small intestinal repair after acute viral enteritis was reported by Butzner and colleagues in 1985.[22] Malnourished and normally fed germ-free piglets were infected with a coronavirus called transmissible enteritis virus. In control piglets, structural changes present in the intestine at 40 hours had virtually recovered by 4 days, but changes persisted through 15 days in malnourished animals. Recovery of mucosal enzymes and glucose-stimulated sodium absorption was also delayed in malnourished piglets, suggesting that malnutrition delays intestinal repair after viral injury. This observation reinforces the need for early and effective nutritional rehabilitation during episodes of diarrhea.

Studies of rotavirus in malnourished piglets have shown that the small intestinal inflammatory response is elevated, and diarrhea persists in malnourished animals.[19] Such prolonged disease in malnourished animals is associated with local mediators or markers of intestinal inflammation. The identification of specific rotavirus-induced alterations that are responsive to malnutrition may allow determination of how macronutrients contribute to host responses to viral infection and viral clearance.

Vitamin A and zinc deficiencies are associated with diarrheal diseases in developing countries. In mouse studies, vitamin A deficiency resulted in much more severe intestinal pathology, as well as impaired antibody- and cell-mediated responses to rotavirus infection.[23,24] Zinc supplements have shown some efficacy in the treatment of acute watery diarrhea in the developing world.[25]

BREASTFEEDING

Breastfeeding reduces the incidence of diarrheal diseases in infants and reduces mortality in children hospitalized with diarrhea in developing countries.[26] It also reduces diarrheal disease in children who contract rotavirus as a nosocomial infection. There is some information about the influence of breastfeeding on rotaviral diarrhea. A prospective study in Finland showed that if breastfeeding

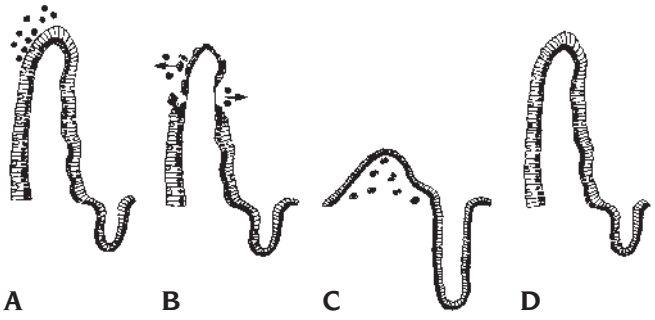

FIGURE 38.3-1 Traditional view of pathogenesis of viral diarrhea. *A*, Mature enterocytes selectively infected. *B*, Virus multiplies in enterocytes that are damaged and shed by 24 hours. *C*, Crypts hypertrophy by 42 hours, repopulating the villi with immature enterocytes. Villi are variably stunted; mononuclear cells increase in lamina propria. Disaccharidases, glucose absorption, glucose-stimulated sodium absorption at the brush border, and sodium-potasium adenosine triphosphatase at the basolateral membrane are diminished. Thymidine kinase is increased. Cyclic adenosine monophosphate and cyclic guanosine monophosphate are not increased. *D*, Structure and function return to normal in 7 to 14 days.

ceased before 6 months of age, the incidence of rotavirus diarrhea between 7 and 12 months of age increased but was the same thereafter.[27] A study of risk factors associated with rotavirus in England found that breastfeeding is protective.[28] There is also some evidence of increased risk of rotavirus diarrhea in children who continue to be breastfed after a certain age, suggesting that infection is delayed but not prevented.[29]

An interesting animal study suggested that persistent asymptomatic excretion of rotavirus by cows may protect their calves from infection, perhaps by reinforcing the immune stimulus to the cow, thus encouraging secretion of antirotavirus antibodies in the milk.[30] Thus, breast milk may be an attenuator of viral diarrheal disease, as well as providing nutritional advantages to affected infants.

IMMUNODEFICIENCY

Virus infections of the intestinal tract are common in patients with immunodeficiency. One child with severe combined immunodeficiency chronically excreted five different viruses.[31] Prolonged excretion of rotavirus may occur in such children. One group demonstrated changes in the strain of virus, suggesting that reinfection, rather than prolonged infection, was the problem.[32] Enteric viral infection may be seen after bone marrow transplant[33] and as a complication of acquired immune deficiency virus infection.[34] CMV is frequently associated with diarrhea in HIV-infected individuals, but the detection of other enteric viral infections varies among studies, and their role in inducing disease remains controversial. rotavirus appears to be more invasive after liver transplant.[35] Passive treatment with oral gammaglobulin has been used in immunodeficiency[36] and as prophylaxis in premature newborn infants.[37]

ENTERIC VIRUSES THAT ARE NOT PRIMARY GUT PATHOGENS

Most viruses that traverse or even replicate within the gut cause no discernable enteric disease. Such viruses can be found in many stool samples from patients with and without symptoms of enteritis. Enteroviruses such as echovirus, hepatitis A virus, coxsackievirus, and poliovirus are excellent examples of viruses that enter the host through the gut, often via M cells overlying Peyer's patches, prior to primary replication in intestinal lymphoid tissue. Other commonly identified stool viruses that do not usually cause diarrhea include nonenteric adenoviruses, reoviruses, and bacterial phages.

VIRAL GUT PATHOGENS

ROTAVIRUSES

Epidemiology. These viruses are the single most important cause of diarrhea requiring admission to hospital during the first 6 to 24 months of life, although most infections are asymptomatic or associated with mild symptoms. Infection is common worldwide from birth to old age.[11] Every child in the world becomes infected with rotavirus, and approximately 2% of infected children are hospitalized for these infections in the United States. The attack rates for *Rotavirus* diarrhea in children aged 6 to 24 months are 0.3 to 0.8 episode per child per year in both developing and developed countries,[38] resulting in at least 600,000 deaths annually in developing countries. The frequency and severity of rotavirus infection provide clear and compelling data for the need for an effective vaccine.[39]

Rotaviruses have been identified in stools from 10 to 40% of children admitted to hospital with acute diarrhea in developing countries and in 35 to 50% in developed countries. Severe infection occurs at a younger age in children in developing countries, where the majority of children admitted to hospital are 6 to 12 months old[38] compared with 12 to 18 months for children in developed countries.[40] All children can be expected to come in contact with rotavirus by 5 years of age, and most will experience asymptomatic boosts in mucosal immunity several times each year. Rotavirus is endemic in the community, and repeated contacts maintain a high level of protection against symptomatic disease after primary infection. In temperate climates, severe rotavirus infections peak during the winter months, but some cases are seen throughout the summer. In tropical areas, seasonal variations are less pronounced.

Neonatal rotavirus infection is often asymptomatic in healthy full-term infants; presumably, these infections are modified by passive immunity from placental and breast milk antibodies. Clinical observations that unique strains of rotavirus may be responsible for endemic nursery infection have been supported by RNA/RNA hybridization experiments using nursery strains and strains from children with acute enteritis.[41]

Infection in children after 3 years of age is not usually severe, but it can necessitate admission to hospital.

Rotaviruses have been identified in 16% of children aged over 5 years admitted for enteritis in Australia[40] and in 5% of adults admitted to hospital in Thailand for severe diarrheal disease.

Some studies from developing countries have reported similar rates of rotavirus isolation from both controls and diarrhea patients. The balance among an ingested dose of virus, mucosal immunity, breastfeeding, and sensitivity of detection methods probably influences these observations.

Outbreaks of diarrhea caused by "atypical" rotaviruses have been widespread in China, where they have affected adults, children, and newborn infants.[42] These atypical rotaviruses lack the group A–specific common antigen, but they are morphologically identical to conventional human strains. They account for 1 to 3% of cases in Finland, Mexico, and the United States.[39] Overall, they account for less than 1% of all severe rotavirus disease worldwide, but if they become more common, current vaccine development strategies may need to be reconsidered. Other recent outbreaks in adults have been caused by rotavirus strains that are not the common circulating strains, suggesting that natural immunity to common strains does not always provide adequate heterotypic protection.[43]

Virology. Rotaviruses are classified as a genus within the family Reoviridae. The prefix "rota-" refers to the wheel-like appearance of particles in feces seen by negative-contrast electron microscopy (Figure 38.3-2). Complete particles, about 70 nm in diameter, exhibit a triple-shelled capsid (Figure 38.3-3). Incomplete double-shelled particles are common but not infectious.

There are four major groups (A, B, C, and D) of rotaviruses as determined by antigens on the middle layer of the viral capsid. Group A rotaviruses are responsible for the great majority of human infections. Epitopes on the outer capsid layer (VP7 and VP4) of group A rotaviruses determine the G (glycoprotein) and P (protease-sensitive) serotypes. G1, G2, G3, and G4 are the most common infecting serotypes in humans, against which current vaccines are directed. In recent years, a global increase in G9 strains has been observed.[44,45] Serotypes can be identified by EIA or by PCR methods. Rotavirus strains can be further subdivided by RNA gel electrophoresis to follow epidemiologic patterns in a given locality. Multiple electropherotypes and serotypes exist simultaneously in most communities, but, usually, one or two are dominant in any 1 year in children admitted to hospital.

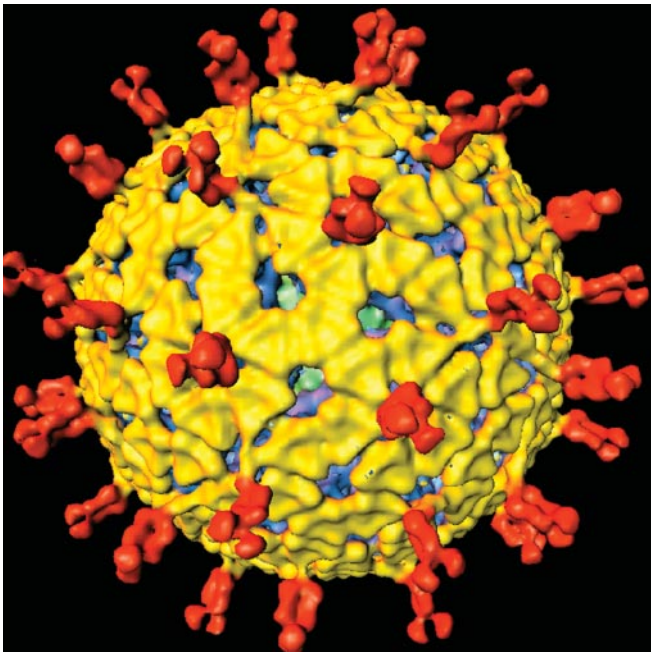

FIGURE 38.3-3 Three-dimensional structure of rotavirus as determined by cryoelectron microscopy and image processing. Note the red spike-like projections (VP4), which mediate cell attachment, the yellow surface consisting of the glycoprotein, VP7, which is the determinant of the G serotype. Small amounts of the inner capsid layers (blue and green) can be seen through channels that penetrate the virion core (×500,000 original magnification) (see CD-ROM for color image). Courtesy of B. V. V. Prasad, Baylor College of Medicine.

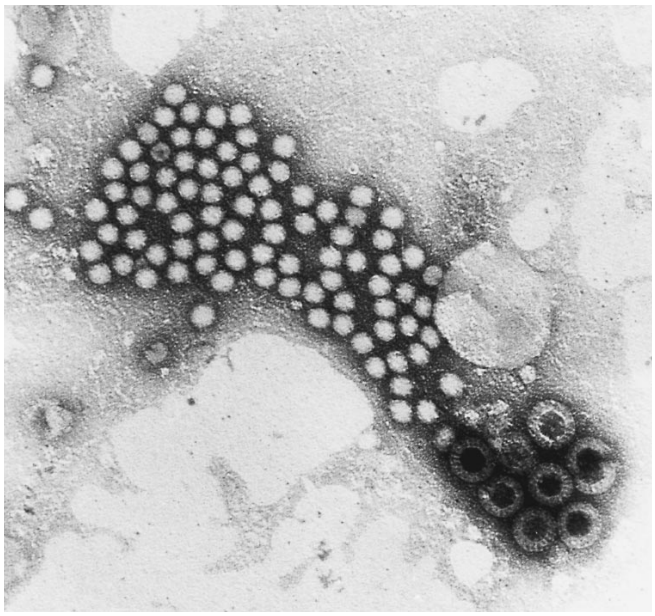

FIGURE 38.3-2 Electron microscopy of feces from an infant with acute diarrhea. The larger (70 nm diameter) particles are rotaviruses that have lost their electron-dense core. A group of smaller unidentified virus particles is seen here in association with rotavirus (×17,000 original magnification.)

Pathophysiology. The traditional view of rotavirus pathophysiology is that diarrhea is a direct result of rotavirus tissue tropism. Rotavirus infects only differentiated villus enterocytes in the small intestine. Virions are ingested, activated by trypsin in the small intestine, and infect the villus enterocytes, leading to their destruction and the release of thousands of progeny, which are locally activated by trypsin to infect more enterocytes. The epithelium is rapidly repopulated with less differentiated enterocytes from the crypts, which lack both digestive enzymes such as lactase and mechanisms for active sodium and water absorption such as sodium-potassium adenosine triphosphatase (ATPase) (Figure 38.3-4). This results in diarrhea

by two mechanisms. Undigested and therefore unabsorbable carbohydrates such as lactose lead to an osmotic diarrhea, whereas the loss of active absorption of water in the face of intact or hypertrophied crypt secretion of chloride and water leads to a low-grade secretory diarrhea. According to this model, symptoms resolve when the new enterocytes have differentiated, which may require 7 days or more in the setting of a severe primary infection.

Recently, Ball and colleagues have proposed that a rotavirus nonstructural protein, NSP4, functions as a novel viral enterotoxin. They have reported that this protein (or a derivative peptide) is capable of inducing diarrhea in susceptible suckling mice when administered by either intraluminal or intraperitoneal routes.[15] NSP4 is reported to cause chloride secretion and thus diarrhea by increasing intracellular calcium when it is either expressed intracellularly or applied externally to cells.[46] Further evidence for the role of NSP4 in the pathophysiology of *Rotavirus* diarrhea is the fact that antibodies against NSP4 can ameliorate rotavirus diarrhea in suckling mice. It has been suggested that changes in NSP4 sequence correlate with rotavirus virulence in porcine rotavirus strains.[47] Of note, NSP4 appears to exert its chloride secretory effects through a previously unrecognized, age-dependent anion channel that is distinct from the CFTR.[48] The ability of NSP4 to induce diarrhea in sucking mice has been reported for several rotavirus strains, including group C and avian rotaviruses, suggesting that the structural elements of this protein are important in enterotoxin function.[49,50] A few studies have questioned the role of NSP4 as an enterotoxin. One group was unable to replicate the secretory diarrhea seen with administration of the NSP4 peptide.[51] Furthermore, although one study found a correlation of virulence with NSP4 sequence of human rotavirus strains, different studies have failed to find correlation of virulence with NSP4 sequence in other human and mouse rotavirus strains.[51–53] This lack of correlation between NSP4 sequences may have been due to mutations in other virulence genes. The role of NSP4 as an enterotoxin in pathogenesis of rotavirus diarrhea remains an area of active investigation.

Another recent hypothesis is that modifications in intracellular tight junctions between enterocytes during rotavirus infection lead to an enhanced paracellular flux of ions and small macromolecules. Morphologic studies show alterations in components of the tight junctions during *Rotavirus* infection. Ussing chamber experiments demonstrate enhanced transepithelial flux of 458 Da and 4 kDa but not 70 kDa markers in rotavirus-infected murine jejunal epithelium.[54] In another study, rotavirus NSP4 increased paracellular fluxes in vitro.[55]

Other possible mechanisms of diarrhea during intestinal viral infection include microischemia of villi,[17] impaired polar transport of sucrase-isomaltase and other apical proteins to the correct membrane surface,[56] cytokine genera-

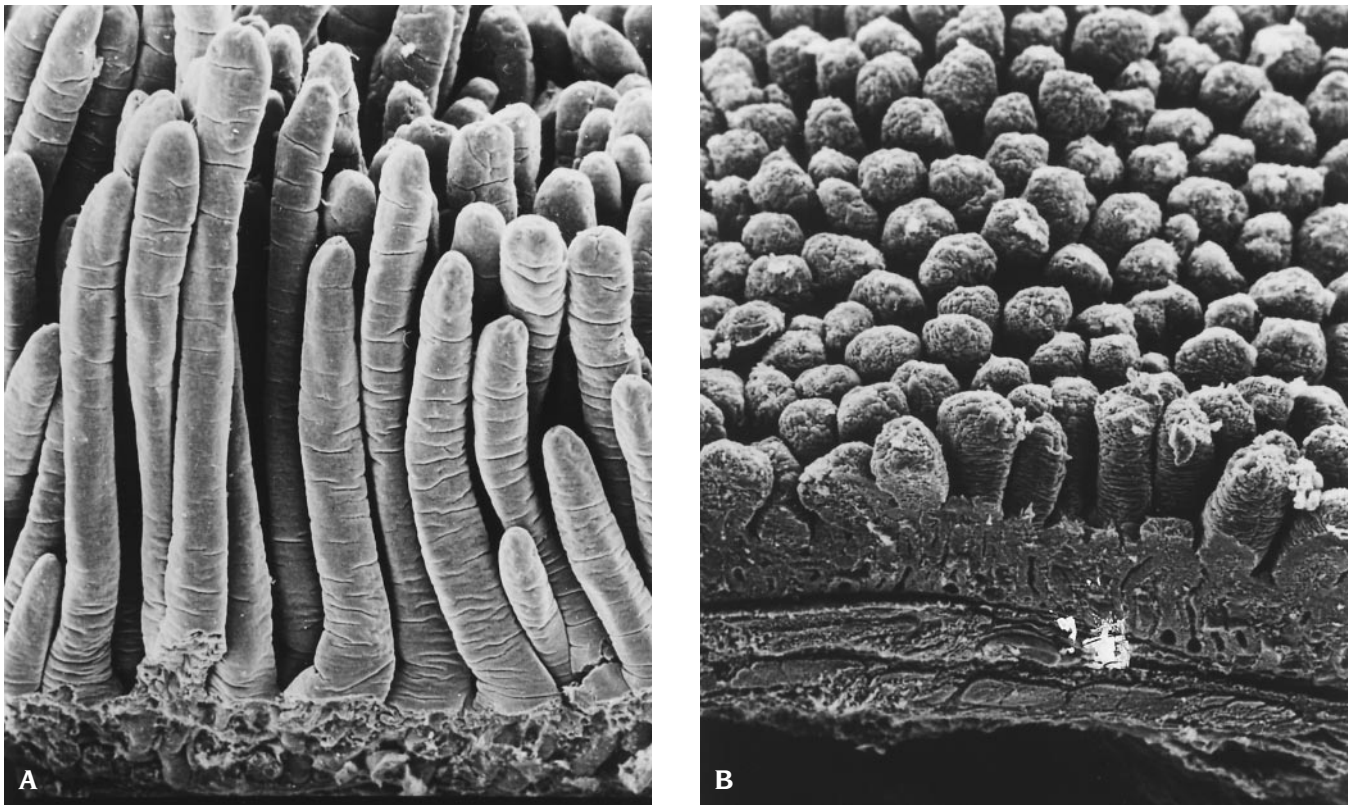

FIGURE 38.3-4 Scanning electron microscopic appearance of normal and rotavirus-infected calf jejunum. *A*, Jejunum from a normal, conventionally reared calf showing tall, fingerlike villi. *B*, rotavirus-damaged intestine from a moribound calf. rotavirus antigen was detected by immunoperoxidase staining of paraffin sections from adjacent tissue. Most of the epithelial cells on the surface of the stunted villi contained antigen. Hall, Institute for Animal Health, Compton, UK.

tion by the epithelium or underlying mononuclear cells,[57] and neuronally mediated intestinal hypersecretion.[16] It is noteworthy that none of these proposed pathophysiologic mechanisms are mutually exclusive, and the etiology of rotavirus diarrhea may well be multifactorial. Discernment of the relative contribution to disease of these mechanisms may be important in devising treatment strategies.

Clinical Features. In severe cases, after an incubation period of 2 to 7 days, there is an abrupt onset of vomiting and fever.[58] Profuse watery diarrhea soon follows, leading to dehydration, acidosis, and electrolyte imbalance. In contrast to bacterial enterocolitis, the stool fluid does not contain blood, white cells, or mucus. Abdominal cramps are less frequent, but irritability and lethargy are often present. Respiratory symptoms have been reported in 20 to 40% of patients, but in several studies, an equally high incidence has been found in controls. The temperature falls to normal quickly. Usually, vomiting settles within 24 to 48 hours and diarrhea in 2 to 7 days.

Acute complications include hypernatremia or hyponatremia when water and electrolyte losses are discrepant. Febrile convulsions can occur as with any other cause of sudden high fever. Reye syndrome, encephalitis, rectal bleeding, afebrile seizures, and intussusception have been described in association with rotavirus infection, but the evidence linking them as cause and effect is tenuous. Case reports of PCR detection of the rotavirus genome in cerebrospinal fluid are noteworthy, but their significance is not clear.[59] Raised aminoaspartate transferase levels are common in severe disease.[60] Depressed mucosal lactase activity is frequent,[61] but persistent lactose malabsorption is not common because disaccharidase activities return to normal within a few days.

Treatment. Initial management is directed at correcting dehydration, acidosis, and electrolyte imbalance. The assessment of the degree of dehydration and treatment with oral or intravenous fluids are considered elsewhere (see Chapter 75.1, "Fluid and Dietary Therapy of Diarrhea"). Early resumption of normal feeding is encouraged, especially in undernourished children, with particular emphasis on breastfeeding. Breastfeeding can almost always be continued, even in children with lactose malabsorption. However, in very small infants, lactose malabsorption can be a serious problem, requiring lactose-free feeding for days or even weeks. These cases, although rare, should not be overlooked in the appropriate enthusiasm for continued breastfeeding.

For the breastfed infant with severe diarrhea, a combination of oral rehydration solution and increasing volumes of breast milk can be offered. In older children, early introduction of a balanced diet should be encouraged, capitalizing on the fact that temporary mucosal damage leaves a much larger reserve of maltase and isomaltase than lactase. Small amounts of fruit juices can be given, but large volumes of sucrose-containing fluids should be avoided in the acute phase.

Drugs are contraindicated. Antibiotics have no place in viral diarrhea. Antiperistaltic agents may lead to pooling of fluid, which is effectively removed from the circulation and yet not revealed to the observer. Complications include ileus and respiratory depression.[62] Antiemetics should be avoided. Vomiting is usually self-limiting, and dystonic reactions to these drugs may occur. Probiotics, such as *Lactobacillus* GG, have been reported to decrease the duration of diarrhea in relatively mild disease[63] but were not of benefit in severe disease.[64]

Prevention. Improved sanitation and hygiene are unlikely to radically alter the incidence of rotavirus diarrhea in developing countries. Such measures have proved unsuccessful in North America and Europe, where the attack rates are similar to those in less developed parts of the world. In pediatric wards, hand washing and isolation procedures may limit nosocomial outbreaks.

Breastfeeding reduces the incidence of diarrheal diseases overall in the first year of life.[65] This is especially true for nonviral pathogens but is not consistent for rotavirus infection.[66] The period immediately after weaning is associated with higher risk of diarrhea in general[67] and rotavirus diarrhea in particular.[29] Breastfeeding may thus delay rotavirus infection rather than prevent it. However, if infants are older when they contract the illness, they are likely to tolerate it better, and the many other benefits of breastfeeding will not be lost.

Passive prophylaxis has been tried in special situations. Human gammaglobulin, given by mouth to newborn premature infants, delays onset of viral excretion and decreases the severity of rotavirus disease.[37] Additions of bovine milk rotavirus antibody to formula given to infants protected them against symptomatic infection[68] and have been reported to hasten recovery.[69]

Vaccine Development. Because of the high morbidity and mortality of rotavirus infection in pediatric populations throughout the world, vaccine development has been a major priority. The initial vaccine prototypes have been based on animal rotavirus strains that are not virulent in humans. This approach has been termed "Jennerian" after Edward Jenner, who used cowpox to immunize against smallpox in the late eighteenth century.[70] Both simian and bovine strains were employed in early trials, which were promising but failed to provide sufficient protection from rotavirus disease. A second generation of vaccines included reassortant viruses, which contained the RNA segment that encodes the viral glycoprotein for each of the four epidemiologically significant human rotavirus G types inserted in a background of the genome of an avirulent simian rotavirus.[71] A tetravalent rotavirus vaccine, Rotashield, based on such simian/human reassortant viruses, was shown in major trials to provide 80 to 100% protection against dehydrating rotavirus diarrhea.[72] In 1998, the Advisory Committee on Immunization Practices endorsed the vaccine and the US Food and Drug Administration granted a license to Wyeth-Ayerst Pharmaceuticals (Philadelphia, PA) to produce it. Subsequently, the American Academy of Pediatrics included, for the first time in its recommended childhood immunization schedule, three doses of oral rotavirus vaccine to be given at 2, 4, and

6 months of age. Nine months later, after the administration of approximately 1.5 million doses of Rotashield, the Centers for Disease Control and Prevention (CDC) reported 15 cases of intussusception in infants who had received the vaccine.[73] Eleven of the intussusceptions occurred within 1 week of the first vaccine dose. Therefore, the CDC recommended suspending further vaccination while further investigation was carried out.[74] Subsequent case-control and case-series investigations confirmed the temporal association, and the manufacturer removed the vaccine from the market.[75] Despite widespread vaccination in some states, no significant increase in intussusception was detected in ecologic studies.[76] The most recent consensus of the increased attributable risk for intussusception for infants receiving Rotashield vaccine was on the order of 1 in 10,000.[72] As shown in Table 38.3-2, immunization of the entire cohort of US infants would have resulted in a net reduction of approximately 50,000 rotavirus hospitalizations and 15 to 30 deaths in young children in the United States.

Other rotavirus live attenuated vaccine candidates are currently under development, including a multivalent bovine-human reassortant vaccine that is similar in concept to Rotashield and an attenuated human rotavirus. Eventually, other strategies may be employed, such as noninfectious virus-like particles, which can be produced using recombinant technology, parenteral inactivated virus vaccines, or DNA vaccines.

Astrovirus

Epidemiology. Astroviruses were first observed in 1975 by Madley and Cosgrove using negative-stain electron microscopy to examine stools obtained from children with acute enteritis.[77] Astroviruses were distinguished by their size (28–34 nm) and morphology containing five- or six-pointed stars. Because the only method of detection was electron microscopy and because the star-like morphology was variably observed, the true significance of this agent of enteritis was grossly underestimated until the development of EIAs and reverse transcriptase (RT)-PCR assays. Astroviruses are now known to be an important cause of infantile enteritis, second or third only to rotavirus in several studies.[78–81]

Astrovirus infection accounts for 7 to 15% of infantile diarrhea in a variety of settings. Most symptomatic infections occur in infants less than 1 year of age, with a peak incidence in winter months in temperate climates. Transmission appears to be fecal-oral. Astrovirus is an important agent of diarrhea in the developing world,[78–80, 82] in nosocomial outbreaks,[81,83] and in day-care–related diarrhea.[3] Asymptomatic infection appears to be common, particularly in day-care and hospital settings. Such asymptomatic infections are important in maintaining and amplifying outbreaks. Most children have developed antibody against astrovirus by age 5 years. Astrovirus has also been reported as an important cause of diarrhea in immunocompromised hosts such as acquired immune deficiency syndrome (AIDS)[81,84] and bone marrow transplant patients.[85] Less common serotypes of astrovirus have been reported as responsible for outbreaks of enteritis among immunocompetent military personnel[86] and nursing home residents.[87,88] Astroviruses also infect a variety of animals. To date, it appears that strains are species specific, so that animal viruses are not commonly transmitted to humans.

Virology. Astroviruses have a unique genome organization, resulting in these viruses being assigned to their own viral family, Astroviridae. Particles consist of small (28–34 nm) nonenveloped capsids that consist of two to three proteins of 20 to 34 kD mass. The genome is positive-sense, single-stranded RNA containing three open reading frames that encode a viral protease, a 90 kD capsid precursor protein, and an RNA polymerase. Infected cells contain considerable amounts of subgenomic RNA that encodes the capsid precursor. Mammalian astroviruses grow efficiently only in tissue culture in the presence of exogenous trypsin. Eight human serotypes have been identified, with serotype 1 being the most common. It is not known whether infection with one serotype confers protection against subsequent infection with other serotypes.

Pathogenesis. Knowledge of pathogenesis in humans is limited to a single observation by electron microscopy of astrovirus particles in the epithelium of a child with enteritis. Studies in lambs have shown infection of villus tip epithelial cells, with subsequent shortening of the villi, and crypt hypertrophy.[89] Studies in calves with bovine astrovirus have shown preferential infection of M cells overlying Peyers patches.[90] In calves, astrovirus appeared to be pathogenic only as a coinfection with either Breda virus or bovine rotavirus.

Clinical Features. Astrovirus infection is associated with a moderate enteritis syndrome that is usually milder than primary rotavirus disease. The incubation period is between 1

TABLE 38.3-2 PROJECTED RESULTS OF UNIVERSAL USE OF ROTASHIELD IN THE UNITED STATES

EVENTS	UNIVERSAL ROTASHIELD	NO ROTAVIRUS VACCINE
Hospitalization: rotavirus dehydration	2,750	55,000
Hospitalization: intussusception (excess)	320	0
Death: (secondary to rotavirus dehydration)	2	20–40
Death: intussusception* (excess)	4	0

Adapted from Kapikian AZ[72] and *Annals of Pharmotherapy*.[73]
Assume birth cohort of 4 million, 95% efficacy of vaccine against very severe disease, excess intussusception at 1 in 12,000 vaccinees.

and 4 days, probably depending on the size of the inoculum. The illness is characterized initially by low-grade fever and vomiting, followed by 3 to 4 days of watery diarrhea without blood or white blood cells. Immunocompromised hosts may experience more severe and prolonged illness. Similarly, coinfection (which is common) with rotavirus or other enteric pathogens may lead to particularly severe symptoms. Adult volunteers have very mild or no symptoms after inoculation with astrovirus.[91] Adults almost uniformly possess serum antibodies against astrovirus and astrovirus-specific T helper cells in their small intestine.[92]

Astrovirus infection can be diagnosed by electron microscopy, EIA, or RT-PCR assay. A commercial monoclonal antibody–based diagnostic EIA kit is available in Europe but is not currently approved for use in the United States.

Treatment and Prevention. As with other viral enteritides, there is no specific treatment for astrovirus. Attention should be directed toward maintaining hydration and nutritional status. A single case report describes successful administration of intravenous immunoglobulin to an immunocompromised adult with severe astrovirus disease.[93] There are currently no active vaccine development programs.

Human Caliciviruses (Noroviruses and Sapoviruses)

Norwalk virus was observed by electron microscopy in stools from a severe outbreak of enteritis in Norwalk, Ohio, in 1972.[94] This was the first direct confirmation of a viral etiology for human enteritis. Subsequent volunteer studies proved its pathogenicity. Other morphologically similar viruses were observed and named for their outbreak sites (Montgomery County, Hawaii, Snow Mountain, Sapporo, Toronto), and these viruses were often called "Norwalk-like viruses" or small round structured viruses.

Recently, these human viruses, which cause enteritis, have been reclassified as members of a distinct genus called *Norovirus* in the Caliciviridae family. None of these agents has been adapted to tissue culture, but the genomes of several, incuding the prototypic Norwalk virus, have been completely sequenced and characterized.[95]

Other human caliciviruses are classified in a separate genus called *Sapovirus*. These viruses exhibit typical calicivirus structure when observed by electron microscopy, cause disease primarily in young children, and have a slightly different genome organization when compared with the noroviruses.

Epidemiology. Knowledge of the full extent of norovirus epidemiology remains limited because the only available diagnostic tests until quite recently were electron microscopy and immunoelectron microscopy. These methods are not sufficiently sensitive to detect the low number of virus particles found in most diarrhea samples. Norovirus enteritis is best known for explosive outbreaks of disease that affect both children and adults. Such outbreaks frequently occur in closed or semiclosed settings, such as schools, camps, and cruise ships. The CDC has shown that more than 95% of such outbreaks, which are not caused by conventional bacterial or parasitic pathogens, are caused by noroviruses.[96] Transmission in these outbreaks has been linked to a variety of foodstuffs, including shellfish, cake icing, and lettuce (washed with contaminated water). Outbreaks are distinguished from those caused by preformed toxins by the appearance of secondary cases in household contacts and the slightly longer incubation period (12–24 hours versus 2–6 hours for toxins). Vomitus has been shown to contain infectious virus and can rapidly amplify outbreaks. Noroviruses are also common nosocomial pathogens in children.[97] In addition, noroviruses are emerging as important causes of endemic childhood enteritis. Like rotavirus, there appears to be an increase in the incidence of norovirus disease in winter months in temperate climates. Sapoviruses cause disease in young children but are generally less severe than norovirus- and rotavirus-induced disease.[9]

Virology. Caliciviruses are small, 28 to 34 nm, nonenveloped, positive-sense RNA viruses. Human caliciviruses are classified into several distinct genogroups within each genus and viruses in each genogroup that are genetically and serologically distinct. Despite this, there are some common epitopes among viruses in genogroups 1 and 2 of the noroviruses, and an EIA based on cross-reactive monoclonal antibodies has been developed and is commercially available in Europe.[98] The RNA genome contains three open reading frames that encode a polyprotein that makes a nucleotide triphosphatase, viral proteinase, RNA polymerase, the capsid protein, and a small basic protein that is found in virions. The capsid consists of 180 molecules of a single major protein and a few molecules of a minor protein. When the capsid protein is expressed in a recombinant baculovirus system, it spontaneously assembles into virus-like particles, which have been used to create diagnostic reagents and candidate vaccines (Figure 38.3-5). The most common means of diagnosis of infections is by RT-PCR using primers, but this is not straightforward because several sets of primers or probes must be used to confirm infection. The EIA for noroviruses currently available in Europe is being evaluated for use in the United States, and other EIAs are being developed.

Pathophysiology. Human volunteer studies demonstrate villus shortening and crypt hypertrophy in the proximal duodenum associated with villus tip vacuolization and infiltration of the lamina propria with inflammatory cells.[99] Intestinal sucrase, alkaline phosphatase, and trehalase are diminished with demonstrable mild carbohydrate intolerance.[100] Mild steatorrhea is also noted. Gastric and colonic mucosa are completely normal. Delayed gastric emptying has been formally demonstrated in symptomatic volunteers and may account for the pronounced nausea and vomiting associated with this infection.[101] Animal studies show similar histologic features. Several recent studies have suggested that specific blood group determinants may confer susceptibility or resistance to specific noroviruses.[102,103]

Clinical Features. The most striking characteristics of calicivirus infections are the rapid onset of symptoms, rapid spread of disease through groups, predominance of vomiting as a symptom, and the high attack rate across all age groups. Generally, the illness is mild and self-limited to 12 to 24 hours after a 1- to 2-day incubation. Attack rates are usually about 50% of exposed populations.[104] Asymptomatic infections are common. Recent studies have shown that virus is excreted for much longer times than previously recognized.[105,106] This asymptomatic shedding of virus likely contributes to virus transmission. Infantile norovirus enteritis is clinically similar to rotavirus enteritis, although it results in less severe dehydration.

Treatment and Prevention. No specific treatment is available. There is evidence that protective short-term immunity to the same serotype of calicivirus develops after infection. However, this immune protection wanes fairly rapidly. Because of the economic and military liability associated with large outbreaks, there is considerable interest in finding methods of prevention. A virus-like particle vaccine is being evaluated.

Enteric Adenovirus

Adenoviruses are ubiquitous human pathogens and cause a variety of syndromes, ranging from respiratory infections to hepatitis. Only 2 of more than 50 serotypes, types 40 and 41, are clearly associated with human enteritis, although a variety of serotypes may be found in stool samples. Adenovirus enteritis tends to last longer (up to 2 weeks) than disease caused by other enteritis viruses.

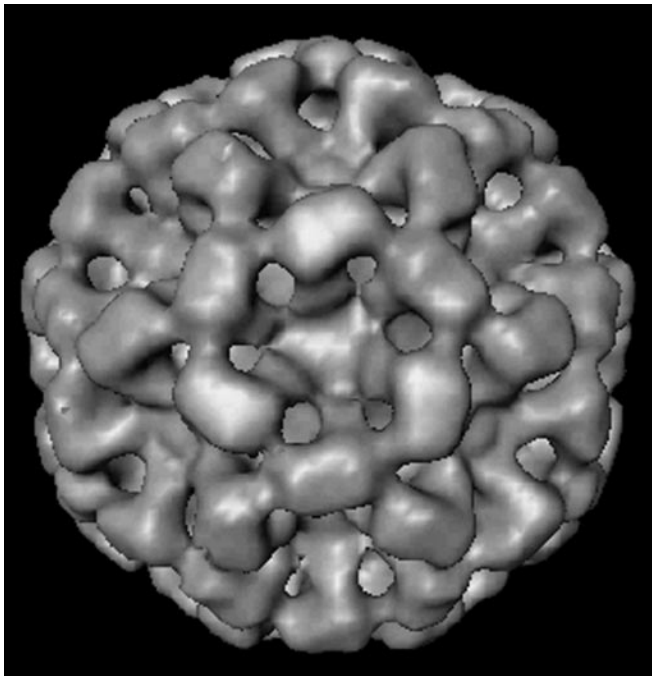

FIGURE 38.3-5 Three-dimensional structure of recombinant Norwalk virus–like particles generated by expression of the capsid protein in insect cells. Images were prepared by cryoelectron microscopy, followed by image processing (uranyl acetate and lead stain; ×1,000,000 original magnification). Courtesy of B. V. V. Prasad, Baylor College of Medicine.

Epidemiology. Like all of the agents of viral enteritis, enteric adenoviruses have a worldwide distribution. Most symptomatic infections occur in children less than 2 years of age. Unlike rotavirus and astrovirus, there does not seem to be a winter peak in the incidence of adenovirus enteritis. In longitudinal studies, there is considerable year-to-year variation in the extent of adenovirus diarrheal disease in a given geographic area.[107] Adenovirus infections generally account for 3 to 5% of acute pediatric enteritis. Like the other agents of viral enteritis, enteric adenoviruses commonly cause asymptomatic infections, especially in day-care centers.[108] Seroconversion studies suggest that enteric adenovirus infection is not as common as rotavirus infection during early childhood. Fecal shedding of adenovirus of various serotypes is common in AIDS patients but is not clearly associated with disease manifestations.[109–112] Despite the fact that up to 10^{11} virions/g stool have been reported in patients with enteric adenovirus enteritis, there are fewer reports of explosive diarrhea outbreaks from enteric adenovirus than from rotavirus, calicivirus, or astrovirus.[112]

Virology. Adenoviruses are 80 nm nonenveloped particles containing a double-stranded DNA genome. Enteric adenoviruses are more fastidious in tissue culture than the other adenovirus serotypes but can be grown on selected cell lines, such as CaCo-2 cells. Diagnosis can be made by commercially available EIAs.[113]

Pathophysiology. Adenoviruses replicate in host nuclei, and intranuclear inclusions are observed in enterocyte nuclei in patients with diarrhea. There are no systematic studies of the pathophysiology of these infections in humans or animals.

Treatment and Prevention. There is no known specific treatment, although the use of ribavirin in immunocompromised patients has been reported.[114] No major efforts are under way to develop a vaccine.

Other Related Pathogens and Infections

Cytomegalovirus. In the modern era of both acquired and iatrogenic immunodeficiency states, CMV has emerged with increasing frequency as an enteric pathogen. Several clinical syndromes have been described, including a protein-losing gastropathy,[115] deep ulcers, which may occur anywhere in the gastrointestinal tract, and an enterocolitis endoscopically similar to Crohn disease. Most cases occur in immunocompromised or very young patients.[116,117] Diagnosis is made by finding characteristic nuclear inclusions in mucosal biopsies or by culture of such material. Yield is much higher from the center of ulcer craters. Treatment consists of restoration of immunologic function, if possible, and the administration of ganciclovir. Selected cases may also benefit from CMV immunoglobulin.

Epstein-Barr Virus. In immunosuppressed, solid organ transplant patients, infection with EBV may trigger an immunoproliferative syndrome, which may present with fever and diarrhea. Endoscopic evaluation shows nodular or ulcerated lesions in the bowel that may contain many cells with EBV genome demonstrable by in situ hybridization. Treatment consists mainly of withdrawal of immunosuppression and the use of ganciclovir.

Small Round Viruses. Small round viruses are morphologically characterized particles observed by electron microscopy in diarrheal stools. Almost all of the previously described small round viruses and "minireoviruses" are now known to be caliciviruses and astroviruses. Parvoviruses and picobirnaviruses also share this morphology. It is likely that some small round viruses represent uncharacterized, novel viral agents of diarrhea or bacterial phages.

Aichi Virus. An example of a newly described small round enteritis virus is the Aichi virus. This virus was isolated in cultured cells from individuals who had enteritis associated with eating oysters.[118] Aichi virus has since been detected in Pakistani children with acute enteritis children and Japanese travelers from Southeast Asia.[119] The virus contains a single-stranded RNA genome and is a new member of the Picornaviridae family.[120] RT-PCR assays have been developed to detect the viral genome.[121]

Picobirnavirus. These are small (35 nm) double-stranded RNA viruses with a two-segment genome. They have been associated with animal diarrhea and have been found on occasion in humans with HIV infection.[122,123] Diagnosis can be made by visualizing two distinct bands of genomic RNA on electrophorectic gels of RNA extracted from stool samples.

Parvovirus. This is a small round virus containing single-stranded DNA that causes severe diarrhea in young animals. Human diarrheal disease has not been established.

Torovirus. Large (100–150 nm) pleomorphic, enveloped, single-stranded RNA viruses have been associated with diarrhea in livestock. Several reports suggest that they may be pathogenic in young children.[124–126]

Coronavirus. Large enveloped single-stranded RNA viruses related to toroviruses, coronaviruses cause severe enteritis in several species of animals and are common respiratory pathogens in humans. The pleomorphic particles have been observed in stools from infants with enteritis and from patients with tropical sprue, but their true role in human disease remains uncertain.

Measles. In the developing world, severe measles infection is often accompanied by severe diarrhea. The pathophysiology of measles enteritis is not well understood, although viral-mediated intestinal inflammation has been described.[127] The incidence of measles-associated diarrhea has been greatly reduced with use of the measles vaccine.

Human Immunodeficiency Virus. Even in the absence of identifiable pathogens, AIDS patients frequently develop diarrhea that is likely related to HIV infection of the intestinal mucosa. Pathology in such cases shows apoptosis and disproportionate CD4+ T-cell depletion as well as demonstrable viral nucleic acid in tissue mononuclear cells.[128] The diarrhea usually responds to appropriate multiagent antiretroviral therapy.[112,128,129]

4. *Parasitic and Fungal Infections*

Michael J. G. Farthing, DSc(Med), MD, FRCP, FMedSci

Parasitic infections of the gastrointestinal (GI) tract occur in all geographic regions of the world and produce a substantial morbidity in children. Recent evidence confirms that there is increased mortality in children with some parasitic infections such as that due to *Cryptosporidium parvum*, especially when infection is associated with undernutrition and other comorbidities. Prevalence is highest in the economically deprived regions of the world, notably in the tropics. Infants and young children are particularly susceptible to *Giardia lamblia*, *C. parvum*, *Ascaris lumbricoides*, and *Trichuris trichiura*. In addition to producing GI symptoms, these parasites may impair growth and development.

There has been controversy regarding the clinical relevance of many of these common intestinal parasitic infections, which often appear to coexist with their hosts without causing significant clinical problems. However, recent studies confirm the importance of many of these infections, particularly in immunocompromised children with severe undernutrition or human immunodeficiency virus (HIV) infection.

Diagnostic tests for many GI parasites continue to be limited, usually relying on microscopic techniques and a skilled observer. Similarly, the development of new drugs for the control of these infections has been slower than that for other infectious diseases because drug development programs tend to focus on the needs of the more profitable industrialized world.

These common infections can have a major impact on child health and, therefore, need to be considered as one of the objectives of any diarrhea control and nutritional intervention program. Several GI parasites (*G. lamblia*, *C. parvum*) have become common in industrialized parts of the world, partly owing to increased foreign travel and immigration.

PARASITES OF THE STOMACH: ANISAKIS ANISAKIS

Anisakis is a nematode parasite that is transmitted to humans by the ingestion of uncooked fish. It is found most commonly in Japan, Holland, Scandinavia, and the Pacific coast of South America.[1–3]

Following the ingestion of contaminated food, there is usually an acute upper GI illness with epigastric pain, nausea, and vomiting. Symptoms are produced through the direct attachment of larvae to the gastric mucosa, where they cause ulceration and, occasionally, perforation.

Larvae attaching to the gastric mucosa can be identified at endoscopy and can be removed by biopsy or by grasping forceps. It is suggested that endoscopy should be performed early in suspected anisakiasis because this is the mainstay of therapy.

PARASITES OF THE SMALL INTESTINE

A variety of protozoa and helminths may infect the small intestine (Table 38.4-1); some can simultaneously colonize the large intestine as well, notably *Crypotosporidium* species and *Strongyloides stercoralis*, the latter as part of the hyperinfection syndrome.

PROTOZOA

Giardia lamblia. This flagellate protozoan exists as a motile trophozoite and as a cyst, the latter being the infective form of the parasite. The trophozoite has a smooth

†Parasites that can cause diarrhea and malabsorption.

dorsal surface and a convex ventral surface occupied by the ventral disk (Figure 38.4-1). This disk consists of contractile proteins that are thought to mediate the attachment of the parasite to the intestinal epithelium. The surface membrane of *Giardia* contains a lectin that is activated by trypsin and is thought to participate in the attachment to intestinal epithelial cells.

The chemotaxonomy of *G. lamblia* has been reported using a variety of techniques, including antigen, isoenzyme, and deoxyribonucleic acid (DNA) analyses.[4–6] These approaches have confirmed that *G. lamblia* isolates differ from one another, although the sensitivity of the techniques varies. Molecular genetic approaches show that *G. lamblia* isolated from humans can be divided into two major genotypes, types I and II.[7] Some animal isolates have been shown to possess the same genotypes, thereby providing evidence that giardiasis can be a zoonosis.

Epidemiology. *Giardia* is found in most countries of the world, its prevalence being highest in the developing world, where rates can approach 30%,[4,8] particularly in young children. Age-specific prevalence rates increase throughout infancy and childhood but approach adult levels only during adolescence.[4] *G. lamblia* is transmitted by food, water, and direct person-to-person contact. There is now compelling evidence to suggest that giardiasis is a zoonotic infection.[8,9]

The precise mechanisms by which *Giardia* causes diarrhea and malabsorption have not been determined.[5,9] Jejunal morphology may be normal, although partial atrophy and even total villous atrophy are reported.[10,11] The presence of a mucosal inflammatory response, with an early increase in intraepithelial lymphocytes,[12,13] suggests that mucosal damage may be immunologically mediated. Nude mice with T-cell deficiency fail to develop significant alterations in villous architecture during experimental infection, supporting the view that activated T cells are responsible for the mucosal abnormality.[9] Steatorrhea, however, can occur in the absence of significant histopathologic abnormality, suggesting that other factors, such as bacterial overgrowth, bile salt uptake by the parasite, and inhibition of pancreatic lipase, may be additional pathogenic mechanisms.[5,9] Evidence indicates that different *Giardia* isolates vary in virulence in experimental models of infection.[14] This relates specifically to the ability of different isolates to affect water and electrolyte absorption and to alter the expression of disaccharidases in the microvillous membrane.

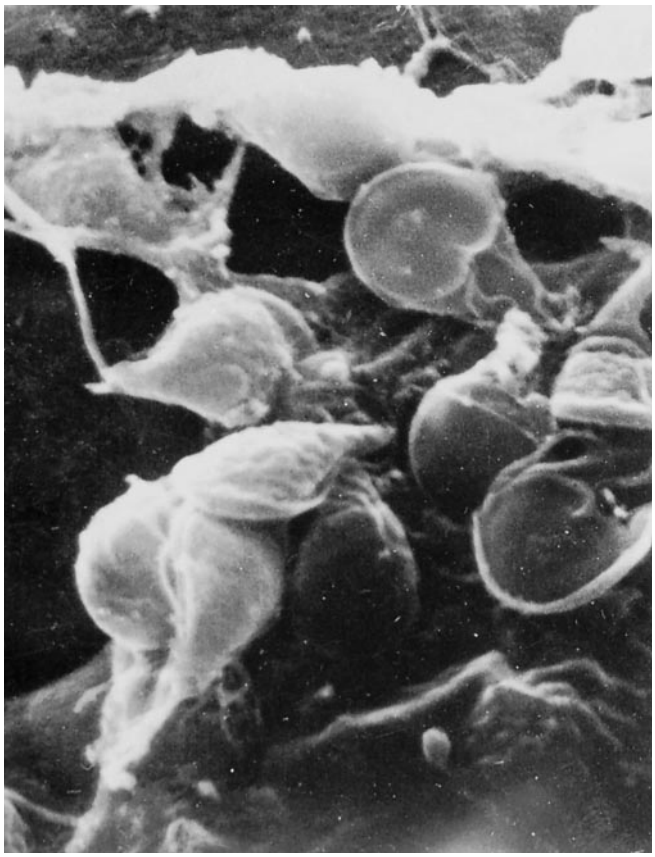

FIGURE 38.4-1 Scanning electron micrograph of *Giardia lamblia* trophozoites in mucus on human jejunal mucosa.

Clinical Aspects. Adults and older children commonly harbor *Giardia* without symptoms, but infection early in life is usually symptomatic. Acute infection often begins with watery diarrhea that persists and is associated with anorexia and abdominal distention. Untreated chronic diarrhea with steatorrhea ensues, and growth may be impaired.[15] Chronic giardiasis is associated with immunoglobulin (Ig) deficiency,[16] which may be accompanied by diffuse nodular lymphoid hyperplasia involving the small and sometimes the large intestine.[17]

Diagnosis. Identification of *Giardia* forms by microscopy of feces, duodenal fluid, or mucosal biopsy specimen remains the "gold standard" for diagnosis.[9] However, even after examination of multiple stool specimens, only 80% of positive individuals will be detected. The measurement of specific anti-*Giardia* IgG antibody has not been helpful, but there is an early IgM response in acute giardiasis that can distinguish current from past infection. Sensitive and specific IgG-based immunoassays have been developed, and some of these assays are now marketed commercially.[18,19] Sensitivity and specificity are reported to be between 87% and 100%.[20,21] However, further studies are awaited to determine if their use can be recommended in the routine diagnostic laboratory setting.[22,23]

Treatment. The drugs of choice are nitroimidazole derivatives, namely metronidazole (30 mg/kg as a single dose on 3 consecutive days) or tinidazole (30 mg/kg as a single dose).[8] Alternatives include mepacrine (2 mg/kg 3 times daily for 7 days) and furazolidone (1.25 mg/kg 4 times daily for 7 days). Recent trials indicate that the antihelminthic drug albendazole is also effective in giardiasis (400 mg once daily for 5 to 7 days). Adverse effects with nitroimidazole derivatives include anorexia, nausea, vomiting, and peripheral neuropathy. In addition to GI side effects, mepacrine causes yellowing of the skin, sclerae, and blood dyscrasias.

***Cryptosporidium* Species.** This coccidian takes up an intracellular but extracytoplasmic location in host intestinal epithelial cells. Although recognized by veterinarians as an important cause of diarrhea in animals, the first human infection with *Cryptosporidium* was discovered in a

3-year-old immunocompetent child in 1976.[24] Subsequently, the majority of reported cases have occurred in immunocompromised individuals, particularly those with HIV infection.[25] The parasite can be found in both the small bowel and large intestine and reproduces both sexually and asexually. Its ability to complete its life cycle within the human host is probably a major factor in persistent infection.[26,27]

Epidemiology. *C. parvum* is found throughout the developed and developing world, with prevalence rates of 10% or more in the latter. As with *Giardia*, asymptomatic carriage is well recognized. Infection is spread by water and by direct person-to-person transmission.[27]

The mechanism by which this parasite produces acute watery diarrhea is unknown, although various morphologic abnormalities have been described, including disruption of the microvillous membrane (Figure 38.4-2) and a spectrum of morphologic abnormalities from partial to subtotal villous atrophy.[28] Although specific virulence factors have not been identified, the organism does possess an *N*-acetylgalactose–binding lectin thought to be involved in the mediation of adherence to the epithelial cells. In addition, a parasite phospholipase has been identified that appears to have a role in parasite invasion in in vitro models.[29] Studies in experimental models indicate that impairment of water and sodium absorption is mediated, at least in part, by local production of prostaglandins in the intestinal mucosa. Intestinal perfusion studies in HIV-infected humans with cryptosporidiosis, however, fail to demonstrate any abnormality of water and electrolyte absorption in the jejunum.

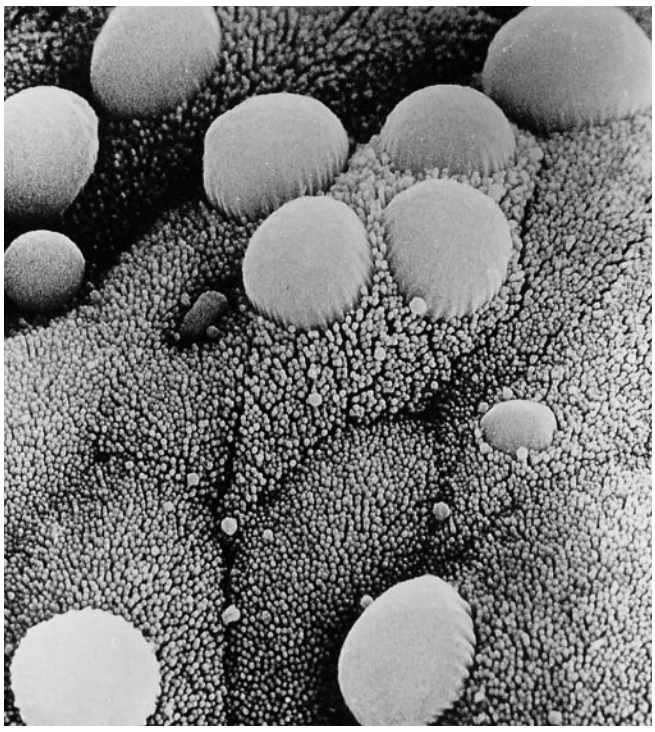

FIGURE 38.4-2 Scanning electron micrograph of *Cryptosporidium* species. Courtesy of Patricia Bland and David Burden, ARFC Institute for Animal Disease Research, Compton.

Molecular genetic typing techniques clearly identify two different strains of *C. parvum*: one that appears to infect animals (particularly cattle) exclusively and another that can infect both humans and animals. The ability to detect differences between animal and human isolates has been helpful in understanding the sources of human waterborne epidemics originating from domestic water supplies.

Clinical Features. Acute infection in an immunocompetent individual usually has an incubation period of 1 to 7 days, followed by fever, abdominal discomfort, nausea, vomiting, and high-volume watery diarrhea. The illness may resolve within 2 days or continue for 2 to 3 weeks.[26] Dehydration occurs in children, and the illness tends to be more severe in the malnourished. Work from West Africa indicates that cryptosporidiosis is an important risk factor for poor survival in infants and young children and is associated with a 3.5-fold increased risk of death. Isaacs and colleagues found that 7 of 213 children (3.2%) with chronic diarrhea in the United Kingdom had cryptosporidiosis.[30] Two had symptoms for more than 4 months, with failure to thrive. Asymptomatic carriage is reported in children, particularly those in the developing world. Symptoms tend to be more severe and prolonged in the immunocompromised host and may contribute to the terminal illness of patients with acquired immune deficiency syndrome (AIDS).[25]

Diagnosis. Oocysts can be detected in feces, duodenal fluid, and, occasionally, sputum with a variety of stains, including trichrome, modified acid fast, and auramine.[31] Cyst concentration techniques may be required. Diagnostic precision can be increased by exposing cyst preparations to fluorescent-labeled monoclonal antibody directed toward cyst antigens. Serum antibody responses occur in cryptosporidiosis, but serology has not found a place in routine laboratory diagnosis.[32]

Treatment. Macrolide antibiotics such as erythromycin, spiramycin, and clindamycin fail to eradicate the parasite but reduce parasite numbers and, transiently, stool volume.[33] Paromomycin and diclazuril also reduce parasite load, but neither is able to achieve eradication. A broad-spectrum antihelminthic drug, nitazoxanide, appears to have activity against *C. parvum* in vitro, and preliminary clinical studies suggest that it may be able to eradicate the parasite.[34] Further controlled studies are required before this drug can be widely recommended.

In patients with HIV infection, azidothymidine is reported to reduce stool volume and eradicate the parasite.[35] Recent experience with highly active antiretroviral therapy (HAART) has had a major impact on the prevalence and severity of opportunistic infections such that cryptosporidiosis is now rarely seen in HIV-infected patients treated with this regimen. Although HAART may not completely eradicate infection, it reduces parasite numbers to such low levels that they no longer produce clinically relevant disease. However, infection may recur if HAART is discontinued and CD4 counts decrease. Hyperimmune bovine colostrum induced a remission in a 3-year-old child with hypogammaglobulinemia and cryptosporidiosis but has not found a place in routine therapy.[36] Treatment is otherwise

supportive, with oral glucose electrolyte solutions for dehydration. In the past, before HAART, immunocompromised individuals required parenteral fluids and total parenteral nutrition. Antidiarrheal medications, such as opiates (morphine) and opioids (loperamide), or the somatostatin analogue octreotide also may prove useful in those patients who are intolerant or who fail to respond to HAART.

Microsporidia Species. In many respects, species of *Microsporidia* resemble *Cryptosporidium*, both in life cycle and in clinical features. Two parasites, *Enterocytozoon bieneusi* and *Encephalitozoon intestinalis* (formerly *Septata intestinalis*) are now known to infect humans. The clinical importance of these organisms is recognized in immunocompromised patients, particularly those with AIDS-related diarrhea.[37–40]

Epidemiology. Microsporidia species constitute their own phylum within the protozoa and are obligate intracellular spore-forming organisms with a wide range of hosts. Infection is acquired via the spore, which, following ingestion, extrudes a polar tube through which the sporoplasm is passed into the enterocyte. The organism then multiplies within the infected cell by binary fission, taking up an intracytoplasmic location surrounded by a simple membrane (parasitophorous vacuole). In industrialized countries, *Microsporidium* species appear to be emerging as the dominant coccidial parasite in AIDS and have recently been described in African patients.[40]

The pathogenesis of infection is poorly understood, largely because of the difficulties of establishing in vitro cultures of these organisms and the limited availability of animal models representative of intestinal disease. In humans, infection appears to be confined to the small intestine and is generally associated with varying degrees of villous atrophy.[39]

Clinical Features. Clinically, infection with *E. bieneusi* resembles cryptosporidiosis, with chronic watery diarrhea, anorexia, nausea, and abdominal pain. This organism has also been associated with sclerosing cholangitis in patients with HIV infection. *E. intestinalis* also causes diarrhea, but dissemination can also occur, particularly into the kidneys, with shedding of spores in the urine. *E. intestinalis* can be distinguished from *E. bieneusi* by its development within a septate parasitophorous vacuole.

Diagnosis. The diagnosis of these infections is made by detection of spores in stool with a chromotrope stain or the fluorescent stain calcafluor. Experienced parasitologists are able to distinguish these different *Microsporidium* species using light microscopy, although this differentiation is more reliably done by electron microscopy of small intestinal biopsy specimens. Giemsa-stained small bowel biopsy specimens may also reveal the parasite.

Treatment. Albendazole is effective against microsporidia, although this usually results in suppression rather than eradication of infection. Albendazole inhibits microtubule formation and, thus, reduces cell division and, possibly, polar tubule action. The usual dose is 400 mg twice daily for 4 weeks. There is evidence that *E. bieneusi* responds much less satisfactorily than *E. intestinalis*. There is preliminary evidence suggesting that the antihelminthic drug nitazoxanide also may have activity against microsporidia.

Isospora belli and Sarcocystis Species. These intracellular coccidian parasites are rare in immunocompetent individuals but have been recognized in increasing numbers of patients with HIV infection and AIDS. Oocysts are ingested in contaminated food, namely, undercooked beef and pork. Like *Cryptosporidium* species, these parasites produce varying degrees of partial villous atrophy and an associated inflammatory response in the mucosa, consisting of lymphocytes, plasma cells, and eosinophils.[41,42]

Although these parasites are carried without symptoms, children can develop profuse watery diarrhea and go on to a chronic malabsorptive state with steatorrhea and weight loss. Diagnosis is by the detection of oocysts in feces, duodenal fluid, or jejunal mucosal biopsy specimens.[42] Nitroimidazole derivatives, furazolidone, and trimethoprim-sulfamethoxazole are effective, but recurrence of infection is common. Treatment may need to be continued for many weeks.

Cyclospora cayetanensis. This is another relatively newly recognized member of the intracellular intestinal protozoa. The organism was first detected in travelers returning from Nepal with persistent diarrhea but has subsequently been isolated in parts of the developing world and North America; in the latter, the infection has been found in immunocompromised individuals.[43,44] The infection is seasonal, with peak prevalence during the periods of high rainfall, strongly suggesting that it is waterborne. Diarrhea is usually prolonged, lasting approximately 7 weeks if untreated. The organism has been identified within enterocytes and is associated with varying degrees of villous atrophy.[45]

Oocysts can be identified in feces by light microscopy, and the addition of potassium dichromate induces the oocysts to sporulate. Intracellular parasites are identified in small intestinal biopsy specimens by electron microscopy. The parasite is probably underdiagnosed, and its precise role as a cause of acute and chronic diarrhea worldwide needs to be established by further epidemiologic studies. The parasite can be eradicated with cotrimoxazole given in conventional doses for 7 days. This therapy eradicates more than 90% of infections; the remainder can be cured by continuing therapy for a further 3 to 5 days.[46]

Nematodes

Many helminths appear to be able to coexist with their human hosts without causing marked disturbance of intestinal function. Small intestinal nematodes may be considered as two groups: those that cause diarrhea and those that do not (see Table 38.4-1).

Strongyloides stercoralis. The adult worms of this parasite live predominantly in the duodenum and jejunum, although, occasionally, there is extensive involvement of the whole gut. The life cycle is summarized in Figure 38.4-3. *S. stercoralis* is found in the tropics and subtropics and also in eastern Europe, Italy, Australia, and the south-

ern United States. An important group of individuals still carrying this parasite are ex-servicemen who served in Southeast Asia, particularly those who were forced to work on the Thai-Burma railroad.[47,48]

Adult worms invade the intestinal mucosa (Figure 38.4-4) and produce an inflammatory response involving mononuclear cells and eosinophils. In addition, there may be varying degrees of partial villous atrophy.

Clinical Features. Penetration of the skin by filariform larvae often produces a local reaction, followed 1 week later by respiratory symptoms, including coughing, wheezing, and transient pulmonary infiltrates as adolescent worms migrate through the airways. Diarrhea follows some 2 weeks later as the parasite colonizes the small intestine.

Abdominal symptoms may pass unnoticed, but children can develop a sprue-like syndrome. Occasionally, severe infection is associated with protein-losing enteropathy[49,50] and intestinal obstruction.[51]

Autoinfection can occur in the same individual by invasion of either the colon or the perianal area, which results in a form of cutaneous larva migrans known as larva currens. The serious and often fatal hyperinfection syndrome may occur in immunocompromised individuals.

Diagnosis. Larvae or adult females can be detected in feces, duodenal fluid, sputum, or jejunal biopsy specimens. Multiple stool specimens may need to be examined to find larvae. Thus, a negative stool examination does not exclude infection.[48] Serology is usually positive in up to 80% of patients.

Treatment. Ivermectin as a single oral dose (200 µg/kg) repeated after 1 week or 200 µg/kg daily for 3 days is an effective intervention. Albendazole and thiabendazole are also effective, but the latter, in particular, is frequently accompanied by unwanted side effects, including nausea, anorexia, vomiting, and diarrhea.

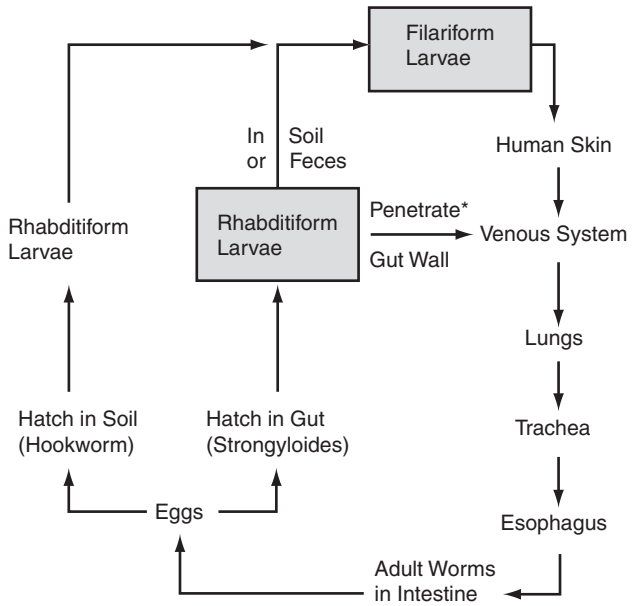

FIGURE 38.4-3 Life cycle of *Strongyloides stercoralis* and hookworm.

Capillaria philippinensis. Infection with this important parasite of Southeast Asia, particularly the Philippines and Thailand, results in severe diarrhea and malabsorption.

Infection generally follows the ingestion of raw fish. After an incubation period of 1 to 2 months, nonspecific abdominal symptoms may be noted, followed by severe, watery diarrhea. In some cases, this progresses to intestinal malabsorption with profound weight loss. If untreated, mortality approaches 10%.[52]

Parasite forms (ova, larvae, adult worms) are detected in stool or intestinal biopsy specimens. Infection is successfully eradicated by mebendazole and thiabendazole, provided that treatment is continued for 3 to 4 weeks.[52] Albendazole is an effective alternative therapy.

Trichinella spiralis. *Trichinella spiralis* occurs worldwide in communities that eat pork.[53] Unlike other nematodes, *T. spiralis* requires two hosts to complete its life cycle (Figure 38.4-5). Initially, diarrhea and abdominal pain predominate, usually occurring several days after eating contaminated pork. After 1 to 2 weeks, infected individuals experience an acute febrile illness associated with periorbital edema, an erythematous rash, and severe muscular pains, which may last for up to 6 weeks. Associated complications include pneumonitis, myocarditis, and encephalitis.[53,54]

Diagnosis can be confirmed by demonstrating larvae in skeletal muscle biopsy specimens. Often there is eosinophilia and elevation of serum creatinine phosphokinase and serum glutamicoxaloacetic transaminase. Treatment is with mebendazole or thiabendazole for 10 days, but in patients with disseminated infection, concurrent corticosteroid therapy is recommended to minimize allergic reactions.

Trichostrongylus orientalis. Found predominantly in the Far East, this small roundworm infects those who ingest contaminated food or drink. Diarrhea occurs, but usually infection is asymptomatic. Ova can be detected in duodenal fluid or feces, and treatment is with a single dose of levamisole (2.5 mg/kg). Thiabendazole is less effective.

Ascaris lumbricoides. *Ascaris*, one of the most common parasitic infections of humans, is the largest human intesti-

FIGURE 38.4-4 Scanning electron micrograph of *Strongyloides* adult worms invading intestinal mucosa. Courtesy of Tim McHugh.

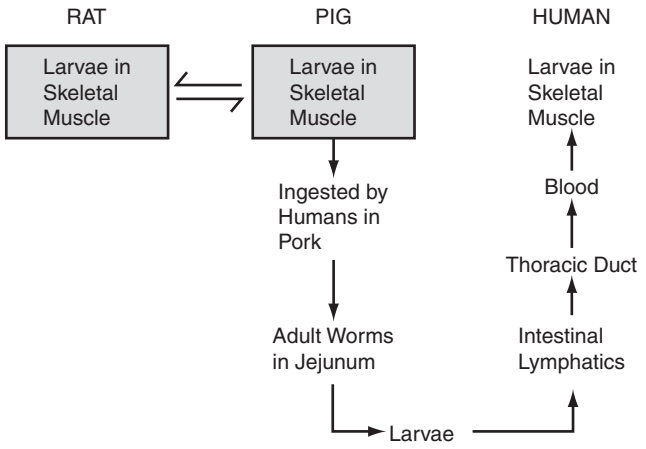

FIGURE 38.4-5 Life cycle of *Trichinella spiralis*.

nal nematode. It is found worldwide, but it is most evident in the developing world, where its prevalence may exceed 90% in very deprived communities.[55] The life cycle is summarized in Figure 38.4-6.

***Clinical* Features.** Most individuals with *Ascaris* infection are symptom free, but during the pulmonary phase, migrating larvae may produce coughing with sputum, wheezing, fever, and eosinophilia. Heavy infections, particularly in children, may cause anorexia and abdominal cramps. Some evidence suggests that the parasite also may impair growth and development. Large worm burdens can produce intestinal obstruction, particularly in children. Worms may migrate into a variety of locations, including the pancreatic and biliary system, causing duct obstruction with jaundice and pancreatitis, obstruction of the appendix, appendicitis, volvulus, intussusception, intestinal perforation, and peritonitis.[55]

Diagnosis and Treatment. Ova and adult worms can be detected in feces and larvae in sputum or gastric washings. Albendazole (200 to 400 mg as a single dose), mebendazole (100 mg twice daily for 1 day), and levamisole (2.5 mg/kg as a single dose) are the drugs of choice. Other drugs include piperazine citrate and pyrantel pamoate. Intestinal obstruction from nematode infestation may require operative treatment, but antihelminthic drugs combined with intestinal suction and intravenous fluids are often tried first. Bile and pancreatic duct obstructions can be relieved endoscopically.

***Ankylostoma duodenale* and *Necator americanus*.** *A. duodenale* (Old World hookworm) is found in Africa, Asia, Australia, and parts of southern Europe, whereas *N. americanus* predominates in Central and South America, together with some locations in Southeast Asia, the Pacific, and Nigeria. Morphologically, the parasites are similar, with identical life cycles (see Figure 38.4-3). Adult worms attach firmly to the small intestinal mucosa by a buccal capsule consisting of tooth-like or plate-like cutting organs. It is estimated that more than 500 million persons in the world are infected with these parasites.

***Clinical* Features.** Filariform larvae penetrate the skin, where a local inflammatory reaction may develop (ground itch). Pulmonary symptoms are less dramatic than those of *Ascaris* infections, but upper abdominal discomfort, mild diarrhea, and associated eosinophilia usually ensue. The dominant clinical response to infection is iron deficiency anemia, which is proportional to the worm load and the amount of iron taken in the diet. Occasionally, heavy infection can result in protein-losing enteropathy and hypoproteinemia.

Diagnosis and Treatment. Ova and rhabditiform larvae can be detected in stool and duodenal fluid. Mebendazole (100 mg twice daily for 3 days) and albendazole (200 mg daily for 3 days) are effective against both species of the hookworm, but other drugs, including pyrantel pamoate and levamisole, are also active. Oral iron supplements should be given to treat iron deficiency.

Cestodes (Tapeworms). Four tapeworms are common human pathogens: *Taenia saginata, Taenia solium, Diphyllobothrium latum,* and *Hymenolepis nana*. These flatworms are similar structurally, and their heads have suckers; *T. solium* has additional hooks. The head is joined by a short, slender neck to several segments called proglottids, which form the body of the worm. Nutrients are absorbed directly through the cuticle because these worms do not possess an intestinal tract. Tapeworms are hermaphrodites, with cross-fertilization occurring between proglottids. Adult worms reside in the intestinal tract, whereas larvae exist in tissues, particularly muscle; infection is transmitted to humans by the eating of infected tissues (Figure 38.4-7).

T. saginata (*Beef Tapeworm*). Most patients infected with this tapeworm are symptom free, although mild vague abdominal discomfort and occasional diarrhea may occur. Occasionally, adult worms obstruct the appendix or pancreatic duct, causing appendicitis and pancreatitis, respectively. Generally, infection is apparent to the host only when proglottids are identified in the feces. Praziquantel (10 mg/kg as a single dose) is the treatment of choice, although niclosamide (2 g as a single chewed dose) is also effective. Infection can be avoided by thorough examination of beef for encysted larvae known as cysticerci,

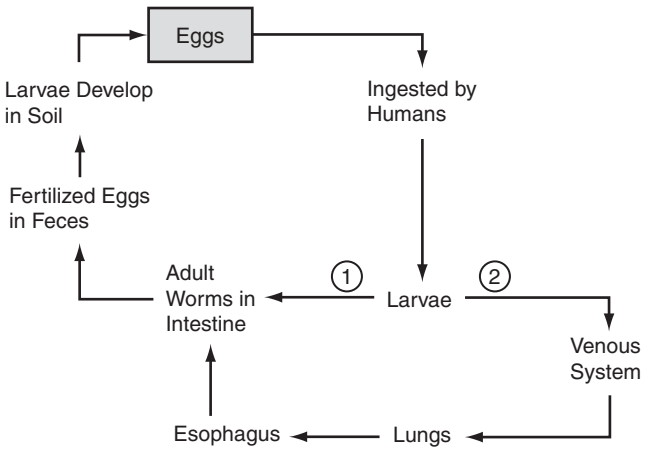

FIGURE 38.4-6 Life cycle of (1) *Trichuris trichiura* and *Enterobius vermicularis* and (2) *Ascaris lumbricoides*. The shaded area indicates the infective form of parasites.

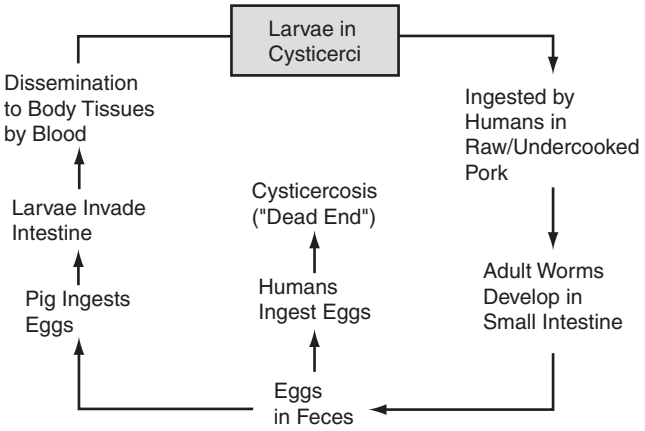

FIGURE 38.4-7 Life cycle of *Taenia solium* (pork tapeworm).

although freezing at –10°C for 5 days or cooking at 57°C for several minutes destroys them.

T. solium (*Pork Tapeworm*). The clinical features and treatment of the adult worm infection are similar to those of *T. saginata* infection. However, a serious complication occurs when infection with *T. solium* larvae results in their dissemination to many sites, including skeletal muscle, brain, subcutaneous tissue, the eye, and myocardium, a condition known as cysticercosis. The cysts remain alive for many years but eventually produce a local inflammatory reaction and calcify. Cerebral involvement presents as epilepsy, as a space-occupying lesion, or as focal neurologic deficits. Ocular involvement produces retinitis, uveitis, conjunctivitis, or choroidal atrophy. Diagnosis can be established by biopsy of skin nodules, although calcified cysticerci usually can be detected radiographically. Encouraging results in the treatment of cysticercosis have been obtained with the use of praziquantel (10 mg/kg). Surgery or photocoagulation may be required for retinal lesions.

D. latum (*Fish Tapeworm*). This tapeworm is found mainly in Scandinavia, the Baltic countries, Japan, and the Swiss lakes region. Infection in humans occurs by the ingestion of raw or undercooked fish containing the infective plerocercoid form of the parasite. Infection is usually asymptomatic, although there may be abdominal discomfort, vomiting, and weight loss. Occasionally, intestinal obstruction can occur. *D. latum* cleaves the vitamin B_{12}–intrinsic factor complex and consumes more than 80% of dietary vitamin B_{12}. Nevertheless, megaloblastic anemia owing to vitamin B_{12} deficiency is relatively uncommon, although it is well recognized in Finland. Diagnosis and treatment are as for other tapeworms.

H. nana (*Dwarf Tapeworm*). This worm infects children more frequently than adults but has other natural hosts in rats and mice. Infection generally produces no symptoms, although very heavy infection may result in diarrhea and abdominal pain. Treatment is with praziquantel or niclosamide.

Trematodes. A large number of flukes infect the biliary and intestinal tracts of humans, producing a broad spectrum of disease. *Fasciolopsis buski*, the largest human fluke (up to 7 cm in length), is found most often in the Far East.[56] It attaches to the proximal small intestine, causing ulceration, bleeding, and abscesses. Although asymptomatic infection occurs, heavy parasite burdens in undernourished children result in intermittent diarrhea, abdominal pain, and protein-losing enteropathy with hypoalbuminemia, edema, and ascites. Progressive weight loss and even ileus may develop. Although hexylresorcinol and tetrachloroethylene were used previously, praziquantel is now the treatment of choice.

Heterophyes heterophyes and *Metagonimus yokogawai* are very small flukes found in the Far East. Natural hosts include dogs, cats, foxes, humans, and other fish-eating mammals. Infection may be asymptomatic, but heavy infections produce intermittent diarrhea and abdominal discomfort. Ova can be detected in feces, and treatment is the same as for *F. buski*.

PARASITES OF THE COLON AND RECTUM

PROTOZOA

Entamoeba histolytica and a ciliate, *Balantidium coli*, are the important protozoal pathogens of the large intestine (Table 38.4-2). However, it is now clear that *C.* parvum can infect the entire small and large intestine; indeed, the first case of human infection was diagnosed by rectal biopsy. *G. lamblia* is predominantly a pathogen of the small intestine, but isolated reports in both humans and animals purport that this parasite occasionally causes colitis.

E. *histolytica*. This organism is found worldwide, but its prevalence is highest in developing countries. Up to 500 million individuals carry the parasite, with an annual mortality of approximately 75,000.[57] Amebiasis is relatively uncommon in infancy and childhood,[58] but when infection occurs, morbidity and mortality tend to be high.

The parasite exists in two forms, the motile trophozoite and the cyst. In the infective form of *E. histolytica*, the cyst can exist for long periods outside the human host.[59] Cysts are spread in food and water and also by person-to-person contact.

Virulence varies among strains of *E. histolytica*, which can be distinguished by isoenzyme electrophoresis and DNA analysis.[60] This finding may explain some of the clinical diversity of *E. histolytica* infection, which varies from asymptomatic carriage to severe invasive disease. It is now clear that there is a phenotypically and genotypically distinct nonpathogenic ameba that morphologically resembles *E. histolytica* but does not produce invasive disease. This organism is now known as *Entamoeba dispar*. These two species can be distinguished by using specific monoclonal antibodies or discriminatory DNA probes, which confirm that many individuals with asymptomatic carriage, in fact, have the nonpathogenic form, *E. dispar*.

The capacity of *E. histolytica* to kill colonic epithelial cells on contact appears to depend on a number of factors, including a surface lectin that mediates adherence to epithelial cells together with a range of cytotoxic proteins, including proteolytic and hydrolytic enzymes and probably a pore-forming protein known as amebapore.[61]

Clinical Features. The term *amebiasis* covers a wide range of clinical syndromes, from asymptomatic infection to amebic colitis and extraintestinal amebiasis, usually hepatic abscess. Most infected individuals throughout the world (80–90%) are asymptomatic carriers.[57] Acute amebic dysentery produces symptoms similar to those of bacterial dysentery; in its most severe form, it may progress to colonic dilatation and severe toxemia. This progression is particularly likely to occur in pregnancy, in the puerperium, and in malnourished infants and young children.[62]

Chronic amebic colitis begins more insidiously, with cyclic remissions during which bowel function may return to normal or even be reduced to constipation. The pattern may mimic nonspecific inflammatory bowel disease such as Crohn disease.[63] Constitutional upset is mild to moderate, although complications such as colonic stricture and fibrotic masses of granulation tissue (known as an ameboma) may occur.[64]

An amebic liver abscess can develop within days, months, or even years after the onset of amebic colitis, but in up to 50% of cases, there is no clear antecedent history of colonic involvement.[65] Nonspecific symptoms, such as low-grade fever and weight loss, may begin insidiously, or there may be an acute fulminant illness with localized hepatic pain or evidence of direct extension into pleural or pericardial cavities. Distant spread to lung, brain, and kidney occurs when the abscess ruptures into a hepatic vein.

Diagnosis. Demonstration of *E. histolytica* trophozoites and cysts in feces remains the mainstay of diagnosis. Examination of a fresh saline wet mount should reveal motile trophozoites containing ingested red blood cells. Nonpathogenic intestinal amebae are not erythrophagic. Trophozoites may be seen in rectal mucosal biopsy specimens or in slough from rectal ulcers. It is unusual to see trophozoites in pus from a liver abscess. Serology for IgG antibodies is positive in 70 to 80% of patients with amebic colitis and approaches 100% in those with amebic liver abscess.[66] The treatment of amebiasis in children is summarized in Table 38.4-3.

*These are rough approximations that attempt to take into account marked geographic variations.
†Parasites that can cause diarrhea and malabsorption.

B. *coli*. This protozoan is the only ciliate that produces clinically significant infection in humans; it is restricted largely to communities that live in close proximity to pigs, the preferred host.[67–69] It occurs mainly in Papua New Guinea, the Philippines, and Central and South America. The cyst is the infective form, although the trophozoite can survive outside the human host for a week or more in moist conditions. Clinically, *B. coli* infection closely resembles amebiasis, and diagnosis is made by identification of the large motile trophozoite in feces. Cysts are seen relatively rarely. Tetracycline (500 mg 4 times daily for 10 days) is the usual treatment, but the parasite is also sensitive to ampicillin, metronidazole, and paromomycin.

***Trypanosoma cruzi* (South American Trypanosomiasis or Chagas Disease).** *T. cruzi*, a protozoan hemoflagellate, does not directly affect the GI tract. The primary infection generally occurs in early childhood. The parasite is transmitted through the bite of a blood-sucking vector insect of the family Reduviidae. During the blood meal, the infective form of the parasite is deposited with the insect's feces on the skin and rubbed into the bite wound or a mucous membrane susceptible to invasion, such as the conjunctiva. The vast majority of initial illnesses pass unnoticed, but in some cases, there is marked fever, lymphadenopathy, and hepatosplenomegaly. In severe infection, there may be signs and symptoms of acute myocarditis. Death can occur as a result of this acute illness, but the individual may recover within a few weeks or months.

The development of the "megasyndromes" occurs many years later, with more than 90% of symptomatic patients being 20 or more years of age. In Brazil, achalasia and megaesophagus occur in approximately 6% of seropositive patients, whereas megacolon appears to be less common, affecting only 1%. In Argentina and Chile, however, megacolon is more common than megaesophagus.

A medical approach to the management of these conditions is usually attempted with either nifurtimox (10 mg/kg in three divided doses for at least 90 days) or benznidazole (5 to 10 mg/kg in two divided doses for 60 days).

NEMATODES

The most common nematodes to infect the colon and rectum are *T. trichiura* (whipworm) and *Enterobius vermicularis* (threadworm). In the hyperinfection syndrome, *S. stercoralis* also colonizes the large intestine, producing ulceration and inflammatory changes after invasion and autoinfection.

T. *trichiura*. This parasite is found worldwide, with a high prevalence in the developing world. In some particularly deprived communities, prevalence may be as high as 90%.[70,71] Infection is transmitted by ingestion of ova that have matured outside the host for several weeks. Colonization involves the distal ileum and cecum, although the entire colon may be involved.

TABLE 38.4-3 TREATMENT OF AMEBIASIS IN CHILDREN

INTESTINAL AMEBIASIS
Metronidazole
50 mg/kg daily for 10 d, followed by diloxanide furoate, 20 mg/kg daily for 10 d
AMEBIC LIVER ABSCESS
Metronidazole
50 mg/kg daily for 10 d
ASYMPTOMATIC CYST PASSER
Diloxanide furoate
20 mg/kg daily for 10 d + metronidazole

Clinical Features. Light infections are often asymptomatic, but when larger numbers of parasites are present (greater than 20,000 ova per gram of feces), diarrhea with blood and mucus is characteristic.[72,73] Other symptoms include abdominal pain, anorexia, weight loss, tenesmus, and rectal prolapse. Evidence suggests that within endemic areas, some children are more susceptible than others to whipworm infection. There is now persuasive evidence indicating that chronic heavy infection is an important contributor to the impairment of growth and development in young children.[71,74]

Diagnosis and Treatment. Typical barrel-shaped eggs can be detected in feces, and adult worms can endoscopically be seen attached to the colonic mucosa, often with the presence of ulceration and inflammatory changes. Albendazole (400 mg) or mebendazole as a single dose is now the treatment of choice, although mebendazole should not be used in children under the age of 2 years. Multiple courses may be necessary to clear infection. Ivermectin (200 µg/kg) is also highly effective.

Enterobius vermicularis. This parasite is found worldwide, although it is more prevalent in temperate and cold climates. Children are most often infected, but infection can spread rapidly among family members, those in residential institutions, and any group living in overcrowded circumstances. Infection is spread by direct transmission of ova from person to person or indirectly, on clothing or housedust. The life cycle is summarized in Figure 38.4-6.

Anal pruritus is usually the only symptom, occurring mainly at night, when adult females lay their eggs in the perianal region. Symptoms of appendicitis may result from worms entering the lumen of the appendix. Occasionally, adult worms migrate through the intestinal wall and are found in the genital tract, peritoneum, omentum, lung, urinary tract, liver, spleen, or kidney.[75–77.]

Diagnosis. Ova can be detected in the perianal region by applying clear adhesive tape to the perianal skin and examining this microscopically. Ova can also be found under fingernails. Adult worms may be observed directly emerging from the anal canal or on the perineal skin.

Treatment. Albendazole is the drug of choice (in a single oral dose of 10 to 14 mg/kg), although mebendazole, pyrantel pamoate, and piperazine are also effective. It is wise to treat the entire family and to consider a second course of treatment 2 to 4 weeks later to eradicate worms that may have matured since the first treatment.

***Oesophagostomum* Species.** This organism infects mainly ruminants, primates and pigs, but occasionally causes human infection. The worm often penetrates the intestinal wall, resulting in multiple nodules along the intestine, some of which develop into paracolic abscesses requiring surgical drainage.

Angiostrongylus costaricensis. Infection with this nematode was first described in Costa Rican children presenting with severe pain in the right iliac fossa, fever, and anorexia.[78] An inflammatory mass involving the cecum, appendix, and terminal ileum is characteristic.[78] In its acute form, the syndrome can be confused with appendicitis. The inflammatory reaction is the result of intramural eggs that have been discharged from adult worms living in terminal mesenteric arterials. Surgical resection may be required.

TREMATODES

***Schistosoma* Species.** Schistosomiasis is one of the most important parasitic infections worldwide, with a high morbidity and mortality. More than 200 million individuals are infected with this parasite.[79] Five species are known to cause intestinal disease in humans: *Schistosoma mansoni* (Africa, Central and South America, the Caribbean, and the Middle East), *Schistosoma japonicum* (Japan, the Philippines, southeast China, and Taiwan), *Schistosoma haematobium* (Africa), *Schistosoma mekongi* (Southeast Asia), and *Schistosoma intercalatum* (Zaire and Gabon). Human infection is totally dependent on the intermediate host, the freshwater snail. The life cycle is summarized in Figure 38.4-8.

Clinical Features. Invasion of the skin by cercariae produces a local inflammatory response known as "swimmer's itch." Within a week, there may be a generalized allergic response, with fever, urticaria, myalgia, general malaise, and associated eosinophilia. The acute phase of *S. japonicum* infection is known as Katayama fever. Hepatosplenomegaly also occurs in the early stages; in children, it is more marked in those with heavy parasite loads.[79] Intestinal symptoms of diarrhea, blood, and mucus can occur immediately but may be delayed for months or even years. Extensive colonic ulceration and polyp formation are characteristic of *S. mansoni* infections.[80] In severe cases, there may be marked iron and protein loss. Stricture formation and intestinal obstruction are characteristic, as are localized granulomatous masses within the gut wall, known as bilharziomas. *S. japonicum* can involve both small and large intestines, and infection may be more severe than that from *S. mansoni*. *S. japonicum* colitis, like extensive long-standing ulcerative colitis, has premalignant potential.[81] *S. haematobium* produces rectal inflammation and bladder involvement. The inflammatory changes in the intestine in schistosomiasis are due entirely to an intense T lymphocyte–related immune response to eggs deposited in the intestinal wall.

Diagnosis and Treatment. Characteristic ova of each species can be detected in feces or in intestinal biopsy

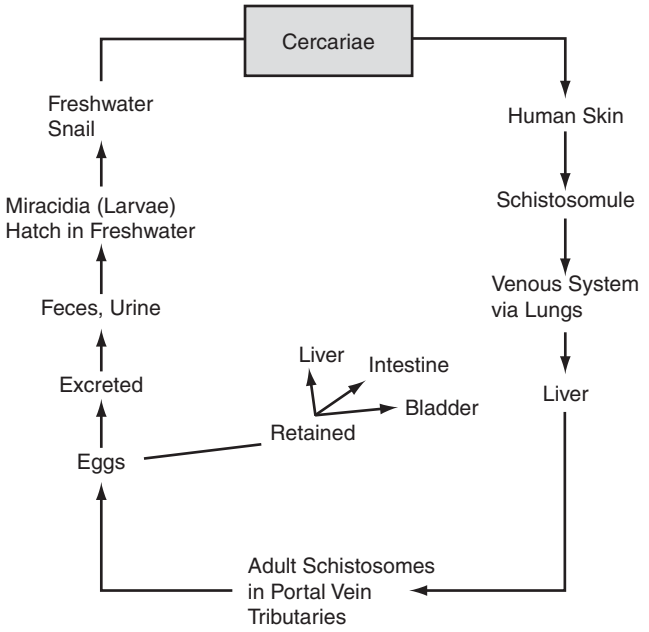

FIGURE 38.4-8 Life cycle of *Schistosoma* species.

specimens. Specific antibodies can be detected by immune assay in more than 95% of patients during the first few weeks of infection.

Praziquantel given as a single dose (40 mg/kg for *S. mansoni*; 60 mg/kg in divided doses for *S. haematobium*) is probably the drug of choice. Oxamniquine is also effective.[82,83]

FUNGAL INFECTONS

A well child with intact host defense mechanisms is generally not considered to be susceptible to fungal infections of the digestive tract. As immunosuppressive therapies become more aggressive and myelotoxic regimens more effective, opportunities increase for fungi to invade and establish themselves in humans. Patients disabled from chronic malnutrition and those exposed to intense antimicrobial infection are also susceptible to these organisms. HIV infection and AIDS have produced a group of chronically immunosuppressed patients susceptible to a wide range of organisms, including fungi. The digestive tract is not a preferred site of infection in cases of disseminated fungal infection, but certain species are capable of infecting the esophagus, the stomach, or the intestine.

A consequence of modern treatment and recently evolving patterns of disease, these opportunistic infections have been recognized only in recent years. No doubt, additional GI fungal infections of significance will emerge and will be recognized in the years to come.

CANDIDIASIS

Candida species are oval cells (4 to 6 μm in size) that reproduce by budding. There are at least 80 species, of which 8, including *Candida albicans*, are of GI significance. In disseminated candidiasis, there is widespread involvement of several organs. The major risk factor leading to this serious problem is neutropenia. The liver may be involved in addition to the heart, brain, kidney, lung, spleen, and eye.[84]

Esophagitis caused by *Candida* species is seen in immunosuppressed children and in those with hematologic malignancy. In such cases, oral thrush may be seen in as few as 20% of cases.[85] Treatment with nystatin usually is effective. Ketoconazole and fluconazole also can be used, and in severe disease (particularly when oral medication cannot be taken), intravenous amphotericin B is employed.

Candida is isolated from up to 15% of gastric ulcers, but no pathogenetic role for the organism in ulcer disease has been established.[86] *Candida* peritonitis, with infection localized usually to the peritoneum, is seen after bowel surgery and in patients undergoing chronic ambulatory peritoneal dialysis. *Candida* infection has been associated with acute watery diarrhea in newborn infants, although its causative role has not been definitely established.[87] *C. albicans* can invade the small bowel and large intestine in terminally ill patients.

ASPERGILLOSIS

The molds of the genus *Aspergillus* reproduce by means of spores that germinate, resulting in hyphae, the form in which they are associated with disease. Most cases of invasive *Aspergillus* infection are seen in severely immunocompromised patients. In about 20% of such cases of invasive infection, the small and large intestines are involved, in addition to the esophagus and stomach.[88] Amphotericin B is the treatment of choice.

ZYGOMYCOSIS

Zygomycetes are ubiquitous agents found in organic debris, on fruit, and in soil. They grow rapidly on any carbohydrate substrate. The terms "mucormycosis" and "phycomatosis" have been used in the past for these infections. These agents can infect the subcutaneous and submucosal tissues in an immunocompetent host, but in the debilitated host, they can cause acute fulminant invasive infection.[89] Intestinal zygomycosis is encountered in severely malnourished children and sometimes as a complication of severe chronic intestinal disease, such as amebic colitis.[90] On occasion, the infection can occur without apparent predisposition.

COCCIDIOIDOMYCOSIS

Coccidioides is a dimorphic fungus endemic in the southwest of the United States. Arthroconidia arising from mycelial growth causes infection when inhaled. Coccidioidomycosis is usually a pulmonary infection; spores can escape the chest during primary infection and with dissemination; on rare occasions, the terminal ileum and colon are involved.[91]

5. Bacterial Overgrowth

Steven N. Lichtman, MD, FRCPC

Bacteria do not inhabit the upper small intestine and stomach in significant numbers, whereas in the colon, concentrations of 100 billion organisms/mL are the norm. Colonic microflora will proliferate in the small intestine, however, whenever intrinsic cleansing mechanisms are interrupted. Classically, colonic flora proliferate in the small intestine in areas of stasis. The clinical syndrome that results has been given a variety of names: stagnant loop, blind loop, contaminated small bowel, small bowel stasis, and small bowel bacterial overgrowth (SBBO) syndrome. In this chapter, I use the latter term, small bowel bacterial overgrowth. The characteristic features of SBBO are (1) abnormal colonization of the upper small intestine by organisms that characteristically reside in the colon, (2) steatorrhea, and (3) anemia.

NORMAL INTESTINE

At birth, the intestine is sterile, but soon after parturition, orally ingested organisms begin to colonize the gut.[1] Commensal bacterial populations are not uniform in either number or type (Table 38.5-1). In the upper small intestine, aerobic bacteria typical of the oral cavity predominate. Their numbers do not exceed 10^6 organisms/mL. In the colon, strict and facultative anaerobes, adapted to growth within the fecal mass, where bacterial metabolism quickly deprives the environment of oxygen, are most common. The total number of colonic bacteria/mL is at least 1 million times greater than that of the upper small intestine. Colonic species are listed in some detail in Table 38.5-1, but the list is, nevertheless, incomplete. There are at least 60 different bacterial species.[2] Many are present in trace numbers, but under specific circumstances, some of them, such as *Clostridium difficile*, proliferate and cause disease, such as antibiotic-associated colitis. The number of bacteria in the distal small intestine is greater than that of the proximal small bowel. Near the cecum, there may be 10^9 organisms/mL, and the composition of the microflora is similar to that of the colon.

TABLE 38.5-1 COMMENSAL ENTERIC FLORA OF THE NORMAL INTESTINAL TRACT

PROXIMAL SMALL INTESTINE
$< 10^6$ organisms/mL

$> 10^9$ organisms/mL
Greater numbers of anaerobic and facultative anaerobic bacteria
Bacteroides, *Escherichia coli*, *Bifidobacterium*
COLON
$10^{9–10}$ organisms/mL
Anaerobic and facultative anaerobic bacteria
Bacteroides, *Escherichia coli*, *Bifidobacterium*, *Clostridium*

PRESERVATION OF THE NORMAL ENVIRONMENT

The relative sterility of the small intestine depends on a number of factors (Figure 38.5-1) that act to reduce bacterial load and prevent colonization. They may be conveniently divided into nonimmune and immune categories.

NONIMMUNE ANTIBACTERIAL FACTORS

Gastric acidity acts as an initial line of defense against ingested bacteria. Gastric juice with a pH < 4.0 is bactericidal for most organisms, although not immediately. In one experiment, bacteria instilled into the normal lumen of the stomach were killed within 15 minutes, but when instilled into the achlorhydric stomach, they remained viable for at least an hour.[3] Chronic inhibition of gastric acid increases

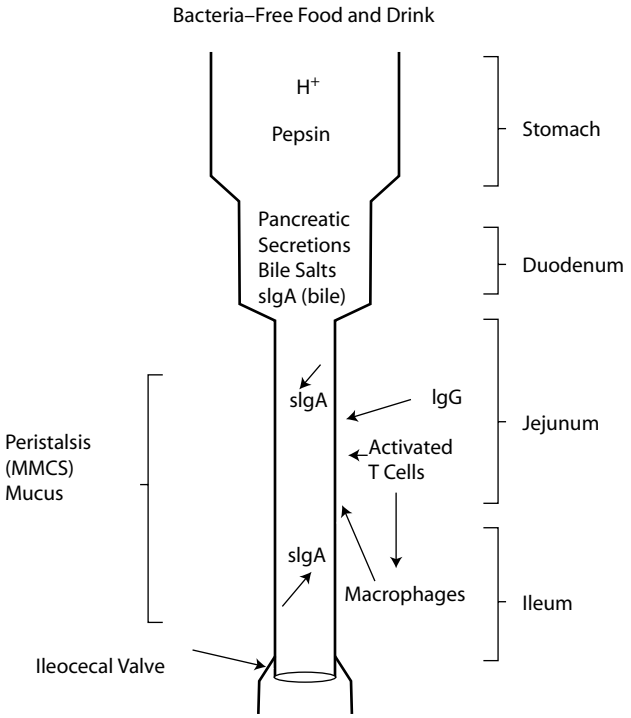

FIGURE 38.5-1 Prevention of small bowel bacterial overgrowth in health.

the number of gastric bacteria substantially.[4] The number of bacteria presented to the duodenum, therefore, depends on the number of organisms ingested and the length of their exposure to low pH.

Two concerns have been raised about low gastric acid and increased bacterial counts induced by the chronic use of drugs that prevent gastric acid secretion. First, *N*-nitroso compounds are associated with an increased incidence of gastric cancer. Second, when histamine$_2$ blockers were used in an intensive care unit to prevent stress ulcers, there was a twofold increased incidence of gram-negative bacteria-induced pneumonia in ventilated patients compared with those taking sucralfate, an agent that does not alter gastric pH or bacterial numbers.[5] No studies have been performed on children to determine the effects of acid suppression on SBBO. However, several studies in the elderly show that both omeprazole and ranitidine cause high duodenal bacterial counts and induce intestinal symptoms,[6,7] but this was not found in a third study.[8]

Peristaltic propagation of luminal contents in a steady distal flow toward the colon is of major importance in reducing the growth of bacteria in the proximal intestine. Interdigestive migratory motor complexes (MMCs) are especially important in this role. Bacterial populations rise within hours when the complexes are ablated pharmacologically.[9]

Enzymatic digestion is probably of significance as well because small numbers of bacteria might be expected to undergo normal digestive degradation. Pancreatic juice has antibacterial activity,[10] possibly because of its proteolytic and lipolytic enzymes, although other factors, such as competitive binding and specific antibacterial activities, cannot be ruled out. Bile acids and digestive secretions probably help to limit growth as well. Colonization requires access to preferential growth sites in stagnant niches, such as the lumina of intestinal glands and membrane sites to which bacteria can bind. Just as importantly, it also requires a relatively large number of available bacteria to exploit these niches at any given instance. Intestinal secretions from the stomach, intestine, and pancreas are, therefore, a deterrent to growth owing to their ability to dilute the bacterial mass.

Mucus is an example of an epithelial secretion with special properties that enable it to trap bacteria in an intraluminal location while moving organisms distally in bolus fashion. Mucus is composed of a variety of proteins and salts anchored within a viscous gel formed by a single carbohydrate-rich protein. About 80% of the mucus glycoprotein by weight is carbohydrate, and the protein itself is organized as a long thread of disulfide-bonded units, often amounting to a molecular weight of $5 - 10 \times 10^7$ D. These huge threads bind bacteria through specific lectin-like reactions with carbohydrate,[11] by hydrophobic interactions,[12] and probably also through simple trapping. The carbohydrate serves as a nutrient for some bacteria, thus attracting them to a mobile colonization site that is continuously replaced. Huge numbers of organisms (Figure 38.5-2) are found in the mucus coats of the colon[13] and stagnant loops,[14] whereas bacteria are relatively scarce on the underlying mucosa and glands, suggesting that mucus limits access of bacteria to the intestinal surface even in stagnant circumstances. This may explain why cellular damage is often minor in stagnant portions of the bowel even when bacterial counts are high.[15]

The ileocecal valve prevents retrograde colonization of the distal small bowel to a significant extent.[16] As noted in Table 38.5-1, the concentration gradient across the valve is not large, on the order of 100 times. In the absence of the valve, however, free reflux of right-sided liquid colonic content occurs, and the total load of colonic bacteria exposed to the distal small intestine increases greatly.

Bacterial load also conditions intestinal colonization. Coprophagic animals, for example, harbor higher numbers of bacteria in the proximal small intestine than do humans, although colonic bacterial populations are equivalent. Poor environmental sanitation, particularly in warm climates, encourages ingestion of excessive numbers of bacteria and may increase the small intestinal bacterial count in this manner.

Immune Antibacterial Factors

Antibodies to indigenous intestinal bacteria develop early in life[17] and probably play an important role in controlling membrane colonization and mucosal penetration by bacteria and bacterial products. Antibodies to bacterial pilus proteins have been shown to inhibit binding to specific attachment sites on intestinal membranes.[18] Combined immunodeficiency states, notably acquired immunodeficiency syndrome (AIDS) and combined B- and T-cell immunodeficiency, predispose the upper intestine to opportunistic infestation by a variety of parasites. Surprisingly, studies of the prevalence of SBBO in patients with human immunodeficiency virus (HIV) infection yield conflicting results. For example, no relationship was found between gastric pH, diarrhea, and small bowel bacterial colonization in HIV-infected patients.[19] Loss of the capacity to secrete immunoglobulins into the intestinal lumen generally produces less dramatic effects, but upper intestinal colonization by specific parasites, such as *Giardia lamblia*, occurs frequently in hypogammaglobulinemia and secretory immunoglobulin A (sIgA) deficiency. Specific IgG and IgA antibodies hasten the elimination of intestinal parasites such as *Giardia* and nematodes,[20] possibly by activating macrophages. The role that the immune system plays, if any, in modulating growth of intraluminal commensal bacteria in the intestine is less clear. There is evidence that agammaglobulinemic and hypogammaglobulinemic patients develop small intestinal bacterial overgrowth,[21–23] but it has been argued that other complications arising in these conditions, such as achlorhydria, are critically important. Dolby and others, for example, compared three groups of patients: one with pernicious anemia, another with hypogammaglobulinemia and achlorhydria, and a third with hypogammaglobulinemia and normal gastric acidity.[23] Bacterial overgrowth was found in the first two groups but not in the third. Although an impressive amount of sIgA enters the intestinal lumen in bile, direct transmucosal secretion is also important. Upper intestinal blind loops, produced experimentally in rats, produce and

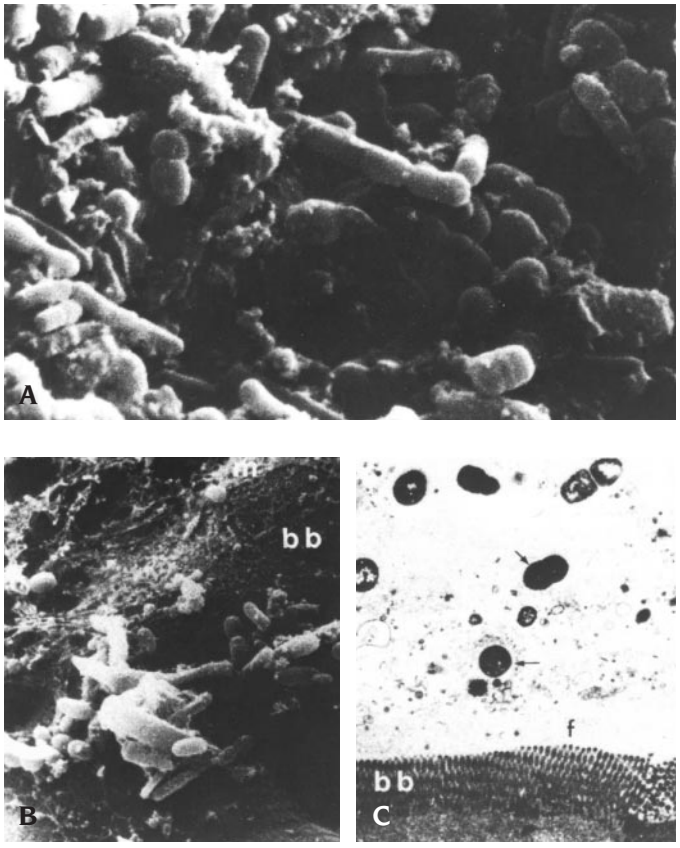

FIGURE 38.5-2 Association of bacteria with the mucous coat in small bowel bacterial overgrowth. *A,* Scanning electron micrograph of the unwashed small intestinal surface showing bacterial rods and chains embedded in multiple layers within the surface mucous coat. *B,* After gentle washing with saline, the brush border surface (bb) is exposed under strands of mucus. Bacteria remain bound to the mucous strands and not to the brush border. *C,* Transmission electron microscopy of an enterocyte with a layer corresponding to surface filaments (f) on the surface of the brush border (bb). Bacteria (*arrows*) are confined to the mucus outside the filamentous layer.

secrete sIgA with specificity for the colonic-type bacteria.[24] Antibodies secreted by the mucosa may help to prevent mucosal attachment by luminal bacteria. Secretory IgA may also enhance binding of certain bacteria to mucus.[25]

FACTORS PREDISPOSING TO THE DEVELOPMENT OF SBBO

A large number of specific clinical entities are reported to cause SBBO. Seemingly unrelated illnesses, however, can be grouped into four categories, depending on the mechanism by which the SBBO is produced. As summarized in Table 38.5-2, these include (1) anatomic abnormalities, (2) disorders of intestinal motility, (3) lesions that increase the number of bacteria presented to the upper small intestine, and (4) deficiencies of host defense.

Anatomic lesions include diverticula (Figure 38.5-3), duplications, and mucosal strictures.[26] These lesions each interrupt normal gut motility and thereby provide a site of relative stasis for bacterial colonization and replication. Surgical procedures such as side-to-side anastomoses,[27] jejunoileal bypass,[28] and neoreservoirs[29] (Koch pouch, ileoanal anastomosis) may create areas of poorly drained bowel and SBBO. Disruption of normal intestinal motor activity causes intestinal stasis by interfering with peristaltic clearing function. Short-term disruption, such as occurs with abdominal surgery, is rarely a problem because although SBBO develops, it rapidly clears with return of motor function. Severe clinical symptoms develop when motility is adversely affected on a more long-term basis. Idiopathic intestinal pseudo-obstruction syndrome is a frequent cause of symptomatic SBBO in children. Secondary causes of a disrupted motility pattern, such as progressive systemic scleroderma and diabetes mellitus with associated autonomic neuropathy, are more frequent considerations in adults. In the elderly, otherwise isolated absence of the MMC is associated with SBBO.[30] The MMC normally has an important "housekeeper" function, helping to keep the proximal small intestine relatively sterile.[31,32] Vantrappen and colleagues showed that 5 of 18 patients with clinically documented SBBO had an absent or disordered MMC pattern.[32] These results have been confirmed and extended.[33] In addition, several studies show that SBBO is associated with delayed gastric emptying.[33,34] Because the activity of the MMC is not fully developed in the immature gut,[35] the premature infant may be at particular risk. Motor abnormalities have subsequently been shown to occur in experimentally produced SBBO,[36] indicating that bacterial overgrowth can cause a motor abnormality independently and thus exacerbate the tendency to stasis.

An increased bacterial load that overwhelms the normal host defenses also can result in SBBO. Coloenteric fistulae (Crohn disease, surgical misadventures), loss of the ileocecal valve (postresection, eg, in Crohn disease or necrotizing enterocolitis), and loss of normal gastric acid output (autoimmune gastritis, malnutrition) may all permit entry into the small intestine of abnormally large numbers of bacteria and initiate SBBO even without appreciable early stasis. Poor sanitation, particularly in the absence of a clean

water supply, may also lead to the habitual ingestion of such a large oral load of bacteria that gastric acidity is overwhelmed. Abnormalities of host defense, such as, for example, the achlorhydria associated with hypogammaglobulinemia, are frequently associated with SBBO. Protein-calorie undernutrition is associated with SBBO in children[37–39] and causes loss of gastric acidity,[40,41] decreased mucin production,[42] and impaired cellular and humoral immune function.[43] End-stage renal failure, with creatinine above 6 mg/dL, also has been associated with SBBO.[44] SBBO is reported in patients following liver transplant.[45] Patients with chronic pancreatitis may have an increased incidence of SBBO owing to dysmotility or because of the antibacterial properties of pancreatic juices.[46]

In many clinical settings, etiologic risk factors for SBBO overlap. For example, in underdeveloped countries, it is difficult to separate the effects of an increased bacterial load owing to poor hygenic conditions from the effects of coexisting protein-calorie undernutrition. In experimental animals, using the self-filling blind-loop model of SBBO, malnutrition hastens the onset of deficiencies in mucosal hydrolase activities following intestinal stasis.[47] However, in the rat model, protein-calorie deprivation without surgical intervention to induce intestinal stasis does not depress specific activities of brush border disaccharidases. Infants with short-bowel syndrome frequently have associated SBBO that complicates their clinical course and medical management. In this setting, SBBO is multifactorial because it can be related to intestinal dysmotility, loss of the ileocecal valve, prior abdominal surgery, and associated malnutrition of the host. In some cases of postinfectious enteropathy, symptoms of chronic diarrhea appear to be related to associated SBBO.[48–51] Although the etiology of bacterial overgrowth in this setting is not clearly established, changes in gut motility, altered host defenses, and coexisting malnutrition each may be contributing factors. Inadequate preparation of food may also be a factor in some countries. For example, the red kidney bean contains a lectin, phytohemagglutinin, which is readily destroyed by heating but which can produce bacterial overgrowth in experimental animals when raw beans are fed to them.[52]

PATHOPHYSIOLOGY

Excessive numbers of intraluminal bacteria alter intraluminal secretions and produce metabolic products, enzymes, and toxins that damage the mucosa and are absorbed. As a consequence, they produce intraluminal, mucosal, and systemic effects (Table 38.5-3) that greatly alter the performance of their human host.

INTRALUMINAL EFFECTS

Bacteria are metabolically active organisms, and it is not surprising, therefore, that their nutritional demands conflict with those of the host when their numbers increase in a metabolically active area of the intestine. Pathologic effects are maximal when overgrowth involves the proximal small intestine. Intraluminal anaerobic bacteria, particularly fecal strains, possess enzymes that deconjugate bile salts and convert their component cholic and chenodeoxycholic acids to the secondary bile acids deoxycholate and lithocholate.[53] The net result is to lower the concentration of bile salts in the duodenum and jejunum below the critical micellar concentration (CMC).[54,55] Above the CMC, much of the triglyceride and cholesterol in the lumen is present in mixed micelles containing hydrolyzed lipid products (fatty acids and mono- and diglycerides) and bile salts. Below the CMC, large liquid crystalline and insoluble emulsoid forms predominate. Because pancreatic lipase is

TABLE 38.5-3 INTRALUMINAL BACTERIA: EFFECTS ON THE HOST

Release of proteases, toxins		

water soluble and must operate at a lipid–water interface, the great reduction in lipid surface area has disastrous consequences for fat digestion, and malabsorption of triglyceride, fat-soluble vitamins, and other lipid molecules results. Patchy histologic abnormalities, impaired uptake of lipolytic products, and slow chylomicron transport also may contribute to fat malabsorption.[56]

Intraluminal bacteria, particularly *Bacteroides* species and coliforms, also use vitamin B_{12} and thus directly compete for dietary vitamin B_{12}, preventing its absorption. When radioactive vitamin B_{12} is administered to animals or patients with SBBO, most of the radioactivity subsequently recovered from the small bowel contents is bound to enteric microorganisms.[57,58] Once bound, the vitamin is unavailable to the host unless the bacteria die. Luminal bacteria also produce inactive cobamides that are not available to the affected host.[59] Vitamin B_{12} malabsorption not correctable by exogenous intrinsic factor may be the most consistent feature of clinically significant SBBO.[54]

Mucosal Effects

An enteropathy is less dramatically expressed but in aggregate is equally deleterious. Although bacteria that accumulate in SBBO do not produce classic enterotoxins,[60] they do produce enzymes[61,62] and metabolic products[63,64] that are potentially capable of injuring the mucosa. In experimental blind loops, anaerobic bacteria elaborate proteases with elastase-like properties that remove or destroy glycoprotein enzymes on the brush border surface.[61,62] As a result, mucosal disaccharidase activities are reduced.[65] Monosaccharide transport may also be impaired, reflecting damage to the microvillus plasma membrane and the toxic effects of deconjugated bile salts.[63] Impaired transport of sodium and chloride has also been demonstrated.[66] In the self-filling blind loop, bacterial overgrowth produces a relatively mild morphologic lesion. Both villus height and crypt depth are increased.[67,68] Approximately 10 to 20% of the columnar cells in the upper half of the villi are swollen and vesiculated. Apical membrane microvilli of some, but not all, enterocytes are blunted, swollen, and budded. Damaged mitochondria and endoplasmic reticulum can be found. These experimental findings are in keeping with morphologic reports in humans,[69] which suggest that bacterial overgrowth causes a patchy mucosal lesion with segments of subtotal villus atrophy and a marked subepithelial inflammatory response. In infants, particularly, there is a well-established association between carbohydrate intolerance and small intestinal bacterial overgrowth.[47,70] Protein loss in the intestine may be sufficiently profound in both experimental animals[71] and humans[71,72] to cause hypoproteinemia. Chronic intestinal blood loss also has been documented as a cause of anemia.[73]

Batt and colleagues described German shepherd dogs that spontaneously develop SBBO.[74] These dogs have chronic diarrhea, weight loss, vitamin B_{12} deficiency, increased folate, and a relative serum IgA deficiency.[75] This model of SBBO differs from that in rats and humans because aerobic bacteria play a more important role in dogs, and total bacterial numbers are generally lower. This causes different types of brush border injury because dogs with aerobic bacterial overgrowth have normal disaccharidase and aminopeptidase N activities. Ten of 17 dogs had aerobic bacterial overgrowth that induced increased γ-glutamyl transferase and decreased alkaline phosphatase.[76] Other than the relative IgA deficiency, the etiology of this spontaneously occurring SBBO is unknown. Riordan and colleagues examined the difference between overgrowth of colonic-type and oropharyngeal-type organisms and found no difference in the morphology of villus height and crypt depth.[77]

Systemic Effects

Bacterial products and antigens are absorbed through the damaged mucosa, causing systemic effects. SBBO increases intestinal permeability in humans[78] and in rats causes enhanced absorption of the bacterial polymer peptidoglycan.[79]

Abnormalities in both hepatic function and liver architecture develop in the rat self-filling blind-loop model of bacterial overgrowth.[80–82] Immune responses are probably responsible for complaints of arthritis and dermatitis. Circulating immune complexes containing IgG, IgA, IgM, and complement are detected during episodes of arthritis associated with SBBO caused by intestinal bypass surgery.[83,84] IgM, IgA, and C3 depositions in the reticular dermis have been demonstrated in association with necrosis of the upper dermis and adjacent vasculitis.[85,86]

Following surgical creation of jejunal self-filling blind loops, SBBO in susceptible rat strains induces hepatobiliary injury.[80] Female Lewis and male and female Wistar and Sprague-Dawley rats develop liver injury by 4 to 9, 12, and 14 weeks, respectively, but Fischer and Buffalo rats do not develop hepatobiliary injury even after 16 weeks. Total anaerobic bacteria within the loops are similar (approximately $10^{8–10}$ organisms/mL), and loop sizes are similar in each rat strain. Metronidazole and tetracycline prevent the lesions in the livers of susceptible strains.[81] Histopathology

demonstrates inflammatory infiltration in the portal tracts, with bile duct proliferation and destruction, as well as fibrosis with some inflammation of the parenchyma.[80] Cholangiograms demonstrate widened extrahepatic bile ducts that are thickened and intrahepatic bile ducts that are dilated, tortuous, and irregular.[82] Taken together, these histologic and cholangiographic features resemble primary sclerosing cholangitis in humans. Further studies are required to determine the differences and similarities between SBBO-induced hepatic injury and primary sclerosing cholangitis. It should be noted that SBBO causes translocation of viable bacteria to mesenteric lymph nodes in the rat model, but its significance is unknown because translocation occurs in all rat strains and in the presence of metronidazole, tetracycline, and mutanolysin, which prevent hepatic injury.[80,81] Intravenous doses of lipopolysaccharide and SBBO (which increases serum lipopolysaccharide levels) worsened liver disease in rats with bile duct ligation.[87] The precise relevance of these animal models to humans remains speculative because in one study with eight adults with anaerobic colonic-type SBBO, only one patient had elevated γ-glutamyl transferase and alkaline phosphatase.[88]

Recently, Kaufman and colleagues showed that in patients with short-bowel syndrome, SBBO causes longer total parenteral nutrition dependency and correlates with small intestinal inflammation.[89] They noted that antibiotic therapy was not always successful, resulting in the use of other therapies, including saline enemas, polyethylene glycol (Golytely) infusions, and probiotics.[90]

IMMUNOLOGIC EFFECTS

Rats with self-filling blind loops produce high levels of luminal sIgA specifically targeted against colonic bacteria.[24] Luminal IgA2 and IgM are increased in humans, but IgG1–4 is not.[91] C4 is also not influenced by SBBO.[92] Interleukin-6 is elevated in the lumen of patients with SBBO, but tumor necrosis factor (TNF)-α and interferon-γ are not.[93] Interestingly, increased luminal levels of antigliadin IgA antibodies are observed in patients with SBBO.[94] Serum IgG3 levels are decreased in humans with SBBO but not other serum immunoglobulins and interleukin-2 receptor levels.[93] SBBO may reduce IgG3 in humans via an interaction with mucosa-related immunoregulatory mechanisms, a type of "tolerance."[95] In a rat model of monoarticular arthritis, the acute creation of SBBO reactivates arthritis that may be mediated by release of cytokines from the blind loop.[96] Interestingly, one study found that adults with rheumatoid arthritis have an increased incidence of SBBO.[97] In German shepherd dogs with SBBO, duodenal biopsies show increased TNF-α and transforming growth factor-β messenger ribonucleic acid expression that decreases after antibiotic treatment.[98] A single-dose of oral cholera vaccine administered to children results in less seroconversion when the children have SBBO.[99] Studies are, therefore, now showing that SBBO affects the local intestinal immune responses, which can have significant distant effects.

CLINICAL FEATURES OF SBBO

Clinical symptoms (Table 38.5-4) occur in approximately one-third of all patients.[56,100] In those who are symptomatic, clinical effects range from mild inconvenience to complaints that are both chronic and disabling. In general, overgrowth of bacteria in the proximal small bowel results in greater disability than overgrowth in the distal small intestine. SBBO may occur at any age, but relative deficiencies in mucosal defenses in the immature host may place the very young at increased risk.

Diarrhea is a common presenting symptom. Stools may be foul and greasy owing to steatorrhea or watery and explosive owing to maldigestion of dietary carbohydrates. In children, growth failure may be an important additional presenting clinical feature. Arrested weight velocity is usually the first feature to be noticed, but later a delay in height velocity and resultant short stature can appear. Nutritional debilitation is multifactorial. Appetite is frequently diminished. Diets may be restricted in an attempt to decrease stool frequency. Maldigestion of fat, dietary carbohydrate,[63] and protein[72] and increased intestinal losses of endogenous proteins[71] also contribute.

Clinical evidence of vitamin deficiency is rarely seen. Usually, vitamin B_{12} deficiency is prevented in the pediatric population by adequate body stores of cobalamin. Iron deficiency anemia can occur, however, secondary to enteric iron losses.[73] Osteomalacia, rickets, and pellagra-like symptoms each have been reported as a consequence of vitamin D malabsorption[101] and water-soluble B-vitamin[102] deficiency. Because luminal bacteria produce vitamin K and folic acid and these become available to the host, absorption may be enhanced. Serum folic acid levels may be elevated.[103]

Davidson and colleagues indicate that SBBO may be a cause of abdominal pain in young children owing to sec-

ondary carbohydrate intolerance.[104] De Boissieu and coworkers confirmed this observation in children under age 2 years and produced a dramatic improvement in diarrhea and abdominal pain using metronidazole and colistin.[105] Pimental and colleagues reported that 78% of 202 adults with irritable bowel syndrome had SBBO, and that eradication, using antibiotic therapy, reduced clinical symptoms.[106] Others have commented that, by definition, irritable bowel syndrome is not associated with underlying intestinal pathology, so these patients may not truly have irritable bowel syndrome.[107,108]

Recurrent episodes of arthralgia, nondeforming polyarthritis, tenosynovitis, and cutaneous vasculitis (the arthritis-dermatitis syndrome) occur commonly following intestinal bypass operations but also have been reported in other forms of SBBO.[85,109] Skin lesions are typically vesiculopustular or erythema nodosum–like. Paresthesias and Raynaud phenomenon are common. Renal damage[110] and hepatic steatosis[111] have also been reported following jejunoileal bypass surgery and could conceivably appear in other forms of SBBO. SBBO may affect drug metabolism. The half-life of antipyrine is increased by 78% in rats with SBBO.[112] Oral digoxin bioavailability is decreased owing to bacterial degradation.[113] A case of pneumoperitoneum and ascites was reported secondary to SBBO.[114]

LIVER DISEASE AND SBBO

Many studies have reported that liver disease is associated with SBBO in humans. Dame Sheila Sherlock first described this relationship in alcoholics.[115] Subsequent studies confirmed this finding and extended it to other causes of liver disease, including viral hepatitis.[116,117] These studies show that the incidence of SBBO increases with the severity of liver disease and may exceed 50% in patients with Childs-Pugh Class C liver disease.[116,117] Data suggest that the incidence of spontaneous bacterial peritonitis (SBP) increases with SBBO, but both SBP and SBBO are more frequent as liver disease worsens.[118] Runyon and colleagues used a rat model of cirrhosis to show that increased bacterial translocation is associated with SBBO, with or without SBP.[119] They postulated that the first step toward SBP is SBBO, which causes translocation of bacteria, and then local factors (such as ascites and ascitic complement levels) ultimately determine whether SBP will occur.[119] Chang and colleagues showed that risk factors for SBP in humans were lower serum C_3 and C_4 concentrations, lower ascitic total protein, and SBBO.[120] The incidence of SBBO in patients with SBP was 68% compared with a frequency of only 17% SBBO in cirrhotics without SBP.[120] However, two other groups, although confirming that adult cirrhotics had a higher incidence of SBBO than noncirrhotics, could not correlate SBBO with SBP.[121,122] In another study of adults with cirrhosis, a 6-month treatment trial with cisapride (n = 12) or antibiotics (neomycin and norfloxacin; n = 12) enhanced small bowel motility, diminished SBBO, and was associated with slightly improved liver function.[123] Finally, as interest in nonalcoholic steatohepatitis increases,[124] Wigg and colleagues showed that patients with nonalcoholic steatohepatitis have a 50% prevalence of SBBO compared with only 22% of controls.[125] No study of SBBO in the setting of liver diseases in children has yet been published.

DIAGNOSIS OF SBBO

A well-directed medical history often provides important clues to indicate that a more detailed investigation related to the possibility of underlying bacterial contamination of the small intestine is warranted. A history of previous abdominal surgery should always be sought because SBBO owing to either alterations of intestinal motility or the creation of anatomic regions of intestinal stasis can occur as a long-term adverse complication of intestinal surgery. Specific surgical procedures that affect normal nonimmunologic host defenses may also predispose the patient to SBBO. For example, interruption of the vagus nerve inhibits output of gastric acid and thereby can result in an increase in the load of viable organisms that enter into the proximal small intestine. Similarly, signs and symptoms suggestive of systemic disease—in particular, collagen vascular diseases—should be explored in a detailed history. Long-standing diabetes mellitus can result in alterations in intestinal motility owing to an autonomic neuropathy. Although not uncommon in adults, SBBO owing to autonomic dysfunction is very unusual in children with diabetes mellitus. This age-related difference may simply relate to the duration of the underlying chronic disease.

Table 38.5-5 summarizes alternatives that are useful in establishing the diagnosis of clinically significant bacterial overgrowth. Not all patients with overgrowth of bacteria in the small bowel have clinical symptoms. Therefore, an initial evaluation should be directed toward first determining if there is evidence of malabsorption of either fat or cobalamin (vitamin B_{12}). Serum levels of cobalamin are not, in general, a useful screening test for SBBO in children because body stores of the vitamin are sufficient to maintain normal circulating levels for at least 5 years after the onset of cobalamin malabsorption in the gut. Elevated levels of folic acid may be useful as a screening test.

In the appropriate clinical setting, abnormal values of quantitative fecal fat excretion, Schilling test with intrinsic factor, and serum folate indicate the need for more detailed investigations to establish a diagnosis of bacterial overgrowth. Although some physicians would proceed directly to an empiric course of antibiotic therapy, it should be emphasized that clinical symptoms and abnormalities in screening laboratory tests are not specific to this diagnostic consideration.

A barium meal with follow-through should be performed to document the presence of intestinal strictures, diverticula, and delayed intestinal transit. Abnormalities in the radiologic study should prompt more extensive, directed investigations. A normal barium meal study does not exclude the presence of clinically significant bacterial overgrowth in the small intestine. A biopsy of the duodenum should also be obtained because the presenting symptoms of gluten-sensitive enteropathy in children can mimic

SBBO. Patchy enteropathic changes with increased numbers of inflammatory cells are typical of SBBO.

Specific Diagnostic Tests

Quantitative culture of increased numbers of anaerobic bacteria in luminal fluid obtained from the proximal small intestine establishes the diagnosis of SBBO. The presence of more than 10^6 colony-forming units/mL of bacteria that are not typical residents of the oral cavity is an abnormal finding. Documentation of coliforms and anaerobic colonic-type bacteria is important because these bacterial species normally do not reside in the mouth or stomach and do not colonize the upper human small intestine. However, the culture of duodenal fluid as a diagnostic technique is not without its problems. Many hospitals do not have bacteriology laboratories with the ability to routinely culture fastidious strict anaerobes. Fortunately, the presence of more than 10^6 colony-forming units of facultative anaerobic bacteria, such as *Escherichia coli* strains, is relatively good evidence of associated colonization by strict anaerobic bacteria. Therefore, quantitative duodenal cultures should be performed even if one lacks anaerobic culture facilities. When culture of duodenal aspirates was compared with that of gastric aspirates and duodenal biopsies in 75 adults, duodenal aspirates proved to be significantly more sensitive.[126]

Neither duodenal aspiration nor quantitative bacterial estimation is easily performed. A great deal of investigation, therefore, has been focused on establishing the utility of other diagnostic techniques. Two alternative tests that depend on the detection of bacterially derived products (unconjugated bile acids and short-chain fatty acids) may be performed on duodenal aspirates: (1) determination of conjugated and deconjugated bile acid profiles in duodenal fluid[127] and (2) assay of duodenal fluid for the presence of short-chain, volatile fatty acids (ie, acetic, propionic, butyric, isobutyric, valeric, and isovaleric).[128,129] Each test may be helpful, if decidedly abnormal, but neither has been evaluated fully.

Duodenal aspiration is relatively invasive, and sedation or physical restraint is usually required in children to permit the passage of an aspiration tube through the oral cavity into the upper small bowel. Because fluorography is often used to establish localization of the catheter tip, a small dose of radiation is frequently required. The string test is not an accurate substitute for duodenal intubation.[130] Accurate, noninvasive diagnostic methods are, therefore, an attractive alternative. Although the optimal noninvasive diagnostic probe for use in children has not yet been defined, a number of options are available. Measurement of elevated urinary indican, produced by the conversion of dietary tryptophan to indican by intraluminal bacteria, is perhaps the simplest technique. Specificity is low, however, because indicanuria is not limited to bacterial overgrowth in the small intestine.[131]

Konishi and colleagues used a newly synthesized conjugate of monophosphated ursodeoxycholic acid with 5-aminosalicylic acid (5-ASA) monophosphate to diagnose SBBO in rats with surgical blind loops.[132] They found an elevation of urinary acetylated 5-ASA in rats 24 hours after oral administration.[132] This test has potential for future use in humans, with the intent of eliminating the need for obtaining duodenal aspirates.

Provided that the technique is available, a relatively simple quantitative estimate of serum conjugated and free bile acids may be helpful. Total serum bile acids are often elevated in patients with SBBO, and almost all of the increase is represented by free bile acids, which are normally present in trace amounts.[133] Individual bile acid profiles show that deoxycholate is uniquely elevated, a finding that distinguishes SBBO from ileal resection, which is also associated with high serum levels of free bile acids.[133,134]

A number of studies have examined the utility of various breath tests as diagnostic tools (Table 38.5-6). Measurement of carbon 14 in expired air following oral ingestion of an appropriate substrate, which is conjugated to the radioisotope, appears to be an excellent alternative for noninvasive diagnostic purposes. ^{14}C-labeled bile acids, such as glycocholate, were the first substrates to be used.[135] Use of the substrate by luminal bacteria releases ^{14}C, which then equilibrates within the tissues of the host and is excreted from the lungs as $^{14}CO_2$ in expired air. A negative test may occur if the bacteria are not able to deconjugate bile acids.[136] In fact, several different breath tests may be required to detect SBBO because of the different metabolic capabilities of the contaminating flora.[137] False-positive results may occur in patients with mucosal inflammation affecting the distal ileum. Several reports indicate that ^{14}C-labeled D-xylose is superior to ^{14}C–bile acid as substrate.[138,139] Improvement in the ^{14}C–D-xylose breath test may be possible by incorporating transit time markers.[140] Another group showed that combination of the lactulose breath hydrogen test with urinary *p*-aminobenzoic acid (PABA) collection following ursodeoxycholic acid–PABA increases the chance of diagnosing SBBO.[141] Urinary cholyl-PABA excretion is a reliable test in adult patients with SBBO and correlates well with the D-xylose breath test.[142] Unfortunately, the use of ^{14}C is not satisfactory for use in diagnostics for children. Stable isotopes, such as ^{13}C-substrate,[143] have been used to study children. For

example, in six patients with known SBBO, 50 mg of ^{13}C-xylose produced a maximum breath $^{13}CO_2$ with 100% sensitivity but only 67% specificity.[144]

Measurement of hydrogen (H_2) levels in samples of expired air provides an alternative approach that is currently applicable to the pediatric population. Mammalian cells do not produce H_2, whereas many prokaryotes produce it as a by-product of substrate use. The commensal colonic bacteria are generally excellent H_2 producers. The H_2 is absorbed and distributed throughout the body and is subsequently expired in the breath. Provision of a nonabsorbable sugar, such as lactulose, supplies substrate to the colonic microbial flora and results in an increase in levels of expired H_2.[145] If a colonic type of microflora is present in the small intestine, an early H_2 peak is observed following lactulose challenge (Figure 38.5-4). Absorbable carbohydrates, including lactose[146] and D-glucose,[147] may also prove useful as substrates in testing for SBBO by measurement of breath H_2. However, the glucose breath hydrogen test correlated poorly with duodenal cultures in one study of 40 cirrhotic patients.[148]

Perman and colleagues reported that elevations in the fasting level of breath H_2 in children correlate with the presence of SBBO.[149] Previous meals containing nonabsorbable carbohydrates[150–152] and endogenous glycoproteins,[153] however, may elevate fasting breath H_2 and cause false-positive results. In children, however, a breath H_2 level of greater than 42 ppm was seen only in those with SBBO.[149]

Breath H_2 testing has shortcomings, however, which may limit its effectiveness. For instance, Douwes and colleagues reported that 9.2% of 98 healthy school-age children who were tested were non-H_2 producers.[154] Children with diarrhea and low fecal pH have an altered intestinal flora that may not yield H_2 in expired air samples.[155–157] Concurrent use of medications, particularly antibiotics,[158] also affects bacterial fermentation of test sugars, which can lower breath H_2 levels. A clear separation of "early" and "late" H_2 peaks following lactulose ingestion can be affected by the rate of gastric emptying and by intestinal transit time. In practice, two distinct peaks are often not documented.[159] Riordan and colleagues showed that the lactulose breath test was only 16% sensitive and 70% specific, and the double peak was frequently missing in cases of proven SBBO.[160] The same group also found that sensitivity for the rice-based breath hydrogen test was only 33% and did not provide a suitable alternative to culture of duodenal aspirates.[161] One study in adults found that a single resting breath hydrogen test was unreliable.[162] Several reports indicate that the normal microbial flora of the oral cavity also can contribute to the fermentation of carbohydrate substrates and produce modest elevations in the levels of H_2 in expired air.[163,164]

Breath H_2 tests require careful attention to technical details, which are sometimes difficult to reproduce. End-expiratory samples are most representative, but they are often difficult to obtain in toddlers and preschool-age children. Flow-through appliances that allow collection through a face mask are available and appear to be more readily tolerated.[165,166] Storage of collected samples in appropriate sealed containers is also critical for accurate results.[167,168] Although breath tests are more convenient, Corazza and colleagues documented their inferiority compared to jejunal cultures; the glucose breath test yielded a sensitivity of just 62% and a specificity of only 83%.[169]

Comparative studies in adults suggest that ^{14}C–D-xylose is the most appropriate substrate for use in breath testing.[138,159] The comparative sensitivity and specificity of other noninvasive diagnostic assays that are more suitable for use in children have not been clearly defined. However, comparison of a 1 g ^{14}C–D-xylose breath test with the 50 g hydrogen glucose breath test showed that the hydrogen glucose breath test was slightly more sensitive for detecting bacterial overgrowth.[170]

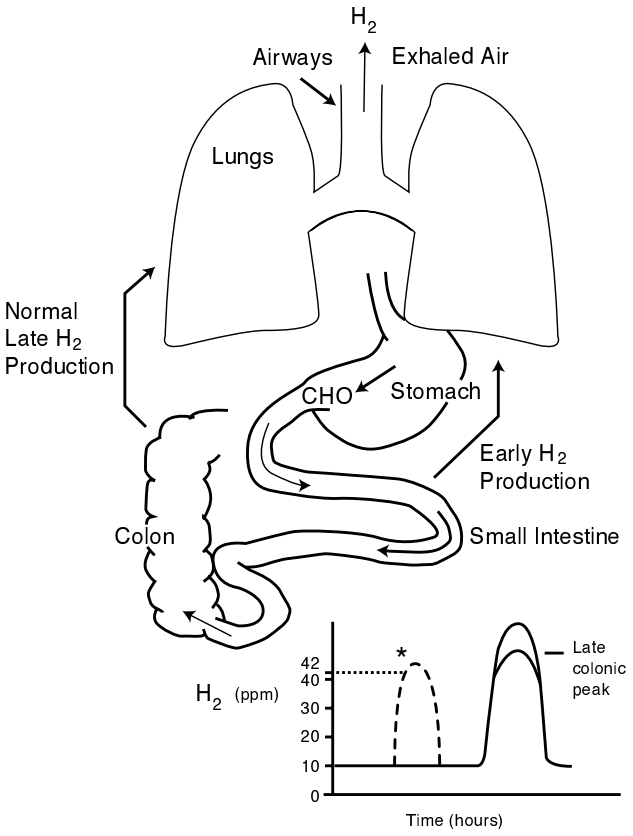

FIGURE 38.5-4 Conceptual framework for breath hydrogen testing. CHO denotes ingesting carbohydrate. *An early peak and an elevated baseline of hydrogen measured in expired breath samples are both suggestive of small bowel bacterial contamination.

TREATMENT

Correction of the Underlying Disease

As illustrated in Table 38.5-2, there are multiple causes of SBBO, some of which are potentially treatable by surgery. Reports of surgical correction include an ileal carcinoid tumor causing obstruction,[171] a large Meckel diverticulum,[172] and an ischemic jejunal stricture following blunt trauma to the abdomen.[173] Gastrointestinal, gastrocolic, and jejunocolic fistulae and intestinal strictures that occur following radiation or surgery or in Crohn disease are also amenable to surgery. The fact that some cases of SBBO can be cured by surgical intervention emphasizes the importance of investigating each patient carefully for such lesions.

Other cases may be improved by treatment of the primary disease, such as, for example, by employing the use of corticosteroids in patients with symptoms of active Crohn disease. When disordered motility is the primary problem, as in diabetes mellitus, scleroderma, and intestinal pseudo-obstruction, pharmacologic agents occasionally may prove effective. Cisapride, a prokinetic agent, can, for example, improve motility patterns in some patients with diabetic neuropathy[174] and certain forms of intestinal pseudo-obstruction.[175] The long-acting somatostatin analog octreotide stimulates propagative phase 3 motor activity in the duodenum of patients with scleroderma, which can result in decreased symptoms of SBBO and reduce bacterial counts in the proximal bowel.[176] SBBO associated with scleroderma has also been treated successfully with antibiotics.[177]

Supportive Therapy

Careful attention should be given to ongoing nutritional and metabolic complications. Nutritional deficits should be anticipated and prevented by using appropriate supplements. Energy intake may be limited by anorexia, abdominal pain, and malabsorption. Easily digestible nutritional supplements, which are low in fat, may be required to maintain normal growth and development. Medium-chain triglycerides have been advocated[56,171,178] and may be helpful. In intractable situations, such as occur in the pseudo-obstruction syndromes, enteral nutrition with elemental formulae or parenteral nutrition should be employed to maintain growth. Because the course of these diseases can be unpredictable, marginal improvement may eventually allow an adequate oral intake to meet nutritional requirements.

Clinical evidence of vitamin deficiency is rare, but fat-soluble vitamin deficiencies have been reported in patients with SBBO, including a striking case of neurologic deterioration owing to vitamin E deficiency,[179] night blindness owing to vitamin A deficiency,[180] and osteomalacia owing to vitamin D deficiency.[101,181] Patients with steatorrhea should receive fat-soluble vitamins. A good rule is to follow the recommendations for cystic fibrosis outlined in Chapter 68, "Liver Biopsy Interpretation."

Vitamin B_{12} deficiency is rare in children because of the time required to deplete body stores. It is correctable by monthly injections of cyanocobalamin. Anemia may also require treatment with supplemental iron to correct iron deficiency secondary to enteric losses.[73] Treatment with iron may unmask a coexistent and unrecognized macrocytic anemia. B vitamins, vitamin K, and folic acid are normally not depleted by bacteria, which may, indeed, add to host supplies. Tabaqchali and Pallis reported a very interesting case of nicotinamide deficiency that developed in an elderly patient with multiple jejunal diverticula, steatorrhea, and severe protein malnutrition several weeks after apparently successful treatment with protein infusions and antibiotics.[102] The sudden elimination of nicotinamide-producing bacteria in the upper intestine may have precipitated pellagra. The possibility of sudden loss of a vitamin source should be considered whenever evidence of deficiency appears during treatment.

Antibiotic Therapy

A variety of antibiotics have been used to treat SBBO successfully, but large studies comparing different antibiotics and protocols do not exist. The specific mechanisms by which antibiotics reverse different pathophysiologic events, such as disaccharide intolerance, protein-losing enteropathy, and steatorrhea, have not been entirely explained. Goldstein and colleagues stressed the importance of culturing intestinal contents to determine which antibiotic was most effective in treatment.[182] They found that antibiotics effective against aerobes reduced both aerobic and obligate anaerobic bacterial counts. Aerobes lower oxygen tension and maintain low oxidation-reduction potentials (E_h), thereby allowing anaerobes to thrive. When broad-spectrum antibiotics are successful, they may work by altering the intestinal microecology to reduce the growth of a critical organism. Beeken and Kanich also advocate the measurement of antibiotic sensitivities to plan treatment of SBBO in patients with Crohn disease.[183] Bouhnik and colleagues state that this should be done in all patients with SBBO.[184] On the other hand, because no single organism is responsible for all of the abnormalities that occur in SBBO, other investigators believe that isolation of organisms and testing for antibiotic sensitivity are not necessary.[178]

Table 38.5-7 summarizes a number of studies in which the antibiotic treatment of SBBO was evaluated by at least one objective parameter. Antibiotics have rarely been compared for effectiveness in the same group of patients. Barry and colleagues showed, however, that metronidazole was superior to kanamycin when evaluated in five patients with pseudo-obstruction.[185] In the table, total aerobic and anaerobic bacteria counts were reported in four separate studies in which jejunal cultures were obtained.[71,185,186,187] In three studies, bacterial counts decreased using antibiotic therapy, but in the fourth study, which used metronidazole,[186] only 1 of 12 patients had lower bacterial counts, although the drug was clinically effective in most patients. A similar discrepancy between bacterial counts and clinical outcome was observed in rats with experimentally induced SBBO treated with chloramphenicol.[15] Although total anaerobic counts were unchanged, *Bacteroides* species virtually disappeared, suggesting that the effectiveness of antibi-

Mixed	10	Breath H_2, stool number	Norflox (9); Amox-Clav (6); Saccharo (0)	ND	191

Amox = amoxicillin; Chlor = chlortetracycline; Clav = clavulanic acid; Fluclox = flucloxacillin; Kan = kanamycin; Linc = lincomycin; Metr = metronidazole; ND = not done; Neo = neomycin; Norflox = norfloxacin; Rifax = rifaximin; Saccharo = *Saccharomyces boulardii*; Sulf = sulfisoxzole; Tetr = tetracycline.

otics against that organism may be crucial. The antibiotic responses shown in Table 38.5-7 are generally consistent with the crucial role of anaerobes, particularly *Bacteroides*, in the pathogenesis of SBBO. Patients improve on tetracycline, metronidazole, trimethoprim-sulfamethoxazole, lincomycin, and broad-spectrum antibiotics, whereas kanamycin and neomycin, two antibiotics to which *Bacteroides* is generally resistant, have proven ineffective. *Bacteroides* also plays a crucial role in experimentally produced SBBO. Welkos and colleagues showed that kanamycin and penicillin lowered the number of aerobic bacteria in rats with self-filling blind loops but did not reverse vitamin B_{12} malabsorption.[188] By contrast, metronidazole greatly diminished *Bacteroides* counts and corrected the vitamin B_{12} malabsorption. Subsequently, *Bacteroides* species were shown to bind to intrinsic factor–vitamin B_{12} complex much more avidly than to five aerobic bacteria and seven other anaerobic bacterial species.[188]

These and other studies suggest that the most appropriate therapeutic approach is to choose an antibiotic that is effective against *Bacteroides*, such as tetracycline, metronidazole, chloramphenicol, or lincomycin. Of these four antibiotics, metronidazole is the least likely to cause untoward side effects in children and is probably the antibiotic of choice for initiating treatment. An initial course of 2 to 4 weeks duration may be followed by clinical improvement lasting many months. If relapse occurs, a second course of the same antibiotic for a longer period (4–8 weeks) may be tried. Relapse or persistence of steatorrhea, vitamin B_{12} malabsorption, or other complications may be amenable to relatively continuous antibiotic administration, accompanied by periodic alternation with broad-spectrum antibiotics, such as trimethoprim-sulfamethoxazole or gentamicin. Chloramphenicol and lincomycin should be reserved for cases in which other antibiotics have failed.

A nonabsorbable derivative of rifamycin, rifaximin, was shown to be effective in treating SBBO.[189] Using breath hydrogen following a 50 g glucose load as an indicator of SBBO, rifaximin for 7 days normalized breath tests in 70% of subjects compared with chlortetracycline, which normalized breath tests in only 27%.[190] Norfloxacin and amoxicillin–clavulanic acid decreased diarrhea and improved breath hydrogen tests in a randomized crossover trial of 10 patients with SBBO.[191]

Increasingly, probiotics are becoming a therapeutic tool for use in a variety of gastrointestinal disorders. One study failed to show improvement in 17 patients with SBBO following treatment with *Lactobacillus fermentum*.[192] In contrast, there was some success reported in eight hemodialysis patients with SBBO by using the probiotic agent *Lactobacillus acidophilus*.[44] In another study, 22 patients with proven SBBO were treated with either a combination of *Lactobacillus casei* and *Lactobacillus acidophillus* (n = 12) or placebo (n = 10).[193] Probiotic treatment improved stool frequency and glucose breath hydrogen test results but did not improve the patients' other symptoms. Use of *Saccharomyces boulardii* failed to provide clinical benefit in an open trial of 10 patients with SBBO.[191]

CHAPTER 39

GASTROINTESTINAL MANIFESTATIONS OF IMMUNODEFICIENCY

1. *Primary Immunodeficiency Diseases*

Olivier Goulet, MD, PhD
Ernest G. Seidman, MD, FRCPC, FACG

The importance of the intestine as an immune barrier is highlighted by the intimate proximity of the gut-associated lymphoid tissue (GALT) to the luminal surface of the gastrointestinal (GI) tract, an external environment rich in microbial pathogens and dietary antigens. Thus, it is not surprising that there is a strong clinical relationship between immunodeficiency (ID) states and significant GI disorders.[1,2] ID states are usually classified as primary or secondary disorders. The best known among the latter acquired type is the ID resulting from infection by human immunodeficiency virus (HIV) type 1 and its outcome, acquired immune deficiency syndrome (AIDS) (see Chapter 39.2, "HIV and Other Secondary Immunodeficiencies"). Past decades have seen enormous progress in the field of primary ID. More than 70 different primary IDs are now described in the world's literature. This chapter presents an approach to the GI complications of primary ID. Most primary IDs are diagnosed in infants and children and, therefore, are managed by pediatricians and pediatric gastroenterologists. Advances in the treatment of these diseases have also been impressive. Antibody replacement, cytokine, and humanized anticytokine are now possible through recombinant technologies. The ability to achieve lifesaving immune reconstitution of patients with lethal combined ID by administering rigorous T cell–depleted allogeneic related haploidentical bone marrow stem cells has extended this option to virtually all such infants if diagnosed before untreatable infections develop. Finally, the past few years have witnessed the first truly successful gene therapy. Therefore, it is imperative that pediatric gastroenterologists have a high index of suspicion for these problems in that such patients will present to them in consultation early. Early diagnosis and treatment of patients are vital, allowing most pediatric patients affected by primary ID now to survive into adulthood.[3]

INTESTINAL MUCOSAL IMMUNE SYSTEM

The mucosal membranes that line the respiratory, digestive, and urogenital tracts, as well as the conjunctiva, ear, and ducts of exocrine glands, are constantly exposed to environmental factors. Complex protective systems have been elaborated to defend the host against pathogens, toxins, and allergens. There is a wide array of innate and specific acquired immune mechanisms that normally operate in forming a mucosal barrier to protect the host.[1]

The fetal intestine plays an important role in the ontogeny of both the cellular and humoral immune systems. Postnatally, the human intestine develops histologic characteristics of a secondary lymphoid organ. Lymphoid follicles, germinal centers, small lymphocytes, and plasma cells are abundant. This association demonstrates the critical role of the immune system in maintaining GI homeostasis. Not only are GI abnormalities frequently encountered in patients with ID syndromes, they are also occasionally severe enough to become the patient's presenting complaint. Furthermore, primary intestinal diseases may secondarily cause substantial losses of immune system components so as to induce a secondary ID.

Nonimmune host defense factors, in addition to the major contribution by the GALT, are known to play an important role in mucosal protection against the abundant, potentially noxious antigens and pathogens present in the gut lumen. These include bactericidal fluids such as gastric

acidity and proteases, intestinal motility, the mucus-glycocalyx, and the normal intestinal flora.[1,2] These adjunctive mucosal defense mechanisms may explain why major deficiencies in either the humoral or cell-mediated immune system can exist without the presence of significant GI symptoms.

Recurrent, persistent, severe, or unusual infections are the hallmark of ID states. Chronic diarrhea, often associated with malabsorption and concomitant failure to thrive, is characteristic of several of the ID syndromes. Paradoxically, autoimmune diseases and/or excessive production of immunoglobulin (Ig)E antibodies also characterize many ID syndromes. As discussed below, there is also an increased incidence of malignancies in patients with certain ID states.[2]

COMPONENTS OF THE IMMUNE RESPONSE

An immune response consists of two components: a specific response to a particular antigen and a nonspecific augmentation of the effect of that response (Table 39.1-1). Specific immune responses may be divided into humoral and cellular responses. Humoral responses result in the generation of antibodies reactive with a given antigen. In contrast, cell-mediated responses involve the induction of specific effector cytotoxic cells or the secretion of cytokines that trigger inflammation (Table 39.1-2). Thymectomized animals, or congenitally athymic animals (including humans), have grossly impaired cell-mediated responses yet are able to generate some antibodies. In contrast, children incapable of making antibodies may be able to mount cell-mediated responses. They appear to handle many viral and fungal infections and can even reject grafts. The thymus-dependent cells (T cells) and the antibody-producing lymphocytes (B cells) are the key cells involved in specific immune responses (Figure 39.1-1). The latter may be considered to involve two phases. First is the recognition phase, involving antigen-presenting cells (APCs) (dendritic cells, macrophages, and B cells) and T cells that recognize the antigen as foreign. The effector phase then ensues, in which antibodies (B-cell products) and effector T cells eliminate the antigen.[1]

The nonspecific effector component of the immune response includes certain factors that can augment the effects of antibody, and some of these factors are older, in evolutionary terms, than antibody production itself. The major factors are phagocytic cells (macrophages and polymorphonuclear leukocytes), which remove antigens (including bacteria), and complement, which can either directly destroy an organism or facilitate its phagocytosis.

Humoral immunity depends not only on antibody synthesis but also on effector mechanisms that eliminate antigen bound to antibody. Microorganisms coated (ie, opsonized) with IgG antibodies are readily bound and ingested by phagocytic cells. Complement-dependent lysis of bacteria needs a functioning complement pathway and a complement-fixing antibody. Thus, specific immunity requires nonspecific effector mechanisms for its efficient operation.

The primary ID syndromes are a heterogeneous group of relatively rare diseases that result in failure to manifest an efficient immune-mediated inflammatory response, accompanied by repeated bacterial, fungal, and viral infections of variable severity (see Table 39.1-1). An ID may involve any of the components of the immune system, including lymphocytes, phagocytic cells, and complement proteins, as described in detail below.

CELLULAR BASIS OF THE SPECIFIC IMMUNE RESPONSE

T Cells

The progenitors of immunocompetent cells are derived from the lymphoid stem cell, whose nature still remains unclear. Within the thymus, bone marrow precursor T cells are induced to express thymus-associated surface antigens (glycoproteins) that serve as differentiation markers, as well as antigen receptors. A network of epithelial cells in the thymic cortex and in Hassall corpuscles secretes soluble thymic "factors" needed for functional T-cell maturation. Each T cell is committed to a given antigen, which it recognizes by one of two types of T-cell receptors (TCRs), depending on the cell's lineage. The T cells have either TCR1, composed of γ and δ chains (determined early in ontogeny), or TCR2, another heterodimer of α and β chains. The TCR2 cells predominate in adults, although 10% of T cells in epithelial structures bear TCR1. The TCR is closely associated on the cell surface with the CD3 protein responsible for transmitting the antigen recognition signal inside the cell (transduction). Nearby accessory molecules, such as lymphocyte function antigen (LFA)-1, CD2, CD4, and CD8, are responsible for increased leukocyte adhesion. The CD4 and CD8 proteins,

TABLE 39.1-2 LYMPHOCYTE SUBGROUPS, CYTOKINE PROFILES, AND THEIR FUNCTION

CELL POPULATION	CYTOKINES	FUNCTIONS
Th1	IL-2, IFN-γ, TNF	Initiation and augmentation of inflammatory reactions Enhance MHC expression
Th2	IL-3, IL-4, IL-5, IL-6, IL-10, IL-13	Enhance B-cell antibody production Inhibit Th1 cytokine production
Tc	IFN-γ	Enhance MHC expression; activation of NK cells; lysis of antigen target
Ts	Suppressor factor(s)	Suppress Th and Tc cells
B	Antibody: IgM, IgG, IgA, IgE, IgD, IL-10	Neutralization, opsonization, cell lysis Inhibit Th1 cytokine production

IFN = interferon; Ig = immunoglobulin; IL = interleukin; MHC = major histocompatibility complex; NK = natural killer; Tc = cytotoxic T cell; Th = T helper cell; TNF = tumor necrosis factor; Ts = suppressor T cell (may not be a distinct subpopulation).

present (predominantly) on TCR2 cells, recognize histocompatibilty antigens. Class II molecules show restriction for the antigen receptor of $CD4^+$ T cells and class I molecules for the TCR of $CD8^+$ T cells.

Lymphocytes initiate specific immune responses and possess immune memory. Some are involved in recognition, whereas others carry out effector functions. Effector T lymphocytes have several different functional activities. They may cause the death (cytotoxicity) of antigenic cells or initiate inflammation in response to an antigenic stimulus (delayed-type hypersensitivity). Other T cells have a regulatory rather than an effector role. The T-lymphocyte subpopulations can be classified into helper (Th) and suppressor (Ts) or cytotoxic (Tc) groups. Two types of Th cells, defined by their cytokine secretion patterns, have been described in the mouse (see Table 39.1-2). The Th1 cells generally secrete cytokines, which activate other T cells (interleukin [IL]-2), natural and cytotoxic T cells (interferon [IFN]-γ), and other inflammatory cells (tumor necrosis factor [TNF]). The Th1 cells are thus particularly effective against intracellular infections with viruses and organisms that grow in macrophages.[1] On the other hand, Th2 cells secrete those cytokines that activate B cells (IL-4, IL-5) or induce T cells and hematopoietic cells (IL-6) to grow and differentiate. Several other cytokines are secreted by both types of Th cells. The Th2 cells are excellent helpers for antibody production and, in the absence of Th1 cells, will induce high IgE levels owing to IL-4 production. They are well adapted for defense against parasites.

Although Th1 cells can provide help for antibody production, excessive Th1 activation inhibits B-cell activation. The Th1 cells induce a strong delayed-type hypersensitivity

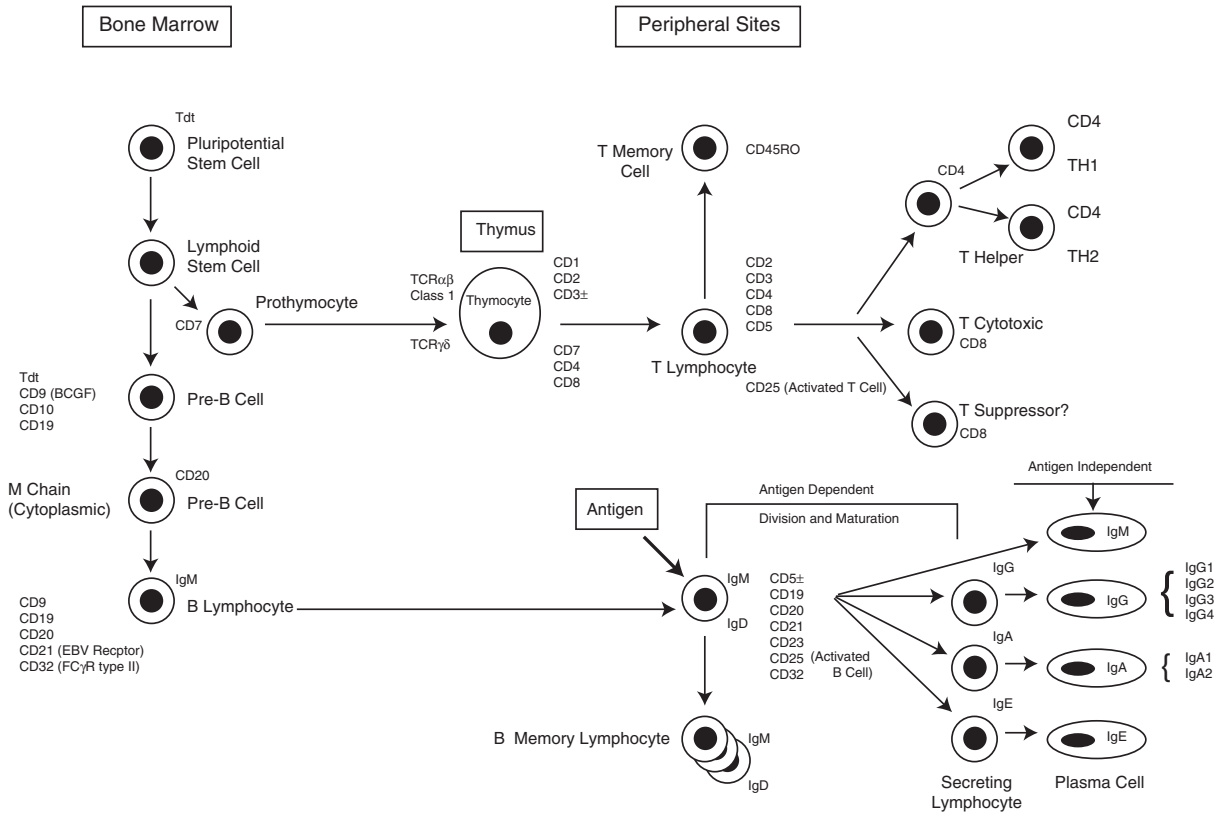

FIGURE 39.1-1 Maturation of T and B lymphocytes. Ig = immunoglobulin.

reaction, and IgE production is inhibited at all levels of Th1 activation owing to IFN-γ production. T-cell functions of help or suppression may depend on various stimuli, resulting in different cytokines being produced, with predominantly activating or inhibitory effects. Only Th cells that have responded to antigen presented by macrophages can subsequently help B cells already committed to that antigen. The effects of Th cells are balanced by those of functional Ts cells. Such Ts cells carry the characteristic surface glycoprotein CD8. Suppression by T cells is only partly understood. These cells are activated by an antigen and release factors that mediate suppression, which may be antigen specific or nonspecific. The $CD8^+$ T cells also include Tc cells, which lyse cells infected with virus in a specific manner. The Tc cells recognize viral antigens together with major histocompatibility complex (MHC) class I molecules. All endogenous antigens (including viral antigens) are presented in the context of MHC class I antigens. This combination probably activates $CD8^+$ T cells and certainly provides target cells for virally induced T-cell cytotoxicity and, consequently, a potential mechanism for autoimmune damage. Cytotoxic T cells play a role in graft rejection, in which Tc cells mature and are able to lyse target cells carrying the MHC class I molecules of the stimulating cells.

Antigen-Presenting Cells

Antigen is processed by specialized cells and then carried and "presented" to lymphocytes. Such specialized cells are known as APCs (Figure 39.1-2). The T cells cannot recognize antigen without such processing. Because activation of T cells is essential for most immune responses, antigen processing is a crucial step. The efficiency of T-cell activation is enhanced by the secretion of cytokines such as IL-1 by the APCs previously activated by antigen. The most efficient APCs are the interdigitating dendritic cells found in T-cell regions of lymph nodes. APCs are able to move about, and increased numbers are found in inflamed sites. Their recruitment is due to the adhesion molecules expressed on their surface that bind to receptors in the target sites. Follicular dendritic cells trap immune complexes that contain antigen and process and express it closely associated with MHC class II molecules on their surface. Class II molecules themselves determine the responsiveness of an individual to a particular foreign antigen because they interact with the antigen before T-cell help can be triggered. Macrophages in gut, Kupffer cells in liver, and astrocytes in brain, as well as activated B cells and intestinal epithelial cells, are also able to present antigen to T cells. Additional stimuli are provided by the binding of adhesion molecules on the cell surfaces of lymphocytes and APCs. For example, the LFA-3 on the APC binds to CD2 on the Th, giving an additional signal for activation. Likewise, intercellular adhesion molecule (ICAM)-1 binds to LFA-1 on the T-cell surface. Other cell to cell interactions, such as T-cell effector with a B lymphocyte or Tc cell and its target, are also enhanced by these molecules. Following the interaction of the TCR with antigen presented in association with MHC molecules, T cells become acti-

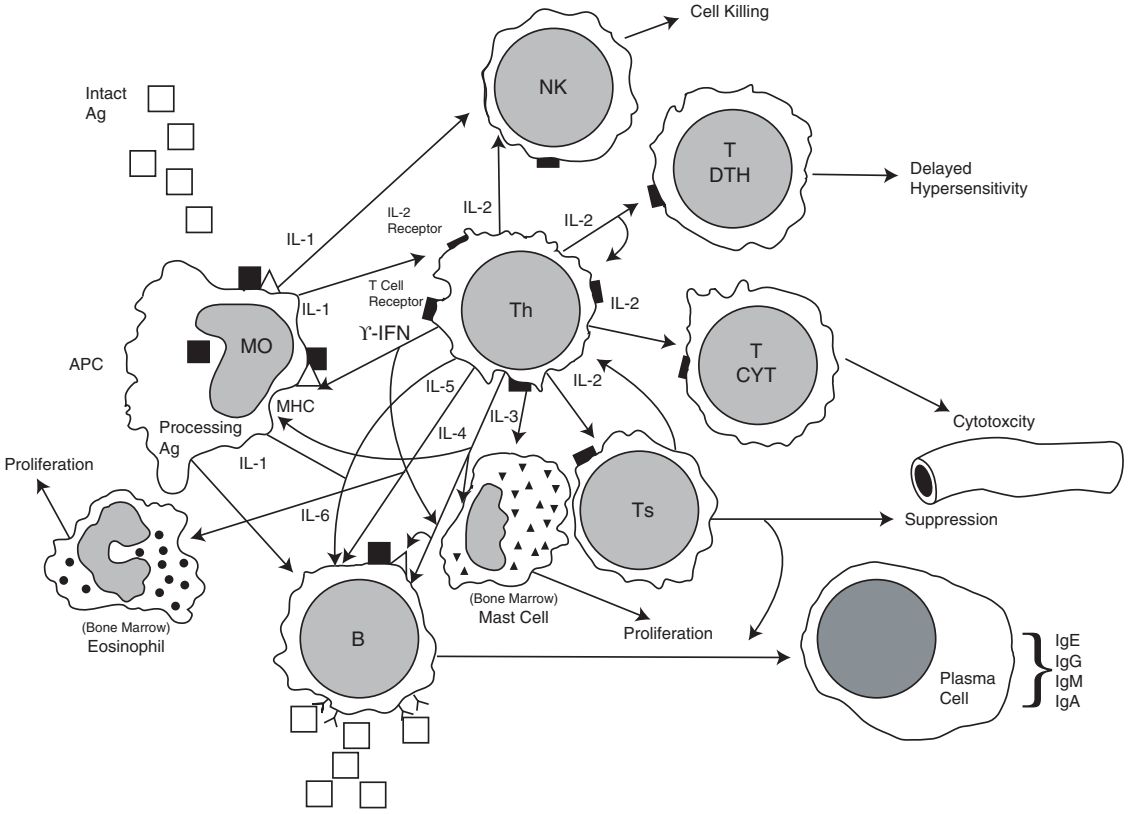

FIGURE 39.1-2 Cytokines and the immune response. vated to produce cytokines, such as IL-2, and to express IL-2 receptors. The subsequent interaction of IL-2 with its receptor is a critical step in immune regulation and is required for many effector and regulatory T-cell functions (see Figure 39.1-2).

B Cells

The B-lymphocyte development begins within the fetal liver and subsequently continues in the bone marrow (see Figure 39.1-2). Precursor cells give rise to a rapidly dividing population of pre-B cells that lack Ig receptors but produce cytoplasmic heavy chains. The next differentiation stage is characterized by immature surface Ig–bearing B lymphocytes that express IgM, which are already committed to the specificity of the antibodies that they and their plasma cell progeny will secrete. Most B lymphocytes then further mature and acquire surface IgD. During subsequent development of isotype diversity, one of the subclasses of IgG (1 to 4), IgA (1 to 2), or IgE is expressed by separate subpopulations of B cells, which then lose their surface IgM and IgD (see Figure 39.1-1). The maturation sequence of B cells fits with the kinetics of an antibody response; the primary response is mainly IgM and the secondary response is predominantly IgG. During this diversification process, B lymphocytes acquire other cell-surface receptors that allow them to respond to antigens and to T-cell help by proliferation and differentiation to plasma cells. Simultaneously, a population of memory cells is produced, which expresses the same Ig receptor. This clonal expansion helps account for the increased secondary response.

The initiation and completion of specific immune responses involve a complex series of genetically restricted interactions between APCs and T-cell subpopulations for cell-mediated immunity and between these cells and B cells for antibody response. The Th and Ts lymphocytes exert positive and negative regulatory effects, respectively, on B-cell responses. Similarly, B cells and antibodies can affect the activities of functionally distinct subpopulations of T cells through specific receptors. A minority of B cells can respond directly to antigens, referred to as T-independent antigens. They have repeating identical antigenic determinants and provoke predominantly IgM antibody responses. Such substances may also provoke nonspecific proliferation of other memory B cells and are therefore known as polyclonal B-cell mitogens. Such antigens include bacterial polysaccharides and endotoxin.

BASIS OF THE NONSPECIFIC IMMUNE RESPONSE

Macrophages

Macrophages and monocytes represent the mononuclear phagocytic system and are derived from stem cells closely related to lymphocytes in the bone marrow. Each lineage, either for lymphocytes or macrophages, has a different colony-stimulating factor. Once differentiated, functional differences between polymorphonuclear leukocytes, mononuclear phagocytes, and lymphocytes are evident. Most polymorphonuclear leukocytes develop in the bone marrow andy emerge only when mature, whereas macrophages differentiate principally in various tissues, including the gastrointestinal mucosa. Tissue macrophages are heterogeneous cells, which have as their major function the phagocytosis of invading organisms and antigens by lysosomal granules containing acid hydrolases and degradative enzymes. To be functional, macrophages must be activated by cytokines or substances that bind to their surface receptors (such as IgG:Fc receptors) or endotoxin (bacterial polysaccharides) to its receptor, or by soluble mediators such as C5a. Their activation results in release of TNF-α or IL-1, IL-6, and other cytokines (monokines), which then further amplifies the immune response and can cause further damage in already inflamed tissues (see Figure 39.1-2).

Neutrophils (Polymorphonuclear Leukocytes)

Neutrophils and macrophages constitute the main phagocytic cells.[1] In response to chemotactic agents (anaphylotoxins, C3a, C5a), cytokines released by Th1 cells, and mast cell products (kallikrein), neutrophils migrate out of blood vessels into tissues by the expression of adhesion receptors. Organisms adhere to the surface of phagocytic cells and activate the engulfment process. They are then taken inside the cells, where they fuse with cytoplasmic granules. Neutrophils are able to kill the microorganisms and degrade the substances that they internalize. These processes occur in association with their "respiratory burst" and superoxide production.

Natural Killer Cells

Natural killer (NK) cells are considered important in immunosurveillance against tumors, as well as viruses. Their cell lineage is not completely known, but there is some overlap with T cells. IL-15 is important in inducing precursors to develop into NK cells. They can kill target cells in the absence of any antibody or antigenic stimulation. Agents such as mitogens and IFN can nonspecifically activate NK cells.

Complement

The serum proteins of the complement system provide an important means of removing or destroying foreign antigens. The lysis of whole invading microorganisms and the opsonization of microorganisms and immune complexes are key functions of the complement pathway. This multicomponent-triggered enzyme cascade attracts phagocytic cells to microbes. Microorganisms coated with Ig and/or complement are more easily recognized by macrophages and more readily bound and phagocytosed through IgG:Fc and C3b receptors. All complement components are acute-phase proteins whose synthetic rates are increased by injury or infection. Most components are synthesized by hepatic macrophages. Complement activation occurs in two phases: cleavage of C3, the most abundant component, followed by activation of the "attack" or lytic sequence. The critical step is enzymatic cleavage of the C3 component by "C3 convertase." The classic and alternate pathways, both of which can generate C3 convertases in response to different stimuli (antigen-antibody complexes including IgM or

IgG, with bacterial cell wall antigens and endotoxin, respectively), achieve the cleavage of C3a. The next component (C5) is activated, yielding C5a, a potent chemotactic agent for neutrophils. The C3a and C5a components act on mast cells, inducing the release of mediators such as histamine, leukotriene B_4, and TNF-α. The influx of leukocytes and increase in vascular permeability constitute major components of the acute inflammatory response.

HEMOLYMPHATIC CYCLE

Peyer patches (PPs) are intramucosal lymph nodes made of B follicles separated by T areas and topped by an area rich in B cells, T cells, and macrophages called "the dome." The dome is overlaid by a particular epithelium, deprived in the small intestine of villi and containing unusual epithelial cells, the M cells. These cells have neither brush border nor basement membrane. They do not synthesize the secretory component necessary for the transport of IgA. They form cytoplasmic folds into which lymphocytes and macrophages can worm to come in close contact with the intestinal lumen. These properties enable M cells to be the elective entrance for intraluminal antigens, either soluble or particular, in their native form, as can be demonstrated by electron microscopic studies. After crossing M cells, antigens can then be trapped and digested by macrophages, which are numerous under the dome epithelium. It is likely that antigen-pulsed macrophages can then migrate into the B- and T-cell areas, where cellular interactions initiating the intestinal immune response will take place (see Figure 39.1-2).

Intraluminal antigenic stimulations indeed induce proliferation of B and T cells in the B and T areas of PPs, respectively. Interestingly, 70% of B blasts differentiated in the PP microenvironment bear membrane IgA, in marked contrast with other lymphoid organs, in which such cells are in a very small minority.

Hemolymphatic cycle T and B blasts are able to leave the PPs using subserosal lymphatics. They migrate toward the mesenteric lymph nodes, and then via the thoracic duct, they get into blood. Having circulated, blasts, which have arisen in the PPs, selectively migrate back into the intestinal mucosa. The hemolymphatic cycle thus allows dissemination of the immune response initiated at one intestinal site to the entire intestinal mucosa (Figure 39.1-3). This cycle has been well demonstrated in rodents by comparing migration patterns of blasts obtained from various lymphoid organs. Its existence in humans has been inferred but not proven.

During their circulation, T and B blasts undergo progressive maturation. B blasts lose their membrane IgA and acquire intracytoplasmic IgA. They transform into fully mature plasma cells when they have settled in the intestinal mucosa. Similarly, T cells stop dividing and acquire various intracytoplasmic and membrane markers, which reflect their mature and activated state.

MUCOSAL HUMORAL IMMUNITY

SECRETORY IGA

The mucosal surface of the GI tract normally represents an extensive and efficient barrier protecting the host internal milieu, preventing penetration by pathogenic organisms and potentially noxious luminal antigens and toxins.[1] An important component of the host mucosal defense at the gut epithelial surface (GALT) is the presence of intestinal antibodies, most notably secretory IgA. A deficiency in secretory intestinal antibody may impair mucosal barrier function, resulting in increased uptake of macromolecular antigens that could then contribute to the pathogenesis of intestinal or systemic disease states.[1,2] The interaction of intestinal antibodies with antigens, enterotoxins, or bacteria can prevent their attachment to epithelial cell mem-

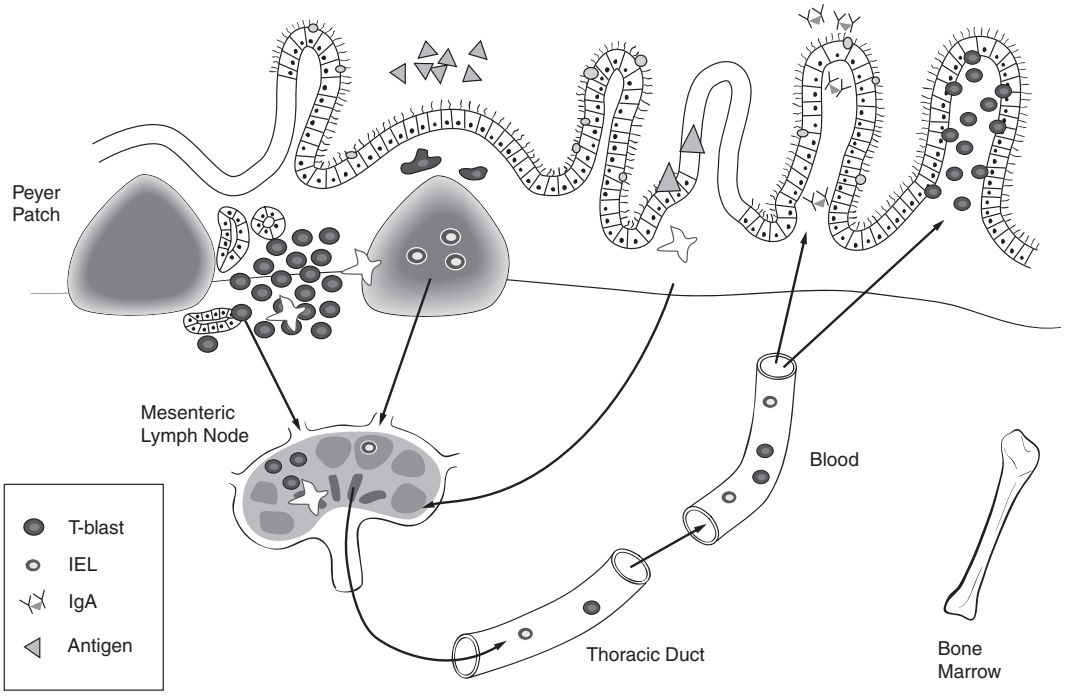

FIGURE 39.1-3 Hemolymphatic cycle of thymodependent T cells and IgA plasma cells. IEL = intraepithelial lymphocyte; IgA = immunoglobulin A.

branes, inhibiting antigen uptake or penetration by pathogens. The formation of antigen-antibody complexes on the surface of the small intestine may also facilitate the operation of other nonimmunologic host defense mechanisms. Thus, under normal conditions, the mature mucosal immune system (GALT) limits antigen uptake and eliminates pathogens.

These theories have been supported by studies in patients with common variable hypogammaglobulinemia, who were shown to have markedly increased absorption of dietary antigens.[4] An increased incidence of intestinal infections is noted in children with defects of the humoral system, such as *Campylobacter jejuni* enteritis.[5] Although symptoms were similar to those seen in normal children, the clinical course in immunodeficient patients tended to be prolonged and more often unimproved by antibiotic therapy. Chronic diarrhea is the second most common infectious complication of antibody deficiency syndromes.

Implication for Mucosal Immunization

The mucosal immune system is primarily protected by secretory IgA antibodies. Resident T cells produce large amounts of transforming growth factor-β, IL-4, and IL-10. These factors, also elaborated by intestinal epithelial cells, then promote the B cells to "switch" to IgA production. Site-specific vaccination by oral immunization leads to antibody production primarily in the small bowel but little in the colon. There is concomitant antibody production by the mammary and salivary glands. Intranasal immunization apparently gives rise to an antibody response in the upper airways and salivary glands, without provoking an immune response in the gut.[1]

CLASSIFICATION OF PRIMARY ID DISEASES

ID in children may be classified as primary or secondary. Primary ID diseases may be attributable to a wide variety of inherited defects in the development and function of the various components of the host immune system, reviewed above. The primary IDs have been classified (Table 39.1-3) by the World Health Organization.[3] The GI manifestations of primary IDs are reviewed below and classified according to the predominant type of ID: humoral, cellular, or combined defects.

PREDOMINANTLY ANTIBODY DEFICIENCIES

As a group, antibody deficiencies represent the most common types of primary IDs in human subjects. Often symptoms do not appear until the latter part of the first year of life, as passively acquired IgG from the mother decreases to below protective levels. As with the T-cell IDs, the spectrum of antibody deficiencies is broad, ranging from the most severe type of antibody deficiency with totally absent B cells and serum Igs to patients who have a selective antibody deficiency with normal serum Ig. In addition to the increased susceptibility to infections, a number of other disease processes (eg, autoimmunity and malignancies) can be involved in the clinical presentation. Fortunately, the availability of intravenous serum Ig has made the management of these patients more complete. Recently, molecular immunology has led to identification of the gene or genes involved in many of these antibody deficiencies. This has led to a better elucidation of the B-cell development and differentiation pathways and a more complete understanding of the pathogenesis of many of these antibody deficiencies.

X-Linked Agammaglobulinemia

X-linked agammaglobulinemia (XLA) is a congenital disorder that was first described by Bruton in 1952 as the congenital inability to form antibodies.[6] Patients were typically infants or young children with recurrent, severe bacterial infections. Since the discovery of the defective gene in XLA in 1993,[7] it has been shown that a significant number of male patients with sporadic or acquired hypogammaglobulinemia actually have XLA.[8–10] In addition to the virtual absence of serum Igs of all classes, an inability to produce antibody after antigen stimulation characterizes XLA. In almost all cases, circulating mature B cells are absent, and no plasma cells are detected in lymphoid tissues, including the gut.

Genetics. Mutations in Bruton tyrosine kinase gene (*BTK*), a B lymphocyte–specific kinase, disrupt intracellular signaling pathways, resulting in maturational arrest of B lymphocytes at the pre-B-cell stage. The abnormal *BTK* gene, a member of a family of proto-oncogenes that encode protein tyrosine kinases, was mapped to the proximal part of the long arm of the X chromosome.[7,8] The mutation results in the inability of tyrosine kinase to function in intracellular signaling involved in the production of Igs by B cells. Female carriers can be detected, and prenatal diagnosis of affected or unaffected male fetuses can be accomplished using closely linked probes and restriction fragment length polymorphism analysis. A similar condition, likely owing to another defect, has been described in females.[11]

Pathophysiology. Cell-mediated immunity is normal, and a normal number of pre-B cells are found in the bone marrow. However, plasma cells and blood lymphocytes bearing surface Ig (CD23, CD19, and CD20) or reacting with anti–B-cell monoclonal antibodies are absent or present only in very low numbers.[9] The underlying defect lies within the early B-lineage cells, reflecting an intrinsic maturation block in pre-B- to B-cell differentiation.[1] The maturational block may be in the transition between terminal deoxynucleotidyl transferase–positive, Cu^- pre-B, and Cu^+ pre-B cells.

Clinical Presentation. The afflicted infants generally remain well during the first 6 months of life by virtue of maternally transmitted Ig. The typical patient is a male presenting thereafter with severe and repeated respiratory infections or meningitis owing to extracellular pyogenic, often gram-positive, encapsulated organisms (such as staphylococci, pneumococci, streptococci, *Neisseria*, *Haemophilus*, or *Mycoplasma* species), unless given pro-

TABLE 39.1-3 CLASSIFICATION OF IMMUNODEFICIENCIES

ANTIBODY DEFICIENCIES
X-linked agammaglobulinemia
Non–X-linked hyper-IgM syndrome
Ig heavy-chain gene deletions
κ-Chain deficiency
Selective deficiencies of IgG or IgA subclasses or IgE class:
γ1 (IGHG1); γ2 (IGHG2); partial γ3 (IGHG3); γ4 (IGHG4); α1 (IGHG1); α2 (IGHG2); ε (IGHE)
Antibody deficiency with normal Igs
Common variable immunodeficiency
IgA deficiency
Transient hypogammaglobulinemia of infancy
Autosomal recessive agammaglobulinemia

T-CELL DEFICIENCIES
Purine nucleoside phosphorylase deficiency
CD3γ deficiency
CD3ε deficiency
70 kD Syk-family protein tyrosine kinase ZAP-70 deficiency

COMBINED IMMUNODEFICIENCIES
Severe combined immunodeficiencies (SCIDs)
T-B + SCID
X-linked γc chain deficiency
Autosomal recessive Jak3 deficiency
T-B-SCID
RAG1 deficiency
RAG2 deficiency
Adenosine deaminase deficiency
Reticular dysgenesis
Other SCIDs
X-linked hyper-IgM syndrome
CIITA, MHC-II transactivating protein deficiency
RFX-5, MHC-II promoter X box regulatory factor 5 deficiency
RFXAP, regulatory factor X-associated protein deficiency
TAP-2 deficiency
Other well-defined immunodeficiency syndromes
Wiskott-Aldrich syndrome
Ataxia-telangiectasia
DiGeorge syndrome

PHAGOCYTIC IMMUNODEFICIENCIES
Severe congenital neutropenia
Cyclic neutropenia
Leukocyte adhesion defect 1 (deficiency of β chain [CD18] of LFA-1, Mac-1, p150,50)
Leukocyte adhesion defect 2 (failure to convert GDP mannose to fructose)
Chediak-Higashi syndrome
Specific granule deficiency
Shwachman syndrome
X-linked chronic granulomatous disease (CGD) (cytochrome *b* 91 kD)
Autosomal recessive CGD deficiency of $p22^{phox}$
Autosomal recessive CGD deficiency of $p47^{phox}$
Autosomal recessive CGD deficiency of $p67^{phox}$
Neutrophil G6PD deficiency
Myeloperoxidase deficiency
IFN-γ receptor deficiency

COMPLEMENT DEFICIENCIES

OTHER PRIMARY IMMUNODEFICIENCY DISEASES
Primary CD4 deficiency
Primary CD7 deficiency
IL-2 deficiency
Multiple cytokine deficiency
Signal transduction deficiency

CONGENITAL OR HEREDITARY DISEASES ASSOCIATED WITH IMMUNODEFICIENCY
Chromosomal abnormalities
Bloom, Seckel, Dubowitz, ICF, Turner, Nijmegen, and Down syndromes
Fanconi anemia
Abnormalities in chromosomes 1, 9, 16, and 18
Multiorgan system abnormalities
Partial albinism
Congenital dyskeratosis
Cartilage hair hypoplasia
Agenesis of the corpus callosum
Hereditary metabolic defects
Transcobalamin-2 deficiency, biotin-dependent carboxylase deficiency
Acrodermatitis enteropathica
Type I orotic aciduria, mannosidosis, methylmalonicacidemia
Intractable diarrhea, associated with small for gestational age facial dysmorphy, and trichorrhexis
Hypercatabolism of Ig
Familial hypercatabolism of Ig
Intestinal lymphangiectasia
Others
Chronic mucocutaneous candidiasis
Hypo- or asplenia
Graft-versus-host disease

CGD = chronic granulomatous disease; CIITA = MHC class II transactivator; GDP = guanosine diphosphate; G6PD = glucose-6-phosphate dehydrogenase; ICF = immunodeficiency, centromere instability, and facial dysmorphism; IFN = interferon; Ig = immunoglobulin; IL = interleukin; LFA = lymphocyte function antigen; phox = phagocyte oxidase; RFX = regulatory factor X; RFXAP = regulatory factor x-associated protein; TAP-2 = antigen-peptide-transporter 2.

phylactic antibiotics or gammaglobulin therapy. The IgG, IgA, and IgM are far below the 95% confidence limits for appropriate age- and race-matched controls (usually less than 100 mg/dL total Ig). Polymorphonuclear functions are usually normal if IgG antibodies with intact Fc functions are provided. However, patients with this condition can have transient, persistent, or cyclic neutropenia.[10] In such cases, chronic fungal infections or *Pneumocystis carinii* pneumonia may be seen.

In addition to recurrent bacterial infections, patients may have persistent viral infections, particularly with hepatitis or enteroviruses, despite normal T-cell function. From the GI point of view, the child characteristically presents with chronic diarrhea or a malabsorptive syndrome associated with a protein-losing enteropathy.[12] In general, GI manifestations are much less notable than those encountered in patients with late-onset common variable immunodeficiency (CVID) discussed below. Giardiasis,

bacterial overgrowth syndrome (not correlating with diarrhea), nonspecific colitis, and chronic rotavirus infection are other well-recognized complications of XLA.[13,14] Recurrent fissuring necrosis of the small bowel resembling Crohn disease has been described.[12] The important role of antibody in protecting against these infectious and inflammatory complications is highlighted by the favorable response of these patients to replacement therapy with Ig.[14] The XLA has also been reported in association with growth hormone deficiency.[15]

IgA Deficiency

Selective IgA deficiency (IgAD) is the most common primary ID, with an incidence of about 1 in 400 to 600 in whites.[16] Most subjects are asymptomatic, but some may suffer from frequent respiratory and GI infections. Patients who suffer from frequent infections usually have a defect in antibody responses toward polysaccharides, which is often associated with IgG2 deficiency. Some IgA-deficient patients are also prone to develop more severe ID, called CVID, which is associated with decreased IgG and sometimes IgM production, as well as partial T-cell defect. In a few cases, IgAD may reveal a severe disease such as ataxia-telangiectasia. Although the majority of patients are entirely well, the literature is replete with reports associating IgAD with many conditions, including recurrent infections and various autoimmune diseases.[17]

Genetics. The occurrence of IgAD is consistent with autosomal inheritance. In some families, this appears to be dominant, with variable expression. The defective expression of regulatory factors important for IgA-immunocyte differentiation has been suggested to have its origin in certain human leukocyte antigen (HLA)-gene rearrangements. Molecular genetic studies suggest that the susceptibility genes for IgAD and CVID may reside in the MHC class III region on chromosome 6.[18] Genetic predisposition to develop IgAD has been shown to be linked to at least one locus on 6p21. Normally, there is a differential distribution of IgA subclasses throughout the body (Table 39.1-4). The IgA in bone marrow plasma cells and serum is predominantly IgA1. In contrast, IgA in secretions and intestinal plasma cells contain equal amounts of IgA1 and IgA2. Most IgA-deficient patients lack both serum and secretory IgA1 and IgA2. However, in some patients with serum IgAD, IgA2-producing plasma cells may be plentiful in the bowel. An IgG subclass deficiency and IgE deficiency may also be seen in patients with "selective" IgAD, thus reflecting a more generalized abnormality in the terminal differentiation of B cells in such patients. This mixed defect is particularly characteristic of those patients with GI symptoms.[19] Susceptibility to infection among children with selective IgAD has been linked with associated IgG subclass 2 or 4 deficiency.[17] The identification of an IgG subclass deficiency may theoretically lead to therapeutic options in that an associated IgG subclass deficiency may benefit from replacement therapy. However, the risks of blood product administration in such patients, as mentioned above, preclude their routine use.[20]

Pathophysiology. The basic defect leading to selective IgAD is unknown. Most IgA-deficient patients have immature B cells that express membrane-bound IgA, with IgM and IgD coexpression.[21] These B cells resemble those in umbilical cord blood and are not easily induced to become mature IgA-secreting plasma cells, suggesting a B-cell maturation arrest.[21] In some patients, the defect involves the secretory component as well. Of possible etiologic and clinical importance is the presence of antibodies to IgA in the serum samples of as many as 44% of patients with selective IgAD.[22] However, it is uncertain whether these antibodies prevent development of the IgA system or whether lack of tolerance resulting from IgAD permitted the production of antibodies to exogenous determinants that are immunologically related to IgA. Patients deficient in IgA may thus have severe or even fatal anaphylactic reactions after intravenous administration of IgA-containing products.[19] For this reason, parenteral administration of blood or blood products, including serum Ig, is potentially hazardous. Only extensively washed normal donor erythrocytes or blood products from other IgA-deficient individuals should be administered to such patients.

Clinical Presentation. There is an association between IgAD and a wide variety of GI disorders (Table 39.1-5). The majority of patients do not, however, suffer from significant clinical symptoms. Other host defense mechanisms likely compensate and protect the mucosal barrier, including an increase in IgG,[23] IgM-secreting cells,[24] and various nonimmune factors, discussed above.[1,2] As would be anticipated in the deficiency of the primary Ig of mucosal secretions, there is a high rate of infections of the respiratory, GI, and urogenital tracts. Bacterial pathogens are similar to those seen in other types of antibody deficiency syndromes, with no evidence of undue susceptibility to viruses. *Giardia lamblia* infestation is a common

TABLE 39.1-4 SECRETORY AND SERUM IGA

CHARACTERISTICS	SECRETORY	SERUM
Molecular form	Polymeric	Monomeric
Subclasses	IgA1 = IgA2	IgA1 > IgA2
Origin	Mucosal tissues	Bone marrow
IgA deficiency	Decreased or normal IgA2	Decreased

Food allergies
Gluten-sensitive enteropathy
Pernicious anemia/atrophic gastritis/increased risk of gastric cancer
Idiopathic inflammatory bowel disease (Crohn disease, ulcerative colitis)

Ig = immunogloblin.

problem in these patients. The prevalence of selective IgAD among patients with Crohn disease also appears to be significantly increased. Although there is an increased prevalence of both serum IgG antibodies against food antigens and circulating immune complexes in IgA-deficient patients, an association with food allergy is not clearly established.[25] As with CVID (discussed below), there is a frequent association of IgAD with collagen vascular and autoimmune diseases.[18] Finally, an increased risk of GI malignancy has been associated with IgAD.[26]

Celiac Disease in IgA-Deficient Patients. In addition to the high prevalence of chronic diarrhea and steatorrhea, there is a 10- to 20-fold increased incidence of celiac disease (CD) among IgA-deficient patients.[27–29] Indeed, selective IgAD and CD are frequently associated and share the ancestral haplotype HLA-8.1, which is characterized by a peculiar cytokine profile. As in nonimmunodeficient patients, the classic syndrome of chronic diarrhea, failure to thrive, and malnutrition is less common than more subtle, irritable bowel–like presentations of the disease.[28–30] In a prospective study of 65 consecutively diagnosed IgA-deficient children, routine jejunal biopsies revealed a diagnosis of CD in 7.7%.[27] Serum antigliadin or antiendomyseal antibodies (IgA) are often falsely negative. The IgG antigliadin antibodies and IgG antibodies against tissue transglutaminase are useful to screen for CD in such cases.[31,32]

CD in the IgA-deficient patient cannot be distinguished clinically, radiologically, or by laboratory means from CD in otherwise normal individuals. The only differentiating feature is that immunohistochemical staining of small intestinal biopsies reveals a lack of IgA-producing plasma cells. Patients with IgAD may also have chronic diarrhea and villous atrophy on jejunal biopsy without a concomitant gluten-sensitive enteropathy. The clinical differentiation depends on response (symptoms and biopsy) to a gluten-free diet (Figure 39.1-4). Even among treated patients on a gluten-free diet and those without CD, immunohistochemical studies have revealed a significant increase in $CD25^+$ cells in the surface epithelium and lamina propria of jejunal biopsy specimens among individuals with IgAD.[33] The increase in $CD25^+$ cells, along with an increase in the mitotic rate of crypt epithelial cells, was taken as evidence in favor of mucosal T-cell activation in IgA-deficient subjects.[33]

Treatment. Currently, there is no specific treatment for IgAD beyond the vigorous treatment of infections with appropriate antimicrobial agents.[34] Even if serum IgA were to be replaced, it could not be transported into external secretions because the latter is an active process involving epithelial cells and locally produced IgA. Selective IgAD contraindicates Ig administration. Only the minority of IgA-deficient patients who develop severe or frequent infections in association with IgG2 deficiency or impaired antibody response are candidates for prophylactic intravenous Ig substitution. Ig preparations containing particularly low amounts of IgA are required to avoid adverse effects related to anti-IgA alloantibodies.

Hyper-IgM Syndrome

Genetics and Pathophysiology. The hyper-IgM syndrome is a rare, inherited ID disorder resulting from defects in the CD40 ligand/CD40-signaling pathway.[35,36] CD40 is a member of the TNF receptor superfamily, expressed on a wide range of cell types, including B cells, macrophages, and dendritic cells. CD40 is a receptor for CD40 ligand, a molecule predominantly expressed by activated $CD4^+$ T cells. CD40-CD40L interaction induces the formation of memory B lymphocytes and promotes Ig isotype switching, as demonstrated in mice knocked out for either the CD40L or the CD40 gene and in patients with X-linked hyper-IgM syndrome.[37,38] X-linked hyper-IgM (XHIM) is caused by mutations in the CD40 ligand gene, whereas autosomal recessive hyper-IgM is caused by defects in the CD40-activated ribonucleic acid (RNA)-editing enzyme, activation-induced cytidine deaminase, which is required for Ig isotype switching and somatic hypermutation in B cells. This lack of inter-

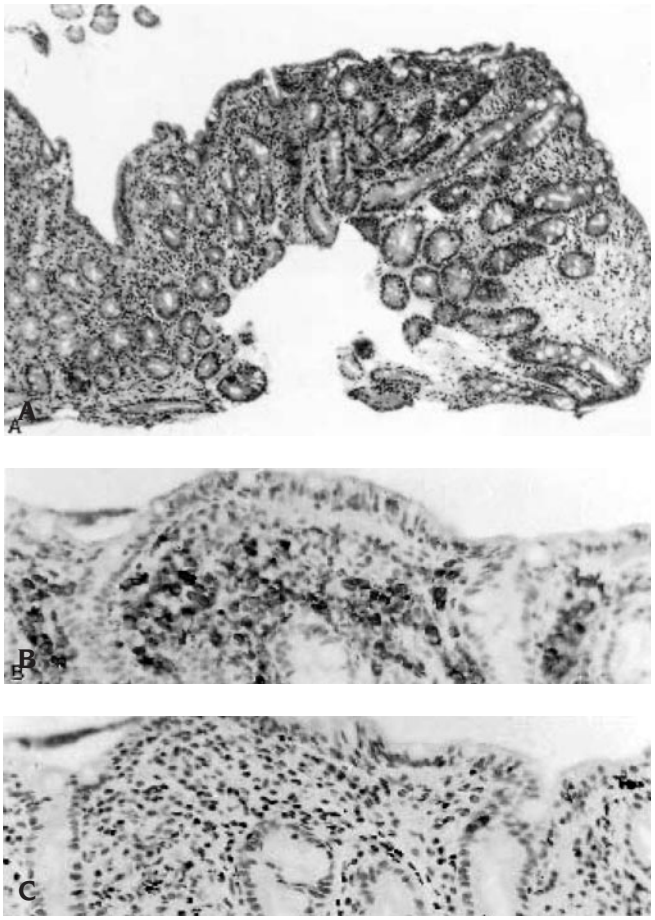

FIGURE 39.1-4 Gluten-sensitive enteropathy in association with autosomal recessive agammaglobulinemia. The patient was a 13-year-old female who presented with chronic diarrhea and growth failure that responded to a gluten-free diet. *A*, Jejunal biopsy shows a moderate to severe villous atrophy, crypt hyperplasia, and chronic inflammatory changes. (hematoxylin phloxine saffron stain; ×120 original magnification). Russo, MD.

action between T and B cells is thought to lead to the unregulated production of IgM. This is accompanied by an inability to switch from IgM- to IgG- and IgA-secreting cells unless cocultured with a "switch" T-cell line or anti-CD40 plus IL-2, -4, or -10.[38]

Clinical Presentation. The clinical presentation resembles that in XLA, with recurrent pyogenic infections including otitis media, sinusitis, pneumonia, and tonsillitis in the first 2 years of life.[39] Chronic diarrhea and liver involvement are common. Both, at times, may be caused by infection with *Cryptosporidium parvum*.[40] Mouth or rectal ulcers, neutropenia, and *P. carinii* pneumonia are frequent presentations.[40] Unlike XLA, however, lymphoid hyperplasia is often seen in the hyper-IgM syndrome. Serum IgA, IgG, and IgE levels are usually very low, whereas a markedly elevated polyclonal IgM is typically present. Although lymphocyte counts and in vitro proliferative response to mitogens were reported to be normal, a defective response to antigens was observed.[40] Thus, additional defects of cell-mediated immunity may be presumed to be present in CD40 ligand mutations.

As described with other antibody deficiencies, an association with autoimmune disorders is quite frequent. Sclerosing cholangitis requiring liver transplant has been reported in 4 of 56 cases.[40] In that series, 23% of patients with XHIM syndrome died of infections or liver disease, whereas 6% underwent bone marrow transplant.[40] Successful bone marrow transplant was reported to promote complete recovery from *C. parvum* infection with gastroenteritis and sclerosing cholangitis.[41] XHIM syndrome is thus a severe ID, with significant cellular involvement and a high mortality rate without bone marrow transplant.

Transient Hypogammaglobulinemia of Infancy

Postnatally, there is a physiologic decrease in the serum IgG concentration as maternally derived IgG is catabolized. A nadir is reached between the third and sixth months. In premature infants, the amount of transplacentally acquired Ig is considerably less; thus, serum IgG concentrations are even lower. Intrinsic Ig synthesis follows as the neonate begins to respond to antigenic stimuli, with the appearance of IgM first, followed by IgG and IgA much later.

Transient hypogammaglobulinemia is primarily a deficiency of serum IgG. Normal antibody responses are demonstrable after antigenic stimulation to tetanus, polio, and pneumococcal vaccines.[42] Circulating B cells are normal in number, but the B-cell response to T cell–dependent stimulation with pokeweed mitogen is decreased, probably secondary to a lack of T-cell help.[43] Infants with this disorder usually have recurrent respiratory infections. Some may present with chronic diarrhea and malabsorption. The disease resolves spontaneously before the age of 4 years, often between the ages of 1 and 2 years.

IgG Subclass Deficiency

Patients may have deficiencies of one or more subclasses of IgG, despite normal or even elevated total serum IgG levels.[44] There is little value in measuring IgG subclasses in patients under 1 year of age owing to wide variations among normal infants.[45] Most of those with absent IgG2 are also IgA deficient,[46] whereas a minority evolve toward CVID.[47] Although many patients are asymptomatic, others resemble Ig-deficient patients. Chronic diarrhea is a common mode of presentation. Nonspecific colitis is a frequent problem among infants with IgA, IgG2, and IgG4 deficiency.[19] Some of these patients will not respond to protein and polysaccharide antigens in various vaccines, as opposed to cases of transient hypogammaglobulinemia. A recent study suggested that hypogammaglobulinemia may be associated with chronic intestinal pseudo-obstruction.[48] The children had a history of recurrent infections requiring gammaglobulin infusions. However, it is unclear as to whether the IDs in chronic intestinal pseudo-obstruction are primary or secondary to the intestinal problem.

Common Variable Immunodeficiency

CVID is one of the most frequent primary IDs.[42,45] CVID is characterized by reduced serum levels of all switched Ig isotypes (IgG, IgA, IgE), predisposing patients to recurrent infections of their respiratory and GI tracts. In addition to serious infection, CVID is associated with a number of comorbid disorders, including a variety of autoimmune diseases and neoplasms.[49] Many patients are diagnosed as adults, and delay in the recognition of the antibody defects is common.[50,51] This congenital ID, inherited in an autosomal recessive way, has not fully elucidated pathogenesis in spite of over 40 years of studies.[52,53]

Genetics. Although the genetic basis of CVID is not completely known, a large proportion of CVID patients possess the same HLA haplotypes as in IgAD. These two disorders have been reported in the same family.[54] In addition, certain patients with IgAD later manifest a CVID. There is also a high incidence of autoimmune disease and malignancies in both of these disorders. It has thus been suggested that IgAD and CVID share a common genetic basis. Studies suggest that the susceptibility genes are in the class III MHC region on chromosome 6. A small number of HLA haplotypes are shared by individuals with CVID and IgAD, consistent with a common genetic basis.[54,55] However, not all members of a pedigree with these susceptibility genes will manifest an ID.[54] Thus, this suggests that environmental factors trigger the disease expression in genetically susceptible individuals.

Pathophysiology. CVID represents a heterogeneous group of familial or sporadic diseases characterized by B-cell dysfunction, low levels of serum Igs, and a failure of B cells to differentiate into mature plasma cells.[3,49–53] Although the antibody deficiencies in CVID may be as profound as those in XLA, circulating Ig-bearing B lymphocytes and lymphoid cortical follicles are present in two-thirds of cases. However, when present, B lymphocytes from CVID patients do not differentiate into Ig-producing cells or plasma cells, despite pokeweed mitogen (PWH) stimulation or coculture with normal T cells.[51,53] Although T-cell subsets are usually present in normal quantities, T-cell functional abnormalities

have also been described and are thought to either cause or exacerbate the B-cell defects.[51–53] A decreased proliferative response to phytohemagglutinin (PHA) or anti-CD3 monoclonal antibody activation has been noted, as has lower IL-2 secretion.[50] These abnormalities are restored by addition of exogenous IL-2 or by using phorbol myristate acetate (PMA), a protein kinase activator, as a mitogen. The IL-2 receptor expression is also impaired in CVID when patients' peripheral blood mononuclear cells are incubated with anti-CD3 antibodies. However, IL-2 and IL-2 receptor messenger RNA expression by peripheral blood mononuclear cells are normal, suggesting a possible defect at the post-transcriptional level.[53] The defective IL-2 production in CVID is also reversed by normal allogeneic macrophages, reflecting a potential defect of macrophage activation in selected patients with this disorder.[52,53] The T cells from CVID patients have been found to be deficient in a number of cytokine genes.[56] In most cases, however, the defect is intrinsic to the B cell, with abnormal terminal differentiation.[53] The pattern of expression of Ig genes after PWM stimulation varies among CVID patients, suggesting that B-cell defects may occur at different stages of maturation in such patients.[54]

Classification. Patients with CVID are no longer classified as having a predominantly antibody- or cell-mediated immune defect.[3] Nevertheless, such a distinction may be useful clinically. The first category is similar clinically to XLA and is characterized by low levels of IgG and of the other Ig classes. It can occur sporadically at any age, but familial cases have been identified, primarily with autosomal recessive inheritance. The peak age at onset is in the second decade of life.[42] Peripheral B cells do not synthesize Ig normally when stimulated by mitogens, as described above. Although CVID patients generally have a decreased number of Ig-secreting cells in GALT, this is not a consistent finding. CVID patients with predominant cellular defects may have profound deficiencies of total T cells and T-cell subsets. Despite the numeric deficiency, there is usually a normal helper (CD4) to suppressor (CD8) cell ratio, in contrast to AIDS, as described in Chapter 39.2. Peripheral lymphoid tissues are hypoplastic, with paracortical lymphocyte depletion. The thymus is typically very small, and no Hassall corpuscles or thymic epithelium is present. Thrombocytopenia and neutropenia are seen in some cases.[42,45]

Clinical Presentation. There is a great deal of clinical variability in this syndrome.[51] Patients may present late in infancy and childhood, whereas others present earlier and are indistinguishable from those with severe combined immunodeficiency (SCID) syndrome. Children with this disorder typically present with a history of recurrent otitis media, bronchopulmonary infections, and chronic diarrhea with malabsorption.[49,51] A number of GI symptoms and signs are associated with CVID (Table 39.1-6). The majority of patients develop significant malabsorption, which is often due to giardiasis. Such patients usually have mild steatorrhea, and small bowel biopsy reveals mild to moderate villous atrophy.[57] These abnormalities may sometimes respond favorably to treatment with metronidazole. There is little evidence demonstrating an increased incidence of parasites other than *Giardia* in CVID patients from industrialized countries.[58] Although bacterial overgrowth is commonly recognized, its presence does not correlate with achlorhydria, diarrhea, steatorrhea, lactose intolerance, vitamin B_{12} malabsorption, or the presence of *Giardia*. Other specific pathogens noted in CVID patients include *Rotavirus*, *Campylobacter jejuni*, and *Campylobacter fetus*. In some patients with early onset of symptoms, as with SCID patients, respiratory tract infections are severe, and malnutrition is often secondary to diarrhea and malabsorption. The GI manifestations include oral, esophageal, and perianal candidiasis.

Gastrointestinal Involvement. Nonspecific enterocolitis in the absence of microbial pathogens is also commonly encountered in CVID.[58] The entire small and large intestine may be involved, contributing to the chronic diarrhea and malabsorption (Figure 39.1-5). In some cases, small bowel biopsies in CVID may contain foamy histiocytes in the lamina propria, resembling Whipple disease. In others, biopsies are similar to those observed in chronic granulomatous disease (CGD), with numerous apoptotic bodies in the crypts or poorly formed granulomas, resembling Crohn disease. Patients with CVID thus manifest a spectrum of abnormalities in the GI tract, with patterns superficially resembling graft-versus-host disease (GVHD) or inflammatory bowel disease, as well as Whipple disease or collagenous colitis.[58,59]

Gastritis may be observed in a large number of patients with hypogammaglobulinemia and CVID. Gastritis is associated with pernicious anemia–like syndrome without antibodies to intrinsic factor, gastric parietal cells, or thyroglobulin.[60]

Nodular lymphoid hyperplasia is often encountered in the bowels of CVID patients who do have B cells. However, nodular lymphoid hyperplasia is also seen in selective IgAD, as well as in normal individuals. Malignancy is frequent, including GI tumors and generalized lymphomas.[57,61] Those with gastritis carry an increased risk of gastric carcinoma.[61] The association with lymphoreticular malignancies and CVID has recently been attributed to an increased radiation-induced chromosomal instability.[62]

Management and Outcome. Patients frequently require nutritional support in the form of enteral elemental diets or total parenteral nutrition. In our experience,

TABLE 39.1-6 GASTROINTESTINAL MANIFESTATIONS OF COMMON VARIABLE IMMUNODEFICIENCY

Gluten-sensitive enteropathy

bone marrow transplant can be curative in such cases. One report on eight childhood cases of CVID focused on the autoimmune manifestations that may dominate the clinical course, leading to significant morbidity and mortality.[63] These included idiopathic thrombocytopenia, hemolytic anemia, secretory diarrhea, arthritis, chronic active hepatitis, parotitis, and Guillain-Barré syndrome. Most patients also had lymphadenopathy, splenomegaly, growth failure, and delayed puberty, reflecting the multisystemic nature of CVID.[63] Patients who have been treated with intravenous gammaglobulin are susceptible to an aggressive progression of hepatitis C, which can respond to IFN-α therapy.[64]

The clinical and immunologic status of 248 CVID patients was reported with survival 20 years after diagnosis, being only 64% for males and 67% for females.[50] Parameters associated with mortality were lower levels of serum IgG, weaker T-cell responses to mitogens, and, particularly, a lower percentage of circulating B cells. Of interest is a report that a subset of CVID patients with excessive suppressor cell activity benefited from therapy with cimetidine.[65] This H_2-receptor antagonist reduced suppressor cell activity, presumably allowing for endogenous Ig production. Improved B-cell differentiation has also been reported with 13-*cis*-retinoic acid,[66] as well as with ketoprofen,[67] the latter, however, in vitro only.[66–68]

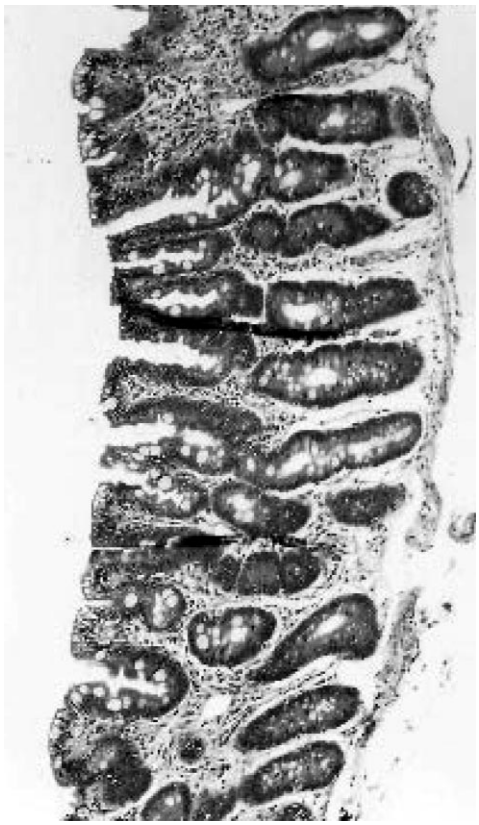

FIGURE 39.1-5 Nonspecific enteropathy of common variable immunodeficiency can be seen in this small bowel biopsy specimen from a 3-year-old boy with chronic diarrhea and failure to thrive who was unresponsive to a gluten-free diet or prednisone. There is irregular, partial villous atrophy with acute and chronic inflammatory cell infiltrates of the lamina propria (hematoxylin phloxine saffron stain; ×120 original magnification). Hyper-IgE Syndrome and IPEX Syndrome

Intractable diarrhea associated with absence of islets of Langerhans and neonatal insulin-dependent diabetes mellitus has been reported in the hyper-IgE syndrome.[69,70] Affected male infants usually die of overwhelming infection. More recently, the association of diabetes mellitus, severe enteropathy, and endocrinopathy involving boys has been shown to be related to mutations of the *FOXP3* gene, which is the human equivalent of mouse scurfy.[71] This syndrome of immune dysregulation, polyendocrinopathy, enteropathy, X-linked (IPEX) is one of a group of clinical syndromes that present with multisystemic autoimmune disease, suggesting a phenotype of immune dysregulation.[72,73] Several mutations of *FOXP3* have been reported in patients with IPEX.[74,75] *FOXP3*, the gene responsible for IPEX, maps chromosome Xp11.23-Xq13.3 and encodes a putative deoxyribonucleic acid (DNA)-binding protein of the forkhead family. Data indicate that the *FOXP3* gene is expressed primarily in the CD4+CD25+ regulatory T-cell subset, where it may function as a transcriptional repressor and key modulator of regulatory T-cell fate and function.[76]

Clinically, IPEX manifests most commonly with severe persistent diarrhea despite complete bowel rest, early onset of insulin-dependent diabetes mellitus, thyroid disorders, and eczema (see Chapter 44.3, "Autoimmune Enteropathy"). IPEX can be differentiated from other genetic immune disorders by its genetics, clinical presentation, characteristic pattern of pathology, and, except for high IgE, absence of substantial laboratory evidence of ID. Immunosuppression may provide temporary benefit for some patients but does not allow complete remission. Remission has been observed after allogeneic bone marrow transplant, but the long-term outcome is uncertain.[77]

DEFECTS AFFECTING BOTH T AND B CELLS

Severe Combined Immunodeficiency

The SCID syndromes are hereditary disorders characterized by a profound deficiency of both T- and B-lymphocyte function, resulting in the virtual absence of immune function from birth, and by the onset of severe, life-threatening infections in the first months of life.[1,3,78,79] The frequency of all types of SCID is 1 in 50,000 to 75,000. A great diversity of genetic, enzymatic, hematologic, and immunologic features (see Table 39.1-3) characterizes this large category of syndromes, all of which manifest clinically as a severe congenital ID.

Genetics. Over half of the cases derive from mutations in the γ_c chain of the receptors for the cytokines IL-2, -4, -7, -9, and -15. Among these, IL-7R is the most crucial for lymphocyte differentiation. In the X-linked form, the abnormal gene produces a truncated γ chain of the IL-2 receptor on T cells.[80] Among autosomal recessive cases, approximately half have a genetic deficiency in the purine degradation enzymes (see Table 39.1-3), purine nucleoside phosphorylase (PNP), or adenosine deaminase (ADA) (Figure 39.1-6).[81,82] This results in the accumulation of metabolites

(deoxyguanosine triphosphate and deoxyadenosine triphosphate, respectively) toxic to lymphoid stem cells. A few cases involve mutations in the *RAG* genes that catalyze the introduction of DNA double-strand breaks.

Where a biochemical defect has been defined, recognition of heterozygote carriers and prenatal diagnosis become possible. For example, in ADA deficiency, prenatal prediction of affected fetuses can be made by measuring ADA activity in amniotic fibroblasts obtained at amniocentesis.

Clinical Presentation. The affected infant presents within the first few months of life with severe infections, chronic diarrhea, malabsorption, and failure to thrive. There may be a history of a neonatal hyperpigmented rash secondary to GVHD, resulting from transplacentally acquired maternal lymphocytes. GVHD may also occur after transfusion of nonirradiated blood products or subsequent to allogenic bone marrow transplants. Intractable diarrhea and recalcitrant oral and perineal thrush are common presentations. The diarrhea may begin slowly and become massive, watery, bloody, and mucopurulent. The pathophysiologic mechanisms underlying the intractable diarrhea are poorly understood. These patients are extremely susceptible to viral infections and often succumb to overwhelming varicella, measles, Epstein-Barr virus (EBV), herpes, or cytomegalovirus infection. It is worthwhile investigating stools for viral particles in these patients in that viruses—singly or in concert—may play an important role in the pathogenesis of the diarrhea.[83] Some viral agents, such as rotavirus, adenovirus, and picornavirus, which normally cause self-limited diarrhea, may cause a chronic enteropathy in SCID.[84] These patients are also susceptible to systemic infections caused by organisms such as *Candida albicans*, *P. carinii*, and *Listeria monocytogenes*. Enteropathogenic bacteria such as *Salmonella* and *Escherichia coli* can also cause chronic infections in these patients.[85] Death usually occurs within the first 1 to 2 years of life unless immunologic reconstitution can be achieved, either by bone marrow transplants, enzyme replacement therapy, or gnotobiotic isolation in the absence of the above.[86]

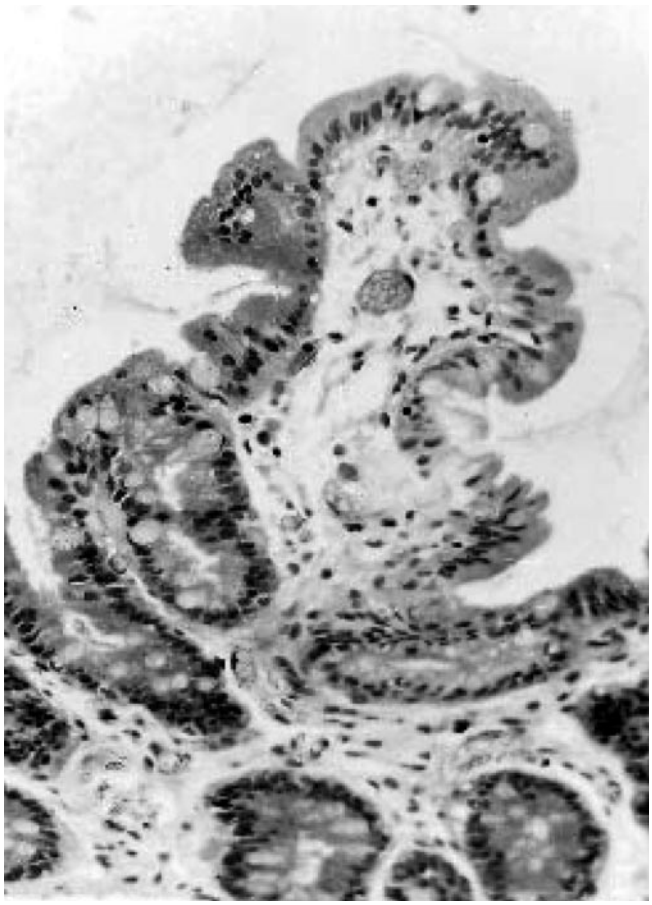

FIGURE 39.1-6 Intestine in severe combined immunodeficiency. The patient presented with intractable diarrhea, failure to thrive, and persistent oral candidiasis during infancy. Investigations confirmed adenosine deaminase deficiency. The jejunal and rectal biopsy specimens (not shown) demonstrate a markedly hypocellular lamina propria with absence of plasmocytes (hematoxylin phloxine saffron stain; ×300 original magnification). Courtesy of P. Russo, MD.

Histologic Features. Histologic features of the intestinal mucosa in SCID include the absence of plasma cells, blunted villi, and the presence of periodic acid–Schiff–positive macrophages in the lamina propria (see Figure 39.1-6). Most patients have a paucity of lymphoid tissue and profound lymphopenia with few mature T cells and low levels of Igs. Despite the uniformly profound lack of T- or B-cell function, many patients may have elevated percentages of B cells. There is, however, marked heterogeneity among SCID patients, even in groups with similar inheritance patterns or ADA deficiency. The SCID cases with Omenn syndrome are exceptional for the presence of lymphoid hyperplasia and hepatosplenomegaly.[87] Cutaneous anergy and failure to reject transplants are typical, and peripheral eosinophilia is not uncommon. As noted above, these patients are very susceptible to GVHD; thus, bone marrow transplant is better performed after removal of T cells from the donor marrow using monoclonal antibodies.[88]

Management. The management of patients with SCID involves not only appropriate antimicrobial therapy but also education to avoid potentially infectious situations. Immunization with live vaccines or bacille Calmette-Guérin (BCG) and conventional blood transfusions must be avoided in patients with proven or suspected defects in cellular immunity.[89] Live vaccines can lead to disseminated infection, and blood transfusions may result in GVHD unless the blood is first irradiated.

Grafting of viable immunocompetent cells offers the only hope of permanent restoration of immune responsiveness. Bone marrow transplant is the treatment of choice for all forms of SCID and some of the other defects. Replacement of missing factors is a logical approach to treatment but has achieved only limited success. Cytokine replacement was encouraging in the short term. IL-2 binding to polyethylene glycol has been used in some patients with defective cellular immunity. This induced an increase in Ig synthesis in vitro, as well as a

clinical response. However, the treatment is limited by the toxicity of IL-2. Common side effects are mild bone marrow suppression and abnormal liver function. The most serious side effect is the vascular leak syndrome. IL-2 provokes massive release of IL-1 and TNF-α, both mediators of enhanced vascular permeability.

Enzyme replacement is beneficial to patients with ADA or PNP deficiency (see Table 39.1-3). Frozen, irradiated red blood cells may also provide a source of PNP. An ADA replacement is successful provided that a chemically modified enzyme with a prolonged in vivo life is used. Transfection of the missing gene involved in SCID into benign retroviral vectors has led to hopes that gene therapy may be another practical approach. Both ADA and PNP deficiency forms of SCID meet the theoretic requirements for gene transfer. The gene for ADA has been identified on chromosome 20, and the DNA has been cloned. To transfer the ADA gene to patient cells, a modified retrovirus vector called SAX has been prepared. Treatment has involved repeated apheresis to collect circulating T cells, culture of these cells with anti-CD3 and IL-2 to induce T-cell expansion, gene transfer by SAX, and reinfusion of cells into the patient. Treated patients with ADA-SCID have shown transient ADA activity in T cells and some clinical benefit. Stem cells have been transfected and reinfused to provide a renewable source of "normal" cells. Half of the ADA-deficient SCID patients respond to transfusions of normal erythrocytes containing the enzyme. Others more severely affected also require treatment with the enzyme modified by polyethylene glycol, which prolongs its half-life. These patients are excellent candidates for gene therapy. Some patients have been successfully treated with periodic infusions of their own T cells or umbilical cord blood cells that have been transfected with the ADA gene linked to a retroviral vector.

Outcome. In a series of 117 patients with SCID, 22 died before transplant could be performed.[90] Among the various subtypes, infants with ADA deficiency and Omenn syndrome (large numbers of oligoclonal T cells and eosinophilia)[87] had the highest rate of mortality before transplant could be performed. The survival rate among recipients of HLA identical bone marrow grafts was significantly higher (80%) than that among recipients of HLA-haploidentical T cell–depleted bone marrow (56%).[90] Of the latter group, 35% had a persistent requirement for Ig administration after bone marrow transplant.

MHC Class II Deficiency

MHC class II deficiency is a rare primary ID disorder characterized by defects in HLA class II expression, inconsistent class I molecule expression, and a lack of cellular and humoral immune responses to foreign antigens. Clinical onset occurs early in life, with recurrent infection and severe protracted diarrhea.[91] Small bowel biopsies show moderate to severe villous atrophy. The diagnosis is usually performed by using HLA-DR immunostaining. [91] The prognosis is poor, with death usually occurring at a mean age of 4 years. Bone marrow transplant should thus be considered early in life.

OTHER PRIMARY ID DISORDERS

IFN-γ deficiency has been associated with neonatal intractable diarrhea and weight loss owing to *C. parvum*.[92] This illustrates the importance of specific cytokine deficiencies in the recovery from cryptosporidiosis and other GI disorders.

IMMUNODEFICIENCY ASSOCIATED WITH OTHER DEFECTS

Wiskott-Aldrich Syndrome

Wiskott-Aldrich syndrome is an X-linked recessive condition characterized by a triad including thrombocytopenia (small, dysfunctional platelets), severe eczema, and ID. The ID involves an inability to respond to polysaccharide antigens, later to all antigens, and deficient cellular immunity leading to repeated opportunistic infections.

Genetics. A gene on chromosome 16 encodes sialophorin, whereas the abnormal gene responsible for Wiskott-Aldrich syndrome has been closely linked to the novel hypervariable locus DXS255 on the proximal arm of the X chromosome.[93,94] The responsible gene on the X chromosome codes for a protein that functions in signal transduction.

Clinical Presentation. Patients present in the first few months of life with the above clinical picture, often accompanied by bloody diarrhea.[3,95] Although other GI complications are not prominent, malabsorption and nonspecific colitis may be encountered.

The median survival has been shown to be less than 6 years, with more than 50% of patients dying of infection, 27% with hemorrhage, and 5 to 12% with tumors, almost all of which involve the lymphoreticular system.[96] In younger patients, infections are caused by pneumococci and other bacteria with polysaccharide capsules. They characteristically present with otitis media, pneumonia, meningitis, and/or sepsis. Later, infections with agents such as *P. carinii* and herpesvirus become more frequent. Such patients produce specific antibodies poorly but have normal numbers of B lymphocytes and plasma cells, along with normal or increased rates of globulin synthesis. Their T cells exhibit a progressive decrease in number and function. Patients with this defect have an impaired humoral immune response to polysaccharide antigens. Studies of Ig metabolism have shown an accelerated rate of synthesis as well as hypercatabolism of albumin, IgG, IgA, and IgM. This results in highly variable Ig concentrations, even within the same patient. The predominant pattern is a low serum IgM, elevated IgA and IgE, and normal or slightly low IgG concentration. Lymphocyte responses to mitogens are depressed, and cutaneous anergy is frequently noted. There are low percentages of CD3 T cells, as well as CD4 and CD8 subsets. There is defective expression of the sialoglycoprotein CD43 on all leukocytes and platelets owing to its instability on cell surfaces in this syndrome.[94]

Optimal therapy requires bone marrow transplant, which appears to correct all of the problems with the exception of thrombocytopenia.

Ataxia-Telangiectasia

Ataxia-telangiectasia is a chromosomal instability disorder marked by progressive ataxia, oculocutaneous telangiectasias, and variable ID because of low IgA and IgG. This multisystem hereditary disease is associated with a complex ID, impaired organ maturation, x-ray hypersensitivity, and a high incidence of neoplasia.[97]

Pathophysiology and Genetics. The synthesis of antibodies and certain Ig subclasses appears to be disrupted owing to abnormal B-cell and Th-cell function in these patients. Individuals affected have various disorders of cell-mediated immunity, including the inability to produce antigen-specific cytotoxic lymphocytes against viral pathogens.[98] Moderately depressed proliferative responses to T- and B-cell mitogens are noted. Reduced percentages of total T cells and T cells of the helper phenotype, with normal or increased percentages of Ts cells, are found. Studies of Ig synthesis have revealed Th-cell and intrinsic B-cell defects. The thymus is very hypoplastic, with poor organization. This disease is considered a model of aberrant gene control, with persistently increased production of α-fetoprotein and carcinoembryonic antigen. However, these tests are not reliable markers of malignancy in ataxia-telangiectasia because they are elevated in the absence of cancer.[99] Cells of affected patients have an increased sensitivity to ionizing radiation, defective DNA repair, and frequent chromosomal abnormalities.[98] Breakpoints involve the genes that code for the TCR and Ig heavy chains, thus explaining the combined T- and B-cell abnormalities. The inheritance follows an autosomal recessive pattern. The abnormal gene has been mapped to the long arm of chromosome 11[98] and codes for a protein with similarity to DNA-dependent protein kinases and functions in DNA repair.

Clinical Presentation. Cerebellar ataxia becomes apparent at the time the child begins to walk, usually progressing until he or she is confined to a wheelchair, typically early in the second decade. Oculomotor abnormalities consist of nystagmus and difficulty in initiating voluntary eye movements. Oculocutaneous telangiectasia first appears as dilated venules on the conjunctiva between the ages of 3 and 6 years. Patients present with repeated sinopulmonary infections and progressive bronchiectasis (80% of cases).[98] Common viral exanthema and smallpox vaccinations have not usually resulted in untoward sequelae, although fatal varicella infection has been described.[98] GI disease is not a characteristic feature in these patients unless secretory IgA is also deficient, reported in 50 to 80% of cases.[98]

Outcome. The patients are at increased risk of developing malignancies, including non-Hodgkin lymphoma, lymphocytic leukemia, Hodgkin disease, and adenocarcinoma of the stomach. No satisfactory treatment has yet been found to treat this immune disorder and to prevent malignancy.

DiGeorge Syndrome

Thymic dysplasia is observed in several primary ID states, the most frequent of which is SCID (reviewed above).[100] DiGeorge syndrome is a rare syndrome characterized by a triad including hypocalcemia, congenital heart disease, and T-cell lymphopenia from thymic hypoplasia.

Pathophysiology and Genetics. Thymic dysplasia results from the failure of formation of the third and fourth pharyngeal pouches early during embryogenesis.[101] Other structures forming at the same time are also frequently affected, resulting in anomalies of the great vessels (right-sided aortic arch), esophageal atresia, bifid uvula, congenital heart disease (interrupted arch or truncus arteriosus, atrial and ventricular septal defects), and dysmorphic facial features. The thymic hypoplasia or aplasia is associated with a cellular immune deficit and severe infections. Defect is due to a deletion of a large region on chromosome 22, and definitive diagnosis is possible using a fluorescent DNA probe on patient cells.

Clinical Presentation. Clinically, the syndrome is characterized by absent T-lymphocyte function, cardiovascular abnormalities, and hypoparathyroidism.[101,102] Patients present with hypocalcemic tetany early in life, congenital cardiac abnormalities, and dysmorphic features, including a shortened philtrum, micrognathia, ear anomalies (low-set, notched lobes), an antimongoloid slant to the eyes, and hypertelorism. Those with the complete syndrome may resemble patients with SCID in their susceptibility to infection with low-grade or opportunistic pathogens (fungi, viruses, and *P. carinii*) and to GVHD from nonirradiated blood transfusions. It has become apparent that a variable degree of hypoplasia is more frequent than total aplasia of the thymus and parathyroid glands. Some affected children may grow normally, and such patients are referred to as having partial DiGeorge syndrome.

Concentrations of serum Igs are nearly normal for age, but IgA may be diminished, and IgE is sometimes elevated. The T-cell percentages are decreased, with a relative increase in the percentage of B cells. Despite low $CD3^+$ T cells, the proportions of CD4 and $CD8^+$ cells are usually normal. Proliferative response of lymphocytes may be absent, reduced, or normal, depending on the degree of thymic deficiency.[102] The GI manifestations in the children who survive the hypocalcemic seizures may include esophageal atresia, GI candidiasis, and intractable diarrhea. It has recently been reported that early transplant of thymus tissue, before the development of infectious complications, can promote successful immune restitution.[103]

X-Linked Lymphoproliferative Disease

X-linked lymphoproliferative (XLP) syndrome is a rare, often fatal, primary ID that has profound and damaging effects on the immune system of affected children. It is characterized by a dysregulated immune response, most commonly to Epstein-Barr viral infection.[104–106] In this syndrome, also known as Duncan disease or Purtilo syndrome, the affected patient typically develops a chronic,

often fatal, infectious mononucleosis, progressive hypogammaglobulinemia, aplastic anemia, or malignant B-cell lymphoma following EBV infection.[106,107] Although this severe susceptibility to EBV appeared to be transmitted as an X-linked recessive trait, cases have been reported in female patients.

Genetics. The defective gene in this syndrome has been identified as a signaling lymphocyte activation molecule (SLAM)-associated protein (SAP).[108,109] It is a T and NK cell–specific protein containing a single SH2 domain encoded by a gene that is defective or absent in patients with XLP syndrome. The SH2 domain of SAP binds with high affinity to the cytoplasmic tail of the hematopoietic cell-surface glycoprotein SLAM and five related receptors. SAP regulates signal transduction of the SLAM family receptors by recruiting SRC kinases.[110,111]

Pathophysiology. These patients generally appear to be healthy prior to EBV infection.[107] However, immunologic studies have demonstrated elevated IgA or IgM and/or variable IgG subclass deficiencies prior to EBV infection.[112] Subsequent to EBV infection, circulating B-cell population and Igs decrease. The predominant T cell in the peripheral circulation becomes the NK cell. Subsequently, a proliferative B-cell disorder (lymphoma) may develop in approximately 35% of patients.[113,114]

There is a marked impairment in the production of antibodies to the EBV nuclear antigens, whereas titers of antibodies to the viral capsid antigen are extremely variable. Antibody-dependent cell-mediated cytotoxicity against EBV-infected cells has been low in most affected individuals, and NK function is also depressed. There is also a deficiency in long-term T-cell immunity to EBV.[114] Studies of lymphocyte subpopulations have revealed elevated percentages of cells of the suppressor phenotype (CD8). Ig synthesis in response to polyclonal B-cell mitogen stimulation in vitro is markedly depressed.[107] Thus, both EBV-specific and nonspecific immunologic abnormalities occur in these patients.

Clinical Presentation. The clinical spectrum is variable, as typified by the following cases. In our experience, school-age children have presented with aplastic anemia, followed by a fulminant infectious mononucleosis with renal and hepatic failure, resulting in death within weeks. Another case presented with a history of a fever of unknown origin of several years duration. Massive hepatosplenomegaly was noted on physical examination. Liver biopsy revealed microabscesses focally without granulomas, resembling a septic hepatitis. Multiple cultures were negative for bacterial, fungal, and viral pathogens. Splenectomy revealed a lymphoproliferative disorder and erythrophagocytosis. Specific antibody titers to EBV were demonstrated to increase significantly. The patient was treated with antiviral agents but eventually died of a lymphoma. Most patients present in the preschool-age group with a severe, often fatal (80%), mononucleosis owing to severe hepatitis.[107] The majority of those who survive the primary infection progress to a combined type of ID with hypogammaglobulinemia and/or lymphomas.

DEFECTS OF PHAGOCYTIC FUNCTION

A number of genetically determined defects affecting polymorphonuclear and/or mononuclear phagocytes have been described (see Table 39.1-3). Neutrophil function involves cell migration in response to chemotactic stimuli, adherence, endocytosis, and killing or destruction of ingested particles. Cell motility depends on the integrity of the cytoskeleton and the contractile system, whereas directional motility is adhesion molecule receptor mediated. Endocytosis depends on the expression of membrane receptors (eg, for IgG, C3b, IC3b) and on the fluidity of the membrane.

Defects in intracellular killing of ingested microorganisms result from failure of the "respiratory burst," which is critical to production of superoxide radicals, oxygen singlets, hydroxyl radicals, and hydrogen peroxide. The organisms cultured from the lesions of patients with this type of defect are generally catalase producing and typically include *Staphylococcus*, *E. coli*, fungi, and other opportunistic organisms. Patients with defective endocytosis and killing tend to have chronic infected granulomas, especially of the lymph nodes, liver, and lung. Patients whose neutrophils fail to adhere normally to surfaces have a biosynthetic defect of a 94 kD glycoprotein (CD11/CD18).[115] These molecules are present on the surfaces of all leukocytes and play a critical adhesive role in cell-microbe, cell-cell, and cell-surface interactions.

In a classic case, a patient with a neutrophil functional defect has had multiple invasive bacterial (especially *Pseudomonas*, *Serratia*, and *Staphylococcus aureus*) and fungal (*Aspergillus* and *Candida* species) infections, beginning during the first year of life. The early infections involve primarily the skin and portals of entry: impetigo, paronychia, periodontitis, sinusitis, and perirectal abscesses. Later infections involve deeper structures: lymphadenitis, pneumonia, osteomyelitis, and splenic and hepatic abscesses. Table 39.1-3 summarizes the primary defects of phagocytic function.[3] Interestingly, several of these phagocyte disorders present with Crohn disease–like involvement of the GI tract and perianal area, as described below.

Chronic Granulomatous Disease

CGD is a primary ID that affects phagocytes of the innate immune system and is characterized by a greatly increased susceptibility to pyogenic infections with catalase-positive organisms of the respiratory tract, skin, and soft tissues.[116–119]

Genetics. CGD is caused by mutations in any one of four genes that encode the subunits of phagocyte reduced nicotinamide adenine dinucleotide phosphate (NADPH) oxidase, the enzyme that generates microbial proinflammatory oxygen radicals. Of the 410 CGD mutations identified, 95% cause complete or partial loss of protein. The CGD phenotype has two major forms of inheritance: X-linked recessive and autosomal recessive.[116] The cytochrome has 92 and 22 kD subunits. In the X-linked form of the disease, mutations

occur in the larger of these subunits. In the majority of cases, the GP92 mutation of the phagocyte oxidase (phox) permits no cytochrome production. In a $P92^{phox}$ variant that permits low levels of superoxide production, the condition can be improved with IFN-γ. The 30% of CGD patients with the autosomal recessive disease have mutations of the smaller $P22^{phox}$ cytochrome subunit and the cytosolic $P47^{phox}$ and $P67^{phox}$ components of the total NADPH-oxidase system. Recent CGD studies have revealed that recombination events between the $P47^{phox}$ gene and its pseudogenes not only cause the absence of $P47^{phox}$ but also predict the generation of a novel fusion protein.[119]

Pathophysiology. The neutrophils of patients with CGD demonstrate normal chemotaxis, engulfment, and degranulation, but their ability to kill microorganisms is impaired owing to defective oxidative burst capacity. Neutrophils and monocytes from these patients, activated in vitro by phagocytosis with a variety of particulate and soluble stimuli, fail to consume the oxygen needed for the production of superoxide anions, hydrogen peroxide, and hydroxyl radicals. The reduced form of NADPH oxidase is found exclusively in phagocytes and is dormant unless activated. The NADPH is the physiologic electron source; a flavin and a phagocyte cytochrome *b* are also postulated to function in a short electron transport chain that transfers a single electron to molecular oxygen to form the superoxide anion. The failure to produce superoxide anions in CGD can result from abnormalities in the components of the oxidase itself, as well as in its activation pathway.

Clinical Presentation. The clinical presentation of CGD comprises recurrent infection, multifocal abscesses affecting the skin and liver, lymphadenopathy, hepatosplenomegaly, chronic lung disease, and persistent diarrhea. Patients with CGD are particularly susceptible to infections with microbes that produce catalase, allowing them to survive destruction by endogenous peroxide. The most common pathogen is *S. aureus*. Others include gram-negative bacilli and fungi such as *Aspergillus fumigatus* and *C. albicans*.

The GI tract involvement, present in the majority of cases, may be present initially and recurrently, causing substantial morbidity and mortality.[118] Steatorrhea and vitamin B_{12} malabsorption are often present. Jejunal biopsy usually reveals normal villi. However, lipid-filled pigmented foamy histiocytes are present in the lamina propria throughout the GI tract.

Diagnosis. The sine qua non for the diagnosis of CGD is the demonstration of an absent or greatly diminished respiratory burst capacity. This defect can be demonstrated by measuring superoxide (O_2^-) production in response to both soluble (PMA) and opsonized particulate stimuli (zymosan). In the majority of cases, there is either no detectable O_2^- generation or production at rates between 0.5 and 10% of controls.[102] An alternative method for measuring respiratory burst activity is the commonly employed nitroblue tetrazolium (NBT) test. Neutrophils able to produce a normal oxidative burst reduce the NBT, causing a change in color from clear to blue. In the most common forms of CGD, no NBT reduction is observed in any of the cells. In some of the variant forms, however, a high percentage of cells may contain small amounts of formazan. The NBT test is helpful in classifying variant forms of CGD. Historically, the major classification criteria for CGD depended on the cytochrome *b* spectrum. Its determination can be accomplished using intact neutrophils or in subcellular fractions by Western blot analysis using antibodies to the two subunits of cytochrome *b*.[120]

Enterocolitis. Patients with CGD often present with an enterocolitis greatly resembling Crohn disease.[118,121] Manifestations typically include vomiting, diarrhea, abdominal pain, weight loss, and fever. Disordered intestinal motility, ulceration, obstruction, and infection (eg, abscesses) can occur anywhere along the GI tract, from the mouth to the anus. The other similarities to Crohn disease include physical findings (most notably perianal abscesses and fistulae), endoscopic appearance, and radiographic abnormalities. Granulomas and giant cells are found quite frequently in colonic biopsies (Figure 39.1-7). The mechanism of granuloma formation in CGD is unknown. It has been postulated that the defective respiratory burst in phagocytes results in persistent inflammation because chemoattractants are not oxidatively inactivated. Delayed clearance of microorganisms may also explain these inflammatory changes. Similar hypotheses have been proposed to explain granuloma formation in Crohn disease.

A recent study of colonic mucosal biopsies of patients with CGD showed that the inflammatory infiltrate differed from the normal controls by an increase in eosinophils and macrophages.[121] There was a paucity of neutrophils compared with ulcerative colitis. Expression of HLA-DR was increased in the epithelium and vascular endothelium compared with normal controls. Moreover, patterns of expression of the adhesion molecules (ICAM-1, vascular cell adhesion molecule 1 [VCAM-1], E-selectin) differed significantly in CGD from those in other inflammatory bowel disease: ICAM-1 was more strongly expressed in the lamina propria, VCAM-1 was more patchily expressed, and E-selectin was present only in the small vessels.[121]

Gastritis. In addition to frequent hepatic and perirectal abscesses, patients with CGD may develop a granulomatous narrowing of the gastric antrum, with symptoms suggestive of gastric outlet obstruction.[117–119] It is important to consider a diagnosis of CGD in patients presenting with an unexplained annular narrowing of the antrum.[122–124] The differential diagnosis includes pyloric stenosis, peptic ulcer disease, eosinophilic gastroenteritis, or Crohn disease. However, tissue examination, the NBT test, and analysis of CD68-positive cells are diagnostic.[118,123]

Management and Outcome. Management depends on the extent of intestinal involvement and its complication:

- Antimicrobial therapy and drainage of abscesses lead to clinical improvement.[118]

- The use of steroids can hasten the resolution of colitis or gastric outlet obstruction and is recommended by several groups.[118,125]
- Sulfasalazine may be helpful to manage colonic disease.
- Malnourished patients may require parenteral nutrition. The gastric outlet obstruction often can be managed medically with broad-spectrum antibiotics and continuous enteral alimentation. Nutritional support and antimicrobial agents may obviate the need for surgery,[124] with symptomatic resolution of the obstruction after 2 to 4 months of therapy.
- IFN-γ was reported to be active on CGD phagocyte superoxide generation, NADPH-oxidase kinetics, and expression of the gene for the phagocyte cytochrome *b* heavy chain.[126] In vitro treatment with IFN-γ increased the respiratory burst activity of polymorphonuclear neutrophil (PMN) leukocytes and macrophages from patients with CGD type IA variant (X-linked; A designates a form in which phagocytes exhibit decreased but detectable superoxide production). Phagocytes from classic type I, IIA, and II CGD did not respond to IFN-γ. In vivo studies demonstrated similar responses. IFN-γ appears to upregulate expression of cytochrome *b* genes by increasing their transcription or through post-translational stabilization of messenger RNA.[127] These studies support the reported potential efficacy of IFN-γ in the treatment of these patients.[118] The safety and effectiveness of long-term recombinant human IFN-γ therapy has been reported in CGD.[128] Thirty patients received recombinant IFN-γ three times weekly for an average of 2.5 years. The rate of serious infection was 0.13 per patient-year, compared with 1.10 in untreated patients.[128] Fever (23%), diarrhea (13%), and flu-like illness (13%) were the most common adverse effects of recombinant IFN-γ. No serious adverse effects or impairments in growth or development were observed.

Finally, it is critically important for the clinician to consider the possibility of CGD in patients with a "Crohn-like" disease in whom a history of recurrent infections and abscesses is noted. The intestinal and perianal manifestations are remarkably similar, although the treatments differ.

Leukocyte Adhesion Molecule Deficiency 1

This immune disorder is characterized by the inability of phagocytes to adhere to vascular endothelium and migrate into tissues owing to an absence of CD11/CD18 β_2 integrins on the phagocyte surface. Leukocyte adhesion molecule deficiency 1 is a rare inherited adhesion molecule disorder that is manifested by recurrent and often fatal bacterial infections.[116]

Pathophysiology. The leukocytes of affected individuals are characterized by absent or deficient expression of plasma membrane glycoproteins that are members of the leukocyte integrin family. The LFA-1 (CD11a/CD18) serves as an adhesion-promoting molecule, facilitating lymphocyte blastogenesis, cellular cytotoxicity (cytotoxic T lymphocyte, NK, and K), and lymphocyte endothelial cell adhesion. The Mac-1 (CD11b/CD18) is the receptor for C3b1 (CR3), an adhesion-promoting molecule facilitating PMN aggregation, PMN/macrophage (Mp) adhesion to substrates, and PMN/Mp chemotaxis. The P150,95 (CD11c/CD18) is a less well-defined glycoprotein that may promote adhesion of PMN and Mp to substrates and also bind C3bi.[116,128] Leukocytes in affected individuals have defective migration and adherence, resulting in an increased susceptibility to infections. There are at least two variants of CD11/CD18 leukocyte glycoprotein deficiency.[116,129] The degree of CD11/CD18-deficient expression (ranging from 10% of normal to totally absent) correlates closely with the severity of the clinical manifestations and the magnitude of the in vitro cellular abnormalities. In vitro leukocyte abnormalities include a defect in adhesion by unstimulated or PMA-stimulated cells. Neutrophils fail to demonstrate

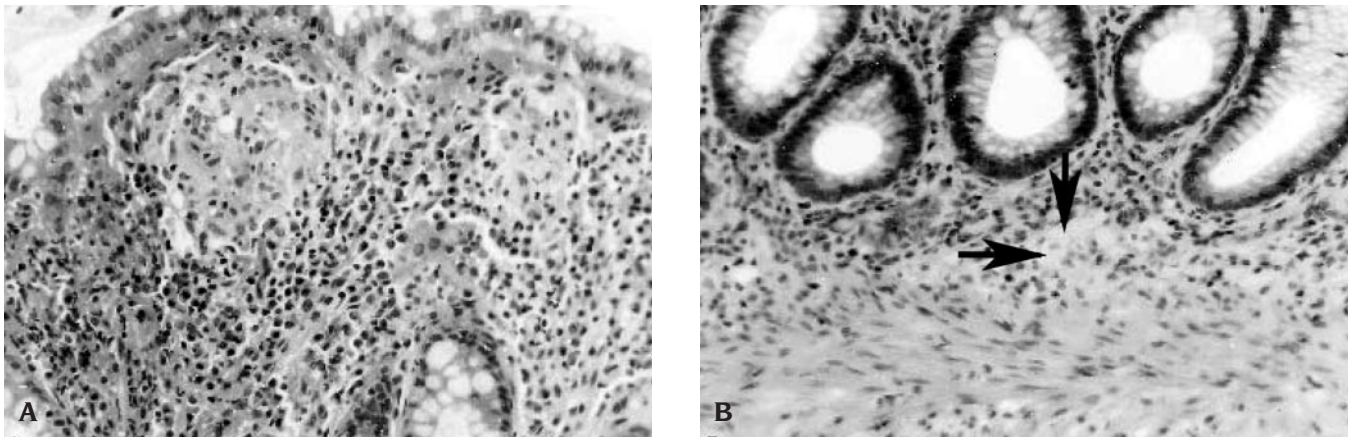

FIGURE 39.1-7 Long-standing colitis in a patient with chronic granulomatous disease. His severe colitis and perianal involvement resembling Crohn disease were resistant to usual therapy (salazosulfapyridine, 5-acetylsalicylic acid, prednisone, 6-mercaptopurine) but responded to total parenteral nutrition and complete bowel rest. *A*, Rectal biopsy specimen shows two granulomas in the superficial part of the mucosa and a dense chronic inflammatory reaction peripherally. *B*, Foamy macrophages (*arrows*) are seen near the muscularis mucosae (hematoxylin phloxine saffron stain; ×300 original magnification). Courtesy of P. Russo, MD.

aggregation in response to stimulants (eg, C5a, PMA). Impairment of directed motility is demonstrated in vitro in response to chemoattractants. A severe defect in CR3 aggregation activity is noted. The NBT for respiratory burst activity is impaired, as is secretion of granular contents by neutrophils and monocytes when induced by particulate stimuli. Lymphoid cells present a diminished blastogenic activity to mitogen (PMA). There is also an impairment in cytotoxic activity mediated by T lymphocytes, NK cells, and K cells.[129]

Clinical Presentation. Infants frequently present weeks after birth (2–3 weeks), with delayed umbilical cord separation and cellulitis of the umbilical stump (omphalitis). Other tissue infections such as cellulites, perirectal abscesses, and necrotizing bowel infections are characteristic. Stomatitis or pharyngitis is present in 40%, and gingivitis or periodontitis is present in 56% of patients.[130,131] The oral and perineal manifestations of this disorder may be mistaken for Crohn disease. We have seen a patient presenting with an ischiorectal abscess and distal ileocolitis, greatly resembling Crohn disease.[130] GI tract involvement has been reported in very few patients, including appendicitis, peritonitis, ischemic ileitis, and necrotizing enterocolitis.[130,131]

Bacterial septicemia is a common complication and may frequently be fatal. Common bacterial pathogens include *S. aureus*, group A β-hemolytic *Streptococcus*, *Proteus mirabilis*, *Pseudomonas aeruginosa*, and *E. coli*. Severe viral infections (viral meningitis or fatal enteroviral infection) and oral candidiasis have also been described.

Management and Outcome. No specific therapy has been shown to ameliorate the clinical manifestations of the disorder. Antibiotic therapy has proved to be successful in most situations, but patients have often died from bacterial sepsis. Leukocyte adhesion molecule deficiency 1 is uniformly fatal within the first 10 years of life, and bone marrow transplant is the only effective cure. It rapidly reversed the intractable Crohn-like ileocolitis in one of our young patients.[130] Because the *CD18* gene has been cloned and sequenced, this disorder is a leading candidate for gene therapy.[132]

Other Disorders of Neutrophils

In addition to CGD and the CD11/CD18 adhesion molecule deficiency, other hereditary errors of neutrophil number and function are notable for their association with GI manifestations. These include glycogen storage disease type 1B and the Hermansky-Pudlak syndrome. Both of these disorders are also characterized by a nonspecific colitis that greatly resembles inflammatory bowel disease. In the former disorder, treatment with human recombinant granulocyte colony-stimulating factor has been shown to improve both the neutropenia and the colitis. Finally, Shwachman syndrome is another multisystem congenital disorder associated with cyclical neutropenia. The primary GI manifestations, exocrine pancreatic insufficiency, and failure to thrive are discussed in detail elsewhere in this book.

OTHER DISORDERS AT TIMES ASSOCIATED WITH ID

A number of other clinical disorders are associated with various forms of primary ID (see Table 39.1-3). The discussion is limited to those conditions with prominent GI manifestations.

Chronic Mucocutaneous Candidiasis

Chronic mucocutaneous candidiasis is a syndrome characterized by *Candida* infection involving the esophageal and buccal mucosa, skin, and nails. It is frequently associated with an endocrinopathy (Addison disease, hypoparathyroidism, hypothyroidism) and pernicious anemia.[133] This condition may result from a variety of causes, including a primary defect in cell-mediated immunity to *Candida* (autosomal recessive). Patients may present with esophageal candidiasis in the presence or absence of oral involvement. Therefore, any patient with mucocutaneous candidiasis who has dysphagia, odynophagia, or hematemesis should be suspected of having *Candida* esophagitis, even if oral involvement is not evident. These individuals are at risk for development of esophageal stricture and thus require aggressive treatment for chronic *Candida* infection. The use of antacids of H_2 antagonists may worsen the esophageal involvement with *Candida* by reducing gastric acidity.

Patients with familial chronic mucocutaneous candidiasis may also present with a chronic indeterminate colitis. The colitis may be unresponsive to medical management, including sulfasalazine, steroids, elemental diet, parenteral nutrition, 6-mercaptopurine, and cyclosporine. The unrelenting colitis eventually required colectomy, without subsequent recurrence of disease in a patient. Interestingly, his mother, who is also affected by chronic mucocutaneous candidiasis, has primary biliary cirrhosis.

Autoimmune Polyendocrinopathy-Candidiasis-Ectodermal Dystrophy

This autosomal recessive disease is characterized by a variety of clinical manifestations occurring in variable combinations. The polyendocrinopathy may include failure of parathyroid glands, the adrenal cortex, pancreatic beta cells, gonads, gastric parietal cells, and thyroid gland. Other manifestations may include hepatitis, chronic mucocutaneous candidiasis, dystrophy of the dental enamel and nails, severe alopecia, vitiligo, and keratopathy.[134,135] In one series of 68 patients from 54 families, 60% initially presented with oral candidiasis, 9% with malabsorption, and 3% with keratopathy.[136] A malabsorptive syndrome has been reported in up to 24% of patients with autoimmune polyendocrinopathy-candidiasis-ectodermal dystrophy or type I polyglandular autoimmune syndrome.[137] The steatorrhea has been attributed to a number of causes. Our experience is similar to that recently reported by Ward and Scirè and their colleagues, who reported that intestinal infections (including bacterial overgrowth) may play a role but that exocrine pancreatic insufficiency is the major factor.[135,137] The malabsorptive syndrome and accompanying

decreased absorption of calcium and vitamin D may aggravate the severe hypocalcemia in those patients who have a polyendocrinopathy. Use of pancreatic enzymes dramatically improved symptoms and the hypocalcemia. However, control of the various autoimmune manifestations of the disease was only achieved using cyclosporine.[135]

GRAFT-VERSUS-HOST DISEASE

Hematopoietic stem cell transplant is the treatment of choice for a number of primary ID involving cellular immunity. Bone marrow transplant is also largely used in the treatment of leukemia. However, GVHD has long been regarded as a serious complication of this procedure.[138] GVHD can present as two, but not mutually exclusive, clinical syndromes: acute GVHD and chronic GVHD.

Acute GVHD is a distinctive syndrome of dermatitis, hepatitis, and enteritis occurring within 3 months of allogeneic bone marrow transplant. Although GVHD may affect any organ, intestinal GVHD is particularly important because of its frequency, severity, and impact on the general condition of the patient. Severe diarrhea is common and usually associated with symptoms of protein-losing enteropathy. The GI tract plays a major role in the amplification of systemic disease because GI damage increases the translocation of endotoxins, which promote further inflammation and additional mucosal damage. Translocation may be complicated by septic shock and multivisceral failure. Clinical symptoms, together with timing after bone marrow transplant, make the diagnosis easy. Data in adults suggest the usefulness of transabdominal ultrasonography, color Doppler imaging, and endoscopy in the diagnosis of acute GVHD.[139,140] Intestinal biopsies show villous atrophy, apoptotic enterocytes within glands, and lamina propria infiltration. Progressive elucidation of the mechanisms of GVHD has shown that donor T cells are critical for the induction of GVHD because depletion of T cells from bone marrow grafts effectively prevents GVHD. The standard regimen that is used to prevent GVHD classically includes cyclosporine plus short-term methotrexate. Corticosteroids can be added to this regimen, but adverse effects have to be considered. Tacrolimus is a more potent alternative to cyclosporine. Mycophenolate mofetil can be used as part of a combination therapy. Systemic antibacterial therapy, including eradication of intestinal bacteria, prevents the intestinal translocation of lipopolysaccharide and avoids the subsequent increase of inflammatory cytokines.

Chronic GVHD is a more pleiotropic syndrome, involving skin, liver, lung, and intestine, suggesting a sclerodermatous-like syndrome that develops after 3 months, and includes diffuse collagen deposition resulting in fibrosis, production of autoantibodies, and ID. Digestive symptoms include nausea, vomiting, food intolerance, diarrhea, and failure to thrive. The clinical presentation and endoscopic findings are nonspecific, and there is a broad differential diagnosis, including bacterial, fungal, viral, and parasitic infections. Intestinal lesions are poorly described in the literature, primarily being described in the esophagus.[141] A recent study compared the histologic features of chronic GVHD and control children.[142] Chronic GVHD with intestinal involvement was usually multisystemic (88.2%) and preceded by acute GVHD in 88.2% of cases. Histologic features from duodenal and/or colonic biopsies included (1) villous atrophy; (2) glandular lesions, mainly apoptotic with variable intensity; and (3) lamina propria infiltrate with cytotoxic T lymphocytes ($CD3^+$, $CD8^+$, $TiA1^+$, granzyme B^-). Differential diagnosis of GVHD includes cytomegalovirus colitis and *C. parvum* infection. In chronic GVHD, the apoptotic process could be related to Tc lymphocytes, probably with other cells, such as the enterocytes via the Fas/Fas ligand pathway. The outcome of chronic GVHD is usually severe, especially in cases of GI involvement, and requires an intensive immunosuppressive treatment that renders the host vulnerable to opportunistic infections.[142] Long-term parenteral nutrition is often necessary to maintain growth and nutritional status. For all of these reasons, histologic confirmation is recommended to avoid inappropriate treatment of patients.

CONGENITAL OR HEREDITARY DISEASES ASSOCIATED WITH ID

Chediak-Higashi Syndrome

This syndrome is due to defective lysosomal granule formation in a variety of cells, resulting in phagocytic dysfunction, partial albinism, and mild neurologic impairment. Phagocytosis occurs, but lysosomal fusion with the phagosomal membrane is deficient, with subsequent impaired bacterial killing. The gene responsible presumably functions in intracellular granule trafficking.

Affected individuals suffer from pyogenic infections, which can be fatal. From the GI point of view, Crohn disease–like involvement of the bowel has been observed.

Acrodermatitis Enteropathica

Metabolic or transport disorders, such as acrodermatitis enteropathica, result in hypogammaglobulinemia and abnormal cell-mediated immunity. This autosomal recessive disease, characterized by an eczematous rash, alopecia, chronic diarrhea, malabsorption, and recurrent sinopulmonary infections, can be mimicked by acquired conditions, resulting in severe zinc deficiency, such as Crohn disease and intractable diarrhea of infancy. The symptoms and immunologic abnormalities respond to zinc supplementation. Hypogammaglobulinemia may occur in some patients with more advanced disease; it is not known whether this is due to a protein-losing enteropathy or a direct effect on lymphocytic function.

Intestinal Lymphangiectasia

This intestinal disorder may be classified as ID because it is responsible for a combination of lymphopenia and hypogammaglobulinemia (IgA, IgG). Symptoms of protein-losing enteropathy suggest the diagnosis of intestinal lymphangiectasia. The T lymphocytes are lost from the intestine or into chylous effusions, and this may be associated with a failure to manifest delayed-hypersensitivity skin reactions. Susceptibility to infections is variable, but

rarely severe. Diagnosis requires confirmation by intestinal biopsy. Lymphangiography may show other lymphatic abnormalities in familial cases. As with other protein-losing enteropathies, serum IgM tends to remain within normal limits, whereas the serum IgG and IgA levels may fall to very low levels. This pattern may be seen in patients with primary hypogammaglobulinemia, although the serum IgA is usually much lower. However, it differs from that seen in the hypogammaglobulinemia secondary to lymphoproliferative disease, in which the serum IgM is usually the first Ig class to fall.

There is usually a good response to a fat-restricted diet and supplementation with medium-chain triglycerides. This reduces the lymphatic flow in the intestine, thus reducing the pressure driving the gut losses. Steroids are helpful when the lymphangiectasia is due to local inflammation, such as in Crohn disease, and may also have a short-term palliative effect in malignant infiltration.

Facial Dysmorphy, Intractable Diarrhea, and ID

These patients present with diarrhea starting in the first 6 months of life (less than 1 month in most cases). They are small for gestational age and have an abnormal phenotype, including facial dysmorphism with prominent forehead, broad nose and hypertelorism, and a distinct abnormality of hair, trichorrhexis nodosa. These patients have defective antibody responses despite normal serum Ig levels and defective antigen-specific skin tests despite positive proliferative responses in vitro.[143] Small bowel biopsy specimens show moderate or severe villous atrophy with variable mononuclear cell infiltration of the lamina propria and absence of epithelial abnormalities. Histologically, there are no specific abnormalities. Prognosis of this type of intractable diarrhea of infancy is poor because most patients have died between the ages of 2 and 5 years, some of them with early onset of liver disease.[143] The cause of this diarrhea is unknown, and the relation between low birth weight, dysmorphism, severe diarrhea, trichorrhexis, and ID is unclear (see Chapter 43.3, "Congenital Enteropathy Involving Intestinal Mucosa Development").[144,145] Among the congenital forms of hair dysplasia, trichorrhexis nodosa is very common and can be present in several pathologic conditions.[146–148]

Intestinal Atresia Associated with ID

Intestinal atresia, which is a common congenital defect, has been reported to be associated with ID.[149–151] However, the first report involved three siblings from healthy, nonconsanguineous parents, with multilevel intestinal atresias.[149] One sibling had documented SCID, whereas the clinical histories of the two other siblings strongly suggested a congenital ID syndrome. All patients died before 2 years of age. One last sibling was born in 2001 with the same defects and documented SCID. He survived $2^1/_2$ years with short-bowel syndrome on total parenteral nutrition but finally died from sepsis. This rare syndrome appears to have an autosomal recessive mode of transmission. Other cases have been reported, such as two affected siblings born 18 months apart and a third child with duodenal atresia.[151] One additional child with multiple intestinal atresia was diagnosed for ID after a post-transfusion GVHD. In case of multiple GI atresias, attention should be given to possible associated immune disorder, and irradiation of blood products is recommended pending evaluation of immune sytem status. Donor immune reconstitution after liver-intestine transplant was recently reported in a child with multiple intestinal atresia and SCID.[152] This child did not experience intestinal graft rejection but only a mild GVHD. It is postulate that this child engrafted a donor intestine–derived immune system and is incapable of rejecting transplanted organs.

Congenital Hypothyroidism

Bidirectional interactions between the immune and endocrine systems have been well described, particularly in relation to the growth hormone and adrenal axes. More recently, an association between congenital hypothyroidism and ID was described.[153] Severe and persistent lymphopenia was associated with bronchiectasis and chronic diarrhea. It was proposed that the prolonged thyroid hormone deficiency might be related to the impaired cellular immunity.[153]

DIAGNOSIS OF PRIMARY ID

Primary ID states are relatively rare compared with those that occur secondary to various diseases or their treatment.[42,154] Patients with primary ID have an increased susceptibility to infections, as well as to diverse GI problems, as reviewed above. A systematic approach to investigating children with suspected ID is necessary.[42,155] Early treatment may prevent otherwise inevitable and devastating complications or death. By classifying them into disorders of antibody production, cell-mediated immunity, combined humoral and cellular immunity, phagocytic function, and complement components, a logical approach to their diagnosis can be developed.

Clinical Analysis

In general, one should consider a possible diagnosis of primary ID on the basis of the pattern or type of infection rather than on their frequency alone. Multiple benign viral infections of the upper respiratory tract are of much less significance than a single episode of *P. carinii* pneumonia or recurrent staphylococcal and gram-negative infections. The pattern of infection may often give a clue to the component of the immune system that is most likely affected, as summarized in Table 39.1-1. Most patients with a significant ID present in the first year of life. Infants with predominantly cellular or combined defects present slightly earlier than those with humoral ID. In the latter group, maternally acquired antibodies serve to protect the child for the first 5 months or so. The age at presentation is, however, quite variable and is influenced by the timing of exposure to infectious organisms. By virtue of their associated GI manifestations, pediatric gastroenterologists are most likely to be consulted for the primary ID detailed in this chapter.

Microbiologic Investigations

In patients who are febrile or severely ill, a septic workup should include blood cultures for aerobic and anaerobic bacteria, as well as fungi. Serologic diagnosis of viral or other infections may be unreliable owing to the inability to produce specific antibodies, as discussed above. Thus, efforts should focus on attempts to isolate infectious organisms from respiratory secretions, urine, stool, blood, and cerebrospinal fluid. The polymerase chain reaction may be useful to enhance the sensitivity for the detection of viral genomes. Perhaps more than any other possibility, HIV infection must be extensively ruled out in cases of suspected primary ID. The immunologic and GI manifestations (reviewed in Chapter 39.2) bear an overlap with many of the cellular immune defects described above. The diagnosis should be excluded by identification of HIV antigens and virus isolation, in addition to standard serologic methods.

Digestive and Nutritional Assessment

Patients with chronic diarrhea should have serum albumin, blood urea nitrogen, and electrolyte levels measured. If malabsorption or sinopulmonary disease is present, a sweat test and nasal ciliary biopsy should be considered to exclude cystic fibrosis and the immotile cilia syndrome, respectively. Micronutrient deficiencies of vitamins, minerals, and trace metals should be assessed in cases with malnutrition or chronic diarrhea.

Immunologic Assessment

Screening tests employed for suspected ID are summarized in Table 39.1-7. Detection of an ID requires careful assessment of the patient's ability to develop and express B-cell, T-cell, and combined B- and T-cell functions. Both the amplification of the immune response (cytokine production, complement factors) and effector mechanisms (phagocytosis and inflammatory response) require investigation. Evaluation starts with enumeration of immune cell populations. This should include T- and B-cell, granulocyte, and monocyte counts. Quantitative measurement of Ig concentrations is necessary. Serum total Ig levels lower than 2 g/L are abnormal. The humoral immune response can be examined by screening for natural antibodies to ubiquitous antigens (A and B isohemagglutinins, heteroantibodies to sheep erythrocytes, bactericidins against *E. coli*). Specific antibody response to well-tolerated active immunizations (diphtheria and tetanus toxoids, killed poliovirus antigens, and *Haemophilus* conjugates) can be analyzed. Live vaccines are prohibited. The B-cell markers (CD19, -20, and -22) can be examined by immunofluorescence and flow cytometry.

T-cell function can be assessed by skin testing for delayed hypersensitivity to antigens, which generally reveals positive results in healthy individuals, such as *Candida*, *Trichophyton*, streptokinase or streptodornase, and mumps. Response to active skin sensitization may be assessed with dinitrochlorobenzene. The T-cell function can also be examined by in vitro reactivity of peripheral blood mononuclear cells to PHA, other mitogens, and common antigens. Anti-CD3 is a good indicator of general T-lymphocyte reactivity, as is the one-way mixed lymphocyte reaction (see Table 39.1-7). Enumeration of T cells and their subsets is achieved by surface markers by flow cytometry. In vitro assays for complement components (classic and alternate pathways) can be evaluated immunochemically and functionally in those patients with relevant symptoms. Specific testing of bactericidal and other functions of polymorphs is available (see Table 39.1-7). Patients suspected of having CGD should have phagocytic function evaluated by the semiquantitative reduction of NBT dye and the stimulation of superoxide production. Additional phagocyte testing includes chemiluminescence following stimulation with PMA or dichlorofluorine, as well as by quantifying the capacity of cells to ingest and kill catalase-positive microorganisms. In vitro analysis of inflammatory response capacity can be examined by measuring chemotaxis, chemokinesis, and cytokine production. Adhesion molecule expression can also be determined. Specific details are reviewed in detail elsewhere.[3] Specific investigations that may provide clues to certain primary IDs include thrombocytopenia with small platelets in the Wiskott-Aldrich syndrome, α-fetoprotein in ataxia-telangiectasia, and a deletion on chromosome 22 in DiGeorge syndrome.

TABLE 39.1-7 INITIAL LABORATORY SCREENING FOR IMMUNODEFICIENCY

CBC, WBC and differential, platelets (count and size)
Serum protein electrophoresis
Chest radiography for thymic evaluation
Quantitative serum Igs
IgG, IgM, IgA, IgE, and IgG subclasses
Flow cytometry
Quantitation of total T cells (CD2, CD3)
T-cell subsets (CD4, CD8)
B cell1s (CDI9, CD20)
NK cells (CD16, CD56, CD57)
HLA-DR (to rule out bare lymphocyte syndrome)
Metabolic bursts (to rule out CGD), including NBT testing
In vitro proliferative response to mitogens (PHA, Concanavalin A) and antigens (MLR)
Isohemagglutinin titers
Antibody titers (to documented immunizations) (diptheria, tetanus, rubella, measles)
C3, C4, CH50
If indicated
Sweat Cl^- (to rule out cystic fibrosis)
α_1-Antitrypsin
Celiac disease screening

CBC = complete blood count; CGD = chronic granulomatous disease; HLA = human leukocyte antigen; Ig = immunoglobulin; MLR = mixed leukocyte reaction; NBT = nitroblue tetrazolium; NK = natural killer; PHA = phytohemagglutinin; WBC = white blood count.
