Pathophysiology • Diagnosis • Management

CHAPTER 1

MALDIGESTION AND MALABSORPTION

Jacques Schmitz, MD

Malabsorption syndromes are characterized by the association of chronic diarrhea, abdominal distention, and failure to thrive. During the period between 1955 and 1970, the widespread use of intestinal biopsy, the emergence of basic concepts such as lipolysis at an interface, miscellar solubilization, Na^+-coupled solute transport, and brush border as a digestive-absorptive organelle permitted the breakdown of clinical malabsorption into many distinct congenital and acquired conditions affecting one or several of the different steps in hydrolysis or transport of nutrients. Thus, the term malabsorption syndrome now also designates such different situations as those characterized by exocrine pancreatic insufficiency (eg, cystic fibrosis), intestinal villous atrophy (eg, celiac disease), specific hydrolysis (eg, congenital lipase or sucrase deficiencies), or transport (eg, glucose-galactose malabsorption) defects. To understand how the clinician should interpret chronic diarrhea, the main symptom of these disease states, and how to orient the approach to the precise defect involved, it is necessary to recall the physiology and pathophysiology of digestion and absorption.

PATHOPHYSIOLOGY OF DIGESTION AND ABSORPTION

Carbohydrates

Physiology. Carbohydrates in food comprise mainly starch (50–60% of total energy supplied by carbohydrates), sucrose (30–40%), and lactose (from 0–20% in adults, 40–50% in infants). Only starch molecules (amylose and amylopectin), which are glucose polymers of high molecular weight (MW), require preliminary intraluminal digestion by salivary and (predominantly) pancreatic amylases. These structurally related endoamylases only split α_{1-4} bonds at some distance from the ends of the glycosidic chains and from the branching (α_{1-6}) positions. They release mainly maltose, maltotriose, and residues of a higher degree of polymerization (branched-α-limit dextrins if the substrate is amylopectin) but no glucose.[1] Intraluminal α-amylase activity is 10 times that required for digesting the amount of starch ingested daily.[2]

The final hydrolysis of di- and oligosaccharides occurs at the brush border of enterocytes where act three main glycoproteins of high MW (greater than 200 kD), the disaccharidases: two α-glycosidases: sucrase-isomaltase, which accounts for 75 to 80% of the hydrolysis of maltose in the intestinal mucosa, the total hydrolysis of sucrose, and the nearly total hydrolysis of isomaltose (α_{1-6}), and glucoamylase, an exoamylase that is responsible for 20 to 25% of total mucosal maltase activity and releases glucose from glucose polymers of four or more residues, and one β-galactosidase, lactase-phlorhizin hydrolase, which accounts for over 95% of lactase activity in the intestinal mucosa and for the hydrolysis of glycosyl ceramides, complex glycolipids that are important constituents of milk globule membranes.[3] Sucrase-isomaltase and lactase activities are highest in the proximal intestine, whereas glucoamylase activity is highest in the ileum.[4] The ingested disaccharides, which physiologically are not absorbed as such, are thus ultimately broken down into their constituent monosaccharides: glucose, galactose, and fructose.

Entry into the enterocytes through the brush border membrane occurs via carrier molecules. Entry of glucose and of galactose, occurring through the same carrier, sodium glucose linked transporter (SGLT)1, is linked to the entry of Na^+ along its electrochemical gradient; the latter blocks glucose exit from the cell and eventually provides the energy necessary for its accumulation in the cell against a concentration gradient.[5] The electrochemical Na^+ gradient is maintained by Na^+, K^+-adenosine triphosphatase located in the basolateral membrane of the enterocyte. Thus, glucose and galactose absorptions are indirectly active. Mutations of the gene coding for SGTL1 are the cause of congenital glucose-galactose malabsorption.[6]

Entry of fructose occurs through another specific carrier (glucose transporters [GLUTs]). It is not Na^+ dependent.[7] Fructose is more metabolized in the enterocyte than glucose; exit from the cell of both monosaccharides occurs via a facilitated transport system (a carrier) similar to the one present in red blood cell membranes (GLUT2).[8]

Final hydrolysis and absorption of carbohydrates are closely integrated in the brush border so that when sucrose is perfused into the jejunum, no or low amounts of glucose diffuse back into the intestinal lumen. Perfusion studies in adults, as in children, have shown that the limiting factor in the overall process of disaccharide absorption is absorption of glucose and fructose in the case of sucrose and of maltose but lactase activity in the case of lactose. This relationship is not modified in cases of mucosal atrophy.[9]

Pathophysiology. Pancreatic amylase insufficiency occurs normally in newborns, whose amylase activity remains extremely low during the first weeks of life. Yet substantial amounts of starch (greater than 40 $g/m^2/d$) can be given to 1-month-old infants before fermentation, the sign of carbohydrate malabsorption, occurs.[10] Similarly, in cases of exocrine pancreatic insufficiency (cystic fibrosis or Shwachman syndrome), symptoms related to amylase insufficiency are modest. In the stools, volatile fatty acids are notably increased, but lactic acid is low or absent, and pH is above 5.5. This is probably due to the fact that starch is a poorer substrate for colonic bacteria than are oligosaccharides.[11]

Indeed, congenital or acquired defects of intestinal digestion and absorption of oligosaccharides lead to a major digestive symptom: fermentative diarrhea. It is characterized by watery stools whose volume is roughly proportional to the amount of ingested carbohydrates. Stool volume may thus be extremely variable from one day to another. The stools have an acidic smell, resembling that of rotten apples or vinegar. They have an acidic pH (5.5–4.0) and usually contain unabsorbed reducing sugars or undigested disaccharides. The child may be thirsty and presents some degree of abdominal distention—the more impressive, the younger the child.[12]

Diarrhea and abdominal distention (with gas-fluid levels on plain abdominal radiographs) are secondary to a cascade of events. Maldigested di- or trisaccharides or malabsorbed monosaccharides are small, osmotically active molecules that drive water inside the lumen of the gut in direct proportion to their amount. The increased volume of chyme leads, in turn, to an increased peristaltic activity and a reduced transit time, decreasing the chance of digestion and/or of absorption.[13] In the cecum, the unabsorbed small carbohydrate molecules are readily fermented by colonic bacteria. The latter produce CO_2, H_2, and mainly acetic but also butyric and propionic acids. If the availability of carbohydrates further increases, lactic acid, a strong acid with a low pK_a, is produced and the pH decreases below 5.5 (a stool pH less than 5.5 indicates lactic acid in the stools[12]). This low pH disturbs Na^+ absorption by the colonic mucosa, which tends to further increase stool volume, as does the presence of the osmotically active molecules of volatile fatty acids in the lumen of the colon.

The same mechanism applies in all cases of carbohydrate malabsorption: in isolated congenital defects of intestinal hydrolysis (congenital sucrase-isomaltase, lactase, or trehalase deficiencies, or late-onset lactase deficiency) or of absorption (congenital glucose-galactose malabsorption) or as a consequence of mucosal atrophy (mainly in cow's milk protein intolerance and celiac disease). Excluding the malabsorbed carbohydrate(s) from the diet stops diarrhea in a few hours; it is again triggered in a similar short period of time if the malabsorbed oligosaccharide is reintroduced in the diet. Dextrins or starch, however, may lead to diarrhea only after several (2–6) days in sucrase-isomaltase deficiency, probably because of the complementary glucoamylase activity.[12]

Proteins

Physiology. Digestion of proteins starts in the lumen of the stomach, where gastric acid denatures them and activates pepsinogens I and II into the corresponding pepsins. The latter are inactive at a pH of less than 5 and have a broad specificity, splitting peptide bonds mostly involving phenylalanine, tyrosine, and leucine.[14,15] In view of the buffering capacity of food, it is unlikely that gastric secretion plays a major role in protein digestion. In contrast, the efficiency of pancreatic proteolysis is demonstrated by the fact that as soon as 15 minutes after a test meal, about half of the amino acids in the lumen are free or in the form of small peptides.[16] After activation by enterokinase, a glycoprotein of high MW synthesized by and anchored in the brush border membrane of enterocytes in the proximal small intestine,[17] trypsinogen is converted into trypsin, which, in turn, activates the other zymogens into active proteases. The endopeptidases—trypsin, chymotrypsin, and elastase—are serine proteases of similar MW (25–28 kD) but with different and strictly defined specificities. Trypsin splits only bonds involving at the amino end basic amino acids (lysine and arginine); chymotrypsin splits those involving aromatic amino acids (phenylalanine, tyrosine, tryptophan), and elastase splits those involving uncharged small amino acids (such as alanine, glycine, and serine), which are left at the carboxy end of the newly formed peptide. They are released by exopeptidases; by carboxypeptidase A, which releases from a peptide its last amino acid when it is aromatic, neutral, or acid; and by carboxypeptidase B, when the last amino acid is basic.[1,18]

In contrast to carbohydrates, peptides enter enterocytes either after preliminary digestion by brush border peptidases into amino acids, or as peptides, in the case of di- or tripeptides, which are then split inside the cell by cytoplasmic peptidases.[19] In humans, the following brush border peptidases are now well defined: several aminopeptidases (oligoaminopeptidase or neutral aminopeptidase, the main brush border peptidase, acid aminopeptidase, dipeptidyl-peptidase IV, an ileal *N*-acetylated α-linked acidic dipeptidase with dipeptidase and dipeptidyl peptidase IV activity[20]), two carboxypeptidases (carboxypeptidase P and angiotensin-converting enzyme), two endopeptidases (including para-aminobenzoic acid [PABA] peptidase), and

γ-glutamyl transpeptidase. These enzymes are glycoproteins of MW somewhat lower than that of disaccharidases and altogether are able to hydrolyze all peptide bonds, except those involving a proline at the carboxyl side.[3] Their highest activities are in the ileum.[4,21] The released amino acids are absorbed through the following systems: neutral amino acids enter the enterocytes mainly through the B°, Na^+-dependent system, whose defect is probably responsible for Hartnup disease[22]; they can also use at least two other systems shared with basic amino acids: $B^{+,0}$ Na^+ dependent and $b^{+,0}$ Na^+ dependent, defective in type I cystinuria.[23,24] Proline and hydroxyproline mainly use the Na^+, Cl^--dependent imino carrier and, in a lesser proportion (~ 30%), the B° carrier to enter the enterocyte. Bicarboxylic acids enter through a specific Na^+-dependent, electroneutral X^-_{AG} system whose defect is responsible for dicarboxylic aminoaciduria.[23,24]

Di- and tripeptides can also cross the brush border membrane as such via a (main) peptide transport system that has been shown to have a broad specificity.[25] This carrier protein is able to transport dibasic and diacid peptides as well as di- and tripeptides (but no tetrapeptides).[15] Transport of peptide is coupled to a proton rather than to a Na^+ gradient.[26,27] Once in the absorbing cell, di- and tripeptides are split into amino acids by soluble peptidases of which glycine-leucine dipeptidase, a prolidase hydrolyzing X-Pro bonds, and a tripeptidase are known.

At the basolateral membrane, neutral amino acids leave the enterocyte using the Na^+-dependent L system; basic amino acids use Na^+-dependent y^+ and y^{+L} systems, which also accept neutral amino acids. Mutations in the gene coding for a subunit of y^{+L}, y^{+LAT} are the cause of lysinuric protein intolerance.[28] Ubiquitious Na^+-dependent A and ASC systems, of high specificity and low capacity, are probably more involved in the metabolism of the enterocytes than in protein absorption. Recently, a peptide transporter has been characterized in basolateral membranes of Caco-2 cells.[29]

Small peptides are the form in which amino acids are, in general, the more readily absorbed. Even when a di- or tripeptide is susceptible to rapid hydrolysis by brush border peptidases, an important proportion of it (30–50% depending on its concentration) is directly absorbed as such.[19,30] Thus, peptides represent the main physiologic route of entry of amino acids in the enterocytes.

Pathophysiology. In adults, nitrogen absorption is not affected by gastrectomy, which indicates that gastric acid and pepsins do not play a critical role in protein digestion. In contrast, selective absence of pancreatic protease activities—in congenital enterokinase deficiency, for example—leads to dramatic situations. Although stools are only moderately overabundant and foul smelling, fecal losses of nitrogen are massive, with the consequence of early failure to thrive. The latter is more probable and severe because the protein content of milk is low (as in human milk). Hypoproteinemia develops, leading to edema. Replacing the standard formula by a formula containing a protein hydrolysate is usually enough to normalize the stools, to decrease the fecal loss of nitrogen, and for the infant to start catching up its growth retardation.[31]

The consequences of pancreatic exocrine insufficiency on protein digestion are similar to those of selective pancreatic proteolytic deficiency. They are associated with significant losses of energy in the stools owing to the defect in starch and, mostly, in fat digestion with a massive steatorrhea. The stools are often whitish, greasy, soft but not liquid, and extremely foul smelling. Malnutrition and growth failure follow when food intakes are not sufficient to compensate for the fecal losses.

No specific congenital defect of peptide digestion or absorption by the intestinal mucosa is known, although assays of the main peptidase activities have been systematically included in the workup of diarrheal states in several pediatric gastroenterology teams for several years now. This is not surprising considering that peptides may enter enterocytes by two routes of roughly similar physiologic importance: when one is blocked, the other one can still be used. Indeed, such defects may exist but go undiagnosed. Similarly, specific absorption defects involving neutral (Hartnup disease), basic (cystinuria), or imino (prolinuria) acids are well known. Yet they have been recognized not because of digestive symptoms, which do not exist in these conditions, but because of associated specific aminoaciduria, reflecting defective tubular reabsorption of the homologous amino acids by the kidney. The absence of diarrhea in these diseases is clearly due to the fact that the specifically malabsorbed amino acids can cross the brush border membrane as peptides.[19,25] Indeed, the only known disease affecting amino acid absorption in which diarrhea is a real problem, often associated with severe malnutrition, is protein intolerance with lysinuria (or lysinuric protein intolerance). In this condition, the congenital defect does not affect the entry of arginine, lysine, and ornithine into the absorptive cell but rather their exit out of the cell through the basolateral membrane. Whatever the way of entry into enterocytes, these basic amino acids cannot get out, and symptoms occur.[32] Diarrhea is usually liquid, being probably mainly osmotic in its mechanism.

Nonspecific inflammatory alterations of the intestinal mucosa, such as those seen in celiac disease, do not lead to symptoms that can easily be assigned to protein or peptide maldigestion or absorption. A certain degree of creatorrhea exists in children with mucosal atrophy, yet it is usually mild and, because of the complex origin—both endogenous and exogenous—and the fate of protein in the human gut—absorbed or used by colonic bacteria—it is difficult to relate it directly to malabsorption. Similarly, it is difficult to decide whether the fecal losses of nitrogen observed in cases of intestinal malabsorption are the only explanation of the hypoalbuminemia that may be seen in severe celiac disease when anorexia (and, consequently, decreased protein intake) and protein-losing enteropathy are also symptoms of the disease.

Fat

Physiology. Unlike carbohydrates and proteins, fats are insoluble in water; although they diffuse through the lipid phases of the brush border and basolateral membranes of

enterocytes, they have to be "wrapped" in outwardly hydrophilic, inwardly lipophilic particles—bile salt micelles in the gut lumen, chylomicrons in the absorbing cell and circulation—to reach their site of metabolic use.[33]

Digestion of fat starts in the stomach, acted on by a lipase that has been shown recently to originate exclusively from the gastric fundus in humans,[34] whereas it is produced by the serous glands of Ebner at the base of the tongue in the rat (hence the often used term lingual lipase). In humans, this lipase has an acidic optimum pH (4.5–5.5); at the pH of the stomach, it hydrolyzes medium-chain triglycerides at the same rate as long-chain triglycerides, it preferentially splits the outer ester bonds of triglycerides, and it is not appreciably dependent on bile salts. It acts as a "starter" of pancreatic lipolysis by favoring emulsification of lipid droplets by the free fatty acids (FFAs) it releases. It plays a particularly important role in neonates whose pancreatic lipase activity is low.[35]

In the duodenum, pancreatic lipase acts only at the oil-water interface, adsorbed to the lipid droplets. Bile salts both increase the interface by emulsifying the ingested lipid droplets, thus favoring lipase activity, and, on the contrary, by forming a film between oil and lipase, inhibit its action. Colipase restores lipase activity by anchoring lipase to the interface and by keeping its active site open, giving it access to its substrate.[36] In the presence of bile salts, pancreatic lipase has an optimum pH of 8. It has an absolute specificity for the outer ester bonds (positions 1 and 3) of the glyceride molecule and releases FFAs and 2-monoglycerides.[36] Other lipolytic enzymes are secreted by the pancreas: (1) carboxylesterhydrolase, whose structure resembles that of human milk, bile salt–dependent lipase, and which acts on soluble substrates; in the presence of bile salts, it becomes active toward cholesterol esters and esters of vitamins A and E, whose absorption is thus dependent on normal bile salt secretion[37]; and (2) phospholipase A_2, which releases lysophosphoglycerides and fatty acids from phosphoglycerides, major membrane constituents.

From the onset of lipolysis, FFAs and 2-monoglycerides are solubilized in bile salt micelles, forming bigger "mixed micelles," which, in their turn, can solubilize more hydrophobic lipids such as diglycerides, un-ionized FFAs, cholesterol esters, and lipid-soluble vitamins whose absorption is therefore improved when ingested with other fats.

Primary bile acids (cholic and chenodeoxycholic acids) are synthesized in the liver from cholesterol; they are glyco- and tauroconjugated, excreted, and transformed by colonic bacteria into secondary acids (deoxycholic and lithocholic acids). Because of their lower pK_a, conjugated bile acids allow a much better micellar solubilization of the products of lipolysis.[38] Bile acids, whose pool amounts to 1 to 2.5 g, are efficiently reabsorbed in the distal ileum by a Na^+-dependent, carrier-mediated process that is responsible for the reabsorption (and recirculation) of 95% of the bile salts secreted in bile.[39]

Micelles diffuse from the gut lumen through the unstirred water layers lining the luminal surface of brush borders, where the products of lipolysis are liberated. They diffuse across the apical cell membrane. At low concentrations, there is evidence that FFAs can enter enterocytes by a fatty acid binding membrane protein with high affinity for saturated or unsaturated long-chain fatty acids[40,41]; entry of cholesterol is also mediated by brush border membrane lipid exchange proteins.[42] In enterocytes, FFAs of 12 carbon atoms or more bind to small carrier proteins, the fatty acid–binding proteins (I, ileal, the majority, and L, liver).[43] In the smooth endoplasmic reticulum, long-chain fatty acids are activated in acyl coenzyme A before entering the monoglyceride pathway responsible for at least 70% of postprandial triglyceride resynthesis (whereas the role of glycerophosphate pathway in triglyceride resynthesis increases between meals and during fasting).[33] Microsomal triglyceride transfer protein transfers resynthesized triglyceride in the rough endoplasmic reticulum where, together with phospholipids and cholesterol, triglyceride is joined by newly synthesized apolipoproteins, A-I, A-IV, and B-48. The absence of one of the microsomal transfer protein subunits, but not of B-48,[44] has recently been shown to be responsible for abetalipoproteinemia.[45] Chylomicron formation is then completed in the Golgi apparatus. Chylomicron-containing Golgi vesicles are released from the Golgi apparatus. After fusion of these vesicles with the basolateral membrane, chylomicrons are excreted by exocytosis into the intercellular spaces, from which they reach the lymphatics and, by the thoracic duct, the systemic circulation.[46]

Pathophysiology. Because of their hydrophobicity, digestion and absorption of dietary fats are dependent on many auxiliary molecules other than enzymes and carriers: bile salts, colipase, fatty acid–binding proteins, and apolipoproteins. It is thus remarkable that, given this complexity, more than 95% of ingested fat should be ultimately absorbed in children over the age of 1 year.

However, these auxiliary mechanisms are also sites for potential disturbances; indeed, causes of fat malabsorption and steatorrhea are much more numerous than those of carbohydrate and protein malabsorption. Fat malabsorption may result from lipase and/or colipase deficiency(ies); abnormal bile salt synthesis, excretion, deconjugation, and reabsorption; impaired triglyceride resynthesis; chylomicron formation and/or excretion; or obstruction of intestinal lymphatics.

Isolated fat malabsorption is extremely rare. In the case of congenital lipase deficiency, for example, stools are greasy but not liquid or even soft: nonabsorbed fat constitutes an oil phase distinct from, or surrounding, otherwise nearly normal stools. Steatorrhea is massive, with the fat absorption coefficient being less than 50%. Such a steatorrhea is painless and may have no other consequence for the patient than greasy soiling and a strong appetite to compensate for the loss of energy in the stools.[47] Colipase deficiency leads to less severe steatorrhea, and biliary atresia, although leading to no other digestive symptom, presents usually with its own signs, such as jaundice and hepatomegaly.[48]

In most cases, fat malabsorption is part of a more general pathologic condition. It may result from exocrine pancreatic insufficiency: severely reduced lipase and colipase secretions result in abnormally great quantities of neutral triglyceride reaching the colon, where the bacterial flora hydrolyzes part of them, releasing FFAs and glycerol. Steatorrhea is usually

severe, with fat absorption being reduced to 70 to 40% of ingested fat. Because undigested starch is not so osmotically active, stools are soft or pasty, not liquid, like mastic.

Absorption of fat and particularly of fat-soluble vitamins is severely impaired in congenital disorders of bile salt synthesis or secretion (Byler disease) with massive steatorrhea and, occasionally, prominent rickets.[49] However, bile salt metabolism abnormalities other than reduced or absent secretion may disturb fat absorption. Bile salts may be deconjugated by certain bacterial species in cases of bacterial overgrowth. Nonconjugated bile salts are less ionized than conjugated ones at the pH of the gut lumen; thus, they have a lower ability to form micelles than the latter. Significant steatorrhea may follow. It is usually associated with other symptoms of bacterial overgrowth in a stagnant loop: increased degradation of protein and particularly of vitamin B_{12} binding proteins, fermentation of carbohydrates with production of H_2 released in breath and of volatile fatty acids resulting in diarrhea, hypoproteinemia, loss of weight, and megaloblastic anemia.[50] Bile salts also may not be absorbed because of a congenital defect[51] or ileal disease (Crohn disease) or because of ileal resection with two consequences: on the one hand, abnormally high amounts of nonabsorbed bile salts reach the colon, where they inhibit Na^+ and water absorption; on the other hand, depletion of the bile salt pool progressively leads to poor micellar solubilization and steatorrhea. In this situation, however, the direct effect of bile salts on colonic mucosa is probably more responsible for the abnormal loose or watery stools than is the increased fecal loss of fat.

Intestinal mucosal abnormalities never affect only fat absorption, even when, as in abnormal chylomicron formation and/or excretion, fat transport alone is disturbed by the disease. Most frequently, fat malabsorption is secondary to nonspecific intestinal mucosal atrophy, as observed in celiac disease or cow's milk protein intolerance. In these conditions, malabsorption of fat, as of other nutrients, results from both a decreased absorptive surface and a disturbed enterocyte metabolism. In fact, abnormal accumulation of lipid droplets occurs in active celiac disease by mechanisms that are not completely elucidated but may involve impaired apolipoprotein synthesis. It is not clear whether lipids in the stools originate directly from ingested fat or indirectly from desquamated fat-filled enterocytes. In any case, fat lost in the stools is mainly FFA partly hydroxylated by the colonic flora, which accounts for at least 1 g daily of obligatory loss of fat in the stools.[52] Interestingly, steatorrhea is usually far less severe in intestinal mucosal disorders than in exocrine pancreatic insufficiency. This may be due to the fact that most intestinal pathologic conditions, such as celiac disease, affect only the proximal small intestine or to the existence of "accessory" pathways of fat absorption, as suggested by the paradoxic absorption of 50 to 70% of ingested fats in situations in which no absorption is expected, as in congenitally impaired formation or excretion of chylomicrons.[53] The moderate steatorrhea observed in conditions with subtotal villous atrophy is usually not sufficient to make the stools grossly greasy; in fact, stool features in these situations result more from the degree of associated carbohydrate fermentation than from the degree of steatorrhea.

Even when chylomicron formation and/or excretion is blocked, as in abetalipoproteinemia or Andersen disease, with enterocytes filled with fat droplets, malabsorption is not restricted to fat. Balance studies in these conditions show fecal excretion of fat, nitrogen, and volatile fatty acids that is similar to that observed in celiac disease.[53] Stools have the same aspect. Yet a fat-free diet is sufficient to normalize the fecal excretions of nitrogen and volatile fatty acids. This indicates that nitrogen and carbohydrate malabsorption is induced by the accumulation of fat observed in enterocytes in these conditions.

Similarly, in intestinal lymphangiectasia, reflux of absorbed fat into the intestinal lumen because of blocked lymph flow is never isolated, and steatorrhea, which is usually moderate, is associated with signs of enteric loss of the other constituents of intestinal lymph: albumin, immunoglobulins (Igs), and T lymphocytes. However, fats lost in the lumen are excreted in the stools, whereas proteins are easily digested and reabsorbed, and balance studies usually fail to find a significant increase in fecal nitrogen. Diarrhea is often moderate in this condition, in which low serum albumin levels and edema are major symptoms.[54]

NUTRITIONAL CONSEQUENCES OF MALABSORPTION

Malabsorption may have no or minor nutritional consequences (eg, lipase deficiency) or, at the opposite extreme, may lead to severe malnutrition and eventually death (eg, celiac disease). Furthermore, the same disease may be life-threatening in infancy and well tolerated in adolescence (eg, celiac disease or congenital sucrase-isomaltase deficiency). Finally, malnutrition may become the consequence of a stable state of malabsorption under the influence of exogenous factors (eg, bronchopulmonary infection in cystic fibrosis). Thus, a given nutritional disturbance is not strictly linked to a given malabsorption syndrome, and it seems appropriate in dealing with nutritional consequences of malabsorption to describe first the different consequences that malabsorption syndromes may have on the nutritional status of the child and then to analyze the general mechanisms by which malnutrition occurs. Nutritional disturbances involving micronutrients will not be considered here.

States of Malnutrition

The most obvious nutritional consequences of malabsorption syndromes concern the growth of the child. Malabsorption always first reduces weight gain before it slows down growth rate. The clinical situation may deteriorate, with disappearance of subcutaneous fat, muscle wasting, and the appearance of the skin being too large for the child. Growth stops. Life may be threatened. Such a severe evolution was described in toddlers with historic celiac disease. Nutritional consequences are not so dramatic in older children with celiac disease, for example; a certain equilibrium may be reached, the child having a weight roughly adapted to his height, yet growth is retarded, and the child

may progressively become a dwarf. In adolescents, puberty may be delayed.[55]

In most severe and/or rapidly evolving malabsorption syndromes, not only is growth affected but also other general functions; malabsorption of vitamin K, whatever its mechanism (mucosal atrophy, fat malabsorption, bacterial overgrowth), may result in decreased synthesis of blood clotting factors and disturbed hemostasis, with hematomas and easy bleeding; long-term Ca^{2+} and vitamin D malabsorption, as occurs primarily in celiac disease, usually leads to osteoporosis, with hypocalcemia, hypocalciuria, and, in severe cases, "spontaneous" bone fractures, and, rarely, to rickets.[55] Bone mineral density, now easily assessed by dual-energy x-ray absorptiometry, is, indeed, decreased at diagnosis of celiac disease[56] and, to a lesser extent, in the silent form of the disease.[57] Severe protein-losing enteropathy, often associated with malabsorption syndromes (celiac disease, bacterial overgrowth, Crohn disease, intestinal lymphangiectasia), may be an additional factor responsible for hypoalbuminemia and edema and for hypogammaglobulinemia.[54]

Other biologic anomalies, also present in children with overt malnutrition, may be used in others to detect malnutrition when it is not clinically certain. They include hyposideremia, microcytic anemia with low reticulocyte counts secondary to iron malabsorption, low serum folate levels usually without hematologic consequences in case of mucosal atrophy, low serum vitamin A levels (whose ophthalmologic consequences are nonetheless rare), and low vitamin E levels, which may lead, after years of evolution, to loss of proprioception and tendon reflexes and to ataxia, in cases of fat malabsorption; vitamin E deficiency is most severe in biliary atresia and in abetalipoproteinemia.[58]

Mechanisms of Development of Malnutrition

Our knowledge concerning the mechanisms resulting in malnutrition is limited because of the complexity of a phenomenon with intricate causes, always studied when already present, with often only crude parameters (weight and height).

Although malabsorption per se is the most obvious mechanism leading to malnutrition, it is probably less often responsible for failure to thrive than decreased food intake. This has been clearly demonstrated in the case of Crohn disease,[59] but it may be also true for active celiac disease, in which anorexia is a major symptom; more generally, decreased food intake may be a main factor of malnutrition in all situations in which fermentation is a major consequence of malabsorption (congenital disaccharidase deficiencies or disaccharidase deficiencies secondary to villous atrophy) leading to abdominal distention, discomfort, and poor appetite, whereas fecal losses of protein and energy are usually modest. At the opposite end of the spectrum, fecal losses of up to 40% of ingested protein and energy in cases of exocrine pancreatic insufficiency, associated with no major discomfort, do not lead to malnutrition as long as they are compensated by an increased appetite.[60] In this situation, any factor[61] decreasing food intake—bronchopulmonary infection in cystic fibrosis, for example—triggers malnutrition and retards growth.[61]

Malabsorption per se—independently of anorexia—may induce malnutrition only when fecal loss cannot be compensated by increased intake; this is the case in infants with undiagnosed exocrine pancreatic insufficiency when nutrient intakes are low, particularly proteins, the levels of which in commercial formulas tend to parallel those of human milk. Weight gain decreases, and hypoalbuminemia and edema develop. The same symptoms occur in the short-bowel syndrome when losses of nutrients in the stools are too high to be compensated by increased intakes without digestive symptoms.

Other mechanisms may induce or contribute to malnutrition: (1) chronic inflammation, which has been shown, as in Crohn disease, to increase protein degradation and thus protein turnover, with consequent increased energy needs for rest metabolism[62]; (2) protein-losing enteropathy, which may exceed the capacity of the liver to synthesize albumin and which occurs not only in intestinal lymphangiectasia but also in celiac disease and Crohn disease; and (3) bacterial overgrowth, which results in energy losses (fermented carbohydrates, malabsorbed fat) and leads to diversion of nitrogen fluxes toward bacterial growth, with the ultimate consequences of hypoalbuminemia and loss of lean body mass. In all of these situations, protein malnutrition is responsible for low plasma levels of insulin-like growth factor I (IGF-I or somatomedin C), whereas growth hormone secretion is normal.[63] Thus, decreased plasma levels of IGF-I explain, at least in part, growth retardation during malnutrition, and IGF-I levels may be used as accurate markers of nutritional sufficiency.[63]

Finally, impaired absorption appears to be much more harmful than impaired digestion because in the vast majority of cases, mucosal lesions affect not only absorption of major nutrients but also of vitamins (lipid-soluble vitamins [A, D, E, K] and folic acid, when intestinal lesions are proximal, as in celiac disease; vitamin B_{12} when they are distal, as in ileal Crohn disease), of major minerals such as iron and Ca^{2+}, and of trace minerals. These deficiencies hasten and aggravate malnutrition, whereas their absence, in states of impaired pancreatic digestion, contributes to the relatively satisfactory nutritional tolerance of the latter conditions.

PRACTICAL APPROACH TO MALABSORPTION

The main clinical expression of malabsorption is diarrhea. It is the direct consequence of malabsorption, which, in its turn, when chronic, may result in malnutrition and failure to thrive, the usual other features of malabsorption syndromes. Because the consequences of malabsorption on growth have been dealt with elsewhere, this part of the chapter focuses on chronic diarrhea, or more properly on "abnormal stools,"[64] as the main clue to the diagnosis and etiology of malabsorption.

Chronic diarrhea is usually defined as diarrhea lasting for more than 14 days. In toddlers who already control their stools, abnormal stools are not missed by the family, which often tends to exaggerate their importance. On the contrary, when diarrhea starts from birth or soon after, the abnormal features of the stools are less easily recognized, especially if the infant is breastfed and is the first child in the family.

For many years, balance studies with recording of ingested foods and collection of the stools during at least 3 days have been extremely useful in ascertaining malabsorption and showing that chronic diarrhea had different biochemical features, explaining its gross macroscopic characteristics (consistence, volume, smell, pH), according to its pathophysiologic mechanism: impaired intraluminal digestion, intestinal malabsorption, or fermentation (Table 1-1). It is with this pathophysiologic classification in mind that the cause of chronic diarrhea can best be looked for.

A careful clinical history remains the most important step in getting to the diagnosis of malabsorption. The fluidity, number, size, color, and smell of the stools should first be ascertained. Stools may be as liquid as water and mistaken for urine in infants with congenital chloride diarrhea, for example[65]; be passed noisily with flatus, be loose and bulky; or be pasty and yellowish. The number of stools may vary from 2 (bulky) to 10 or more (small and liquid). Stools may be homogeneous or, on the contrary, may contain undigested pieces of vegetables and mucus. Whether the stools are greasy or not is often difficult to ascertain; the less liquid the stools are, the easier this is to determine. Liquid stools may be odorless, or they may have an acidic smell owing to fermentation. In exocrine pancreatic insufficiency, stools have a penetrating, cheesy odor. Finally, the mode of evolution of diarrhea should be recorded: stools may be abnormal every day or periodically.[64]

The necessary time, then, should be spent in trying to correlate the occurrence of diarrhea with modifications in the diet—introduction or elimination of cow's milk proteins, wheat flour, lactose, sucrose, and vegetables, for example. Associated symptoms should be systematically looked for: anorexia (intestinal malabsorption), increased appetite (exocrine pancreatic insufficiency), thirst (when diarrhea is fluid and severe as in sugar intolerance), abdominal pain, cramps, discomfort, bloating (indicative of fermentation), vomiting (protein intolerance), asthenia, and weakness (celiac disease, Crohn disease).

Equally important is to establish whether the growth of the child is normal or not by recording carefully his growth charts from birth for height and weight. Clinical examination will appreciate the activity and psychomotor development of the child. One should look for abdominal distention, which is best observed in the standing position in profile, taking into account the physiologic distention in toddlers, and for finger clubbing. It is important to evaluate the state of nutrition by recording skinfold thickness, muscle tone and volume, paleness of the skin and conjunctiva, color and quality of hair, and dryness of the skin.

At the end of this clinical evaluation, the most frequent cause of chronic diarrhea in childhood—"nonspecific chronic diarrhea" or "toddler's diarrhea" (characterized by periods of frequent, heterogeneous [with vegetable matter], often mucus-containing, foul-smelling stools, often alternating with periods of normal stools or even constipation, and a normal state of nutrition)—has been eliminated. Frequently, the clinical history, the growth chart, and the physical examination of the child allow evoking of one of the following three main mechanisms of malabsorption (Figure 1-1).

Diarrhea owing to Impaired Intraluminal Digestion. Diarrhea owing to exocrine pancreatic insufficiency, the predominant cause of impaired intraluminal digestion, is remarkable by the macroscopic appearance of the stools: they are more frequently loose and pasty than liquid, homogeneous, often obviously greasy with undigested triglycerides oozing like oil from the stool when it is passed in a pot or floating on the surface of the water in the toilet, and pale (hence the mastic aspect of the stools), with an offensive cheese smell. The volume of the stools is rather constant from one day to another. These features are well explained by the large amounts of fat, nitrogen, and volatile fatty acids they contain (see Table 1-1).[66] Fecal elastase 1 appeared recently to be a relatively simple yet sensitive and specific test of exocrine pancreatic function.[67,68]

Apart from acquired surgical conditions (short-bowel syndrome, stagnant loop), such a massive fecal loss of the three classes of nutrients can be explained only by exocrine pancreatic insufficiency, whose most frequent cause in children is, by far, cystic fibrosis.The sweat test

TABLE 1–1 RESULTS OF BALANCE STUDIES IN CHILDREN WITH CHRONIC DIARRHEA, ACCORDING TO PATHOPHYSIOLOGIC MECHANISMS

		STOOLS				
PATHOPHYSIOLOGIC MECHANISM	ETIOLOGY (*N*)*	VOLATILE FRESH WEIGHT (G/DAY)	NITROGEN (G/DAY)	FAT (G/DAY)	FATTY ACIDS (MMOL/DAY)	LACTIC ACID (MMOL/DAY)
Intraluminal digestion insufficiency	Cystic fibrosis	235 ± 36†	3.2 ± 0.5	24.9 ± 3.5 (42 ± 9)‡	42.3 ± 8.0	2.8 ± 5.1
	Shwachman syndrome (9)					
Intestinal malabsorption	Celiac disease < 3 yr (28)	118 ± 75	0.88 ± 0.27	6.7 ± 2.0 (75 ± 8)	16.6 ± 11.3	4.4 ± 5.8
	> 3 yr (22)	161 ± 88	1.48 ± 0.39	7.3 ± 3.2 (85 ± 7)	24.9 ± 11.5	2.1 ± 2.8
	CMPI (11)	118 ± 68	0.64 ± 0.26	4.7 ± 2.4 (76 ± 8)	15.1 ± 8.0	9.2 ± 2.1
Fermentation	CSID (13)	413 ± 175	0.95 ± 0.79	4.6 ± 2.3 (85 ± 7)	44.6 ± 17.9	30 ± 15.3

CMPI = cow's milk protein intolerance; CSID = congenital sucrase-isomaltase deficiency.
*N = number of children studied during 6-day balances.
†Mean ± 1 SD (personal data).
‡Fat absorption coefficient (%).

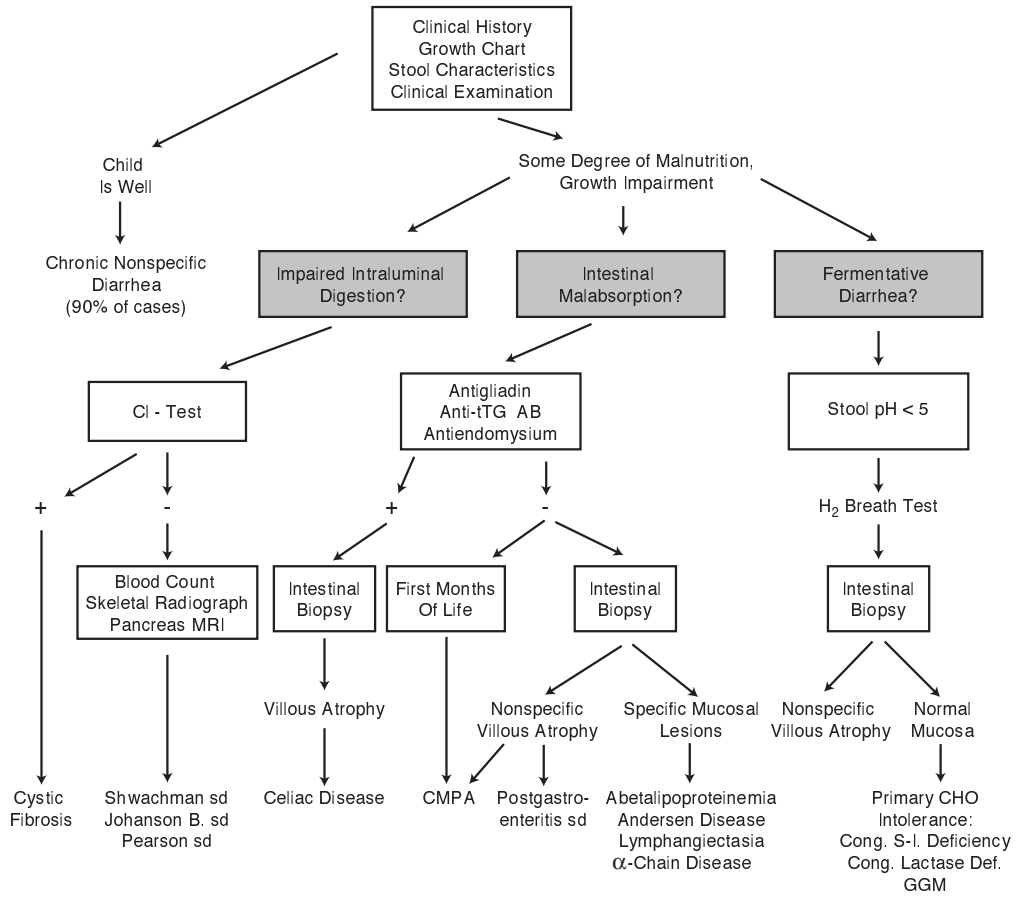

FIGURE 1-1 Diagnostic algorithm in a child with chronic diarrhea, suspect of malabsorption. CHO = carbohydrate; Cong. = congenital; CMPA = cow's milk protein allergy; Def = deficiency; GGM= glucose-galactose malabsorption; MRI = magnetic resonance imaging; sd = syndrome; S-I = sucrase-isomaltase; tTG = tissue transglutaminase.

confirms the diagnosis. If chloride concentration in sweat is normal, exocrine pancreatic insufficiency is due to hypoplasia of the pancreas. Hypoplasia may be associated with congenital lipomatous infiltration. Such is the case when exocrine pancreatic insufficiency is part of several syndromes, the most frequent of which is Shwachman syndrome. In this rather rare condition, exocrine pancreatic insufficiency is associated with chronic or cyclic neutropenia or other hematologic abnormalities, with metaphyseal chondrodysplasia, especially in ribs and hips, often with severe growth retardation.[69] Rarer is Johanson-Blizzard syndrome, in which exocrine pancreatic insufficiency is associated with morphologic abnormalities: congenital aplasia of the alae nasi, ectodermal scalp defects, and imperforate anus.[70,71] In both cases, magnetic resonance imaging may be useful in showing the typical fatty infiltration of the pancreas.[72] In Pearson syndrome, pancreatic hypoplasia is linked to fibrosis and exocrine pancreatic insufficiency is associated with refractory sideroblastic anemia and vacuolization of marrow precursors. This syndrome was recently shown to be due to mitochondrial deoxyribonucleic acid (DNA) deletions.[73] Finally, seldom in children is exocrine pancreatic insufficiency due to chronic pancreatitis. It has been described in the course of cystinosis.[74] In all cases, exocrine pancreatic insufficiency may be confirmed by direct assay of pancreatic enzyme activities in the duodenal juice (Table 1-2). Whereas the canalicular water and electrolyte secretion is impaired in cystic fibrosis, the lobular enzyme secretion is affected in cases of exocrine pancreatic insufficiency owing to lipomatosis.[75]

Impaired intraluminal digestion rarely involves only one class of nutrient. A massive isolated steatorrhea may be due to isolated congenital lipase or colipase deficiency, which can be confirmed by the direct assay of lipase activity in the duodenal juice.[47,48,76] In this situation, normal lipase activity would orient the diagnosis toward defective micellar solubilization owing to congenital absence of bile acid synthesis,[49,77] abnormal biliary excretion (congenital biliary atresia),[78] interrupted bile acid enterohepatic circulation because of bacterial overgrowth,[50] ileal resection, Crohn disease, or congenital bile acid malabsorption.[51] Bile acid assay in blood or the duodenal juice, or, less easily, in stools, may lead to one of these diagnostic possibilities. Isolated pancreatic proteolytic insufficiency has also been described; congenital trypsinogen deficiency has been reported, yet it is less well established than congenital enterokinase deficiency suspected in a malnourished infant, failing to thrive, with abnormal stools from birth.[31] Diagnosis is suspected when exogenous enterokinase restores a previously severely reduced or absent proteolytic activity in the duodenal juice;

TABLE 1–2 DIARRHEA OWING TO IMPAIRED INTRALUMINAL DIGESTION

PATHOPHYSIOLOGY	DIAGNOSIS	
	SUSPECTED	EVIDENCE FOR PROBABLE OR CERTAIN DIAGNOSIS
Impaired digestion affecting all nutrients	Cystic fibrosis	Sweat test positive
	Pancreatic hypoplasia with lipomatosis (Shwachman syndrome)	Neutropenia
	Metaphyseal chondrodysplasia	
	Johanson-Blizzard syndrome	Morphologic anomalies
	Fibrosis (Pearson syndrome)	Sideroblastic anemia
	Cystinosis	Tubular acidosis
Impaired digestion affecting fat proteins		
Fat	Isolated lipase or colipase deficiency	Direct assay in duodenal juice
	Abnormal micellar solubilization	
	Impaired bile acid synthesis	Bile acid assay in blood, duodenal juice, stools
	Bile duct atresia	Cholestasis
	Interrupted enterohepatic circulation	
	Ileal resection	Clinical history
	Crohn disease	Clinical history
	Congenital malabsorption of bile acids	Bile acid assay in blood, duodenal juice, stools
	Blind loop syndrome	Clinical history, H_2, breath test
Proteins	Congenital trypsinogen deficiency	Direct assay in duodenal juice
	Congenital enterokinase deficiency	Assay in duodenal mucosa

it is confirmed by the direct measurement of enterokinase activity in the duodenal mucosa (see Table 1-2).

Diarrhea owing to Intestinal Malabsorption. Diarrhea owing to intestinal malabsorption is loose or liquid, often with an acidic smell, typical of fermentation with production of acetic acid. The stools are rarely greasy (steatorrhea is usually mild).

Such a diarrhea in a child with abdominal distention and suboptimal growth should evoke celiac disease, the most common cause of intestinal malabsorption. Whereas tests of malabsorption (xylose test) or blood markers of malnutrition (low hemoglobin, folate, or cholesterol levels) have long been used to assess the jejunal absorption function before the necessary small intestinal biopsy, serologic markers of celiac disease (antigliadin, antiendomysium, antitransglutaminase antibodies) are now by far more reliable tests to perform before prescribing a biopsy of the jejunal mucosa. In this context, antiendomysium antibodies remain the most reliable test (nearly 100% sensitivity and specificity) of celiac disease.[79] The intestinal biopsy mandatory in such clinical situations discloses a flat mucosa (total villous atrophy) ascertaining the diagnosis, which, especially in younger children, may have to be confirmed several years later by relapse of the intestinal lesions after challenge with gluten.[80]

In cases in which the serologic tests specific for celiac disease are negative, the intestinal biopsy may be necessary to unravel the other causes of intestinal malabsorption. Nonspecific inflammatory alterations leading to partial villous atrophy in an infant of less than 6 months of age are most often secondary to sensitization to food proteins, most often to cow's milk proteins and more seldom to soy, rice, or wheat proteins. Given the lack of a reliable laboratory test to confirm such a sensitization, proof of it relies mainly on the curative effect of an exclusion diet and eventually on relapse of symptoms after challenge with the suspected protein.[81] Partial villous atrophy may also occur in the postgastroenteritis syndrome or in *Giardia lamblia* infestation; motile trophozoites may then be seen on histologic sections in the mucus layer covering the mucosa. Finally, partial villous atrophy and chronic diarrhea may reveal a state of immune activation[82] or of immunodeficiency: hypogammaglobulinemia or combined immunodeficiency syndromes, some of which may be linked to the absence of expression of human leukocyte antigens.[83] Measurements of Ig levels and of specific antibodies, counts of Ig-containing cells in the intestinal mucosa, and immunohistochemical or in situ hybridization studies should be performed in these situations as studies of delayed-type hypersensitivity. Although it is probable that intestinal lesions, in these situations, are linked to bacterial overgrowth,[60] the latter is often difficult to demonstrate, either indirectly by H_2 breath measurements after a glucose load[84] or directly by bacterial counts in the intestinal juice. A combination of several of these factors—food sensitization, depressed immune status, bacterial overgrowth—probably explains the partial villous atrophy often observed in children with protracted diarrhea (Table 1-3).

In other, much rarer, cases, the intestinal biopsy reveals specific lesions. The mucosal architecture is normal, but enterocytes appear full of lipid droplets that reflect abnormal chylomicron assembly or excretion. Such a disorder may reveal abetalipoproteinemia, which will be quickly confirmed by the finding of acanthocytosis, extremely low plasma cholesterol levels, absence of low-density lipoprotein and apolipoprotein B from the plasma, loss of tendon reflexes, and, eventually, retinitis[85]; the same intestinal lesions may also be the main finding in Andersen disease (or chylomicron retention disease), the clinical features of which are similar to those of celiac disease.[86,87] In plasma, cholesterol levels are low and apolipoprotein B is present, although at a low level.

TABLE 1–3 DIARRHEA OWING TO INTESTINAL MALABSORPTION

PATHOPHYSIOLOGY	DIAGNOSIS: SUSPECTED	DIAGNOSIS: EVIDENCE FOR PROBABLE OR CERTAIN DIAGNOSIS
IIntestinal biopsy: nonspecific inflammatory lesions		
Total villous atrophy (flat mucosa)	Celiac disease	Antigliadin antibodies, relapse at gluten challenge
Partial villous atrophy*	Sensitization to food proteins: CMP, rice, soya, wheat	Relapse at challenge
	Dermatitis herpetiformis	Dermal IgA deposit
	Giardia lamblia infestation	*Giardia* on biopsy specimen
	Immunodeficiency status, among these absence of HLA expression	HLA typing
	Bacterial overgrowth	Bacterial counts in duodenal juice, H_2 test
	"Protracted diarrhea" syndrome (may be postgastroenteritis)	Clinical history
Intestinal biopsy: specific lesions		
Fat-filled enterocytes	Abetalipoproteinemia	Absence of plasma LDL, apolipoprotein B; acanthocytosis
	Andersen disease	Decreased levels of plasma LDL, apolipoprotein B
Villi distorted by ectatic lymphatics	Lymphangiectasia	Lymphopenia, hypoalbuminemia, increased α_1 PI clearance
Dense monomorphic lymphoplasmocytic infiltrate	α-Chain disease	Monoclonal abnormal IgA in plasma
Normal intestinal biopsy	Lysinuric protein intolerance	Dibasic aminoaciduria Severe osteoporosis

CMP = cow's milk protein; HLA = human leukocyte antigen; Ig = immunoglobulin; LDL = low-density lipoprotein; PI = pancreatic insufficiency.
*In severe cases, villous atrophy may be subtotal.

In other cases, lymphangiectasia distorts the shape of villi. Lymphopenia, hypoalbuminemia with eventual edema, and hypogammaglobulinemia are usually associated with a modest steatorrhea. Measurement of α_1-antiprotease clearance confirms the loss of lymph in the digestive tract.[54] Finally, the lamina propria of the intestinal mucosa may be densely infiltrated by a monomorphic lymphoplasmocytic population, composed of packed plasma cells or, later, of lymphoblasts, which disrupts crypts and widens and flattens villi, whose epithelium is barely altered. In such cases, α-chain disease should be suspected. The presence of an abnormal monoclonal IgA in plasma confirms the diagnosis (see Table 1-3).[88] In rare cases, plasma cells produce polyclonal IgA.[89]

Diarrhea owing to Fermentation. Diarrhea owing to fermentation is liquid often passed with flatus and acidic, with a pH less than 5.5 owing to the abnormal presence of lactic acid in addition to the usual volatile fatty acids. Such an acidic pH is extremely evocative of fermentation owing to carbohydrate intolerance and must lead to a systematic search for reducing substances in the stools.[12] The stool volume is variable and roughly proportional to the amount of malabsorbed carbohydrate that has been ingested (see Table 1-1).

Although overexcretion of H_2 in breath after an oral load of a suspected sugar may orient the diagnosis, the most useful investigation, here also, is an intestinal biopsy. The intestinal mucosa appears normal on histologic sections in cases of congenital (or primary) sugar intolerance. The assay of disaccharidase activities in a homogenate of the mucosa detects sucrase-isomaltase deficiency,[90,91] the most frequent of these intolerances, more often than glucoamylase deficiency[92] or congenital lactase deficiency,[93] which has been ascertained principally in Finland.[93] In nonwhite children or adolescents, late-onset lactase deficiency[94] is, on the contrary, frequently the cause of a mild lactose intolerance. Normal enzyme activities, as well as clinical trials with different sugars, lead to the possibility of congenital glucose-galactose malabsorption, which can be proven by studies in an Ussing chamber (glucose does not trigger any short-circuit current, as it should) with brush border vesicles (glucose is not taken up even in the presence of Na^+),[95] eventually using molecular genetics (Table 1-4).[6]

However, much more frequently, the intestinal mucosa looks abnormal, with more or less severe villous atrophy. Disaccharidase activities are, like peptidase activities, nonspecifically decreased as a consequence of mucosal damage. Sugar intolerance and fermentation are, then, secondary to villous atrophy, as in celiac disease.[96] In the latter condition, secondary sugar intolerance is probably the main factor responsible for the volume of stools (see Table 1-4).[97]

Diarrhea Starting in the Neonatal Period. Chronic diarrhea starting in the hours or days following birth is usually extremely severe, leading in a few weeks to life-threatening malnutrition. The features of a malabsorption syndrome are thus gathered, although in some of the conditions characterized by such a diarrhea, malabsorption may involve only one ion. The age at which these conditions are discovered—the neonatal period—the often abundant and watery character of the stools, the severity of the dehydration and of malnutrition resulting from diarrhea, and the fact that these conditions are all familial justify their grouping independently from their pathophysiology (Table 1-5). Keeping these conditions in mind

TABLE 1–4 DIARRHEA OWING TO FERMENTATION

PATHOPHYSIOLOGY	DIAGNOSIS: SUSPECTED	DIAGNOSIS: CONDITIONS OF PROBABLE OR CERTAIN DIAGNOSIS
Intestinal biopsy: normal or subnormal intestinal mucosa	CSID	Assay of saccharidases in mucosal homogenate: *one* activity affected
	Congenital lactase deficiency	
	Late-onset lactase deficiency	
	Congenital trehalase deficiency[98]	
	Congenital glucose-galactose malabsorption	Absence of glucose-induced short-circuit current in Ussing chamber
Intestinal biopsy: nonspecific inflammatory lesions	All causes of villous atrophy (cf Table 1–3), mainly	*All* saccharidase activities affected
	Celiac disease	Cf Table 1–3
	CMPI	Cf Table 1–3
	Postgastroenteritis syndrome	Cf Table 1–3

CMPI = cow's milk protein intolerance; CSID = congenital sucrose-isomaltase deficiency.

TABLE 1–5 CHRONIC DIARRHEA STARTING IN THE NEONATAL* PERIOD

CONDITION (IN ORDER OF DECREASING SEVERITY)	DISTINCTIVE CLINICAL FEATURES	KEY LABORATORY INVESTIGATION	THERAPEUTIC DECISION
Congenital microvillous atrophy[99]	Intractable† watery diarrhea	Intestinal biopsy (PAS stain)	Total parenteral nutrition
Tufting enteropathy[100,101]	Intractable watery diarrhea	Intestinal biopsy	Total parenteral nutrition
Intractable diarrhea with phenotypic abnormalities[102]	Intractable watery diarrhea Low birth weight	Immune system investigations	Total parenteral nutrition
Congenital glucose-galactose malabsorption	Acid diarrhea	Intestinal biopsy (Ussing chamber, brush border vesicles)	Replacement of glucose and galactose by fructose in the diet
Congenital lactase deficiency	Acid diarrhea	Intestinal biopsy (assay of activity)	Lactose-free diet
Congenital chloride diarrhea	Hydramnios, intractable watery diarrhea	Assay of electrolytes in stools	IV then oral Cl supplementation
Congenital defective jejunal Na^+/H^+ exchange[103]	Hydramnios, intractable watery diarrhea	Assay of electrolytes in stools	IV then oral Na^+ supplementation
Congenital bile acid malabsorption	Steatorrhea	Bile acid assay in plasma, stools	MCT, cholestyramine
Congenital enterokinase deficiency	Failure to thrive, edema	Intestinal biopsy (assay of kinase activity)	Protein hydrolysate

Cl = chloride; IV = intravenous; PAS = periodic acid–Schiff; MCT = medium-chain triglyceride.
*Neonatal = within the first week of life.
†Intractable = persisting despite nothing by mouth.

in the presence of any newborn presenting with a persistent diarrhea should improve the quality of the care offered to these neonates at risk.

CHAPTER 2

MICROBIAL INTERACTIONS WITH GUT EPITHELIUM

Nicola L. Jones, MD, FRCPC, PhD
Philip M. Sherman, MD, FRCPC

Increasingly, it is recognized that there is crosstalk between microbes and the environment in which they reside.[1] For pathogens causing human disease, this communication generally takes place first with epithelial cells lining mucosal surfaces. Study of the mechanisms underlying interactions between microbes and host epithelia has considered the gut as an excellent model system to test and delineate the responses of gut epithelial cells and M cells overlying Peyer patches to agents contained in the lumen. This review focuses on recent evidence elucidating the interaction of both bacterial commensals and enteropathogens with gut epithelia.

Although less work has been undertaken with viruses, protozoa, and helminths, it appears from evidence in initial studies that the general principles underlying host interactions with parasites are frequently shared features, even if the specific microbial gene products mediating the observed effects may differ. Understanding these common mechanisms, employed by agents coming into contact with the mammalian host, has implications for the design of new antimicrobial drugs, the use of prebiotics and probiotics in maintaining human health and treating human illnesses, and the development of vaccines to employ in the prevention of disease.

Study of the mechanisms underlying interactions between microbial products and the gut epithelium also provides insight into normal gut function. For instance, identification of guanylate cyclase C as the apical receptor on enterocytes to which a heat-stable enterotoxin is elaborated by some strains of enterotoxigenic *Escherichia coli* led to the search and subsequent discovery of an endogenous ligand. The protein, referred to as guanylin, changes levels of intracellular cyclic guanosine monophosphate, resulting in modulation of ion and water fluxes in the human intestine. In addition, guanylin may influence epithelial cell proliferation.[2]

The role of microbes, including organisms classically considered as commensals, in the pathogenesis of chronic inflammatory bowel diseases has been emphasized in animal models.[3] Knockout of genes involved in host immunity (such as interleukin-2, interleukin-10, and T-cell receptor expression) in mice causes relapsing and chronic inflammation involving the intestinal tract. However, gut inflammation does not occur in germ-free animals. Furthermore, *CARD15/NOD2*, a putative intracellular pattern recognition receptor for the bacterial product peptidoglycan, has been identified as the first susceptibility gene for Crohn disease in humans.[4,5] These findings emphasize the role of microbes or their products in modulating host responses. Such changes also may play a role in illnesses affecting the immature and developing host, for instance, in the pathogenesis of necrotizing enterocolitis and allergic gastroenteropathies. Thus, when one considers that the majority of cells that reside in the human gastrointestinal tract are, in fact, bacterial cells, understanding the diverse interactions between microbes and epithelial cells is highly relevant to clinicians because it provides insight into both physiology and pathophysiology.

VERSATILITY OF MICROBES

Increasingly, it is recognized that microbial pathogens frequently employ more than one virulence determinant to result in human disease.[6] This principle has important ramifications when considering the development of intervention strategies, including, for instance, the design of effective vaccine constructs.

For example, the development of attenuated *Vibrio cholerae* strains for use as oral vaccines to prevent epidemics in developing nations and to intervene in the eighth worldwide pandemic of cholera focused on deleting the gene encoding choleragen. In human volunteer studies, it became apparent that the *V. cholerae* mutant deficient in the production of cholera enterotoxin still caused diarrhea, albeit at much lower volumes than the wild-type parent strain producing cholera toxin. These observations led to the discovery of additional open reading frames in the bacterial genome adjacent to genes coding for choleragen (*ctxA*, *ctxB)* that result in the production of proteins with effects on the gut epithelium.[7] These proteins have been called zona occludins toxin (ZOT) for their effect on the intercellular tight junctions and accessory cholera enterotoxin (ACE). The level of complexity of the effects of this organism on gut epithelial responses is further emphasized by the observation that *V. cholerae* deficient in *CTXA*,

CTXB, *ZOT*, and *ACE* genes still causes diarrhea in human volunteers challenged orally with the isogenic mutant.[8]

Such evidence suggests the possibility of additional enterotoxins yet to be discovered. Other bacterial factors, such as lipopolysaccharide and outer membrane proteins (ie, components of the bacterial cell wall), may well participate in interactions with the host epithelium. These findings also indicate that vaccine constructs developed in consideration of a single bacterial virulence factor are likely to have diarrhea as a side effect. Alternatively, vaccines designed for future use in humans could require the use of more attenuated bacterial strains containing interruptions or deletions of multiple genes.

DELIVERY OF BACTERIAL ENTEROTOXINS

Noninvasive bacteria cause diarrhea in humans by the delivery of toxins that can effect fluid homeostasis in the gut. Cytotonic enterotoxins are characterized by massive volumes of nonbloody diarrhea without affecting the architectural integrity of the villus crypt axis in the small bowel. Many of these toxins, such as those elaborated by *V. cholerae*, enterotoxigenic *E. coli*, enterotoxigenic *Bacteroides fragilis*, and *Clostridium difficile*, are multimeric.[9] Such toxins are composed of a binding, or B, subunit and an active, or A, subunit that cause ion and water secretion by effecting second messengers in enterocytes lining the small intestine.

For instance, as outlined schematically in Figure 2-1, cholera toxin binds to the ganglioside GM_1 via a pentamer of B subunits and delivers the holotoxin by retrograde transport to the endoplasmic reticulum. The A subunit then dissociates from the B subunit and translocates to the cytosol, where it exerts its effects by irreversible activation of cyclic adenosine monophosphate and protein kinase A.[10] The net effect of these changes in intracellular second messengers is the opening of the cystic fibrosis transmembrane regulator (CFTR) chloride channel on the apical plasma membrane of enterocytes.

In contrast to the previously held notion that the plasma membrane is homogeneous, it is now clear that this membrane is heterogeneous, with specialized domains referred to as either cholesterol-enriched microdomains or lipid rafts. Lipid rafts are discrete domains in the plasma membrane that are enriched in cholesterol, glycosphingolipids, and glycosylphosphatidylinositol-anchored proteins.[11] Lipid rafts function in many aspects of cellular metabolism, including signal transduction.[12] Recent evidence indicates that binding of cholera toxin (CT) to GM_1 associates the toxin with lipid rafts. Alteration of lipid raft structure and function by cholesterol depletion alters the endocytosis, trafficking, and cytotoxicity of CT, indicating that cholesterol may function to associate CT with lipid raft domains.[11] Thus, lipid rafts are employed by the toxin to gain entry into the cell and thereby cause disease. Furthermore, a growing list of pathogens induces signal transduction responses through binding to and activation of constituents of lipid rafts. Accordingly, these microdomains are potential therapeutic targets that could be used to interrupt the infectious process.

The outline of events summarized in Figure 2-1 is very likely to be an oversimplification of events occurring in the in vivo setting. Many of the studies detailing the series of cellular responses to bacterial enterotoxins were undertaken employing reductionist models. Toxins purified from bacterial enteropathogens are incubated with epithelial cells of intestinal origin, grown in tissue culture or mucosal epithelium obtained from animals but stripped of the underlying muscle, nerves, and immune cells before use in in vitro studies. More recent studies employing intact gut epithelium indicate important differences from those identified previously.[13] For example, the effects of cholera enterotoxin on gut epithelial cells can be indirect, mediated by the activation of enterochromaffin cells and via secondary effects of the released secretagogue 5-hydroxytryptamine on enteric neurons and their neurotransmitters.[14]

It is also clear that in addition to choleragen,[10] other toxins elaborated by enteric bacteria, such as Shiga tox-

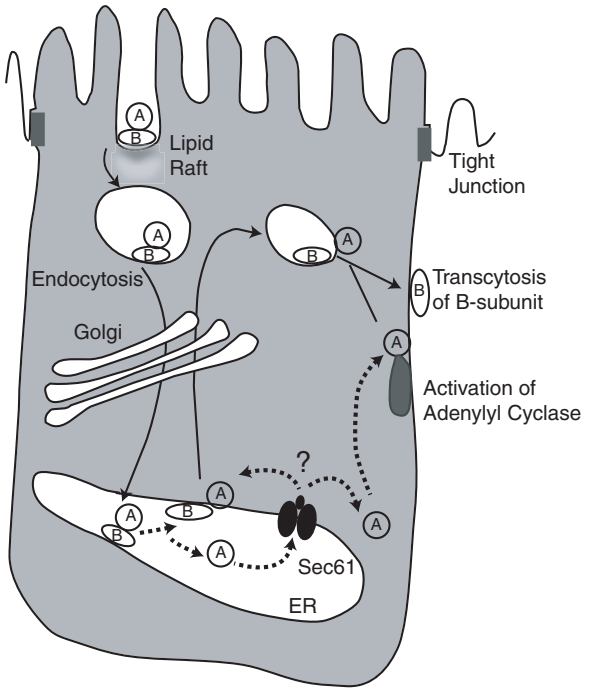

FIGURE 2-1 Working model for trafficking of cholera toxin (CT) into polarized cells. The CT holotoxin binds to ganglioside GM_1 in the apical membrane. After endocytosis, the CT-GM_1 complex trafficks retrograde through Golgi cisternae into the lumen of the endoplasmic reticulum (ER), where the A1 peptide is unfolded and dissociated from the B pentamer. The unfolded A1 peptide is probably dislocated to the cytosol through the sec61p complex. The A1 peptide may then gain access to adenosine diphosphate–ribosylate, its substrate, the heterotrimeric guanosine triphosphatase Gsα on the cytoplasmic surface of the basolateral membrane, by diffusion through the cytosol (if the A1 peptide breaks away from the membrane after translocation) or by membrane traffic back out the secretory pathway (if the A1 peptide remains membrane associated). The B subunit is not unfolded in the ER, remains membrane associated (presumably bound to GM_1), and moves to the basolateral membrane by trafficking back out the secretory pathway in anterograde vesicles in a process we have termed indirect transcytosis. Reproduced with permission from Lencer WI.[10]

ins,[15] can be transported intact across the cytosol of polarized gut epithelial cells (Figure 2-2). Paracellular delivery of the bacterial toxins across intact polarized gut epithelium through intercellular tight junctions appears to be less likely, even when there is enhanced transepithelial permeability to macromolecules of molecular mass smaller than that of the holotoxins.[15]

Intact toxin can be presented as antigen on the basolateral membrane of enterocytes. Delivery of holotoxin to other body organs where they may have systemic effects is a consequence of these series of events. This possibility still requires direct experimental confirmation because it could explain the systemic effects of orally ingested bacterial pathogens, including, for example, the renal and neurologic sequelae of infection with enterohemorrhagic (Shiga toxin producing) *E. coli*.

PATHOGEN-ASSOCIATED MOLECULAR PATTERNS

Innate immunity to bacterial pathogens is triggered by the binding of conserved structures, termed pathogen-associated molecular patterns (PAMPs), to specialized host cell receptors known as pattern recognition receptors.[16,17] Toll-like receptors (TLRs) are responsible for extracellular recognition of a variety of PAMPs, including lipopolysaccharide (TLR-4), peptidoglycan (TLR-2), lipoproteins, flagellin (TLR-5), double-stranded ribonucleic acid (RNA) (TLR-7), and CpG deoxyribonucleic acid (DNA) (TLR-9). These receptors trigger immune responses by stimulating secretion of proinflammatory cytokines mediated by activation of transcription factors such as nuclear factor (NF)-κB. Recently, members of a new group of cytoplasmic proteins, called CARD4 (Nod1 for nucleotide-binding oligomerization domain) and CARD15 (Nod2), that sense and respond to bacterial products within the cell have been identified.[18] With the discovery that mutations in CARD15 (Nod2) are associated with Crohn disease,[4,5] much interest has focused on understanding the role of CARD/Nod proteins in mediating gut epithelial interactions with bacteria and bacterial products.

Recent studies indicate that CARD4/Nod1 and CARD15/Nod2 recognize distinct bacterial peptidoglycan molecular motifs, resulting in the activation of transcription factors such as NF-κB.[19] In addition, current experimental evidence suggests that CARD4/Nod1 is solely responsible for recognition of these motifs in epithelial cells in steady-state condi-

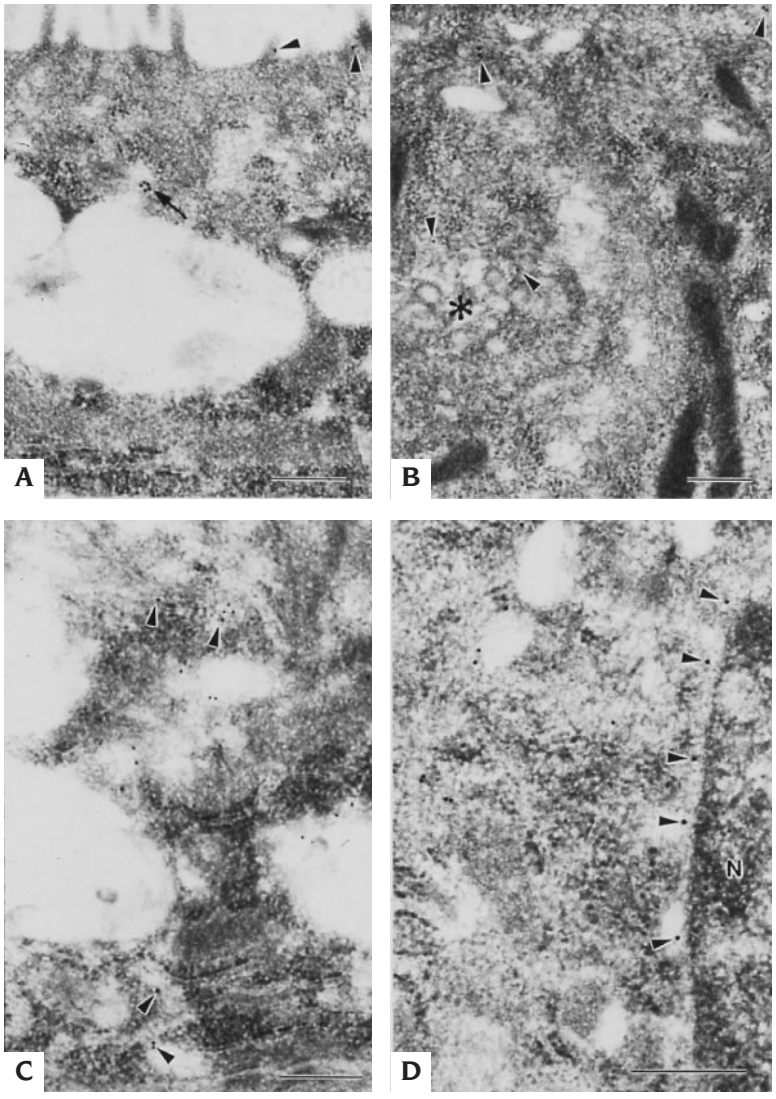

FIGURE 2-2 Intracellular trafficking of bacterial toxins. Transmission electron photomicrographs of immunogold-labeled Shiga toxin-1 present within T84 cells. Reproduced from Philpott DJ et al.[15]

tions, whereas CARD15/Nod2 appears to be nonfunctional. However, exposure to inflammatory cytokines results in the up-regulation of CARD15/Nod2 expression in intestinal epithelial cells.[20,21] Furthermore, intestinal cell lines engineered to express mutant CARD15/Nod2 display deficient clearance of an intracellular pathogen.[20] Taken together, these results suggest that CARD4/Nod1 and CARD15/Nod2 serve complementary roles in the host detection and response to intracellular bacterial pathogens.

Based on current understanding of the function of CARD15/Nod2, several hypotheses have been proposed to explain the molecular defect in Crohn disease. One attractive theory is that deficient CARD15/Nod2 in intestinal epithelial cells results in an abnormal NF-κB–mediated chemokine response to microbial products, thereby allowing the proliferation of bacteria and disruption of mucosal barrier function.[3] Alternatively, defective CARD15/Nod2 could result in persistent infection of intracellular pathogens owing to lack of their recognition. An additional hypothesis includes abnormal conditioning of antigen-presenting cells and resulting failure in the appropriate development of cellular immune responses.

TYPE III SECRETION SYSTEM AND PATHOGENICITY ISLANDS

Recent experimental evidence shows that multiple bacterial pathogens employ a specialized secretion system to deliver virulence determinants into the infected host.[22] Referred to as type III secretion, to distinguish it from previously identified secretion systems in prokaryotes (Figure 2-3), the protein effectors exported from bacteria are characterized by the absence of an obvious signature signal sequence. Many of these effectors are not expressed except when in the microenvironment exposed to host epithelia. In response to the specific environment (eg, bile salts, ambient pH, oxygen tension, and host cell markers), the bacterium turns on the expression of a secretory apparatus and produces proteins that are injected via the secretion system directly into the cytoplasm of the host cell.[23] In contrast to a marked heterogeneity in the sequence and structure of the injected effector proteins, the structural apparatus is more preserved. This has led Anderson and colleagues to propose that these conserved components of the secretory system recognize common signals that couple messenger RNA translation to the secretion of peptides.[24]

Role of Pathogenicity Islands in Transmission of Type III Secretion Systems

In pathogenic bacteria, these type III secretion systems frequently are encoded on a pathogenicity island. The term pathogenicity island refers to large pieces of DNA (often up to 40 kb) containing multiple open reading frames that can be characterized as distinct from the rest of the bacterial genome.[25] For instance, the guanine plus cytosine (G + C) content is usually lower than that found in the remainder of the bacterial genome. There is usually evidence of transmissibility of the large piece of DNA; for instance, features characteristic of transposable elements (referred to as transposases) may be present at one or both ends of the pathogenicity island. It is of interest that pathogenicity islands are not randomly inserted into the bacterial genome.[26] Rather, there are hot spots into which the pathogenicity islands are inserted. Frequently, these are at sites coding for transfer RNAs (Figure 2-4). In fact, the pathogenicity island encoding virulence determinants for uropathogenic *E. coli* is at precisely the same location (82 minutes) on the genome where the pathogenicity islands of enteropathogenic *E. coli* and some strains of enterohemorrhagic *E. coli* insert into selenocysteine transfer RNA.

Type III Secretion as a Method of Bacterial Delivery of Virulence Determinants

In enteropathogenic *E. coli*, host consequences of infection occur in response to products encoded on genes contained on a single pathogenicity island referred to as the locus for enterocyte effacement (LEE).[27] As shown in Figure 2-5, LEE codes a type III secretion system for the delivery of bacterial effectors into the host cell. Some genes code for structural proteins, such as EspA and EspcF, that form the needle or channel of the molecular syringe required to deliver proteins into the host epithelia (Figure 2-6).[28] Other proteins serve as chaperones that facilitate transport of effector proteins. In enteropathogenic *E. coli*, CesT is a 15 kD chaperone protein.[29] The CesT promotes the transfer of secreted proteins by binding to the aminoterminus, thereby forming a stable multimeric protein complex that is resistant to degradation.[30] Still other proteins serve as pores to permit the transfer of large proteins through the cell wall of the bacterial pathogen. Proteins EspB and EspD are encoded on the LEE of enteropathogenic *E. coli* and enterohemorrhagic *E. coli* that display homology to known pore-forming molecules.[31] An additional level of complexity is provided by the control of gene expression in the LEE of enteropathogenic *E. coli* by regulatory genes that are contained on a large extrachromosomal plasmid.[32]

Intact effector proteins are then injected through the molecular syringe into the cytosol of the eukaryotic cell to which the organism has adhered. In enteropathogenic *E. coli*, one of these injected proteins, translocated intimin receptor (Tir), is phosphorylated at the tyrosine residue.[33] Following integration into the host-cell plasma membrane, Tir functions as a receptor for intimate binding of the bacterium mediated by an outer membrane protein referred to as intimin. Intimin is itself encoded by a gene, *eae*, which is also present on the LEE. These recent studies provide the first evidence of a bacterium providing its own receptor for mediating attachment to the host.[33,34]

Moreover, the host signaling machinery is "hijacked" to modify the bacterial protein (ie, tyrosine phosphorylation). Deletion of genes contained in the LEE renders enteropathogenic *E. coli* unable to induce rearrangements of the cytoskeleton characteristic of the attaching and effacing lesion observed in infected epithelial cells. Conversely, transfer of the LEE locus from enteropathogenic *E. coli* into a nonvirulent laboratory *E. coli* strain is sufficient to result in all of the morphologic features of the attaching and effacing lesions in infected host epithelia.[35]

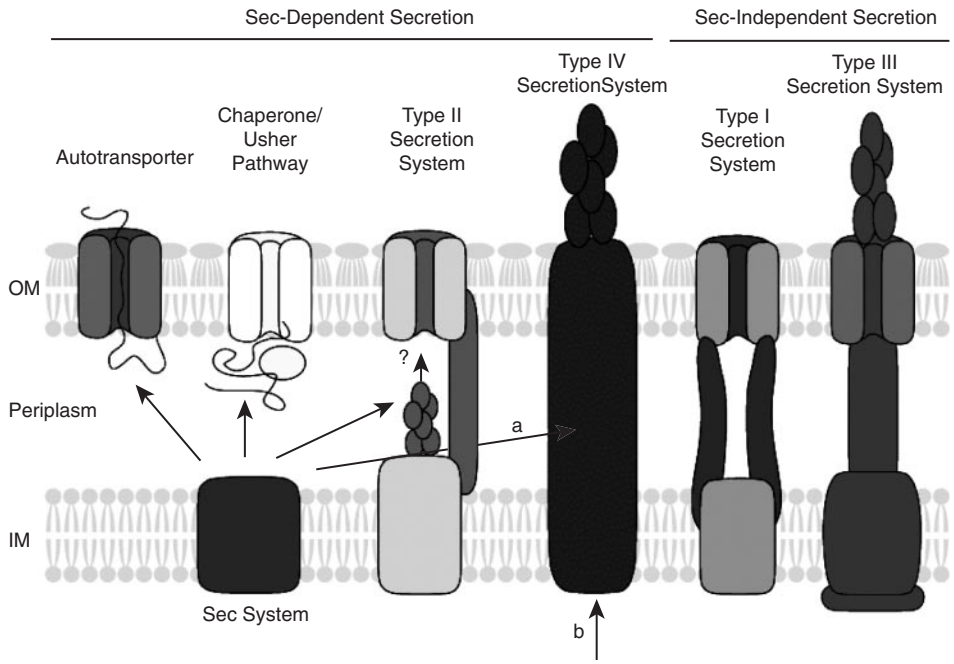

FIGURE 2-3 Protein secretion systems in gram-negative bacteria. Among the six major protein-secretion pathways of gram-negative bacteria, four depend on the Sec system for protein transport across the inner membrane (IM). Autotransporters (also known as type V secretion systems) mediate the transport of a passenger domain across the outer membrane (OM). Secretion by the chaperone/usher pathway requires a chaperone and an OM protein, termed an usher, and is dedicated to the transport of pilus subunits, which are assembled at the bacterial surface. The more complex type II secretion systems, which mediate transport of extracellular enzymes and toxins, involve 12 to 16 proteins, most of which are associated with the IM. Four IM proteins are proposed to form a pilus-like structure that could act as a piston to push proteins through the OM pore (*arrow*). Type IV secretion systems transport a variety of substrates, some of which, for example, pertussis toxin, require the Sec system for secretion (*a*), whereas others, such as the T-DNA-protein complexes of *Argobacterium tumefaciens*, are exported directly from the cytosol (*b*). The type I and type III secretion pathways are Sec independent. Type I systems secrete toxins, proteases, lipases, and S-layer proteins into the extracellular milieu, whereas type III secretion systems also mediate delivery of virulence proteins into the host cell. Extracellular appendages are associated with several type III and type IV systems. Reproduced from Buttner D and Bonas U.[23]

Enterohemorrhagic *E. coli* also contains the LEE pathogenicity island with most of the same genes, including *eae* encoding the outer membrane protein intimin, the bridging protein EspA, and the *espB* and *espD* genes coding for proteins injected into the infected host cell.[27,28] At least three sites of insertion of the pathogenicity island into the bacterial genome have been described using various clinical isolates. Another distinct feature of enterohemorrhagic *E. coli* is that the homologue to the intimin receptor EspE does not contain tyrosine residues. Thus, tyrosine phosphorylation is not a feature of host responses to infection by Shiga toxin–producing *E. coli*.[36,37] Moreover, tyrosine phosphorylation appears not to be an absolute requirement for the sequence of events leading to attaching and effacing lesion formation and to diarrhea.[38] In fact, recent evidence indicates that the outer membrane protein intimin not only binds to the bacteria-derived proteins that are injected into the host cell but also interacts with additional receptors present in the plasma membrane such as nucleolin that are of eukaryotic origin.[39]

Current experimental evidence indicates that the pathogenesis of infection by enterohemorrhagic *E. coli* differs from enteropathogenic *E. coli*.[40,41] The transfer of the LEE from *E. coli* O157:H7 does not confer the attaching and effacing phenotype to an avirulent, laboratory bacterial strain.[42] Thus, enteropathogenic *E. coli* and enterohemorrhagic *E. coli* use different mechanisms to trigger actin polymerization.[28] Enteropathogenic *E. coli* Tir recruits the adapter protein Nck to sites of actin assembly.[43,44] This recruitment is essential for pedestal formation. In contrast, enterohemorrhagic *E. coli* can form actin pedestals independent of Nck. Furthermore, the disruption of host signaling pathways by enteropathogenic and enterohemorrhagic *E. coli* appears to differ. For example, enterohemorrhagic *E. coli*, but not enteropathogenic *E. coli*, disrupts signal transducer and activator of transcription 1–mediated interferon-γ signaling in epithelial cells in vitro.[45]

In summary, pathogens that express these sophisticated secretion systems can alter many host cell functions, including signal transduction, cytokine production, and cytoskeletal structure. Furthermore, the components of the type III secretion apparatus tend to be conserved, leading to the suggestion that these specialized organelles may be attractive targets for the development of novel antimicrobial agents.

Horizontal Transmission of Pathogenicity Islands

The origin of virulence cassettes contained in the genome of pathogenic bacteria, including *Yersinia*, *Shigella*, and

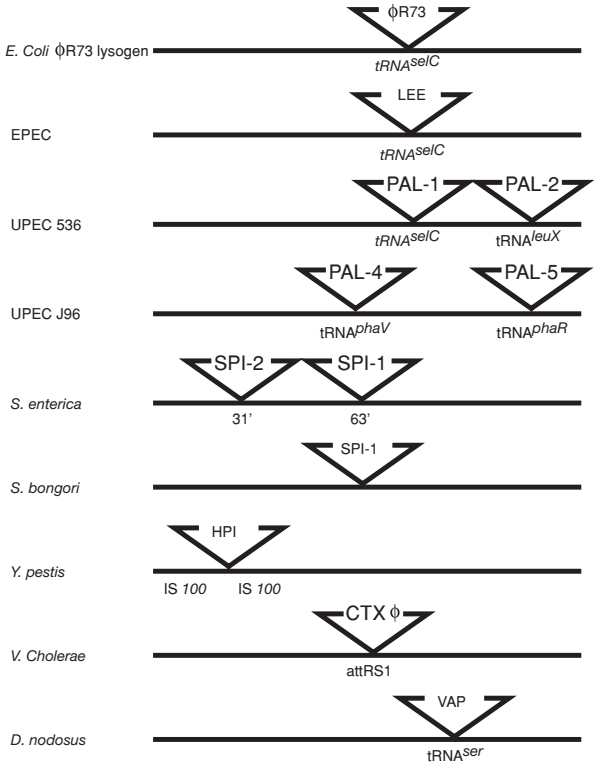

FIGURE 2-4 Location of selected pathogenicity islands and phages of gram-negative bacteria. Chromosomes and pathogenicity islands are depicted as the solid horizontal lines and triangles, respectively (but are not drawn to scale). The site of insertion is depicted below the pathogenicity island. Reproduced with permission from Groisman EA and Ochman H.[26] EPEC = enteropathogenic *Escherichia coli*; UPEC = uropathogenic *E. coli*.

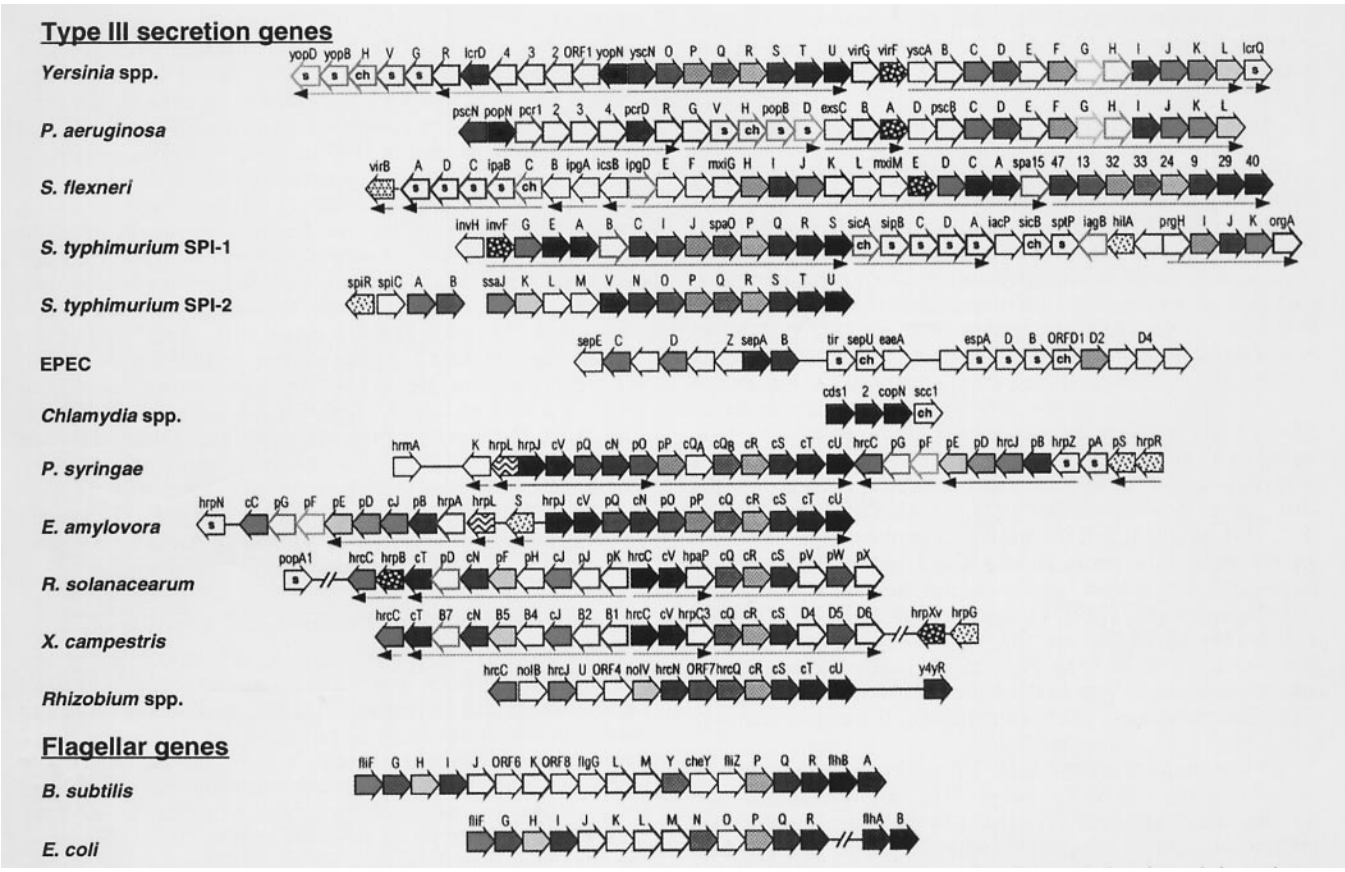

FIGURE 2-5 Genetic organization of the type III secretion system and of flagellum biosynthesis proteins. The type III secretion systems of animal and plant pathogens are grouped according to genetic similarities. Homologies of encoded proteins are indicated by the color code (see CD-ROM). Reproduced with permission from Hueck CJ. Type III protein secretion systems in bacterial pathogens of animals and plants. Microbiol Mol Biol Rev 1998;62:379–433. EPEC = enteropathogenic *Escherichia coli*

Salmonella species and pathogenic *E. coli*, remains uncertain. The natural transformation of enteric bacteria and their ability to take up and integrate foreign DNA[46] raise serious concerns about the safety of attenuated bacterial strains for use in humans as oral vaccine candidates. There is the potential that these strains, either in the complex environment of the microflora of the human large intestine or when excreted into environmental reservoirs, might acquire pathogenicity islands containing virulence genes from other bacteria in their immediate environment.

There is evidence that such concerns are more than theoretic. In the past decade, the first non-O1 *Vibrio* to cause epidemic cholera was identified in the Indian subcontinent. The *V. cholerae* strain is new, having acquired changes in the *rfb* gene cluster encoding a distinct bacterial polysaccharide, and is referred to as O139.[47] *V. cholerae* O139 appears to have acquired from *V. cholerae* O1, in the aquatic environment serving as a reservoir for the organism, the pathogenicity island containing genes encoding both toxin production and attachment factors to receptors in human small intestinal epithelium.[48] Evidence that the transmissible element is a bacteriophage[49] raises additional anxieties about the acquisition of virulence determinants by nonpathogenic organisms present in the environment, thereby transforming these microbes into pathogens capable of causing disease both in humans and in animals.[50]

Campylobacter jejuni is reported to secrete proteins that are injected into tissue culture epithelial cells even though the organism does not contain any genes with homology to those known to code for type III secretion proteins.[51] In addition, *C. jejuni* does not contain regions of G + C content lower than the rest of the bacterial genome, indicative of a pathogenicity island.[52] How then might the bacterium secrete proteins without signal sequences? It has been proposed that flagella may serve as an alternate structure for use in the delivery of bacterial proteins into the cytosol of infected epithelial cells. The biosynthesis of the motor apparatus of the flagellum is well characterized and appears to have many features in common with those described for the type III secretion system encoded on pathogenicity islands.[53] Indeed, it has been proposed that the genes encoding bacterial flagellum and those of the type III secretion system may well share a common ancestor.[53]

Loss of bacterial DNA is another potential mechanism for enhancing the virulence of microbes. In fact, recent evidence suggests that deletion of genomic DNA promotes the virulence of *Shigella* species and enteroinvasive *E. coli*.[54] How frequently such an event accounts for the emergence of new pathogens or promotes the virulence of known microbial enteropathogens requires clarification.

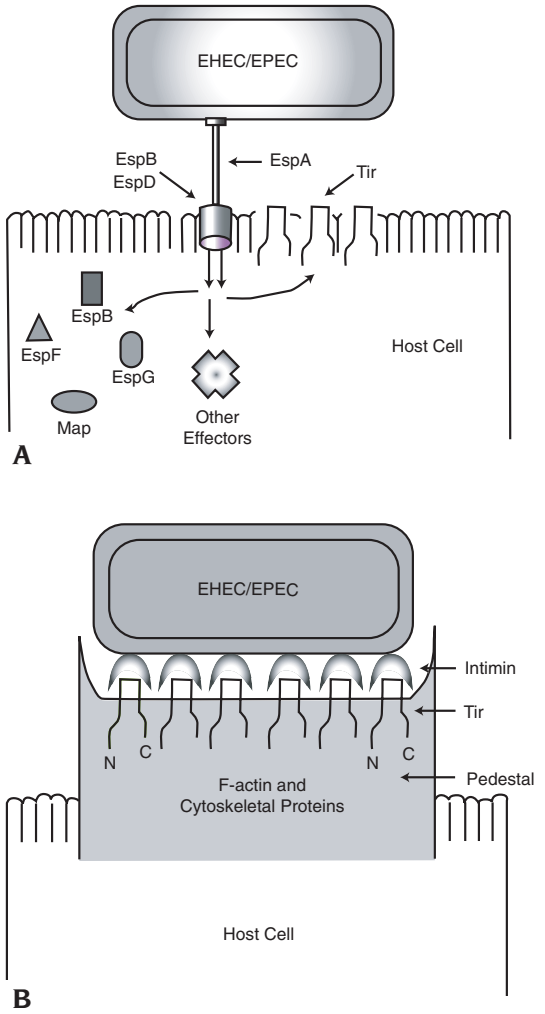

FIGURE 2-6 Model of translocation of bacterial effectors into host cells. *A*, Upon contact, enteropathogenic *Escherichia coli* (EPEC) and enterhemorrhagic *E. coli* (EHEC) use a type III translocation apparatus to inject bacterial effector proteins into mammalian cells. These bacteria translocate a number of proteins: EspB and EspD, which form a translocon in the plasma membrane; the cytoplasmic proteins EspF, EspG, and Map (there is also a cytoplasmic pool of EspB); the translocated intimin receptor Tir, which inserts into the plasma membrane; and other unidentified effectors. *B*, Membrane-localized Tir contains a central extracellular domain that binds to the bacterial outer membrane protein intimin and amino- and carboxyterminal cytoplasmic domains that interact with cytoskeletal elements. The interaction between Tir and intimin is the final bacterial signal to trigger the assembly of actin into pedestals within host cells. Reproduced with permission from Campellone KG and Leong JM.[28]

REARRANGEMENT OF THE HOST CYTOSKELETON

Changes in F-Actin following Microbial Infection

Both invasive and noninvasive enteric bacterial pathogens have developed mechanisms to disrupt and hijack the host cytoskeleton in a manner that enhances survival and transmission of microbes in the host.[55] Invasive pathogens such as *Listeria monocytogenes*, *Salmonella* species, and *Shigella* species have dramatic effects on the host cytoskeleton.[55,56]

Increasingly recognized as a foodborne pathogen causing intestinal disease, as well as severe systemic complications,[57] *L. monocytogenes* has developed unique mechanisms to invade into the host (Figure 2-7). During the course of infection, the organism produces a protein product, Act A, which recruits F-actin from the host cytosol to form a tail at one end, which then serves to propel the bacterium forward during intercellular spread.[58] The Arp 2/3 protein

complex, capping protein, vasodilator-stimulated phosphoprotein (VASP), profilin, α-actinin, and likely cofilin, but not myosin, are the host proteins that interact with actin filaments in response to the bacterial infection.[59] These proteins provide the driving force for moving *L. monocytogenes* in the cytosol and between epithelial cells.[60]

Other invasive bacteria employ host second messengers, such as Rac, Rho, and Cdc42, to effect changes in the host cytoskeleton to facilitate their own uptake by nonphagocytic cells, including intestinal epithelial cells.[61] For example, expression of mutant Cdc42 inhibits the internalization of *Salmonella typhimurium* into eukaryotic cells.[62] Through a type III secretion system, *S. typhimurium* injects effector proteins, referred to as SopE and SptP, that have opposing effects on the actin cytoskeleton via their actions on Cdc42 and Rac-1.[63] In contrast, the interaction of enteropathogenic *E. coli* with host cells does not involve these second messengers.[64] Such heterogeneity provides experimental evidence supporting the concept that different enteric pathogens have adapted a variety of strategies to interact with the cytoskeleton of host epithelial cells.

Classically noninvasive bacteria can also reorganize the host cytoskeleton. Attaching and effacing bacteria contain the locus for enterocyte effacement (including enteropathogenic *E. coli*, enterohemorrhagic *E. coli*, some strains of *Hafnia alvei*, and *Citrobacter rodentium*). Infection with these bacteria results in the recruitment of F-actin to the region of the plasma membrane below adherent bacteria where the integrity of the normal apical microvillus membrane has been disrupted. As shown in Figure 2-8, use of the mushroom-derived toxin phalloidin, which binds specifically to polymerized actin when conjugated to fluorescein, has been used to detect attaching and effacing lesions developing in response to bacterial infection. The rearranged F-actin contains additional cytoskeletal elements, including the actin bridging protein α-actinin, talin, ezrin, and myosin light chain, which is phosphorylated at serine and threonine residues.[28]

Precisely how the changes in cell morphology cause diarrhea is not known. The loss of microvillus membrane surface area is a theoretic possibility, but it is unlikely to be a predominant feature.[65] In most infections, attaching and effacing lesions are patchy in nature, with only a subset of enterocytes demonstrating morphologic changes. Moreover, when tested experimentally, brush border hydrolase activities are not markedly reduced.

Impact of Bacterial Infection on Intercellular Tight Junctions

The effects of the altered cytoskeleton on the integrity of intercellular tight junctions are another potential explanation that could account for passive transport of ions and water into the gut lumen.[44] Tight junctions seal the space between cells to limit the paracellular diffusion of solutes. Several groups have shown that the infection with attaching and effacing enteropathogenic *E. coli* alters phosphorylation of myosin light chain, ezrin, and occludin[66] and disrupts the morphologic integrity of the intercellular tight junction by causing dissociation of proteins such as zona occludens-1.[67] Such ultrastructural changes are accompanied by physiologic responses to infection, including a drop in transepithelial electrical resistance (Figure 2-9),[68] and increases in intercellular uptake of luminal antigens indicative of enhanced gut permeability (Figure 2-10).[69]

Another result of a disruption in the integrity of the epithelial cell monolayer overlying the gut surface could be the exposure of previously protected and unexposed host antigens and potential receptor-binding sites. For example, it is evident that microbes can attach to extracellular matrix proteins, such as fibronectin and vitronectin, and to sulfated polysaccharides, including heparin, and other glycosaminoglycans in vitro.[70] These findings now need to be extended to the in vivo setting, both in experimental animals and in humans, to clarify the biologic significance of these observations.

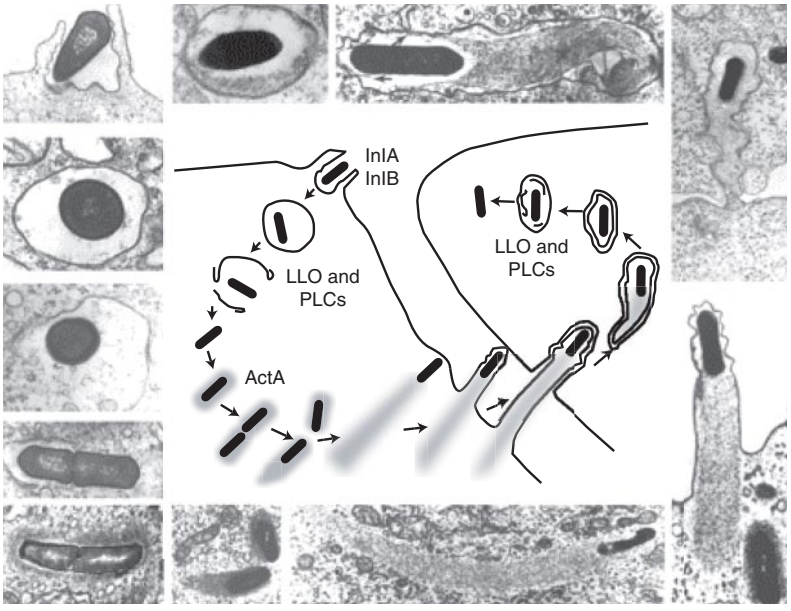

FIGURE 2-7 Stages in the intracellular life cycle of *Listeria monocytogenes*. *Center*, Cartoon depicting entry, escape from a vacuole, actin nucleation, actin-based motility, and cell-to-cell spread. *Outside*, Representative electron micrographs from which the cartoon was derived. The cartoon and micrographs were adapted from Tilney LG, Portnoy DA. Actin filaments and the growth, movement, and spread of the intracellular bacterial parasite, *Listeria monocytogenes*. FIGURE 2-8 Attaching and effacing lesions in eukaryotic cells infected with attaching and effacing *Escherichia coli* for 6 hours at 37°C. *A*, Transmission electron photomicrograph showing three attaching and effacing lesions on tissue culture cells infected with enteropathogenic *E. coli*, strain E2348/69 (serotype O127:H6). There is loss of the apical microvillus membrane and intimate binding of bacteria to the plasma membrane of the eukaryotic cell. Beneath the bacteria are foci of electron-dense material (F-actin) contained in the cytoplasm of infected cells and the formation of cup-like pedestals to which the microbes have adhered (approximately ×30,000 original magnification). *B*, Fluorescent actin staining (FAS) assay showing fluorescein-labeled phalloidin binding to foci of F-actin accumulating in regions of tissue culture cells to which Shiga toxin–producing *E. coli*, strain Cl-56 (serotype O157:H7), have adhered (approximately ×100 original magnification). Reproduced from Philpott DJ, Sherman PM. Signal transduction responses in eukaryotic cells following verocytotoxin-producing *Escherichia coli* infection. Germs Ideas 1995;1:15–21.

Role of Cytosolic Free Calcium

Elevation in intracellular levels of calcium by incubation with calcium ionophores disrupts the apical microvillus membrane architecture of enterocytes and results in the formation of vesicles and membrane blebs. Changes in levels of calcium subjacent to the apical membrane serve as a second messenger mediating altered cytoskeleton following infection with enteric bacteria. Several groups have shown that increases in cytosolic free calcium, released from intracellular stores via activation of the inositol trisphosphate receptor, occur in response to infection with attaching and effacing bacteria, including both enteropathogenic *E. coli* and enterohemorrhagic *E. coli* (O157:H7). Inhibitors that block release of calcium from intracellular stores, or chelate intracellular calcium, disrupt the ability of these pathogenic bacteria to induce attaching and effacing lesions in tissue culture epithelial cells.[71]

Enteropathogenic *E. coli* infection also induces activation of protein kinase C in infected epithelial cells, with transfer of active isoforms from the cytosol to the plasma membrane.[72] These findings suggest that bacterial infection activates phospholipase C and the production of diacyl glycerol, but direct experimental proof has yet to be provided.

Potential Therapeutic Implications

If confirmed in in vivo experiments, these findings should have important therapeutic applications. For instance, DuPont and colleagues employed a calcium-calmodulin inhibitor, called zaldaride maleate, in human volunteers vis-

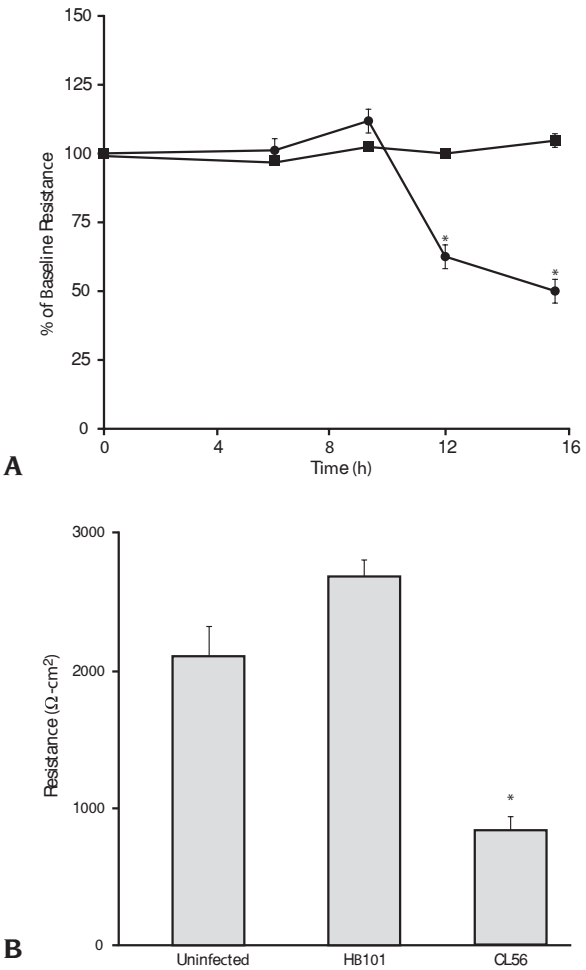

FIGURE 2-9 Transepithelial electrical resistance of T84 cell polarized monolayers following *Escherichia coli* infection. *A*, Time course of enterohemorrhagic *E. coli*–induced resistance decreases in T84 cells. In comparison with that of the uninfected cells (*solid squares*), the monolayer resistance of cells infected with bacteria (*solid circles*) first shows a decrease 12 hours after infection. Monolayer resistance was maximally decreased 15 hours postinfection. *B*, Monolayer resistance of uninfected T84 cells and cells infected for 15 hours with a nonadherent control *E. coli* strain (HB101) or a Shiga toxin–producing enterohemorrhagic *E. coli* (strain CL56). The pathogenic bacterium induced a significant decrease in monolayer resistance compared with that of both the uninfected and HB101-infected epithelial cells. Reproduced with permission from Philpott DJ et al.[67]

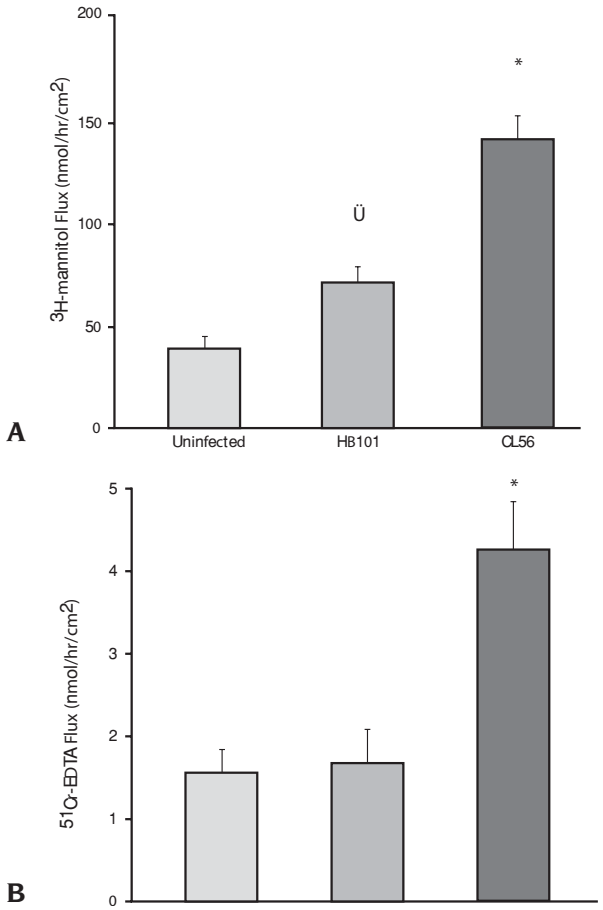

FIGURE 2-10 Permeability of polarized T84 cell monolayers as assessed by the transepithelial flux of radiolabeled probes. *A*, Flux of tritiated mannitol across uninfected T84 cell monolayers and monolayers infected for 15 hours with either the control *Escherichia coli* strain HB101 or enterohemorrhagic *E. coli* strain CL56 (serotype O157:H7). Infection with Shiga toxin–producing CL56 leads to a significant increase in the flux of radiolabeled mannitol. *B*, ^{51}Cr-EDTA flux across uninfected and *E. coli*–infected monolayers. Following 15 hours of infection with Shiga toxin–producing *E. coli* O157:H7 strain CL-56, the permeability of T84 monolayers to the radiolabeled probe increases compared with that of both uninfected and HB101-infected polarized epithelial cells. Reproduced with permission from Philpott DJ et al.[67]

iting Mexico.[73] As shown in Table 2-1, compared with the young adults receiving placebo, those taking the inhibitor demonstrated a reduction in both the severity and duration of diarrhea caused by enterotoxigenic *E. coli*, known also to elevate levels of cytosolic free calcium in the experimental setting. These findings need to be extended to an evaluation of efficacy following infection with other enteropathogens because other investigators describe attaching and effacing lesions occurring in response to enteropathogenic *E. coli* infection in the absence of detectable changes in cytosolic free calcium.[74] Thus, even though the use of selective and nontoxic inhibitors of second messengers holds promise as novel therapeutic agents, further evaluation is clearly required. The pleiotrophic effects of pathogenic bacteria on host epithelia may impair the therapeutic efficacy of highly selective inhibitors of signal transduction cascades.

Much of the experimental evidence cited in this review is from work undertaken in the in vitro setting. It is increasingly apparent that bacterial gene expression can vary widely depending on the environment in which they reside.[75] For example, a number of outer membranes are expressed in vivo in animals that are not identified when *V. cholerae* is cultured in the laboratory setting, either in broth culture or on agar plates. In contrast, other membrane proteins that are expressed in vitro are turned off when the organism resides in the gut lumen. New technologies, such as in vivo expression technology and signature tagged mutagenesis, have been devised to help to determine the biologic relevance of putative bacterial virulence factors.[76] Future studies using these complementary tools in appropriate experimental animals likely will provide data that are relevant to the human condition.

A variety of factors, including levels of iron, manganese, and other micronutrients, as well as ambient temperature, oxygen tension, pH, and the presence of bile salts, can each impact on gene expression in prokaryotes.[77] Whether or not a microbe is growing in the liquid phase or on a solid surface, as part of a biofilm, will also have profound effects on gene expression.[78]

QUORUM SENSING

Many gram-negative bacteria employ a regulatory system where the signal is produced by the organism itself.[79] Referred to as quorum sensing, the tightly controlled regulatory system permits the microbe to respond to the environment in which they reside. For example, *Pseudomonas aeruginosa* produces diffusible molecule *N*-acylated homoserine lactones, via the enzyme LuxI, in amounts that are proportional to the number of bacteria present in the immediate vicinity.[80] At a critical concentration, a second enzyme, LuxR, is activated and binds to regulatory DNA. Recently, a unique autoinducer termed AI-2, encoded by the *luxS* gene, has been identified.[79] AI-2 is widespread in the bacterial kingdom and is considered a universal signal because it can be used for interspecies cell-to-cell communication. AI-2 regulates a variety of functions, including expression of virulence factors in *V. cholerae*,[81] enteropathogenic *E. coli*, and enterohemorrhagic *E. coli*.[82] The crystal structure of AI-2 has been determined and found to contain a boron atom, which is interesting because the biologic functions of boron remain largely unknown.[83] Although it is not known how the diverse intestinal flora is established and maintained, communication between microbes of different species through quorum sensing could well play a role.

NUCLEAR TRANSCRIPTION RESPONSES IN INFECTED EPITHELIAL CELLS

Recent evidence points to the epithelial cell as an integral part of the host immune response to infection. For instance, epithelial cells produce chemokines and cytokines in response to a variety of bacterial pathogens to promote an influx of leukocytes, macrophages, T cells, and plasma cells to the site of infection.[84]

TABLE 2-1 IMPROVEMENT IN DIARRHEA DURING THE FIRST 24 HOURS OF THERAPY WITH ZALDARIDE MALEATE OR A PLACEBO FOUR TIMES DAILY AND FAILURE OF CLINICAL CURE 24 HOURS AFTER THERAPY*

	PLACEBO *n* (%)	ZM, 5 MG *n* (%)	ZM, 10 MG *n* (%)	ZM, 20 MG *n* (%)	*p* VALUE
Diarrhea improved in first 24 h	20/41 (49)	17/38 (45)	19/43 (44)	32/42 (76)	.013
Failure of cure after 24 h of therapy	5/39 (13)	6/36 (17)	0/38 (0)	0/40 (0)	.026

Zm = zaldaride maleate.
*Adapted from Dupont HL et al.[73]

As shown in Figure 2-11, enterocytes produce the polymorphonuclear leukocyte chemoattractant interleukin-8 in response to enteropathogenic *E. coli* and enterohemorrhagic *E. coli* O157:H7 infection.[71] Transcription of the chemokine occurs in response to the activation of NF-κB.[85] Activation of NF-κB is regulated by inhibitory proteins termed IκBs, which maintain NF-κB in an inactive state within the cytosol. Phosphorylation of IκB by IκB kinases leads to ubiquitination and degradation of IκB, resulting in release of NF-κB in the cytosol of infected epithelial cells. NF-κB can then translocate to the nucleus, where it binds to the promotor region of DNA upstream of the gene encoding interleukin-8.[85] Although originally considered to be a host response to invasive pathogens, it is now clear that polarized epithelial cells mount a vigorous chemokine response to the adhesion of pathogenic organisms to apical surfaces.[86,87]

Activation of NF-κB may also indirectly impact on ion and water secretion in response to bacterial infection through the activation of neuropeptide receptors. For instance, Hecht and colleagues have shown that enterohemorrhagic *E. coli* infection up-regulates NF-κB–dependent galanin-1 receptor expression in mouse intestine.[88] Short circuit current responsiveness to the neuropeptide galanin (Isc serving as an electrical marker of ion secretion in epithelia mounted into Ussing chambers) is also enhanced in the large intestine of mice challenged with Shiga toxin–producing *E. coli*. Human T84 cells also express the galanin-1 receptor, which, when activated by infection with enteropathogenic *E. coli* and enterohemorrhagic *E. coli*, enhances chloride secretion through a calcium-dependent mechanism.[89]

In addition to the conventional view that pathogens promote mucosal inflammation, recent evidence indicates that other bacteria are capable of limiting inflammatory responses. For example, infection with certain avirulent *Salmonella* strains abrogates the ability of proinflammatory strains and cytokines to activate NF-κB and thereby induce secretion of interleukin-8 from intestinal epithelial cells. This effect is mediated by the inhibition of ubiquitination and degradation of phosphorylated IκB. [90] Therefore, both pathogenic and nonpathogenic organisms can modulate host defenses.

THE ROLE OF COMMENSAL BACTERIA AS MEDIATORS OF GUT HOMEOSTASIS

It is clear that the complex interaction between the intestine and its microflora is dynamic and modulates gastrointestinal physiology.[1] For example, indigenous bacteria modulate the development of intestinal villus microvasculature by signaling through epithelial Paneth cells.[91] The small intestines of adult germ-free mice have arrested capillary network formation, which can be restarted following colonization either with microbiota from conventionally raised animals or with a predominant member of the murine gut microflora *Bacteroides thetaiotaomicron*. Furthermore, comparisons of mice lacking Paneth cells demonstrate that this lineage is responsible for the regulation of angiogenesis. In addition to regulating angiogenesis, recent evidence indicates that the gut microflora controls resident bacterial populations by modulating the induction of endogenous microbicidal proteins by epithelial cells. For instance, Hooper and colleagues demonstrated that intestinal colonization of germ-free mice with *B. thetaiotaomicron* stimulates Paneth cells to produce angiogenin 4.[92] Angiogen 4 displays a species-specific antimicrobial action against pathogens, but not commensals, thereby identifying this protein as a new class of antimicrobials.

Several groups have begun to sequence the genomes of members of the resident gut flora to provide additional insights into the complex interplay between the commensal flora and gut epithelia.[93,94] For example, the genome sequence of the mouse commensal *B. thetaiotaomicron* con-

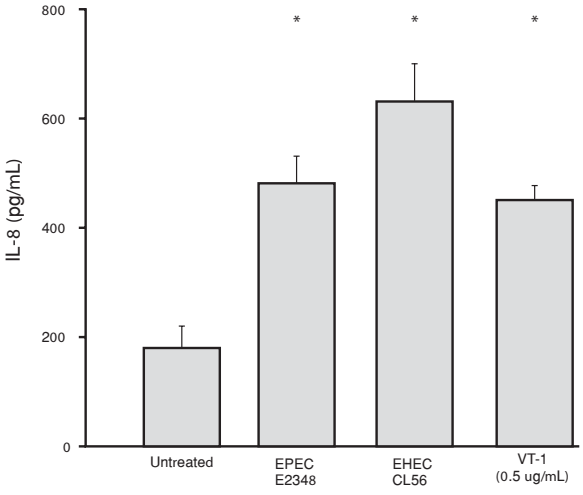

FIGURE 2-11 Nuclear transcription response in epithelial cells infected with attaching and effacing bacteria. Interleukin (IL)-8 production in T84 cells infected for 18 hours at 37°C with enteropathogenic *Escherichia coli* (EPEC) strain E2348/69, Shiga toxin–producing *E. coli* (STEC) strain CL56, or treated with 0.5 µg of Shiga toxin (Stx-1). Increases in the levels of the proinflammatory chemokine are greater than those observed in uninfected host cells. Reproduced with permission from Ismaili A et al.[71]

tains a large number of utilization pathways for breaking down undigestible carbohydrates, which can then be used as nutrients by both the bacterium and the host.[93]

SUMMARY

In the past several years, there have been great advances made in our understanding of the complex interplay between the commensal microflora and pathogenic microbes and the environment in which they reside. In the gut, it is clear that microbes modulate and impact on a wide variety of epithelial cell responses. Unraveling the communication strategies between microbes and their host has provided new understanding regarding both normal gut function and clinically relevant gastrointestinal diseases.

The study of host–parasite interactions bridges multiple scientific disciplines. The use of microbes and their products (eg, toxins and lipopolysaccharide) has had a major impact on our understanding of cell biology. Since the coining of the term "cellular microbiology,"[95] which describes the new discipline that has arisen from the marriage of microbiology and cell biology, our understanding of the relationship between prokaryotic and eukaryotic cells has increased greatly. Enhanced knowledge of the mechanisms underlying the diverse interactions between microbes and the gut epithelia holds exceptional potential for the future development of novel therapeutic interventions. As an example, administration of the probiotic bacterium *Lactococcus lactis*, engineered to produce interleukin-10 (an anti-inflammatory cytokine), reduces disease severity in a mouse model of inflammatory bowel disease.[96] Accordingly, we can now look forward to a continuing explosion of knowledge in this area in the years to come.

CHAPTER 3

INFLAMMATION

Steven J. Czinn, MD
Claudio Fiocchi, MD

Inflammation is the most common type of response that the body mounts when facing an assault from the surrounding environment. This is true for all tissues, organs, and systems, but in each one of these compartments, the inflammatory response varies depending on two key factors: the nature of the inciting agent(s) and the characteristics of the microenvironment in which inflammation ensues. The gastrointestinal tract is the ultimate example of how specific cellular and functional features shape the type, degree, and duration of inflammation. In this regard, the digestive system is unique owing to several specialized features: it is permanently exposed to the external environment, is constantly stimulated by a myriad of antigens, and harbors a luxuriant mix of bacteria, fungi, and viruses making up the endogenous enteric flora. Therefore, even under completely physiologic conditions, the intestinal tract contains enormous amounts of leukocytes, which are diffusely scattered in the lamina propria and the intraepithelial compartment or are organized in the Peyer patches of the terminal ileum and the isolated lymphoid follicles of the colon.[1] Combined, they form the anatomic basis of the gut- or mucosa-associated lymphoid tissue and functionally represent a tightly controlled form of self-contained inflammation termed "physiological inflammation."[2] The latter occurs in response to stimuli coming from the luminal surface of the mucosa and is found exclusively in the gut. In fact, other body surfaces exposed to alternate external or internal environments contain comparatively minimal amounts of lymphoid cells, as found in the lungs, skin, and urinary tract. In contrast to physiologic inflammation, which is anatomically restricted, tightly controlled, beneficial, and actually indispensable to health, pathologic inflammation in the gut is an injurious process that, particularly if severe and protracted, can lead to major functional and structural changes, causing clinical symptoms and impairing the quality of life of affected individuals. Fortunately, most forms of intestinal inflammation are transient and of limited impact on the general health of the patients, as are most acute viral and bacterial infections in children. Nevertheless, there is still a considerable number of other forms of gastrointestinal inflammation that result in serious clinical manifestations, as described in other chapters of this textbook. The focus of this review is on intestinal inflammation that induces tissue damage and functional derangements.

In addition to lymphoid cells, extremely diversified and highly specialized cell types of ectodermal, mesodermal, and endodermal origin compose the intestine. These include epithelial, mesenchymal, endothelial, and nerve cells, to which the extracellular matrix (ECM) must be added in view of increasing evidence for active participation of this acellular component in both immunity and inflammation.[3] A review of intestinal inflammation includes all of the above cellular and acellular elements because of accumulating evidence that an inflammatory response is not simply the consequence of a deranged immune response but a far more complex interplay of immune and nonimmune cell interactions.[4] How such interactions take place is incompletely understood, but at least two classes of elements are involved: one is represented by an enormous variety of soluble mediators released by immune and nonimmune cells such as cytokines, eicosanoids, neuropeptides, reactive metabolites, and proteases, and the other is represented by cell adhesion molecules, structures that are primarily, although not exclusively, involved in cell-to-cell adhesion events. Combined, soluble factors and cell adhesion molecules facilitate, allow, and amplify the exchange of signaling among cells that is essential to induce and mediate inflammation. Thus, in addition to the cellular components of inflammation, soluble factors and cell adhesion molecules are included in this review.

Because intestinal inflammation encompasses numerous and diverse factors, knowledge of the exact mechanisms and sequential interactions is far from complete. To provide the reader with a reasonably comprehensive overview of intestinal inflammation, information was derived from various sources, including human (pediatric and adult) and animal studies. An inherent caveat with this approach is that most human studies are based on chronic inflammatory conditions, whereas animal studies generally use acute models of intestinal inflammation. In addition, information is complemented by data derived from in vitro studies with single or multiple cellular systems. These sources of information are used to achieve functional and conceptual integration and generate a cohesive view of inflammation in the gastrointestinal tract. Finally, inflammation will be discussed as a broadly applicable response, keeping in mind that, in spite of a lack of direct supporting evidence, differences may exist between how this response is mediated in children and adults.

INFLAMMATORY CELLS

Plasma Cells

Immunoglobulin-producing plasma cells, which represent terminally differentiated B cells, are the most abundant type of lymphoid cell in the intestinal mucosa under both physiologic and inflammatory conditions. The majority of them normally produce dimeric immunoglobulin (Ig)A antibodies that are carried to the luminal surface by a well-defined transfer pathway involving a polymeric Ig receptor produced by the adjacent epithelial cells.[5] The expression of certain molecular determinants, such as the integrin $\alpha_4\beta_7$ on migrating B cells (and T cells) and of the mucosal addressin cell adhesion molecule (MAd-CAM) 1 on high endothelial venules, is believed to underlie the preferential migration of B cells to the mucosa, but cell differentiation and the functional status probably also play an important role.[6] In fact, normal intestinal B cells are in a higher state of activation compared with those in the peripheral circulation.[7] During inflammation, migratory patterns, cell proliferation, and state of activation are all drastically altered, resulting in major modifications in the distribution, number, class, and subclass of immunoglobulin-producing plasma cells. There is a consistent increase in IgG-secreting plasma cells that appears to be independent of the segment of the gastrointestinal tract involved, as observed in gastritis and inflammatory bowel disease.[8,9] In addition, the production of different subclasses of Igs is markedly abnormal, with predominance of IgG1- or IgG2-producing cells depending on the type of inflammatory process, as in ulcerative colitis versus Crohn disease.[10,11] Altered proportions of monomeric (systemic) and dimeric (mucosal) IgA or IgA1 versus IgA2 also can be found.[12,13] It is still uncertain what the consequences of an increased number of B cells in the inflamed mucosa might be because they are not, per se, pathogenic. Changes in IgA class could impair defenses against dietary and bacterial antigens, the production of complement-fixing antibodies, primarily of the IgG1 subclass, could contribute to or amplify tissue damage, and an increase in IgE-producing cells could mediate allergic reactions, leading to the release of a vast array of inflammatory mediators.

T Cells

The migration, distribution, and localization of T cells in the intestinal mucosa involve some of the same molecular mechanisms used by B cells.[6] However, these mechanisms tend to be more complex than those for B cells and are drastically altered during inflammation. In contrast to granulocytes, whose high cell number in an inflamed tissue is directly related to an increased emigration rate, changes in T-cell number and function involve multiple abnormalities in the entry, proliferation, exit, and death in the inflamed gut.[14] Expectedly, the number and state of activation of T cells are both increased in the inflamed intestine, but the proportions of CD4+ to CD8+ T cells in the mucosa are usually not remarkably shifted away from the normal CD4-to-CD8 ratio, regardless of the type and location of inflammation.[15–17] This is true for T cells infiltrating the lamina propria, which predominantly express the $\alpha\beta$ T-cell receptor. Alterations in the composition of intraepithelial T cells, which are predominantly CD8+ and tend to express the $\gamma\delta$ T-cell receptor in higher proportions, are less marked in some types of inflammation, such as inflammatory bowel disease.[18] In celiac disease, on the other hand, their number can increase, as well as the type of T cells that preferentially express the $\gamma\delta$ T-cell receptor.[19,20]

Because T cells control all aspects of cell-mediated immunity, their presence and abnormal state of activation suggest that they play a pivotal role in most, if not all, aspects of intestinal inflammation.[21] Their role likely includes antigen-specific responsiveness, immunoregulation, immunosuppression, cytokine production, and perhaps cytotoxic activity. With the exception of cytokine production (which is discussed in another section of this chapter), evidence that intestinal T cells exert all other functions is still fragmentary and incomplete. Mucosal T cells substantially differ from T cells circulating in the periphery in regard to their intrinsic ability to respond to receptor-mediated activation. They are preferentially stimulated through the CD2 pathways, in contrast to blood T cells that use the classic CD3 pathway for optimal activation,[22,23] an event perhaps conditioned by mucosal factors.[24] If true, one could also expect that when the mucosa is involved by inflammation, this may also influence and modify the behavior of local T cells. Mucosal T cells from inflammatory bowel disease display an enhanced proliferative response to bacterial antigens in both humans and experimental models,[25–27] as small intestinal T cells do in response to gliadin in celiac patients[28] and probably gastric T cells to *Helicobacter pylori* antigens.[29] Additional investigation is needed, however, to understand how these antigen-specific responses may trigger the cascade of events leading to the changes recognized as hallmarks of gastrointestinal inflammation. That these events actually occur in the mucosa is suggested by experiments in which nonspecific activation of local T cells induces an enteropathy manifested by anatomic adaptation of the mucosal architecture or even damage to the mucosa.[30,31] Additional supporting evidence comes from studies of celiac disease, in which the typical morphologic changes of flattened mucosa can be reproduced in vitro and in vivo by gliadin challenge,[32] an event associated with major histocompatibility complex (MHC) class II–restricted specific recognition of selectively modified gliadin peptides by gut mucosal T cells.[33] Detailed knowledge of the steps leading from antigen-specific T-cell recognition to overt tissue damage is nevertheless limited. In particular, evidence for the existence of classic cytotoxic T cells, which specifically recognize and destroy intestinal cell targets, is still missing. On the other hand, a study suggests that proteolytic injury mediated by broadly active proteases is active downstream of the T-cell activation events.[34]

The most recent type of T cells to attract considerable attention in intestinal inflammation is regulatory T cells (Treg). Previously called suppressor T cells, Treg cells represent a diverse group of cells with potent immunosuppressive activity capable of controlling and preventing autoimmunity and inflammation.[35] The best defined types are T regulator

1 (Tr1) cells, which mediate suppression primarily through the release of immunosuppressive cytokines such as interleukin (IL)-10 and CD4+CD25+ cells, which seemingly exert suppression by direct cell contact, and T helper (Th) 3 cells, which produce large amounts of transforming growth factor (TGF)-β. Tr1 and CD4+CD25+ cells have been shown to suppress intestinal inflammation in vivo in animal models of inflammatory bowel disease.[36,37]

Monocytic Cells and Toll-Like Receptors

Monocytes and macrophages are prominent inflammatory cells that, like neutrophils, lack immunologic memory but are extremely potent in their capacity to mediate tissue damage. The normal small and large bowel contain a moderate number of resident macrophages, which are made up of heterogeneous populations of monocytic cells identifiable by morphologic characteristics and expression of specific cell surface molecules that separate them into categories with preferential antigen-present or scavenger activity.[38,39] Depending on the type of inflammatory process, macrophage heterogeneity is amplified, underlying the recruitment of new cells types as well as diversification of function.[40] They undergo an enhanced respiratory burst activity with release of reactive radicals that contribute to inflammation and local tissue damage.[41] During inflammation, monocytes are actively recruited from the peripheral blood into the mucosa, where they differentiate into macrophages expressing the CD68 and L1 antigens, which differentiates them from preexisting RFD 7+ macrophages.[42] This recently recruited subset of macrophages with monocyte-like phenotype appears to be primed for release of several proinflammatory cytokines and to have greater pathogenic potential compared with macrophages normally residing in the gut.[43] Mucosal macrophages express several costimulatory molecules, including B7-1 and B7-2, which allow them to adhere to and activate T cells, an interaction that can further contribute to expand immune-mediated inflammation.[44]

Macrophages also express a newly described family of cell surface molecules termed pattern recognition receptors (PRRs). These PRRs recognize conserved, pathogen-associated molecular patterns (PAMPS) expressed by various microbes but not the host. One particular family of PRRs, the Toll-like receptors (TLRs), recognizes PAMPs and can influence the character of the inflammatory or immune response through synthesis of proinflammatory cytokines such as IL-1, IL-6, tumor necrosis factor (TNF)-α, and IL-12.[45,46] It is thought that TLRs use signaling components similar to the receptor for IL-1. Once a TLR recognizes the appropriate PAMP, this ultimately results in the activation of NF-κB inducing kinase and, subsequently, the phosphorylation of I-κB. Phosphorylation causes I-κB to physically dissociate from NF-κB, which is then free to translocate into the nucleus and initiate the gene transcription process that leads to the production of a variety of proinflammatory molecules.[47] Activation of NF-κB by bacterial products is not mediated exclusively by TLRs, and some members of the nucleotide-binding oligomerization domain (NOD) family of cytosolic proteins, particularly NOD1 and NOD2, also participate in the innate recognition of microorganisms and regulation of inflammatory responses.[48]

In humans, 10 TLRs have been described with different ligand-binding specificities, including flagellin, bacterial deoxyribonucleic acid (DNA), CpG motifs, peptidoglycan, and lipopolysaccharide (Table 3-1). The binding of specific TLRs dictates the role of the macrophage in promoting the inflammatory response. TLRs also can be found on other cell types, including mast cells and dendritic cells and, to a lesser extent, epithelial cells. In the intestinal epithelium, TLRs are predominantly expressed on the basolateral surface of the cell, but apical expression of TLR-4 is up-regulated during chronic inflammation.[49,50] Some reports have demonstrated that intestinal epithelial cells from patients with Crohn disease and ulcerative colitis expressed TLR-4, whereas intestinal epithelial cells from healthy individuals do not. TLR-3 and TLR-5 also have been identified in the small intestine.[51,52]

Other Inflammatory Leukocytes

A variety of other myeloid and lymphoid cells are found in inflamed gut, including neutrophils, eosinophils, mast cells, basophils, and dendritic cells. All of these cells are present in increased numbers in affected areas, but such an increase often represents a nonspecific response to inflammation. Less frequently, this represents a selective infiltration of cells that plays a specific role in the inflammatory reaction, such as in the case of eosinophilic gastroenteritis, allergic reactions, or helminthic infestations. Information about the contribution of these cell types is substantially less compared with what is currently known about T and B cells in gastrointestinal inflammation.

Polymorphonuclear neutrophils are virtually absent from the normal gut mucosa, and any increase in this cell type, no matter how minute, should raise suspicion that an inflammatory response is occurring. Because neutrophils are short-lived and quickly undergo apoptotic death once translocated into tissues, their numeric increase in the gut is exclusively due to and sustained by emigration from the circulation. This occurs through the expression of multiple adhesion molecules by the neutrophils and the mucosal microvasculature, a topic that is discussed in greater detail later in this chapter.[53] Once localized in the tissue, neutrophils mediate local injury by releasing broad-spectrum proteases and various free radicals,[54] as detailed in the section dealing with soluble mediators of inflammation.

TABLE 3-1 TOLL-LIKE RECEPTORS AND ASSOCIATED PATHOGEN-ASSOCIATED MOLECULAR PATTERNS

TLR	PAMP
TLR-2	Peptidogolycan, bacterial lipoprotein
TLR-3	Double-stranded RNA
TLR-4	Lipopolysaccharide
TLR-5	Flagellin
TLR-7	Small antiviral compounds
TLR-9	Cytosine-phosphorothioate-guanine

PAMP = pathogen-associated molecular pattern; RNA = ribonucleic acid; TLR = Toll-like receptor.

A moderate number of eosinophils are present in the normal intestinal mucosa, whereas mast cells and basophils are less common. All of these cells are increased in number during active inflammation, as seen in inflammatory bowel disease.[55] This is a nonspecific phenomenon, except in conditions in which each cell type can predominate. For example, eosinophils dominate the inflammatory infiltrate during allergic reactions[56] and in conditions of unknown etiology such as eosinophilic gastroenteritis. Like neutrophils, eosinophils are recruited from the circulation, but once localized in the mucosa, they release mediators specifically involved in allergic and parasitic responses, such as IL-4 and IL-5. This is in contrast to mast cells, which, although also involved in similar reactions, are heterogeneous and composed of at least two well-defined populations with distinctive features: connective tissue (typical) mast cells and mucosal (atypical) mast cells.[57] Mucosal mast cells are involved in food allergy, resistance to parasites, and inflammatory bowel disease.[58] Their action is mediated by several soluble products, prominent among which is histamine, an early messenger of inflammatory and immune reactions.[59]

Dendritic cells also need to be mentioned, even though their diversity, complexity, and function in normal mucosal immunity and inflammation have just begun to be investigated. Dendritic cells represent a heterogeneous group of cells with an interdigitating morphology, which are present in low numbers in most tissues of the body and express high levels of human leukocyte antigen (HLA) class II antigens, which make them highly efficient in antigen presentation. Dendritic cells work at the host-pathogen interface to sample antigens and influence the host response to bacterial antigens.[60] Their type and localization along the intestinal tract may provide key determinants of localized mucosal immune and inflammatory responses.[61]

ADDITIONAL CELLS INVOLVED IN INFLAMMATION

Until quite recently, mucosal inflammation was viewed as a response dominated by the action of classic immune cells, whereas all other cells had only a passive role as targets of immune cells and their products. This view is no longer tenable considering a growing body of information showing that multiple cell types display functional characteristics that make them active players in inflammation.[62] Multiple cell types composing the intestinal wall participate in inflammation, including epithelial cells, endothelial cells, nerve cells, and mesenchymal cells (fibroblasts and myofibroblasts).

Epithelial Cells

The involvement of intestinal epithelial cells in mucosal immune reactivity was initially suggested by the secretory, absorptive, and digestive adaptive changes that these cells undergo during immune and parasitic responses.[63] The identification of epithelial cell heterogeneity and the role of Paneth cell–derived defensins in innate immunity also indicate an active role of the epithelium in intestinal immunity.[64] Levels of defensin expression may vary in different types of intestinal inflammation.[65] Subsequent studies generated evidence for an active role of epithelial cells in normal mucosal immunity and inflammation. Immunohistochemistry detected MHC class II (HLA-DR) antigens on human intestinal epithelial cells,[66] and their capacity to function as antigen-presenting cells was documented in both human and animal studies.[67,68] The expression of HLA-DR antigens is enhanced during intestinal inflammation, as in inflammatory bowel disease, celiac disease, and gastritis,[69–71] indicating that it is a nonspecific response to inflammation unrelated to the type or location of disease. Enhanced expression of accessory molecules is also noted on gastric and colonic epithelial cells during inflammatory conditions, as in the case of the costimulatory molecules CD80 (B7-1) and CD86 (B7-2) in *H. pylori* gastritis and ulcerative colitis,[72,73] and intercellular adhesion molecule 1 (ICAM-1) is expressed during bacterial invasion.[74] Additional evidence for the participation of epithelial cells in inflammation comes from studies demonstrating their capacity to both produce and respond to proinflammatory and immunoregulatory cytokines[75] and to express chemokine receptors.[76] In response to bacterial invasion or inflammatory signals, intestinal epithelial cells produce a broad spectrum of bioactive molecules, including IL-1 receptor antagonist, IL-6, IL-7, IL-8, IL-15, monocyte chemotactic protein 1, granulocyte-macrophage colony-stimulating factor (GM-CSF), TNF-α, growth-regulated oncogene (GRO)-α, GRO-γ, macrophage inflammatory protein 2, nitric oxide (NO), and cyclooxygenase (COX) 2.[77–85] Some of these products act on intestinal cells, altering their function, such as the rate of proliferation and barrier function.[86–88] Finally, the normal ability to preferentially activate suppressor CD8+ T cells appears to be shifted to stimulation of helper CD4+ T cells in inflammatory bowel disease,[89] suggesting that epithelial cells may actually contribute to amplification or persistence of certain forms of chronic inflammation. Altogether, the number and variety of agents and functions mediated by intestinal epithelial cells combined with vigorous responses to multiple inflammatory stimuli provide irrefutable evidence of an essential role of intestinal epithelium in inflammation.

Endothelial Cells

Among the various cell types present in the intestinal wall, none is more directly involved in regulating inflammation than endothelial cells. In fact, the microvascular endothelium is a true "gatekeeper of inflammation" because translocation of leukocytes from the intravascular into the interstitial space, under both physiologic and inflammatory circumstances, is tightly controlled by the junctions between endothelial cells.[90] For translocation to occur, leukocytes must adhere to the endothelium through steps mediated by activation of both leukocytes and endothelial cells followed by the expression of adhesion molecules of the selectin, integrin, and Ig superfamily groups and their corresponding ligands in a highly orchestrated process regulated by multiple cytokines.[91] When inflammation ensues, all of these events occur at the level of the microcirculation

in each specific tissue and organ.[92] This is also true for the gastrointestinal tract, in which high endothelial venules, a specialized type of endothelium, play a central role in lymphocyte migration and extravasation.[93] Among others, MAd-CAM-1 is exclusively expressed by the microvascular cells of the gut mucosa, and its level of expression is enhanced during inflammation in both human and animals.[94,95] Thus, considering the importance of the mucosal microvascular endothelium, it is not surprising that leukocyte-endothelial interactions are critical to gastrointestinal inflammation,[96] when the selectivity of lymphoid cell binding to the vascular endothelium may be lost.[97] Studies of the intestinal microvasculature in intestinal inflammation are relatively few. Nonetheless, there is good evidence that inflamed mucosal endothelial cells are in a high state of activation, as indicated by enhanced expression of HLA-DR molecules and inducible nitric oxide synthase (NOS) in areas involved by inflammatory bowel disease.[98,99] More direct evidence of the importance of the microvasculature in inflammation is provided by in vitro studies with human intestinal microvascular endothelial cells (HIMECs). When these cells are obtained from inflamed mucosa of ulcerative colitis or Crohn disease patients, their capacity to up-regulate leukocyte adhesion is markedly increased.[100] This response is detected only when HIMECs are derived from the chronically inflamed but not the uninvolved mucosa of the same subject.[101] In addition, activated platelets interact with HIMECs via the CD40/CD40 ligand pathway and cause them to up-regulate adhesion molecule expression and chemokine production, inducing a proinflammatory response of the mucosal microvasculature.[102] These observations indicate that in the chronically inflamed intestine, the local mucosal microvascular bed undergoes important functional modifications, conditioned by prolonged exposure to a cytokine-rich milieu and other proinflammatory cellular elements, which are likely to contribute to the maintenance of the inflammatory response.

Nerve Cells

The participation of the nervous system in inflammation is well established.[103] In the gastrointestinal tract, the enteric nervous system forms a rich network of fibers regulating not only motility and secretion but also the local immune response.[104] A dramatic example of the critical role of enteric nerves on inflammation is illustrated by the development of jejunoileitis in animals whose enteric glia are specifically ablated.[105] The action of the enteric nervous system on inflammation is exerted through the release of a large number of neuropeptides that have both stimulatory and down-regulatory effects on the immune response.[106] These mediators play a modulatory role in many forms of intestinal inflammation, such as those induced by infectious agents,[107] or of idiopathic origin, such as in inflammatory bowel disease.[108] Perhaps a more important aspect of the nerve cells is to provide an anatomic basis for the effect of stressful events of life on intestinal immunity and inflammation, a connection proposed in both animal models and humans. Objective evidence supporting this connection is fairly convincing in models of experimental gut inflammation,[109] particularly with the recent demonstration that susceptibility to reactivation by stress requires CD4+ T cells and can be adoptively transferred by these cells.[110] The link between the enteric nerves and intestinal inflammation is more tenuous in humans, in whom the negative effects of stress on the outcome of inflammatory bowel disease are still a matter of controversy.[111] Various anatomic changes of enteric nerve fibers have been documented in both Crohn disease and ulcerative colitis,[112,113] but these are probably secondary to inflammation. Nevertheless, once established, they can alter the production and release of a variety of molecules involved in the mediation of inflammation.

Mesenchymal Cells

Mesenchymal cells have been traditionally viewed as simple structural cells, but during the last decade, abundant data demonstrate an active role of these cells in intestinal immunity and inflammation.[114] Distributed from immediately below the subepithelial basement membrane to the lamina propria, in the muscularis mucosae, submucosa, and in the muscularis propria, mesenchymal cells form a pleiotropic group of cells that respond to and secrete a large number of products that modulate the activity of surrounding epithelial and immune cells.[115] Under inflammatory conditions, mesenchymal cells display the intrinsic capacity of altering their phenotype and function evolving from pure fibroblasts to myofibroblasts, stellate cells, and muscle cells.[115,116] Resting and activated mesenchymal cells produce a variety of substances involved in inflammation, including IL-1, IL-6, TNF-α, GM-CSF, TGF-β, and prostaglandin E_2 (PGE_2), as well as adhesion molecules.[117,118] Through the specific action of these molecules, mesenchymal cells influence the response of epithelial cells to inflammation, such as enhancing their electrolyte secretory responses[119] or promoting wound healing by the stimulation of cell migration.[120] The recent demonstration that intestinal mesenchymal cells spontaneously express COX-2, leading to PGE_2 production, has been interpreted as evidence for their contribution to the maintenance of tolerance during intestinal immune responses.[121]

On the other hand, intestinal mesenchymal cells also modulate immune function by directly and indirectly interacting with T cells. Intestinal fibroblasts bind T cells through an ICAM-1–mediated pathway, and adherence is enhanced by proinflammatory cytokines such as IL-1, TNF-α, and interferon (IFN)-γ.[122] Intestinal smooth muscle cells can present antigens and activate T cells in a MHC class II–dependent fashion.[123] In addition to interacting with epithelial and immune cells, intestinal mesenchymal cells also interact with the local bacterial flora, as indicated by stimulation of IL-1, IL-6, and TGF-β expression in cultured myofibroblasts and induction of fibrosis and stenosis in normal and colitic animals.[124,125] Finally, all types of intestinal mesenchymal cells are the primary source of ECM proteins, whose production is dramatically enhanced under inflammatory conditions and is responsible for fibrosis and stricture formation, a topic that is addressed in more detail in a subsequent section.

INFLAMMATORY MEDIATORS

Cytokines

Cytokines represent one of the most numerous and complex group of secreted molecules. Cytokines are involved in multiple aspects of an inflammatory response, and an extensive body of literature exists with regard to intestinal inflammation.[126–128]

Within the cytokine network, a number of properties are attributed to these proteins.[129] Pleiotropy translates the observation that a single cytokine can be synthesized by multiple cell types, induce a response in multiple target cells, and mediate a number of stimulatory or inhibitory signals within one or multiple cell types. Redundancy indicates that multiple cytokines can elicit the same biologic response, whereas cross-regulation indicates that cytokines not only directly activate immune and inflammatory cells, but this activity is, in turn, modulated by the products secreted by the cells they activate. Owing to these various properties, the classification of cytokines is often arbitrary. Cytokines can be classified according to common characteristics to facilitate understanding of the role of individual molecules in gastrointestinal inflammation. A convenient classification groups IL-2, IL-7, IL-12, and IL-18 as immunoregulatory cytokines because they play a primary role in activating, modulating, and expanding the immunoregulatory T-cell population, although they also exert activities on other immune and nonimmune cells (Table 3-2). Some cytokines exert both immunosuppressive and immunoregulatory functions, such as IL-4, IL-10, and IL-13 (Table 3-3). Other immunoregulatory and effector cytokines, including IFN-γ, GM-CSF, IL-3, IL-5, IL-9, IL-11, and IL-15, act primarily during the effector phase of the immune response and impact on how immune and nonimmune cells function to eliminate a pathogen or perpetuate immunity and inflammation (Table 3-4). The last group includes the proinflammatory cytokines IL-1α, IL-1β, TNF-α, and IL-6, which are primarily produced by cells of monocytic and macrophage lineage (Table 3-5). Although classically categorized as a proinflammatory molecule, a number of anti-inflammatory activities have been attributed more recently to IL-6 because this molecule fails to induce activities traditionally associated with inflammation, such as enhancement of eicosanoid, NO, and metalloproteinase production and adhesion molecule expression.[130] An alternate way of classifying cytokines, which is restricted to cytokines produced by CD4+ Th cells, is following the Th1 and Th2 paradigm. According to this conceptual framework, a balance between Th1 (IL-2, IFN-γ, and TNF-α producing) and Th2 (IL-4, IL-5, IL-6, IL-10, and IL-13 producing) cytokines implies a physiologic immune response, as found in health, whereas an imbalance between Th1 and Th2 cytokines leads to conditions dominated by a delayed-type hypersensitivity/cell-mediated (Th1) or an allergic-type/antibody-mediated (Th2) pathologic response.[131]

The bulk of information on cytokine abnormalities in intestinal inflammation is based on studies of abnormalities found in human inflammatory bowel disease. The study of IL-2 has shown differential activity in Crohn disease and ulcerative colitis. Mucosal levels of IL-2 protein and messenger ribonucleic acid (mRNA) are consistently higher than in ulcerative colitis, as are levels of the IL-2Rα chain.[132] In both adult and pediatric Crohn disease patients, mucosal immune cells exhibit a hyperreactivity to IL-2 when compared with cells from ulcerative colitis patients.[133,134] The Th1 disease connotation presently attributed to Crohn disease is supported by the enhanced spontaneous production of IFN-γ by mucosal mononuclear cells.[135] In addition, both protein and mRNA for IL-12 and IL-18, cytokines essential for IFN-γ induction, are expressed at higher levels in Crohn disease– than ulcerative colitis–affected tissues.[136–138] Low production of IL-4 by lamina propria mononuclear cells and T-cell clones of Crohn disease patients also reinforces the concept that this is a condition with a prominent Th1-like profile.[139] The classification of ulcerative colitis as a Th2-like condition, however, is still in doubt. In support of this possibility are lower levels of IFN-γ produced by mucosal mononuclear cells and higher IL-5 levels in ulcerative colitis than Crohn disease mucosa.[140,141] Little information exists on mucosal levels of IL-10 in inflammatory bowel disease,[142] probably reflecting a nonspecific response to gut inflammation. Mucosal production of IL-15, a cytokine with many of the biologic activities of IL-2, is enhanced in both forms of inflammatory bowel disease.[143]

Levels of proinflammatory cytokines are elevated in tissues involved by inflammatory bowel disease. High concentrations of IL-1α and -β are found in both Crohn disease and ulcerative colitis,[144,145] but local effects are largely determined by the relative concentration of the natural antagonist IL-1RA. A mucosal imbalance between IL-1RA and IL-1 has been reported in inflammatory bowel disease, showing a relative deficiency of IL-1RA, which could con-

TABLE 3-2 IMMUNOREGULATORY CYTOKINES

CYTOKINE	MAIN CELLULAR SOURCE	MAIN TARGET CELL	DOMINANT FUNCTION
IL-2	T cells	T cells, all IL-2R–bearing cells	T-cell activation, proliferation, clonal expansion, and differentiation
IL-7	Stromal cells, epithelial cells	Leukocyte differentiation	T-cell proliferation and cytotoxicity
IL-12	Phagocytes, B cells, dendritic cells	T cells	Th1 differentiation, infectious responses, induction of IFN-γ
IL-18	Macrophages, dendritic cells, epithelial cells	T cells	IL-12–like

IFN = interferon; IL = interleukin; IL-2R = interleukin-2 receptor; Th = T helper.

TABLE 3-3 IMMUNOREGULATORY AND IMMUNOSUPPRESSIVE CYTOKINES

CYTOKINE	MAIN CELLULAR SOURCE	MAIN TARGET CELL	DOMINANT FUNCTION
IL-4	T cells, mast cells, basophils	Multiple cell types	Th2 differentiation, mediation of allergy, immunosuppression, and anti-inflammatory activity
IL-10	Monocyte, macrophages, T and B cells, nonimmune cells	Multiple cells	Anti-inflammatory activity and immunosuppression
IL-13	T cells	Multiple cells (except T cells)	IL-4–like

IL = interleukin; Th = T helper.

tribute to the chronicity of inflammation.[146] IL-6 is also consistently elevated in inflammatory bowel disease mucosa, where it primarily derives from macrophages and epithelial cells.[147,148] In contrast to IL-1 and IL-6, protein and mRNA levels of TNF-α have been inconsistently reported as both normal and elevated in inflammatory bowel disease. High TNF-α concentrations are found in the stools of children with Crohn disease and ulcerative colitis,[149] and production of TNF-α is higher in cultures of Crohn disease than in ulcerative colitis mucosal mononuclear cells.[150] In situ hybridization reveals elevated TNF-α mRNA in macrophages infiltrating inflammatory bowel disease tissues,[151] but some studies found no differences in TNF-α mRNA expression in normal and inflammatory bowel disease biopsies.[148,152]

Chemokines

Chemokines are cytokines that exhibit the ability to directionally attract leukocytes into sites of inflammation. They constitute a very large group of functionally related molecules usually divided into four families based on their content of cysteine (C) residues, which are separated by variable numbers of amino acids (X).[153] Chemokines are produced by most cells in the body, and each family displays relative selectivity in its capacity of attracting neutrophils, monocytes, macrophages, dendritic cells, T cells, natural killer cells, eosinophils, and basophils, depending on these cells' expression of multiple chemokine receptors (Table 3-6). Chemokines are involved not only in the recruitment of nonspecific inflammatory cells but also in the positioning and the preferential induction of Th1 and Th2 cells, making them active participants of cell-mediated immunity and Th1 and Th2 responses.[154] Therefore, it is not surprising that chemokines play a central role in intestinal inflammation,[155] in which their levels tend to be high and correlate with the histologic grade of inflammatory activity regardless of the organ involved, as observed in *H. pylori*–induced gastritis and colitis.[156,157] In actively inflamed intestine, multiple cell types are sources of chemokines, including macrophages, T cells, endothelial cells, and epithelial cells.[158,159] However, it is likely that most mucosal cells produce some type of chemokines, making it difficult to dissect out the relative contribution of each cell and chemokine to the initiation, amplification, and persistence of mucosal inflammation. In particular, the precise contribution of epithelial cells to chemoattraction in vivo is unclear, except for the production of the neutrophil chemokine epithelial cell–derived neutrophil activity peptide (ENA)-78 in active inflammatory bowel disease.[160] In addition to the type of chemokines produced during intestinal inflammation, it is also important to consider the expression of the various chemokine receptors by circulating and infiltrating leukocytes. This determines which cells are attracted into the mucosa and may explain the differences that exist among infiltrating cells in different types of gut inflammation and the preferential localization of particular cell subsets in distinct segments of the gut.[161,162]

Growth Factors

Intestinal inflammation has traditionally been considered as an excessively strong insult by activated immune cells and their products that ultimately results in a tissue-destructive process. An alternate and complementary view is that intestinal inflammation results from an inadequate

TABLE 3-4 IMMUNOREGULATORY AND EFFECTOR CYTOKINES

CYTOKINE	MAIN CELLULAR SOURCE	MAIN TARGET CELL	DOMINANT FUNCTION
IFN-γ	T cells, natural killer cells	Most cells	Induction of MHC class II antigens, monocyte activation, Th1 differentiation, and IL-4 suppression
GM-CSF	Phagocytes, B cells	Hematopoietic cells	Leukocyte differentiation
IL-3	Multiple cells	Hematopoietic cells	Leukocyte differentiation
IL-5	T cells, mast cells	Eosinophils	Mediation of allergic and parasitic diseases
IL-9	Th2 cells	T cells, mast cells	Undefined
IL-11	Hematopoietic stromal cells	Multiple cells	Stimulation of intestinal crypt cells
IL-15	Most cells	IL-2R–bearing cells	T-cell expansion, epithelial cell differentiation

GM-CSF = granulocyte-macrophage colony-stimulating factor; IFN = interferon; IL = interleukin; IL-2R = interleukin-2 receptor; MHC = major histocompatibility complex; Th = T helper.

TABLE 3-5 PROINFLAMMATORY CYTOKINES

CYTOKINE	MAIN CELLULAR SOURCE	MAIN TARGET CELL	DOMINANT FUNCTION
IL-1α, IL-1β	Monocytes, macrophages	Most cells	Mediation of infectious and inflammatory responses
IL-6	Multiple cells	Most cells	Enhancement of immunoglobulin production and immunoregulation
TNF-α	Macrophages	Multiple cells	Mediation of inflammatory and cytotoxic responses

IL = interleukin; TNF = tumor necrosis factor.

capacity of the gut mucosa to defend itself against infectious, immune, toxic, or ischemic injuries. Because cytokines and chemokines are generally considered mediators of injury, growth factors can be considered as mediators of defense and, once damage has occurred, of remodeling and healing. Like cytokines, growth factors derive from multiple cellular sources that are primarily nonimmune, such as mesenchymal cells, and also exert a great variety of diverse functions, essential among them being the ability to induce cell proliferation.[163] In addition to proliferation, other fundamental activities include cell differentiation, cell migration, angiogenesis, and ECM deposition, all of which are necessary to wound healing and resolution of inflammation.[163] Growth factors can be divided in families, including TGF-β, epidermal growth factor (EGF) and TGF-α, insulin-like growth factors, fibroblast growth factors, hepatocyte growth factor, and trefoil factors (Table 3-7).

In a reductionistic model of epithelial cell wounding in vitro, TGF-β is centrally important in reconstitution of epithelial integrity by stimulating cell migration, a response that is selectively enhanced by other growth factors and cytokines including TGF-α, EGF, IL-1, and IFN-γ.[164,165] Fibroblast growth factor also promotes epithelial cell restitution.[166] A similar protective effect is exerted by TGF-α in repair of acute gastric injury in animals.[167] Keratinocyte growth factor, a member of the fibroblast growth factor family, mediates a comparable healing effect in the inflamed colonic mucosa of rats exposed to trinitrobenzenesulfonic acid.[168] Increased expression of keratinocyte growth factor in the mucosa of inflammatory bowel disease patients can be interpreted as a defense against inflammatory damage by stimulating epithelial cell proliferation and promoting healing.[169] On the other hand, other growth factors, such as insulin-like growth factor I, may be more involved in the development of fibrosis.[170] Trefoil peptides represent a different class of growth factors whose main function is to reinforce the protective action of mucus by enhancing its physical resistance to mechanical injury.[171] This concept is supported by the beneficial effect of oral trefoil peptides in ethanol- and indomethacin-induced gastric inflammation and their enhanced levels in epithelial cells overlying areas involved by active inflammatory bowel disease.[172,173]

Eicosanoids

Eicosanoids include a group of substances derived from the metabolism of arachidonic acid resulting from the breakdown of cell membrane phospholipids by the action of phospholipases. Two main classes of enzymes are involved in the metabolism of arachidonic acid: the COXs and the lipoxygenases.[174] A large spectrum of vasoactive, pro- and anti-inflammatory, and immunomodulatory activities are mediated by various eicosanoids, whose main categories include prostaglandins, thromboxanes, and leukotrienes. An extensive literature exists on the various biologic functions of these eicosanoids in the gastrointestinal tract,[174–177] and their enhanced production in mucosa affected by various forms of inflammation is well documented.[178,179] COXs exist in constitutive (COX-1) and inducible (COX-2) forms and are intimately involved in the mechanisms of cytoprotection and destruction associated with various forms of gastrointestinal inflammation.[174–177] It is firmly established that prostaglandins primarily exert a cytoprotective action, which is lost when COXs are inhibited by the action of nonsteroidal anti-

TABLE 3-6 CHEMOKINES

GROUP	MAIN CHEMOKINES	MAIN CELLULAR SOURCE	MAIN TARGET CELLS
C-C	MCP-1/5, MIP-1α/β, RANTES, eotaxin-1, SDF-1, IP-10	Multiple immune and nonimmune cells	Monocytes, activated T cells, eosinophils, basophils
C	Lymphotactin, SDF-1	Multiple immune and nonimmune cells	Resting T cells
C-X-C	IL-8, MCP-1/5, MIP-1α/β, RANTES, eotaxin-1, SDF-1, GRO-α/β/γ, IP-10, ENA-78	Multiple immune and nonimmune cells	Neutrophils, dendritic cells
C-XXX-C	IL-8, MCP-1/5, MIP-α/β, RANTES, IP-10	Multiple immune and nonimmune cells	Natural killer cells

ENA = epithelial cell–derived neutrophil-activating peptide; GRO = growth-regulated oncogene; IL = interleukin; IP = IFN-γ–inducible protein 10; MCP = monocyte chemoattractant protein; MIP = macrophage inflammatory protein; RANTES = regulated on activation normal T cell expressed and secreted; SDF = stromal cell–derived factor.

TABLE 3-7 GROWTH FACTORS

FACTOR	MAIN TARGET CELL	PREDOMINANT EFFECT
TGF-α	Nonimmune cells	Enhancement of mucus protection, cell proliferation, differentiation, and migration and deposition of extracellular matrix
TGF-β	Immune and nonimmune cells	Enhancement of cell proliferation, differentiation, and migration; deposition of extracellular matrix; mediation of immunosuppression and tolerance
EGF	Nonimmune cells	Enhancement of mucus protection, cell proliferation, differentiation, and migration and deposition of extracellular matrix
IGF	Nonimmune cells	Enhancement of cell proliferation, differentiation, and migration and deposition of extracellular matrix
FGF	Nonimmune cells	Enhancement of cell proliferation, differentiation, and migration; deposition of extracellular matrix; collagenase production; and angiogenesis
Trefoils	Epithelial cells	Enhancement of mucus protection and cell migration and inhibition of proliferation

EGF = epidermal growth factor; FGF = fibroblast growth factor; IGF = insulin-like growth factor; TGF = transforming growth factor.

inflammatory drugs, a key step in the development of gastric ulceration.[180] This protective effect is mediated through multiple mechanisms, including stimulation of mucus and bicarbonate secretion, maintenance of mucosal blood flow, enhancement of epithelial cell resistance to cytotoxicity, inhibition of neutrophil recruitment and mast cell degranulation, and a broad immunosuppressive action (mostly by PGE_2) on macrophage and T-cell responses.[174] The anti-inflammatory activity of prostaglandins has been investigated more extensively in gastric injury and less in the rest of the intestinal tract. However, it appears that prostaglandins also mediate cytoprotective and anti-inflammatory activities in the small intestine and large bowel, as indicated by their mediation of enhanced survival of crypt stem cells in a model of radiation injury,[181] and the exacerbation of experimental colitis in animals receiving a selective COX-2 inhibitor.[182] A recent report suggests that the beneficial action of prostaglandins in the intestine may be even more fundamental than previously thought. This is based on evidence showing that PGE_2 produced through COX-2–dependent pathways is crucial to down-regulate physiologic immune responses to dietary antigens and, thus, maintains intestinal immune homeostasis by promoting immunologic tolerance.[183]

Leukotrienes are produced by the action of the enzyme 5-lipoxygenase, which is dependent on activation of 5-lipoxygenase activation protein. One of the main leukotrienes is LTB_4, which has a potent chemotactic effect for neutrophils and, as a result, acts as a strong proinflammatory substance. LTB_4 proinflammatory activity is probably exerted in both the upper and the lower gastrointestinal tract, as suggested by its elevation in the stomach of patients taking nonsteroidal anti-inflammatory drugs,[184] and in the colon of patients with inflammatory bowel disease.[185] Thromboxanes are COX-1–dependent products of platelets, and they are powerful vasoconstrictors believed to contribute to inflammation in various portions of the gastrointestinal tract, including the stomach[186] and small[187] and large bowel.[188]

Neuropeptides

Neuropeptides are small peptides released at nerve cell endings that influence the activity of immune and inflammatory cells, although many other cell types are also affected (Table 3-8). This effect can be stimulatory or inhibitory, depending on the type of neuropeptide and the target cells.[106] For instance, substance P tends to enhance immunity and promote inflammation, whereas vasoactive

TABLE 3-8 NEUROPEPTIDES

PEPTIDE	MAIN TARGET CELL	PREDOMINANT EFFECT
SP	T cells	Modulation of proliferation, enhancement of antigen-specific responses
	B cells	Enhancement of proliferation and antibody production
	Natural killer cells	Enhanced activity
	Macrophages	Enhancement of activity and chemotaxis
VIP	T cells	Inhibition of proliferation, enhancement of cAMP, enhancement of IL-2 and IL-4 and inhibition of IL-5 production, modulation of homing
	B cells	Inhibition of proliferation, modulation of antibody production
	Natural killer cells	Modulation of activity
	Macrophages	Inhibition of activity
SOM	T cells	Modulation of proliferation, inhibition of antigen-specific responses
	B cells	Inhibition of antibody production
	Natural killer cell	Modulation of activity
CGRP	T cells	Inhibition of proliferation, enhancement of cAMP
	Macrophages	Inhibition of activity
	Eosinophils	Enhancement of activity

cAMP = cyclic adenosine monophosphate; CGRP = calcitonin gene–related peptide; IL = interleukin; SOM = somatostatin; SP = substance P; VIP = vasoactive intestinal polypeptide.

intestinal peptide (VIP) has a predominant inhibitory action on the immune response. Consequently, changes in neuropeptide levels in the intestinal mucosal can modulate immunity and alter the degree of inflammation. Loss of VIP- and somatostatin-expressing fibers and decreased VIP tissue levels are reported in active Crohn disease and ulcerative colitis,[189–191] whereas substance P levels are generally increased, particularly in ulcerative colitis.[189,192] The exact meaning of these observations to disease pathogenesis is uncertain, but the data are compatible with a decrease of inhibitory and an increase of stimulatory peptides, with a net balance in favor of a proinflammatory response. In postproctocolectomy pouchitis, both VIP and substance P are increased.[193] When gut inflammation is induced by *Clostridium difficile* toxin A, both substance P and neurotensin contribute to neurogenic inflammation.[194,195] Not only neuropeptide levels are abnormal in inflamed tissue; so are the levels of specific receptors, such as those for substance P and somatostatin.[196,197] Owing to the large number and pleiotropic activities of the various neuropeptides, their overall impact on intestinal inflammation still remains to be defined but probably depends on the cause, type, and chronicity of the inflammatory process.

Reactive Oxygen and Nitrogen Metabolites

Although a plethora of different cells and secreted products are involved in inflammation, the vast majority of them act as initiators, mediators, or amplifiers of the inflammatory process, and few directly mediate tissue damage. Among the latter are molecules classified as reactive oxygen and nitrogen metabolites, both of which are abundantly produced during gut inflammation.[198]

Oxygen metabolites are highly reactive molecules that exert a direct cytotoxic effect on a broad scale by degrading amino acids, proteins, and biopolymers (eg, hyaluronic acid, mucin), oxidizing carbohydrates and sulfur-containing compounds, bleaching hemoproteins, causing lipid peroxidation, and inducing DNA strand scission.[54] Reactive oxygen metabolites are evanescent products released by activated polymorphonuclear leukocytes and include both radical and nonradical molecules (Table 3-9). All of them exhibit variable degrees of toxicity on multiple type cells, which explains, in addition to the release of proteolytic enzymes, the tissue-destructive capacity of neutrophils whose presence is the hallmark of inflammation.[199] The presence of neutrophils in the inflamed gut fluctuates depending on the type and phase of the disease process, but reactive oxygen metabolites are invariably produced and acquire particular importance in highly destructive conditions such as inflammatory bowel disease and necrotizing enterocolitis.[200,201] That active oxygen species are produced in heightened quantities by circulating neutrophils and monocytes of patients with intestinal inflammation is well documented,[202] but far more important is the demonstration that reactive oxygen metabolites are generated at the very sites of active inflammation, as observed in both humans and animals.[203,204]

A second group of reactive metabolites that has attracted intense attention in recent years is that of reactive nitrogen metabolites, formed by its major product NO and others resulting from its rapid oxidation, such as NO_2, NO_2^-, N_2O_3, N_2O_4, *S*-nitrosothiols, and peroxynitrite ($OONO^-$).[205] Essential to NO production are the enzymes responsible for its synthesis, NO synthesis (NOSs), which are produced by different cell types and are both constitutive or inducible.[206] NO has a broad range of activities in all tissues and organs of the body, and the gastrointestinal tract is no exception.[207] Elevated production of NO and the inducible form of NOS is extensively documented in the bowel of patients with inflammatory bowel disease and toxic megacolon,[83,208,209] as well as in various models of experimental gut inflammation.[210,211] Although there is general agreement that NO and NOS are intrinsic components of any intestinal inflammatory process, what is still unresolved is whether NO plays a protective and therefore beneficial role or whether its action is predominantly destructive and deleterious to gut tissue.[212] Examples of the noxious effects of NO are its ability to increase epithelial cell permeability and induce mucosal damage.[213,214] An explanation for the existing confusion is partly due to the multitude of actions mediated by NO but also the practical observation that the role of inducible NOS in inflammation varies in different settings and diseases, ranging from those in which the enzyme has a predominantly noxious effect to those in which it appears to benefit the host.[205] The exact roles of NO and NOS need to be better elucidated before modulation of their activity can be considered for their potentially therapeutic effects on intestinal inflammation.

Proteolytic Enzymes

ECM-degrading proteinases (endopeptidases) include aspartic, cysteine, and serine proteinases and metalloproteinases, each of them composed of several distinct enzymes synthesized and released by both immune and nonimmune cells (Table 3-10). The components of the ECM, including most collagens, fibronectin, elastin, laminin, entactin, and heparan sulfate proteoglycan, are susceptible to the destructive action of these proteases. This action is counterbalanced by the protective activity of a large number of endogenous inhibitors that include α_2-macroglobulin, serine protease inhibitors (serpins, kunins, and others), cysteine protease inhibitors (kininogens, stefin, cystatin, and calpastatin), and matrix metalloproteinase (MMP) inhibitors (tissue inhibitors of metalloproteinases (TIMP)-1, -2, and -3).

TABLE 3-9 REACTIVE OXYGEN METABOLITES

TYPE	NAME	STRUCTURE
Radicals	Superoxide anion radical	O_2^-
	Hydroperoxyl radical	HO_2^-
	Hydroxyl	$OH^\cdot$
	Alkoxyl radical	$RO^\cdot$
	Hydroperoxyl radical	$ROO^\cdot$
Nonradicals	Hydrogen peroxide	H_2O_2
	Hydroperoxide	ROOH
	Hypochlorous acid	HOCl
	N-Chloramine	RNHCl

TABLE 3-10 PROTEOLYTIC ENZYMES

ENZYME	MAIN SOURCE	SUBSTRATE
Aspartic proteinases	Lysosome	Collagens
Cysteine proteinases	Lysosome, cytosol	Aggrecan core protein, collagens, fibronectin, elastin
Serine proteinases	Plasma, neutrophils, fibroblasts, endothelial cells, mast cells	Collagens, fibronectin, elastin, heparan sulfate proteoglycan
METALLOPROTEINASES		
Interstitial collagenase (MMP-1)	Fibroblasts	Aggrecan core protein, collagens, fibronectin, elastin, laminin, entactin
Gelatinase A (MMP-2)	Fibroblasts	
Stromelysin (MMP-3)	Fibroblasts	
Matrilysin (MMP-7)	Macrophages	
Neutrophil collagenase (MMP-8)	Neutrophils	
Gelatinase B (MMP-9)	Neutrophils, macrophages, fibroblasts, other mesenchymal cells	

MMP = matrix metalloproteinase.

MMPs are attracting increasing attention as key molecules mediating injury in most tissues because of their ability to degrade all components of the ECM.[215] This is also true in the setting of intestinal inflammation.[216] Direct evidence of ECM degradation in intestinal inflammation is relatively limited, but abnormalities of ECM glycoaminoglycans and loss of glycoaminoglycans in the subepithelial basal lamina and from vascular endothelium are detected in tissues involved by ulcerative colitis and Crohn disease.[217] In these diseases, as well as in peptic ulcers, there is an enhanced expression of the MMPs matrilysin, collagenase, and stromelysin-1,[218] suggesting a cause-and-effect relationship among inflammation, release of proteases, and tissue injury. There is also mounting evidence that the mucosal immune system can trigger events leading to MMP-dependent tissue injury. In an intestinal organ culture model, activation of lamina propria T cells is accompanied by proteolytic degradation of ECM mediated by local release of MMPs.[219,220] These enzymes derive primarily from mucosal mesenchymal cells on stimulation by cytokines produced during the inflammatory reaction, such as TNF-α.[221] This event is inhibited by immunosuppressive cytokines, such as IL-10,[222] and exaggerated by amplifying the activity of Th1 cells with IL-12,[34] indicating that the extent of inflammatory damage is under the control of the strength and the type of ongoing immune responses. However, the degree of damage inflicted to gut tissue exposed to the action of MMPs depends not only on the absolute concentration of these proteases but also the relative proportion of MMPs and TIMPs. In inflammatory bowel disease, there is evidence for MMP overproduction, whereas the expression of TIMPs remains unaltered[223,224]; such an imbalance could well underlie the loss of mucosal integrity.

Extracellular Matrix

The ECM is recognized as an important player in mucosal inflammation because of its crucial role in leukocyte trafficking and activation, wound healing, and fibrosis,[225] as well as the ability to integrate (immune and nonimmune) cell-to-cell and cell-to-matrix interactions.[226] The ECM is a complex protein network secreted by various cell types and forms the intercellular space, where all cells reside.[227] The effects of the ECM are mediated primarily by integrins, a family of cell surface receptors that attach cells to the matrix and mediate mechanical and chemical signals from it.[228] In the gastrointestinal tract, the main components of the ECM are the basement membrane and the interstitial connective tissue matrix. The basement membrane is a specialized sheet-like ECM underlying and essential for adhesion and differentiation of epithelial and endothelial cells. It is composed of a number of multimeric glycoproteins and proteoglycans, including laminins, entactin/nidogen, type IV collagen, fibronectin, and perlecan. The interstitial connective tissue matrix serves as a working environment for all nonanchored cells and is the site of immune and inflammatory reactions. It is synthesized primarily by local mesenchymal cells and contains collagenous and noncollagenous glycoproteins such as the fibrillar collagens (collagen types I, III, and V); glycoproteins such as fibronectin, tenascin, and thrombospondin; and proteoglycans such as versican, decorin, lumican, fibromodulin; and the glycosaminoglycan hyaluronic acid.[227]

The participation of the ECM in intestinal inflammation comprises two domains. The first relates to the functional interaction of the ECM with leukocytes, resulting in the alteration of the migration, activation, and differentiation of these cells.[229] This interaction is influenced by cytokines and chemokines[226] and determines the type and strength of the resulting immune response.[3] There is a paucity of information in this area, but emerging evidence suggests that the ECM profoundly increases its capacity to adhere and retain T cells in inflammatory bowel disease[230] and that leukocyte-matrix interactions regulate mucosal inflammatory responses.[231] The second area of investigation is related to the quantitative and qualitative changes occurring in the intestine during inflammation. Information in this area is more abundant, although it is necessarily restricted to chronic inflammatory processes in which major structural changes are part of the natural history of the disease, as in ulcerative colitis and Crohn disease.[232] In both forms of inflammatory bowel disease, procollagen gene transcripts are increased in sites of inflammation, but they are more abundant in the subepithelial layers in ulcerative colitis and in the deeper layers in Crohn disease, sug-

gesting different regulatory mechanisms in each disease.[233] The same appears to be true in collagenous colitis, in which the subepithelial basement membrane deposit of ECM stain prominently for type VI collagen and tenascin.[234] In contrast, other ECM changes are not disease specific, such as the increased expression of tenascin in colons involved by ulcerative colitis or Crohn disease.[235] Regardless of specificity, changes in ECM translate to an active process of tissue remodeling in the inflamed intestine resulting from the action of agents that both promote and hinder ECM deposition. For instance, TGF-β1 selectively augments collagen synthesis by intestinal smooth muscle cells,[236] a response that contributes to intestinal fibrosis. On the other hand, inflammatory mediators, such as IL-1β, promote intestinal muscle cell proliferation while concomitantly down-regulating collagen synthesis and augmenting collagenase expression.[237] In addition to classic inflammatory mediators, the local intestinal flora also appears to promote intestinal fibrosis by directly stimulating local mesenchymal cells to secrete enhanced amounts of TGF-β1, IL-1β, and IL-6.[124,125]

Cell Adhesion Molecules

The involvement of cell adhesion molecules in inflammation depends on the organ affected and the nature of the inflammatory stimulus. In the gastrointestinal tract,[238,239] it is modulated by cytokines, chemokines, eicosanoids, bacterial products, and complement fragments.[240] Cell adhesion molecules, which can be both cell surface bound and secreted into the intercellular space, are a large number of structurally and functionally related and unrelated molecules forming four major families: the selectin family, which is primarily responsible for leukocyte-endothelial cell interactions; the integrin family, which mediates cell-cell and cell-ECM interactions; the immunoglobulin superfamily, which mediates homophilic adhesion between an identical cell adhesion molecule on another cell; and the cadherin family, which establishes molecular links between adjacent cells (Table 3-11).[241] In intestinal inflammation, cell adhesion molecules of all families are involved, but perhaps the most important are those regulating the adhesion of leukocytes to the vascular endothelial cells and their subsequent translocation into the interstitial space.[53] These include ICAM-1, vascular cell adhesion molecule (VCAM)-1, platelet–endothelial cell adhesion molecule 1, and MAd-CAM-1 of the Ig superfamily; CD11/CD18, very late activation antigen (VLA)-4, and $\alpha_4\beta_7$ of the integrin family; and L-, E-, and P-selectin of the selectin family (Figure 3-1).[242]

The bulk of information on the function and level of expression of cell adhesion molecules in intestinal inflammation derives from studies of chronic inflammatory processes such as inflammatory bowel disease or chronic gastritis.[94,243–246] As expected, there is an active recruitment of leukocytes by the microvascular mucosal beds in areas of active mucosal inflammation,[247] which is associated with a disruption of the normal selectivity of leukocyte-endothelial interaction.[97] This results in abnormal homing patterns of inflammatory cells to both intestinal and extraintestinal sites.[248] In addition, the level of expression of several cell adhesion molecules is increased on both leukocytes and vascular cells (CD11/CD18; VCAM-1; ICAM-1, -2, and -3; E-selectin; and VLA-4), further contributing to the inflammatory response.[94,243–246,249] Addi-

TABLE 3-11 CELL ADHESION MOLECULES

CELL ADHESION MOLECULE	MAIN CELLULAR SOURCE	MAIN LIGAND	MAIN TARGET
Selectin family			
E-selectin	Endothelial cells	L-selectin	Neutrophils, monocytes, T cells
L-selectin	Lymphocytes, neutrophils, monocytes	MAd-CAM-1	Mucosal HEV, endothelial cells
P-selectin	Platelets, endothelial cells	L-selectin	Neutrophils, monocytes, platelets
Integrin family			
LFA-1 (CD11a/CD18)	All leukocytes	ICAM-1, -2, -3	Lymphoid, nonlymphoid cells
LFA-3	All cells, some T cells	CD2	T cells, natural killer cells
Mac-1 (CD11b/CD18)	Neutrophils, monocytes	ICAM-1 and -3, fibrinogen	Lymphoid, nonlymphoid cells, ECM
VLA-1, -2, -3	Collagen, laminin	ECM	
VLA-4	Lymphocytes, monocytes	VCAM-1, fibronectin	Endothelial cells, fibroblasts, monocytes, ECM
VLA-5	Lymphocytes, monocytes	Fibronectin	ECM
VLA-6	Lymphocytes, monocytes	Laminin	ECM
$\alpha_4\beta_7$	Lymphocytes	MAd-CAM-1, fibronectin	Mucosal HEV, ECM
Immunoglobulin superfamily			
ICAM-1 (CD54)	Lymphoid, nonlymphoid cells	LFA-1, Mac-1	Neutrophils, lymphocytes, monocytes
VCAM-1 (CD106)	Endothelial cells, fibroblasts, monocytes	VLA-4, $\alpha_4\beta_7$	Neutrophils, lymphocytes, monocytes
MAd-CAM-1	Mucosal HEV	$\alpha_4\beta_7$, L-selectin	Lymphocytes, monocytes, neutrophils
PECAM-1	Endothelial cells, neutrophils	PECAM-1	Endothelial cells, neutrophils
Cadherin family			
Cadherin, α- and β-catenin	Adjacent cells	Cadherin	Same cell type
Other			
CD44 (Hermes)	Lymphoid, nonlymphoid cells	Hyaluronan, collagen	Endothelial cells, ECM

ECM = extracellular matrix; HEV = high endothelial venules; ICAM = intercellular cell adhesion molecule; LFA = leukocyte function–associated antigen; MAd-CAM = mucosal addressin cell adhesion molecule; PECAM = platelet–endothelial cell adhesion molecule; VCAM = vascular cell adhesion molecule; VLA = very late activation antigen.

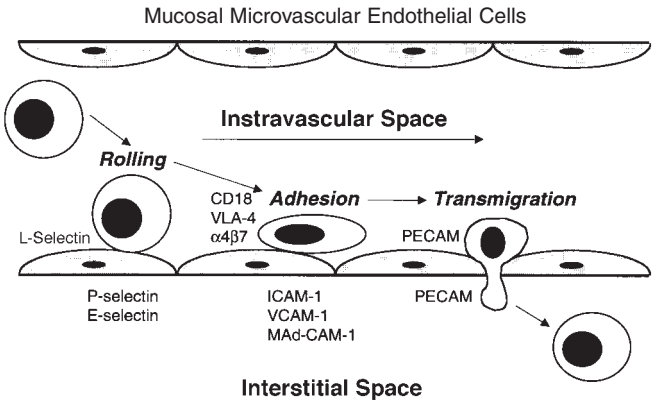

FIGURE 3-1 Major cell adhesion molecules involved in the various steps (rolling, adhesion, and transmigration) necessary to move leukocytes from the intravascular to the interstitial space. Molecules expressed by leukocytes are listed to their left, and molecules expressed by endothelial cells are listed below them. ICAM = intracellular adhesion molecule; MAd-CAM = mucosal addressin cell adhesion molecule; PECAM = platelet–endothelial cell adhesion molecule; VCAM = vascular cell adhesion molecule; VLA = very late activation antigen.

tional information derives from animal models of gastrointestinal inflammation, in which the administration of blocking antibodies confirms the importance of selected cell adhesion molecules in the mucosal inflammatory reaction. Representative examples are CD11/CD18 in rabbit gastritis,[250] ICAM-1 in rat colitis,[251] and $\alpha_4\beta_7$ and VLA-4 in monkey colitis.[95,252]

CONCLUSIONS

Intestinal inflammation is a highly complex phenomenon initiated by a myriad of different triggers and involving all of the components described in this chapter. For the sake of completeness, two additional components deserve mention. One is the endogenous enteric flora, whose capacity to control the overall function of the gastrointestinal tract under physiologic and inflammatory conditions has been underestimated.[253] The second is the phenomenon of apoptosis, which plays a central role in keeping the necessary balance between cell death and survival in the gastrointestinal tract.[254] If this balance is lost, defects of apoptosis can contribute to some forms of intestinal inflammation.[255,256] How these multiple components behave, how much each of them contributes to inflammation, and how they functionally interact among themselves will depend on the quality and quantity of the initial stimulus and the genetic makeup of the host. Together, they will ultimately determine the type, strength, and duration of the immune response and whether physiologic or pathologic inflammation will ensue (Figure 3-2). Each portion of the gastrointestinal tract displays specialized features that reflect adaptation to particular physiologic and metabolic requirements so that the outcome of an inflammatory process may vary in different segments of the intestine. In spite of diversity, however, gut inflammation is primarily a stereotypical event mediated by common pathways of tissue injury regardless of the initiating event.[257]

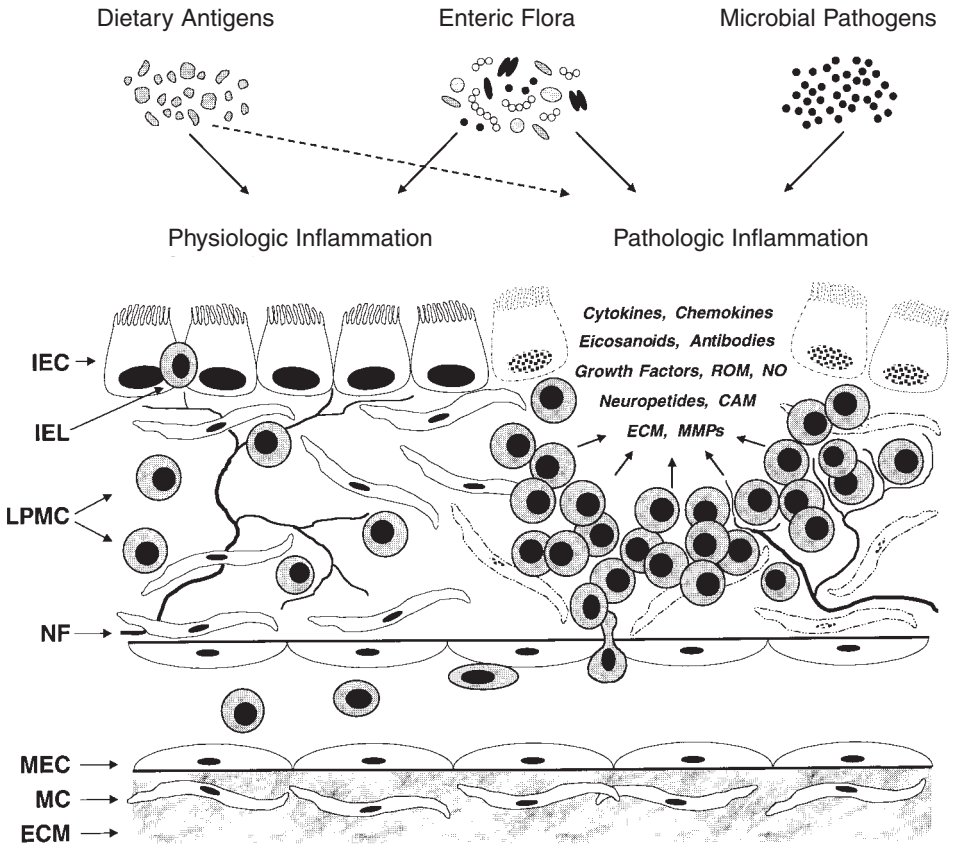

FIGURE 3-2 Key components of intestinal inflammation. In response to antigens derived from the diet and the normal enteric flora, a controlled physiologic inflammatory response is induced by the various cellular and soluble immune and nonimmune elements normally present in the intestinal mucosa. Depending on circumstances, microbial pathogens, the enteric flora, or selected dietary antigens induce a pathologic inflammatory response mediated by increased numbers of local immune and nonimmune cells and blood-derived immune cells and enhanced secretion of multiple soluble mediators. CAM = cell adhesion molecule; ECM = extracellular matrix; IEC = intestinal epithelial cells; IEL = intraepithelial lymphocytes; LPMC = lamina propria mononuclear cells; MC = mesenchymal cells; MEC = microvascular endothelial cells; MMPs = matrix metalloproteinases; NF = nerve fibers; NO = nitric oxide; ROM = reactive oxygen metabolites.

CHAPTER 4

MOTILITY

Frances Laura Connor, MBBS, FRACP
Carlo Di Lorenzo, MD

Gastrointestinal motility is the result of the muscular activity of the gut, responsible for mixing and propulsion of ingesta from mouth to anus. It consists of organized patterns of contractions and relaxations of enteric smooth muscles. Regional specialization gives rise to functions such as rapid propulsion, as in swallowing, vomiting and defecation, storage, mechanical grinding, controlled delivery, mixing, dispersion, and expulsion. Tonically contracted sphincters function to limit retrograde flow of ingesta. Unique biochemical and mechanical properties of smooth muscle myocytes reflect adaptation to these specialized functions.

Physiologic patterns of motility require the coordinated activity of enteric and autonomic nerves, interstitial cells of Cajal (ICC), and gastrointestinal smooth muscle cells and are modulated by different hormones. Contractions of gastrointestinal smooth muscle are initiated by specialized pacemaker cells. Propagation of contractions occurs as waves of membrane depolarization spread via gap junctions between adjacent smooth muscle cells. Regulatory neural input originates either from local reflexes within the enteric nervous system (ENS) or from the autonomic division of the central nervous system (CNS). Similarly, hormonal regulation occurs by both local paracrine and systemic endocrine mechanisms.

In this chapter, we review recent advances in knowledge about motility, including elucidation of the complex interplay between enteric neurons, smooth muscle, and the immune system and the role of the ICC as pacemaker cells of the gut. The many signaling molecules currently being explored for their physiologic roles and their potential as therapeutic targets are discussed. Further, the chapter outlines developing knowledge of learning and plasticity within the ENS. These processes are fundamental to common gastrointestinal conditions such as irritable bowel syndrome and to developmental and acquired lesions of the ENS. Although the control of motility is intimately linked with gastrointestinal sensation and the regulation of secretion, absorption, and blood supply, with changes in any one of these areas affecting all of the others, the current review focuses on motility. Familiarity with all of these new insights should facilitate understanding of gastrointestinal motility and of the many novel therapeutic strategies being developed to treat dysmotility syndromes.

This chapter discusses the structure and function of each of the neuromuscular components of motility and then outlines their integrated activity in normal and abnormal motility states. Detailed discussions of normal and disordered regional motility are given in Chapter 23, "Disorders of Deglutition"; Chapter 26, "Other Motor Disorders"; Chapter 31, "Motor Disorders including Pyloric Stenosis"; and Chapter 46, "Hypomotility Disorders." Diagnostic techniques (see Chapter 70, "Gastrointestinal Manometry: Methodology and Indications") and drug therapy for motility disorders (see Chapter 76.3, "Motility") are also covered elsewhere in this book in detail.

NEUROMUSCULAR COMPONENTS OF GASTROINTESTINAL MOTILITY

Gastrointestinal Smooth Muscle

The digestive tract from the posterior pharynx to the anus has two major muscular layers: the muscularis externa and the muscularis mucosae. In general, each layer consists of an inner circular and an outer longitudinal layer. Regional modifications of this schema include the addition of a third, oblique layer to the inner aspect of the muscularis externa in the stomach and the condensation of the outer longitudinal layer of the muscularis externa in the colon into three longitudinal bands, the tenia coli. Within each layer, smooth muscle fibers are oriented parallel to one another and communicate with one another via gap junctions, forming a functional syncytium, which transmits waves of depolarization and permits coordinated contraction.[1] Gastrointestinal myocytes are spindle-shaped cells 200 to 300 μm in length and 10 to 20 μm in diameter. Myocytes in neonates are up to 50% smaller. During contraction, gastrointestinal myocytes shorten up to 25%.

Within each smooth muscle cell, the contractile machinery consists of a complex of proteins: actin, myosin, and the regulatory proteins calmodulin and caldesmon. In contrast to the contractile proteins in cardiac and skeletal muscle, actin and myosin in smooth muscle are not arranged in regular arrays and cross-striations are not present. Instead, they are arranged in a net-like structure, with actin filaments anchored to dense bodies in the cytoplasm and on the cell membrane by α-actinin. Mechanical force

is transmitted at points where dense bodies on adjacent cells align, termed intermediate junctions.

Myogenic Control of Electrical and Mechanical Activity. Myogenic mechanisms control the rate and propagation of enteric contractions. Smooth muscle cells in the gastrointestinal tract exhibit spontaneous periodic depolarizations from a resting membrane potential of –50 to –60 mV. These depolarizations, also called electrical slow waves, govern both the maximum frequency and the direction of propagation of phasic contractions. The depolarizations are triggered by specialized pacemaker cells, the ICC. The morphology of these slow-wave depolarizations is similar to those in cardiac muscle (Figure 4-1), with a rapid upstroke, followed by a plateau phase owing to influx of extracellular calcium, and then a rapid repolarization.

Without additional stimulus, these spontaneous depolarizations increase membrane potential to only –40 to –50 mV and do not reach the excitation threshold necessary for cell contraction. If, however, an excitatory stimulus such as acetylcholine (ACh) from enteric nerves is present at the time of a spontaneous depolarization, the membrane depolarizes further. When it reaches the excitation threshold, depolarization spikes are superimposed on the plateau phase (see Figure 4-1). These spikes depolarize the membrane to –30 to 0 mV. Calcium influx is maximal at this voltage. Further calcium-induced calcium release occurs, with liberation of additional calcium from intracellular stores. This increase in intracellular free calcium initiates a cascade of signaling pathways, which cause myocyte contraction; this mechanism is termed electromechanical coupling. Thus, neural stimulation modulates but does not initiate smooth muscle depolarization. Neurotransmitters regulating smooth muscle contraction are listed in Table 4-1. The maximum frequency of phasic contractions at a given site is governed by the rate of slow-wave depolarization, but the actual frequency of contractions is determined by the number of slow waves that have concurrent excitatory stimulation and spike depolarizations.

Electromechanical Coupling. When the intracellular calcium concentration rises during depolarization, calcium binds to calmodulin, a regulatory protein, which has dual actions. Calcium-activated calmodulin binds to a second regulatory protein, caldesmon, which undergoes a conformational change to expose the myosin-binding domain of actin. The calcium-calmodulin complex also activates the enzyme myosin light-chain kinase. Phosphorylation of myosin light chains by this enzyme activates the adenosine triphosphate (ATP)-hydrolyzing region on the head portion of the myosin heavy chain, resulting in cross-bridge formation with actin. Cross-bridge formation and conformational change in the myosin head result in fiber shortening and muscle contraction, the so-called "myosin motor." When intracellular calcium subsequently falls during cell repolarization, myosin is dephosphorylated, and relaxation occurs. One phasic contraction occurs per slow wave when spike depolarizations are present.[4]

Conduction of Depolarization. Propagating contractions are generated when adjacent areas of gastrointestinal smooth muscle depolarize in sequence. Because adjacent myocytes are connected by gap junctions, waves of depolarization can spread rapidly through the tissue. Myocytes with faster cycles of depolarization and repolarization can entrain adjacent cells of lower intrinsic frequency, such that all myocytes at a given site contract almost simultaneously at the rhythm of the fastest cell. The cycling time for spontaneous membrane depolarizations increases along the intestine.[5] This allows for antegrade propagation of contractions along the

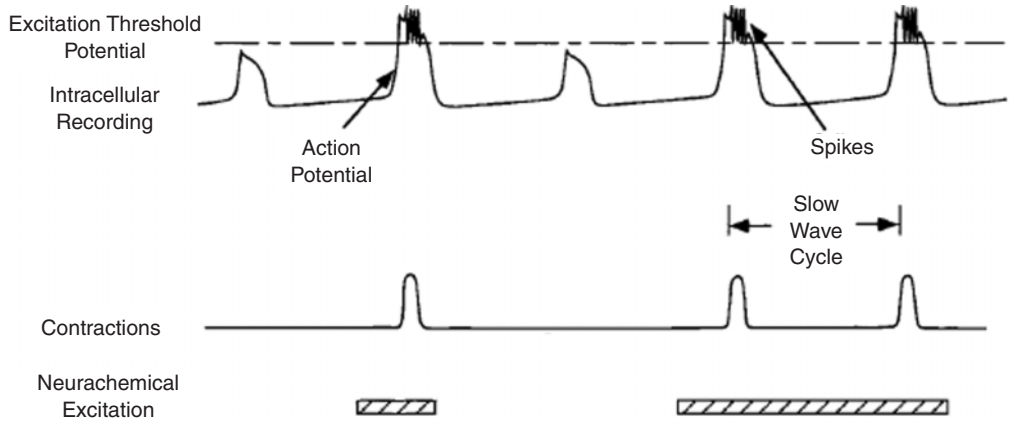

FIGURE 4-1 Illustration of regulation of rhythmic phasic contractions by slow waves and spikes. The resting potential of smooth muscle cells is negative with respect to the extracellular fluid potential. The depolarization during spontaneous slow waves does not exceed the excitation threshold; therefore, no contractions occur. The release of acetylcholine by neurochemical excitation depolarizes the plateau phase of the slow waves beyond the excitation threshold; spikes are superimposed on the plateau phase and the cell contracts. Motility and circulation. Bethesda (MD): The American Physiological Society; 1989. p. 817–63.

TABLE 4-1 PHYSIOLOGIC STIMULI AND INHIBITORS OF GASTROINTESTINAL SMOOTH MUSCLE CONTRACTION

AGENT	MECHANISM	INTRACELLULAR SECOND MESSENGER	RESULT
Stimuli			
Acetylcholine	Muscarinic receptors (GPCR)	Phospholipase C and IP_3 (M_3); ↓ cAMP (M_2)	↑ Ca
Substance P and neurokinin A	Neurokinin receptors (GPCR)	Phospholipase C and IP_3	↑ Ca
Mechanical stretch	Stretch-activated Ca channels[2]	None	↑ Ca
Inhibitors			
Nitric oxide	Diffusion into cells	↑ cGMP	↓ Ca
Vasoactive intestinal polypeptide (VIP)	VIP receptors (GPCR)	↑ cAMP	Hyperpolarizes membrane (activates K channels)
Adenosine triphosphate	P_2 purinergic receptors (GPCR)[3]	Phospholipase C and IP_3 and ↓ cAMP	Hyperpolarizes membrane (activates K channels)
Catecholamines	Beta receptor	↑ cAMP	↓ Ca

cAMP = cyclic adenosine monophosphate; cGMP = cyclic guanosine monophosphate; GPCR = G protein–coupled receptor; IP_3 = inositol 1,4,5-triphosphate.

gut as depolarization spreads from cells of faster intrinsic slow-wave rhythm to those with slower cycles. The maximum contraction frequency at any point is governed by the slow-wave frequency; in the duodenum, it is 11 to 12 per minute, decreasing to 7 to 8 per minute in the terminal ileum. The distance over which a contractile wave is propagated is determined by the length of gut receiving excitatory stimulation at the time of the contraction.

Specializations in Smooth Muscle for Continuous Contraction. In addition to the syncytial nature of gastrointestinal smooth muscle, other differences between skeletal and smooth muscle represent specializations that permit prolonged continuous contraction. Gastrointestinal sphincters have increased numbers of mitochondria and smooth endoplasmic reticulum compared with nonsphincter muscle, providing energy and calcium needed for prolonged contraction. The initiation of contraction in response to increased intracellular calcium is slower in smooth muscle myocytes, and the contraction duration is longer. Cycling of myosin cross-bridges, that is, the attachment of myosin to actin, release, and reattachment, occurs much more slowly in smooth muscle. Also, the fraction of time in which myosin is attached to actin is greater. As one molecule of ATP is required for each cross-bridge cycle, the longer cycle length considerably reduces the energy required to sustain contraction in smooth muscle cells. Once the smooth muscle contracts, full force can be maintained with little additional energy expenditure. This is called the "latch" mechanism. The latch mechanism permits the sphincter sustained contraction with little requirement for ongoing stimulation from nerves or hormones.

Gastrointestinal Myopathies. Disorders of smooth muscle that result in motility disturbance may be familial or sporadic, primary or secondary to a variety of conditions, such as autoimmune myositis, muscular dystrophies, Ehlers-Danlos syndrome, and connective tissue diseases, especially scleroderma. For a detailed account of visceral myopathies and neuropathies, the reader is referred to Chapter 46.3.

The effect of myopathy on gastrointestinal function is the reduction of the amplitude of contractions while preserving normal temporal and spatial coordination (Figure 4-2). Milder cases may present with abdominal pain, nausea, or constipation. More severe cases manifest as chronic intestinal pseudo-obstruction. Detection of concurrent extraintestinal involvement may assist in differential diagnosis. Urinary tract dysfunction, such as when megacystis is diagnosed, suggests hollow visceral myopathy; however, cases of hollow visceral disease may also be due to neural abnormalities.[6–9] Alternatively, the presence of progressive ptosis, external ophthalmoparesis, peripheral neuropathy, deafness, and lactic acidosis suggests mitochondrial neurogastrointestinal encephalomyopathy.[10,11] In this condition, a nuclear gene responsible for maintenance of mitochondrial deoxyribonucleic acid (DNA) is mutated, resulting in a mitochondrial disease phenotype that is inherited as an autosomal recessive trait.[12] Motility and pathologic features of both myopathy and neuropathy are present.

Enteric Neuromuscular Junction

Role of ICC in Enteric Neurotransmission. Previously, it was believed that enteric nerves controlled smooth muscle activity via diffusion of neurotransmitters released from varicosities located along nerves as they passed through the smooth muscle.[13,14] Neurotransmitters were

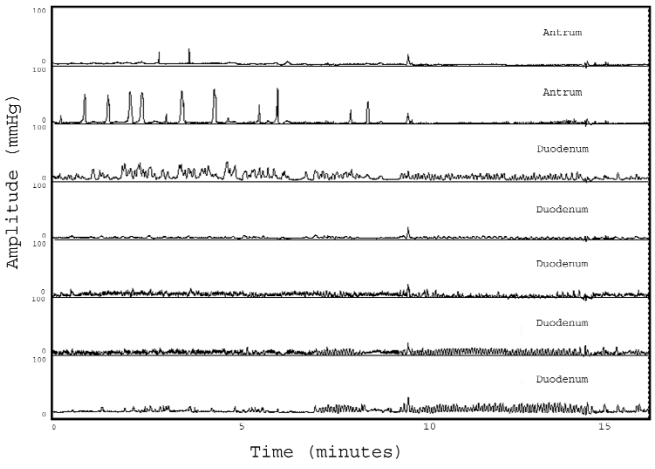

FIGURE 4-2 Fasting antroduodenal manometry in visceral myopathy: contraction amplitudes are reduced, but temporal organization is preserved.

believed to diffuse across relatively large spaces (up to hundreds of nanometers) to activate many nearby smooth muscles directly.[14] This was called volume theory or en passant innervation.[15] However, in recent years, it has become apparent that neural input is mediated by a specialized group of cells, the ICC,[16–20] which are the primary target of the ENS. ICC are critical components of the enteric neuromuscular junction (Figure 4-3), integrating and modulating neural input. Their presence is fundamental to normal motility.

Networks of ICC are intercalated between enteric nerve and smooth muscle cells.[16,17,21,22] Both excitatory[20,23,24] and inhibitory[18,19,24] enteric motoneurons are closely associated with ICC. Immunoelectron microscopy has revealed specialized synapse-like contacts between enteric neurons and ICC.[24] Far fewer contacts exist between enteric motoneurons and smooth muscle cells.[25]

Animals lacking ICC show severely impaired enteric neurotransmission, despite the presence of normal innervation and neurotransmitter release.[18–20] Such animals have a phenotype consistent with intestinal pseudoobstruction. The mediating effect of ICC at the enteric neuromuscular junction is also the likely reason for observed differences between responses to neural stimulation and to application of exogenous neurotransmitters such as ACh to enteric smooth muscle.[26] Current research aims to identify specific pharmacologic agents to modulate enteric neurotransmission at the level of the ICC.

ICC are modified smooth muscle cells expressing a receptor tyrosine kinase called kit,[27] which is important in the proliferation of ICC[28] and in their identification for scientific study. Apart from their critical role in enteric neurotransmission, ICC are now known to be the pacemakers of gastrointestinal smooth muscle.[27,29–31] Rhythmic depolarizations in ICC are the basis for enteric slow waves and phasic contractions throughout the gastrointestinal tract.[32–36] They are essential for coordinated peristaltic contractions.[32] In this sense, they resemble cardiac pacemaker (Purkinje) cells, which are also modified smooth muscle cells exhibiting spontaneous rhythmic depolarization. ICC depolarizations are the result of rhythmic inward currents that are unique to ICC.[34] Recent research demonstrates that high-conductance chloride channels are involved in spontaneous ICC depolarizations,[36] but other ion channels are also likely to contribute.

Although the ICC receive neural input via chemical neurotransmitters across synapse-like structures, they communicate with smooth muscle cells via gap junctions.[21,22,37] This permits rapid transmission of coordinated electrical activity and muscle contraction.

Diseases Associated with Abnormalities of ICC. Theoretically, ICC could be congenitally absent, displaced from their normal distributions, or damaged by infections, metabolic derangements (such as hyperglycemia or uremia), toxins, or autoimmune attack. Abnormal ICC networks have been identified in chronic constipation,[38] intestinal pseudoobstruction,[39–42] hypertrophic pyloric stenosis,[43] inflammatory bowel disease,[44] dysmotility associated with diabetes,[45,46] and paraneoplastic syndrome.[47] However, whether

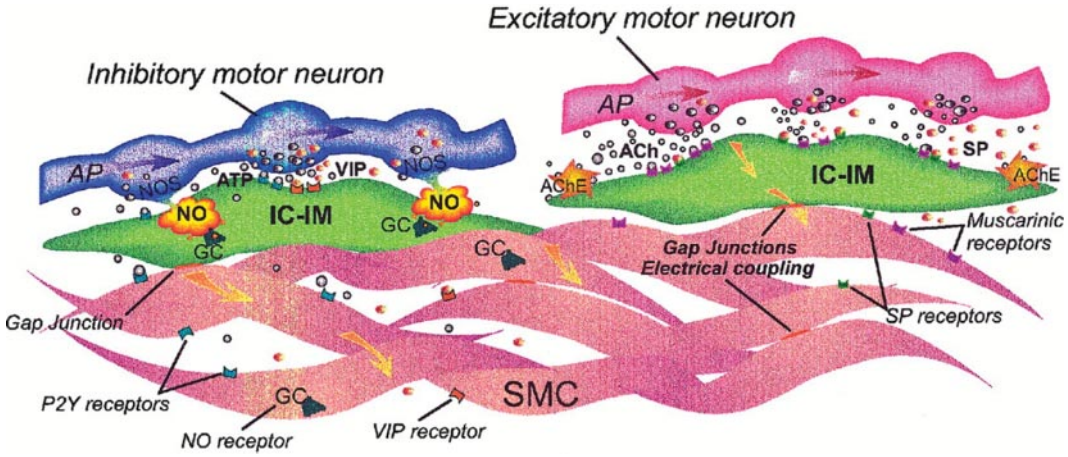

FIGURE 4-3 Diagram of the enteric neuromuscular junction. Neuromuscular junctions in gastrointestinal muscles are composed of enteric nerve fibers, interstitial cells of Cajal (ICC:IC-IM = intermuscular ICC in esophagus, stomach, colon, and sphincters; IC-DMP = deep muscular plexus ICC in the small intestine), and smooth muscle cells (SMC). When action potentials (AP) invade varicosities, stored transmitters are released and enzymes responsible for de novo transmitters are activated (ie, nitric oxide [NO] is made by nitric oxide synthase [NOS]). The close apposition between varicose nerve terminals and ICC facilitates rapid diffusion to ICC receptors. ICC are electrically coupled to smooth muscle via gap junctions, and electrical responses elicited in ICC are conveyed to smooth muscle cells via electrical conduction. ICC express receptors for major neurotransmitters: inhibitory transmitters NO, soluble guanylyl cyclase (GC), vasoactive intestinal polypeptide (VIP), and adenosine triphosphate (ATP) and excitatory transmitters acetylcholine (ACh) and substance P (SP). Extrajunctional receptors are also expressed by smooth muscle cells, but these may or may not be connected to the same cellular effectors as the receptors in ICC. Smooth muscle receptors may be "spare receptors" under most circumstances and may not receive stimulation from neurotransmitters released from neurons because diffusion distances are too great or metabolic enzymes (eg, acetylcholine esterase [AChE]) break down transmitters before effective concentrations can diffuse to extrajunctional receptor sites. Adapted from Ward SM, Sanders KM. Interstitial cells of Cajal: primary targets of enteric motor innervation. Anat Rec 2001;261:125–35.

the loss of ICC function is causative in the pathophysiology or a secondary phenomenon is unknown.[48] Delayed maturation of ICC may be a mechanism for transient dysmotility in infants.[39,43,49] Because of their role in neuromuscular transmission, the absence of ICC might result in a motility pattern similar to a neuropathic process.[42]

Nerves

Autonomic Innervation of the Gastrointestinal Tract. The gut has a rich and complex intrinsic nervous system, the ENS, which controls all gastrointestinal activities. However, the activities of the ENS are modulated by input from the CNS (Figure 4-4). Extrinsic innervation comprises parasympathetic and sympathetic neurons. Parasympathetic fibers from the vagus control motility, secretion, and absorption from the esophagus to the mid-transverse colon. Sacral parasympathetic fibers control distal colonic and rectal functions. Sympathetic nerve fibers from thoracic segments provide secretomotoneurons containing transmitters such as vasoactive inhibitory polypeptide (VIP), presynaptic cholinergic nerve endings, and nerves to submucosal blood vessels and sphincters.[50]

Enteric Nervous System. Congenital or acquired abnormalities of the ENS underlie many gastrointestinal diseases. Recent research has exponentially increased knowledge about this complex network of intrinsic neurons. Intramural enteric nerves are organized into two major plexuses of ganglia linked by bundles of axons: the myenteric (Auerbach) and submucous (Meissner) plexuses. For many years, it was believed that these ganglion cells were simply the postganglionic cells of the parasympathetic nervous system, acting as simple relay stations for signals from the CNS. However, recently, it has become clear that most ENS neurons receive no direct innervation from the CNS. The ENS contains complete neural circuits, which are capable of controlling many gastrointestinal functions independently of the CNS.[51–53] Programs for complex gastrointestinal motility patterns such as the interdigestive migrating motor complex (MMC) of the small intestine reside entirely in the ENS. This is evident after complete extrinsic denervation, with persistence of the MMC even after small bowel transplant.[54] Like the CNS, the ENS contains neurons, interneurons, and glial cells. There are more neurons in the ENS than in the spinal cord. All major neurotransmitters present in the CNS are also present in the ENS (Table 4-2). These facts have led to the ENS being termed "the little brain in the gut."

The ENS is composed of sensory and motoneurons as well as interneurons. The complex network of specialized enteric neurons is illustrated in Figure 4-5 and is reviewed in detail by Furness.[53] All gastrointestinal motor and secretory activity is controlled by the ENS; efferent neurons supply smooth muscle cells, mucosal secretory cells, neuroendocrine cells, blood vessels, and the immune and inflammatory cells involved in mucosal immunologic, allergic, and inflammatory responses.[55] Local reflexes control peristalsis,[56] fluid and electrolyte secretion[57,58] and absorption,[59,60] and mucosal blood flow.[61,62]

Origins of ENS Cells. ENS neurons arise from neural crest cells migrating from the vagal and sacral segments of the fetal CNS. A subset of foregut neurons arise from truncal somites.[63] Vagal cells predominate,[64] populating the entire length of the gut, with sacral neural crest cells comprising less than 20% of neurons in the distal bowel.[65] Migration of vagally derived neural crest cells occurs craniocaudally, with cells appearing in the rectum at 12 weeks gestation.[66] The myenteric plexus forms first, and then the submucous plexus is formed by myenteric neuroblasts migrating inward across the circular muscle layer.[66] Interruption of normal migration leads to distal aganglionosis

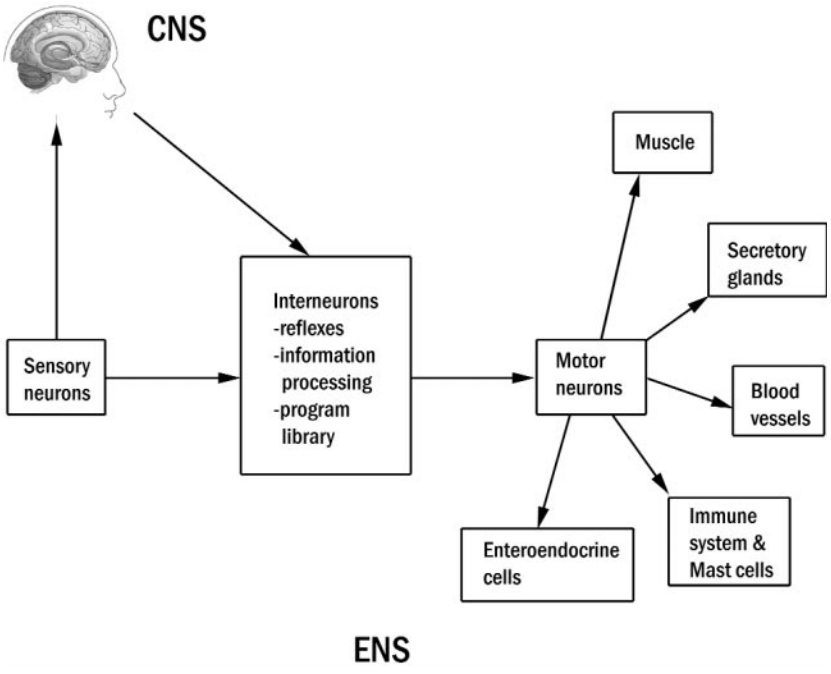

FIGURE 4-4 Relationship between the central nervous system (CNS) and the enteric nervous system (ENS) in control of gastrointestinal motility.

(ie, Hirschsprung disease). Mutations in several genes that control neural crest cell survival, migration, proliferation, differentiation, and ganglion formation have been described in patients with Hirschsprung disease. These include *RET*,[67] the endothelin B receptor gene,[68] glial cell line–derived neurotrophic factor,[69–71] and endothelin 3.[72] Interactions between susceptibility genes may explain the complex multigenic inheritance observed in this condition.[73,74] Genetic abnormalities in Hirschsprung disease are reviewed in Chapter 46.3, "Hirschsprung Disease."

Transmission in the ENS. Within the ENS, synaptic transmission occurs by the same mechanisms as elsewhere in the nervous system. Depolarization of the presynaptic cell results in calcium-mediated exocytosis of vesicles of stored neurotransmitters into the synaptic cleft. Neurotransmitters diffuse across the cleft to bind to receptors on the postsynaptic cell membrane. The resulting cellular response is mediated by two broad types of receptors. In ionotropic receptors, the receptor itself is an ion pore. Binding of neurotransmitter to ionotrophic receptors causes rapid changes in membrane potential by altering the permeability of the ion channel. For example, nicotinic ACh receptors are cation channels that become permeable to sodium and calcium ions when activated by ligand binding. In contrast, metabotropic receptors use intracellular second messengers, such as cyclic adenosine monophosphate, to mediate their effects. Many of these receptors belong to the G protein class of membrane receptors.[75] Cellular responses to metabotropic receptor stimulation are usually slower than those elicited by excitation of ionotrophic receptors. Examples of neurotransmitters that operate via metabotrophic receptors are ACh at muscarinic receptors, VIP, and most other neuropeptides. Neurotransmitters also stimulate presynaptic receptors. This occurs both on the cell of origin and on other adjacent neurons to produce feedback effects in the presynaptic cell and to modify the activities of nearby neurons. Eventually, the neurotransmitters are inactivated by enzymatic degradation or reuptake.

Neurotransmitters in the ENS. Currently, approximately 30 putative neurotransmitters have been recognized in the gastrointestinal tract (see Table 4-2). Excitatory motoneu-

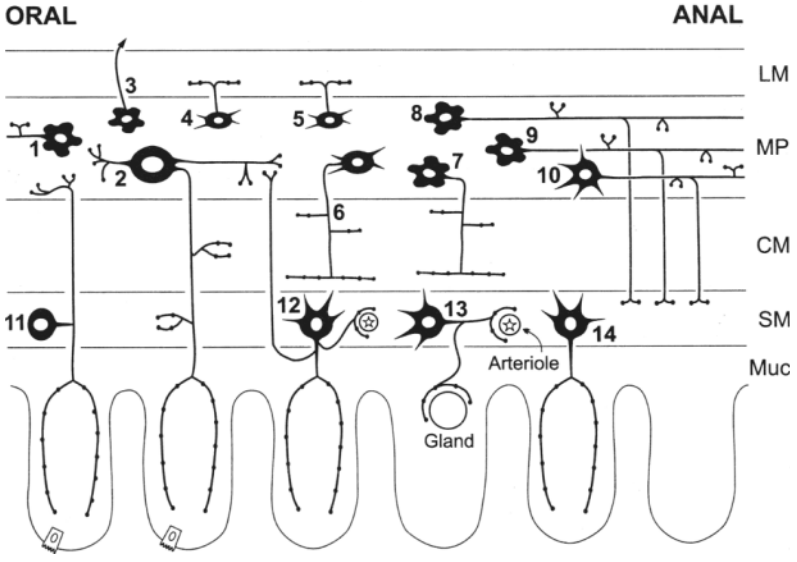

FIGURE 4-5 The types of neurons in the small intestine of the guinea pig, all of which have been defined by their functions, cell body morphologies, chemistries, and projections. 1 = ascending interneuron; 2 = myenteric intrinsic primary afferent neuron; 3 = intestinofugal neuron; 4 = excitatory longitudinal muscle motoneuron; 5 = inhibitory longitudinal muscle motoneuron; 6 = excitatory circular muscle motoneuron; 7 = inhibitory circular muscle motoneuron; 8 = descending interneuron (local reflex); 9 = descending interneuron (secretomotor reflex); 10 = descending interneuron (migrating myoelectric complex); 11 = submucosal intrinsic primary afferent neuron; 12 = noncholinergic secretomotor/vasodilator neuron; 13 = cholinergic secretomotor/vasodilator neuron; 14 = cholinergic secretomotor (nonvasodilator) neuron. rons mostly release ACh, which is the predominant excitatory neurotransmitter throughout the gut. The constipating effect of anticholinergic medications demonstrates the importance of basal ACh stimulation for normal gastrointestinal function. Tachykinins such as substance P provide additional motor stimulation and are important in secretory and sensory function. Mast cells and enteric nerves participate in the regulation of substance P–induced intestinal secretion.[76] Enteric neurons often contain several neurotransmitters. Motoneurons are immunoreactive for both ACh and tachykinins. Similarly, inhibitory neurons may contain several inhibitory transmitters, including nitric oxide (NO), ATP, VIP, and pituitary adenylyl cyclase–activating peptide (PACAP).[53] Other ENS neurotransmitters include 5-hydroxytryptamine (5-HT)[77] and histamine, both of which have complex effects at various receptors. The following paragraphs will focus on recent developments in the understanding of some key enteric neurotransmitters: tachykinins, VIP, PACAP, NO, and 5-HT.

Tachykinins. Substance P and other tachykinins (neurokinins A and B) are important excitatory neurotransmitters in the ENS. ICC and smooth muscle cells have different neurokinin receptors, NK1 and NK2, respectively.[75] Although there is some cross-reactivity of different neurokinins for different receptors, the differential distribution of NK1 and NK2 likely confers differential responses to neurokinin released from excitatory motoneurons. In addition to their motility effects, tachykinins are important in the control of gastrointestinal secretion and sensation.

Nitric Oxide. NO is the major inhibitory neurotransmitter mediating neurogenic smooth muscle relaxation in the gastrointestinal tract. Nitrergic neurons make up 34% of all neurons in the myenteric plexus.[78] Deficiencies of nitrergic neurons have been associated with achalasia of the cardia,[79] pyloric stenosis,[80] Hirschsprung disease,[81] and internal anal sphincter achalasia.[82] Histochemistry for NO synthase activity has been used in the diagnosis of Hirschsprung disease.[83] It has recently been advocated as a simple, reliable, and rapid means for intraoperative determination of the extent of aganglionosis.[84,85] The inhibitory action of NO has been exploited clinically with the use of topical nitrates to relax the anal sphincter in conditions such as anal fissure.

VIP *and* PACAP. VIP- and PACAP-containing neurons are found in both the myenteric and submucosal plexuses. Although VIP was previously considered an endocrine hormone, it is now considered a neurocrine because all circulating VIP appears to be derived from neurons. VIP and PACAP are involved in the descending inhibitory reflex of peristalsis and in the regulation of secretion.

5-HT. Ninety-five percent of the body's 5-HT (serotonin) is present in the wall of the gut. It is present in enteric neurons, where it acts as a neurotransmitter, and in enterochromaffin cells, where paracrine release of 5-HT mediates sensory transduction. 5-HT elicits a wide range of responses throughout the gut owing to the presence of many different receptor types with varying mechanisms of action. In fact, the multiple different 5-HT receptor types make this the largest of all known neurotransmitter families. In general, 5-HT_1 receptors relax gastrointestinal smooth muscle, whereas 5-HT_2, 5-HT_3, and 5-HT_4 receptors are involved in contractile responses.[86]

As a neurotransmitter, 5-HT is synthesized, stored, and released and undergoes reuptake in enteric nerves. Reuptake is by the same mechanisms as in serotonergic neurons in the CNS and is antagonized similarly by antidepressant medications such as tricyclic antidepressants and selective serotonin reuptake inhibitors.[77] Slow excitatory postsynaptic potentials that depolarize myenteric neurons and increase their excitability are mediated by the 5-HT_{1P} receptor. Fast excitatory postsynaptic potentials can be mediated by 5-HT_3 receptors, although most fast excitatory postsynaptic potentials are due to cholinergic or purinergic mechanisms. Other receptor types on neurons include 5-HT_4, which facilitates cholinergic fast neurotransmission via presynaptic enhancement of ACh release. By contrast, stimulation of 5-HT_{1A} receptors inhibits some classes of neurons.

Enterochromaffin cells have important sensory functions (see below), releasing 5-HT to activate intrinsic and extrinsic primary afferent neurons. 5-HT then initiates a variety of responses, including peristalsis and secretion, mediated by intrinsic nerves, and nausea and vomiting via extrinsic afferents. Stimulation of intrinsic sensory nerves in the submucosal plexus occurs via 5-HT_{1P} and 5-HT_4 receptors, whereas 5-HT_3 is the predominant receptor type on extrinsic afferent nerves.

The presence of different receptor types for 5-HT on intrinsic and extrinsic afferent nerves allows selective pharmacologic manipulation, and this is currently the subject of intensive research. For instance, selective blockade of 5-HT_3 receptors on extrinsic afferent nerves by drugs such as ondansetron provides effective relief of nausea without interfering with intrinsic enteric reflexes. Drugs that stimulate or antagonize 5-HT_3 and 5-HT_4 receptors are currently being evaluated in the treatment of dysmotility and visceral hypersensitivity (see Chapter 76.3).

Sensation in the ENS. ENS control of gastrointestinal motility in response to the chemical and physical nature of the luminal contents relies on sensory input from chemical and mechanosensors within the gut wall. ENS sensation has recently been reviewed in detail.[87]

Three types of detectors are present: neurons, enteroendocrine cells, and immune cells. Sensory neurons include varieties with cell bodies and connections entirely in the gut wall, called intrinsic primary afferent neurons (IPANs), those with cell bodies in the ENS, and projections outside the gut, called intestinofugal neurons, and autonomic neurons with bodies in the brain or dorsal root ganglia.

IPANs are sensory nerves located in the myenteric and submucosal plexuses. Some project to the gut mucosa (see Figure 4-5) and respond to chemical stimuli, such as acid, alkali, and short-chain fatty acids, or to small movements of intestinal villi.[87] Projections from submucosal IPANs transmit information to the myenteric plexus to initiate local reflexes.

Mechanosensors, or stretch receptors, in the wall of the gut include three types of IPANs in the myenteric plexus,[88] as well as enterochromaffin cells (see below). There are

both slow-adapting and fast-adapting mechanosensitive neurons. Fast-adapting units signal the onset of a mechanical stimulus with a brief discharge and then cease firing even during prolonged stimulation. The slow-adapting neurons continue to fire for the duration of the mechanical stimulus, with a discharge frequency proportional to the intensity of the stimulus.[89] A third class of mechanosensors responds to mechanical stimulation with a prolonged burst of spike discharges that continues for a period after the cessation of the original stimulus.

Reflexes such as enteroenteric inhibitory reflexes are mediated by intestinofugal neurons and pass through the prevertebral sympathetic ganglia. CNS sensory pathways are involved in (1) control of organs distant to the site of a sensory stimulus (such as receptive gastric relaxation in response to fat in the duodenum), (2) integration of inputs from multiple sites and/or multiple different sensory modalities (such as the perception of satiety after a meal), and (3) coordinated control of several organs (such as swallowing and gastric receptive relaxation).

In addition to sensory neurons, mast cells and enterochromaffin cells perform sensory functions. Both cell types relay sensory information by paracrine means, secreting histamine and 5-HT, respectively. Mast cells provide the gut with specific immune memory for potentially damaging antigens. When mast cells in the epithelium encounter an antigen to which they have previously been sensitized, degranulation of histamine, prostaglandins, and leukotrienes occurs. Histamine signals to the ENS to increase secretion and to initiate motor activity in order to expel the noxious substance.[90–93]

Enterochromaffin cells function as pressure sensors, initiating the peristaltic reflex in response to pressure on the mucosa by food after a meal. In response to shear forces on the mucosa, enterochromaffin cells release 5-HT. 5-HT then stimulates intrinsic sensory nerves in the submucosal plexus, which initiate the peristaltic reflex by communication with neurons in the myenteric plexus.[77,94] Stimulation of peristalsis can also occur via mechanical stretch of the muscle wall by stimulating the mechanoreceptors in the myenteric plexus. This mechanism does not involve 5-HT.

Reflexes Mediated by the ENS. Local reflexes mediated entirely by the ENS include peristalsis and the rectoanal inhibitory reflex (RAIR). Peristalsis is defined as a migrating contraction proximal to an intraluminal bolus, with relaxation distal to the bolus, that causes rapid propulsion.[95] Giant migrating contractions such as swallowing and colonic high-amplitude propagating contractions (HAPCs) are typical peristaltic contractions. Orad stimulation is mediated by Ach and substance P. Receptive relaxation of the distal segment is mediated by descending interneurons in the ENS (see Figure 4-5). These activate inhibitory postsynaptic neurons to relax basal tone and inhibit phasic contractions using VIP and NO as the inhibitory transmitters. This descending inhibition is clearly evident at the lower esophageal sphincter, which relaxes at the onset of esophageal peristalsis (Figure 4-6). The antegrade propagation of peristaltic contraction is due to polarity of the neural circuits in the myenteric plexus. Thus, an intestinal segment that is isolated, reversed, and reanastomosed remains persistently antiperistaltic. The rhythmicity of peristaltic contractions in the gut is regulated by the underlying electrical slow-wave activity originating in the ICC.[96]

The RAIR consists of reflex relaxation of the internal anal sphincter in response to rectal distention by stool, balloon, or air during manometry testing. It is mediated by intramural nerves descending from the rectum to the internal anal sphincter, with NO being the putative inhibitory transmitter.[97–101] This reflex is absent in Hirschsprung disease, reflecting the absence of intramural ganglion cells of the ENS in the affected tissue.

Plasticity and Adaptation in ENS. Like the CNS, the ENS has considerable adaptive ability, enabling it to maintain gastrointestinal function in spite of injury and disease. There is also evidence that ENS function changes in response to variations in input. These changes can persist after discontinuation of the stimulus, a kind of enteric memory effect that may underlie the gastrointestinal hypersensitivity and hyperreflexia found in irritable bowel syndrome.[102] Remodeling of the ENS occurs throughout life, being most marked in the embryo, fetus, and young infant. All of these processes are examples of the phenomenon called neuronal plasticity.[103,104]

Mechanisms of ENS neuronal regeneration after injury are currently the subject of intense research activity, both for their potential relevance to the treatment of gastrointestinal disease and for their possible contribution to the understanding of disease in the CNS. Polypeptide nerve growth factors, called neurotrophins, are involved in recovery from injury, promoting differentiation and survival of neurons. They may also play roles in modulating the expression of neurotransmitters and in adaptive changes in response to inflammation.[104] Neurotrophins include nerve growth factor, brain-derived neurotrophic factor, and neurotrophin 3. They are released from neurons, glial cells, and fibroblasts. Pharmacologic agents may increase the potency of endogenous neurotrophins. In par-

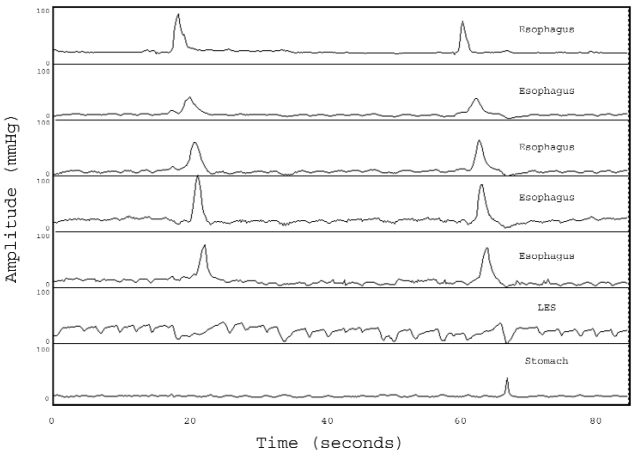

FIGURE 4-6 Esophageal manometry showing normal peristalsis during swallowing. LES = lower esophageal sphincter.

ticular, the recent finding that drugs such as cyclosporine and tacrolimus stimulate the regrowth of injured neurons has led to the development of experimental agents that stimulate neuronal repair without causing immunosuppression.[105] The concept that immunosuppressive medications may serendipitously assist neural recovery after small bowel transplant is tantalizing.

ENS and Inflammation. Inflammation alters ENS responses to mechanical and chemical stimulation.[106,107] There is extensive communication between enteric nerves and immune cells. Mast cells[108] and Peyer patches[109] receive direct innervation, and some enteric neurons release inflammatory mediators and cytokines. In turn, histamine and other substances released from mast cells alter neural function. Inflammation induces changes in neuron phenotypes, electrophysiology, neurotransmitter release, and receptor expression.[106] Substances such as nerve growth factor, released during inflammation, may alter the morphology of local intrinsic and extrinsic neurons, with resulting changes in function. Inflammation also damages ICC, impairing electrical slow-wave activity in smooth muscle.[110] The role of inflammation in the initiation of gastrointestinal hypersensitivity and motility disturbances in irritable bowel syndrome has recently been the focus of intense research activity.

ENS and Allergy. Acute allergic reactions to food proteins cause gastric and intestinal dysmotility in experimental animals.[111–115] Mast cell degranulation appears to activate ENS and extrinsic neural pathways via prostaglandins and serotonin rather than histamine release.[116,117] Similarly, gastric dysmotility has been demonstrated in children with cow's milk protein intolerance on exposure to the offending antigen.[118] Electrogastrography and manometry have even been proposed as objective tests for clarification of gastrointestinal symptoms in food allergy.[118, 119]

Response to Injury. Propagated peristaltic contractions may be interrupted by gut transection and anastomosis.[120,121] Rhythmic contractions appear distal to the anastomosis at the rate of the intrinsic slow-wave cycle for that location.[122,123] Local regeneration of ENS continuity is associated with return of peristalsis across the anastomosis in a proportion of cases.[122,124] Propagation of giant migrating contractions has even been reported from native to allograft intestine after small bowel transplant,[54] but the possibility that propagation in the distal segment may have been due to distention of the allograft by the received bolus, rather than neural continuity, must be considered. In general, transplanted bowel demonstrates persistent MMC activity asynchronous with the activities of the native gut.[54]

Diseases of ENS. In addition to abnormalities of neural crest cell migration discussed above, ENS pathology may be underlying a number of gastrointestinal diseases. Like visceral myopathies, visceral neuropathies may be congenital or acquired, familial or sporadic. A detailed discussion of visceral neuropathy is provided in Chapter 46.4, "Chronic Intestinal Pseudo-obstruction." From a functional perspective, neuropathy manifests as disordered, uncoordinated gastrointestinal motility (Figure 4-7). Unless the gut is abnormally dilated, the amplitude of contractions is normal. Pain may be a prominent symptom, especially in the presence of abnormally increased contractile activity. Because abnormal motility may affect gut development, a history of malrotation is frequently encountered in both myopathy and neuropathy and suggests antenatal disease onset.

The ENS is also a target for bacterial toxins. Enterotoxins from *Vibrio cholerae*, *Clostridium difficile*, and *Escherichia coli* are believed to activate local intrinsic neurons to produce motor and secretory responses by mechanisms involving substance P, mast cells, and NO.[106,125]

HORMONAL REGULATION OF GASTROINTESTINAL MOTILITY

The gut is the largest endocrine organ in the body. Enteroendocrine cells interspersed with mucosal epithelial cells throughout the gastrointestinal tract respond to changes in luminal contents by secreting over 30 different hormones. These act at endocrine, paracrine, neurocrine, and autocrine levels to complement myogenic, neuronal, and ICC mechanisms controlling gastrointestinal motility. There is close coordination between neural and hormonal mechanisms, and, in some instances, the same transmitters are released from both enteric neurons and endocrine cells. Enteroendocrine cells receive ENS innervation; conversely, the hormones secreted from endocrine cells modify neuronal function.

Microvilli on the luminal aspect of enteroendocrine cells allow them to "taste" the intestinal contents.[87] Specific responses to luminal stimuli include the release of cholecystokinin (CCK) from duodenal enteroendocrine cells in response to fat and protein from a meal. CCK acts locally by paracrine stimulation of vagal afferents, causing reflex delay of gastric emptying and contributing to the conscious perception of satiety. Systemically active CCK stimulates pancreatic secretion of digestive enzymes and acts on neurons in the gallbladder to trigger contraction and delivery of bile

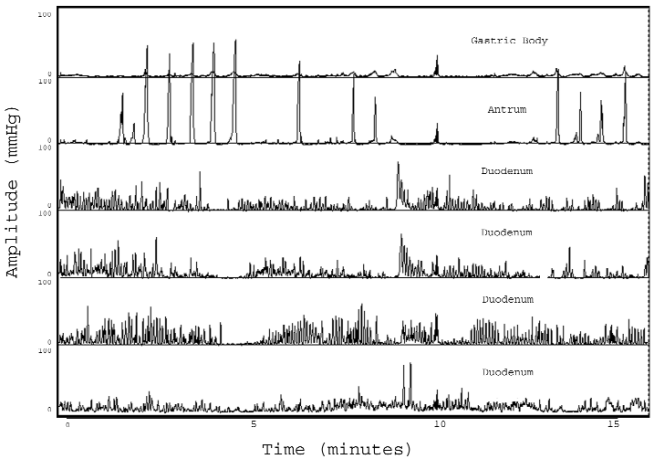

FIGURE 4-7 Fasting antroduodenal manometry in visceral neuropathy: contraction amplitudes are normal, but motility is disorganized, and normal patterns are absent.

to the duodenum. During fasting, another group of duodenal endocrine cells releases motilin, the physiologic stimulus for the interdigestive MMC.

NORMAL AND DISORDERED MOTILITY

Gastrointestinal contractions can be broadly divided into three basic types: phasic, tonic, and ultrapropulsive contractions. Ultrapropulsive contractions consist of giant migrating contractions in the antegrade direction and retrograde giant contractions in the orad direction. These peristaltic contractions move the luminal contents rapidly over relatively large distances. Giant migrating contractions include the esophageal phase of swallowing (Figure 4-6) and the HAPCs responsible for mass movements in the colon (see Figure 4-8). Retrograde giant contractions in the small intestine move the luminal contents back into the stomach prior to vomiting.

Phasic contractions are relatively brief and may be propagated, as in phase III of the MMC in the small intestine (Figure 4-9), or nonpropagated, such as most contractions observed in the small intestine after meals (Figure 4-10). Nonpropagated phasic contractions are also called segmenting contractions and serve to mix the intestinal contents, allowing maximum exposure of the mucosa to luminal contents.

Tonic contractions are prolonged contractions lasting minutes to hours. This type of contraction is typical of gastrointestinal sphincters (see Figure 4-6). The gastric fundus and colon also exhibit tonic contractions, whose function may be to reduce the luminal diameter, increasing the propulsive effects of superimposed phasic contractions, and to promote gradual transfer of luminal contents from areas of higher to lower intraluminal pressure. Tonic contractions are not associated with electrical slow-wave activity. They are sometimes initiated by continuous repetitive spike depolarizations, with greater spike frequency increasing the intensity of contraction. At other times, they are due to continuous partial depolarization or continuous calcium entry into cells.

ESOPHAGUS

The esophagus functions as a conduit, transferring food from the oral cavity to the stomach. Motility in the body of the esophagus is therefore characterized by high-amplitude peristaltic contractions (see Figure 4-6). Swallowing induces primary peristalsis, which originates at the pharynx. Secondary peristalsis, originating in the body of the esophagus, is stimulated by wall distention, such as by the presence of gastroesophageal reflux in the esophageal lumen. Its function is to return refluxed material to the stomach.

In contrast, the lower esophageal sphincter is tonically contracted to prevent the return of gastric contents. Vagally mediated transient relaxations occur during swallowing, vomiting, and burping to allow the passage of fluids. At other times, transient relaxations occur spontaneously, and these have been found to be the predominant mechanism for gastroesophageal reflux in both children[126] and adults.[127,128] Motility abnormalities of the esophagus may be primary or secondary and are detailed in Chapter 26. They may result in dysphagia, food bolus impaction, chest pain, or recurrent aspiration pneumonia.

STOMACH

This section focuses on postprandial gastric motility. Fasting motility is discussed in conjunction with small intestinal motility. The stomach has two functionally discrete regions. The fundus acts as a receptacle, relaxing to receive food, storing the meal, and controlling delivery of material to the antrum. With each swallow, there is receptive relaxation of the fundus, which is mediated by vagal efferents. Subsequently, the fundus exhibits tonic contractions, which transfer the luminal contents to the antrum. Strong propagated antral contractions then grind the solid components of the meal against the pylorus, which closes as each contractile wave reaches it. Consequently, only particles of less than 1 mm in size enter the small bolus of chyme delivered to the duodenum with each wave of contraction. This process is known as gastric sieving (Figure 4-11). The rate of delivery of chyme to the duodenum is

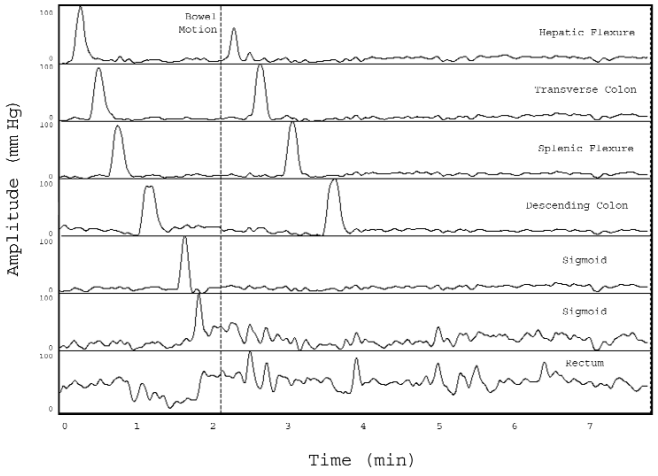

FIGURE 4-8 Colonic manometry showing high-amplitude propagated contractions (HAPCs).

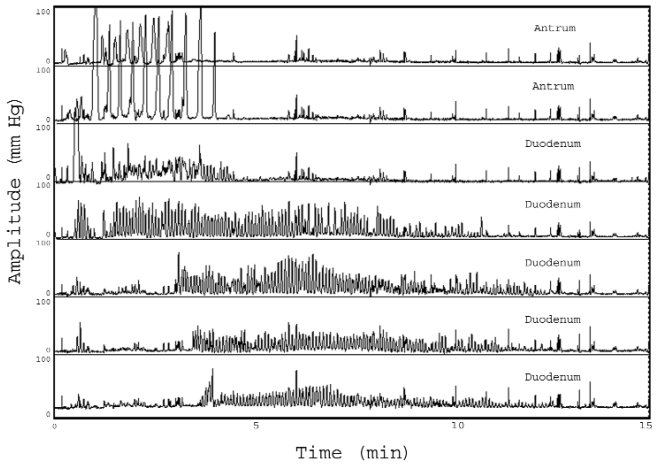

FIGURE 4-9 Antroduodenal manometry showing normal fasting motility: the migrating motor complex (MMC).

regulated both by occlusion of the antral lumen by advancing high-amplitude contractions and by the closure of the pylorus itself.

Whereas liquid meals tend to flow from the fundus to the antrum and begin to enter the duodenum without delay, gastric emptying of solid meals is delayed until food has been reduced to small particles. This accounts for the lag phase seen on gastric emptying tests performed using solid meals and explains why solids are superior for testing the "fitness" of the gastric antrum.

The physiology and pathophysiology of gastric motility are detailed in Chapter 31. Of note, the fundus lacks electrical slow waves and is electrically "silent," whereas the antrum exhibits regular contractions at three cycles per minute originating from the "pacemaker" region on the greater curvature.

Motility abnormalities in the stomach may be the result of damage to or dysfunction of muscle, nerve, or ICCs. Clinically, gastric dysmotility may result in sensations of fullness, early satiety, pain, nausea, and vomiting. Impaired fundic relaxation is a prominent feature of neuropathy states such as diabetic gastropathy and after vagotomy. Absence of antral contraction in response to a meal is typical in postviral gastroparesis but also occurs in idiopathic gastroparesis.

Small Intestine

The small intestine displays distinctly different patterns of motility in the fasting and postprandial states. Programs for both patterns reside in the ENS, and switching between the two states is regulated by neural and hormonal mechanisms. During prolonged fasting, such as overnight, motility of the stomach and small bowel consists of a stereotyped pattern known as the interdigestive MMC, whose function is to sweep the intestine clear of undigested food, sloughed enterocytes, and bacteria.[129] The MMC consists of three separate phases, illustrated in Figure 4-9, which occur in continuous cycles during fasting but are interrupted within minutes after the ingestion of a meal. There is a wide intra- and interindividual variation in the duration of the difference phases of the

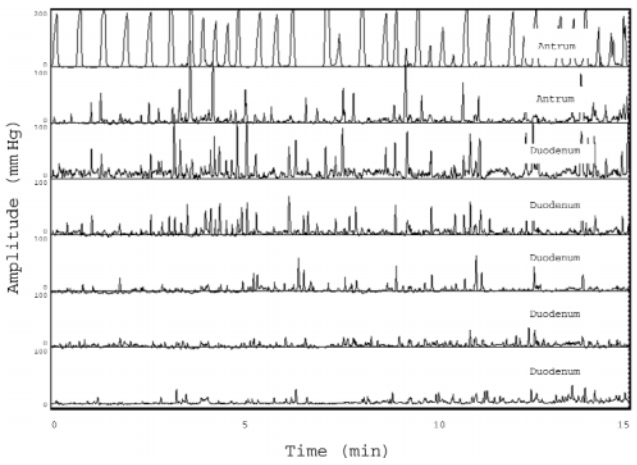

FIGURE 4-10 Antroduodenal manometry showing normal postprandial motility: apparently random contractions of varying amplitude and frequency.

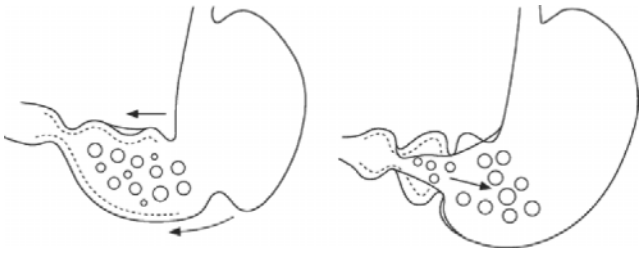

FIGURE 4-11 A diagram to show the nature of antral retropulsion or sieving. At first, particles of many sizes flow toward the pylorus under the influence of the shallow contractions of the body of the stomach. As these deepen and progress into the antrum, the narrowing lumen allows only smaller particles to proceed, whereas the larger ones return toward the gastric body. MMCs. Phase I typically lasts 10 to 15 minutes. Phase II lasts 50 to 80 minutes, whereas phase III lasts 3 to 5 minutes. Phase I always follows phase III. During phase I, there is almost complete motor quiescence. Although electrical slow waves are continually present in the smooth muscle, the lack of neural and hormonal excitation prevents contractions from occurring. Following phase I, there is a period of irregular contractions of variable frequency and amplitude. Although a proportion of contractions are propagating, the majority are nonpropagating segmenting contractions. This is phase II. At night and after vagotomy, there is a paucity of phase II activity. Phase III consists of migrating groups of regular propagating contractions occurring at the maximum amplitude and frequency for the site. Groups of phase III contractions normally originate either in the gastric antrum (70%) or duodenum (30%), and the pattern migrates distally along the intestine at a rate of 3 to 10 cm per minute to the ileum. The regular occurrence of the MMC is linked to cyclic secretion of motilin.

Within minutes of ingestion of a meal, the MMC is interrupted, and a pattern of seemingly random contractions results. This pattern of irregular contractions of varying amplitude, frequency, and propagation resembles phase II of the MMC. However, the overall contractile activity is greater after a meal (see Figure 4-10).

Disorders of small intestinal motility fall into two broad categories that may be defined manometrically. The myopathic type of dysmotility is characterized by contractions of reduced amplitude but normal spatial and temporal organization (see Figure 4-2). The second, neuropathic, type of small bowel dysmotility results in disorganized contractions that have normal amplitude unless the bowel becomes pathologically distended (see Figure 4-7). In the presence of distention, manometric recording of contraction amplitude is unreliable because contractions may not produce the occlusion of the lumen necessary for them to be recorded accurately.

Specific manometric patterns associated with disease include the absence of phase III of the MMC, abnormal migration of phase III, short intervals between phase III episodes, persistent low-amplitude contractions, and sustained tonic-phasic contractions.[130] Motility patterns have prognostic significance. For instance, the absence of MMC has been associated with inability to tolerate enteral feeding and prolonged requirement for parenteral nutrition.[131]

Colon

The colon functions to mix, store, and propel fecal matter. Two broad groups of contractions are present: segmental and propagated activity. Segmental contractions are predominant, occurring throughout the day as isolated contractions or bursts of contractions that may be rhythmic or arrhythmic. These serve to mix the contents, maximizing exposure to the intestinal mucosa to promote absorption of water, electrolytes, and bacterial products such as short-chain fatty acids. A special type of rhythmic contraction, the rectal motor complex, occurs several times per day and overnight. These cycles of three to six contractions per minute occur independently of small bowel MMCs and appear to have a role in the maintenance of fecal continence.[132] Propagated contractions have traditionally been divided into high- and low-amplitude propagating contractions. However, recent evidence suggests that there may not be a discrete group of HAPCs but rather a continuum of amplitudes.[133] The function of propagated contractions is to rapidly move feces and gas over large distances.

Disorders of colonic motility may result in diarrhea, constipation, bloating, and pain. They may be severe and acute, such as Ogilvie syndrome of acute colonic pseudo-obstruction, or subacute and chronic, as in functional constipation. Emerging research suggests that abnormal rectal motor activity may underlie some cases of chronic constipation.[134]

Anorectum

Anorectal function in continence and defecation results from the coordinated activity of the internal and external anal sphincters, pelvic floor, and abdominal muscles. The pelvic floor is critical to continence and is the true target of biofeedback exercises.[135] When stool is delivered to the rectum by colonic HAPCs, there is reflex relaxation of the internal anal sphincter (rectoanal inhibitory reflex) and contraction of the external sphincter and pelvic floor. Stool is retained until socially convenient and then is expelled in a coordinated series of contractions accompanied by pelvic floor relaxation. Although defecation is initiated voluntarily, it is controlled by spinal reflexes.

Disordered anal function is common in children. The most common disorder of defecation is functional fecal retention, where fear of defecation results in voluntary withholding of stool. More serious organic diseases, such as Hirschsprung disease and intestinal neuronal dysplasia, are rare but potentially life-threatening. Disorders of colonic and anorectal motility in children are discussed in Chapter 46.1, "Idiopathic Constipation," and Chapter 46.2, "Hirschsprung Disease."

CHAPTER 5

LIVER FUNCTION AND DYSFUNCTION

1. *Bile Formation and Cholestasis*

Amethyst C. Kurbegov, MD, MPH
Saul Karpen, MD, PhD

The liver, the largest organ in the body, has multiple functions, several of which depend on its ability to make and secrete bile. Bile secretion is the key means by which the liver controls cholesterol balance and toxin excretion, as well as lipid- and fat-soluble vitamin digestion and absorption in the gut. Bile is composed of many substances, including bile acids, cholesterol, phospholipids, heavy metals, and a variety of detoxified metabolites. Processes that impede the formation and secretion of bile lead to the retention of biliary constituents within the liver (cholestasis), which, in turn, can result in hepatic damage, and, if left uncorrected, ultimately lead to liver failure. Moreover, an absence of bile in the gut lumen leads to marked impairments in the absorption of fats and fat-soluble vitamins. This chapter reviews the main anatomic, physiologic, molecular, and genetic determinants of bile formation to provide the reader with an understanding of our current knowledge of how bile is made and the ramifications of cholestasis.

ANATOMIC DETERMINANTS OF BILE FLOW

To allow for simultaneous uptake and excretion functions of the liver, hepatocytes are highly polarized cells with distinct functions at their basolateral and apical surfaces. The basal surface faces the sinusoids and comes into direct contact with portal blood, allowing for secretion of hepatocyte-derived products, as well as the uptake of nutrients, hormones, drugs, bile acids, and other xenobiotics and endobiotics. The lateral surface is contiguous with the basal surface, also in full contact with portal blood, ending at the tight junctions (zonula occludens) that form between hepatocytes. The apical surface is demarcated by these tight junctions and is the cell's excretory pole, responsible for transporting biliary constituents into the canaliculus via its unique array of resident membrane transporter proteins. The space formed between two cells' apical membranes is the bile canalicular lumen, and the tight junctions serve as the anatomic barrier between bile and blood. The hepatocyte's apical membrane is characterized by microvilli that extend into the canalicular space, increasing the cell's excretory surface area.[1,2]

Within the hepatocyte, solutes pass from the basolateral to the apical surface by a variety of methods. Many of the details of intrahepatocyte transport are largely unknown but are under intense investigation.[3,4] Binding proteins play some role in the shuttling of bile acids, bilirubin, and other substances within the cytosol, directing detoxification and transport while preventing toxic interactions with organelles.[5,6] These substances may then move through the cell by diffusion, whereas other components of bile, such as plasma proteins and lipids, are mainly transported by vesicles that fuse with the canalicular membrane.[4,7] In brief, vesicles are trafficked along cytoskeletal actin-based microtubules that extend throughout the cell.[6,8,9] Vesicles may move either apically or basolaterally, depending on the intended destination of the substance being transported.[8,10]

The majority of hepatocyte bile formation activity occurs at the canalicular membrane and within the canalicular space that exists between two hepatocytes. Once biliary components have reached the apical surface of the hepatocyte, they are transported into the canalicular lumen to form bile. Bile canaliculi comprise only about 5% of the total hepatic membrane surface area, forming tiny conduits for bile and interconnecting in what is often called a "chicken wire"–type three-dimensional pattern.[11] These channels, approximately 0.75 μm in diameter, coalesce as they approach the portal triad into larger tubes, histologically the canals of Hering. These, in turn, feed into the bile ductules visible in the portal triad, which then drain into the increasingly larger branches of the biliary tree. The full system of bile ducts resembles an inverted tree root system, with the terminal bile ducts forming the smallest branches that, in sequence, join to form septal ducts, area ducts, seg-

mental ducts, right and left hepatic ducts, and, ultimately, the common hepatic bile duct.[11]

Bile flows countercurrently to sinusoidal blood within the hepatic lobule. Portal blood flows from the portal vein via sinusoids toward the central vein, whereas newly formed bile flows via the canalicular network beginning at the pericentral region and then toward periportal hepatocytes and into the bile ductules of the portal triads. As bile continues to flow through the biliary tree, it is modified by the secretions of cholangiocytes, epithelial cells that line the biliary system from the ductules to the common bile duct.[11–13] Although comprising only 3 to 5% of liver cells, these cholangiocytes play an important role in modifying bile via secretion of electrolytes and water in response to stimulation by secretin and other hormones.[12–15]

As bile exits the liver, it is stored in the gallbladder until a meal activates duodenal release of cholecystokinin, which causes gallbladder contraction and expulsion of bile into the common bile duct and into the duodenum after relaxation of the ampulla of Vater.[16] Bile acids pass through the upper and mid–small intestine, where they may be modified by bacteria to varying degrees (dehydroxylation and deconjugation) and are almost entirely reabsorbed in the terminal ileum and transported back to the liver via the portal vein.[17] Some bile acids may be absorbed passively in the jejunum and in the colon, an important mechanism in people with short-gut syndrome, but the vast majority are actively absorbed via an apical transporter found in terminal ileal enterocytes.[17,18] On reaching the liver, bile acids are taken up by hepatocytes and excreted again into the bile canaliculus. This process, called the enterohepatic circulation of bile acids, occurs approximately 8 to 10 times a day, approximately twice per meal. It is highly efficient, resulting in a loss of only 5% of circulating bile acids per day under normal physiologic conditions, and this fraction (400–600 mg/d in adults) is matched by hepatic bile acid synthesis to maintain a constant bile acid pool size.[17,19] The normal adult liver secretes approximately 600 to 800 mL of bile a day, but neither bile flow rates nor bile acid pool sizes in infants and children have been accurately quantified.[11,19,20] Given the known "physiologic cholestasis" of infancy, the enterohepatic circulation of bile acids is likely to be less efficient in infants and small children than in adults.[21]

BILE COMPOSITION

Bile is unique among bodily fluids in its high lipid and detergent bile acid content. Primarily an aqueous solution, solids constitute about 3 to 5% of bile by weight, and its osmotic activity is largely determined by inorganic salt, concentrations of which closely reflect plasma electrolyte levels.[11,22] Bile acids are the primary organic solute in bile, with a concentration of 20 to 30 mM; the concentration of phospholipids is approximately 7 mM and cholesterol is 2 to 3 mM (Figure 5.1-1).

Bile acids constitute the major organic solute of bile and serve as the most influential determinant of bile flow rates. Related to steroids by their basic ABCD ring structure, they differ from steroids in the length of the side chain (five carbon) that ends with carboxylic acid.[23,24] Bile acids may be categorized as either primary or secondary, and four different bile acids make up more than 95% of the bile acid pool. Cholic and chenodeoxycholic acids are the two primary bile acids in humans and are synthesized from cholesterol in the hepatocyte via two interacting biosynthetic pathways.[25–27] Most of the genes responsible for bile acid synthesis have been cloned.[28] Cholic acid is the major synthetic product of the "neutral pathway" of bile acid formation. This pathway is initiated by the enzyme cholesterol 7α-hydroxylase, which also serves as the pathway's rate-limiting step. The "acidic pathway" is initiated by sterol 27α-hydroxylase and leads primarily to the formation of chenodeoxycholic acid. Mutations in the bile acid biosynthetic pathways lead to significant liver disease and cholestasis (for more on bile acid synthetic disorders, see Chapter 55.4, "Bile Acid Synthesis and Metabolism").[29–33] These primary bile acids are conjugated in the liver to the amino acids glycine or taurine before being excreted into bile. Glycine conjugates outnumber taurine conjugates at about a 3:1 ratio.[34]

The conjugated primary bile acids are modified by bacterial enzymes into the secondary bile acids. Deconjuga-

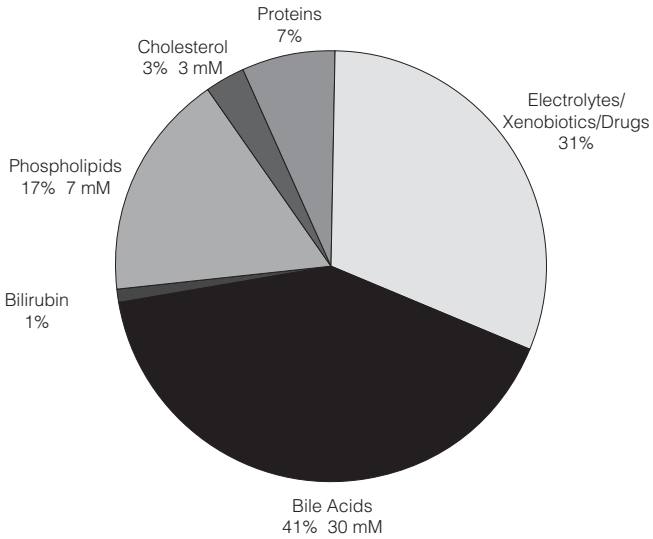

FIGURE 5.1-1 Human bile composition. Bile is predominantly water, with only 3 to 5% of its weight determined by solid solutes. Bile acids are the major solute of bile, and their micelle partners, cholesterol and phospholipids, contribute significantly to the solute composition as well. Xenobiotics, electrolytes, and proteins make up over a third of the biliary solute load, whereas conjugated bilirubin is the smallest component. Adapted from Vlahcevic ZR, Heuman DM, Hylemon PB. Physiology and pathophysiology of enterohepatic circulation of bile acids. In: Zakim D, Boyer J, editors. Hepatology: a textbook of liver disease. 3rd ed. Philadelphia: WB Saunders; 1996. p. 381.

tion, followed by 7α-dehydroxylation, occurs in the proximal jejunum and mid–small bowel, resulting in the more hydrophobic secondary bile acids deoxycholic acid and lithocholic acid.[35,36] Multiple enteric bacteria expressing the enzymes necessary for these reactions have been identified, particularly *Bacteroides*, *Clostridium*, *Bifidobacterium*, and *Escherichia coli*.[37,38] The hydrophobicity of bile acids relates to their detergent property and ability to solubilize phospholipids. This, in turn, translates into enhanced pathophysiology and hepatocyte and other cell membrane toxicity when they come into contact with secondary bile acids.[39] With progression of either liver or bowel disease, the proportion of hydrophobic bile acids increases, thereby altering the bile acid composition to become more hydrophobic and hence more hepatotoxic.[40]

Bile acids combine with phospholipids and cholesterol in the canalicular lumen to form mixed micelles. Phosphatidylcholines make up greater than 95% of the phospholipids in bile, and cholesterol is found in its free or unesterified form.[11,41,42] Plant-derived sterols (phytosterols) originating from the diet make up to about 10% of the total content of bile depending on the individual's intake.[41] Bile acids and phospholipids combine in a 1:2 ratio in bile to make mixed micelles, and these micelles form the primary route by which the body rids itself of cholesterol via the feces. Once in the gut lumen, the micelles exchange phospholipids for dietary lipids, allowing those lipids the contact with detergent bile acids and pancreatic enzymes necessary for digestion.[22] Finally, an imbalance between the ratios of bile acids, phospholipids, and cholesterol may lead to the precipitation of cholesterol in the gallbladder, which, in turn, may be a cause of biliary sludge and cholesterol gallstones (see Chapter 61, "Gallbladder Disease").[43,44]

Bile also contains a wide variety of other organic solutes, lipid-soluble compounds, proteins, drug metabolites, and heavy metals. Organic solutes include glutathione and glutathione conjugates, metabolized drugs, xenobiotics, and endobiotics such as bilirubin. Bilirubin is excreted primarily in its diglucuronide form, with less than 2% of total biliary bilirubin secreted as unconjugated bilirubin.[11,22,45] Lipid-soluble steroid hormones, vitamin D metabolites (25-hydroxyvitamin D), folic acid, pyridoxine, and transcobalamin all may be found in bile. Biliary proteins include those typically found in serum such as albumin and immunoglobulins M and G, as well as immunoglobulin A, which is modified by the liver to add a secretory component before being secreted into bile.[46–48] Other proteins include hepatocellular enzymes such as alkaline phosphatase and γ-glutamyl transferase, as well as bile-specific binding proteins for a variety of substances, such as copper and calcium.[49–51] Finally, bile is the major excretory route for many divalent heavy metals, such as copper, iron, manganese, and zinc.[52,53]

BILE FORMATION: CELLULAR AND BIOCHEMICAL DETERMINANTS

Two main determinates of hepatic bile flow have been designated as bile acid–dependent (BADF) and bile acid–independent (BAIF) flow. In addition, the cholangiocytes lining the biliary tree substantially contribute to bile, depending on the state of feeding and hormonal milieu.[54,55] There is wide variability in the relative contribution of each of these three components of bile formation in different species. In humans, BADF and BAIF contribute fairly equally to total bile flow, although BADF may be increased significantly with increases in bile acid pool size (Figure 5.1-2).[55,56]

Osmotic diffusion of water and electrolytes into bile is primarily determined by the concentration of bile acids in the fluid.[57,58] In this way, bile acid flux is a main determinant of bile flow, and the secretion of bile acids across the hepatocyte apical membrane is the rate-limiting step for BADF.[59–61] Bile acids are highly concentrated in bile, with a 100- to 1,000-fold increase over hepatocyte and portal vein concentrations. Postprandial portal vein bile acid concentration is 50 to 100 μM, whereas bile acid concentration in the canalicular lumen is 20 to 30 mM. By increasing transport of its large reserve of bile acids into bile, the liver can increase bile flow rates up to eightfold.[62] The particular species of bile acid that is transported significantly influences the rate of bile flow. Those bile acids that remain unincorporated into micelles have stronger osmotic properties, resulting in higher bile flow rates, whereas other bile acids have the same effect by enhancing bicarbonate secretion.[63,64] A bile acid's ability to increase bile flow rates is referred to as its choleretic potential and is described in microliters of bile produced per micromole of excreted bile acid.[65,66] Certain bile acids, such as ursodeoxycholic acid, have particularly high choleretic potential, making them attractive for pharmacologic applications.

BAIF is a relatively constant contributor to bile flow in humans at approximately 250 mL per 24 hours in adults.[54] It is mainly related to the liver cell mass, although it may be influenced by hormones and certain drugs.[56,67–70] The osmotic effects of transported glutathione, glutathione conjugates, and bicarbonate in bile are the primary determinate of BAIF.[56,71,72] Cholangiocytes contribute to bile flow both by secretion of water via water channels and by bicarbonate secretion.[13,73] The contribution of cholangiocytes in humans can be considerable, upward of 40% of total bile flow, depending on the state of feeding.[54,74] In

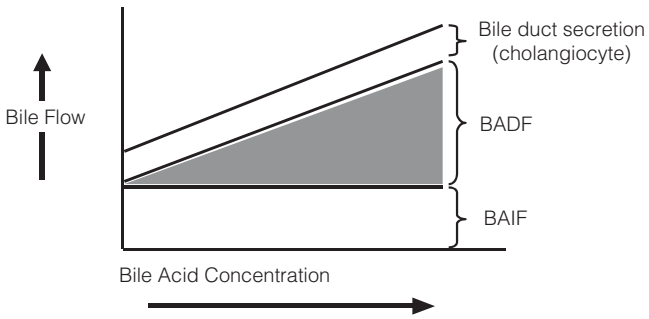

FIGURE 5.1-2 Bile flow determinants. Bile flow is primarily bile acid dependent (BADF) in humans, increasing as the bile acid pool size expands. Bile acid–independent flow (BAIF) remains relatively constant and is determined by glutathione, glutathione conjugates, and bicarbonate, among other solutes. Cholangiocytes secrete water and bicarbonate into bile and can contribute up to 40% of total bile flow, depending on the state of feeding.

response to feeding, the duodenum releases cholecystokinin, secretin, vasoactive intestinal peptide, and other hormones, which, in turn, stimulate cholangiocytes along the biliary ducts to increase water and electrolyte secretion and thus increase bile flow (see Figure 5.1-2).[75–80]

BILE FORMATION AND FLOW: MOLECULAR DETERMINANTS

Significant advances in the understanding of molecular control of bile formation have occurred in the last 10 years. Genes encoding critical transporters on both the basolateral and apical surfaces of hepatocytes have been identified (Figure 5.1-3).[14,81] These transporters are responsible for the uptake and excretion of bile acids, cholesterol, phospholipids, organic anions, xenobiotics, hormones, and other constituents of bile. Enzymatic pathways within the cell play crucial roles in cholesterol processing, bile acid synthesis, and xenobiotic metabolism.[14,15,82,83] These discoveries not only have contributed significantly to our understanding of basic metabolism and drug handling but also have provided a molecular explanation for many rare pediatric cholestatic disorders.[84,85]

BASOLATERAL MEMBRANE TRANSPORTERS

NTCP

The first sinusoidal bile acid transporter cloned was the rat Na+/taurocholate cotransporting polypeptide gene *NTCP* (SLC10A1).[86] Found only on the sinusoidal membrane of hepatocytes, *NTCP* is the primary mediator of hepatic uptake of conjugated bile acids from portal blood.[86–88] Subsequent to its isolation in rats, *NTCP* has been cloned in mice, rabbits, hamsters, zebrafish, and humans.[89–93] The liver extracts 75 to 90% of conjugated bile acids from sinusoidal blood on its first pass, and approximately 75% of this extraction occurs via *NTCP* in a Na+-dependent process.[94,95] Expression of *NTCP* is controlled at both transcriptional and post-translational levels. However, regulation of *NTCP* ribonucleic acid (RNA) expression appears to be the main means of governing its activity, with significant changes in molecular *NTCP* RNA expression during states of inflammation and cholestasis. Moreover, bile acids themselves act as negative feedback regulators of *NTCP* gene expression.[96,97] Mutations in the *NTCP* gene have yet to be described.

Organic Anion Transporting Polypeptide Family

Approximately 25% of bile acid extraction occurs in a Na+-independent process, and the primary transporters involved are the organic anion transporting polypeptides (OATPs).[14,81] It is thought that OATPs are responsible for the majority of BAIF, as well as Na+-independent BADF. These proteins are multispecific and bidirectional transporters of a variety of compounds, including bile acids, bilirubin, xenobiotics, drugs, and hormones. Many xenobiotics, steroids, and other compounds may rely entirely on OATPs for transport into and out of hepatocytes. Three members of the OATP family (Oatp 1 [Slc21a1], Oatp 2 [Slc21a5], and Oatp 4 [Slc21a10]) have been identified as significant Na+-independent transporters in rat liver, whereas primarily two OATPs (OATP-C [SLC21A6] and OATP-8 [SLC21A8]) play similar roles in human liver.[14,81] Human OATP-C, however, is unique in its ability to transport unconjugated bilirubin, a characteristic lacking in rat Oatp 1.[98,99] In fetal rat liver, Oatp 1 messenger RNA is detectable prior to that of *NTCP*, suggesting its importance in both bile acid and other molecular transport.[100] Similar to *NTCP*, rat Oatp 1, 2, and 4 are down-regulated in conditions of sepsis and cholestasis. Expression of human OATP-C and 8 in liver disease has not been determined, but OATP-C polymorphisms have been described that may alter drug pharmacokinetics.[101–106]

Multidrug Resistance Protein 3

Under normal circumstances, minimal efflux of bile acids occurs from the hepatocyte to sinusoidal blood

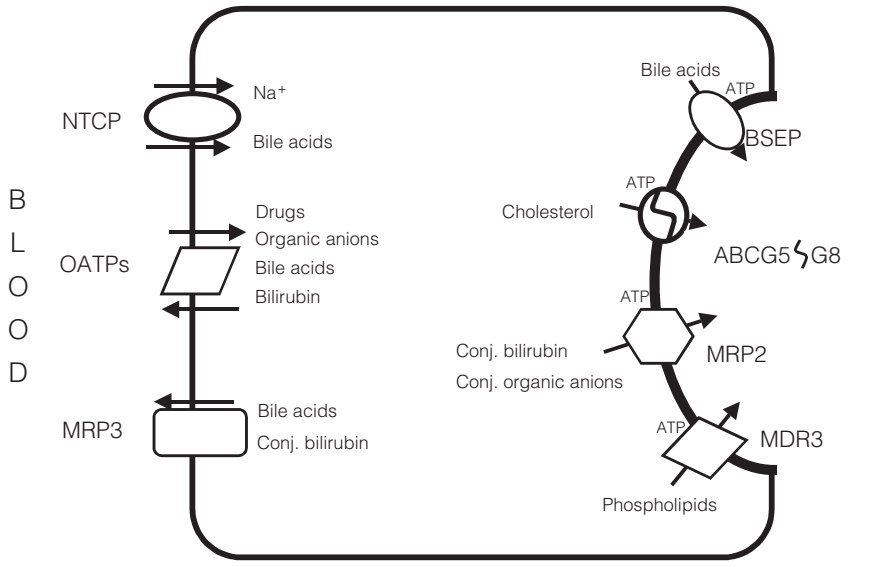

FIGURE 5.1-3 Hepatocyte transporters involved in bile formation. Hepatobiliary transporters on the sinusoidal (blood) and canalicular (bile) membranes of the cell are responsible for the importation of molecules from portal blood and export of biliary components into the canalicular lumen. Arrows connote direction of molecular flow across each transporter. ATP = adenosine triphosphate; BSEP = bile salt export pump; Conj. = conjugated; MDR = multidrug resistance; MRP = multidrug resistance–related protein; NTCP = Na+/taurocholate cotransporting polypeptide; OATP = organic anion transporting polypeptide.

across the basolateral membrane. In cholestatic conditions, however, serum bile acid levels rise, coincident with reduced *NTCP* gene expression as well as increased basolateral expression of the multidrug resistance protein 3 (MRP3 [ABCC3]).[107,108] This protein, also expressed by cholangiocytes, enterocytes, and renal epithelia, transports bile acids, conjugated organic anions, and conjugated bilirubin out of hepatocytes and into plasma.[14,109,110] Finally, although rat hepatocytes show Mrp3 up-regulation in response to cholestasis, the role for human MRP3 induction remains unclear because human liver biopsy samples from cholestatic patients have not shown as robust an activation of MRP3 RNA levels as in bile duct–ligated rats.[111] Patients with Dubin-Johnson syndrome (see below) have increased MRP3 expression, suggesting a compensatory means of unloading conjugated bilirubin into blood because these patients have a molecular defect in canalicular conjugated bilirubin excretion.[112]

CANALICULAR MEMBRANE TRANSPORTERS

Bile Salt Export Pump

The bile salt export pump (BSEP [ABCB11]) was identified in 1998 as the primary transporter responsible for bile acid export into bile.[113] An adenosine triphosphate (ATP)-binding cassette protein, BSEP uses ATP hydrolysis to provide the energy to export bile acids against the very high-concentration gradient found at the canalicular membrane.[114] Multiple mutations have been identified in the gene encoding for BSEP in patients with progressive familial intrahepatic cholestasis type 2 (*PFIC2*), and several of these mutations seem to result in either abnormal trafficking to the membrane or premature degradation of the transporter.[96,115] PFIC2 is a clinical syndrome characterized by progressive intrahepatic cholestasis, pruritus, usually low serum γ-glutamyl transpeptidase levels, normal serum cholesterol levels, and characteristic coarse appearance of canalicular bile on electron microscopy.[116–118] Progression to cirrhosis and liver failure in early childhood is the norm for most PFIC2 patients, resulting in early mortality without transplant.[15,85,116,117,119] Altogether, the rapid progression of liver disease in PFIC2 patients appears to be due to bile acid retention, supporting the notion that bile acids are the main hepatotoxins in cholestatic liver disease. (For more on PFIC2, see Chapter 55.6, "Disorders of Biliary Transport.")

Multidrug Resistance Protein 2

MRP2 (ABCC2) is likely responsible for the majority of bile salt–independent bile flow across the canaliculus.[120,121] The MRP2 transporter exports glutathione, sulfated and glucuronidated conjugates of drugs, toxins, bile acids, and bilirubin into bile. Mutations of the gene lead to reduced BAIF in rodent models and are responsible for the elevated serum levels of conjugated bilirubin seen in Dubin-Johnson syndrome.[120,122] Mouse data also suggest that this transporter may be involved in cholesterol gallstone susceptibility.[123]

Multidrug Resistance Protein 3

MDR3 (ABCB4) acts as the phopholipid translocator ("flippase") across the canalicular membrane in humans and rodents and is responsible for phospholipid secretion into bile.[124,125] Mutations or deletion of the *MDR3* gene results in PFIC3, a syndrome distinct from PFIC1 and PFIC2 in its elevated γ-glutamyl transpeptidase and indicative of more involved biliary tree damage.[126] In addition to PFIC3, cholestasis of pregnancy has been identified in heterozygous carriers of *MDR3* mutations.[127] Mutations may also predispose the patient to cholesterol gallstones given an imbalance of phospholipids to cholesterol and bile acids in the bile. Taken together, research to date displays a wide variation in the clinical manifestation of *MDR3* mutations, and much remains to be discovered about this transporter and its role in liver disease.[126,127]

Familial Intrahepatic Cholestasis 1 (ATP8B1)

This poorly understood protein is analogous to an ATP-dependent aminophospholipid transporter molecule that is found in the apical membranes of hepatocytes, cholangiocytes, pancreas, and small intestine enterocytes.[128–130] It gained attention and is named for its role in PFIC1, which, although clinically similar to PFIC2, is associated with familial intrahepatic cholestasis 1 (FIC1) mutations rather than BSEP.[128] As a consequence of these mutations, hydrophobic bile salts are markedly reduced in bile, suggesting that FIC1 may be involved in transporting highly hydrophobic bile acids such as lithocholate and chenodeoxycholate.[131] Patients with benign recurrent intrahepatic cholestasis also have mutations in the *FIC1* gene.[128,129,132] The clinical scenario in these patients, however, is markedly different from that of PFIC1 patients, characterized by normal liver function and life expectancy with only intermittent episodes of jaundice and pruritus. It is still not understood how mutations in the same region of the *FIC1* gene can result in quite divergent clinical syndromes.

ABCG5 and ABCG8

These two ATP-binding cassette proteins have recently been identified as the biliary cholesterol transporters.[133,134] Both are half-transporters expressed in the canalicular membrane and the apical membrane of enterocytes. Working together, they export sterols, including both dietary cholesterol and plant phytosterols. When mutated, they produce the rare disease of accumulated serum plant sterols, sitosterolemia, and recently have been implicated in cholesterol gallstone formation.[135–138]

MOLECULAR CONTRIBUTION TO CLINICAL CHOLESTATIC DISORDERS

As the molecular understanding of bile flow has advanced, new insight into various well-recognized clinical cholestatic conditions has emerged. The molecular mechanisms of both acute and chronic causes of cholestasis, such as sepsis and pregnancy, as well as congenital cholestatic disorders (eg, PFICs) may be explained in terms of alterations in membrane trans-

porter expression and mutations of critical transporter genes. Several congenital disorders associated with known membrane transporters have been mentioned previously, and their clinical profiles are more fully discussed elsewhere (see Chapter 55.6). In addition to these diseases, there are some prominent acquired and other congenital cholestatic conditions worthy of note.

Intracellular accumulation of bile acids is a key feature of cholestatic conditions, and these bile acids can be toxic to liver and biliary tissues.[39,139] Bile acid toxicity is due not only to its detergent properties (causing protein dissociation from the cell lipid bilayer) but also to its nondetergent mechanisms that alter intracellular signaling and lead directly to hepatocellular apoptosis.[140–143] Thus, situations of hepatic bile acid retention, whether congenital or acquired, intra- or extrahepatic, can lead to significant hepatobiliary damage.

Total Parenteral Nutrition–Associated Cholestasis

Total parenteral nutrition (TPN) has revolutionized the care of many chronically ill and intestinally devasted children over the past 30 years. With widespread use of TPN, however, a consequence of cholestasis has become apparent in some children, particularly premature and extremely low birth weight infants who develop necrotizing enterocolitis.[144–146] Several factors appear to contribute to TPN-associated cholestasis (TPNAC), including various components of the TPN, hydrophobic bile acids, prematurity, repeated bouts of sepsis, and poor bowel function.[145–149] Although most patients' TPNAC resolves following transition to enteral feeding, some infants will progress to end-stage liver disease within a few months.[144,149,150] The molecular explanation of TPNAC remains unclear, although emerging data on the developmental expression of hepatic transporters may help explain the particular vulnerability of premature infants to this disease. (For more on TPNAC, see Chapters 40, 56, and 76.4.)

Sepsis-Associated Cholestasis

Systemic bacterial infections have long been associated with jaundice, particularly in premature and young infants.[151] Recent research has shown the responsiveness of several hepatic transporters to endotoxin and inflammatory cytokines, particularly *NTCP* and the OATP family.[152–158] Expression of these basolateral transporters is significantly down-regulated in inflammatory and septic conditions, and *NTCP* and BSEP RNA expression is reduced in liver biopsies obtained from patients with inflammation-associated cholestasis.[111] Cumulatively, these changes in expression lead to decreased import of bile acids from the systemic circulation into the hepatocyte and into bile. Bile flow is thus reduced, leading to cholestasis and conjugated hyperbilirubinemia.[159] With treatment of the infection, cholestasis and any apparent jaundice typically resolve.

Disorders of Bile Acid Synthesis

In the last several years, at least six specific enzymatic defects in the bile acid synthesis pathways have been characterized.[23,29–33] Combined, these disorders account for approximately 2 to 3% of liver disease cases in the pediatric population. Atypical and often hepatotoxic bile acids accumulate in the liver, potentially leading to cholestasis, liver dysfunction, and end-stage failure if not treated. Cholestasis results from a decrease in the primary bile acids that stimulate bile flow.[23] These defects can be identified via urinalysis for abnormal bile acid species, and treatment with oral bile acid therapy may be curative if started early. (For more on bile acid synthetic disorders, see Chapter 55.4.)

Cystic Fibrosis

Cholangiocytes lining the bile ducts secrete chloride and water into bile via the cystic fibrosis transmembrane regulator (CFTR) transporter.[76] Found on the luminal side of cholangiocytes, CFTR is mutated in patients with cystic fibrosis (CF), resulting in thick, viscous secretions. In addition to the pulmonary and pancreatic complications characteristic of CF, cholestasis and biliary cirrhosis are significant problems for affected patients. The highly viscous bile forms bile duct plugs, which, in turn, can cause biliary obstruction, focal biliary fibrosis, and focal biliary cirrhosis.[160,161] With increased life expectancies in CF, liver disease has become the third leading cause of death in these patients.[162] The hydrophilic bile acid ursodeoxycholic acid has been used to improve the fluidity of bile in CF patients, although the long-term effects on survival or the need for liver transplant are unknown.[163–165] (For more on CF-related liver disease, see Chapter 65.1, "Cystic Fibrosis.")

SUMMARY

Bile production is a crucial function of the liver, constituting the body's primary mechanism for maintaining cholesterol balance, toxin excretion, and lipid- and fat-soluble vitamin digestion and absorption in the gut. The molecular understanding of bile formation, particularly in the handling of bile acids, has expanded considerably in the last several years. This insight has not only helped explain the mechanism of several congenital and acquired cholestatic conditions but also should lead ultimately to new therapies for cholestatic patients, who currently have few options.

2. Fibrogenesis and Cirrhosis

Ross W. Shepherd, MD, FRACP, FRCP
Grant A. Ramm, PhD

FIBROSIS AND CIRRHOSIS IN PEDIATRIC LIVER DISEASES

Almost all causes of chronic liver injury result in fibrosis and ultimately cirrhosis, from which most of the complications of chronic liver disease are derived. Fibrosis is a wound-healing response in which damaged areas of tissue are encapsulated by scar tissue or extracellular matrix. In the liver, this may lead to cirrhosis, which is a chronic diffuse disease characterized by irreversible widespread hepatic fibrosis with regenerative nodule formation. The prominent fibrous tissue contains vascular anastomoses, which cause hemodynamic alterations and portosystemic shunting. This diffuse pathology superimposes on the primary liver disease, often obscuring the nature of the original insult. The major pathophysiologic consequences[1] are the result of impaired hepatic function and portal hypertension, and some cases may be complicated by the occurrence of hepatocellular carcinoma.

In children, a wide range of causes of hepatocellular injury may result in cirrhosis. These include causes of cholestasis, with accumulation of hydrophobic bile acids toxic to hepatocytes (eg, biliary secretory disorders or obstruction), as well as infections, toxins, and metabolic, vascular, and nutritional disorders (Table 5.2-1). Irrespective of the cause of chronic injury, and in the absence of removal of the cause of injury, many complications can ensue (Table 5.2-2). Unfortunately, available therapies for many chronic liver diseases causing cirrhosis in children are ineffective, and treatment is limited to management of these secondary pathophysiologic complications, and when liver failure ensues, liver transplant is the only available definitive option. Advances in knowledge of the mechanisms leading to cirrhosis and its complications may impact on the outcome of this progressive pathologic process via development of new antifibrotic and other specific therapies. Such research may not only further develop traditional management approaches but, importantly, may also provide new directions in the prevention of progression and treatment of these diseases.

The pattern of progression to cirrhosis and its complications in pediatric liver diseases is highly variable. In some conditions, such as neonatal extrahepatic biliary atresia, a severe cholangiopathy of unknown etiology, the development of hepatic fibrosis is extraordinarily rapid, with cirrhosis occurring by 12 to 16 weeks of age and liver failure by as early as 24 weeks of age. Early diagnosis and surgical treatment by portoenterostomy improve outcome in some cases, but the degree of fibrosis at the time of portoenterostomy has been adversely related to poor outcomes in this disease. Other disorders, such as cystic fibrosis (CF)-associated focal biliary cirrhosis, can be compatible with normal liver function for many years, presenting with signs of portal hypertension only in the second decade of life. Despite this wide variation in occurrence and severity, it appears that the cellular mechanisms and factors responsible for the development of liver fibrosis in these two widely differing diseases, and indeed in most chronic liver diseases, are remarkably similar.[2–4]

TABLE 5.2-1 CAUSES OF FIBROSIS AND CIRRHOSIS IN CHILDREN

PEDIATRIC CHOLESTATIC DISEASES
Extrahepatic biliary atresia
Choledochal cyst, tumors, stones
Alagille syndrome, biliary hypoplasia
Progressive familiar intrahepatic cholestasis syndrome
Drug-induced cholestasis
TPN-associated cholestasis
Cystic fibrosis liver disease
Sclerosing cholangitis
Graft-versus-host disease
Histiocytosis X
HEPATOCELLULAR DISEASES
Neonatal hepatitis
Hepatitis B and hepatitis C
Autoimmune hepatitis
Drugs/toxins
Genetic/metabolic diseases
Carbohydrate defects
Galactosemia, fructosemia, glycogen storage III and IV
Amino acid defects
Tyrosinemia, urea cycle disorders
Metal storage defects
Neonatal hemochromatosis, Wilson disease
Lipid storage diseases
Gaucher disease, Niemann-Pick type C
Fatty acid oxidation defects
Peroxisomal disorders
Zellweger syndrome
Mitochondrial disorders
Respiratory chain defects
FIBROPOLYCYSTIC DISORDERS*
CHRONIC HEPATIC VENOUS OUTFLOW OBSTRUCTION
Hepatic vein thrombosis
Budd-Chiari syndrome
Veno-occlusive disease
Cardiac sclerosis

TPN = total parenteral nutrition.
*Does not cause cirrhosis.

TABLE 5.2-2 COMPLICATIONS OF CIRRHOSIS IN CHILDREN

Malnutrition and growth failure
Cholestasis with jaundice, pruritus, and impaired fat absorption
Portal hypertension and variceal bleeding, hypersplenism
Ascites
Encephalopathy
Coagulopathy
Hepatopulmonary syndrome
Hepatorenal syndrome
Bacterial infections, spontaneous bacterial peritonitis
Impaired hepatic drug metabolism
Hepatocellular carcinoma

Adapted from Shepherd RW.[1]

HEPATIC FIBROGENESIS

Liver fibrosis resulting in cirrhosis is a dynamic process in which environmental factors, such as the nature, duration, and intensity of the exposure to liver injury, interact with genetic factors, such as the nature of the immune response, to result in scar formation. Animal and adult human studies of various forms of liver injury suggest that the liver responds to injury in a stereotypic fashion involving programmed cell death (apoptosis), cell necrosis, and fibrosis.[4,5] Apoptosis involves polarization of mitochondria, cytochrome *c* release, nuclear fragmentation, and formation of apoptotic bodies without inflammation. Cell necrosis involves depolarization of mitochondria, depletion of adenosine triphosphate, and cell lysis with inflammation. In response to these cellular events, there is oxidant stress, release of cytokines, accumulation of collagens, increased turnover of components of the extracellular matrix, fibrosis, and replacement or regeneration of hepatocytes, resulting in nodule formation. This latter dynamic and complex series of events is called fibrogenesis. Until recently, little was known about the cells responsible for this increased hepatic extracellular matrix production. Technical advances in the isolation and characterization of hepatic cells[6] have led to the observations that a population of nonparenchymal liver cells, called hepatic stellate cells (HSCs), formerly known as lipocytes, Ito cells, or fat-storing cells, are the principal fibrillar collagen–producing cells in pathologic conditions of the liver.

Role of the HSC

HSCs are found in a perisinusoidal localization, in close contact with hepatocytes, sinusoidal endothelial cells, and Kupffer cells. In normal liver, they are vitamin A–storing cells that produce small amounts of extracellular matrix, which assist in maintaining the integrity of the basement membrane.[5] In conditions of hepatic injury, HSCs can be activated in vivo into a highly proliferative, "myofibroblast-like" cell. This activation process is associated with loss of intracellular vitamin A, increased production of the fibrillar collagen types I and III and other extracellular matrix components, expression of cytokines and cytokine receptors, and elaboration of a network of contractile microfilaments, chiefly α-smooth muscle action.

Mediators of Fibrogenesis

HSC activation is central to the development of hepatic fibrosis and appears to take place in two phases[4]: a phase of initiation followed by a phase of perpetuation (Figure 5.2-1). The earliest events are likely due to interactions with other hepatic cells or products derived from these cells, such as reactive oxygen species and lipid peroxides causing oxidant stress and sinusoidal endothelial cell–derived fibronectin.[6] There is then cytokine-induced perpetuation of the activation process, involving retinoid loss, proliferation, fibrogenesis, matrix degradation, chemotaxis, contractility, and leukocyte chemoattraction (see Figure 5.2-1). Key mediators include transforming growth factor-β_1 (TGF-β_1), which is the most potent stimulus for HSC-derived collagen type I production; platelet-derived growth factor BB (PDGF-BB), which is responsible for increased HSC proliferation; and the chemokine monocyte chemotaxis protein 1 (MCP-1), which sponsors white blood cell attraction.[7] These mechanisms and pathways of HSC contractility, chemotaxis, and chemoattraction are vital for the inflammatory processes associated with hepatic fibrogenesis. Finally, matrix remodeling is an essential facet of fibrogenesis. HSCs express many of the enzymes and inhibitors that mediate liver matrix remodeling, such as matrix metalloproteinases (MMPs) 2 and 3, which take part in the early degradation of basement membrane, which enhances HSC activation, as well as tissue inhibitors of MMPs (TIMPs) 1 and 2, which inhibit protease activity, leading to unhindered matrix accumulation during fibrillar collagen deposition.[8]

Fibrogenesis in Pediatric Liver Diseases

The precise mechanisms responsible for the activation of HSCs and the subsequent development of hepatic fibrosis in most pediatric liver diseases are not well characterized to date. A composite pattern is, however, emerging from recent studies of pediatric cholestatic diseases,[9] as depicted in Figure 5.2-2. Activation of HSCs and associated increased production of type I collagen have been

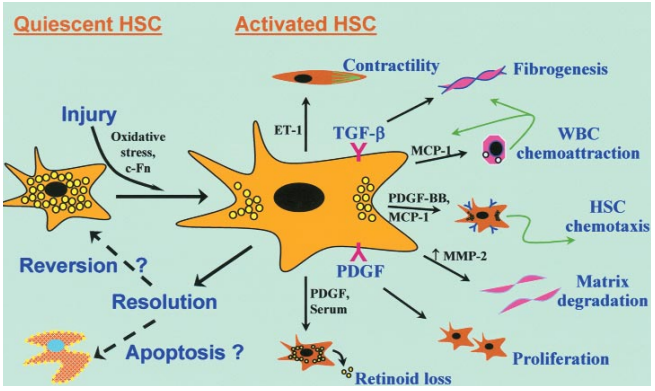

FIGURE 5.2-1 The hepatic stellate cell (HSC) in the quiescent and activated states following liver injury. Adapted from Friedman SL.[4] cFN = cell-associated fibronectin; ET = endothelin; MCP = monocyte chemotaxis protein; MMP = matrix metalloproteinase; PDGF = platelet-derived growth factor; TGF = transforming growth factor; WBC = white blood cell.

documented in biliary atresia[2] and in the focal biliary cirrhosis associated with CF.[3] Myofibroblast-like cells were seen in the extracellular matrix surrounding expanded bile ducts and within fibrosis septa bridging between portal tracts. Activated HSCs, demonstrated by the expression of procollagen, smooth muscle actin, and their stellate cell morphology, were particularly evident at the interface between scar and normal tissue (see Figure 5.2-2). This growing margin of scar tissue formation appears to be the site of maximal HSC activation and type I collagen messenger ribonucleic acid (mRNA) expression, although some evidence of collagen gene expression is also seen in myofibroblast-like cells within established fibrous septa. Whether the myofibroblast-like cells that surround expanded bile ducts within the fibrotic septa are derived from activated HSCs or portal fibroblasts is unknown. Possible mechanisms of injury to bile duct cells and/or hepatocytes are shown in Figure 5.2-2. Notably in biliary atresia, bile duct hyperplasia appears to be an early pathologic event, possibly attributable to, as suggested by studies in bile duct-ligated rats, increased intraductal pressure,[10] circulating cholangiotrophic factors,[11] or depletion of hepatic antioxidants, such as vitamin E or glutathione.[12] Oxidative stress, a result of increased free radical generation and depletion of antioxidant defenses, is thought to play an important role in the development of hepatic injury. In cholestasis, there is an increase in the levels of glycine-conjugated hydrophobic bile acids, which occurs in response to biliary obstruction and decreased hydration of bile.[13] Indeed, hydrophobic bile acid–induced oxidant stress may play a major role in the viability and function of Kupffer cells, hepatocytes, bile duct cells, and HSCs, all of which are capable of producing cytokines and growth factors that may drive inflammation and fibrogenesis (see Figure 5.2-1).

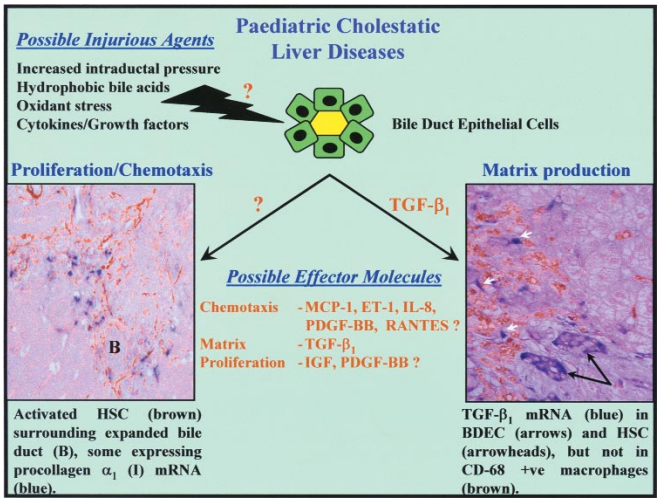

FIGURE 5.2-2 Schema representing mechanisms of liver fibrogenesis in pediatric cholestatic disorders. Adapted from Ramm GA.[9] BDEC = bile duct epithelial cell; ET = endothelin; HSC = hepatic stellate cell; IGF = insulin-like growth factor; IL = interleukin; MCP = monocyte chemotaxis protein; mRNA = messenger ribonucleic acid; PDGF = platelet-derived growth factor; TGF = transforming growth factor.

The most potent fibrogenic mediator released during liver injury appears to be TGF-β, which is responsible for the transactivation of the procollagen α_1 gene in both myofibroblast-like cells and activated HPCs in these same areas of scar tissue formation (see Figures 5.2-1 and 5.2-2). TGF-β_1 is expressed at the scar interface in both biliary atresia and CF liver disease (see Figure 5.2-2), suggesting a spatial and temporal association with the generation of scar tissue. In CF liver disease, TGF-β_1 protein expression in bile duct epithelial cells is significantly correlated with the percentage of portal tracts, and TGF-β_1 mRNA expression correlates with disease progression.[3] Possible effector molecules for activation, proliferation, and chemotaxis include PDGF-BB, at least in biliary atresia.[14] In animal models using bile duct–ligated rats, bile duct cells also express PDGF-BB,[11] and in vitro studies have shown that HSCs are recruited to bile duct segments by PDGF-BB.[15] HSCs also respond to numerous other chemokines in vitro, such as MCP-1, interleukin-8, and endothelin-1 (see Figure 5.2-1).[16] Marked hepatic expression of MCP-1 has been reported in biliary atresia and CF liver disease, although the role of MCP-1 in stellate cell recruitment in vivo remains to be determined.[17]

Genetic Polymorphisms and Fibrogenesis

The importance of genetic influences on the outcomes and progression of chronic liver diseases has recently been a topic of scientific interest, with specific reference to genetic modifiers in the occurrence of and progression of hepatic fibrosis.[18] Although most of the evidence for this relates to adult liver diseases and animal models,[18] epidemiologic studies have identified possible polymorphisms in a number of candidate genes that may influence the progression of liver fibrosis in some pediatric liver diseases. For example, liver disease in pediatric patients with CF has been associated with glutathione *S*-transferase P1 polymorphism.[19] This may be important because the glutathione *S*-transferases play a key role in the protection against oxidative stress. As indicated above, oxidant injury contributes to the development of hepatic fibrosis. Similarly, genetic variations may explain susceptibility to the development of progression to cirrhosis in some patients with nonalcoholic steatohepatitis.[19] In hepatitis C, epidemiologic studies have suggested the presence of rapid and slow fibrosers, and many candidate genes that might explain this phenomenon are being actively researched. Theoretically, any gene involved in the pathogenesis of hepatic fibrosis may potentially modify progression.

Serum Markers of Fibrosis

It is possible to evaluate hepatic fibrosis by measuring serum levels of the components of matrix degradation and remodeling. Numerous studies have examined the utility of a series of potential markers of hepatic injury progression to cirrhosis in adult human liver disease, and there appears to be a disease-specific pattern of the various markers, which also varies with progression of the degree of fibrosis. For example, elevated levels of collagen type III, collagen type IV (CL-IV), prolyl-hydroxylase (PH),[20]

laminin and CL-IV,[21] and MMP-1 have been observed in different cohorts of patients with differing causes of cirrhosis.[22] Levels of hyaluronic acid (HA),[23] TIMP-1, and TIMP-2[24] are elevated in patients with chronic hepatitis C virus infection. In hemochromatosis, levels of CL-IV and MMP-2 are correlated with hepatic fibrosis.[25]

A few studies have assessed the efficacy of serum markers in evaluating liver injury in pediatric liver diseases. Elevated serum levels of procollagen III peptide and CL-IV and/or HA may indicate progression of fibrosis after Kasai portoenterostomy. Serum HA may be of value for monitoring postoperative biliary atresia patients as a noninvasive indicator of progressive hepatic fibrosis.[26–28] In established CF liver disease, collagen type VI,[29] collagen type III, PH,[30] and HA[31] levels are elevated. In one study, serum concentrations of CL-IV, PH, HA, MMP-2, and TIMP-1 were measured in patients with CF liver disease and well-characterized hepatic fibrosis versus age- and sex-matched patients with CF but no liver disease and non-CF controls.[32] Elevated levels of serum TIMP-1, CL-IV, and PH were found in CF liver disease, and higher levels of TIMP-1 and PH were associated with early fibrosis. These may thus be useful markers for the early detection of CF liver disease.[32]

Prospects for Antifibrogenic Therapy

Except for a few therapies for causes of chronic liver disease, such as chelation therapy in Wilson disease and the use of antiviral agents in hepatitis B and C, removal of the cause of the chronic hepatic injury is usually not possible, and therapies targeting the fibrogenic response to mediate progression of chronic liver disease and its complications are being actively researched, holding some promise for the future.[33] These include inhibition of HSC activation (eg, antioxidants), antifibrogenic agents (eg, TGF-β antagonists, inhibitors of the endothelin receptor), and agents that increase degradation of scar (eg, metalloproteinases).

CIRRHOSIS AND ITS COMPLICATIONS IN CHILDREN

Definitions

Cirrhosis may be either active or inactive, depending on the presence of biochemical or histologic evidence of hepatocellular necrosis, apoptosis, and inflammation, and either compensated, where there are no clinical or laboratory features of liver failure, or decompensated, where such features are evident. In general, morphologic and histologic classifications are often unhelpful in clinical settings, although certain features may help in determining the cause of the cirrhosis, as in biliary disease, hepatic venous outflow obstruction, and features specific for particular inherited or infective conditions. Grouping disorders that progress to cirrhosis by etiology is helpful because of the framework this provides for diagnosis, prognosis, treatment, and genetic counseling. Ultimately, the presence or absence of liver failure provides the basis for transition from supportive therapy to considerations of liver transplant when the condition of end-stage liver disease has been realized.

Pathology

Classification of liver pathology is based on morphology, histology, etiology, and degree of activity. Fibrosis is not synonymous with cirrhosis, and fibrosis without nodules occurs typically in congenital hepatic fibrosis and granulomatous liver disease. The *morphologic classification* divides cirrhosis into micronodular, macronodular, and mixed-type disease. Micronodular cirrhosis is characterized by fibrous septa separating small (< 3 mm) regeneration nodules of almost uniform size, present throughout the liver. This is most commonly seen in the early stages of extrahepatic biliary atresia. Macronodular cirrhosis is characterized by nodules up to 5 cm in diameter, separated by irregular septa of varying widths. Regenerative nodules larger than 2 cm in diameter are evidence that the cirrhotic process has persisted for a number of years. This pattern is usually seen in α_1-antitrypsin deficiency, autoimmune hepatitis, late CF liver disease, and Wilson disease. Many cases, however, have characteristics of both types of cirrhosis (mixed), and it is known that micronodular cirrhosis can mature into macronodular or mixed cirrhosis. Macronodular cirrhosis may be suggested on ultrasonography. Care in interpretation of percutaneous needle liver biopsies is needed because of small samples, because of fragmentation of the specimen, or if the specimen is taken from a macronodule. The latter may be suggested by hyperplasia of the hepatocytes or a relative excess of hepatic vein branches. The *histologic classification* is generally more helpful in defining etiology and in management, defining cirrhosis as postnecrotic, biliary (periportal), or hepatic venous outflow (cardiac) cirrhosis. Postnecrotic cirrhosis is the result of liver cell damage and is most commonly seen in chronic hepatitis owing to viral autoimmune factors or drugs. This type of histology is a common sequela of neonatal hepatitis. Features include piecemeal necrosis, bridging fibrosis, collapse of the hepatic lobules, and regeneration, with the development of macronodular cirrhosis. In biliary cirrhosis from cholestatic disorders, there is fibrosis developing from within the portal tracts extending out into the parenchyma linking adjacent portal tracts, with little change in the hepatic parenchyma and preservation of the lobular architecture. In infant cholestasis, bile duct proliferation is a feature of extrahepatic biliary atresia, and bile duct paucity or hypoplasia is a feature of certain intrahepatic cholestatic syndromes. Obstruction to hepatic venous outflow causes centrilobular hemorrhagic necrosis, with fibrosis extending from central veins to portal tracts, and is caused by cardiac lesions, resulting in increased right atrial pressure and vaso-occlusive disorders. In chronic cases, cirrhosis eventually develops, and the initial distinguishing features may be obliterated. Specific histologic patterns occur in Wilson disease (copper pigment deposition), α_1-antitrypsin deficiency (intracellular periodic acid–Schiff–positive, diastase-resistant inclusions), and certain storage disorders.

Pathophysiology

As fibrosis and regenerative nodule formation advances, there is distortion of the liver architecture with compres-

sion of hepatic vascular and biliary structures, resulting in altered hepatic blood flow, and the development of portal hypertension and shunting of blood from hepatic artery to portal vein branches and to hepatic vein tributaries. These hemodynamic disturbances lead to irregular delivery of oxygen and nutrients to the hepatocytes, perpetuating a vicious cycle of events, which may persist even if the original process causing liver injury has ceased. The complications of chronic liver disease and cirrhosis (see Table 5.2-2 and below) are primarily due to impaired hepatic function, cholestasis, and altered hemodynamics.

Malnutrition and Growth Failure

The liver has a central role in regulating fuel metabolism, nutrient homeostasis, and absorption of a number of nutrients. Malnutrition itself may induce further derangements of liver function because the liver requires energy for a number of synthetic, storage, and detoxification functions. These factors, combined with the common symptoms of anorexia and a poor dietary intake, make malnutrition common in chronic liver disease, particularly if the onset is in infants, who are more vulnerable to the debilitating effects of malnutrition because of their higher energy and growth requirements. The body composition of malnourished children with pediatric liver disease is similar to that of protein-energy malnutrition,[34,35] with growth failure and depletion of metabolically active cell mass and body fat stores, resulting from combined disturbances of intake, absorption, and metabolism of nutrients.

Importantly, because many of the above changes are energy linked, overall energy metabolism is compromised in children with chronic liver disease.[35] Studies in biliary atresia show that most patients, compared with controls, are hypermetabolic and catabolic during fasting, with a reduced respiratory quotient (an index of altered substrate oxidation). Protein synthesis is clearly impaired, as evidenced by decreases in circulating protein such as albumin, transferrin, and clotting factors. An abnormal serum amino acid profile is seen, with elevations in plasma aromatic amino acids and depression in branched-chain amino acids.[34] Branched-chain amino acids comprise 40 to 50% of the minimum daily requirement for essential amino acids in humans, playing an important regulatory role in protein synthesis. Neither growth nor positive nitrogen balance is possible without these amino acids. Carbohydrate metabolism is abnormal and is characterized by carbohydrate intolerance, peripheral insulin resistance, hyperinsulinemia, and reduced hepatic glycogen stores. Chronic liver disease also alters the synthesis of lipids, including very-low-density lipoproteins and cholesterol, and hypocholesterolemia has been found to be an adverse factor in the outcome of liver transplant. Disturbances of the growth hormone–insulin-like growth factor 1 axis may also contribute to wasting and growth failure in children with liver disease by virtue of insulin-like growth factor 1 deficiency[36] and growth hormone resistance.[37]

Vitamin K is a necessary cofactor for the conversion of inactive precursors of prothrombin and factors VII, IX, and X into their active forms. Dietary vitamin K requires bile and pancreatic juice for uptake; thus, in cholestasis, vitamin K malabsorption is the primary cause of prolonged prothrombin time. In parenchymal liver disease, there is decreased synthesis of liver-dependent clotting factors. Where vitamin K deficiency results from malabsorption, parenteral vitamin K normalizes the prothrombin time, but in advanced liver disease, vitamin K only partially corrects the prolonged prothrombin time, a useful clinical feature suggesting poor liver synthetic function in advanced chronic liver disease. Vitamin E deficiency is also common, particularly in cholestatic liver diseases and in infants, resulting in a distinctive progressive but preventable neurologic disorder associated with peripheral neuropathy, ophthalmoplegia, and ataxia. Patients with cholestatic syndromes, particularly infants with biliary atresia who have little or no exposure to sunlight, depend primarily on dietary vitamin D to maintain body stores and are particularly likely to develop rickets (defective mineralization) and osteopenia (reduced formation of matrix), with low serum 25-hydroxyvitamin D levels. These have been thought to result mainly from vitamin D and calcium malabsorption, with secondary hyperparathyroidism. However, vitamin D treatment does not easily reverse bone disease, and although there are usually low total 25-hydroxyvitamin D levels, osteocalcin levels are also low, suggesting that decreased bone formation and not increased bone resorption is the main determinant of bone disease.[38] Signs of vitamin A deficiency are not common, but abnormalities of the regulation of metabolism of retinol-binding proteins and biochemical vitamin A deficiency have been reported in infants with biliary atresia.[39] Biochemical deficiencies of water-soluble vitamins, including thiamine and pyridoxine, may occur, and cases of nutritional cardiomyopathy and peripheral neuropathy have been reported. Of the trace elements, iron, zinc, and selenium deficiencies have been reported in children with end-stage liver disease.[34] These can be associated with growth failure and poor protein synthesis.

Ascites and Edema

Ascites and edema are common major complications of decompensated cirrhosis. Although there are differences in the spectrum of etiologies causing end-stage liver disease in pediatric patients, the principles and practices are similar to those in adults. Extravascular fluid accumulation may develop insidiously or be precipitated by events such as gastrointestinal bleeding, infection, or the development of hepatoma, manifest as peritoneal ascites, as peripheral edema, or in the pleural effusion. The two important factors in extravascular fluid accumulation are portal venous pressure and plasma oncotic pressure owing to hypoalbuminemia, both of which interact in chronic liver disease, resulting in fluid redistribution between intra- and extravascular spaces.

Several theories as to the formation of ascites exist. The underfilling hypothesis suggests that increased sinusoidal pressure leads to a cascade of events, resulting in fluid retention owing to elevated portal venous pressure, increased splanchnic volume, decreased systemic vascular resistance, and decreased effective plasma volume. The decreased

plasma volume results in increased activity of plasma renin and aldosterone, resulting in avid renal retention of sodium and water, leading to the accumulation of fluid that is ascites. This hypothesis is supported by the fact that expansion of the plasma volume by methods such as albumin infusion commonly reverses ascites, decreases levels of renin and aldosterone, and results in a diuresis. The overflow hypothesis speculates that inappropriate renal sodium and water retention is the primary abnormality triggered by possible hepatorenal reflex. This hypothesis is supported by some animal models but is mitigated by the observation that the renin-angiotensin-aldosterone system is activated in decompensated cirrhosis. These systems should be suppressed and not activated with sodium retention and volume expansion. The peripheral arterial vasodilation hypothesis suggests that peripheral arterial vasodilation is the initiating event in ascites formation. The fact that patients with chronic liver disease are prone to the development of arteriovenous connections implies the presence of vasoactive hormones. These connections are known to be associated with peripheral vasodilatation and renal sodium retention.

These various models for the development of ascites are not necessarily mutually exclusive. Early overflow secondary to renal sodium retention may be the initiating factor, but in later phases of chronic liver disease, diminished effective plasma volume, with its accompanying hormonal changes, may predominate, leading to peripheral arterial vasodilatation and a further increase in sodium and water retention. Thus, sodium retention seems to be fundamental to the occurrence of ascites and edema. In some patients, sodium retention occurs despite normal activity of the renin-aldosterone and sympathetic nervous systems and increased circulating plasma levels of natriuretic peptides and activity of the so-called natriuretic hormone. This impairment in circulatory function, although less intense, is similar to that in patients with increased activity of the renin-aldosterone and sympathetic nervous systems, suggesting that antinatriuretic factors are more sensitive to changes in circulatory function and that these systems may be important in the pathogenesis of sodium retention. The development of drugs that inhibit the tubular effect of antidiuretic hormone and increase renal water excretion without affecting urine solute excretion has opened a field of great interest for the management of water retention and dilutional hyponatremia in cirrhosis. Two families of drugs, the V_2 vasopressin receptor antagonists[40] and the κ-opioid agonists,[41] have been shown to improve free water clearance and correct dilutional hyponatremia in human and experimental cirrhosis with ascites.

Portal Hypertension and Variceal Bleeding

Portal hypertension is one of the major causes of morbidity and mortality in children with chronic liver disease. It is the result of a combination of increased portal blood flow and increased portal resistance and occurs when portal pressure rises above 10 mm Hg. Signs and symptoms are primarily the result of decompression of this elevated portal blood pressure through portosystemic collaterals. The main clinical features are splenomegaly; the occurrence of esophageal, gastric, and rectal varices; and the development of ascites. Splenomegaly and hypersplenism rarely require specific intervention. The major problems are bleeding from esophageal and other varices, ascites, and nutritional disturbances.

An understanding of portal hypertension requires knowledge of the anatomy of the portal system. Portal capillaries originate in the mesentery of the intestine and spleen and in the hepatic sinusoids. Capillaries of the superior mesenteric and splenic veins supply the portal vein with nutrient-rich and hormone-rich blood supply. At the hilum of the liver, the portal vein divides into two major trunks supplying the right and left lobes of the liver, and these trunks undergo a series of divisions supplying segments of the liver terminating in small branches that pierce the limiting plate of the portal tract and enter the sinusoids through short channels. The partly oxygenated portal venous blood supplements the oxygenated hepatic arterial blood flow to give the liver unique protection against hypoxia. Blood flow from both the hepatic artery and the portal vein is well regulated, allowing the liver to withstand thrombosis of either one of these major vessels. Portal hypertension owing to chronic liver disease may arise because of a prehepatic or intrahepatic block, where the block may be presinusoidal, sinusoidal, or postsinusoidal.

The major pathologic effect from portal hypertension is the development of collaterals carrying blood from the portal venous system to the systemic circulation in the upper part of the stomach, the esophagus, and the rectum and in the falciform ligament and may drain into the inferior vena cava or the left renal vein. Only the submucosal collaterals, such as in the esophagus, stomach, and, rarely, other parts of the intestine, are associated with gastrointestinal bleeding. Collaterals in other parts of the intestine are more frequently likely to occur at sites of surgery along the gastrointestinal tract, particularly from stoma and anastomotic sites. Portal hypertensive gastropathy, which is suggested by dilated mucosal veins and capillaries and mucosal congestion in the stomach, develops particularly in patients who have had variceal obliteration.

Although changes in vascular resistance to flow of blood between the splanchnic bed and the right atrium appear to be the initial events in the development of portal hypertension, a number of other hemodynamic changes contribute to and amplify the increased portal blood pressure. There is a hyperdynamic circulatory state with increased cardiac and decreased splanchnic arteriolar tone, both of which increase portal inflow. Studies in animal models indicate that a number of humoral mediators are involved, including glucagon, prostaglandins, nitrous oxide, and endothelium-derived relaxing factor. Changes in intravascular volume also play an important part in pathophysiology of the hyperdynamic circulation, as do alterations in adrenergic tone in the splanchnic system. All of these observations have led to new experimental and clinical studies, suggesting possible pharmacologic treatments for portal hypertension,[41] although because the major clinical effect is that of bleeding from esophageal

varices, direct treatment of variceal hemorrhage remains the major approach.

Hepatic Encephalopathy

Hepatic encephalopathy is difficult to recognize in children, particularly in infants. Early symptoms of encephalopathy in children are subtle and include neurodevelopmental delay, school problems, and lethargy or sleep reversal. Intellectual impairment and personality change may occur in older children, whereas clouding of consciousness, progressing to stupor and coma, is a late sign. Clinical signs such as ataxia, tremor, and dysdiadochokinesia are difficult to determine in small children. Precipitating factors are common and include an oral protein load, gastrointestinal bleeding, the use of sedatives, infections, and following shunt surgery for portal hypertension.

The pathophysiology appears to be determined by four events: portosystemic shunting, hepatocellular dysfunction, interaction of nitrogen metabolites from the intestine with the central nervous system, and altered neurotransmitter function. From clinical observations and from studies in experimental models, nitrogenous products such as ammonia derived from the gastrointestinal tract appear to be of primary importance. Hepatic encephalopathy is rare when liver function is able to remove nitrogenous intestinal metabolites, although portosystemic shunting alone can result in encephalopathy if the subject is given a high-protein diet. However, serum ammonia levels, which are usually elevated in encephalopathy, do not directly correlate with cerebral state, and experimental evidence suggests that such changes are not the only ones responsible for the encephalopathy. Neuropathologically, there is astrocytic (rather than neuronal) alteration. Magnetic resonance imaging reveals bilateral signal hyperintensities, particularly in the globus pallidus on T_1-weighted imaging, a phenomenon that may result from manganese deposition. Proton (^1H) magnetic resonance spectroscopy shows increases in the glutamine resonance in brain, reflecting increased brain ammonia removal. Although the exact molecular mechanisms are not known, excitatory or inhibitory neurotransmitter imbalance leading to dysfunction of the glutamate–nitric oxide (NO) system is thought to play a major role. Activation of glutamate receptors leads to an increase in intracellular calcium, which initiates several calcium-dependent processes, including NO formation. NO is a gaseous, highly reactive, freely diffusible molecule with a short half-life. Increased expression of the neuronal isoform of NO synthase and the uptake of L-arginine (the obligate precursor of NO) has been demonstrated. Hyperammonemia associated with liver dysfunction results in increased NO, which may lead to learning and memory impairments. Other metabolic factors that have been implicated are short-chain fatty acids such as butyrate, valerate, and octanoate, which are increased in the plasma and cerebrospinal fluid in encephalopathy and may act synergistically with ammonia.

Hepatic encephalopathy may also be affected by the accumulation of inhibitory neurotransmitters in the brain. Neurotransmitters mediate the postsynaptic action of neurons. Inhibitory neurotransmitters may be false (not ordinarily present in the brain) or true, such as the amino acid γ-aminobutyric acid (GABA), which is produced in the brain by the decarboxylation of glutamic acid. False transmitters may be produced by metabolism of amines by gastrointestinal tract bacteria and are normally removed by the portal circulation by the liver. False neurotransmitters have not been found to induce encephalopathy in experimental animals. In contrast, GABA has an important role in central nervous system inhibition, and GABA-like activity has been found in portal blood in both animal models and subjects with chronic liver failure after gastrointestinal hemorrhage. In experimental models, GABA may produce coma. The GABA receptor is activated not only by GABA but also by benzodiazepines. The reversal in some patients of encephalopathy after the administration of a benzodiazepine antagonist supports this hypothesis, although the effect is not entirely consistent. Alterations in neurotransmitter function may also occur as a result of disturbances of amino acid metabolism, particularly deficiency of branched-chain amino acids and excess of aromatic amino acids.

Further alterations in brain function can be induced by hypoglycemia, which is common even with fasting in young children, respiratory alkalosis leading to a decrease in cerebral perfusion, or hypoxemia owing to hemodynamic changes. Aggravating factors include gastrointestinal hemorrhage, hypovolemia, hypokalemia, sedatives, anesthetics, sepsis, and high protein intake, which increase the endogenous nitrogen load, thus precipitating overt encephalopathy.

Coagulopathy

The liver plays an important role in hemostasis by a complex balance between the production of coagulation proteins and inhibitors of coagulation and the removal of fibrin degradation products and coagulation factors. Thus, coagulation disorders are common in chronic liver disease owing to a combination of vitamin K malabsorption and deficiency, reduced synthesis of coagulation factors and inhibitors of coagulation, thrombocytopenia secondary to hypersplenism, or intravascular coagulopathy. These disturbances are particularly important in prognostic assessment and in the genesis and management of gastrointestinal bleeding and may lead to serious complications, such as intracerebral bleeding and intravascular coagulopathy.

Hepatopulmonary Syndrome

This syndrome is defined as a triad of liver dysfunction, intrapulmonary arteriovenous shunts, and arterial hypoxemia and is relatively common in childhood cirrhosis. Oxygen saturations of less than 90% and cyanosis appear unrelated to the severity of liver damage but are associated with the occurrence of clubbing. The pathogenesis appears to be multifactorial, including intrapulmonary shunts, arteriovenous shunts, ventilation-perfusion mismatch, and portopulmonary venous anastomoses. In some cases, the degree of cyanosis may be proportionally greater than the hypoxemia. In infants, hypoxemia can be aggravated by poor respiratory effort related to ascites or hepatomegaly.

Such patients have dyspnea at rest, particularly when upright, which is often relieved by lying down.

The diagnosis is established by ensuring that there is no underlying cardiac defect (echocardiography, electrocardiography, or cardiac catheterization). Simple transcutaneous techniques of oxygen monitoring can be of most diagnostic value.[42] Ventilation-perfusion scans will demonstrate the presence of extrapulmonary isotope in the cerebral blood and other organs; lung function tests are usually normal. Although no specific treatment for this syndrome has been proven, the degree of hypoxemia is improved by oxygen administration, attention to nutrition support, and control of ascites. The hepatopulmonary syndrome may seriously limit tolerance to anesthesia. During or after transplant, worsening hypoxemia may be improved by using inhaled NO. Liver transplant will reverse the systemic and pulmonary vascular changes, although recovery may be slow.

Pulmonary Hypertension

This may occur in cirrhosis as a result of failure of degradation of vasoactive substances in the splanchnic circulation associated with portopulmonary venous anastomoses and paraesophageal portosystemic collaterals within the pulmonary venous system. The presenting feature is cyanosis, but early signs include right ventricular hypertrophy or accentuation of the pulmonary vessels on chest radiography.

Hepatorenal Syndrome

This syndrome is a functional progressive renal failure of unknown cause occurring in patients with severe liver disease. It is a serious complication of cirrhosis and carries a poor prognosis. Although the pathogenesis is not understood, abnormalities of renal cortical blood flow appear central to the pathogenesis. A high incidence of glomerulosclerosis and membranoproliferative glomerulonephritis has been documented in children with end-stage liver disease at the time of liver transplant,[43] probably secondary to chronic reduction in renal cortical blood flow. Studies in adult cirrhotics have suggested that those without hepatorenal syndrome have systemic vasodilatation, whereas those with hepatorenal syndrome have evidence of peripheral vasoconstriction, leading to the hypothesis that patients with the hepatorenal syndrome have increased splanchnic blood pooling, resulting in decreased renal blood flow, possibly related to up-regulated endothelial NO synthase. Administration of vasopressin, which causes splanchnic vasoconstriction, has been shown to increase glomerular filtration and renal blood flow[44] and forms the basis of current approaches to medical therapy. Renal vasoconstriction is also possibly related to an increase in the production of thromboxane, a potent vasoconstrictor, and a decrease in prostaglandin 2, a dilatory metabolite.[45]

Bacterial Infections

Bacterial infections are common in chronic liver disease and may precipitate other complications, such as encephalopathy, ascites, and hepatorenal syndrome. Urinary and respiratory tract infections are frequent, and bacteremia commonly results from invasive investigations. Spontaneous bacterial peritonitis is a common serious complication of ascites and should always be excluded in all children with sepsis. Immune deficits associated with chronic liver disease include abnormalities of complement and opsonization, impaired function of Kupffer cells, neutropenia, and alterations in mucosal barriers, particularly the gastrointestinal tract. Portal hypertension makes patients susceptible to frequent bacteriemia, perhaps by inducing bacterial translocation of the gut. The specific risk factors for infection are low serum albumin, gastrointestinal bleeding, intensive care unit admission for any cause, and therapeutic endoscopy. Certain infectious agents are more virulent and more common in patients with liver disease. These include *Klebsiella*, *Escherichia coli*, *Vibrio*, *Campylobacter*, *Yersinia*, *Plesiomonas*, *Enterococcus*, *Aeromonas*, *Capnocytophaga*, and *Listeria* species, as well as organisms from other species.

Hepatocellular Carcinoma

Hepatocellular carcinoma may occur in the setting of cirrhosis in childhood. The mechanisms for development are unknown. Associations include hepatitis B, in which children with neonatally acquired hepatitis B have developed hepatocellular carcinoma from the age of 7 or 8 years.[46] There is also a close association of the development of hepatocellular carcinoma with tyrosinemia type I, with one study suggesting an occurrence rate of 37% in patients surviving beyond 2 years of age.[47] Patients may present with abdominal pain and/or abdominal mass or an increase in α-fetoprotein, but hepatocellular carcinoma may be found incidentally at liver transplant.

3. Normal Hepatocyte Function and Mechanisms of Dysfunction

Humberto Soriano, MD

The hepatocyte is the most abundant cell type in the liver. It is responsible for most of its metabolic functions and is the target cell of many diseases. Both acquired and congenital diseases of the liver affect hepatocytes. Liver-based metabolic diseases are numerous and often result from the abnormal expression of a single gene in hepatocytes. This chapter presents important structural aspects of hepatocyte function; discusses the role of hepatocytes in the metabolism of carbohydrates, proteins, fat, and other molecules; and focuses on mechanisms of dysfunction and injury, such as apoptosis, necrosis, and regeneration. Hepatocyte transplant is also discussed as a model of function and dysfunction. Biliary excretory function and injury are discussed in Chapter 5.1, "Bile Formation and Cholestasis."

STRUCTURAL BASIS FOR HEPATOCYTE FUNCTION

The liver, the cradle of the soul according to the ancient Greeks, is the largest organ in the body, weighing 2 to 2.5% of total body weight. A closer approximation for liver weight for transplant has been developed as 772 × body surface area (–38 if less than 1 m^2).[1] If hepatocytes are isolated from the liver, each gram of tissue yields an average of approximately 50 million hepatocytes.[2] A human left liver lobe, for example, contains, in general, over 10 billion hepatocytes. Hepatocytes constitute approximately 60% of the total cells in the liver. The other 40% are called nonparenchymal cells and include macrophage-derived Kupffer cells, which are important in host defense and mediators of the inflammatory response; fenestrated endothelial cells; lymphocytes; and the stellate cell, which is responsible for the synthesis of extracellular collagen in response to liver and hepatocyte injury. Hepatocytes provide a selective barrier between the external and internal milieu by cementing themselves with gap and tight junctions, which, in turn, provide polarity and restrict distinct activities to three separate membrane domains: basolateral, apical, and lateral (Figure 5.3-1).[3] At the basolateral (sinusoidal) membrane, hepatocytes exchange metabolites with the blood. At the apical (canalicular) membrane, hepatocytes secrete bile, detoxified waste products, cholesterol, and phospholipids. The bile canaliculi are formed by the tight junction–bound apical membranes and are the earliest component of the bile drainage system. Disruption of tight junctions can permit leakage of bile from canaliculi into the sinusoids and circulation. The lateral membrane is the surface between adjacent hepatocytes. Gap junctions permit attachment between hepatocytes and nerve impulse transmission between hepatocyte acinar zones.

HEPATOCYTE LOBULE

Two models exist of hepatic organization: the lobule and the acinus. The lobules have a central vein, a portal area, and liver plates that converge from portal area to central vein. The portal space at the periphery of the lobule contains a hepatic arteriole, a portal venule, a bile ductule, nerves, and lymphatics. Lobules are cylindrical structures measuring several millimeters in length and 1 to 2 mm in diameter. The human liver contains approximately 50,000 individual lobules. Blood enters the lobule from the portal area, traverses the hepatic sinusoids, and is collected into the central veins toward which the hepatic cellular plates converge (Figure 5.3-2). Central veins join and drain into the hepatic veins and subsequently into the right atrium of the heart.

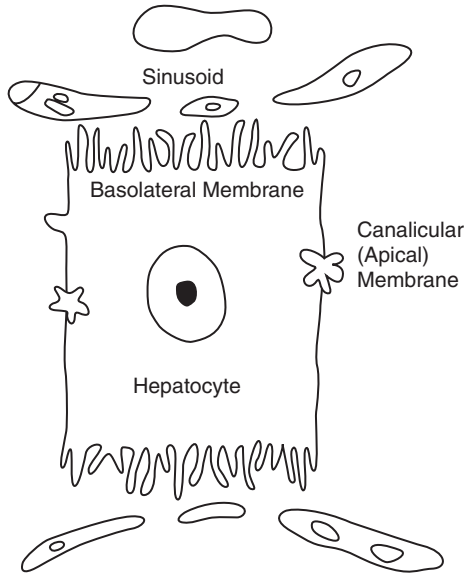

FIGURE 5.3-1 Hepatocytes are polarized and bound by three membrane domains: the lateral membrane between adjacent hepatocytes, the basolateral (sinusoidal) membrane that abuts the sinusoidal space, and the apical or canalicular membrane that forms the bile canaliculi.

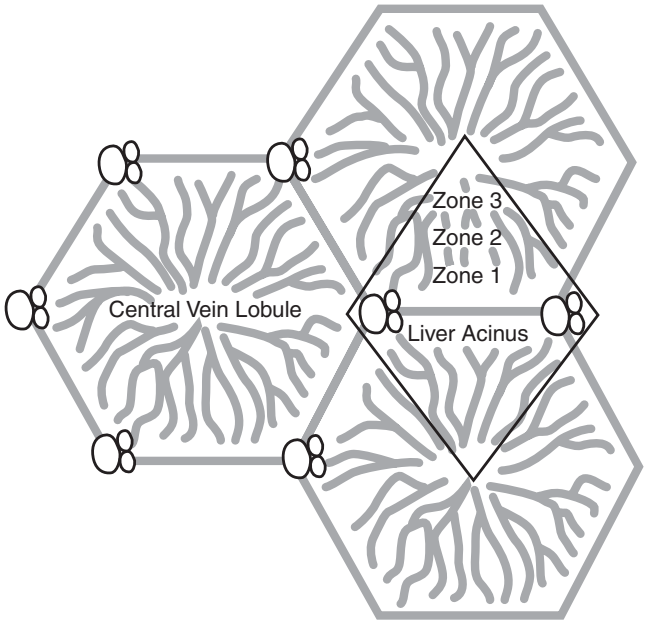

FIGURE 5.3-2 Hepatocyte lobule: blood flow goes from portal triads toward the central vein. Bile is collected in the opposite direction into the portal ducts. Sinusoids and hepatic cords are arranged as trabeculae between portal and central vein areas.

Acinar Zonal Differentiation

The simple liver acinus is arranged around an axis containing the hepatic arteriole, portal venule, and ductule that grow out from one portal area (see Figure 5.3-2, diamond area). Hepatocytes vary in their metabolic functions depending on their location within the hepatic lobule. Periportal hepatocytes (zone 1) receive blood rich in oxygen and nutrients from the portal venules and hepatic arterioles. Pericentral hepatocytes (zone 3) receive blood that has already traversed most of the sinusoid and is thus lower in nutrients and oxygen and higher in waste products. These differences result in variations in hepatocyte synthetic function, proliferative potential, ability to detoxify substances, and susceptibility to drug or ischemia injury. Periportal hepatocytes specialize in oxidative metabolism, whereas pericentral hepatocytes detoxify drugs. The periportal hepatocytes are also predominantly responsible for converting ammonia to urea by the concerted action of the urea cycle enzymes. This is a high-capacity, low-affinity system, and because periportal cells also generate ammonia from deamination of amino acids, ammonia reaches the pericentral hepatocytes. Pericentral hepatocytes exclusively express glutamine synthetase and can uptake this ammonia to synthesize glutamine. Thus, pericentral hepatocytes scavenge ammonia with high affinity, convert it to glutamine, and prevent toxic ammonia from reaching the systemic circulation.

Liver Cellular Structure

Hepatic plates are usually two cells thick and are bound by tight junctions that separate the sinusoidal space from the bile canaliculi. Endothelial cells line the sinusoids. Between adjacent hepatocytes lie the bile canaliculi that empty into bile ductules located in the portal spaces. Hepatocytes are thus polarized and bound by three membrane domains: the lateral membrane between adjacent hepatocytes, the basolateral membrane that abuts the sinusoidal space, and the apical or canalicular membrane (see Figure 5.3-1). Endothelial cells in the liver are very specialized. They have pores measuring almost 1 μm in diameter. This is a very large area considering that a red blood cell measures, on average, 6 μm in diameter. These fenestrated endothelial cells that lack basement membranes facilitate rapid exchange of substances between plasma and hepatocytes. Hepatocytes have microvilli on the sinusoidal plasma membrane, which facilitate the exchange of nutrients. In addition, the low pressure and slow blood flow further enhance bidirectional transfer of solutes. Between endothelial cells and the hepatocytes are narrow spaces called the spaces of Disse, which interconnect and drain into the lymphatic vessels that are located in the portal areas. Hepatic lymph is formed when there is increased sinusoidal pressure, especially with obstruction to the outflow of blood from the liver. This lymph may accumulate as ascites. Two other cell types found around the sinusoidal space include the Kupffer and the stellate cells. The stellate cell, also known as a fat storage or Ito cell, is a major site for vitamin A storage and can be identified by its high lipid content. Relevant to disease, the stellate cell is the major cell type associated with the development of hepatic fibrosis in response to liver injury. With liver injury, stellate cells become activated to a myofibroblast-like state, which is associated with collagen gene expression, reduction of vitamin A content, and morphologic changes. Kupffer cells are prominent in the sinusoids, macrophage derived, and the principal phagocytic cells of the liver. Kupffer cells are important mediators in the inflammatory response in the liver.

Liver's Unique Blood Flow

To understand hepatocyte physiology, it is necessary to know the significance of the liver blood flow. It is surprising how frequently physicians are not aware of the portal circulation's unique characteristics. The liver is the first organ to receive the nutrient-enriched blood from the gut's venous system, which converges via the portal vein and branches into the liver sinusoids.

Whereas blood from the extremities and the rest of the body returns directly to the heart, blood from most abdominal organs collects into the portal vein and its branches within the liver and is distributed into the hepatic sinusoids. About 80% of the liver blood supply comes via the portal vein from the stomach, small and large bowel, spleen, and pancreas. The portal system has high flow (approximately 1 L/min in adults), but low vascular resistance allows the portal pressure to be low, around 9 mm Hg, whereas the pressure in the hepatic vein leading from the liver into the vena cava is close to 0 mm Hg. During cirrhosis, the increase in fibrous tissue results in increased vascular resistance and portal hypertension of 15 to 20 mm Hg above normal. Acute liver failure, possibly owing to inflammation and necrosis in the liver parenchyma, also results in increased portal pressures.

HEPATOCYTE METABOLIC FUNCTIONS

Hepatocytes are key cells in the synthesis and catabolism of carbohydrates, proteins, and lipids.[4] The liver is thus a primary site for the metabolism of organic and inorganic substrates. Such functions allow hepatocytes to prevent disease by detoxifying endogenous and exogenous toxins. Bile formation and secretion into the bowel are dealt with in Chapter 5.1.

Hepatocyte Carbohydrate Metabolism

Normal hepatocyte function is critical to maintain the body's glucose homeostasis and carbohydrate metabolism. Glucose is the primary source of energy for the brain, muscle, and kidney. The liver can store and modulate the availability of ingested nutrients according to the requirements of peripheral organs for energy sources. The ability to fast relies on the ability of hepatocytes to store glycogen and synthesize glucose from amino acids, glycerol, and, principally, glycogen degradation. These metabolic functions are, in turn, regulated by the functions of the pancreas, adrenal glands, and thyroid. Although peripheral need for glucose is met by gluconeogenesis and glycogenolysis, excess glucose is converted by the hepatocytes into amino acids, fatty acids, and glycogen, which is the major form of glucose storage. Glucose entry or exit from the hepatocytes occurs via the glucose transporter 2, a facilitative low-affinity, high-capacity glucose transporter that responds directly to local plasma glucose concentrations.[5,6] During hepatocyte injury such as in acute liver failure, glucose homeostasis ability is impaired and hypoglycemia results, which is occasionally severe enough to cause generalized seizures.

Hepatocyte Protein Metabolism

Synthesis. All proteins in plasma, except the immunoglobulins, are synthesized by the hepatocytes. Immunoglobulins are synthesized in the reticuloendothelial tissues throughout the body by B lymphocytes. Hepatocytes make about 90% of all of the plasma proteins at a rate of 15 to 50 g/d. This is a rapid rate considering that an adult has approximately 350 g of plasma proteins. Indeed, when there are important protein losses, hepatocytes undergo mitosis, the liver size grows, and the plasma protein synthetic rate increases dramatically until the plasma concentration returns to normal. The most prominent of the serum proteins is albumin, and its serum concentration is used to evaluate the liver's synthetic capacity. In cirrhosis, for example, in part owing to decreased synthesis, plasma protein and albumin concentrations can decrease significantly.

Among the proteins synthesized by hepatocytes, clotting factors are of special significance. Other than factor VIII, which is also platelet dependent, all of the coagulation factors are synthesized in the liver. Factors II, VII, IX, and X are also dependent on vitamin K sufficiency. During liver failure, bleeding owing to impaired coagulation occurs often and coagulation factor replacement may be necessary. Hepatocytes are also responsible for the interconversion of the various amino acids through several stages of transamination. All of the nonessential amino acids can be synthesized in this way from other amino acids and the corresponding keto acid.

Catabolism. Hepatocytes are the main cells responsible for the deamination of amino acids in the process of their conversion into energy or for the synthesis of carbohydrates and lipids. Other organs in the body, such as the kidneys, can perform a small amount of deamination.

Detoxification. Hepatocytes are also responsible for converting ammonia into urea for excretion by the kidneys. Ammonia is the principal by-product of amino acid metabolism. In addition, ammonia is continually formed in the bowel by bacteria and absorbed via the portal circulation. During liver failure, as the hepatocyte's detoxifying function is impaired, serum ammonia and several other toxic metabolites accumulate in the bloodstream, resulting in progressive encephalopathy, cerebral edema, and, eventually, death.

Hepatocyte Lipid Metabolism

Most cells in the body metabolize lipids. However, some aspects of lipid metabolism are carried out mainly by hepatocytes. These include fatty acid oxidation to supply energy for other parts of the body; synthesis of cholesterol, phospholipids, and lipoproteins; and synthesis of lipids from excess carbohydrates and proteins.

Triglycerides are broken down in the liver into glycerol and three fatty acid molecules. The fatty acid chains are split into two-carbon units and bound to coenzyme A (CoA) in the form of acetyl CoA. This molecule can enter the Kreb citric acid cycle in the common terminal pathway of carbohydrate metabolism to liberate a large amount of energy. The hepatocytes, however, cannot use all of this energy, and acetyl-CoA molecules are combined to form acetoacetic acid, a highly soluble ketone body, which is transported by the circulation to other parts of the body. In these tissues, acetoacetic acid is transformed back into acetyl CoA and is oxidized for energy.

Hepatocytes uptake cholesterol and lipoproteins from the bloodstream using specific receptors. Genetic diseases of these receptors can lead to severe hypercholesterolemia. The liver also synthesizes cholesterol. About 80% of it is converted into bile salts, which are secreted into the bile. Other cholesterol and phospholipids circulate as lipoproteins to cells everywhere in the body and are used to form membranes, intracellular structures, and other chemical compounds important to cellular function. In chronic cholestatic diseases, cholesterol excretion can be impaired, resulting in hypercholesterolemia.

Most excess carbohydrate and proteins are converted into lipids by the hepatocytes. Lipids thus synthesized are transported as lipoproteins into adipose tissue, where they are stored as fat.

Other Metabolic Functions

Vitamin Storage. The liver stores large amounts of vitamins, in particular vitamins A, D, and B_{12}. Storage of vitamins occurs in nonhepatocyte cells. For example, vitamin A is

stored in perisinusoidal stellate cells. Stellate cells, when activated, produce collagen and contribute to the pathogenesis of cirrhosis. It has been estimated that in a healthy individual, storage of these vitamins is sufficient to prevent deficiencies in spite of no intake for as long as 10 months for vitamin A, 3 months for vitamin D, and 1 year for vitamin B_{12}.

Iron Storage. Hepatocytes contain large amounts of apoferritin. When excess iron is available, it is taken up by hepatocytes and combined with aproferritin to form ferritin. Other than the iron in the hemoglobin, ferritin is the most important iron storage site in the body. Interestingly, several liver disorders, as well as most chronic liver diseases, are associated with increased iron storage in the hepatocytes.

Excretion of Exogenous Substances. Several important substances are excreted by hepatocytes into the bile. For example, the role of hepatocytes in the excretion of calcium via the bile and into the gut and feces is often overlooked. Many drugs are metabolized and excreted by the hepatocytes in the liver. Some of these include penicillins, sulfonamides, erythromycin, cyclosporine, and most anticonvulsants. Hormones, such as thyroxine, estrogen, and cortisol, are also metabolized or excreted by the liver. Liver failure often leads to accumulation of these hormones. For example, excess estrogen effects can be seen in people with chronic liver disease.

LIVER REGENERATION AND HEPATOCYTE PROLIFERATION

Although the conventional wisdom only 20 years ago placed the liver and the brain as organs exhibiting little proliferation, remarkable studies in liver regeneration after hepatectomy, living-related liver transplant, and seminal work in hepatocyte transplant have shown that hepatocytes can proliferate rapidly and are able to undergo over 20 cell divisions.[7] Such remarkable proliferation was already hinted at by the ancient Greeks in the myth of Prometheus, who had his liver eaten daily by an eagle only to regenerate it by night. Hepatocyte regeneration after liver injury is closely regulated by molecular and biochemical processes.[8] Most liver injuries resulting in significant reduction of the liver mass are followed by transcription of immediate early genes and result in key growth factors and mediator release, including hepatic growth factor (HGF), epidermal growth factor, and transforming growth factor-α. The serum concentrations of these factors, in particular that of HGF, vary according to the type and degree of liver injury. HGF promotes proliferation by binding to its receptor, the cellular homologue of the *met* oncogene, in activated cells. HGF is a heterodimer glycoprotein produced by nonparenchymal liver cells as a proprotein. Transcription of the HGF gene increases 12 to 24 hours after surgical resection in rodents. However, infused HGF in the normal rat does not cause hepatocyte proliferation. For hepatocytes to proliferate, initial signals must have moved hepatocytes from their resting G_0 cell-cycle stage to the G_1 stage, where they are committed to undergo regeneration. Deoxyribonucleic acid (DNA) synthesis begins a few hours after hepatectomy or injury, resulting in a reduction of liver mass. A coordinated cascade of events occurs prior to DNA synthesis involving unique genes that are highly expressed early during this process. These genes encode a variety of proteins, such as transcription factors, tyrosine phosphatases, tyrosine kinases, membrane receptors, and, ultimately, enzymes and proteins involved in proliferation. The highest concentrations of liver-related growth factors are seen during acute liver failure and after major hepatic resection. Changes are modest in acute hepatitis and in chronic liver disease. These growth factors directly affect hepatocyte renewal and, provided that the liver environment is permissive, whether regeneration will keep up with cell death. The hope is that in understanding the regulation of these processes, new strategies for the treatment of diseases that injure the hepatocyte are developed.

APOPTOSIS IS A COMMON PATHWAY OF CELL DEATH DURING LIVER DISEASE

Apoptosis is an important component of hepatocyte physiology during organogenesis, regeneration, and liver disease.[9] Apoptosis is the process by which hepatocytes "tagged" for death undergo orderly cell disassembly and removal by macrophages without tissue inflammation. Apoptosis is regulated by a variety of internal and external factors or signals. Cells undergoing apoptosis include those injured by disease but also senescent cells or cells during regeneration, remodeling, and organogenesis. A classic example of apoptosis during organogenesis occurs in the hand during digit formation, which is accomplished by apoptosis of the budding hand tissue between the fingers. Similarly, apoptosis occurs during liver remodeling. During disease, for apoptosis to occur, cell injury has to be severe enough to overwhelm the cell's repair mechanisms. Sudden or too severe injury might cause cell destruction or necrosis instead.[10] At a molecular and ultrastructural level, apoptosis is characterized by internucleosomal cleavage of the DNA into fragments of 180 to 200 bp, chromatin condensation, shrinkage of cell volume, formation of apoptotic bodies, and blebbing of the plasma membrane. Because cleavage occurs at specific internucleosomal or unprotected sites, DNA fragments are formed that are a multiple of 180 to 200 bp, creating a ladder in an agarose gel after electrophoresis (Figure 5.3-3). In contrast, necrosis occurs as the result of rapid cell poisoning and is characterized by immediate loss of plasma membrane integrity.[11] In normal human liver, few apoptotic cells are seen because of the long half-life of hepatocytes. Examples of diseases during which apoptosis plays an important role include ischemia-reperfusion injury, viral hepatitis, autoimmune hepatitis, and toxic injury. FasL binding of the Fas receptor on the hepatocyte cell membrane has been shown to mediate cell death in many of these liver diseases.[12–16] Drugs that inhibit apoptosis have been postulated as potential therapies of some of these diseases. For example, a common medication used in people with liver disease, ursodeoxycholic acid, has antiapoptotic actions in addition to its choleretic effects. Strategies have been suggested for the treatment of liver disease via inhibi-

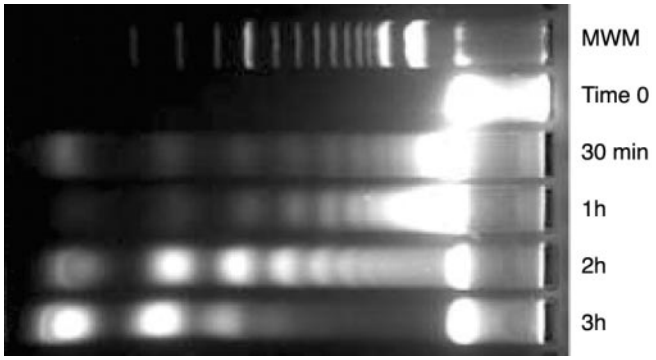

FIGURE 5.3-3 Deoxyribonucleic acid (DNA) fragmentation in detached hepatocytes was confirmed by DNA laddering after 30 minutes in detached culture. The degree of fragmentation, from oligo- to mononucleosomes, increased with time. MWM = molecular weight marker.

tion of tumor necrosis factor (TNF) family pathways and possibly the activation of nuclear factor-κB, a signaling molecule that might inhibit hepatocyte apoptosis.[17]

Specific pathways exist that can trigger apoptosis in hepatocytes. Apoptosis by activation of death receptors of the TNF superfamily, such as CD95/Fas, has been well characterized.[18] Soluble or cell-bound ligands, such as FasL, bind Fas on the surface of hepatocytes and promote formation of a death-inducing signaling complex. This complex, via the Fas-associated death domain protein, activates procaspase 8. In liver cells, caspase 8 activation leads to cleavage of Bid, a proapoptotic Bcl-2 family member.[19] Cleaved Bid translocates into the mitochondria, where it promotes cytochrome *c* release. In the cytoplasm, cytochrome *c* associates with Apaf-1 and then procaspase 9, forming the apoptosome. The apoptosome activates procaspase 3 and the downstream cascade of effector caspases 3, 6, and 7.[18] Effector caspase activation leads to a coordinated program of cell disassembly that results in apoptosis. It includes the selective cleavage of target proteins, DNA fragmentation, phosphatidyl serine translocation to the external aspect of the cell membrane, and characteristic morphologic changes, such as nuclear shrinkage, loss of cell shape, and membrane blebbing.[20] FasL binding of the Fas receptor on the hepatocyte cell membrane often mediates hepatocyte cell death during liver disease and can be readily reproduced in vitro (Figure 5.3-4). One described mechanism of alcohol-induced liver injury involves oxidative stress induced by overexpression of FasL on the surface of hepatocytes. Because hepatocytes constitutively express Fas, the receptor for FasL, overexpression of FasL results in self-induced death or "fratricide."[12,13] Another example of Fas-mediated liver cell death occurs during hepatitis.[15] Indeed, increased Fas antigen is detected in the liver tissue of patients with hepatitis C, and Fas pathways are a major mechanism of T cell–mediated cytotoxicity.[14] Additionally, Fas-mediated apoptosis also occurs in liver allograft rejection.[16] Apoptosis occurs in isolated and transplanted hepatocytes.[21] In liver cell transplant, Fas-FasL interactions have been studied as a way to enhance engraftment of transplanted hepatocytes.[22]

A delicate balance between pathways that promote and inhibit apoptosis exists. Bcl-2 is an example of a molecule that inhibits apoptosis in the liver. Bcl-2, a signaling molecule in the Fas pathway, inhibits Bid-mediated mitochondrial cytochrome-*c* release, a key event during Fas-induced apoptosis. Bcl-2 transgenic hepatocytes are protected from Fas-mediated liver apoptosis. Bcl-2 transgenic hepatocytes were transplanted into wild-type livers of mice treated with nonlethal doses of Jo2 antibody, an activator of Fas. Because of selective death of the recipient's hepatocytes by Fas activation, the transplanted Bcl-2 hepatocytes had a survival advantage and repopulated up to 16% of the host liver.[22] A similar strategy was used to achieve therapeutic liver repopulation in a mouse model of hypercholesterolemia.[23] Genetic manipulation has been used to enhance hepatocyte survival in liver transplants in rodents. Whole-organ liver transplants of mutant graft livers expressing an inactive form of Fas (MRC-lpr/lpr) were resistant to apoptosis induced by FasL overexpression after adenoviral transfection.[24] Although these data illustrate

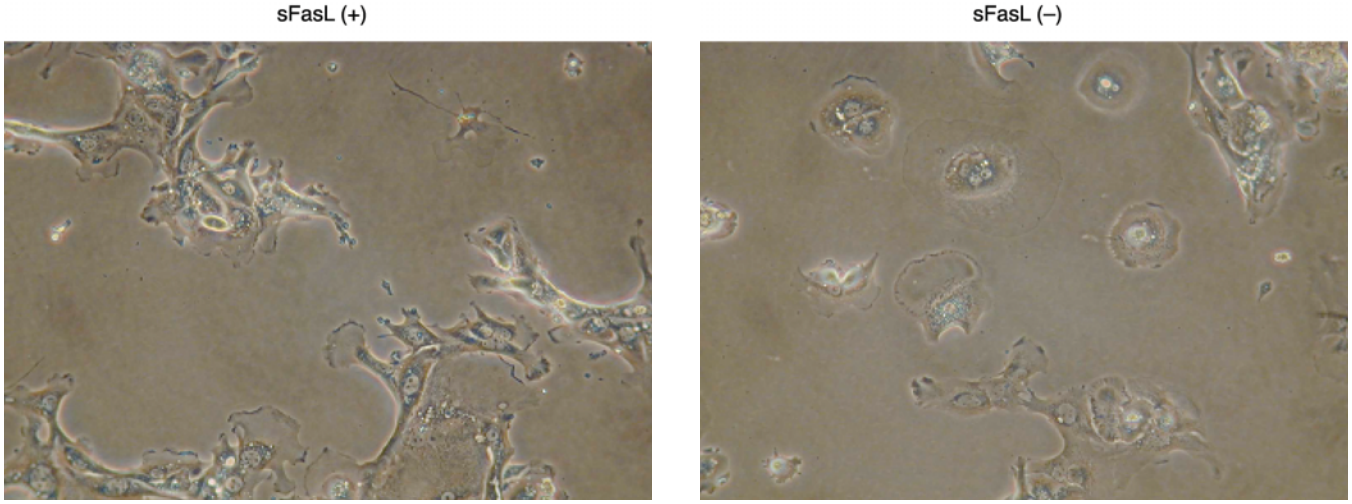

FIGURE 5.3-4 Phase-contrast microscopy of primary mouse hepatocytes in culture incubated with or without sFasL (50 ng/mL) for 12 hours. Changes in cell shape, loss of cytoplasm, and decrease in nuclear size are apparent in sFasL-treated cells (×200 original magnification).

important mechanisms, there is still much to understand regarding liver- and cell-specific signaling pathways. Bcl-2, an inhibitor of apoptosis signal transduction, for example, is actually not expressed normally in hepatocytes but in small bile ducts and in endothelial cells.

HEPATOCYTE NECROSIS

Hepatocyte necrosis occurs in acute liver failure by toxic or ischemic injury. Necrosis results in leakage of hepatocyte cytoplasmatic enzymes into the systemic circulation, which can be detected by elevation of alanine aminotransferase and aspartate aminotransferase. Other enzymes, such as sorbitol dehydrogenase and lactic dehydrogenase, also leak into the systemic circulation. In chronic liver diseases in which apoptosis is a predominant mechanism of injury, such as in hepatitis C, alanine aminotransferase elevation correlates only moderately well with inflammation. Cell death by necrosis occurs when the injury is intense or sudden; the mechanisms of defense and response to injury are overwhelmed. Rather than the organized cell disassembly that occurs with apoptosis, necrosis involves inflammation, accumulation of toxic metabolites, and activation of the liver's reticuloendothelial cells. Necrosis involves coagulation of the cell's proteins and disorganized loss of cell structure. During necrosis, the nucleus is often marginated, the cell swells, and histologic changes persist for days. Different toxins can produce necrosis in different areas of the hepatic lobule. Injury by carbon tetrachloride, for example, affects the centrilobular, less oxygenated hepatocyte zone 3 and is followed by hepatocyte proliferation (Figure 5.3-5). During acetaminophen overdose, an excess of the metabolite *N*-acetyl-*p*-benzoquinoneimine is produced that covalently binds to proteins and macromolecules, causing cellular damage. Under normal circumstances, this metabolite would be inactivated by binding to glutathione. During acetaminophen overdoses, however, free glutathione is quickly depleted, resulting in necrosis. Mechanisms of hepatocellular necrosis involve lipid peroxidation, mitochondrial damage, enzyme inhibition, and disruption of the cytoskeleton. Ceramides, for example, induce liver cell necrosis by causing adenosine triphosphate depletion and mitochondrial depolarization, leading to permeability transition and mitochondrial failure.[25] Other mediators can both protect or promote damage depending on the context. Nitric oxide, for instance, can protect from apoptosis, but it potentiates oxidative damage from warm ischemia reperfusion.[26] The hepatocyte is not the only cell involved during liver necrosis. Cellular events that occur following hepatocyte injury include sinusoidal cell activation, activation of Kupffer cells, and migration of inflammatory cells to the injury site that enhance hepatocyte damage.

MODELS OF HEPATOCYTE TRANSPLANT, PROLIFERATION, AND INJURY

Hepatocyte Transplant and Proliferation

Liver cell isolation has been possible for over 25 years by using calcium chelators that disrupt cell-cell desmosomal adhesion, followed by collagenase enzymes that break

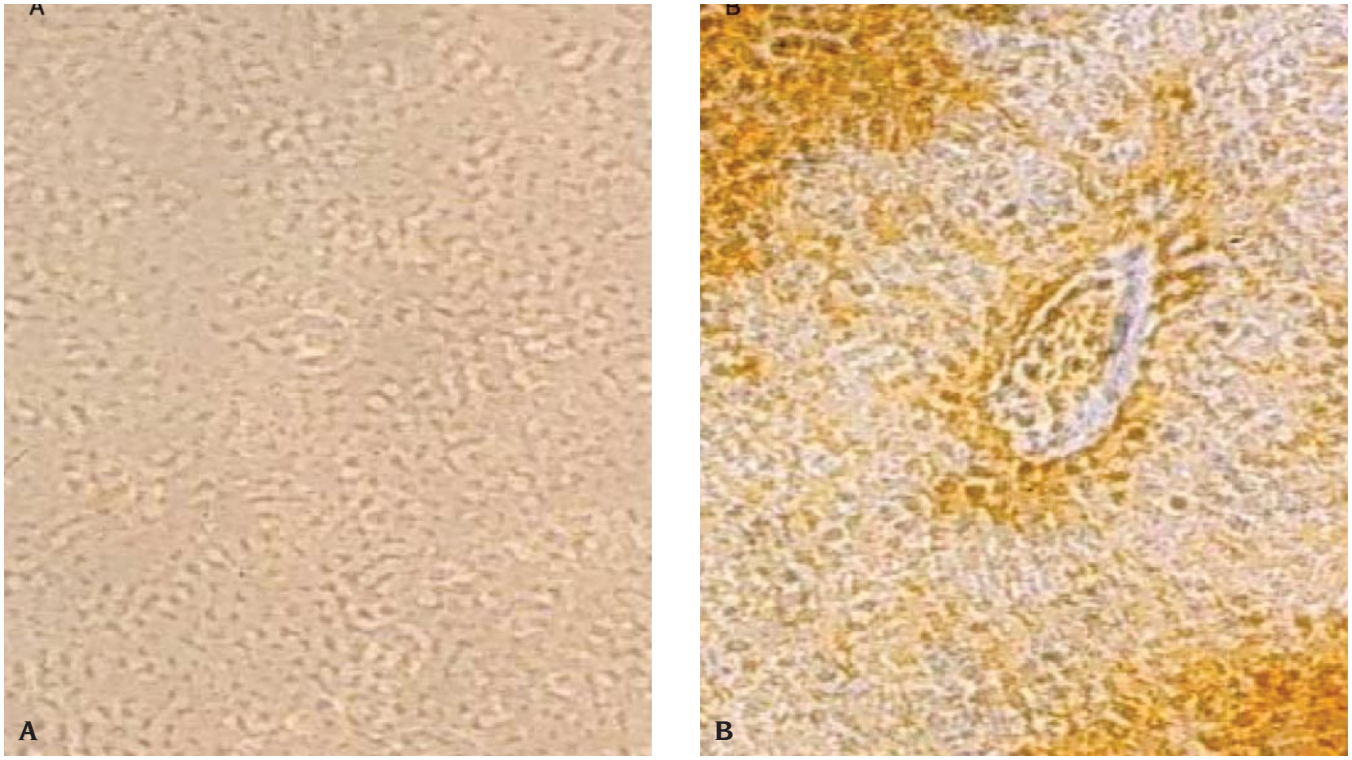

FIGURE 5.3-5 Proliferation and necrosis are evaluated in mouse liver sections 2 days after 0.5 mL/kg CCl_4 (*A*, control; *B*, CCl_4 treated). PCNA immunohistochemistry revealed that over 60% of hepatocytes, mostly periportal, showed positive staining, indicating proliferation. Necrosis is seen in pericentral hepatocytes. Untreated control mouse livers were unaffected. Immunohistochemistry; ×100 original magnification.

apart the organ's supporting structure.[27] It has been shown in animal models and in people with liver disease that hepatocytes can be transplanted into the liver parenchyma via the portal circulation, take permanent residence in the recipient liver, and provide metabolic function for the correction of acute, chronic, and genetic liver insufficiency.[7,28–33] Although the idea of liver cell transplant for the treatment of liver disease was first touted in 1977,[34,35] many hurdles remain before this technique can achieve clinical relevance, including massive cell loss and poor engraftment during liver cell transplant. In part because of poor initial engraftment, the potential of hepatocytes to proliferate after engraftment has been explored in transgenic and knockout animal models.[7,36] The concept that a survival advantage by transplanted cells could repopulate a diseased liver with healthy cells was first developed in a urokinase-type plasminogen activator transgenic mouse model.[36] This repopulation is feasible thanks to a high proliferative potential of hepatocytes, as demonstrated in serial transplant studies of mice with tyrosinemia.[7] More recent advances have shown the ability of non–liver-derived stem cells, such as bone marrow cells, to repopulate the diseased liver with functional hepatocytes.[37–39] However, in spite of this promising work on proliferation, it has been difficult to find clinically applicable methods that will reproduce these "survival advantage" conditions for transplanted liver cells or to create a safe hepatocyte stem cell line.

Transplanted Hepatocyte Function and Death

Hepatocytes can be transplanted and exhibit hepatocyte-specific function in an allogeneic recipient liver. Potential metabolic clinical relevance was suggested by results in a patient with Crigler-Najjar syndrome who had a significant reduction in serum bilirubin concentrations after repeated liver cell transplant.[29] In support of a clinical cure after cell therapy, a recent breakthrough in the field of solid organ cell transplant was recently reported. Patients with insulin-dependent diabetes mellitus were cured after pancreatic islet transplant into the portal vein.[33] A principal reason given for this cell therapy trial's success was the improved cell quality and preparation procedures that prevented cell injury and death. Engraftment efficiency is low after liver cell transplant. Although permanent engraftment and function of transplanted hepatocytes in mice were shown over 10 years ago using transgenically tagged hepatocytes,[40,41] only 0.03 to 0.5% of hepatocytes in the recipient liver could be identified as transplanted cells after a single-cell infusion. This is surprising because, in mouse studies, typically 2 million cells, or approximately 5% of the total recipient liver cells, are infused. This implies that 90 to 99% of the donor-infused hepatocytes are not detected and do not engraft in the recipient liver after cell infusion. Several studies show that ectopic engraftment after splenic or portal infusion in rodents is minimal and could thus not account for this large cell loss.[42,43] Because these studies occur in syngeneic or inbred animals, cell death by rejection is also not likely to occur. However, cell damage related to the isolation procedures and mediated by apoptosis might account for part of this cell loss.[21] Others have also described spontaneous apoptosis in freshly isolated hepatocytes in primary culture.[44] Potential mechanisms for this apoptosis in hepatocytes are being investigated and could involve loss of survival signals induced by collagenase perfusion, activation of Fas pathways, and loss of anchorage-induced apoptosis, termed "anoikis."[45] Attention to the molecular mechanisms that mediate this cell loss might provide information to improve the quality of transplanted liver cells and ultimately enhance engraftment efficiency, as suggested by the use of apoptosis inhibitors during cell transplant (Figure 5.3-6).

Liver Collagen Digestion and Cell Injury

Collagen, as a ligand for both integrins and tyrosine kinase receptors, plays an important role in cell differentiation, proliferation, and survival.[46–48] Collagenase perfusion is known to produce changes on the expression or the activity of several membrane receptors[49–51] and to result in reversible DNA damages.[52] Collagenase perfusion has been described to trigger apoptosis in cells prepared from non-regressing corpus luteum.[53] However, whether this induction is related to the detachment from the extracellular matrix, to the suppression of a survival factor, or to the induction of death signals remains unclear. Possible membrane proteins involved in this collagenase-induced apoptosis are the integrins family, the tyrosine kinase receptors family, and the death-associated domain such as Fas-

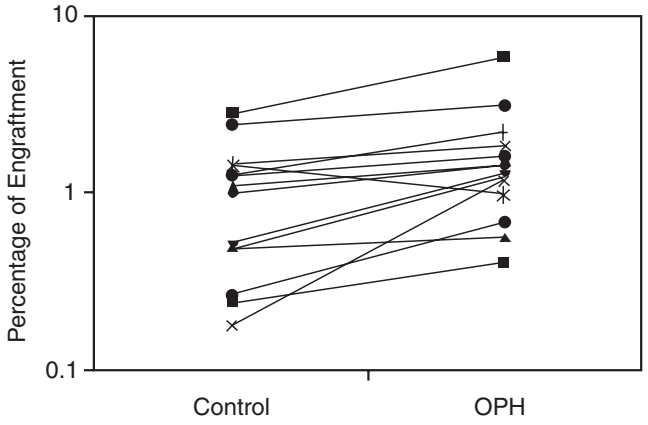

FIGURE 5.3-6 By inhibiting injury related to the hepatocyte isolation and transplant procedure, engraftment efficiency is increased by 60%. The figure shows the percentage of engraftment of transplanted hepatocytes in mice with and without the use of an apoptosis inhibitor, Q-VD-OPH. Two million male hepatocytes were transplanted in female mice. Fifteen paired mice were included in both the control group and the OPH group. In this later group, the broad-spectrum caspase inhibitor Q-VD-OPH was used at 20 μM in all of the solutions and 10 mg/kg was injected intraperitoneally in the recipients after the transplant and 3 hours later. The recipient livers were harvested after 3 days and homogenized, and deoxyribonucleic acid (DNA) was extracted. Donor-related DNA was quantified by real-time polymerase chain reaction for the Y chromosome. The percentage of male DNA in female DNA was 1.0 ± 0.06% and 1.7 ± 0.1% (mean ± SEM) for the control and the OPH group, respectively, with a significant increase of 60% in the OPH group compared with the control group (paired *t*-test, $p < .01$).

associated death domain. The integrins are the major receptors of collagen and extracellular matrix,[54] which maintain downstream transduction of survival signals. Cleavage or loss of signaling through the integrins could induce loss of survival signals such as FAK, PI-3K, and PKB/Akt.[55–57] Often in coordination with integrins, the tyrosine kinase receptors, which are mainly known to bind growth factors, also play a role in cell survival.[58] Collagenase action on liver cells could interact with survival signals mediated by those tyrosine kinase receptors because collagen is known to bind them.[48,59] Moreover, a crude preparation of collagenase also contains other proteases that could be involved in the death signals by nonspecific proteolysis of known receptors.[58–60] For example, the HGF receptor Met has been described to promote survival of a hepatocellular cell line by sequestration of Fas,[61] and its cleavage could lead to decreased activation, overexpression of Fas-associated death domain, and increased apoptosis. Additionally, although cell polarity is conserved immediately after isolation,[62] freshly isolated hepatocytes quickly demonstrate loss of cell polarity in culture, except if they are kept in collagen sandwich or tridimensional conditions.[63–65] Whether this loss of cell polarity could trigger apoptosis is currently unknown.

CHAPTER 6

PANCREATIC FUNCTION AND DYSFUNCTION

Mark E. Lowe, MD, PhD

The mature pancreas has two morphologically and functionally distinct populations of cells required to maintain nutritional balance: the endocrine cells responsible for producing the hormones and the exocrine cells that make the digestive enzymes. The endocrine pancreas, about 2% of the pancreatic cell mass, consists of islets populated by four principal cell types defined by the hormones they secrete. The exocrine pancreas, the portion responsible for producing and secreting digestive enzymes and bicarbonate-rich fluid, makes up the bulk of the gland. The capacity of the exocrine pancreas to synthesize proteins exceeds that of any other organ. Each day, the human pancreas delivers into the duodenum between 6 and 20 g of protein mixed in approximately 2.5 L of fluid. This productivity provides sufficient enzymes to digest dietary nutrients, including complex carbohydrates, proteins, and fats, and ensures an optimal pH for the activity of the enzymes.

Diseases of the exocrine pancreas range from acute pancreatitis, the self-limited inflammation of the gland, to pancreatic insufficiency, the inability to synthesize adequate quantities of digestive enzymes, resulting in the malabsorption of nutrients. In childhood, the first accounts of exocrine pancreatic disease were published in the 1930s with the description of cystic lesions and fibrosis of the pancreas.[1,2] Over time, this entity, cystic fibrosis, was documented as the most common cause of pancreatic insufficiency in childhood. Other causes of pancreatic insufficiency, mostly inherited diseases, are seen infrequently. Children can also develop acute pancreatitis, albeit at lower rates than in adults. Still, acute pancreatitis is seen regularly in large pediatric referral centers, and its incidence in childhood may be increasing.[3] Anomalies of pancreatic development, although rare, can cause acute or chronic pancreatitis or pancreatic insufficiency. This chapter first discusses the normal function of the exocrine pancreas and then describes current knowledge about the pathophysiology of exocrine pancreas dysfunction.

EXOCRINE PANCREATIC FUNCTION

Pancreatic Development

During embryogenesis, the pancreas develops from distinct dorsal and ventral outpouchings from the duodenum.[4] Recognizable pancreatic buds first appear at 4 to 5 weeks gestation. The buds proliferate, with the ventral remnant remaining smaller than the dorsal bud. Differential growth of the duodenum and axial rotation of the gut bring the ventral pancreas below the dorsal pancreas to the left of the duodenum. After the rotation finishes during the seventh week of gestation, the two buds fuse to form the pancreas. Concomitantly, the ductal systems of the two buds anastomose. By 9 weeks of gestation, groups of endocrine cells can be identified, and by 12 weeks of gestation, exocrine cells containing secretory granules are apparent. Genetic and metabolic mechanisms must underlie the commitment of a specific region of gut epithelium to a pancreatic fate, the convergence of the initially separate dorsal and ventral bud development, and the differentiation of specific pancreatic cell types.

To date, investigations, predominantly in mice, have identified only a few genes that influence pancreatic development.[5–8] Even fewer have been shown to function during the development of the exocrine pancreas. Several homeobox and basic helix-loop-helix transcription factors contribute to pancreatic development. Most of the identified factors influence endocrine cell differentiation, but one basic helix-loop-helix transcription factor, p48, is required for the development of exocrine cells.[9] Mice lacking p48 do not develop any exocrine pancreatic tissue. Two genes encoding homeobox proteins have also been implicated in development of the exocrine pancreas. One, *Pdx1*, acts prior to the commitment of the gut endoderm to a pancreatic fate.[10] *Pdx1*-deficient mice and humans fail to develop a pancreas.[10–13] They do, however, undergo evagination of the gut epithelium and form the dorsal and ventral buds. The second homeobox gene, *Hlxb9*, predominantly affects development of the dorsal pancreas, demonstrating a distinct difference in the developmental programs of the ventral and dorsal pancreas. In mice lacking *Hlxb9* function, only the ventral pancreas develops, although it has abnormal spatial organization and a disproportionate number of endocrine cells.[14,15] These observations implicate *Pdx1*, *Hlxb9*, and *p48* in early pancreatic development and also imply the existence of other genes that regulate even earlier stages of pancreatic development.

Multiple investigations have identified several signaling pathways that govern interactions in the developing

pancreas (Figure 6-1). Early experiments established the importance of cellular and humoral interactions between pancreatic epithelium and the adjacent mesenchyme on pancreatic organogenesis.[16,17] Both mouse and tissue culture experiments implicate epidermal growth factor, fibroblast growth factor, activin-β, a transforming growth factor (TGF)-β ligand, and the Notch signaling pathways as mediators of pancreatic growth and morphogenesis. Genetic studies in mice demonstrate that Notch signaling regulates pancreatic endocrine and exocrine cell fate.[18,19] Inhibition of Notch signaling promotes early endocrine cell differentiation at the expense of exocrine cell proliferation. Activin and fibroblast growth factor may act by repressing the expression of a transcription factor, Sonic hedgehog.[20] In mice that ectopically express Sonic hedgehog in pancreatic epithelium, the epithelium develops into gut instead of pancreas.[21] Mice deficient in Sonic hedgehog have overgrowth of the ventral pancreas.[22–24] Thus, repression of Sonic hedgehog in the posterior foregut endoderm prevents intestinal differentiation and promotes differentiation of the pancreas. Several lines of evidence suggest that the Hedgehog and Notch signaling pathways interact or act in parallel during pancreatic development.[5] All of these signaling pathways permit rather than instruct pancreatic development.

Even less is known about the genetic factors that control the specification of pancreatic duct cells. Evidence in mice suggests that a critical event for duct formation occurs in the first 2 weeks of gestation.[25,26] The surrounding mesenchyme influences the formation of pancreatic ducts, but the factors involved have not been identified.[27] One potential candidate is the basement membrane glycoprotein laminin-1.[28] Including laminin-1 in the culture medium of embryonic pancreatic epithelium permits the differentiation of ducts and acini. In contrast, epithelium cultured in the absence of laminin-1 develops into islets.

Exocrine pancreatic development continues after birth with the postnatal maturation of specific digestive enzymes.[29] Many enzymes, particularly the proteases, are produced at adult levels at birth, but there are several notable exceptions. Pancreatic amylase expression is low at birth and rises slowly, reaching adult levels by 2 to 3 years of age.[29] In healthy infants, the amylase deficiency has no clinical consequences, perhaps because infants have limited amounts of complex carbohydrates in their diet. The other major enzyme deficiency is of pancreatic lipase, the enzyme responsible for digesting dietary triglycerides.[29–32] A homologue of pancreatic lipase, pancreatic lipase–related protein-2, may compensate for the low levels of pancreatic lipase expressed during the first months of life, as may

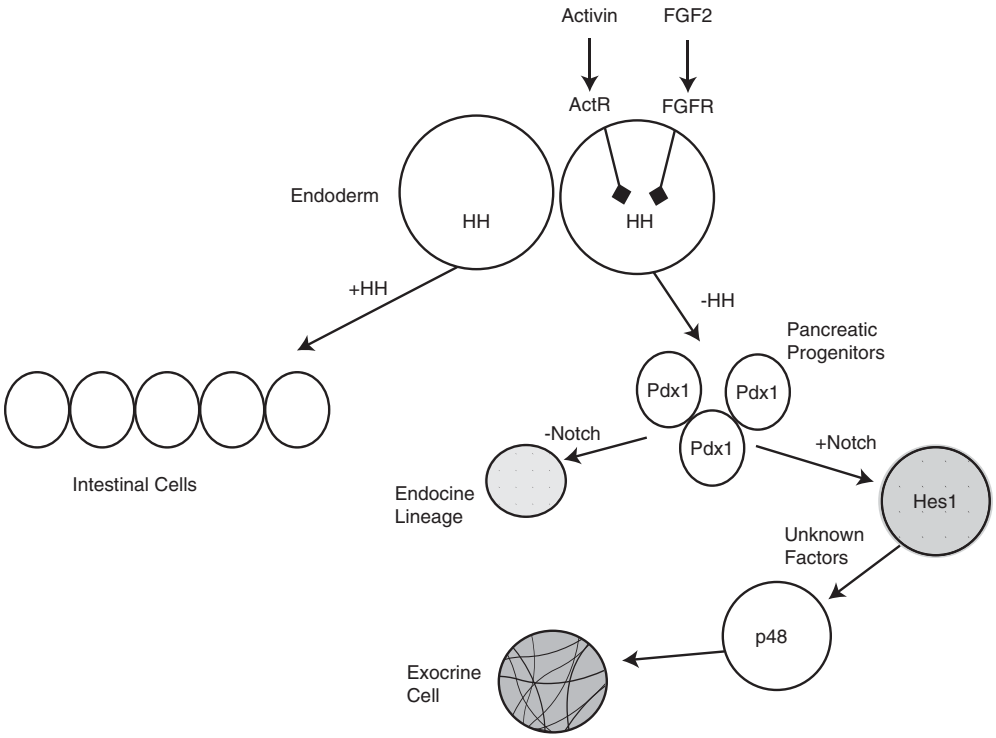

FIGURE 6-1 Differentiation pathway of pancreatic development. In contrast to intestinal progenitors, endodermal pancreatic progenitors do not express hedgehog (HH) signaling molecules. HH signaling is controlled by activin and fibroblast growth factor 2 (FGF2) through interactions with their respective receptors, ActR and FGFR. Evagination and bud formation are independent of the transcription factor Pdx1, but growth and differentiation of the pancreas require Pdx1 expression. Notch signaling pathways appear to control the divergence of the endocrine and exocrine pathways. Active signals through the Notch pathway stimulate cells that express high levels of the transcription factors Hes1 and p48. Other as yet unidentified factors control progression of cells toward the mature exocrine cell. Adapted from Edlund H.[7]

another pancreatic protein, carboxyl ester lipase.[33–36] Consequently, premature and newborn infants absorb large dietary fat loads with only a small increase in steatorrhea compared with that of older infants.[37] The molecular mechanisms that regulate the temporal changes in amylase and pancreatic lipases after birth are unknown but may respond to changes in dietary intake.

Functional Anatomy

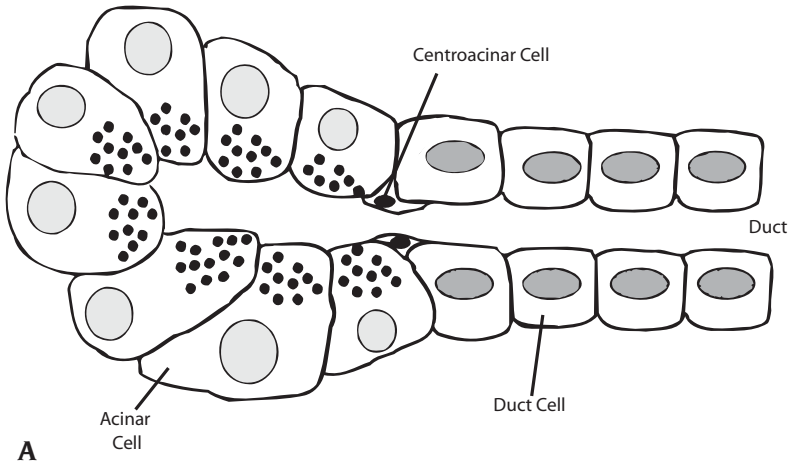
The exocrine pancreas contains lobules of parenchyma bound together by connective tissue. Each lobule contains a complex structure of acini, which account for greater than 80% of the parenchyma, and a ductal system, which makes up about 5% of the gland mass.[38] An acinus may be the terminal structure of a duct, or acini may form on the sides of a duct as it traverses a lobule.[39] In general, each acinus consists of six to eight pyramidal acinar cells with their apical poles facing a lumen that leads into a duct (Figure 6-2A). The acinar cells possess the features of specialized secretory cells, an elaborate network of rough endoplasmic reticulum, a prominent Golgi complex, and large numbers of secretory vesicles called zymogen granules (Figure 6-2B).

Each acinus drains into intercalated ducts, which fuse to form intralobular ducts that eventually drain into interlobular ducts. The interlobular ducts empty into the main duct as it courses through the tail and body of the pancreas. In the pancreatic head, the main pancreatic duct enters the duodenum at the ampulla of Vater. Additional drainage can occur via the accessory duct, which joins the main duct in the pancreatic head and enters the duodenum through a minor papilla in about 33% of people and ends blindly in about 8% of people. Nearly half of individuals do not have an accessory duct.[40] The shape of the ductal cells varies in the different regions. Centroacinar cells, the terminal cells of the duct, are squamous to low cuboidal cells with a sparse cytoplasm containing many mitochondria and no zymogen granules. Further down the ductal tree, the cells become cuboidal and then columnar. In addition to the main ductal cells, the ducts contain a number of specialized cells such as goblet cells.

Composition of exocrine secretions

Secretion of Inorganic Constituents. Pancreatic juice, a clear and colorless alkaline fluid, contains electrolytes and proteins.[41] Water, sodium, potassium, chloride, and bicarbonate are the principal inorganic constituents in pancreatic secretions. Pancreatic juice remains isotonic at all secretion rates, ranging from 0.2 mL/min to 4.0 mL/min, but the concentrations of bicarbonate and chloride change with secretin stimulation, the major regulator of volume output. At low secretion rates, the bicarbonate concentration equals that of plasma. As the secretion rate increases in response to secretin stimulation, the bicarbonate concentration increases to around 140 mEq/L in humans, which makes the pH of the juice about 8.2. Concomitantly, there is a reciprocal decrease in the chloride concentration such that the sum of bicarbonate and chloride remains constant at all secretion rates. These changes in anion concentrations take place because secretin stimulates water and bicarbonate secretion from pancreatic duct cells to a level that overwhelms the relatively small fluid and electrolyte flow from acinar cells. The net result produces pancreatic juice with a concentration of ions nearly identical to the concentrations found in pure ductal fluid.

Secretion of Organic Constituents. The pancreas synthesizes and secretes a variety of proteins, mainly hydrolases.[42,43] Twenty to 25 different proteins can be identified in pancreatic juice from all species, including humans (Table 6-1). Proteolytic, amylolytic, and lipolytic enzymes comprise the majority of the digestive enzymes. Many of these are synthesized and stored as inactive precursors or zymogens prior to secretion into the pancreatic duct. Consequently, there is little to no detectable activity of digestive enzymes in pancreatic fluid. Activity first appears in the duodenum when enteropeptidase, an intestinal brush



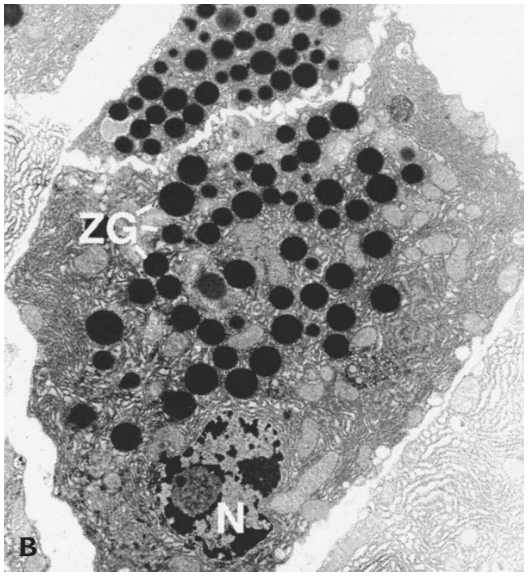


FIGURE 6-2 Anatomy of a pancreatic acinus and acinar cell. *A*, Schematic representation of a pancreatic acinus. *B*, Electron micrograph of an acinar cell (×10,000 original magnification). N = nucleus; ZG = zymogen granules.

border enzyme, triggers an activation cascade by converting trypsinogen to trypsin.[42] Trypsin, in turn, activates additional trypsinogen as well as the other zymogens (Figure 6-3). Through this activation cascade, the inactive zymogens convert to active enzymes.

The synthesis, packaging, and secretion of digestive proteins follow a well-established pathway.[44] Nascent protein chains are produced in the rough endoplasmic reticulum and then are moved into the Golgi apparatus for additional processing. In the Golgi apparatus, the digestive and lysosomal enzymes are efficiently sorted into separate compartments: the lysosomal enzymes into lysosomes and the digestive enzymes into condensing vacuoles. The latter then form mature zymogen granules, which are stored in the apical region of the acinar cell until the contents are secreted.

Protective Mechanisms. Inherent in the process of synthesizing and secreting digestive enzymes are mechanisms to protect the acinar cell from the premature activation of digestive zymogens.[45] The proteases and lipases produced in the acinar cell all have the capability to damage the pancreatic parenchyma if they are activated within the acinar cell or pancreatic duct. Producing inactive zymogens provides one important protective mechanism. Packaging the zymogens in a compartment separated from lysosomal enzymes, some of which can activate trypsinogen, provides another. Once trypsinogen is activated, pancreatic secretory trypsin inhibitor, SPINK1, provides a first line of defense by binding and inactivating trypsin. SPINK1 can inhibit only about 20% of potential trypsin, and if there is excessive trypsin activation, then free trypsin increases and can start activating other digestive enzymes. To protect against this situation, trypsin can be degraded by autolysis and by other proteases.

DIGESTION OF NUTRIENTS

Carbohydrates. Carbohydrates, in the form of starch or simple sugars, account for 40 to 50% of the calories in the Western diet. Starch, polymers of glucose, is the storage form of carbohydrate in plants, accounting for 10 to 80% of the plant volume. Amylose, a straight-chain α-1,4-linked glucose polymer, and amylopectin, a branched starch with a backbone of α-1,4-linked glucose with α-1,6-linked glucose branches about every 20 to 25 residues, are the major dietary starches. About 20% of dietary starch is amylose, and the remainder is amylopectin. Because the intestinal epithelium only absorbs monosaccharides, dietary starch must be hydrolyzed into glucose by the action of α-amylase.

α-Amylase is produced in the salivary glands by the parotids and in the pancreatic acini.[42] About 5 to 6% of the total protein in pancreatic secretions is α-amylase, an enzyme that preferentially cleaves interior α-1,4-glucose linkages. Neither terminal glucose residues nor α-1,6-linkages can be cleaved by α-amylase. The resulting products of α-amylase digestion are called dextrins, a mixture of maltose, maltotriose, and branched oligosaccharides of six to eight glucose units that contain both α-1,4 and α-1,6 linkages. Intestinal brush border enzymes, maltase and isomaltase, finish the digestion of dextrins.

Lipids. Dietary lipids provide an important source of energy in Western diets.[46] Triglycerides account for greater than 95% of the 100 to 150 g of fat consumed by adults each day. Before dietary fats can be absorbed by enterocytes, they must be digested into fatty acids and monoacylglycerols. In humans, the process of fat digestion begins in the stomach with the action of gastric lipase.[47] About 15% of

fatty acids are released in the stomach. Digestion then continues in the proximal small intestine with the addition of several different lipases from the pancreas.[48]

The contribution of two lipases, phospholipase A_2 and carboxyl ester lipase, to dietary fat digestion remains unresolved despite studies in mice deficient in either enzyme. Phospholipase A_2 hydrolyzes the fatty acid from the sn-2 position of phospholipids.[42] Although phospholipase A_2 has the potential to digest luminal phospholipids, phospholipase A_2–deficient mice absorb phospholipids from a test meal at a normal rate.[49] Either phospholipase A_2 makes no contribution to dietary phospholipid digestion or other enzymes compensate for the absence of this enzyme in phospholipase A_2–deficient mice.

Carboxyl ester lipase is one enzyme that could contribute to dietary phospholipid digestion and to the digestion of other dietary fats and fat-soluble vitamins.[50,51] All species from fish to humans produce carboxyl ester lipase, which constitutes up to 5% of the protein in pancreatic juice. In vitro, carboxyl ester lipase demonstrates broad substrate specificity, cleaving cholesterol esters, fat-soluble vitamin esters, triglycerides, ceramides, and phospholipids. Despite many years of research interest in this enzyme, the role of carboxyl ester lipase in dietary fat digestion remains enigmatic. Work with carboxyl ester–deficient mice demonstrates a role for this enzyme in the digestion of cholesterol esters, a minor dietary component, and in the absorption of vitamin A.[52] The contribution of carboxyl ester lipase to the digestion of other vitamin esters, dietary phospholipids, and dietary triglycerides remains speculative.

Pancreatic triglyceride lipase cleaves the majority of fatty acids from dietary triglycerides, as evidenced by patients with congenital deficiency of this enzyme who malabsorb 50 to 65% of dietary triglycerides.[53,54] A carboxyl esterase that prefers acylglycerides over other lipids, pancreatic triglyceride lipase hydrolyzes acyl chains of varying lengths and saturation from the sn-1 and sn-3 positions of tri- and diglycerides to produce fatty acids and 2-monoacylglycerols. Interestingly, the bile salts, dietary proteins, and phospholipids in the duodenum inhibit pancreatic triglyceride lipase. Colipase, a pancreatic protein with no enzymatic activity, restores activity by forming a complex with pancreatic triglyceride lipase.[55]

Proteins. Most adults in the Western world consume 70 to 100 g of protein daily. Protein digestion begins in the stomach with the action of pepsin and reaches completion in the intestine with digestion by pancreatic proteases.[56] The pancreas secretes various proteases, all as inactive enzymes. Trypsin, the predominant protease, plays a central role in the activation of the other zymogens. Three of the proteases, trypsin, chymotrypsin, and elastase, cleave internal peptide bonds, and two proteases, carboxypeptidases A and B, cleave amino acids from the carboxy-terminal of peptides. The combined action of gastric and pancreatic proteases digests dietary proteins into oligopeptides and free amino acids. Intestinal brush border enzymes further digest the oligopeptides prior to the absorption of both amino acids and small peptides by sodium- and hydrogen-coupled transporters.[56]

Control of Secretion

In humans, the exocrine pancreas secretes enzymes and fluid during fasting, the interdigestive period, and after eating, the digestive period.[57,58] The interdigestive period begins when food has cleared the upper gastrointestinal tract, mainly at night. In an individual who eats three meals a day, the digestive period starts after the first meal and continues until the evening meal clears the upper intestine, usually late in the day.

Interdigestive Secretion. The interdigestive secretory pattern cycles every 60 to 120 minutes with the three phases of the migrating myoelectric complex of the stomach and duodenum.[57,58] Phase I is a period of no motor activity and negligible pancreatic secretion. As motor activity increases in phase II, pancreatic secretion increases and reaches a maximum rate just before the onset of phase III motor activity. Both hormonal and neural mechanisms control interdigestive pancreatic secretion. The neural regulation involves vagal cholinergic and parasympathetic inputs. Of the gastrointestinal hormones, motilin and pancreatic polypeptide are the most likely candidates to influence interdigestive pancreatic secretion. Both hormones cycle during the interdigestive period and regulate the migrating myoelectric complex, and motilin stimulates and pancreatic polypeptide inhibits pancreatic secretion. Most likely, interdigestive secretions help clear the gastrointestinal tract of residual food particles, cellular debris, and bacteria.

Digestive Secretion. Exocrine pancreatic secretion during a meal occurs in three phases: the cephalic, gastric, and intestinal phases. Vagal nerves mediate the cephalic phase in response to seeing, smelling, chewing, swallowing, or thinking about food. Cephalic stimulation specifically stimulates acinar cell secretions without affecting ductal cell secretions.[59] The gastric phase begins when food enters and distends the stomach.[60] Gastric distention activates mechanoreceptors located in the body of the stomach and results in a low-volume, enzyme-rich secretion mediated by a vagal reflex. When gastric juice and food enter the duodenum, the intestinal phase of digestion begins, and a variety of hormones and enteropancreatic vagovagal reflexes stimulate pancreatic secretion. Now both ductal and acinar secretions increase. The primary mediator of ductal secretion is secretin, but maximum secretion requires cholecystokinin and cholinergic input as well.[61,62] Cholecystokinin is the major mediator of enzyme secretion, but a vagovagal reflex also contributes input. Other hormones, such as gastrin-releasing peptide, bombesin, and neurotensin, can stimulate pancreatic secretion in experimental models, but the effects may not be physiologically significant.

Exocrine Pancreatic Dysfunction

Exocrine pancreatic dysfunction occurs in a number of diseases, including congenital anomalies, inherited disorders,

and pancreatitis, both acute and chronic. In acute pancreatitis, the dysfunction reverses after resolution of the disease, but in diseases that cause irreversible damage to the gland, important clinical consequences result from malabsorption of nutrients. Because the pancreas secretes a large excess of digestive enzymes, much of the pancreas must be destroyed before malabsorption results. For instance, steatorrhea occurs only after greater than 95% of the capacity to secrete pancreatic lipase has been lost.[63] This section reviews recent studies that have provided insight into the molecular mechanisms of childhood diseases that cause exocrine pancreatic dysfunction.

Congenital Anomalies. Although much remains to be learned about the control of pancreatic development, misregulation of development probably gives rise to congenital anomalies of the pancreas and to some of the inherited disorders of the pancreas. Genetic studies of mice provide support for this concept and have identified candidate genes for many human diseases. Some of these studies have identified pathways involved in normal pancreatic development and suggest mechanisms for the development of pancreatic congenital anomalies. Inactivation of the genes encoding Indian hedgehog or Sonic hedgehog in mice causes overgrowth of ventral pancreatic tissue to produce a phenotype resembling the human disorder annular pancreas.[23,24] Ventral pancreatic ductal abnormalities similar to pancreas divisum occur in mice heterozygous for null alleles of genes encoding Indian hedgehog or Sonic hedgehog, as well as in mice deficient in *Smad2*, a component of the TGF-β signaling pathway.[5] Pancreatic hypoplasia in mice results from inactivation of *Hes-1* and *Jag-1*, genes producing proteins in the Notch signaling pathway.[64,65] Targeted disruption of the gene encoding a transcription factor, *Pdx1*, in mice results in the failure of the pancreas to develop, a rare disorder in humans called aplasia or agenesis of the pancreas. These findings led Stoffers and colleagues to identify a single homozygous nucleotide deletion in codon 63 of the human gene encoding *PDX1* in a patient with pancreatic aplasia.[13] The resultant frameshift mutation in *PDX1* caused the synthesis of a truncated and functionally inactive protein. Analysis of the *PDX1* gene in a second patient with pancreatic aplasia failed to find any abnormalities in the coding region of the gene, and immunohistochemistry showed normal distribution of *PDX1* in gastrointestinal endocrine cells.[66] These findings suggest, as would be expected, that other genes also influence the early development of the human pancreas.

Developmental disorders

Even though many of the molecular pathways controlling development of the exocrine pancreas remain to be identified, genetic defects in these pathways probably result in many of the conditions causing pancreatic dysfunction in pediatrics. Some of these disorders appear to be secondary to defects in early pancreatic development, even before the speciation of the acinar cells, and others involve regulation at later stages of development. Thus, defects of development range from a complete lack of the pancreas to defects in individual cell types of the pancreas, with relative preservation of the other cell types.

Shwachman-Diamond Syndrome. Shwachman-Diamond syndrome is the most common inherited cause of exocrine pancreatic dysfunction after cystic fibrosis. Histology of the pancreas from patients with Shwachman-Diamond syndrome reveals acinar cell depletion and replacement with fat.[67] The ductal system appears to be preserved, and physiologic studies show normal anion and fluid excretion with impaired production of digestive enzymes.[68] Recently, mutations in the *SBDS* gene were associated with this syndrome.[69] The gene resides on chromosome 7q11 and contains five exons, which encode a predicted 250–amino acid protein of unknown function, although the structure of the predicted protein suggests that the protein may be involved in ribonucleic acid processing. Sequence analysis of 316 alleles from affected individuals revealed that 82% had mutations in the *SBDS* gene. Most of the mutations resulted from gene conversion owing to recombination between the gene encoding *SBDS* and a pseudogene of the *SBDS* gene. A few mutant alleles from affected individuals did not have conversion mutations and, instead, had frameshift or missense mutations. None of the mutations were present in the alleles of 100 controls.

Johansson-Blizzard Syndrome and Jeune Syndrome. Several other rare genetic syndromes in which the genetic defect is not known also include pancreatic exocrine dysfunction as part of the phenotype. Patients with Johansson-Blizzard syndrome have absent pancreatic acini with replacement by connective tissue.[70] Their ducts and islets appear normal and, similar to those in Shwachman-Diamond syndrome, function normally.[71] In Jeune syndrome, pancreatic fibrosis and cyst formation produce exocrine pancreatic insufficiency associated with skeletal, renal, and liver abnormalities.[72] Both of these syndromes may well result from the failure of pancreatic acinar cell development.

Pearson Syndrome. In 1979, Pearson and colleagues reported four children with bone marrow failure and exocrine pancreatic disease characterized by both acinar and ductular deficiencies.[73] Histology shows acinar cell loss, fibrosis, and siderosis but no fatty infiltration. The syndrome is caused by deletions in mitochondrial deoxyribonucleic acid (DNA), leading to defects in oxidative phosphorylation and energy production.[74,75] Presumably, the inability to meet the energy demands of the acinar cells leads to their injury and death by apoptosis.

Isolated Enzyme Deficiencies. Several articles report patients with deficiencies of individual pancreatic digestive enzymes and of enterokinase, an intestinal brush border enzyme that activates pancreatic proenzymes.[76] Inherited deficiencies of pancreatic lipase, colipase, amylase, trypsinogen, and enterokinase have all been reported.[76] These entities are extremely rare, and no gene defects have been described in patients with any of these reported deficiencies.

PANCREATITIS

Acute Pancreatitis. The pathophysiology can be conveniently divided into three phases.[77] A variety of extrapancreatic triggering events initiate the onset of pancreatitis (Figure 6-4). In adults, the most important triggers are the passage of gallstone or ethanol ingestion. In children, systemic illness, trauma, and congenital anomalies predominate, although gallstone pancreatitis occurs in childhood. Next, a series of intra-acinar cell events produce cellular injury and local tissue damage. Studies in animals suggest that the normal secretion of digestive enzymes is altered during pancreatitis, and these changes induce activation of trypsinogen and other zymogens within the acinar cell. Lastly, acinar cell damage induces a variety of changes, including the production of proinflammatory cytokines, the generation of reactive oxygen species, and abnormalities in the local circulation. The severity of the clinical course depends on the magnitude of these changes and on the induction of a systemic inflammatory response.

Initiating Events. The triggers of acute pancreatitis fall into several broad categories.[78] Obstructive causes are common in adults but less common in children. Gallstones, pancreas divisum, choledochal cysts, gastric or duodenal duplication cysts, and periampullary lesions such as Crohn's disease or duodenal ulcer disease can obstruct pancreatic flow and lead to acute pancreatitis in children. Several theories have been proposed to explain gallstone pancreatitis, including obstruction of the ampulla with a stone and subsequent reflux of bile into the pancreatic duct, repeated passage of small stones to produce fibrosis, and incompetence of the ampulla of Vater, which allows reflux of duodenal content into the pancreatic duct, and transient obstruction of the pancreatic duct with increasing pressure in the duct, leading to extravasation of pancreatic juice into the interstitium of the gland. Increased ductal pressure secondary to relative stenosis of the minor papilla may be the mechanism of pancreatitis in pancreas divisum. Similarly, periampullary lesions can increase ductal pressure by causing edema or fibrosis around the ampulla of Vater that interferes with drainage of the duct.

The mechanism of other triggers is similarly speculative.[78] Drugs or their metabolites may interfere with cellular metabolism in a variety of ways. For instance, ethanol stimulates pancreatic secretion through the effects on gastric acid secretion, and the metabolites of ethanol are cytotoxic. Thiazides may alter calcium metabolism. In lipid disorders, which may be induced by drugs or associated with familial hyperlipidemias, high local fatty acid concentrations, from the action of either pancreatic lipase or lipoprotein lipase, may overwhelm the capacity of albumin to bind fatty acids and render them nontoxic. The unbound fatty acids may then cause increased cytotoxicity. Another frequent cause, trauma, disrupts the integrity of the ductal system and allows extravasation of digestive enzymes into the pancreatic parenchyma and adjacent fat. A common but often underappreciated cause of acute pancreatitis, low blood flow as in shock, produces pancreatic inflammation and necrosis through an ischemia or reperfusion injury.

Acinar Cell Events. Evidence from animal studies suggests that one of the earliest events in acute pancreatitis is the colocalization of digestive zymogens and lysosomal hydrolases in acinar cells.[77,79] Normally, the digestive zymogens and lysosomal hydrolases are packaged separately, but a disruption of normal secretion, as induced in experimental pancreatitis, leads to a defect in intracellular transport and sorting of enzymes. Consequently, digestive zymogens and lysosomal hydrolases colocalize within the same cytoplasmic vacuoles. The lysosomal hydrolases, in particular cathepsin B, activate trypsinogen. During this process, the vacuoles disintegrate and release their contents into the cytoplasm and injure the acinar cells. Multiple lines of evidence support the colocalization theory, including the observations that formation of cytoplasmic vacuoles containing digestive and lysosomal enzymes occurs before evidence of cell injury, that cathepsin B can activate trypsinogen in vitro, that trypsin activation peptide first appears in these cytoplasmic vacuoles, that specific cathepsin B inhibitors can prevent the activation of trypsin in isolated acinar cells after hyperstimulation with cerulein, and that cathepsin B–deficient mice have a defect in trypsinogen activation after cerulein hyperstimulation. On the release of the vacuole contents, trypsin can activate other zymogens, freeing them to damage the acinar cells.

Although autodigestion of the acinar cell by digestive enzymes plays a central role in most theories of acute pan-

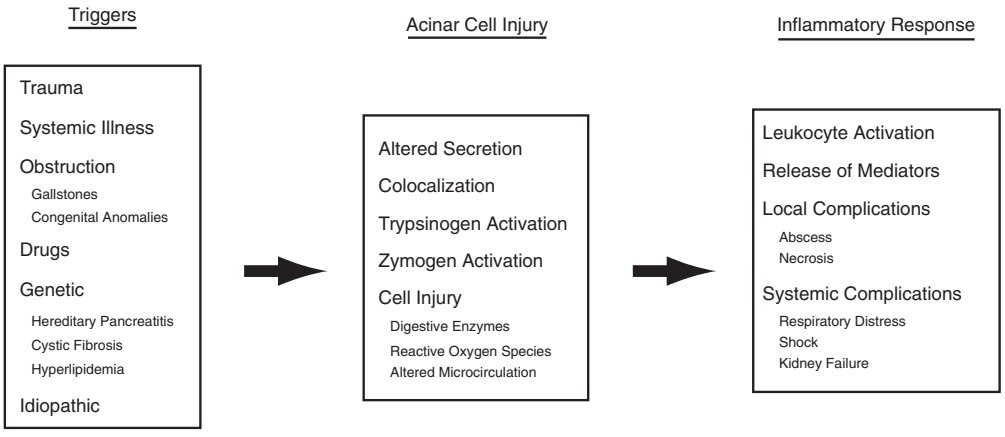

FIGURE 6-4 A model for the pathophysiology of pancreatitis.

creatitis, other processes may also contribute to acinar cell damage in early pancreatitis. Several authors have touted the role of reactive oxygen species in acute pancreatitis.[80,81] They base their arguments on data showing an increase in lipid peroxides during experimental pancreatitis, an alteration in cytoskeleton function by lipid peroxidation leading to abnormalities in transport of digestive enzymes and to their premature activation in acinar cells, and an increase in cell permeability correlated with the high production of both free oxygen radicals and activated zymogens. Additionally, abnormalities of the blood supply probably contribute to early injury. Vascular injuries can clearly induce acute pancreatitis, but alterations in the microcirculation have been documented in other forms of pancreatitis. In experimental pancreatitis, hypoperfusion occurs in severely injured regions, whereas less injured regions maintain good perfusion.[82] Finally, activation of resident macrophages in the pancreas and the migration of activated leukocytes into the pancreas contribute to the severity of gland inflammation in acute pancreatitis.[83–85] Nude mice lacking lymphocytes have decreased severity of pancreatitis in experimental models. The transfer of T lymphocytes into nude mice increases the severity of cerulein-induced acute pancreatitis.

Late Events. Acinar cell damage produces pancreatic edema and a local inflammatory response associated with the release of inflammatory mediators into the systemic circulation.[86,87] These cytokines and chemokines mediate a systemic inflammatory response, a common pathway in many forms of injury. The clinical severity of pancreatitis depends in part on the magnitude of this systemic response, and the balance between proinflammatory and anti-inflammatory mediators ultimately influences the clinical course. In response to a brisk systemic inflammatory response, activated leukocytes migrate into other organs, particularly the lungs, kidneys, and liver, and cause tissue edema and damage. Thus, according to current data, the activated immune response plays the major role in the systemic complications of acute pancreatitis.[86,87] Most likely, the damage of distant organs by circulating pancreatic digestive enzymes is minimal.

Chronic Pancreatitis

Early in the course, chronic pancreatitis may be difficult to distinguish from acute pancreatitis on clinical grounds.[45] In chronic pancreatitis, continued inflammation of the pancreas produces irreversible morphologic changes in the gland. When available, histology shows irregular fibrosis, acinar cell loss, islet cell loss, and infiltration by inflammatory cells. The clinical diagnosis depends on identifying decreased function and chronic changes by imaging studies, which represent late changes in the disease. The difficulties in diagnosing chronic pancreatitis early in its development hinder clinical studies of natural history and of potential therapies to halt the disease process. Consequently, this uncertainty has fostered the proposal of many different theories to explain the pathophysiologic mechanisms in chronic pancreatitis.

Theories of Pathogenesis. Over the past 50 to 60 years, various investigators have suggested theories to connect the development of chronic pancreatitis with environmental factors, many concentrating on alcohol consumption.[88] The dominant view throughout the latter half of the twentieth century held that recurrent acute pancreatitis progressed to chronic pancreatitis. Some authors looked at clinical data and concluded that acute and chronic pancreatitis were separate diseases and developed various theories that did not include acute pancreatitis in the development of chronic pancreatitis. Sarles and colleagues introduced the concept of a primary defect in the pancreatic ducts leading to intraductal obstruction and tissue damage by increased intraductal pressure.[89] Others suggested that chronic pancreatitis results from the toxic and metabolic effects of the inciting agent, in particular alcohol, or from repeated oxidative stress.[90,91] In the early 1990s, Kloppel and Maillet refined the recurrent acute pancreatitis theory and proposed an important role for necrosis and subsequent fibrosis in the development of chronic pancreatitis.[92,93] Accordingly, they believed that repeated episodes of acute pancreatitis would induce areas of focal necrosis and healing with fibrosis. Although some skepticism over the necrosis-fibrosis hypothesis remains, the model recently gained strong support from the descriptions of the molecular defect in hereditary pancreatitis and the understanding that acute pancreatitis leads to typical chronic pancreatitis in these patients. A new proposal, the sentinel acute pancreatitis event or SAPE hypothesis, incorporates elements from each of these theories.[94] An additional feature of this model is the requirement for an initiating event to trigger the first episode of acute pancreatitis, the beginning of chronic pancreatitis, on the background of a continuous stress such as alcohol consumption (Figure 6-5).

Etiology and Risk Factors for Chronic Pancreatitis. Often after the diagnosis of chronic pancreatitis, the etiology remains unclear (Table 6-2). Even the presence of established risk factors does not provide a clear etiology in most cases because the majority of people, for instance those who consume alcohol, with these risk factors do not develop chronic pancreatitis. Other factors must be present for disease to occur, and, with this concept in mind, recent studies have focused on the importance of genetic predisposition to chronic pancreatitis.[45]

Hereditary Pancreatitis. First described in 1952, hereditary pancreatitis causes recurrent episodes of acute pancreatitis and, in about 75% of patients, chronic pancreatitis.[88] Multiple pedigrees have been well described, and it is clear that hereditary pancreatitis has an autosomal dominant inheritance pattern, with about 80% penetrance and a variable clinical course even among family members.[88]

The inheritance pattern of hereditary pancreatitis suggests that a single gene defect produced the disease. In 1996, a single point mutation in the third exon of the gene encoding cationic trypsinogen was shown to segregate with the disease.[95] The point mutation causes an arginine to histidine substitution at position 122. Subsequently,

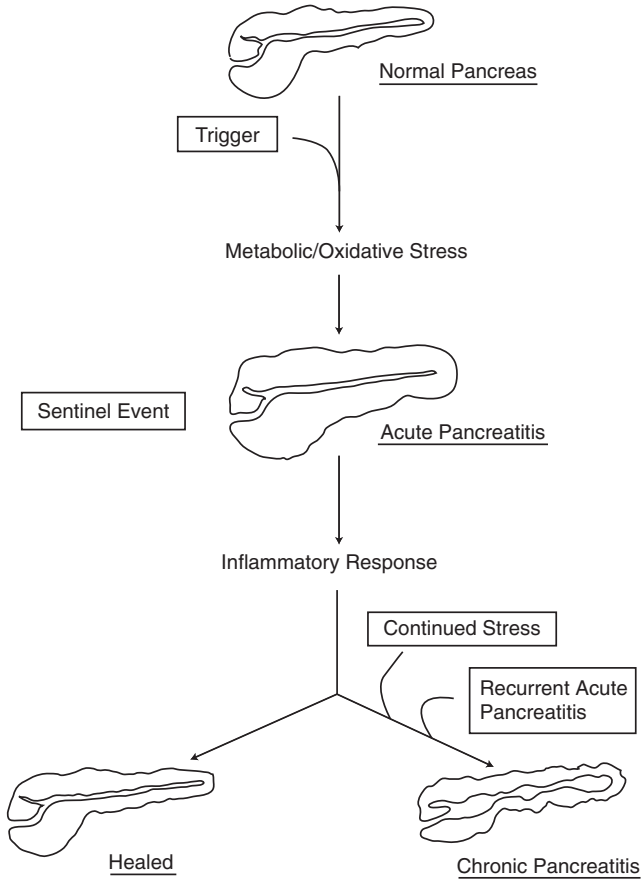

FIGURE 6-5 A hypothesis for the pathophysiology of chronic pancreatitis, the sentinel acute pancreatitis event hypothesis proposed by Whitcomb.[94] In this model, the normal pancreas is exposed frequently to metabolic or oxidative stresses, either drugs or toxins. In some patients, this exposure produces the initial episode of acute pancreatitis, the sentinel event. During the event, activated lymphocytes, macrophages, and stellate cells increase in number within the gland and produce cytokines and small amounts of collagen. With time, the number of cells diminishes, and the gland returns to normal. In the presence of continued stress or recurrent pancreatitis, the tissue macrophages and stellate cells remain active and continue to release cytokine and deposit collagen, a process that eventually causes the fibrosis characteristic of chronic pancreatitis.

other studies of pedigrees with hereditary pancreatitis revealed additional mutations in the gene encoding cationic trypsinogen, including N29I, A16V, D22G, K23R, and R122C. Three of these mutations, R122H, R122C, and N29I, account for the majority of patients.[88] The other mutations are extremely rare and are only weakly associated with pancreatitis.

Increased resistance of the R122H mutant trypsin to hydrolysis has been proposed as a model for the defect in hereditary pancreatitis.[45] Normally, the pancreas synthesizes trypsin as an inactive precursor, trypsinogen, along with pancreatic secretory trypsin inhibitor, SPINK1, at a ratio of 5 to 1. SPINK1 provides a first line of defense against premature trypsinogen activation inside the acinar cell (Figure 6-6). The second line of defense depends on the degradation of trypsin by autolysis and, perhaps, by other proteases. Degradation begins with hydrolysis after Arg122. In most cases of hereditary pancreatitis, the substitution of histidine at position 122 prevents autolysis. In vitro studies confirm the resistance of R122H to autolysis and also demonstrate that the mutation increases autoactivation of the mutant trypsinogen.[96] Similar studies on the N29I human cationic trypsinogen reveal that the mutation results in faster autoactivation and increased trypsin stability.[97] Consequently, both N29I and R122H trypsin mutants are more likely to accumulate in acinar cells and cause increased activation of other zymogens, and people with one of these mutations develop pancreatitis more readily than people who have normal trypsinogen.

Cystic Fibrosis Transmembrane Regulator. Cystic fibrosis is the most common cause of pancreatic insufficiency in pediatrics.[98] The autosomal recessive disorder results from mutations in the cystic fibrosis transmembrane regulator (CFTR), a membrane protein found on the apical membrane of ductal cells, where it regulates chloride conductance and water flow. Over 900 different mutations in CFTR cause disease. These mutations fall into five major classes (Figure 6-7). Classes I, II, and III result in complete loss of CFTR function because of defective protein production, abnormal protein processing, and abnormal regulation of chloride conductance, respectively. In general, these mutations cause more severe disease manifestations. Class IV and V mutations produce milder symptoms because these mutations result in mutant CFTR with decreased conductance properties or in decreased synthesis of normally active CFTR. Individuals with cystic fibrosis may be homozygous for one genetic mutation or heterozygous for two different mutations. About 85% of patients with cystic fibrosis have pancreatic insufficiency. Patients homozygous for severe mutations, classes I, II, and III, are affected. Those with at least one less severe mutation are usually pancreatic sufficient.

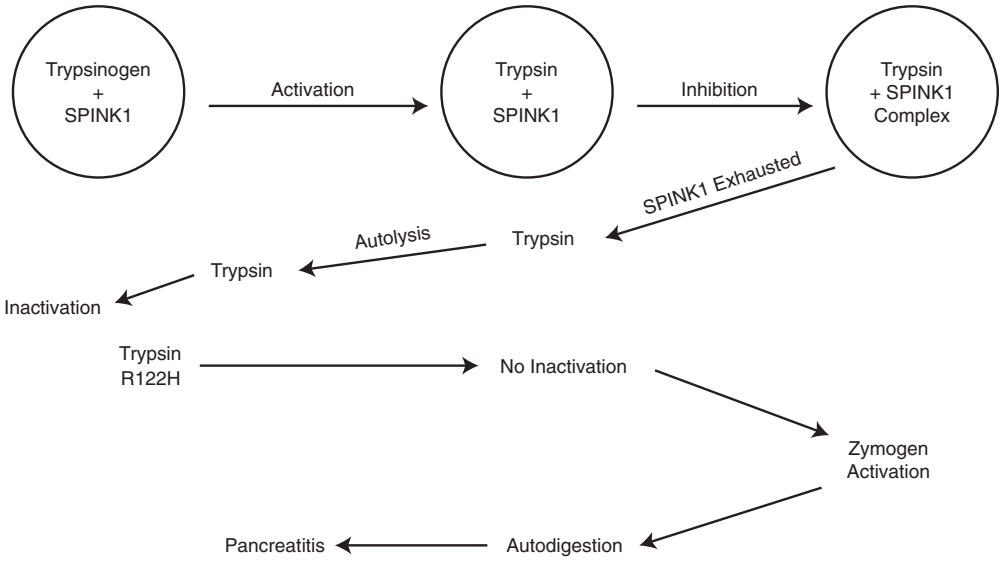

FIGURE 6-6 Model of hereditary pancreatitis. Trypsinogen and SPINK1 are packaged in zymogen granules at a 5:1 molar ratio. When trypsinogen is activated within the acinar cell, inhibition by SPINK1 represents the first line of defense against activation of the zymogen cascade. In the presence of robust trypsinogen activation, SPINK1 concentrations are overwhelmed, and protection depends on the inactivation of trypsin by autolysis. Trypsin hydrolysis begins with cleavage after Arg122, the mutated residue in hereditary pancreatitis. Consequently, this protective mechanism fails in patients with hereditary pancreatitis, and free trypsin levels accumulate, thereby favoring the activation of other zymogens and the development of acute pancreatitis.

The histopathology of the pancreas in cystic fibrosis varies considerably. Patients with mild disease may have a normal pancreas. Severely affected patients have a shrunken, cystic, and fibrotic pancreas with fatty changes.[99] Pancreatic damage results from obstruction of small ducts by precipitated proteins and cellular debris, changes that can be found in the prenatal pancreas. Involvement of large ducts, usually stenosis, is uncommon. Cystic spaces filled with eosinophilic, calcium-containing concretions develop secondary to duct blockage and acinar cell damage (Figure 6-8). Mild inflammatory changes and fibrosis develop around damaged acini. Even as fibrosis progresses, the islets of Langerhans remain intact until later in life.

Decreased chloride and bicarbonate secretion into the duct produces the pancreatic pathology observed in cystic fibrosis.[76,98] Although the mechanism remains debatable, the secretion of chloride by CFTR facilitates the secretion of bicarbonate by ductal cells. The increased concentration of these anions draws water into the duct, thereby producing the alkaline fluid needed to keep the highly concentrated digestive enzymes soluble in pancreatic juice. When CFTR is not present, pancreatic duct cells have greatly impaired secretion of chloride, bicarbonate, and water. The net effect diminishes flow and increases protein concentration in the ducts, a situation that promotes protein precipitation and the formation of inspissated secretions. These secretions obstruct the ducts, which causes acinar cell injury. In addition, the low pH of the duct lumen may inhibit membrane trafficking at the apical surface of the acinar cells, further disrupt secretion, and provide more protein for plug formation.[100]

CFTR and Idiopathic Pancreatitis. Recently, evidence has accumulated to implicate abnormal CFTR alleles in chronic pancreatitis in patients without other clinical features of cystic fibrosis.[101,102] In 1998, two groups reported an association between mutations in the gene encoding CFTR and patients with idiopathic chronic pancreatitis.[103,104] Although the initial reports found a correlation between mutations in a single CFTR allele and chronic pancreatitis, a later study with more detailed analysis of the CFTR alleles correlated risk with having two CFTR mutations.[101] These patients had compound heterozygous genotypes consisting of a severe CFTR mutation and a mild-variable mutation resulting in residual CFTR function. Their risk for developing chronic pancreatitis was increased 40-fold over the general population. The mechanism is probably similar to that described above for patients with cystic fibrosis.

Pancreatic Secretory Trypsin Inhibitor. The association of cationic trypsinogen with hereditary pancreatitis (see above) led to the search for families with mutations in SPINK1. SPINK1 is synthesized in acinar cells and packaged with trypsinogen, where it acts as the first line of defense against premature trypsinogen activation. Loss of SPINK1 function would presumably allow the accumulation of trypsin in the acinar cell and permit activation of other zymogens to cause acute pancreatitis and, eventually, chronic pancreatitis. In 2000, mutations in the gene encoding SPINK1 were correlated with idiopathic chronic pancreatitis.[105] Later, mutations in the SPINK1 gene were associated with tropical pancreatitis in Bangladesh.[106] Interestingly, the mutations N34S and P55S, implicated in

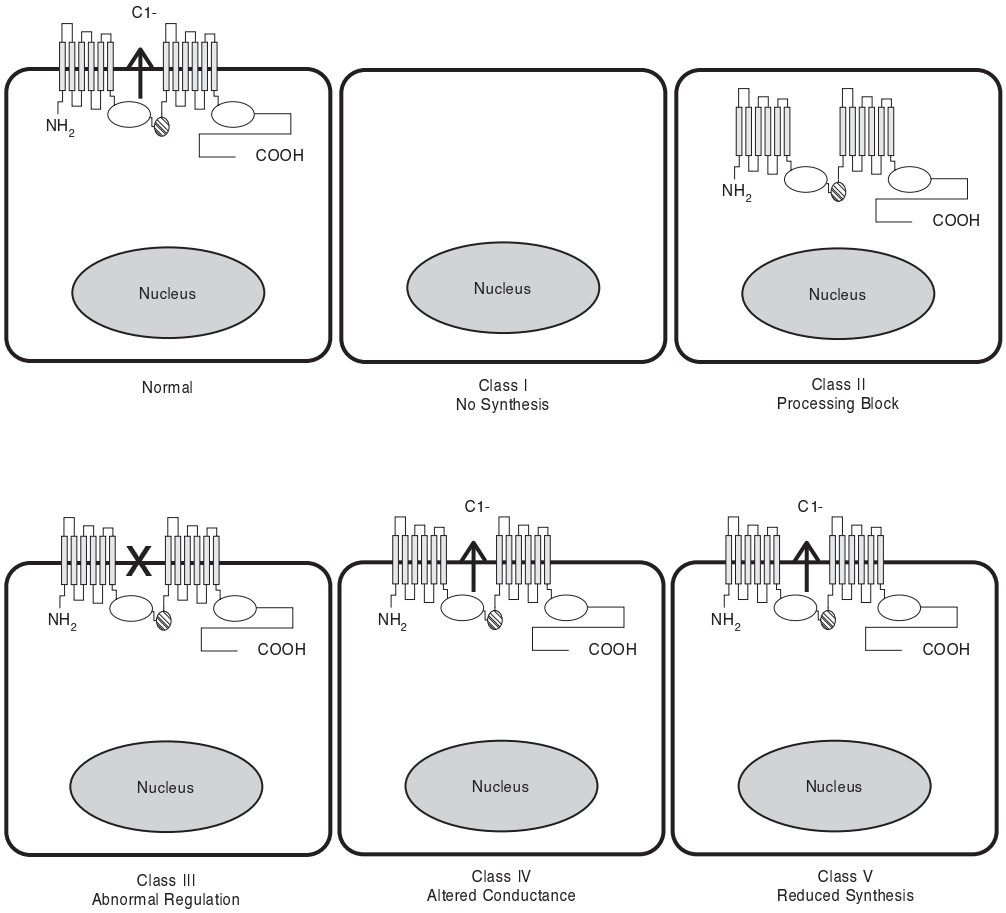

FIGURE 6-7 Mechanisms of defective cystic fibrosis transmembrane regulator (CFTR) function for the various classes of CFTR mutations. Class I: nonsense or frameshift mutations prevent the translation of CFTR protein. Class II: missense or deletion mutants do not block translation of CFTR protein, but the resultant protein does not fold properly and is degraded within the cell without reaching the cell surface. Class III: missense mutations that alter the properties of the regulatory units in CFTR, producing an inactive or poorly active transporter. Class IV: missense mutations that reduce the chloride flux through CFTR. Class V: missense mutations that decrease the synthesis of active CFTR.

chronic pancreatitis, represent 1% and 2%, respectively, of the alleles in the general population. Because of the high prevalence of these alleles and the low incidence of chronic pancreatitis, the risk of a SPINK1 mutation carrier developing chronic pancreatitis is only about 1%. Thus, the disease mechanism cannot simply be autosomal recessive inheritance. It must be more complex. Currently, SPINK1 mutations are considered disease modifiers, as illustrated by studies that analyzed patients with idiopathic chronic pancreatitis for both CFTR and SPINK1 mutations.[45] The risk for developing chronic pancreatitis was increased 900-fold in patients with mutations in both genes.[101]

CHAPTER 7

MITOCHONDRIAL FUNCTION AND DYSFUNCTION

Narmer F. Galeano, MD

The study of the structure and function of mitochondria represents one of the most fascinating chapters in the history of cellular and molecular biology.[1] First described by Altman in 1890, mitochondria were among the first organelles to be studied with the electron microscope by Sjostrand and Palade.[1] An important development in the understanding of mitochondrial physiology was the discovery by Lehninger and others that the process of oxidative phosphorylation (OXPHOS) occurs in mitochondria. Later, the link between the electron transfer of OXPHOS and the synthesis of adenosine triphosphate (ATP) was established by Mitchell, for which he was awarded the Nobel Prize. Major breakthroughs in genetics were the discovery of mitochondrial deoxyribonucleic acid (mtDNA) and the sequencing of human mtDNA. More recently, in 1996, another Nobel Prize was awarded to Walker and Boyer for their studies of the structure and function of mitochondrial adenosine triphosphatase (ATPase).

Mitochondria have been considered the powerhouse of cells because they supply most of the cellular energy needs by synthesizing ATP, following the oxidation of pyruvate via the Krebs cycle and of fatty acids.[2] Notwithstanding, other important mitochondrial functions are the synthesis of heme, the disposal of ammonia via the urea cycle, and the supply of intermediate products for gluconeogenesis and lipogenesis. More recently, the central role of mitochondria in the generation of reactive oxygen species (ROS) and in the regulation of programmed cell death or apoptosis has been recognized.[3]

Following the increasing knowledge of mitochondrial biology, a variety of disorders related to abnormalities of mitochondrial function have been described. The first mitochondrial disease was described by Luft and colleagues in 1962 in a patient who had a hypermetabolic state associated with uncoupled OXPHOS and changes in mitochondrial structure.[4] Subsequently, more than 200 different defects in mtDNA and in nuclear DNA (nDNA) encoding for mitochondrial proteins have been described and associated with a variety of neurologic, muscular, metabolic, cardiac, renal, and gastrointestinal diseases.[5,6] More recently, mitochondrial abnormalities have been implicated in the pathophysiology of such diverse conditions as aging, cancer, and neurodegenerative diseases.[7]

This chapter provides an overview of mitochondrial structure, genetics, and function, as well as of pathologic conditions associated with primary or secondary dysfunction of mitochondria. The reader can find in-depth discussions on these areas in several books and reviews provided as references in this chapter and on specific gastrointestinal metabolic disorders in Chapter 55, "Genetic and Metabolic Disorders."

MITOCHONDRIAL STRUCTURE

Mitochondria are cytosolic organelles varying in size between 0.2 and 5 µm in diameter, with a length up to 20 µm.[8] The number of mitochondria in eukaryotic cells varies among species and tissues. In humans, the number of mitochondria may range from a few in the spermatozoa to about 800 in hepatocytes and approximately 100,000 in the oocyte. The total volume of mitochondria may account for as much as 25% of the cytosol. Within the cytosol, mitochondria may cluster in different areas of the cell. For example, in the spermatozoa, mitochondria are close to the tail, whereas in muscular cells, mitochondria are distributed more regularly along the length of the myofibrils. In other cells, the mitochondria may have a more random distribution.

Mitochondria are mobile.[9] They closely associate with the cytoskeleton and particularly with microtubules, actin and intermediate filaments that serve as cellular tracks. The motion of the mitochondria involves active hydrolysis of ATP and the participation of different motor proteins of the kinase superfamily (eg, KIF1B, KLP67A, KIF5B) and dynamin-related proteins.[10] Mitochondria may constitute an interconnected reticulum that extends throughout the cytosol.[11] The reticular conformation of the mitochondria seems to be necessary for delivering energy to distant areas of the cell and involves fusion and fission mechanisms redistributing the enzymatic respiratory activity of the organelle.[9,12] Fusion and fission are also important in mitochondrial biogenesis. In yeast, the fusion process also allows segregation of the mtDNA during budding.[12] The study of different mutants in yeast has permitted the identification of different proteins belonging to the dynamin family playing a role in mitochondrial dynamics.[10] Some of these proteins (mdm1p, mdm20p, mdm14p, and Rsp5p)

localize in the cytoplasm, whereas others are expressed on the mitochondrial surface (mdm10p, mmm1p, mdp12p). In infertile males of *Drosophila* with defective spermatogenesis, abnormal aggregation of mitochondria was observed, forming "fuzzy onion"–like structures.[10] The identified gene (*fzo*) causing the abnormality encodes a protein belonging to a new family of mitochondrial guanosine triphosphatases. *Fzo* homologues have also been reported in yeast, and *fzo* mutants have shown mitochondrial fragmentation and blocking of fusion.[13,14] Recently, two *fzo* family members, mitofusins 1 (mfn1) and 2 (mfn2), have been identified in humans.[15]

Mitochondria have two membranes: an outer membrane and an inner membrane separated by the intermembrane space.[8,16,17] The matrix is the space within the boundary of the inner membrane. The inner membrane has multiple infolds projecting into the matrix, the cristae. The cristae membrane is connected to the inner membrane by defined tubular structures called cristae junctions. The outer and inner membranes are separated but in close juxtaposition, except in several areas in which the two membranes fuse. It is believed that these contact sites serve as places for direct import of proteins from the cytosol into the matrix. The size of the intermembrane space and the matrix changes according to the metabolic state of the mitochondrion.

The inner and outer membranes have different lipid and protein composition.[18] The outer membrane has a similar composition to the cell membrane with roughly equal proportions of protein and lipid. It contains, among other proteins, a transmembrane porin or voltage-dependent anion channel (VDAC) permitting the passage of small molecules (< 5,000 D) and carnitine palmitoyltransferase I (CPT I), a protein involved in the transport of fatty acids from the cytosol into the mitochondria. Compared with the outer membrane, the inner membrane has less cholesterol and more cardiolipin, a phospholipid containing four fatty acid esters that decreases the ionic permeability of the membrane. The inner membrane has a higher protein-to-lipid ratio (3:1) and contains, among other proteins, the proteins involved in electron transport and OXPHOS.

The intermembranous space contains only a few proteins; some of them are involved in apoptosis. In contrast, the matrix is rich in proteins, such as the enzymes of the Krebs cycle, fatty acid oxidation, urea metabolism, and synthesis of heme. The matrix also contains chaperone proteins (heat shock protein [Hsp]60 and Hsp70) participating in the folding of proteins imported into the mitochondria, enzymes involved in the synthesis of mitochondrial proteins (ribonucleic acid [RNA] and DNA polymerases), and mtDNA.

GENETICS OF MITOCHONDRIA

The sequencing of human mtDNA[19] and the study of mtDNA in a variety of organisms have shed light on the functional and evolutionary aspects of mitochondria.

According to the endosymbiotic hypothesis, mitochondria are derived from an ancestral protobacteria (eubacteria) related to the current *Rickettsia* group, which became incorporated into a host archaebacterium or primitive eukaryotic cell.[20] During the course of evolution, variable transfer of genetic material involving protein synthesis codons and RNA genes from the protomitochondria to the nuclear genome occurred.[21] This reduction in the protomitochondria genome may explain the diverse size and genetic information present in the mtDNA of current living organisms.The size of mtDNA among different organisms ranges from 6 kb in *Plasmodium falciparum*, 14 to 20 kb in metazoan, 40 to 60 kb in fungi, to 200 to 400 kb in plants. Most organisms have circular mtDNA, but others (eg, *Saccharomyces cerevisiae*) may have linear mtDNA. The mitochondria genome encodes for different proteins of the respiratory chain and for a repertoire of ribosomal ribonucleic acid (rRNA) and transfer ribonucleic acid (tRNA). Differences in the expression of specific peptides and RNA exist between organisms.

Human mtDNA is a double-stranded circular DNA composed of 16,569 base pairs (Figure 7-1).[19,22] Based on their separation in alkaline cesium chloride, heavy (H) and light (L) strands have been described. Human mtDNA encodes for two rRNAs (12S and 16S), 22 tRNAs, and 13 peptides of the multimeric respiratory chain proteins. Specifically, mtDNA encodes for 7 (ND1, -2, -3, -4, -4 L, -5, and -6) of 42 subunits of complex I (reduced nicotinamide adenine dinucleotide [NADH]–coenzyme Q [CoQ] oxidoreductase), 1 (cytochrome-*b*) of 11 subunits of complex III (CoQ–cytochrome-*c* oxidoreductase), 3 (subunits I, II, and III) of 13 subunits of complex IV (cytochrome-*c* oxidase [COX]), and 2 (subunits A6 and A8) of 16 peptides of complex V (ATP synthase). The 4 subunits of complex II (succinate-CoA reductase), the remaining subunits of the respiratory chain complexes, and the proteins necessary for the transcription, translation, and replication of mtDNA (such as mtDNA and RNA polymerases) are encoded by the nDNA.

There are between 1,000 and 10,000 copies of mtDNA in somatic cells, whereas in germ cells, the number varies between 100 in sperm and as many as 100,000 in the human egg. Each mitochondrion may have 2 to 10 copies of mtDNA. After fertilization, the paternal mtDNA is eliminated by mechanisms not well understood. As a result, mitochondria and their DNA are maternally derived.

The replication of mtDNA is initiated by the synthesis of an RNA primer by mitochondrial RNA polymerase and of the mitochondrial transcription factor (mtTFA), both encoded by nDNA.[23,24] It is followed by the transcription initially of the heavy chain (clockwise) and subsequently of the light chain (counterclockwise) directed by two promoters, heavy and light strand promoters, respectively. The synthesis of the heavy strand starts at the origin of heavy strand replication (Oh close to position 200) and that of the light strand begins at the origin of light strand replication (Ol near position 5750). The replication requires the presence of DNA polymerase γ, a mitochondrial RNA polymerase, and the mitochondrial single-stranded DNA binding protein (mtSSB). The transcription of both strands is complete and involves the entire sequences, each producing a large polycistron. The translation of the light strand includes the messenger ribonucleic acid (mRNA) for sub-

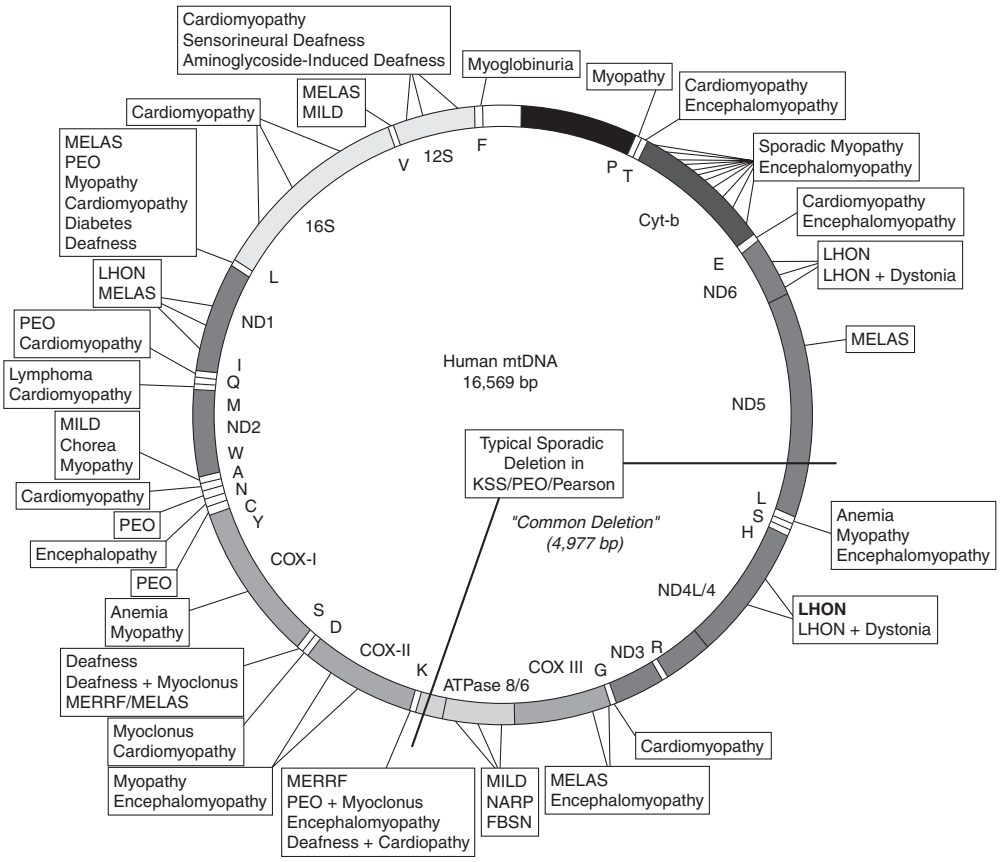

FIGURE 7-1 Mitochondrial deoxyribonucleic acid (mtDNA) and morbidity map of mitochondrial genome. The map of the 16.6 kb mtDNA shows differently shaded areas representing the protein-coding genes for the seven subunits of complex I (ND), the three subunits of cytochrome-*c* oxidase (COX), cytochrome-*b* (Cyt-*b*), and the two subunits of adenosine triphosphatase (ATPase) synthase (ATPases 6 and 8); the 12S and 16S ribosomal ribonucleic acid (rRNA); and the 22 transfer ribonucleic acids (tRNA) identified by one-letter codes for the corresponding amino acids. FBSN = familial bilateral striatal necrosis; KSS = Kearns-Sayre syndrome; LHON = Leber hereditary optic neuropathy; MELAS = mitochondrial encephalomyopathy, lactic acidosis, and strokelike episodes; MERRF = myoclonic epilepsy with ragged red fibers; MILD = maternally inherited Leigh disease; NARP = neuropathy, ataxia, retinitis pigmentosa; PEO = progressive external ophthalmoplegia. Adapted with permission from DiMauro S.[453]

unit ND6 of complex I and eight tRNAs, whereas the translation of the heavy strand includes the sequences for other peptides of the respiratory chain and the remainder tRNA. The termination of transcription requires the presence of a factor called mitochondrial transcription termination factor. The transcripted polycistron is then cleaved to produce rRNA, tRNA, and mRNA sequences. The genetic code of mtDNA differs from nDNA in that in mitochondrial translation, AGA and AGG sequences act as stop codons instead of coding for arginine. Also, sequence UGA codes for tryptophan instead of being a stop codon, and AUU sequence codes for methionine instead of isoleucine.

The translation of mitochondrial mRNA requires the presence of peptides derived from both nuclear and mitochondrial genomes. The replication of mtDNA within the cell does not correlate with that of nDNA.[25] The exact mechanisms participating in the coordination of the two genomes are not understood. Recently, several factors, including NRF1 and NRF2, and other nuclear coactivators (PGC and PRC) have been described as nuclear transcriptional regulators of mitochondrial biogenesis.[26] There is evidence that the two genomes mtDNA and nDNA have coevolved. In experiments in which mtDNA was paired with nDNA of different species, only genomes being phylogenetically very close were able to sustain functional OXPHOS.[27]

Mitochondrial proteins synthesized from nDNA need to be imported into the mitochondria by a complex mechanism. The process requires different proteins that translocate peptides from the cytosol through the outer and inner mitochondrial membranes (Figure 7-2).[28,29] For this purpose, many proteins to be imported into the mitochondria have an N-terminal leader signaling sequence. In hydrophobic membrane proteins, the signaling peptide may reside inside the protein. Proteins located in the mitochondrial intermembrane space may have both N-terminal and internal signal sequences, whereas other proteins may have multiple targeting signals. The proteins bind initially to the chaperone molecules, Hsp70, or the mitochondrion import stimulating factor to keep the peptides unfolded.

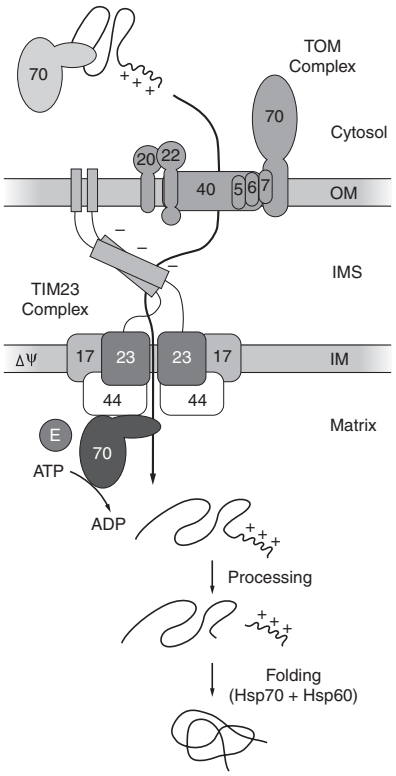

FIGURE 7-2 Mitochondrial import pathway for matrix-targeted preproteins. The nuclear encoded preproteins are synthesized in the cytosol with N-terminal positively charged matrix targeting signals and are bound by cytosolic heat shock protein (Hsp)70 chaperones. The Tom20/Tom22 receptors recognize the mitochondrial preproteins on the surface of the mitochondria and transfer them to the protein-conducting channel of the TOM complex. For translocation across the inner membrane, the TOM complex cooperates with the TIM23 translocase, which initiates the translocation of the preproteins across the inner membrane in a $\Delta\Psi$-dependent manner. In the matrix, the preproteins are bound by mitochondrial Hsp70, which, together with its cochaperone Mge1p, drives the adenosine triphosphate (ATP)-dependent translocation further. The matrix-targeting signals are processed by the mitochondrial processing peptidase, and the preproteins fold into their native conformation with the help of chaperones. Numbers refer to the molecular masses of the respective component in kD. ADP = adenosine diphosphate; E = Mge1p; IM = inner membrane; IMS = intermembrane space; OM = outer membrane; $\Delta\Psi$ = membrane potential across the inner membrane. Reproduced with permission from Paschen SA, Neupert W, Taylor and Francis Ltd (<http://www.tandP.co.uk/journals>).[28]

Import of proteins in the mitochondria is mediated by a translocase in the outer membrane, the TOM complex, and two translocase complexes in the inner membrane, TIM23 and TIM22. Each of these complexes is made of different proteins encoded by nuclear genes. TOM is constituted by the receptor proteins Tom20, Tom22, and Tom70; the channel protein Tom40; and three other associated proteins, Tom5, Tom6, and Tom7. In the mitochondrial outer membrane, proteins to be imported interact with receptor proteins Tom20 and Tom22, which mainly bind proteins with an N-terminal leader sequence, and with Tom70, which recognizes internal sequences. The traveling peptide then passes through the general import (GIP) complex, which includes Tom40, Tom5, Tom6, and Tom7. Of these proteins, Tom40 serves as the protein-conducting channel, and the others have a supportive role. Tom5 facilitates the transfer of proteins from Tom22 to Tom40. Tom6 contributes to the stability of the GIP complex, and Tom7 intervenes in the release of proteins in the outer membrane. Proteins to be integrated into the inner membrane, after passage through the outer membrane, can interact with other TIM molecules in the intramembranous space (Tim8, Tim9, Tim10, Tim12, and Tim13), avoiding aggregation and facilitating the interaction with the TIM22 complex. TIM22 is constituted by three integral membrane proteins, Tim22, Tim54, and Tim18, and by three peripheral proteins, Tim12, Tim10, and Tim9. TIM22 pore activity is dependent on the mitochondrial membrane potential $\Delta\Psi$ and inserts imported multispanning membrane proteins (eg, several metabolic carriers) into the lipid phase of the inner membrane.[30] In the case of molecules to be integrated into either mitochondrial membrane, the leader signal is commonly accompanied by hydrophobic sorting sequences recognizable by TOM and TIM22 complexes, stopping the proteins in the outer or inner membranes.

For proteins with the matrix as the final destination, the passage through the inner membrane occurs after the importing sequence interacts with TIM23, another translocase complex in the inner membrane (see Figure 7-2). The TIM23 complex consists of two transmembrane proteins, Tim23 and Tim17, the former being the actual pore through which the protein is transferred in a process dependent on the membrane potential $\Delta\Psi$. The proteins then associate with a complex of Tim 44, a translocase on the matrix side of the inner membrane, Hsp70, and a cochaperone protein, Mge 1p. The signaling sequence is cleaved by an ATP-dependent mitochondrial processing peptidase. The protein is then refolded with the assistance of other chaperone molecules, such as Hsp70, Hsp60, or peptidyl-prolyl *cis-/trans*-isomerases.

The mechanisms of transport of proteins, such as the components of the respiratory chain from the matrix into the inner membrane, are not well defined. Recently, two proteins, Oxa 1 and Pnt 1, have been proposed as playing a role in this process.[31,32]

MITOCHONDRIAL FUNCTION

Energy Production

The production and use of energy are the fundamental metabolic processes of a living organism. Mitochondria play a pivotal role in the production and storage of energy through the oxidation of nutritional substrates coupled to the synthesis of ATP. The main substrate for the production of energy in the mitochondria is acetyl coenzyme A (CoA) derived from the oxidation of pyruvate via the Krebs cycle or from the β-oxidation of fatty acids (Figure 7-3).[2]

In the cytosol, the initial degradation of glucose produces two molecules of pyruvate and four molecules of ATP, of which two molecules are reused in the glycolytic pathway. Pyruvate is imported into the mitochondria by a pyruvate carrier and is oxidized in the matrix to acetyl CoA

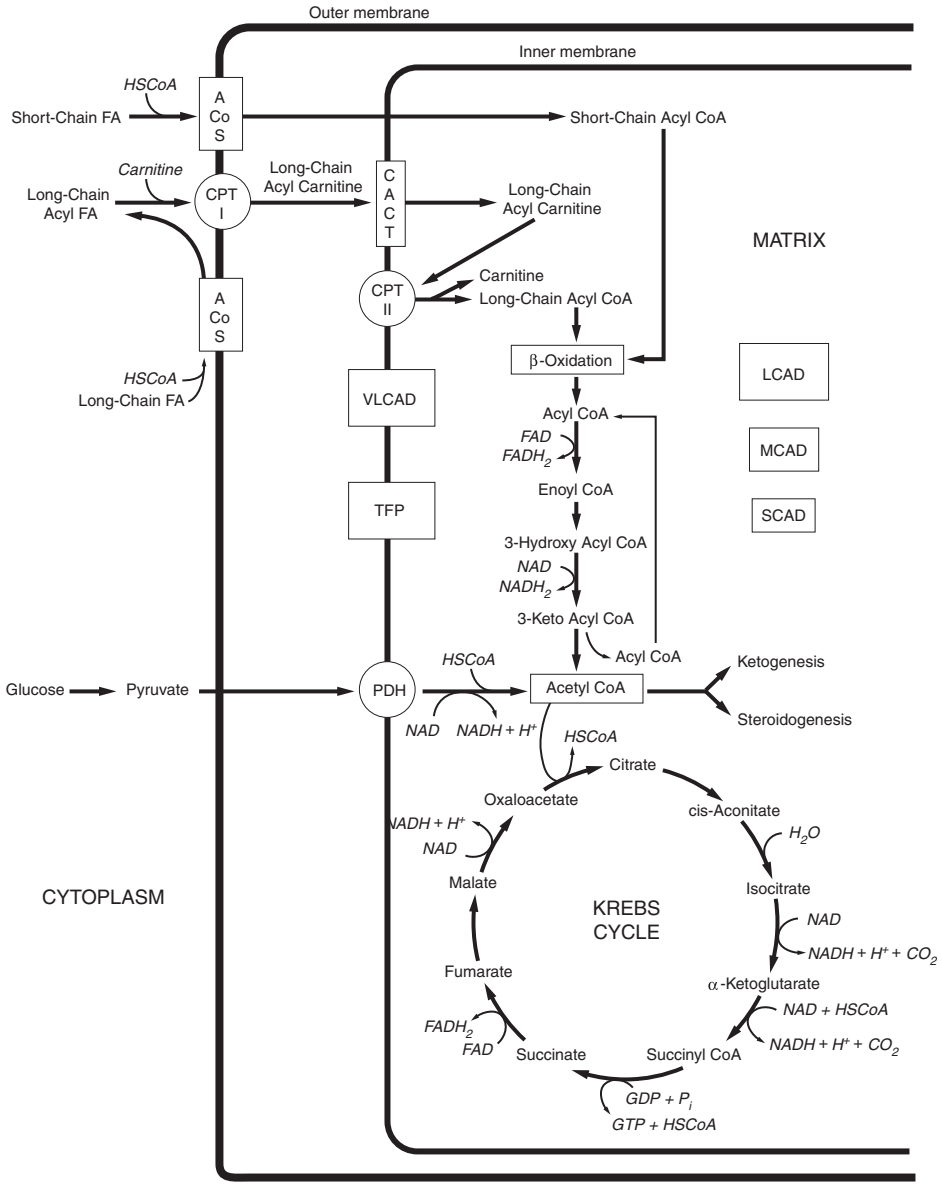

FIGURE 7-3 Oxidation of metabolic substrates pyruvate and fatty acids (FA) by mitochondria. Pyruvate produced by glycolysis in the cytosol is imported into the mitochondria and is oxidized by pyruvate dehydrogenase (PDH), producing acetyl CoA, which undergoes further metabolism in the Krebs cycle. Short- and long-chain FAs are acylated by acyl-CoA synthases (ACoAS) in the outer membrane. Long-chain acyl FAs are transported into the mitochondria after forming acyl carnitine ester by carnitine palmitoyltransferase I (CPTI), which is passed through the inner mitochondrial membrane by a carnitine acylcarnitine translocase (CACT) into the matrix. The acyl carnitine ester is hydrolyzed by carnitine palmitoyltransferase II (CPTII), producing long-chain acyl CoA and carnitine. Acyl-CoA FA then undergoes β-oxidation mediated by the activity of different acyl-CoA dehydrogenases. Reduced nicotinamide adenine dinucleotide (NADH) and flavine adenine dinucleotide ($FADH_2$) can be oxidized in the inner mitochondrial membrane by the electron transport chain. FAD = flavin adenine dinucleotide; GDP = guanosine diphosphate; GTP = guanosine triphosphate; LCAD = long-chain acyl dehydrogenase; MCAD = medium-chain acyl dehydrogenase; NAD = nicotinamide adenine dinucleotide; SCAD = short-chain acyl dehydrogenase; TFP = trifunctional protein; VLCAD = very-long-chain acyl dehydrogenase.

in the presence of CoA and nicotinamide adenine dinucleotide (NAD) by pyruvate dehydrogenase:

$$\text{Pyruvate} + \text{CoA} + \text{NAD}^+ \rightarrow \text{NADH} + \text{acetyl CoA} + \text{CO}_2$$

Pyruvate dehydrogenase is a multimeric protein composed of three units (each with multiple subunits): E1 or pyruvate decarboxylase, E2 or lipoamide transacetylase, and E3 or dihydrolipoyl dehydrogenase. The enzymatic activity requires the presence of five coenzymes: oxidized nicotinamide adenine dinucleotide (NAD^+), flavin adenine dinucleotide (FAD), CoA, lipoamide, and thiamine pyrophosphate (TP).

Krebs Cycle. The 2-carbon acetyl CoA enters the Krebs or citric acid cycle by combining with oxaloacetate to form a 6-carbon molecule, citric acid (see Figure 7-3). This reaction is mediated by citrate synthase. Further metabolism by this pathway involves the formation of isocitrate by aconitase, an enzyme containing a nonheme iron sulfur cluster, which also participates in the cell handling of iron. The synthesis of α-ketoglutarate from isocitrate requires the activity of isocitrate dehydrogenase, NAD^+, and adenosine diphosphate (ADP). α-Ketoglutarate is metabolized to succinyl CoA by α-ketoglutarate dehydrogenase. The subsequent formation of succinate is mediated by succinyl-CoA synthase and requires guanosine diphosphate as a P_i acceptor. The oxidation of succinate to fumarate is catalyzed by succinate dehydrogenase, with the release of two electrons and two protons, with FAD becoming the proton acceptor. Fumarate is next hydrated to form malate by a fumarase. Further dehydrogenation by malate dehydrogenase in the presence of NAD^+ yields oxaloacetate and NADH.

The complete aerobic metabolism of one molecule of glucose results in the production of 6 molecules of CO_2, 10 molecules of NADH, 2 molecules of reduced flavin adenine dinucleotide ($FADH_2$), and 36 molecules of ATP.

Fatty Acid Oxidation. Fat oxidation represents an important source of energy during periods of metabolic

need such as starvation, exercise, or stress. In several tissues, such as the myocardium and skeletal muscle, energy is obtained mainly from fatty acid oxidation.[33] Fatty acids are derived from triglycerides stored in adipose tissue or from triglyceride-rich lipoproteins, such as chylomicrons and very-low-density lipoproteins, after hydrolysis by lipases. Free fatty acids are then bound to albumin and transported into the cell by diffusion or by several fatty acid transporters.[34] Once in the cytosol, fatty acids bind to fatty acid binding proteins.[35]

Most fatty acid β-oxidation occurs in the mitochondria by sequential removal of two carbon acetyl-CoA units.[36,37] Additional α- and β-oxidation of fatty acids may occur in the peroxisomes.[38] Peroxisomes are particularly important in the oxidation of branched- and very-long-chain fatty acids and may initiate the oxidation of long-chain fatty acids. Fatty acid oxidation in peroxisomes may proceed only until the formation of octanoyl CoA and is not accompanied by synthesis of ATP. Compared with mitochondria, the peroxisomes contribute less to the oxidation of fatty acids below 20-carbon chain length.[39]

Long-chain fatty acids enter the mitochondria after esterification with CoA in the outer membrane. The reaction is mediated by a variety of ATP-dependent acyl-CoA synthases, including members of the fatty acid binding proteins, followed by binding of the ester to acyl-CoA binding protein.[37] The entry of the activated fatty acids into the mitochondria proceeds initially by the formation of an acyl carnitine ester mediated by a tissue-specific enzyme, CPTI. The fatty acid–CoA ester is then transferred across the inner membrane into the matrix by carnitine acylcarnitine translocase (CACT) and is reconstituted as acyl CoA and free carnitine in the inner membrane by CPTII. The oxidation of fatty acid occurs in the matrix by different acyl-CoA dehydrogenases (ACADs) for very-long (VLCAD), long-chain (LCAD), medium-chain (MCAD), and short-chain (SCAD) fatty acids. VLCADs localize in the inner membrane and the trifunctional protein (TFP) complex. TFP is an octamer consisting of two tetramers, α and β, which contain the enzymatic activity of long-chain 3-hydroxyacyl-CoA dehydrogenase (LCHAD), 2-enoyl-CoA hydratase, and 3-ketoacyl-CoA thiolase.[40] The other acyl hydrolases, LCAD, MCAD, and SCAD, are present in the matrix. According to the length of the fatty acids, the substrate activity of ACADs has been reported to be C24 to C12 for VLCAD, C20 to C6 for LCAD, C16 to C4 for MCAD, and C6 to C4 for SCAD.[41]

In the first step, a specific length acyl CoA is hydrolyzed by an ACAD specific for a given fatty acid chain length in the presence of FAD as a cofactor, yielding *trans*-Δ2-enoyl CoA and reduced $FADH_2$. The electrons present in $FADH_2$ are then transferred to the electron transfer flavoproteins (ETFs). Subsequently, the electrons present in reduced ETF can be transferred to ubiquinone by another inner mitochondrial membrane, the ETF-ubiquinone oxidoreductase, entering the electron transport chain. Enoyl CoA is then hydrated by 2,3-enoyl-CoA hydratase, producing 3-hydroacyl CoA, which, in the presence of NAD^+ and 3-hydroacyl-CoA dehydrogenase, results in the formation of 3-ketoacyl CoA and NADH. The last step consists of the cleavage of 3-ketoacyl CoA producing acetyl CoA and acyl CoA (shortened by 2 carbons and continuing a similar cycle). In addition, depending on the location of the double bond (even or odd numbered carbons), the oxidation of polyunsaturated fatty acids requires the activity of auxiliary enzymes, including enoyl CoA, dienoyl CoA isomerases, and 2,4-dienoyl CoA reductase.[41]

Acetyl CoA released during fatty acid oxidation may enter the Krebs cycle, be used in ketogenesis, or serve as a substrate in the synthesis of mevalonate, a precursor of cholesterol. The production of the ketone bodies acetoacetate and hydroxybutyrate occurs mainly in the liver,[42,43] but other tissues, such as kidney, intestine, and adipose tissue, also have ketogenic ability. Initially, acetyl CoA reacts with acetoacetyl CoA in the presence of 3-hydroxy-3-methylglutaryl CoA synthase, forming 3-hydroxy-7-methylglutaryl CoA, which is subsequently metabolized into acetoacetate by a specific lyase. The reduction of acetoacetate to hydroxybutyrate is carried by the 3-hydroxybutyrate dehydrogenase. Ketones are used as a source of energy in peripheral tissues, particularly in the brain during glucose deficiency circumstances.[44]

Electron Transport and OXPHOS. Chemical reactions involve the transfer of electrons between reagent molecules. Oxidation refers to the loss of electrons from individual atoms or molecules, whereas reduction refers to the gain of electrons. These processes are coupled in oxidation-reduction reactions. The reduction potential, E, of a molecule describes the facility to gain electrons. The oxidative potential describes the change in charge when there is loss of an electron. In an oxidoreduction reaction, the sum of these potentials, ΔE, defines the direction of the reaction.

In mitochondria, most of the energy produced during the oxidation of sugars and fatty acids is retained in the reduced coenzymes NADH and $FADH_2$ and is released during the oxidation to NAD^+ and FAD.[2] The oxidation of NADH and $FADH_2$ involves the removal of a hydride ion yielding one proton and two electrons ($H^- \rightarrow H^+ + 2e^-$).

The sequential transfer of electrons occurs via the oxidoreduction of several prosthetic groups present in the protein complexes of the electron transport chain and is coupled with the transfer of protons from the matrix to the intermembranous space (Figure 7-4). Because the inner mitochondrial membrane is impermeable to protons, the transfer of protons across the inner membrane creates a proton concentration gradient and therefore a pH gradient of about 1 unit between the matrix and the intermembranous space. Because the matrix side of the inner membrane becomes relatively electronegative owing to the loss of protons, a voltage gradient of about –160 mV is also generated across the membrane: the membrane potential, usually designed as ΔΨ. The sum of the proton concentration gradient and ΔΨ is expressed as the proton motive force. This proton electrochemical gradient drives the synthesis of ATP by the ATP synthase (complex V) present in the mitochondrial inner membrane. The oxidation of one molecule

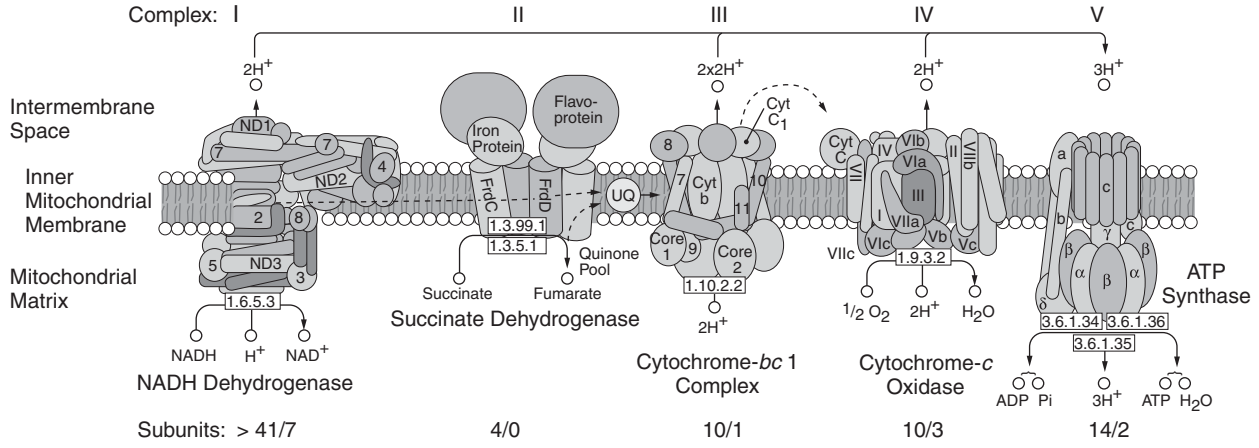

FIGURE 7-4 Electron transport chain. Schematic representation of mammalian electron transport complexes (I–IV). Electrons flow from reduced nicotinamide adenine dinucleotide (NADH) or succinate to complex I or II, respectively, and subsequently to ubiquinone (UQ). Electrons then flow from ubiquinone through complexes III and IV to the final acceptor, molecular oxygen. Electron flow is coupled to proton movement across the inner membrane in complexes I, III, and IV. The resulting proton gradient is harvested by complex V to generate adenosine triphosphate (ATP). The number of subunits encoded by the nuclear/mitochondrial genomes is at the bottom of the figure. ADP = adenosine diphosphate; NAD = nicotinamide adenine dinucleotide. Adapted from Mandavilli BS et al.[170]

of NADH produces three molecules of ATP, whereas that of $FADH_2$ produces two molecules of ATP because the oxidation of succinate is initiated at the level of the second complex in the respiratory chain.

The electron transport chain includes four electron transport proteins (complexes I, II, III, and IV), the ATP synthase (complex V), and two electron shuttles: the CoQ, also called quinone (Q) or ubiquinone (UQ), and cytochrome-*c*. The five complexes are multimeric proteins residing in the mitochondria inner membrane (see Figure 7-4).[45–47] Except for complex II (succinate-CoA reductase), which is encoded by nDNA, the subunits of the other complexes are derived from both the nuclear and mitochondrial genomes and assembled by poorly understood mechanisms. CoQ is a lipophilic molecule containing 10 isoprenoid units. The quinone moiety can be reduced to reduced coenzyme Q ($CoQH_2$) or quinol by collecting the protons entering the respiratory chain and oxidized to CoQ by passing the electrons to the electron transfer chain complexes I and II. Cytochrome-*c* is one of four different cytochromes in the respiratory chain that contains iron inside a porphyrin ring. The iron then may be oxidized or reduced in the coupled reactions involved in the electron transport.

***Complex* I (NADH-Q*uinone* O*xidoreductase*).** In mammalian mitochondria, complex I is the largest of the electron transport proteins, with a molecular weight close to 1,000 kD.[48,49] The enzyme is L shaped, and the primary structures of the 42 units in humans have recently been reported.[49] The complex is made of three different fractions: a flavoprotein, an iron sulfur, and a hydrophobic protein fraction. The latter contains seven subunits: ND1 to 6 and subunit 4L. The complex binds NADH and CoQ and uses flavin mononucleotide, eight to nine iron sulfur clusters, and CoQ as prosthetic groups in the redox reactions. Complex I catalyzes the reaction by which CoQ is reduced, and four protons are transported from the matrix across the inner membrane:

$$NADH + CoQ + 5\ H^+ \text{ (from the matrix)} \rightarrow NAD^+ + CoQH_2 + 4\ H^+$$

The details of the electron transfer and proton translocation within the complex are not completely established, but it is believed that the initial transfer of electrons starts by the transfer of a hydride ion to flavin mononucleotide, and then the electrons are passed to different iron sulfur clusters to reach the ubiquinone.[48]

***Complex* II (*Succinate-Ubiquinone* Reductase).** Succinate-ubiquinone reductase is composed of four subunits: A (70 kD), B (27 kD), C (15 kD), and D (13 kD).[45–47,50] Units A and B constitute a water-soluble peripheral domain with succinate dehydrogenase activity. Unit A, also referred to as flavoprotein, contains a molecule of FAD as a prosthetic group, covalently bound to a histidyl residue. The prosthetic groups of unit B, also known as iron sulfur protein, are three iron sulfur clusters designated as S1, S2, and S3. Units C and D are hydrophobic and constitute the membrane integral domain of the molecule. This domain carries containing another cytochrome-*b*–like redox component that has heme as a prosthetic group. Complex II catalyzes the two electrons oxidation of fumarate and the reduction of ubiquinone to ubiquinol:

$$\text{Succinate} \rightarrow \text{fumarate} + 2H^+ + 2e^-$$
$$CoQ + 2H^+ + 2e^- \rightarrow CoQH_2$$

The reaction, although thermodynamically favorable, does not provide enough energy to pump protons across the inner membrane. The nuclear genes encoding for the four subunits SDHA, SDHB, SDHC, and SDHD have been identified.[51]

***Complex* III (U*biquinone–Cytochrome-c* O*xidoreductase*).** Complex III is a dimeric protein with a monomer mass of 240 kD made of 11 peptides.[45–47] It contains two cytochrome-*b* molecules in subunit III: one with high reduction potential (280 mV), *bh*, and the other with lower potential (30 mV), *bl*. Subunit IV contains another heme-containing cytochrome (cytochrome-*c*1). Two other iron-sulfur clusters are located in subunit V, also know as the Rieske protein. Complex III has two binding sites for the oxidation of ubiquinol: one, Qo, localizes on the cytosolic side of the inner membrane, whereas the other, Qi, locates on the matrix side of the protein. The enzyme catalyzes the reaction:

$$CoQH_2 + 2\ \text{cyt-}c^{3+} + 2H^+\ \text{(from the matrix)} \rightarrow CoQ + 2\ \text{cyt-}c^{2+} + 4H^+$$

The reaction occurs sequentially via the Q cycle.[52] Reduced ubiquinone ($CoQH_2$) originating in complex I diffuses into the membrane and binds to the Qo site of complex III, where oxidation is initiated, freeing two protons and one electron (of two electrons present in the ubiquinone molecule). The first electron is then transferred to the Rieske iron-containing subunit, passed on to cytochrome-*c*1 and subsequently to cytochrome-*c*. The ubisemiquinone ($CoQH^{\bullet}$) passes the other electron, called cyclic electron, sequentially to the cytochrome molecules *bl* and *bh* and to the Qi site of the molecule. After two cycles (two ubisemiquinones passing one electron each), the ubiquinone is reconstituted in its reduced form, and a total of four protons are passed across the inner membrane.

***Complex* IV (*Cytochrome* O*xidase*).** Bovine heart complex IV is a dimeric protein constituted by 13 subunits with a molecular weight of 204 kD.[53] The three larger subunits, I, II, and III, encoded by mtDNA are the core of the protein, which is surrounded by 10 other peptides (IV, Va, Vb, VIa, VIb, VIc, VIIa, VIIb, VIIc, VIII). The molecule contains two heme groups, a and a_3, and two copper centers, Cu_A and Cu_B. Subunit I contains the heme groups a and a_3 and the Cu_B center, whereas subunit II binds the Cu_A center. The molecule catalyzes the reaction:

$$4\ \text{cyt-}c^{2+} + 8\ H^+\ \text{(from the matrix)} + O_2 \rightarrow 4\ \text{cyt-}c^{3+} + 4\ H^+ + 2\ H_2O$$

The transfer of electrons occurs sequentially from cytochrome-*c* to redox centers Cu_A, to heme a, and to the Cu_B-a3 active site, where oxygen is reduced to water with a coupled oxidation of iron (present in heme) and copper. In the process, eight protons from the matrix are used, and four protons are transported to the intermembranous space.

***Complex* V (ATP S*ynthase*).** The ATP synthase is constituted by 12 to 14 subunits arranged into two multimeric complexes: one is embedded in the inner mitochondrial membrane (Fo), whereas the other protrudes into the matrix (F1) (see Figure 7-4).[54–56] In mammals, depending on the species, Fo contains several subunits, including subunits A6, A8, a, and b; several subunits of c; and subunits, e, f, and g. A proton channel is present between the a and c subunits. The F1 section is also multimeric. The protruding stalk contains subunits γ and ε, connected to the hydrophilic segment in the matrix, a hexamer composed of three α subunits intercalated with three β subunits. Another δ subunit associated with the hexamer connects with the b subunit of Fo. According to the current model, the protein has a rotor constituted by the ensemble of hydrophobic c subunits making part of the Fo portion of the molecule, rotating around an axle composed of the δ and ε subunits of F1. The hexamer made of subunits α and β is stabilized by the subunits δ and b (the stator), avoiding rotation around the shaft or stalk when the complex is not active. The protein ensemble may be seen as a turbine or rotary motor transmitting the motion initiated in Fo to F1 through a cam (the γ and ε subunits).

ATP synthase catalyzes the reaction ADP + $P_i \rightarrow$ ATP + H_2O. Under standard conditions, it is an endergonic reaction with a Δ G of 7.3 kcal/mol, requiring input of energy.[2] That energy is provided by the passage of protons through the enzyme, flowing down from the intermembrane space into the matrix. This proton transport is driven by the proton motive force (the sum of the membrane potential, ΔΨ, and the H^+ concentration gradient, Δ pH). The electrostatic interaction between the positive charge of the protons and negatively charged amino acids residues located in the c unit (Glu 58 in the mammalian enzyme) induces the complete rotation of the c unit, releasing the proton into the matrix. The revolving movement of the rotor and the asymmetric shaft inside the matrix portion of the molecule changes the conformation of the catalytic sites located in the β subunits of the αβ hexamer. According to the model of rotational catalysis proposed by Boyer, the catalytic sites may assume three different configurations.[54,55] In the loose configuration (L), ADP and P_i bind to the β subunit. The catalytic synthesis of ATP occurs when the subunit assumes a tight configuration (T). The energy for the reaction comes from the binding of the substrates ADP and P_i to the subunit. The rotational movement of the hexamer induced by the proton translocation then changes the conformation of the β subunit to an open (O) configuration, overcoming the strong affinity of ATP for the subunit, allowing then the release of ATP. By continuous rotation of the hexamer, the open configuration is reverted to the loose configuration. The synthesis of one molecule of ATP appears to require the flow of four protons through complex V, and the enzyme may have a rotation rate close to 8,000 rpm.[57] Depending on the energy requirement of the cell and the relative availability of substrates (ATP, ADP, P_i), the enzyme can have reverse rotation and ATPase activity, binding ATP and yielding ADP and P_i. The rotatory process is under control of the ε subunit, which, depending on its contact with the αβ hexamer, may act as a unidirectional ratchet.[58] The energy derived from ATP hydrolysis may then be used to pump protons from the matrix across the inner mitochondrial membrane.

Mitochondrial Transport Systems

The performance of many of the biologic functions and reactions occurring within the cell necessitates the trans-

port of different molecules among the mitochondria, the cytosol, and other cell organelles.

One of these essential processes is the transfer of newly synthesized ATP from the mitochondrial matrix to the cytosol and the import into the matrix of ADP, produced after cytosolic hydrolysis of ATP. This coupled exchange is mediated by the ADP-ATP translocase or adenine nucleotide translocator (ANT).[59] The ANT is an integral dimeric protein member of the mitochondrial carrier family, with a molecular weight of about 32 kD that can bind the nucleotides ATP and ADP on both sides of the inner mitochondrial membrane. A nuclear gene encodes for three isoforms, with variable tissue expression and possibly different kinetic properties.[60] The ANT molecule exchanges ADP and P_i from the intermembrane space with ATP from the matrix. The cotransport depends on the proton motive force and is energetically expensive, using a quarter of the energy produced by the electron chain transport. The activity of the transporter maintains a high ATP-to-ADP ratio within the cell. In addition to the interchange of ATP and ADP, ANT may function as a nonspecific pore leading to increased permeability of the inner membrane to solutes up to 1,500 D. Along with other proteins, ANT makes part of the permeability transition pore complex (PTPC), a structure important in the process of apoptosis (see below).[61]

The outer mitochondrial membrane is highly permeable to small molecules (< 5,000 D) owing to the presence of pores formed by the porin protein, whereas the inner membrane is impermeable to most molecules. Therefore, intermediate products necessary in different metabolic pathways require specific transport mechanisms between the matrix and the cytosolic compartments.[2] The transport of major fuel substrates (fatty acid and pyruvate) across the mitochondrial membranes has already been described. Once formed in the mitochondria, acetyl CoA necessary for the synthesis of fatty acid in the cytosol cannot cross the inner membrane and needs to convert to citrate to exit the matrix. In the cytosol, citrate is converted to oxaloacetate and acetyl CoA. Oxaloacetate is then reduced to malate, which enters into the mitochondrial matrix using two different transporters. One, the tricarboxylate transporter, couples the ingress of malate into the mitochondria to the exit of citrate, isocitrate, or *cis*-aconitate from the matrix. The second, the α-ketoglutarate transporter, is a dicarboxylic acid translocase that transports α-ketoglutarate from the matrix to the cytosol in exchange for malate.

Although cytosolic coenzymes produced in the cytosol, such as NADH, cannot enter the matrix, the electrons from cytosolic NADH can be transferred inside the mitochondria to be used in OXPHOS by two shuttle systems: the malate-aspartate shuttle and the α-glycerol phosphate shuttle. In the malate-aspartate shuttle, the NADH electrons are used in the synthesis of maleate from oxaloacetate in the presence of a cytosolic malate dehydrogenase. Malate can then be imported into the mitochondrial matrix, where a mitochondrial maleate dehydrogenase in the presence of NAD^+ regenerates NADH, yielding oxaloacetate. Because the mitochondrial membrane is not permeable to oxaloacetate, to leave the matrix, oxaloacetate needs to combine with glutamate to form aspartate. Aspartate can exit the matrix via a specific transporter that also imports glutamate from the cytosol into the matrix. In the α-glycerol phosphate shuttle, the oxidation of NADH to NAD^+ in the cytosol is coupled to the transfer of two electrons to dihydroxyacetone phosphate, a glycolytic intermediate yielding glycerol-3-phosphate. In the mitochondrial membrane, glycerol-3-phosphate dehydrogenase reverts the reaction, oxidizing glycerol-3-phosphate, regenerating dihydroacetone phosphate. The reaction is accompanied by the transfer of the two electrons, reducing the FAD prosthetic moiety of the mitochondrial glycerol-3-phosphate dehydrogenase. Then the two electrons present in $FADH_2$ may enter the respiratory chain by reducing CoQ.

Ions are also transported in and out of the mitochondrial membrane. The phosphate transporter is an HPO_4^{2-}/OH^- carrier that imports HPO_4^{2-} into the matrix coupled to the transfer of OH^- from the matrix to the intermembrane space. Calcium is an important modulator of the production of energy by the mitochondria by activating pyruvate dehydrogenase, isocitrate dehydrogenase, and α-ketoglutarate dehydrogenase, increasing the NADH-to-NAD^+ ratio possibly by regulation of cytochrome-*c* and ATPase.[62] In addition, compartmentalization of calcium in the mitochondria may regulate different calcium-dependent cellular processes by affecting the availability of calcium in the cytosol and organelles (such as the endoplasmic reticulum).[63] Calcium influx into the mitochondria is facilitated by $\Delta\Psi$ and is mediated by a uniporter that also transports other cations.[64] The efflux of calcium from the matrix is an active transport that occurs via Na^+-dependent and Na^+-independent calcium transporters. A recent report suggests that the VDAC or mitochondrial porin located in the outer membrane also controls the influx and efflux into and from the mitochondria.[65] Na^+ may be transported by an Na^+-H^+ antiporter, and K^+, which regulates mitochondrial volume, is transported by a channel activated by ATP and also by a K^+-H^+ antiporter.

Control of OXPHOS

OXPHOS requires the availability of electron donor intermediates NADH and $FADH_2$ derived from fuel catabolism of oxygen and a supply of ADP and P_i as substrates for the synthesis of ATP by complex V. In vitro, OXPHOS is mainly regulated by the availability of ADP and P_i.[66,67] The ratio between the amount of phosphorylated ADP and oxygen consumption is designed as the P-to-O ratio. In the presence of ADP, there is maximal consumption of O_2 by the mitochondria (stage 3), which decreases once ADP is transformed into ATP (stage 4). The ratio between stage 3 and stage 4 of respiration is called the respiratory control ratio and represents a measure of the coupling between electron transport and ATP synthesis. At the cellular level, the short-term control of OXPHOS may also depend on the consumption of ATP and the intramitochondrial concentration of ADP. The ATP-to-ADP cellular ratio may have an effect on OXPHOS by regulating the activity of enzymes such as pyruvate dehydrogenase, increasing the availability

of NADH.[47] In addition, the ATP-to-ADP ratio could regulate OXPHOS via an allosteric effect on cytochrome-*c* activity.[68] However, other levels of control may exist because, in vivo, no significant changes in ADP occur under maximum respiration,[69] and the increase of ATP synthesis and respiration in muscle appears to occur faster than predicted by the availability of ADP.[70] Based on the observation that mitochondrial O_2 consumption inversely relates to the nitric oxide (NO)-to-O_2 ratio in mitochondria, it has been proposed that NO may have a physiologic role in the control of OXPHOS.[71,72]

In uncoupled respiration, respiration by the mitochondria and the generation of $\Delta\Psi$ can occur independently of the synthesis of ATP. In uncoupled respiration, in the absence of ADP (stage 4), proton import from the intermembranous space into matrix through the complex V is limited, and the consumption of oxygen depends on leakage of protons through the inner membrane by other pathways.[73] Under these conditions, the energy generated by the transfer of electron is then not conserved as ATP but rapidly dissipates as heat. The uncoupling of mitochondrial respiration is important in thermoregulation and in the regulation of activity of certain enzymes involved in mitochondrial steroid synthesis in the adrenal cortex.

Recently, three uncoupling proteins (UCP1, UCP2, and UCP3) belonging to the mitochondrial supercarrier family have been described in mammals.[74,75] UCP1 consists of 306 amino acids, is expressed exclusively in brown adipocyte tissue, requires fatty acid to induce uncoupling, and is up-regulated by cold, stress, and leptin. UCP2 is expressed in most tissues, and UCP3 is expressed predominantly in skeletal muscle. Both proteins are about 300–amino acid monomers and require fatty acid for their activity. In rats, fasting increased the expression of UCP3 and, to a lesser degree, of UCP2.[76] Refeeding rats with an isocaloric low-fat diet decreased the expression of both proteins.[77] This effect, however, was not seen with a high-fat diet. In humans, polymorphisms of the three genes have been reported, and the effects of these polymorphisms on body mass index, fat oxidation, and energy expenditure have been reported for UCP2 and UCP3.[74,75]

Other Mitochondrial Functions

In addition to its role in the oxidation of carbohydrates and fatty acids, mitochondria contribute to gluconeogenesis and protein metabolism by the interconversion of aspartate and oxaloacetate by the aspartate aminotransferase and of alanine and pyruvate by the activity of alanine aminotransferases. Also, in mitochondria, pyruvate carboxylase may convert excessive pyruvate to oxaloacetate. Oxaloacetate may be decarboxylated, yielding phosphoenoylpyruvate, a glucose precursor in a reaction catalyzed by phosphoenoylpyruvate carboxykinase. Mitochondria intervene in lipogenesis by providing acetyl CoA for the synthesis of fatty acid and cholesterol. One of the ways in which mitochondria participate in protein metabolism is via the urea cycle, in which excess nitrogen is converted into excretable urea (see Chapter 55, "Genetic and Metabolic Disorders").[78] In the mitochondria, carbamoyl phosphate synthetase forms carbamoyl phosphate from bicarbonate and from ammonia residues derived from amino acid catabolism. In another reaction, carbamoyl phosphate condenses with ornithine to form citrulline by ornithine transcarbamoylase, another mitochondrial matrix enzyme. Citrulline is then transferred to the cytosol, where, in the presence of aspartate, it forms arginine. The latter, after hydrolysis in the liver, yields urea and ornithine.

Heme is an important component of proteins such as hemoglobin and cytochromes such as cytochrome P-450, the prosthetic group of the electron transport chain and of several enzymes, such as catalase and peroxidase.[79] Mitochondria participate in the synthesis of heme initially by synthesizing 5-aminolevulinic acid (ALA) from glycine and succinyl CoA by the mitochondrial enzyme ALA synthase. ALA is transferred to the cytosol, where, by a series of enzymatic steps, it is converted into porphobilinogen and coproporphyrinogen. The latter returns to the mitochondria, where heme is synthesized by a series of reactions involving the coproporphyrinogen oxidase, yielding protoporphyrinogen IX, which is oxidized by protoporphyrinogen oxidase to protophorphyrin. The final reaction mediated by ferrochelatase introduces ferrous iron into the protophorphyrin ring, synthesizing heme.

Production of ROS

Mitochondria use about 90% of the total oxygen consumption by the cell.[80] As described above, the oxygen is reduced to form water in the electron transport chain. It has been calculated, however, that an electron leak of 0.25 to 2% occurs during mitochondrial respiration.[80,81] ROS are by-products of metabolized oxygen in the mitochondria.[3,82,83] The reduction of oxygen to water involves the transfer of four electrons to the molecule of oxygen. Molecular oxygen has two unpaired electrons with a similar spin in different orbitals. Because this electron configuration hampers the insertion of new electrons, oxygen reduction to form water proceeds by the sequential addition of one electron at a time. In the first reaction, oxygen may form superoxide O_2^- by accepting one electron from ubisemiquinone ($CoQH^\bullet$) produced during the electron transport:

$$CoQH^\bullet + O_2 \rightarrow O_2^- + CoQ$$

Most superoxide is produced in complexes I and III.[82] Recent evidence also suggests a role for complex II in the production of ROS.[83,84] Although the majority of oxygen reduction occurs in complex IV (COX), the generation of superoxide is minimal in this reaction, probably because of the high affinity of the molecule for partially reduced oxygen intermediates. Superoxide does not diffuse through the cell and may react with iron sulfur groups present in NADH-ubiquinone oxidoreductase, in succinate dehydrogenase, and as other enzymes such as aconitase, releasing ferrous ions that deactivate the enzymes.[85] Superoxide is rapidly reduced to form hydrogen peroxide:

$$O_2^- + e^- + 2H^+ \rightarrow H_2O_2$$

This reaction is catalyzed by several dismutases,[86] including manganese superoxide dismutase (SOD2) in the mitochondria or in the cytosol by copper zinc superoxide dismutase (SOD1). Another copper zinc superoxide dismutase (SOD3) is present extracellularly.

Recently, the importance of dismutases in avoiding oxidative damage has been demonstrated in knockout animals for these enzymes.[87–93] Mice defective in SOD3 were healthy until 14 months but, when submitted to oxidative stress, had severe pulmonary edema and short survival.[87] Animals with SOD1 deficiency were apparently normal but had significant motor loss after axonal injury.[88] Knockout mice for SOD2 presented with dilated cardiomyopathy, metabolic acidosis, liver steatosis, and fat deposition in muscle and died within the first 10 days. They also had a significant reduction in the activity of complexes I and II; inactivation of aconitase, especially in the heart; organic-aciduria; and DNA damage.[89,90] In a different strain of SOD2 knockout mice, the animals had severe anemia, progressive weakness, and motor abnormalities.[91] Neuronal degeneration in the brain was also observed, and marked mitochondrial injury was seen in neurons and cardiac myocytes. Compared with normal mice, liver mitochondria of animals heterozygous for SOD2 deficiency (SOD +/–) had a 30% reduction in glutathione levels. Oxidative damage of mtDNA but not of nDNA was reported. There was oxidative damage of mitochondrial proteins, including complex I and aconitase, along with an increase in the permeability of the mitochondrial membrane.[92] More recently, abnormalities in mitochondrial function characterized by respiratory inhibition, oxidative damage, proton leak, and enhanced permeability of the mitochondrial membrane were seen in SOD2-deficient animals. The changes were more significant and appeared earlier in SOD2 (–/–) than in SOD2 (+/–) mice.[93]

Hydrogen peroxide does not possess free electrons for oxidation but diffuses freely and may react with ferric or cupric ions, forming a hydroxyl radical, $HO^{\bullet}$. This reaction may be increased by Ca^{2+}, probably by mobilization of intracellular pools of iron.[83] The hydroxyl radical has a short life, causing peroxidation of proteins, lipid, and DNA. Hydrogen peroxide generated by dismutases is metabolized by mitochondrial and cytosolic glutathione peroxidase (GSHPx) in the presence of reduced glutathione to form water and oxidized glutathione.[94] Mutant mice lacking GSHPx produced fourfold more hydrogen peroxide and were 20% leaner than the wild type, probably owing to chronic oxidative stress.[95] Liver mitochondria from the knockout animals also had a lower mitochondria respiratory control ratio. In addition to GSHPx, other enzymes involved in the clearance of peroxide include peroxisomal and mithochondrial catalases[96] and thioredoxin peroxidases.[97] Recently, it was reported that mitochondrial isocitrate dehydrogenase may also be an important enzymatic defense against ROS by supplying the reduced nicotinamide adenine dinucleotide phosphate necessary to regenerate reduced glutathione in mitochondria.[98]

Another potential source for ROS is NO, a highly diffusible signaling molecule involved in many biologic processes. NO is more soluble in membranes than oxygen[99] and binds reversibly to the ferrous heme group in proteins.[100] NO is synthesized from arginine by two constitutional (one neuronal and another endothelial) and one inducible NO synthase.[101] Recently, the existence of a mitochondrial NO synthase has been reported.[102] NO may form NO_2 and NO_3 in the presence of oxygen and peroxynitrite ($ONOO^-$) by reacting with superoxide.[103,104] These NO derivatives or reactive nitrogen species (RNS) may oxidize or nitrate other molecules. Peroxynitrite may nitrite tyrosines and oxidize tryptophan, damaging a variety of enzymes, including aconitase, creatine kinase, ATP synthase, and SODs, as well as producing lipid peroxidation. In addition, NO and RNS may directly affect OXPHOS by inhibiting complexes I,[105] II,[106] and IV.[107] The inhibition of the activity of complex IV is due to reversible competition of NO for the binding site of O_2 located in the Cu_B-cytochrome a_3 center. It seems that in the presence of NO, the initial inhibition occurs at the level of complex IV, but with prolonged exposure, inactivation of complex I owing to *S*-nitrosylation of the protein occurs.[105] These NO effects on mitochondrial respiration may result in enhanced production of ROS, collapse of $\Delta\Psi$, and inhibition of ATP synthesis, leading the cell to necrosis or apoptosis.[108–110]

The generation of ROS depends on the redox status of the mitochondria. The production of ROS decreases during stage 3 of mitochondrial respiration, when the electron chain transport is more oxidized,[111] and is enhanced when the electron transfer decreases, and the system is reduced (stage 4 of respiration).[112] It seems that these different effects relate to the magnitude of $\Delta\Psi$, defining a threshold for ROS production. The importance of cell energy balance in the control of ROS production is illustrated by studies performed in knockout mice for the adenine translocator ANT-1.[113,114] In these animals, the defect has expressed phenotypically with cardiac hypertrophy, exercise intolerance, lacticacidemia, and the presence of ragged red fibers. The muscle showed ragged red fibers, proliferation of mitochondria, and a severe defect in coupled respiration.[113] Mitochondria from muscle, heart, and brain (tissues expressing the ANT-1 isoform) produced large amounts of hydrogen peroxide. Of interest, the increase in ROS production was associated with enhanced production of SOD2 in muscle tissue and muscle mitochondria. The heart, however, had a minimal compensatory increase in SOD2. A moderate increase in GSHPx was seen in both muscle and heart. Noteworthy, mtDNA rearrangements were more significant in the heart than in muscle, likely owing to the lesser ability of the heart to scavenge ROS.[114]

The production of ROS also increases in the presence of mitochondrial calcium loading, hyperoxia, and the use of specific inhibitors of the respiratory chain, such as actinomycin A, and is decreased by uncouplers of the mitochondrial respiration.[83] Recently, a role for UCPs in mitochondrial ROS production has been suggested.[115] In one study, in vitro inhibition of UCP2 induced hydrogen peroxide production.[116] Further support for a role of UCP2 in ROS production came from studies on the UCP2 (–/–) mice. In these animals, no abnormalities in terms of obe-

sity or thermoregulation were seen, but they were resistant to *Toxoplasma gondii* infection owing to increased cell ROS production.[117] Also, in UCP3 knockout mice, no defects in thermogenesis or obesity were observed, but superoxide anion production in the skeletal muscle was present.[118]

The ability of the mitochondria and the cell to limit the deleterious effect of RNS and ROS depends on the balance between the production of these radicals, the enzymatic capability of the mitochondria, and the capacity of the cell to neutralize them, as well as on the presence of lipid-soluble antioxidants such as α-tocopherol, glutathione, and $CoQH_2$.[119] ROS have been long considered to be toxic by-products of oxygen metabolism with only deleterious effects on cells. However, there is growing evidence that both ROS and RNS are participants in multiple physiologic responses. For instance, as described before, NO may regulate mitochondrial respiration by competing reversibly with O_2 for binding to COX.[71,72] In addition, as reviewed, both ROS and RNS are involved in a variety of signaling pathways regulating the expression of numerous genes and serving as messengers for several growth factors.[120,121]

Role of Mitochondria in Apoptosis

Life depends on maintaining the homeostasis of the different biologic processes in the presence of variable conditions in the environment. The integrity of the organism relies on adequate mechanisms of cell replication, differentiation, and proliferation. As part of these regulated processes, the cell possesses an intrinsic, programmed mechanism for cell death, or apoptosis, which removes damaged, aged, or excessive cells. Apoptosis was described in 1972 by Kerr and colleagues[122] and was differentiated from necrosis based on morphologic changes observed in the cell. In necrosis, swelling of the cell and organelles is followed by disintegration (karyorrhexis) and dissolution of the nucleus (karyolysis), as well as rupture of organelles and cell membrane. In contrast, apoptotic changes typically include condensation of the cell and nuclei with aggregation of chromatin, DNA fragmentation, and membrane blebbing. Abnormalities in the regulation of programmed cell death characterized by enhancement of apoptotic mechanisms may be associated with neurodegerative diseases and reperfusion injury, whereas down-regulation of apoptosis may be involved in autoimmunity and cancer.[123–125] Apoptosis is an intricate mechanism involving signals to initiate cell death, followed by the complex interaction of numerous proteins that may promote or inhibit the process. Among cell organelles, mitochondria play a central role in apoptosis.[123,126–130]

A cell may be induced to apoptosis by different normal or abnormal factors. Examples of such stimuli are the binding of specific ligands to receptors of the tumor necrosis factor (TNF) superfamily at the cell surface; the deprivation of growth factors, nutrients, or oxygen; the exposure to xenobiotics or biologic toxins; the presence of oxidative stress; signaling from second messengers (eg, calcium, ceramide); or cellular damage induced by radiation. Once the cell has been induced to apoptosis, an execution phase follows, activating a cascade of interactions between different proteins and cell products, committing the cell to death. The final phase is cell degradation by the action of several catabolic enzymes.

Proteins Involved in Apoptosis. Studies in *Caenorhabditis elegans* by Horvitz identified three different genes inducing cell death: *ced-3*, *ced-4*,and *eg1-1*.[131] Another gene, *ced-9*, was found to inhibit the process. Cd-4, an adaptor protein, likely activates *cd-3*. The activation of *cd-3* by *cd-4* may be inhibited by *cd-9,* and this inhibitory effect can be removed by *egl-1*. Homologous gene products have been identified in mammals, including caspases, proteins of the Bcl-2 family, and the apoptotic protease activating factor 1 (Apaf-1).

Caspases (cysteine aspartate–specific proteases) are a family of 14 proteins homologous to *ced-3*, classified into three different subgroups according to their substrate activity.[132] Caspases are proenzymes with three domains that can be catalytically activated, forming multimeric complexes. The substrate of their activity includes several proteins, including poly-ADP ribose, lamin, actin, DNA-dependent protein kinase, and other caspases themselves, as well as other regulators of apoptosis, such as Bcl-2 proteins. Caspases 2, 8, 9, and 10 participate in the induction and amplification of the cell death program, whereas caspases 3, 6, and 7 are the effector executioners. Depending on the signal and pathway of apoptosis, different caspases are activated (see below). Notwithstanding the important effects of caspases in apoptosis, in several experimental models, inhibition of caspases has not prevented cell death, suggesting that apoptosis may also occur by caspase-independent mechanisms.[133]

Caspases may be inhibited by several members (X-linked inhibitor of apoptosis [XIAP], cellular inhibitor of apopotis protein [c-IAP] 1, c-IAP2, and survivin) of the inhibitor of apoptosis proteins (IAPs) family, a group of proteins initially identified in baculovirus.[126,134] The functional unit of these proteins is an 80–amino acid baculovirus IAP repeat, and multiple repeats are present in most of them. The inhibition of caspase activity by these proteins may be suppressed by a mitochondrial protein called Smac (second mitochondria–derived activator of caspases) or Diablo (direct IAP binding protein with low pH), increasing the number of active caspases available for apoptosis.[135,136] The Smac protein is synthesized as a 239–amino acid precursor with an N-terminal signal of 55 amino acids that targets the protein to the mitochondria and is cleaved on entering the organelle. Another inhibitor of caspases is the Htr A2/Omi protein, a serine protease also imported into the mitochondria.[127]

The Bcl-2 family of proteins is a group of proteins homologous to the ced-9 protein in *C. elegans*.[137] These proteins contain the Bcl-2 homology (BH) domains 1, 2, 3, and 4. The family includes proapoptotic and antiapoptotic proteins. Most of the antiapoptotic proteins (Bcl-2, Bcl-X_L, Bcl-w, Mcl-1, A1, Bfl-1, Brag-1) contain the BH4 domain. The subgroup of proapoptotic proteins is subdivided in those containing the BH3 motif, being homologous with the egl-1 protein described in *C. elegans* (Bid, Bad, Bim, Noxa, Puma) and the Bax subfamily (Bax, Bak, Bok).

The mammalian protein homologous to *C. elegans ced-4* is Apaf-1.[138] Apaf-1 appears to bind to caspases via a caspase recruitment domain, which is also present in *ced-3* and *ced-4*.[139]

Pathways of Apoptosis. Two pathways for apoptosis have been defined. The first, or extrinsic, pathway is initiated by the binding of specific ligands to death receptors of the TNF receptor superfamily, including TNF-R1, Fas (CD95), tumor necrosis factor receptor apoptosis inducing ligand (TRAIL)-R1, TRAIL-R2, death receptor (DR)-3, and DR-6.[129,130,140] These receptor proteins have an extracellular cysteine-rich domain that binds specific ligands, as well as a cytoplasmic death domain capable of binding several adaptor proteins initiating the activation of caspase 8.[141] For example, binding of Fas ligand to the Fas receptor or TNF-α to the TNF-R1 receptor induces trimerization of the receptors and the recruitment of adaptor proteins, FADD (Fas-associated protein with death domain)[142] and TRADD (TNFR-1–associated death domain).[143] The association of TNF-R1/TRADD and FADD constitutes the so-called death-inducing activation complex that activates caspase 8. Activated caspase 8 may then trigger the cascade activation of effector or executioner downstream caspases 3, 6, and 7 with the subsequent cleavage of structural cytoskeleton proteins and the induction of nuclear degradation. In addition to this proapoptotic pathway, TRADD may also induce cell survival by recruiting receptor interacting protein and TRAF-2 (TNFR-associated factor 2), activating the signal transduction pathways for nuclear factor-κB (NF-κB) and JNK/c-Jun. NF-κB is a transcription regulator of several cell survival genes, including the inducible NO synthase,[144] members of the Bcl-2 family (Bcl-2 and Bcl-X_L),[145] c-IAP,[146] and SOD2.[147] Another regulatory mechanism of protection against apoptosis via the extrinsic pathway is provided by FLIPs (FADD-like interleukin-1β converting enzyme such as protease [FLICE/caspase 8]), which binds to the receptor-FADD complex, inhibiting caspase 8 activation.[148]

A second, or intrinsic, pathway for apoptosis is mediated by mitochondria (Figure 7-5).[123,126–128] As described above, a wide range of stimuli, other than the specific ligands that trigger the extrinsic pathway, may induce this intrinsic mechanism of apoptosis. Central events in this pathway are the increase in mitochondrial membrane permeability (MMP), the loss of $\Delta\Psi$, and the release of several mitochondrial proteins from the intermembranous space, including cytochrome-*c*, followed by caspase activation. The increase in MMP, also called mitochondrial permeability transition, appears to be regulated by the PTPC.[149] The nature of the complex is not completely understood but is believed to be composed of several proteins from both mitochondrial membranes and from the intermembrane and matrix spaces. The PTPC includes a cytosolic hexoquinase; two proteins of the outer membrane, the peripheral benzodiazepine receptor and the VDAC or porin; an intermembrane protein, creatine kinase; the ANT localized in the inner membrane; and cyclophilin D, located in the matrix. The pore may assume an open or closed configuration depending on several physiologic or pathologic signals. For example, MMP is induced by increased levels of calcium in the matrix, oxidative stress, fatty acid, bilirubin and bile acids, bacterial and viral proteins, β-amyloid, and respiratory chain inhibitors.[128] In contrast, several other factors may be inhibitors of MMP. For example, divalent cations (other than calcium) such as Mg^{2+} and Sr^{2+} are inhibitory, probably by competing with calcium for binding sites to the complex.[129] Also, an acidic pH in the matrix inhibits the pore activity, as well as adenine nucleotides (ADP, ATP, adenosine monophosphate).[149] The activation of MMP decreases $\Delta\Psi$, uncouples the respiratory chain, increases the formation of ROS, and results in breakdown of energy metabolism.[123,149]

As already stated, proteins of the Bcl-2 family are important regulators of MMP and apoptosis. Antiapoptotic members of the family possessing a BH4 domain (Bcl-2 and Bcl-X_L) are present in the outer mitochondrial membrane and apparently associate with the PTPC,[123,150,151] although the details of that interaction are not clear. Both Bcl-2 and Bcl-X_L prevent the drop in $\Delta\Psi$ induced by different apoptotic stimuli.[123,152] It has been suggested that the antiapoptotic effect of these proteins could be due to modulation of mitochondrial calcium traffic,[153] by regulation of the cellular redox potential,[154] or by interference with the pore-forming ability of other proapoptotic membranes of the family, such as Bax and Bak.[155] The mechanisms of interaction between the pro- and the antiapoptotic molecules of the Bcl-2 family are not completely understood.

There is controversy about the mechanisms involved in the release of mitochondrial soluble intermembrane proteins such as cytochrome-*c* into the cytosol.[123,156] In one model, on receiving an apoptotic signal, proapoptotic proteins of the BH3 family (eg, Bim, Bid, or Bid truncated by caspase 8) interact with Bax or Bak, changing their conformation.[157] The change in conformation of Bax or Bak promotes the formation of oligomers that form pores in the outer membrane, allowing the leakage of proteins from the intermembrane space. In this model, the antiapoptotic proteins Bcl-2 and Bcl-X_L interfere with the conformational change of Bax and Bad, preventing apoptosis. The second model proposes that MMP induced by a variety of stimuli causes massive swelling of the mitochondria, leading to the rupture of the outer membrane.[123,158,159] According to the model, proapoptotic Bcl-2 proteins activate MMP by changing the permeability of VDAC or ANT, affecting the flux of ADP or ATP, water, and ions between the cytosol and the matrix. Antiapoptotic proteins could then block the activation of MMP by mechanisms that have not been elucidated.

The disruption of the outer membrane permeability induces the release of mitochondrial intermembrane proteins, including cytochrome-*c*, caspase inhibitors (Smac/Diablo and Htr A2/Omi), several procaspases (2, 3, 9), the apoptosis-inducing factor (AIF), and endonuclease G into the cytosol.[127] AIF is a protein imported into the mitochondria that has oxidoreductase activity similar to that of flavoproteins. It produces apoptotic changes, including disruption of MMP, condensation of chromatin, and DNA fragmentation.

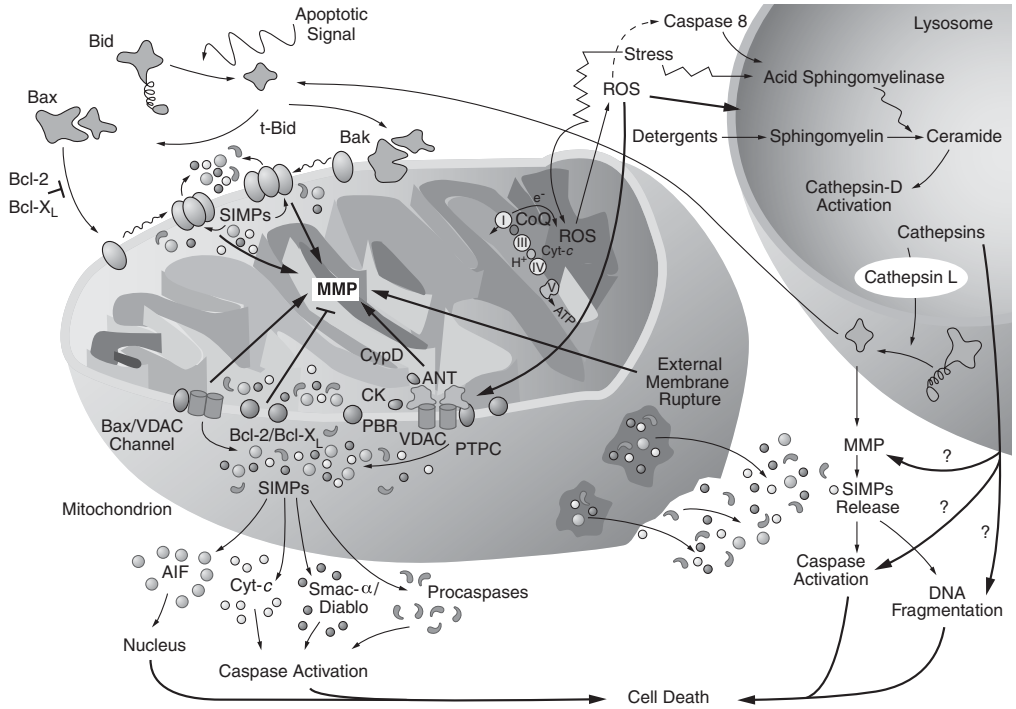

FIGURE 7-5 Organelle-specific permeabilization reaction in apoptosis. Mitochondria undergo membrane permeabilization (MMP) in response to molecules activating Bid by proteolytic cleavage (eg, caspase 8 and cathepsin L), stimulating the insertion or oligomerization of Bax or Bak in the outer membrane or agents acting on the permeability transition pore complex (PTPC). Membrane permeabilization then causes the release of soluble intermembrane proteins (SIMPs), including apoptosis-inducing factor (AIF), cytochrome-*c*, Smac/Diablo, and procaspases. Simultaneously, mitochondria generate reactive oxygen species (ROS) as a consequence of uncoupling of inhibition of the respiratory chain. In response to stress, lysosomes undergo membrane permeabilization and/or local activation and release of cathepsins. Cathepsins then can cause the proteolytic activation of Bid and might have direct effects on caspases and nuclear deoxyribonucleic acid (DNA). Antiapoptotic proteins Bcl-2 and BCL-X_L can inhibit the proapoptotic effect of Bax and Bak. ANT = adenine nucleotide translocator; CK = creatine kinase; CoQ = coenzyme Q; CYP D = cyclophilin D; Cyt-*c* = cytochrome-*c*; PBR = peripheral benzodiazepine receptor; t-Bid = truncated Bid; VDAC = voltage-dependent anion channel. Adapted with permission from Ferri KF and Kroemer G.[128]

Endonuclease G, a mitochondrial nuclease also imported into the mitochondria, translocates to the nucleus, where it produces DNA cleavage.

Once released in the cytosol, cytochrome-*c* binds to Apaf-1, inducing a conformational change that facilitates the binding of deoxyadenosine triphosphate (dATP) or ATP, the unmasking of caspase recruitment domains, and the oligomerization of the complex. This complex, known as the apoptosome, initiates the catalytic activation of procaspase 9.[160] On binding and activation of executer caspases 3 and 7 by caspase 9, downstream activation of caspases 2, 6, 8, and 10 proceeds. These activated caspases, acting on different substrates mentioned previously, initiate the damage of structural elements of the cell and the nucleus. The effects may be amplified by the proteolytic cleavage of apoptosis inhibitors such as XIAP, a member of the IAP family, or of ICAD, an inhibitor of caspase-activated deoxyribonuclease (CAD).[161]

Other organelles, besides mitochondria, also participate in apoptosis, not only as targets for the caspases but also as places where apoptotic signals may be originated.[128] For instance, nDNA damage or oncogene expression may result in activation of the tumor suppressor protein p53, which may activate proapoptotic proteins and suppress the expression of antiapoptotic members of the Bcl-2 family, as well as promote ROS production.[128,162] Under stressful signals, the endoplasmic reticulum (ER) retains unfolded proteins, activates several mediators, and releases calcium, which, in turn, can induce MMP. ER can also influence the traffic and activation of Bcl-2 proteins. For instance, antiapoptotic protein Bcl-2 targeted to the ER protected against mitochondrial apoptosis activation by interacting with an active form of Bad, a BH3 protein, preventing the activation of Bax, another proapoptotic protein.[163] Recently, data have been presented demonstrating that Bax and Bad, both proapoptotic proteins, as well as Bcl-2, localize in the ER, modulating the ER calcium concentration and influencing apoptotic mechanisms in the mitochondria.[164] There is evidence that cathepsins and probably other lysosomal products participate in the apoptotic process. Lysosomal extracts have the ability to cleave Bid, which, in turn, may induce cytochrome-*c* release in the mitochondria.[165] In addition, lysosomes may degrade damaged mitochondria by autophagy, a process in which the membrane of the ER

wraps defective mitochondria, forming a vacuole that fuses with lysosomes to form autophagosomes.

Mitochondria not only play a pivotal role in apoptosis but also probably define the ultimate outcome of the cell. Lemasters and colleagues have proposed a model in which the final fate of the cell depends on the number of mitochondria affected and the availability of energy in the cell. According to their model, when a few mitochondria undergo dysfunction, autophagy is stimulated. If the number of dysfunctional mitochondria increases, but there is still enough ATP available, the cell proceeds with apoptosis. When the mitochondrial failure is extensive, and the cell is unable to generate ATP, the hydrolysis of existent ATP is accelerated and the cell undergoes necrosis.[166]

MITOCHONDRIAL DYSFUNCTION

The metabolic machinery of the mitochondrion results from the coordinated synthesis and assembly of proteins encoded by both nuclear and mitochondrial genomes, and a variety of clinical conditions have been associated with abnormalities in mitochondrial genetics and function.[5–7] Mutations in mtDNA may be maternally inherited or occur sporadically during embryogenesis. Somatic mutations of mtDNA occur later in life and are likely due to exposure to ROS. An exemption to these mechanisms of mtDNA mutation was recently reported in a man who inherited a novel mtDNA mutation in the *ND2* gene from his father, probably owing to a defective mechanism in the exclusion of paternally derived mtDNA during early embryogenesis.[167] Although the majority of mitochondrial products are encoded by nDNA, only a minority of nDNA mutations have been identified. In contrast to mtDNA, which is maternally derived, nDNA mutations affecting mitochondrial function or the replication and integrity of mtDNA follow a mendelian pattern of inheritance (autosomal recessive, autosomal dominant, and X-linked).[5,7]

Compared with nDNA, mtDNA has a high mutation rate.[168] This difference has been attributed to an increased risk of mtDNA damage by ROS generated by the mitochondria[169] and by inefficient repair of mtDNA.[170] When a mtDNA mutation occurs, both mutated mtDNA and normal mtDNA are present in the same cell, a state known as heteroplasmy, whereas normal cells carry only normal mtDNA (homoplasmy).[5,171] Replication of mtDNA occurs independently of cellular division, and different templates of mtDNA may replicate several times during a cell cycle.[172] During cell division, mitochondria partition randomly among daughter cells, and the proportion of abnormal mtDNA may vary in different cells. Hence, during periods of high cell division such as embryogenesis, replicative segregation occurs. This segregation determines differences in the distribution and proportion of mutant mtDNA among cell lineages, producing homoplasmic and heteroplasmic cell populations with variable content of mutant mtDNA.

Depending on the proportion of abnormal mtDNA and the energy requirements of a particular tissue, functional abnormalities manifest after reaching a phenotypic threshold.[5,7,173] The phenotypic threshold may be evident not only depending on the ratio between mutant and normal mtDNA but also according to the ability of the cell and tissue to compensate for the defect at translational, transcriptional, enzymatic, and respiratory levels. Given different energy needs, the threshold varies among tissues, with the brain being the organ most susceptible to mitochondrial dysfunction, followed by the heart, skeletal muscle, endocrine system, kidney, and liver. The impaired mitochondrial function may result in decreased energy production, increased ROS production, and cellular damage. Depending on the magnitude of the defect, a decrease in functional cell mass within a specific organ may occur, presenting with variable degrees of dysfunction or failure.

Clinical Manifestations of Mitochondrial Diseases

Because the process of OXPHOS is vital in all cells and tissues, manifestations of abnormalities in mitochondrial function may be evident in one or several organs.[5,7,174] Given the high energy requirements of brain and muscle, mitochondrial diseases frequently present with neuromuscular abnormalities. Common symptoms are seizures, ataxia, delay or regression of developmental milestones, cortical blindness, muscular weakness, exercise intolerance, and hypotonia. Cardiac manifestations vary from conduction abnormalities to cardiomyopathy. Kidney involvement may present with renal tubular abnormalities or renal failure. Endocrine manifestations such as diabetes, thyroid or parathyroid diseases, adrenal insufficiency, and growth hormone deficiency can also be seen in patients afflicted with mitochondrial disorders. Deafness and retinopathy may be manifestations of the involvement of sensory organs. Defects in the hematopoietic system may result in sideroblastic anemia, neutropenia, and thrombocytopenia and, occasionally, myelodysplasia. Children affected with mitochondriopathies may have poor feeding and malnutrition as a consequence of the neuromuscular or cardiac manifestations of the disease. Other gastrointestinal manifestations include diarrhea, failure to thrive, intestinal dysmotility, pancreatic insufficiency, and liver abnormalities, including fulminant liver failure. Onset of symptoms may occur early or later in life, and multisystemic manifestations may present acutely or insidiously and progressively.

Patients with mitochondrial diseases may have abnormalities in biochemical tests, imaging studies, or tissue biopsy, particularly of muscle.[174,175] Commonly, but not always, patients with mitochondrial diseases have lactic acidosis with an increased lactate-to-pyruvate ratio (usually higher than 20). Accumulation of lactate in the brain may be found in the cerebrospinal fluid or may be demonstrated by proton magnetic spectroscopy. In patients with OXPHOS disorders, a ratio of 3-hydroxybutyrate to butyrate in plasma higher than 2 can be observed. Low levels of free carnitine with a relative increase in plasma acyl carnitines may also suggest a mitochondrial disorder. Analysis of organic acids in the urine may reveal increased amounts of 3-methylglutaconic acid and excretion of lactate and citric acid intermediates. Plasma amino acid analysis may demonstrate relatively high levels of alanine owing to transamina-

tion of accumulated pyruvate and low levels of citrulline. Muscle biopsies may show ragged red fibers in which there are irregular patches of abnormal mitochondria under the sarcolemma. The presence of ragged red fibers, however, is not pathognomonic, nor it is present in all types of mitochondrial diseases.[5] Electron microscopy of biopsies may demonstrate abnormalities in the morphology of mitochondria, including alterations of the cristae, formation of megamitochondria, and the presence of osmiophilic or paracrystalline inclusions (Figure 7-6). Biochemical analysis of the activity of the respiratory complexes in lymphocytes, fibroblasts, or tissue, as well as immunocytochemistry studies, may also give diagnostic clues in patients with clinical symptoms suggestive of mitochondrial disease. Specific molecular genetic studies available at specialized research centers may also be helpful in characterizing the mitochondrial abnormality if present.

Classification of Mitochondrial Diseases

Mitochondrial disorders have been classified based on biochemical and genetic abnormalities.[5,176,177] The following integrated classification proposed by DiMauro and colleagues describes the mitochondrial defects according to the abnormalities in mtDNA and nDNA, including the biochemical defects.[176] Table 7-1 illustrates the phenotype and the associated genetic defect of several mitochondrial diseases. The reader will notice that different genotypes may be responsible for similar phenotypes and that a given genotype may have diverse phenotypic expression.

Mitochondrial DNA Defects. mtDNA-related diseases may be due to (1) point mutations in mitochondrial tRNA or in rRNA genes affecting protein synthesis and in protein coding genes for different subunits of the respiratory chain and (2) rearrangements of mtDNA with deletion of one or more tRNAs, producing protein synthesis defects (see Figure 7-1). In the majority of cases, individuals with mtDNA disorders have mutations in tRNAs.

Point Mutations. More than 100 point mutations have been described. The majority of them occur in tRNA. Examples of these mutations include MELAS (mitochondrial encephalomyopathy, lactic acidosis, and strokelike episodes),[178] which is commonly associated with a tRNA leucine mutation (A3243G), and MERRF (myoclonic epilepsy and ragged red fibers), which is frequently related to tRNA lysine (A 8344G).[179] Several cases of isolated progressive external ophthalmoplegia, myopathy without ophthalmoplegia, and other disorders have also been described in patients with a variety of tRNA mutations.[176] Less common are rRNA mutations that have been described in subjects with deafness[180] or cardiomyopathy.[181]

Point mutations for coding genes of several subunits of the respiratory chain complexes have also been reported.[15,177] Point mutations in several subunits of complex I (ND1, -2, -4, -5, and -6) have been described in patients with Leber hereditary optic neuropathy,[7] MELAS,[182] and exercise intolerance.[183] Patients with exercise intolerance have been found to harbor mutations in the cytochrome-*b* of complex III.[184] Mutations encoding for subunit I of COX-I have been described in patients with sideroblastic anemia[185] and of subunit III (COX-III) in MELAS.[186] Recently, a heteroplasmic G9379A mutation creating a stop signal for the COX-III subunit was reported in a patient with lactic acidosis, exercise intolerance, and poor growth.[187] Mutations in subunit 6 of ATPase have been associated with NARP (neuropathy, ataxia, retinitis pigmentosa) and maternally inherited Leigh disease.[188–190]

***Rearrangements of mt*DNA.** A variety of multisystemic phenotypes are seen in cases of rearrangements of mtDNA, probably owing to differences among insertions and deletions and the variable proportion of abnormal mtDNA in different tissues.[191] Single deletions, including

TABLE 7-1 PHENOTYPIC EXPRESSION AND ASSOCIATED GENETIC ABNORMALITIES IN SEVERAL MITOCHONDRIAL DISEASES

DEFECT	PHENOTYPE	GENETIC ABNORMALITY
MELAS	Strokes, seizures, lactic acidosis, headaches, ataxia, dementia, ophthalmoplegia, diabetes mellitus, hearing loss, limb weakness, exercise intolerance, basal ganglia calcifications, muscular ragged red fibers; onset frequently occurs before 15 years old	Point mutations in $tRNA^{leu\ (UUR)}$, $tRNA^{phe}$, $tRNA^{val}$, $tRNA^{cys}$, complex I (ND1, ND5), complex IV (COX-III)
MERRF	Myoclonus, ataxia, seizures, myopathy, multiple lipomas, hearing loss, retinopathy, ophthalmoparesis, short stature; onset in childhood or adulthood	Point mutations in $tRNA^{lys}$, $tRNA^{ser}$, $tRNA^{leu\ (UUR)}$; multiple deletions
Progressive external ophthalmoplegia	Ptosis, ophthalmoplegia, and limb weakness; onset in adolescence or adulthood	Point mutations in $tRNA^{leu\ (UUR)}$, $tRNA^{leu\ (UCN)}$, $tRNA^{ile}$, $tRNA^{asn}$, $tRNA^{tyr}$, ANT1; single deletions and/or duplications
AD-PEO	Hearing loss, tremor, ataxia, nystagmus, mental retardation; onset in childhood or adolescence	Multiple mtDNA deletions, mutations in *ANT1*, *POLG*, *Twinkle* genes
Diabetes (maternally inherited diabetes mellitus; diabetes and deafness)	Diabetes	Point mutations in $tRNA^{leu\ (UUR)}$, $tRNA^{lys}$
Cardiomyopathy	Hypertrophic or multisystemic cardiomyopathy	Point mutations in $tRNA^{ile}$, $tRNA^{lys}$, $tRNA^{leu}$, $tRNA^{gly}$, 12S rRNA,complex III (cyt-*b*)
	Dilated cardiomyopathy	Point mutations in 12S rRNA, 16S rRNA, $tRNA^{ala}$, $tRNA^{asp}$, $tRNA^{glu}$, $tRNA^{thr}$, complex I (ND2)
Myopathy	Myopathy	Point mutations in $tRNA^{leu\ (UUR)}$, $tRNA^{met}$, $tRNA^{trp}$, $tRNA^{leu\ (CUN)}$, $tRNA^{phe}$, complex III (cyt-*b*), $tRNA^{pro}$; multiple deletions
LHON	Progressive loss of vision; onset in second or third decade of life	Point mutations in complex I (subunits ND1, ND2, ND4, ND5, ND6), complex III (cyt-*b*), complex IV (COX-I, COX-III), complex V (ATPase 6)
NARP	Sensory neuropathy, neurotaxia, seizures, developmental delay, dementia, retinitis pigmentosa	Point mutation in ATPase 6
Kearns-Sayre syndrome	PEO, retinopathy, cardiac conduction block, ataxia, peripheral neuropathy, hearing loss, endocrinopathy	Multiple mtDNA deletions
Leigh disease	Infantile onset, ataxia, developmental regression, hypotonia, optic atrophy, nystagmus, occasional liver involvement and cardiomyopathy, bilateral degeneration of basal ganglia	Point mutations in PDH-E_1, NDUFS 7, NDUFS 8, *SURF1*, $tRNA^{trp}$, $tRNA^{val}$, ATPase 6, SDHA

Adapted from Sevidei S,[6] Rossignol R et al,[173] and Shon EA and DiMauro S.[177]
AD-PEO = autosomal dominant progressive external ophthalmoplegia; ANT = adenine nucleotide translocase; ATPase = adenosine triphosphatase; COX = cytochrome oxidase; cyt-*b*, cytochrome-*b*; LHON = Leber hereditary optic neuropathy; MELAS = mitochondrial encephalomyopathy with lactic acidosis and strokelike episodes; MERFF = myoclonus epilepsy with ragged red fibers; mtDNA = mitochondrial deoxyribonucleic acid; NARP = neuropathy, ataxia, retinitis, pigmentosa; NDUFS = reduced nicotinamide adenine dinucleotide–ubiquinone oxidoreductase Fe-S protein; PDH-E_1 = pyruvate dehydrogenase $E_{1\alpha}$; PEO = progressive external ophthalmoplegia; POLG = mitochondrial deoxyribonucleic acid polymerase gamma; rRNA = ribosomal ribonucleic acid; SDHA = succinate dehydrogenase 2 flavoprotein subunit; *SURF1* = surfeit-1 gene; tRNA = transfer ribonucleic acid.

multiple tRNA genes, are usually heteroplasmic and may occur spontaneously. These abnormalities have been described in patients with Kearns-Sayre and Pearson syndromes and progressive external ophthalmoplegia, as well as in children with non-neuromuscular multisystemic disorders.[192–195] About one-third of patients share the same "common deletion" between ATPase 8 and the *ND5* gene (see Figure 7-1).[177]

Nuclear DNA Defects. The vast majority of the more than 1,000 mitochondrial proteins are encoded by nDNA.[22] Mutations in nDNA may affect the transport and metabolism of substrates, OXPHOS, the import of mitochondrial proteins, the function of mitochondrial transporters, and the intergenomic communication between nDNA and mtDNA.[177,196]

Defects in Substrate Transport. Defects in substrate transport include deficiencies in the transport of fatty acid by CPTI, CPTII, and CACT, producing hypoketotic hypoglycemia and cardiomyopathy in infants.[197]

Defects in Substrate Metabolism. Defects in substrate use involve abnormalities in the metabolism of fatty acid and pyruvate. Deficiencies in several enzymes participating in fatty acid oxidation frequently manifest with hypoglycemia, hepatic dysfunction, including liver failure, and neuromuscular and cardiac abnormalities (see also Chapter 55).[36,197]

In the majority of cases, disorders in the function of the pyruvate dehydrogenase complex are due to X-linked point mutations or, less frequently, to insertions or deletions in the E1α subunit gene.[198, 199] Patients with these defects may present in the neonatal period or early in infancy with lactic acidosis, lethargy, hypotonia, and seizures. The course may be fatal or less severe, with mild lactic acidosis and ataxia or exercise intolerance.[5,199]

Defects in pyruvate carboxylase, the enzyme that transforms pyruvate into oxaloacetate, have variable presenta-

tion, from mild lactic acidosis and delayed development to a severe neonatal presentation with metabolic acidosis, hepatomegaly, hyperammonemia, and death. The deficiency is autosomal recessive, and two missense mutations in the gene have been reported.[200]

Krebs cycle disorders are rare.[201] Patients with α-ketoglutarate dehydrogenase deficiency present early in life with lactic acidosis, encephalopathy, and hypotonia. As of 2000, 13 cases of fumarase deficiency have been described in infants presenting with encephalopathy, hypotonia, seizures, brain magnetic resonance imaging abnormalities, dysmorphic features, and fumaric aciduria.[201,202] Aconitase deficiency has been described in patients with exercise intolerance and myoglobinuria who also had succinate dehydrogenase deficiency.[203]

Nuclear Gene Defects in OXPHOS. nDNA encodes for 73 of 82 structural subunits of the five complexes involved in OXPHOS and for the proteins assembling them. It has been estimated that nDNA defects could be responsible for 80 to 90% of the respiratory chain disorders.[196]

Of the 42 subunits of complex I, mutations in NADH-ubiquinone oxidoreductase flavoprotein 1 have been identified in patients with macrocephaly, leukodystrophy, and myoclonic epilepsy.[204] Mutations in the NADH-ubiquinone oxidoreductase Fe-S proteins 4, 7, and 8 have been seen in Leigh disease and Leigh disease–like syndromes.[205–207] Mutations in the four subunits of complex II have also been reported.[51] Of them, mutation in the succinate dehydrogenase 2 flavoprotein subunit was associated with Leigh disease[208] and optic atrophy with myopathy and ataxia.[209] Interestingly, mutations in units SDHB, SDHC, and SDHD have not manifested with neuromuscular or multisystemic syndromes but with the presence of hereditary paragangliomas, a group of slow-growing neuroectodermal tumors. No nDNA mutations in the structural genes of complex III, IV, or V have as yet been described.

Abnormalities in the function of OXPHOS complexes owing to defects in their assembly have been described. Missense mutations in BCS1L, a protein involved in the assembly of the Rieske Fe-S subunit of complex III, were found in children with encephalopathy, liver failure, and tubulopathy.[210] Mutations in the surfeit 1 gene (*SURF1*), a homologue of a yeast gene, *SHY1*, that contributes to the assembly of COX, were reported in patients with low COX activity and Leigh disease.[211,212] Subsequently, mutations in two mitochondrial copper chaperone genes involved in COX assembly, *SCO2* and *SCO1*, were also described. Defects in the *SCO2* gene have been seen in patients with cardiomyopathy and lactic acidosis[213,214] and of *SCO1* in neonates with liver failure and encephalopathy.[215] Another missense mutation in the *COX10* gene encoding for the heme A farnesyltransferase was found in a patient with proximal tubulopathy and leukodystrophy who also had reduced activity in the COX-II subunit.[216] Because differences exist in tissue expression of COX deficiency, it has been suggested that pathways of COX assembly and regulation may be tissue specific.[217]

***Defects in* Mitochondrial Protein Import, Translocases, and Transporters.** Mutations in TIMM8a, a gene homologue to yeast TIM8p protein of the mitochondrial protein import machinery, was reported in families with deafness-dystonia syndrome. [218] Methylmalonicacidemia, isovaleryl-acidemia, and gyrate atrophy result from mutations in the mitochondrial import leader sequences of methylmalonyl-CoA mutase,[219] isovaleryl-CoA dehydrogenase,[220] and ornithine aminotransferase,[221] respectively. Defects in the ornithine transcarbamoylase gene reduce mRNA levels of the enzyme, causing abnormal synthesis of urea and defective removal of endogenous ammonia.[222] Missense mutations affecting the heart and muscle isoforms of ANT1 have been described in patients with autosomal dominant progressive external ophthalmoplegia.[223,224] Interestingly, consistent with the possible role of ANT in apoptosis, patients with autosomal dominant progressive external ophthalmoplegia and ANT1 mutations have shown no evidence of apoptosis in muscle biopsies.[225]

More recently, mutations in *SLC25A13*, a gene encoding for citrin, an aspartate-glutamate transporter and component of the malate aspartate NADH shuttle, were found in patients with late-onset citrullinemia.[226] These patients present with hyperammonemia in the second decade of life or in adulthood, and the disorder is fatal. A neonatal presentation has recently been described in Japanese children with cholestasis.[227–229] Liver dysfunction is self-limited after a few months, but one case of liver failure necessitating liver transplant has been reported.[229]

Mutations in an ATP binding cassette transporter, the *ABC7* gene, were described in X-linked sideroblastic anemia.[230] Another disorder related to mitochondrial iron metabolism is Friedreich ataxia, which has been found to be due to mutations in the frataxine gene, an orthologue of the yeast *YFHi* gene.[231]

A model for abnormalities in mitochondrial fusion and fission processes necessary in mitochondrial biogenesis is dominant optic atrophy. The defect is caused by a mutation in the *OPA1* gene that encodes for a mitochondrial importing motif similar to some yeast dynamin–related guanosine triphosphatases (eg, mitochondrial genome maintenance proteins in *S. cerevisiae*).[232,233] An example of nuclear mutations related to processes of mitochondrial protein assembly and turnover is spastic paraplegia, which has been associated with mutations in the paraplegin gene, a homologue of yeast AFG3/RCA1 coding for metalloproteases of the Atpases associated with diverse cellular activities (AAA) family.[234]

***Defects in* Intergenomic Signaling/Coordination.** nDNA is responsible for most of the tasks required in the functional expression of mtDNA and its repair. Clinical disorders associated with abnormalities in these processes include a decrease in the number of copies of mtDNA (mtDNA depletion) or defects in the integrity of mtDNA (mtDNA deletions).[235]

The mtDNA depletion syndrome is the first autosomal recessive quantitative disorder of mtDNA described.[235–237] In this syndrome, the affected tissues are almost devoid of mtDNA. Characteristically, they have a significant decrease in the respiratory activity of the mtDNA-encoded complexes I, III, and IV, with normal activity of complex II, which is encoded exclusively by nDNA. Significant proliferation of

mitochondria and the presence of ragged red fibers may be seen in muscle biopsies. One mode of presentation is fatal myopathy with onset in the neonatal period (congenital myopathy) or around the first year of life (infantile myopathy). Another variant is seen in infants with liver failure occurring in the first weeks of life (see below). Mutations in the mitochondrial thymidine kinase (*TK2*) gene were recently reported in some cases of the myopathic form[238] and in the deoxyguanosine kinase (*dGK*) gene in some cases of hepatocerebral mtDNA depletion.[239–241] These findings suggest that imbalances in the cellular pool of deoxyribonucleotide could affect the integrity of mtDNA.

Another example of potential alteration in mitochondrial nucleotide pools affecting mtDNA maintenance includes mutations in the TP gene, found in patients with mitochondrial neurogastrointestinal encephalomyopathy (MNGIE), an autosomal recessive condition with multiple mtDNA deletions (see below).[242] Three different gene mutations associated with multiple mtDNA deletions have been reported in patients with autosomal dominant progressive external ophthalmoplegia. One occurs in the *ANT1* gene, as already described. Another localizes in the *C10orf2* gene encoding for a protein called Twinkle (because of star-like staining in mitochondria), with homology to a T7 bacteriophage helicase.[243,244] A third mutation occurs in the gene for mtDNA polymerase γ (*POLG*).[245,246]

Primary Mitochondriopathies of the Digestive System

Primary Mitochondrial Hepatopathies. Liver manifestations of mitochondrial diseases may be due to defects in OXPHOS, in fatty acid transport and oxidation, in the electron transfer flavoproteins, or in the metabolism of pyruvate.[247] This chapter focuses mainly on defects in OXPHOS associated with liver dysfunction. The reader is invited to review other possible metabolic causes of hepatopathy in Chapter 55.

Among inborn errors of metabolism, OXPHOS disorders are a relatively common cause of liver failure in infancy. In a study of 80 infants with liver failure, respiratory chain disorders accounted for 21% of cases, and inborn errors of metabolism were found in 42%.[248] In another series of 157 children with respiratory chain disorders, 20% developed liver failure.[249] Cormier-Daire and colleagues studied 22 infants with isolated respiratory chain defects and described two modes of presentation.[250] In the first group, which included 40% of patients, a severe neonatal form was found in children who presented with progressive liver failure, hypotonia, and myoclonic seizures in the first weeks of life, followed by death early in infancy. In the second group, initial symptoms of hepatomegaly and jaundice occurred between 2 and 18 months, followed by liver failure. About two-thirds of patients had neurologic impairment such as myoclonic seizures or psychomotor retardation, and 40% of them had a fatal course.

In several reports, children with OXPHOS-related liver failure had isolated deficiencies in complex I or IV,[248,250–252] but children with complex III deficiency presenting with neonatal onset of liver failure and encephalopathy have also been reported.[253] Selective defects of several complexes have also been observed.[248,253]

Patients with mtDNA depletion syndrome may have multiple deficiencies in the activity of mtDNA-encoded respiratory chain complexes I, III, and IV, with normal activity of complex II in different tissues.[236,237,254–257] Hepatic depletion of mtDNA can be observed in as many as 30% of these patients,[235] and symptoms of liver dysfunction, including liver failure, occur more frequently in the immediate neonatal period or during the first months of life.[241,255,257–260] The liver may be the only organ affected. Recently, 21 children with severe liver mtDNA depletion (70 to 80% decrease of mtDNA) were studied.[235] All patients had liver failure, 2 had cardiomyopathy, and 14 (67%) had neurologic symptoms, including myoclonus, hypotonia, developmental delay, and myopathy. The course was fatal in 70% of children in the first 2 years of life. In only three of these patients, mutations in the *dGK* gene were found[241]—hence the possibility of other gene defects causing hepatic mtDNA depletion. An abnormal mosaic pattern of expression of mtTFA and of mtSSB was seen in a child with liver failure and severe mtDNA depletion.[260] The significance of these abnormalities regarding mtDNA replication remains unclear and probably represents a secondary phenomenon.

Children with hepatic mitochondriopathies may present with feeding difficulties preceding other symptoms. They frequently have lactic acidosis with elevated lactate-to-pyruvate ratios, as well as hypoglycemia. Liver function tests most commonly show mild or moderate elevation of transaminases, hyperbilirubinemia, and coagulation abnormalities in cases of liver failure. Liver biopsy findings include cholestasis and steatosis, with variable degrees of fibrosis and iron load (Figure 7-7).[257,261] Electron microscopy reveals abnormalities in the distribution of mitochondria, with matrix changes and disarray of the cristae. The clinical course can be fatal or may stabilize. Occasionally, recovery from liver failure may happen, as reported in a child with cytochrome-*c* oxidase deficiency[252] and in another with mtDNA depletion.[258] Liver transplant is controversial and has been performed in patients with liver failure secondary to OXPHOS disorders.[262–264] Of 18 patients described in these publications, 10 patients died, and the remainder survived after a follow-up of 5 months to 8 years.

Delayed hepatic failure is characteristic of Alpers-Huttenlocher syndrome, also known as progressive infantile polydystrophy.[265,266] Alpers-Huttenlocher syndrome is a neurodegenerative process characterized by microcystic cerebral degeneration with gliosis, spongiosis, and neuronal loss. The onset of symptoms frequently occurs in the first 2 years of life. Common manifestations are feeding difficulties, hypotonia, developmental delay, and ataxia. Patients may subsequently develop seizures, followed by liver failure a few months later. Several of these patients have had liver failure shortly after the use of valproic acid (VPA) for treatment of seizures, and hepatotoxicity owing to the medication was initially considered to be the cause

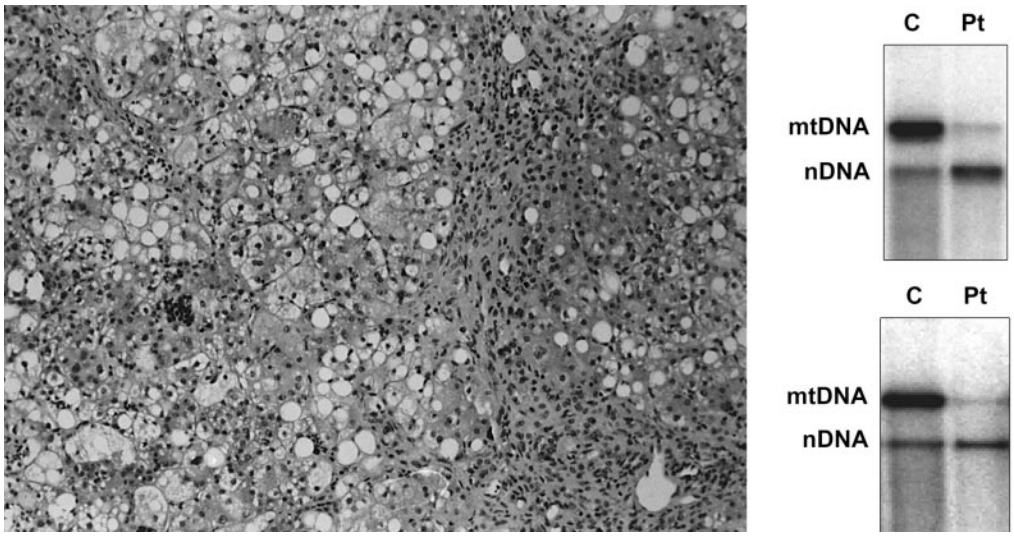

FIGURE 7-7 Liver histology and Southern blots of mitochondrial deoxyribonucleic acid (mtDNA) from an infant with mtDNA depletion. The left panel illustrates the liver biopsy showing steatosis, fibrosis, portal inflammation, and giant transformation of hepatocytes (hematoxylin and eosin stain; ×400 original magnification). Courtesy of Dr. Cyril D'Cruz, Newark Beth Israel Medical Center, NJ. The panels on the right illustrate the Southern blots of mtDNA and nuclear deoxyribonucleic acid (nDNA) from the liver (*top*) and muscle (*bottom*) from a control subject (C) and from the patient (Pt) with mtDNA depletion. Courtesy of Drs. Tuan H. Vu and Salvatore DiMauro, Columbia University, NY.

of the hepatic dysfunction.[267–270] In most cases, death occurs before the fourth year. Patients who underwent liver transplant succumbed to neurologic complications within the first year after transplant.[268,270] Although the cause of the condition has not been established, several mitochondrial defects have been described, including defects in complexes I[271,272] and IV,[273, 274] mtDNA depletion owing to deficiency in mtDNA polymerase,[275] and alterations in pyruvate metabolism and the citric cycle,[271,276] as well as the presence of muscular ragged fibers with cytochrome-*c* oxidase–negative fibers.[277]

Navajo neurohepatopathy is a candidate primary mitochondrial hepatopathy. The condition has been described in Navajo infants and children with sensory neuromotor neuropathy, corneal ulcerations, acral mutilations, failure to thrive, and hepatopathy.[278] Liver disease may be evident during the first months of life or later and progress to liver failure.[279] Histology of the liver shows cholestasis, steatosis, portal fibrosis, cirrhosis, and giant cell transformation. Electron microscopy has demonstrated pleomorphism of the mitochondria with abnormalities in the cristae. A preliminary report suggests that the syndrome might result from a deficiency in the multidrug resistance 3 gene (*MDR3*), based on a significant reduction of *MDR3* mRNA found in the liver of several children affected by the condition.[280] However, no *MDR3* mRNA mutations have been identified to date, and the correlation of the proposed defect with the neuropathy has not been established.[281] Evidence linking Navajo neurohepatopathy to mitochondrial depletion has been recently reported by Vu and colleagues in two infants who developed liver failure in the first 6 months of life.[282] In these infants, compared with controls, the activity of COX was decreased in liver, and one of them also had less activity of complexes II and III. Quantitative Southern blot showed about 85% depletion of mtDNA in the liver. No mutations were found in mtDNA or in the mtTFA gene.

Pearson Syndrome. Pearson syndrome was first described in children with sideroblastic anemia, thrombocytopenia, vacuolization of erythroid and myeloid precursors in the bone marrow, and pancreatic insufficiency.[283] The majority of patients present during the first year of life with hematologic abnormalities,[283–285] although a case without hematologic involvement has been reported.[286] Patients may have gastrointestinal symptoms, including vomiting, diarrhea, and failure to thrive, without evidence of pancreatic insufficiency.[285,287] Others develop renal tubulopathy,[285,288] hepatic dysfunction, including liver failure,[285, 289] neuromuscular symptoms,[285,290] diabetes,[291,292] or heart failure.[293] Frequently, affected patients have lactic-acidemia with high lactate-to-pyruvate ratios, and the analysis of organic acids in urine may demonstrate 3-methylglutaconicaciduria.[294] Pearson syndrome is caused by sporadic mtDNA rearrangements, including deletions and duplications.[285,295] The disorder has also been described in children of mothers with similar deletions.[296,297] The majority of patients have a 4,977 bp deletion in mtDNA, spanning a region between the sequences encoding for the ND5 subunit of complex I and the ATPase 8 subunit (see Figure 7-1). This deletion also occurs in patients with Kearns-Sayre syndrome,[298] a multisystemic disorder presenting with progressive external ophthalmoplegia, retinopathy, and cardiac, renal, and neuromuscular abnormalities. Patients suffering from Pearson syndrome frequently die in the first year of life. Survivors of Pearson syndrome can develop Kearns-Sayre syndrome.[285,299] Some patients improve hematologic abnormalities, presumably

by segregation of normal mtDNA in the hematogenic precursors during cell division.

Mitochondrial Neurogastrointestinal Encephalomyelopathy

This syndrome is characterized by the association of several gastrointestinal, neurologic, and muscular symptoms. Patients with MNGIE have multiple mtDNA deletions and depletion in muscle, associated with various mutations in the TP gene.[242,300] The enzyme catalyzes the phosphorolysis of thymidine to thymine. It is believed that the defect can produce an imbalance in the nucleotide pool available for mtDNA synthesis.[300] As reviewed by Nishino and colleagues[300] and Teitelbaum and colleagues,[301] onset of symptoms most commonly occurs late in the second decade of life. Initial gastrointestinal symptoms are cachexia, vomiting, diarrhea, and abdominal pain secondary to gastroparesis and partial obstruction. Small bowel diverticula may be found in as many as two-thirds of affected subjects. Sensory and motor symptoms owing to peripheral neuropathy are present and are usually mild. Ocular findings, including ptosis and ophthalmoplegia, have been reported in the majority of cases. Hearing loss can also be part of the syndrome in about half of cases. Patients may have lactic acidosis, and muscle biopsy shows ragged fibers, with COX-deficient fibers in most subjects. Other pathologic findings include atrophy of the intestinal muscularis propia with the presence of abnormal mitochondria in ganglion and smooth muscle cells, as well as microvesicular steatosis in liver, skeletal and intestinal muscle, and Schwann cells.[302] The activity of TP as measured in peripheral leukocytes by the conversion of thymidine to thymine is almost undetectable. Brain magnetic resonance imaging (MRI) shows leukoencephalopathy in all patients, and electromyography consistently demonstrates neurogenic changes in all patients. Forty percent of patients may also have myopathic findings.[300] Death commonly occurs in the fourth decade.

Other Mitochondrial Enteropathies. There are several reports of patients in whom clinical symptoms are similar to MNGIE but in whom no evidence of leukoencephalopathy or mutations in the TP gene have been found.[300,303] Mitochondrial enteropathies other than MNGIE, manifesting in infancy and childhood, have been reported. Cormier-Daire and colleagues described two children who presented with severe vomiting, diarrhea, and malnutrition at 6 and 15 months, respectively.[304] During the course of their disease, they were found to have partial villous atrophy and lactic acidosis while receiving a high-carbohydrate diet. Liver and renal abnormalities were present without evidence of pancreatic insufficiency or hematologic disorders. Temporary improvement was noted, and they were able to receive continuous enteral nutrition. Both patients subsequently developed cerebellar ataxia and sensorineural deafness. One of them had retinitis pigmentosa and proximal muscle weakness and the other had diabetes and renal failure. Both children died at 12 years of age. mtDNA deletions (3,380 bp and 4,191 bp) encoding for several tRNAs and subunits of complex I were found.

Verma and colleagues reported a child who, at 3 years of age, had persistent intermittent abdominal pain, episodic vomiting, and diarrhea, resulting in growth failure.[305] He was found to have a borderline gastric emptying time. Gastric and intestinal biopsies were normal. At age 7 years, he developed seizures and, years later, lactic acidosis, cerebellar ataxia, sensorineural deafness, peripheral neuropathy, and retinitis pigmentosa. He did not have ophthalmoplegia or limb myopathy. MRI demonstrated abnormalities in the white matter, thalamus, and basal ganglia. He died when he was 15 years old. A novel mitochondrial tRNA lysine (G8313A) mutation was found in muscle and fibroblasts. The authors suggest that intestinal dysmotility in patients with mithochondrial disease can be secondary to abnormalities in the intestinal muscle or in the neuronal network.

More recently, Chitkara and colleagues reported six children who presented with poor suck, food refusal, vomiting, and diarrhea or constipation in the first days of life.[306] Owing to feeding difficulties, gastric tube feedings were necessary, and in three children, additional parenteral nutrition was required. Neurologic symptoms began after the second year of life and included seizures, muscular hypotonia or hypertonia, and cortical blindness. Brain MRI was normal in four children. Mild dilatation of ventricles and brain atrophy were seen in one patient, and periventricular leukomalacia was reported in another. All patients had abnormal antroduodenal manometry. Several abnormalities in OXPHOS were reported in all patients, but no evidence of mtDNA mutations was seen in multiple mtDNA genes screened. At the time of the publication, patients had been followed for several years, with no fatalities reported.

Secondary Dysfunction of Mitochondria

Abnormalities in mitochondrial structure and function have been observed in a variety of clinical conditions related to apoptosis, to increased production of ROS, or to direct mitochondrial damage produced by different toxins and drugs.

Cholestasis. Patients with liver disease frequently present with cholestasis, which can further compromise liver function by affecting mitochondria. In animal models, bile duct ligation produced swelling of the mitochondria, shortening of the cristae, and changes in the shape of the organelle.[307] Several factors may be responsible for these bile acid–induced abnormalities. Bile acids may derange mitochondrial respiration and electron transfer,[308,309] increase production of ROS,[310,311] and produce cellular ATP depletion.[312] Bile acids may also activate the Fas receptor–mediated pathway of apoptosis.[313,314] The final outcome of these abnormalities may be changes in MMP with release of cytochrome-*c* and initiation of apoptosis.[315,316] Interestingly, ursodeoxycholate, a hydrophilic bile salt, confers cytoprotection against apoptosis induced by other bile salts.[315,316] Noteworthy, in rat neuron and astrocyte cultures, ursodeoxycholate and tauroursodeoxycholate were protective against the apoptotic effects of unconjugated bilirubin

and β-amyloid peptide, two neurotoxins implicated in kernicterus and Alzheimer disease, respectively.[317]

Infections. Several bacterial and viral products may interact with mitochondria, affecting their function.[318,319] For instance, *Neisseria* species possess porin proteins in the outer membrane that have structural similarities to VDAC and localize in the host mitochondria, affecting apoptosis. *Neisseria gonorrhea* has a porin B protein (PorBg) that induces MMP and apoptosis.[320] Interestingly, porin B of *Neisseria meningiditis* (PorBm), which has a minor structural difference with PorBg, has the opposite effect, inhibiting MMP and apoptosis.[321] The N-terminal of the vacuolating cytotoxin A from *Helicobacter pylori* also interacts with VDAC, causing apoptosis.[322] Similarly, *Clostridium difficile* toxin A localizes in host cell mitochondria, causing apoptosis and generation of ROS.[323]

Sepsis is the systemic reaction of the host to infection and can progress to septic shock and multiorgan failure. Evidence in animals and humans has shown mitochondrial respiration abnormalities during sepsis.[324–326] In a recent study, compared with controls, septic patients had decreased OXPHOS, and decreased ATP production, depletion of glutathione, and overproduction of NO. Of clinical relevance, the magnitude of the changes seen in these patients related to their survival.[324]

Several viruses, including Epstein-Barr virus,[327,328] Kaposi sarcoma–associated herpesvirus 8,[329,330] and adenovirus,[331] produce apoptosis inhibitor homologues to Bcl-2 proteins. Others, such as cytomegalovirus, encode an apoptosis inhibitor, viral mitochondrial inhibitor of apoptosis, which interacts with the ANT.[332] Virus can also produce proapoptotic mediators. For example, viral protein R of human immunodeficiency virus (HIV) interacts with ANT, promoting apoptosis and caspase activation.[333,334] Another HIV protein, the transactivating protein (Tat),[335] induced caspase activation, mitochondrial calcium uptake, ROS accumulation, and mitochondrial membrane depolarization. Interestingly, Tat may induce calcium-dependent ion secretion in Caco cells and human colonic mucosa, suggesting a role for this protein in HIV-1 enterophathy.[336]

Factors producing cellular damage in viral hepatitis are complex. There is evidence that in chronic hepatitis B and C, apoptosis may result from activation of Fas-mediated mechanisms.[337–339] In addition, the X gene product of the hepatitis B virus (HBV-X) interacts with mitochondrial VDAC,[340,341] decreasing $\Delta\Psi$,[340] inducing oxidative stress and activating transcription factors NF-κB and signal transducer and activator of transcription-3.[342] There is also evidence of increased oxidation in patients with hepatitis C.[343,344] Experimental cell overexpression of the hepatitis C core protein demonstrated association of the protein with mitochondria, increased ROS production, and release of cytochrome-*c*.[345]

Drugs. The liver plays a central role in the metabolism of potential toxins, including drugs, which can affect mitochondria by several mechanisms.[346,347] For example, amiodarone, an antiarrhythmic medication, may produce liver dysfunction and affect mitochondria at different levels, including inhibition of the electron transport chain, uncoupling of OXPHOS, and inhibition of mitochondrial fatty acid metabolism.[348,349] Several enzymes of fatty acid β-oxidation can be inhibited by tetracyclines, glucocorticoids, nonsteroidal anti-inflammatory medications such as ibuprofen, and several tricyclic antidepressants.[347] Buprenorphine, an analgesic used as a substitute drug in heroine addicts, when used intravenously, produces severe hepatitis secondary to inhibition of β-oxidation, uncoupling and inhibition of mitochondrial respiration, and collapse of $\Delta\Psi$.[350]

VPA is an 8-carbon branched carboxylic acid widely used for the treatment of seizures. Two forms of hepatotoxicity associated with the use of VPA have been described.[351] One is dose dependent and is characterized by mild elevation of transaminases and a minimal, if any, increase in bilirubin. Patients have minimal symptoms. Abnormalities in liver tests and symptoms subside after adjusting the dose or discontinuing the medication. The second form of hepatotoxicity is idiosyncratic and dose independent. It typically presents during the first months of treatment and is heralded by nausea, vomiting, and anorexia, followed by lethargy and seizures. The elevation of hepatic enzymes may be significant but most commonly is mild or moderate and is accompanied by an abnormal coagulation profile indicative of liver failure. The greatest risk occurs in children younger than 2 years, in those receiving multiple medications, or in patients affected by neurodevelopmental delay or metabolic disorders.[352–354] Underlying mitochondrial disease appears also to be a risk factor for VPA-induced liver failure.[355,356] Although reversal of liver failure has been reported,[354,357] the clinical course is usually fatal. Except for one reported case,[358] liver transplant has been unsuccessful.[353,359] The toxicity of VPA has been attributed to abnormalities in the β-oxidation of fatty acid owing to formation of valproyl CoA decreasing the formation of acyl CoA or to the toxic effects of VPA metabolites.[351] In rat liver, VPA[360,361] and its metabolites[361] have been shown to decrease mitochondrial respiration. In a similar animal model, mitochondrial respiratory abnormalities were associated with a decrease in the content of cytochrome aa_3 in complex IV.[362] In vitro studies on rat liver mitochondria have demonstrated the ability of VPA to induce MMP without significant effects on mitochondrial $\Delta\Psi$.[363] The potential apoptotic effects of VPA have also been seen in human leukemic cells. In these cells, treatment with VPA produced apoptotic changes, including cytochrome-*c* release, caspase activation, and DNA fragmentation.[364] Liver and muscle steatosis associated with morphologic abnormalities in mitochondria have been reported as a toxic manifestation of VPA treatment.[365,366]

Epidemiologic evidence in children has correlated the use of aspirin during viral illness with the development of Reye syndrome.[367,368] The incidence of the syndrome has decreased dramatically after the decline in the use of aspirin in children.[369] Reye syndrome usually presents during a viral illness with vomiting and lethargy, followed by variable degrees of encephalopathy, brain edema, and hepatopathy.[370] The encephalopathy may be accompanied

by seizures, and the initial lethargy can progress to severe coma, with decortication and decerebrate posturing and, eventually, brainstem herniation. Hepatomegaly has been found in 50% of cases, and transaminases are elevated, but bilirubin levels are usually normal or minimally increased. Variable degrees of coagulopathy may be present. Analysis of serum fatty acid has demonstrated increased concentration of dicarboxylic acids, suggestive of a fatty acid oxidation defect, which correlates with the clinical status.[371] Other biochemical abnormalities include hypoglycemia, hyperammonemia, aminoaciduria, and lactic acidosis. Liver biopsies characteristically show microvesicular steatosis without necrosis. Steatosis may also be present in renal tubular cells, muscle, myocardium, lungs, and pancreas. Electron microscopy has shown swelling of mitochondria with cristae abnormalities.[372] It has been suggested that salicylates, in conjunction with abnormalities in cell calcium regulation produced by viral illness, might uncouple OXPHOS, inducing MMP and apoptosis.[373]

Nucleoside analogues such as zidovudine, stavudine, and zalcitabine used in antiretroviral treatment may interact with DNA polymerase γ, causing termination of mtDNA replication.[374–376] Significant structural and functional mitochondrial damage, including mtDNA depletion in patients treated with these medications, has been reported.[375,377–380] HIV-infected patients developing mitochondriopathy after the use of these medications have had lactic acidosis, as well as neuromuscular, hematologic, and hepatic symptoms. Fialuridine, another antiviral agent and an inhibitor of mtDNA replication,[381] was tried in patients with chronic hepatitis B but was withdrawn from the market because it caused hepatopathy and lactic acidosis in several patients.[375] Of interest, interferon-α used to treat chronic hepatitis B and C affected mtDNA transcription and reduced mitochondrial mRNA in vitro.[382,383] A recent publication suggests that down-regulation of mRNA in cells treated with interferon could be due in part to mRNA degradation by a mitochondrial ribonuclease.[384] In both, intact cells and isolated mitochondria interferon treatment decreased electron transport.[385]

Alcohol Liver Disease. The pathophysiology of alcohol liver disease is multifactorial and complex.[386] Mitochondria are affected early in the course of the disease and can be the source or the target of ROS.[387,388] Mitochondrial abnormalities, characterized by swelling of the organelle with disorganization of the cristae and formation of megamitochondria, have been correlated with alcohol consumption.[389,390] Alcohol impairs OXPHOS, producing a decline in active respiration of the mitochondria (stage 3).[391,392] Chronic ethanol ingestion can decrease the synthesis of the 13 OXPHOS peptides encoded by mtDNA[393] and reduce the number of mitochondrial ribosomes.[394] The most significant quantitative effect occurs in the activity of COX, which can be reduced by at least 50%.[395,396] Also, the activity of ATPase synthase is impaired[397] as a result of defective synthesis of subunits 6 and 8 of the enzyme.[398] Lesser impairment in the activity of cytochrome-*b* and of the iron sulfur center of complex I has also been reported.[395,399] Isolated fetal hepatic mitochondria exposed to ethanol showed a decrease in the activity of complexes I and IV accompanied by lowered ATP synthesis.[400]

Alcohol may lower the cellular threshold for oxidative damage owing to alterations in the membrane fluidity, decreasing the import of glutathione from the cytosol into the mitochondria.[401,402] In addition, alcohol enhances susceptibility to oxidative damage by reducing the activity of GSHPx.[403] Acute administration of ethanol enhances production of ROS, lowers $\Delta\Psi$, increases MMP, and causes apoptosis.[404] As expected, ethanol-induced ROS damage proteins and DNA and produce lipid peroxidation.[405] Marked loss of hepatic mtDNA in rats after an acute dose of ethanol was reported, suggesting that ethanol-induced ROS affect the integrity of mtDNA.[406] This is of relevance because mtDNA deletions have been observed in alcoholics.[407]

Nonalcoholic Fatty Liver Disease. Nonalcoholic fatty liver disease is the most common hepatic disease in America and is characterized by fatty infiltration of the liver and hepatomegaly.[408] The condition is frequently seen in patients with obesity, non–insulin-dependent diabetes, and hypertriglyceridemia.[409,410] Fat liver accumulation may cause cell necrosis and inflammation with elevation of transaminases, an association known as nonalcoholic steatohepatitis (NASH). The condition may progress to fibrosis and cirrhosis.[411,412] Recently, the role of mitochondria in NASH has been examined. Ultrastructural abnormalities of mitochondria have been described in NASH, including swelling, the appearance of multilamellar membranes and crystalline inclusions, loss of cristae, and formation of megamitochondria.[412,413] A decrease in the synthesis of ATP has been found in patients with NASH,[414] and preliminary reports have described lower activity of the respiratory chain,[415] as well as abnormalities in mtDNA.[416] Similar to alcohol-induced steatohepatitis, in NASH, enhanced production of ROS and lipid peroxidation appear to be central in inducing cellular damage and cytokine production by hepatocytes and Kupffer cells.[409] Recently Sanyal and colleagues showed that compared with individuals with nonalcoholic fatty liver disease, subjects with NASH had higher fasting levels of insulin and free fatty acids, as well as enhanced hepatic fatty oxidation.[413] The authors suggest that patients with NASH may constitute a different subpopulation of individuals who may carry a silent mitochondriopathy, which is then unmasked when patients develop insulin resistance.

Wilson Disease and α1-Antitrypsin Deficiency. Mitochondrial abnormalities have been described in patients with Wilson disease and α_1-antitrypsin (α_1-AT) deficiency. Wilson disease is characterized by cirrhosis and degeneration of the basal ganglia owing to abnormalities in copper metabolism produced by mutations in a copper-transporting ATPase (ATP7B).[417] The ATP7B product is a copper-transporting P-type ATPase present in the cell in two forms: one isoform of 160 kD[418,419] localizes in the *trans*-Golgi, whereas another of 140 kD apparently localizes in the mitochondria.[418] The molecule is necessary for the incorpora-

tion of copper into ceruloplasmin and the excretion of copper into the bile.[420] Polymorphic changes of mitochondria, accompanied by crystalline inclusions, abnormalities in the cristae, and the presence of vacuoles in the matrix, have been seen in liver biopsies from patients with Wilson disease.[421] Using an animal model, Sokol and colleagues demonstrated that copper load decreases COX activity, enhances ROS production, and produces oxidation of protein and lipids.[422] Similar findings were reported in patients with Wilson disease.[423] Deletion of mtDNA secondary to oxidative stress was reported in 50% of Wilson disease patients younger than 30 years of age.[424] A more recent study described significant decrease in the activities of aconitase and in the activity of respiratory complexes I, II, III, and IV in three Wilson disease patients, supporting the notion that abnormalities in mitochondrial OXPHOS may contribute to the pathogenesis of the disease.[425]

α_1-AT deficiency is the most common genetic liver disorder in children.[426] The condition is due to abnormalities in the PiM allele for the gene. Individuals with cirrhosis secondary to α_1-AT deficiency have a gene base substitution (342 lysine), and the mutated allele is known as PiZZ. The mutated gene product has impaired secretion and is retained in the ER, triggering an autophagic response. Recent studies in patients with α_1-AT deficiency showed marked autophagia of the mitochondria in the liver of α_1-AT patients.[427] Noteworthy, many mitochondria not associated with the phagosome vacuoles showed variable degrees of damage, which included condensation of the cristae and matrix, formation of multilamellae, and loss of matrix structures. Similar mitochondrial changes associated with activation of caspase 3 were seen in the liver of PiZ transgenic mice, a model for α_1-AT deficiency. Of interest, these abnormalities improved in animals receiving cyclosporine, an inhibitor of MMP. The cause and possible consequences of these mitochondrial abnormalities in α_1-AT deficiency await further investigation.

Ischemia-Reperfusion. Ischemia and hypoxemia occur in a variety of clinical circumstances and affect the metabolism, energy production, and function of tissues and organs. The re-establishment of appropriate blood flow with adequate supply of nutritional substrates and oxygen paradoxically may further impair cell and organ function. Several pathophysiologic events seen in ischemia-reperfusion injury, such as increased ROS production, mitochondrial dysfunction, failure in energy production, induction of inflammatory response, and production of cytokines acting in concert, may lead the cells to apoptosis or necrosis.[428–430] Given the different metabolic rates of specific tissues, the ability to recover depends on the magnitude of the ischemic-hypoxia insult and the intrinsic adaptive mechanisms of the tissue. Because mitochondria are central in the consumption of oxygen and production of energy, the important role of mitochondria in the pathophysiology of ischemia-reperfusion is not surprising. For example, in the liver, morphologic alterations of mitochondria have been observed early under hypoxemic conditions, which are reversible after reoxygenation.[428] Hypoxia and ischemic injury affect OXPHOS and the production of ATP. In vitro studies on mitochondria have shown that after reoxygenation, mitochondria uncoupled respiration and decreased phosphorylation activity.[431] In liver cells, without suitable energy substrates, respiratory inhibition produced by ischemia-reperfusion increased ATPase activity, leading to cellular ATP depletion.[429] Mitochondria can also be the source of ROS under hyperoxia or hypoxia-hyperoxia, and there is experimental evidence of ROS production during ischemia-reperfusion[432,433] Therefore, ROS generation may contribute to cellular and tissue damage occurring in ischemia-reperfusion. Alterations in oxygen and nutrient cell supply during ischemia, along with the above-mentioned mitochondrial abnormalities, are triggering signals for apoptosis.[434–437]

Aging, Cancer, and Degenerative Disorders. Aging is a complex biologic process involving genetic and environmental factors resulting in functional decline of cells and organs. Aging is frequently associated with the development of degenerative disorders and increased incidence of malignancy. Since Harman proposed that the life span of an organism relates to the rate of oxygen use and accumulation of oxidative damage in the mitochondria,[438] the relationship between aging and mitochondrial function has been the focus of extensive research.[439,440]

The mitochondrial free radical theory of aging considers that aging is accompanied by a progressive dysfunction of OXPHOS and energy production, proton leakage, and enhanced production of free radicals, causing further mitochondrial and cellular damage.[441] Miguel suggested that during aging, oxidative damage of mtDNA in postmitotic cells could produce defects in replication and mutation of mtDNA, resulting in lower cell energy production.[442] According to this model, a vicious circle is established in which the abnormalities in mtDNA amplify the process by further affecting OXPHOS and ATP synthesis, increasing the production of ROS. The role of primary mtDNA mutations in aging, however, has not been completely established.[443]

Mitochondrial dysfunction and oxidative stress have also been considered to have a common link with cancer[7,444,445] and degenerative diseases.[446,447] Early in the past century, Warburg and later Szent-Gyorgyi proposed that abnormalities in mitochondria could be related to malignant transformation.[446] Mitochondria could play a role in oncogenesis by different mechanisms. For example, it is hypothesized that in addition to inducing mtDNA damage, oxidative stress could damage nDNA, activating oncogenes or deleting tumor suppressor genes, resulting in activation of mitogenic pathways. An altered cellular redox state and enhanced ROS can affect cell differentiation and transformation via the regulation of expression of numerous genes, of which the MAP kinase and the NF-κB signal transduction pathways have been more investigated.[448] Another potential role for mitochondria in oncogenesis could be through its role in apoptosis because abnormalities in apoptosis have been associated with cancer.[125] Other possible roles for mitochondria in the development of malignancy have been considered, including incorporation of fragments of mtDNA into nDNA, the transmission of onco-

genic viral DNA, the mitochondrial activation of chemical carcinogens, and the regulation of calcium homeostasis.[444]

Several mitochondrial genetic abnormalities have been identified in various types of cancer, as recently reviewed.[449,450] Somatic mtDNA changes include point mutations, insertions, transitions, and deletions. In several tumors (eg, breast, colon, hepatic, gastric), mtDNA mutations frequently occur in the D-loop region. Abnormalities in mitochondria have also been described in Alzheimer[451] and Parkinson disease, the two most common neurodegenerative disorders.[452]

SUMMARY

The presence of metabolic functions is central to life. The most important aspect of metabolism is the generation of energy, without which no life phenomena can be sustained.

From a thermodynamic perspective, living organisms may be considered as open, nonequilibrium systems exchanging matter and energy with their environment. Mitochondria in synthesizing ATP are pivotal in this process by harvesting the energy contained in electrons present in $NADH^+$ and $FADH_2$ produced during the oxidation of fat and carbohydrates. Mitochondria and specifically the electron transport chain may be considered the interface at which the transformation of energy contained in substrates from endogenous or exogenous sources is made available for the biologic functions of aerobic organisms. Conversely, impairments in the generation of ATP by the mitochondria may lead to cellular depletion of energy, failure of vital systems, and, ultimately, death.

Living organisms maintain their integrity by adapting to changes in the inner and outer environments. The presence of an atmosphere rich in oxygen determined adaptation in the evolution of life, providing aerobic organisms with the potential to couple the generation of energy with the reduction of oxygen in the mitochondria. In these reactions, however, potentially cell-damaging ROS may be produced, and mechanisms to neutralize them may emerge. Cell differentiation, development, and growth are constitutive processes in the life of multicellular organisms. As part of these processes, metazoans developed mechanisms of cell death, eliminating damaged, abnormal, or excessive cells to maintain tissue homeostasis. As described in this chapter, mitochondria play a central role in apoptosis, a cell death process involving the complex, concerted action of several proteins, resulting in disruption and collapse of energy production. Mitochondria are therefore at the crossroad of life and death and, not surprisingly, mitochondrial dysfunction and failure frequently associated with ROS production may be the ultimate consequence of diverse pathologic states.

Advances in the understanding of the biology and genetics of mitochondria have permitted the recognition of diseases owing to abnormalities in mitochondrial function. Primary mitochondrial diseases can occur as a consequence of abnormalities in mtDNA or in nDNA affecting mitochondrial proteins or the integrity of mtDNA. These disorders are frequently, but not always, multisystemic and involve organs and tissues of high energy demand, such as brain, heart, and muscle, although other systems may also be compromised. Manifestations in the digestive system include liver dysfunction and, frequently, liver failure, but pancreatic insufficiency, intestinal dysmotility, and failure to thrive may also occur. Secondary dysfunction of mitochondria may accompany a broad group of conditions, including aging, cancer, neurodegenerative diseases, ischemia-reperfusion injury, certain infections, and exposure to endogenous or exogenous toxic substances. Clinicians should consider the possibility of a mitochondrial disorder in the differential diagnosis of patients affected with multisystemic and progressive disorders, without forgetting that mitochondrial diseases may also manifest in one system.

A better understanding of the synthesis, transport, assembly, and function of known mitochondrial proteins, as well as the perspective of new discoveries in mitochondrial biology and function, will certainly have an impact on the diagnosis and the treatment of mitochondrial disorders.

ACKNOWLEDGMENTS

I thank Drs. Salvatore DiMauro, Columbia University, NY; Adam Aronsky, Children's Specialized Hospital, NJ; and Kenneth S. Nord, Saint Barnabas Medical Center, NJ; for their insightful comments. I express my gratitude to Colleen Ngai and Elizabeth Bohrer for their assistance in the preparation of the manuscript and to Ellen Thorne for her help with the references.

CHAPTER 8

GASTROINTESTINAL INJURY

1. *Drug-Induced Bowel Injury*

Shinya Ito, MD

Pharmacotherapy is often associated with adverse effects in the gastrointestinal tract. Oral administration of drugs exposes gastrointestinal mucosa to relatively high concentrations of the drug. Even parenteral use of drugs may cause adverse reactions, which are specific to the gastrointestinal system.

The classification system of adverse drug reactions (ADRs) proposed by Patterson and colleagues categorizes them as predictable or unpredictable, providing a practical framework to deal with the phenomenon that often leads to significant morbidity and mortality.[1] Predictable ADRs are further divided into side effects (commonly seen unwanted effects stemming from the drug's pharmacology and mechanisms of action), secondary effects (relatively rare side effects), drug interactions, and toxicity (a consequence of overdose). Unpredictable ADRs include intolerance (exaggerated effects at usual drug doses), idiosyncratic effects (severe unwanted effects that may not be fully explained by the drug's mechanisms of action), and allergic reactions mediated by immunologic mechanisms.

ADRs that target the gastrointestinal tract are numerous, ranging from nausea and vomiting without significant pathology to severe colitis. This chapter describes drug-induced bowel injury defined as gastrointestinal ADRs with pathologic changes. Although nausea and vomiting without gastrointestinal pathology are commonly encountered, they are not discussed. Similarly, overdoses and poisonings with corrosive nonmedicinal agents are beyond the scope of the chapter. The ADRs are discussed in a section of each major target anatomic site, but it is important to note that multiple sites may be involved. Because the field of pediatrics encompasses premature infants to young adults, the chapter covers both pediatric-specific ADRs and those commonly reported in adults.

ESOPHAGUS

Pill Esophagitis

Tablets and capsules are common drug formulations for older children, adolescents, and adults. These drug formulations are designed for optimal dissolution in an appropriate gastrointestinal environment for absorption. As a conduit for ingested substances, the esophagus is not directly involved in drug absorption. However, a swallowed tablet or capsule may lodge itself in the esophagus, releasing its contents onto the esophageal mucosa. If a pill is dissolved in such a confined small area, concentrations of active ingredients in the local milieu may become extremely high. If exposed to the drug at a high concentration for a prolonged period of time, the esophageal mucosa may be damaged. Hence, lodged and immobilized pills become a cause of esophageal mucosal injury. This condition is called *pill esophagitis* or *pill-induced esophageal injury*.[2,3] Although the risks of developing pill esophagitis may be small, it is estimated that 10,000 cases occur per year in the United States.[2]

Case reports indicate that patients' ages vary, ranging from 3 to 98 years.[2] Surprisingly, associations with specific underlying conditions, including esophageal disease, are not known, and the majority of pill esophagitis cases are reported in patients with no apparent predisposing conditions.[2] However, swallowing without water, supine positioning, and certain surface characteristics of pills (eg, larger pills, gelatinous capsules, certain sustained-release formulations) are considered risk factors for developing the condition.[4,5] Despite the lack of apparent association, patients with preexisting esophageal functional and/or anatomic pathology that delays esophageal emptying should be considered at risk until proven otherwise.

Drugs reported to cause pill esophagitis are numerous (Table 8.1-1),[2,3] but the most frequently quoted medications include antibiotics, potassium chloride, nonsteroidal anti-inflammatory drugs (NSAIDs), and quinidine, comprising nearly 90% of all reported cases.[2] However, the drug-specific risks of developing the condition are unknown. Despite the recent introduction into clinical practice, case reports of esophageal injury by bisphosphonates such as alendronate and pamidronate are relatively common and severe in nature.[2] The exact mechanisms of caustic effects probably differ among these offending drugs and are not fully understood.

The symptoms include acute-onset retrosternal pain that is continuous or worsened by swallowing (ie, odynophagia).

TABLE 8.1-1 DRUGS FREQUENTLY IMPLICATED FOR ESOPHAGEAL MUCOSAL INJURY

ANTIMICROBIALS
Doxycycline
Tetracyclines
Oxytetracycline
Minocycline
Penicillin
Ampicillin
Zidovudine
NSAIDS AND SALICYLATES
Naproxen
Aspirin
Ibuprofen
Indomethacin
Piroxicam
OTHERS
Bisphosphonates (alendronate, pamidronate)
Potassium chloride
Ferrous sulfate/succinate
Quinidine
Theophylline
Corticosteroids

Adapted from Kikendall JW.[2]
NSAID = nonsteroidal anti-inflammatory drug.

Dysphagia may also be associated. A long-standing injury may lead to a stricture. Esophageal hemorrhage (especially in those receiving aspirin and NSAIDs), perforation, penetration, strictures, and mediastinitis have been reported in those receiving drugs such as NSAIDs,[6,7] potassium chloride,[8] alendronate,[9] sustained-release ferrous sulfate, and sustained-release valproate.[10] Endoscopic examinations usually confirm the diagnosis. The symptoms usually subside in a few days to weeks on discontinuation of the drug therapy, although cases with complications may require intensive therapy, including total parenteral nutrition and surgery.

ORAL AND ESOPHAGEAL MUCOSITIS INDUCED BY CANCER CHEMOTHERAPY

Anticancer drugs affect tissue turnover and remodeling maintained by rapidly proliferating epithelial cells in the gastrointestinal tract. Consequently, ulceration and inflammation may occur following systemic administration of cancer chemotherapy agents throughout the gastrointestinal system, including oral cavity mucosa, the esophagus, and other parts of the gastrointestinal tract. Usually, oral lesions accompany the esophageal changes. Methotrexate, vinca alkaloids (such as vincristine and vinblastine), dactinomycin, doxorubicin, bleomycin, cytosine arabinoside, and 5-fluorouracil are often implicated as causative agents.[11] Treatment is supportive, and uncomplicated lesions usually heal in 2 weeks. A well-known example of effective prevention of toxicities caused by high-dose methotrexate regimens is folinic acid rescue (leucovorin).

STOMACH AND DUODENUM

NSAID-INDUCED GASTRODUODENAL ULCER

NSAIDs (in this chapter, NSAIDs indicate nonselective cyclooxygenase [COX]-1 inhibitors and do not include selective COX-2 inhibitors, unless otherwise stated), including aspirin, are by far the most common causes of drug-induced mucosal injury of the stomach and duodenum in children and adults.[12] The mechanisms are multifactorial but most likely involve inhibition of COX in the mucosa of the gastrointestinal tract, thereby reducing mucosa-protective prostaglandins.[12–14] This pathologic process develops not only through topical mucosal contact with the offending agents but, more importantly, via the systemic effects of the drugs.[12–16]

Overall, about 15 to 30% of patients receiving NSAIDs on a regular basis have either dyspeptic symptoms without overt ulcer, endoscopically proven mucosal damages without symptoms, or both, each comprising roughly one-third of the cases.[12] Risk factors for developing NSAID-induced gastroduodenal ulcers include advanced age, past history of ulcer, use of concurrent corticosteroids, higher NSAID doses, multiple NSAID use, anticoagulant use, and serious systemic disorder.[12] In adults, the risk of NSAID-induced upper gastrointestinal mucosal damage is highest within the first month of its use, although the risk seems to accumulate during the first 6 months.[17]

In a large prospective study of more than 8,000 adult patients with rheumatoid arthritis, the rate of serious gastrointestinal complications, such as perforation, gastric outlet obstruction, and bleeding, was found to be about 0.8% per 6 months,[17] approaching an annual incidence of 2%. In patients without risk factors such as old age (75 years or older) and previous peptic ulcer and bleeding, they reported that the logistic regression model predicted a risk for developing gastrointestinal complications such as bleeding and endoscopically proven mucosal lesions of 0.4%.[17] The risk in pediatric patients is probably close to this estimate, although there are no explicit data. In a retrospective study of 702 pediatric patients with juvenile rheumatoid arthritis, 5 children had a total of 10 events of symptomatic "gastropathy," defined as esophagitis, gastritis, or peptic ulcer disease, which were associated with NSAIDs, including tolmetin (seven episodes), diclofenac, aspirin, and indomethacin.[18] In premature infants receiving corticosteroids or NSAIDs for lung maturation or closure of patent ductus arteriosus, severe gastrointestinal complications such as perforation have been well recognized and are discussed in this chapter (see dexamethasone-induced gastrointestinal perforation and NSAID-induced intestinal injury in the section on the small intestine and colon).

Although there is an apparent rank order of ulcer bleeding and perforation risks of NSAIDs (eg, low risk: ibuprofen and diclofenac; medium risk: naproxen, indomethacin, and piroxicam; high risk: ketoprofen and azapropazone),[19] caution should be exercised in interpreting it because the data are not available for risks standardized by equivalent doses. Given the dose-response relationship between NSAID use and the risk of gastrointestinal complications, this aspect cannot be ignored.

Children with the acute phase of Kawasaki disease are treated with immunoglobulin and high-dose aspirin, followed by low-dose aspirin therapy during the convalescent phase. Surprisingly, there has been no systematic study on

aspirin-induced gastrointestinal damages in children with Kawasaki disease. A 1996 report described two children with overt gastrointestinal hemorrhage during aspirin therapy for Kawasaki disease in the convalescent phase.[20]

A new subclass of NSAIDs (eg, celecoxib and rofecoxib) has recently been introduced, which consists of relatively selective inhibitors for COX-2, one of the two isoforms of the COX enzyme. They are called coxibs, COX-2 inhibitors, or COX-1–sparing NSAIDs. The gastrointestinal tract constitutively expresses COX-1, which plays a key role in protecting and maintaining the integrity of the gastrointestinal mucosa by producing mucosa-protective prostaglandins.[16] Therefore, by sparing COX-1, these COX-2 inhibitors appear to be beneficial in minimizing the risk of the mucosal damages.

Clinical trials in adults suggest that the COX-2 inhibitors are better tolerated than nonselective NSAIDs such as ibuprofen, diclofenac, or naproxen.[21–25] In patients receiving no aspirin, the annualized occurrence rate of gastroduodenal ulcers and their complications was 0.44% for celecoxib and 1.27% for the nonselective NSAIDs.[21] Similarly, in adults with rheumatoid arthritis, rofecoxib was associated with fewer gastrointestinal ulcers and complications (2.1% per year) than naproxen (4.5% per year); the difference was most pronounced in the frequency of gastric ulcer.[22] Together with other studies,[23–25] these data suggest an improved adverse-effect profile of the COX-2 inhibitors, especially for complicated ulcer. However, the difference may not be so distinct for alleviating dyspeptic symptoms. Although more data are clearly needed, COX-2–selective inhibitors seem a reasonable alternative for nonselective NSAIDs in adult patients with risk factors such as a history of gastroduodenal ulcers.[26] However, given the relatively low risk of gastroduodenal ulcers and complications in children and young, otherwise healthy adults, the cost-effectiveness of the relatively costly COX-2–selective inhibitors over cheaper nonselective NSAIDs with or without antiulcerogenic therapy in pediatric populations remains to be clearly demonstrated.

Pharmacologic approaches to counteract ulcerogenic effects of NSAIDs include the use of misoprostol,[17,27–29] proton pump inhibitors,[30–32] histamine$_2$ (H_2) receptor antagonists,[33–38] and nitric oxide.[39,40] Misoprostol, a prostaglandin analogue, is expected to replace cytoprotective prostaglandins depleted by NSAIDs. Although misoprostol 100 to 200 μg four times a day in adults was shown to prevent NSAID-induced gastroduodenal ulcers, dyspeptic symptoms were not improved.[28] H_2 receptor antagonists such as ranitidine were shown to be effective in reducing dyspeptic symptoms and preventing duodenal ulcers in patients receiving NSAIDs,[33–37] although they may mask ulcer-associated symptoms.[12,38] Proton pump inhibitors such as omeprazole, pantoprazole, and lansoprazole have recently been advocated as an effective modality for NSAID-induced peptic ulcer diseases. In adult patients receiving NSAIDs regularly, omeprazole is more effective than ranitidine in healing and preventing gastroduodenal erosions and ulcers.[30] Omeprazole is also as effective as misoprostol but more tolerable owing to a lack of diarrhea,[31] a major side effect of misoprostol. In comparing proton pump inhibitors and H_2 receptor antagonists, a prevailing view[41] is that the level of acid suppression, rather than a drug class–specific mechanism, is the key to successful therapy and prevention for NSAID-induced gastroduodenal ulcers, although high-dose H_2 receptor antagonists are usually more costly than equipotent proton pump inhibitors. In children, a retrospective study suggested that misoprostol alleviates gastrointestinal symptoms associated with NSAIDs.[27] In that series, only 1 of the 25 children receiving an NSAID and misoprostol had diarrhea, which is in sharp contrast to the adult study.[28] Table 8.1-2 summarizes the major drugs and drug groups for NSAID-induced gastroduodenal damages.

Nitric oxide shares multiple antiulcerogenic effects with mucosa-protective prostaglandins. A case-control study showed that the use of nitric oxide–releasing nitrovasodilators is associated with a reduced risk of upper gastrointestinal bleeding in adults receiving NSAIDs or low-dose aspirin.[39] Nitric oxide–releasing NSAIDs are currently under investigation for clinical use.

In summary (see Table 8.1-2), a proton pump inhibitor or an H_2 receptor antagonist may be used for NSAID-induced dyspepsia symptoms. Misoprostol or a proton pump inhibitor is for prophylactic therapy of gastrointestinal ulcers associated with nonselective NSAIDs; alternatively, a COX-2 inhibitor may replace an NSAID in patients with significant risk factors for developing gastroduodenal ulcers. Patients with active ulcer, who need to continue NSAIDs, should be treated with a proton pump inhibitor.[12]

Helicobacter pylori infection and NSAID use are major and independent risk factors for gastroduodenal mucosal injury. Although the prevalence of *H. pylori* infection is lower in the pediatric population than in adults, it remains an etiologically important risk factor for gastroduodenal lesions. When endoscopically confirmed mucosal damages caused by NSAIDs are used as an end point, *H. pylori* infection does not seem to substantially increase the frequency and severity of the NSAID-induced mucosal damages for both short- and long-term (more than 4 weeks) use of the drug.[42] However, it is recommended that *H. pylori* be eradicated in those NSAID-receiving patients with *H. pylori*–associated ulcers because the two conditions are indistinguishable.[41,42]

TABLE 8.1-2 MAIN PHARMACOLOGIC APPROACHES FOR NSAID-INDUCED GASTRODUODENAL INJURY

DRUG/DRUG GROUP	INDICATIONS
Misoprostol	Ulcer prophylaxis
Proton pump inhibitors	Ulcer prophylaxis Dyspepsia treatment Ulcer treatment*
H_2 receptor antagonists	Dyspepsia treatment Ulcer treatment†

*In patients who continue nonsteroidal anti-inflammatory drug (NSAID) treatment.
†For those who discontinued NSAIDs.

Currently, no evidence exists to clearly support or refute *H. pylori* eradication before NSAID use in adult patients with no preexisting mucosal lesions.

Prostaglandin E_1–Induced Antral Hyperplasia

Antral mucosal hyperplasia, with no evidence of pyloric stenosis, causing gastric outlet obstruction has been reported in neonates with congenital heart disease such as transposition of great arteries and hypoplastic left heart syndrome, who were receiving prostaglandin E_1 infusion to sustain circulation dependent on the ductus arteriosus.[43] The condition is distinct from infantile hypertrophic pyloric stenosis because there is significant hyperplasia of the antral mucosal glands with no muscular thickening at the pyloric sphincter. Diarrhea is recognized as an adverse effect of prostaglandin E_1 infusion, which responds to dose reduction. One study showed that 5 of 74 neonates evaluated had clinical, radiologic, and pathologic evidence of the gastric outlet obstruction with no evidence of hypertrophic pyloric stenosis.[43] These 5 patients received the drug for a significantly longer period (mean 569 hours) at significantly higher cumulative doses than the remaining neonates. On withdrawal of the drug in 2 patients, the condition improved clinically and ultrasonographically. The authors recommended close monitoring of the gastric outlet functioning in neonates receiving prostaglandin E_1 for more than 120 hours.

Erythromycin-Induced Infantile Hypertrophic Pyloric Stenosis

The association between perinatal and neonatal exposures to erythromycin and development of infantile hypertrophic pyloric stenosis has been reported since 1976.[44] In particular, data indicating a close epidemiologic link of early neonatal exposure have been accumulating. Systemic use of erythromycin within the first 2 weeks of life (eg, for pertussis prophylaxis) appears to pose a 7- to 10-fold increased risk of developing pyloric stenosis over the incidence in the general population of about 1.5 to 4 patients per 1,000 live births.[45–47] Data are scarce to define the exact relationship between the dose and duration of the therapy and the development of the condition.

Erythromycin is a potent gastrointestinal kinetic agent through its action on the receptor for motilin, a peptide stimulating gastrointestinal contraction. Although the exact mechanism is not fully understood, breakdown products generated in the stomach from acid-labile erythromycin may play an important role in its prokinetic actions.[48] Because of its prokinetic action, erythromycin has been investigated for the treatment of feeding intolerance for premature infants. So far, however, no report exists linking the drug to hypertrophic pyloric stenosis in this population.[49,50]

The association between maternal use of erythromycin late in the pregnancy or early in the lactation period and the development of infantile hypertrophic pyloric stenosis is less clear and still controversial.[46,51–53] There has been no report linking other macrolides, such as clarithromycin and azithromycin, to pyloric stenosis.[48]

SMALL INTESTINE AND COLON

Neutropenic Enterocolitis (Typhlitis, Necrotizing Enterocolitis, Ileocecal Syndrome)

Severe inflammation leading to bowel necrosis may be seen in the cecum, ascending colon, and terminal ileum of leukemic patients receiving chemotherapy.[54] The condition is also seen in noncancer patients,[55–57] such as those with drug-induced neutropenia, acquired immune deficiency syndrome (AIDS), or organ transplants. The patient usually has severe granulocytopenia (< 500–1,000 cells/mm^3), and mortality may be as high as 50%.[58] Although the etiology is likely to be multiple and the pathophysiology poorly understood, cytotoxic drugs apparently play a key role in some patients. Vinca alkaloid–induced myenteric nerve damages may contribute to adynamic ileus and cecal distention that further enhances intestinal ischemia.

Pain in the right lower quadrant of the abdomen, fever, diarrhea with or without blood, and nausea and vomiting are usually seen. As the disease progresses, clinical signs of intestinal perforation, peritonitis, and sepsis may become apparent. Abdominal computed tomography, ultrasonography, and radiography provide diagnostic clues, including a fluid-filled dilated lumen, pneumatosis, and cecal wall thickening.

Treatment for the drug-induced neutropenic enterocolitis is no different from treatments for other forms of necrotizing enterocolitis. Namely, the therapy includes antibiotics covering intestinal bacteria, antifungal agents, supportive measures, and surgical resection.

Intestinal Mucositis Induced by Cancer Chemotherapy

Cancer chemotherapeutic agents affect intestinal cells with rapid cell turnover, disrupting the integrity of the epithelia (see "Esophagus"). Methotrexate is one of the most commonly cited offending agents. The affected patients have abdominal pain, diarrhea, vomiting, and, occasionally, melena. Protein-losing enteropathy has also been reported.

Drug-Induced Intestinal Hypomotility

Intestinal motility is reduced by drugs with anticholinergic properties (eg, anticholinergics, tricyclic antidepressants, and opioids). These are consequences of their pharmacologic actions of functional cholinergic inhibition. In contrast, vincristine damages nerve tissues, including the myenteric plexus, which may lead to adynamic ileus.[11,59,60] The condition develops within 2 to 3 days of the therapy.[11] Conservative treatment usually brings complete recovery in 2 weeks unless other complications, such as neutropenic enterocolitis (above), develop. If patients concomitantly receive itraconazole, vincristine neurotoxicity, including adynamic ileus, may become more severe.[61] This vincristine-itraconazole interaction may be due to itraconazole inhibition of a drug-metabolizing enzyme (eg, cytochrome P-450 3A4) and a drug transporter (eg, P-glycoprotein), which handle vincristine as a substrate.

Dexamethasone-Induced Intestinal Perforation in Premature Infants

A clinical trial of early use of high-dose dexamethasone in extremely low birth weight infants to prevent chronic lung disease was terminated before completion owing to a high incidence of spontaneous gastrointestinal perforation.[62] The rate of gastrointestinal perforation without necrotizing enterocolitis during the first 2 weeks of life was 13% (14 of 111) in the dexamethasone group that received a 10-day tapered course of the drug starting at 0.15 mg/kg/d within 24 hours after birth. The incidence in the placebo group was 4% (4 of 109). The sites of perforation were the small bowel (13 infants), the stomach (1), and unknown (4). A concurrent use of indomethacin appeared to contribute to development of the adverse event in both groups. Trends toward higher rates of spontaneous perforation associated with dexamethasone or indomethacin were also reported in other studies.[63–67] Given the established inhibitory effects of corticosteroids and NSAIDs on gastrointestinal prostaglandin synthesis, it is not surprising to see an increased incidence of spontaneous gastrointestinal perforation in this vulnerable patient population.

Antibiotic-Associated Diarrhea

Antibiotics are responsible for about one-fourth of the cases of drug-induced diarrhea.[68] About 70 to 80% of the cases of diarrhea associated with antibiotics use are nonspecific, self-limited, and unrelated to *Clostridium difficile*.[69,70] Some of these patients may develop the condition as a result of altered carbohydrate metabolism induced by changed bacterial flora in the large intestine. Erythromycin may cause diarrhea owing to its prokinetic property. The nonspecific diarrhea subsides on discontinuation of the antibiotics.

C. difficile infection is a nosocomial illness, comprising about 20% of antibiotic-associated diarrhea.[69] *C. difficile* produces toxins, causing intestinal damage with a wide spectrum of severity. *C. difficile* disease occurs 4 to 18 days after a first dose of the offending agent[71] and usually requires a cascade of events: changes in normal gut flora, acquisition and colonization of the bacteria, and toxin production.[69] Clearly, loss of colonization resistance as a result of disruption of the normal intestinal microflora by antibiotics is an important etiologic process, although *C. difficile* disease in pediatric patients may be less dependent on prior exposures to antibiotics than in adults.[70] The most commonly implicated antibiotics are ampicillin, amoxicillin, cephalosporins (second and third generations), lincomycin, and clindamycin, but use of virtually any antibiotic can be a predisposing factor.[72–74] Notably, as many as 60% of neonates and infants are asymptomatically colonized by *C. difficile*, the mechanism of which is not fully understood.[69,75–77] Compared with neonates, the isolation rates of the bacteria decrease to 0 to 3% in older asymptomatic children, similar to those seen in asymptomatic healthy adults.[70] Clinical pictures of *C. difficile* infections range from asymptomatic carriers, mild diarrhea, and uncomplicated colitis to pseudomembranous colitis and fulminant colitis.

Pseudomembranous enterocolitis affects mainly the large intestine and rarely the small intestine. *C. difficile* has been the most common cause, often induced by preceding antibiotic therapy. Other causes of pseudomembranous colitis include ischemia, verotoxin-producing *Escherichia coli*, and drugs such as chlorpropamide, gold, and NSAIDs.[69]

C. difficile infections usually present with profuse watery or mucoid diarrhea with or without blood, abdominal pain, and fever. Supportive care and discontinuation of the offending antibiotics, if any, may be sufficient for those with mild symptoms. Symptomatic therapy with antidiarrheal agents should be avoided. Patients with severe symptoms, for whom supportive therapy has failed, may be treated with oral metronidazole or vancomycin for 1 to 2 weeks. Of those who underwent the therapy for the first time, as high as 40 to 60% may relapse.[78–81] Currently, a new strategy to neutralize the toxin by a synthetic oligosaccharide mimicking toxin receptors is being tested for treating recurrent *C. difficile* infections.[70]

NSAID-Induced Intestinal Injury

Intestinal damages inflicted by NSAIDs manifest themselves in several distinct pathologic forms. Some of the lesions share the same pathologic processes as NSAID-induced gastric damages.

Ulceration. Whereas gastroduodenal damages caused by NSAIDs have been long known and relatively well characterized, NSAID-induced small intestinal and colonic lesions are a recent addition to its adverse-effect profile. An autopsy study involving 249 adult patients on NSAIDs found the prevalence of small intestinal ulcers to be 8.4% compared with 0.6% in the control group.[82] Although gastric and duodenal ulcers were also seen in the NSAID users, no correlation was found between the gastric or duodenal lesions and the small intestinal ulcers,[82] implying that prediction of the small intestinal ulcers from the upper gastrointestinal damages may not be valid. Small intestinal perforation associated with slow-release NSAIDs is well documented in adults,[83,84] suggesting that slow-release formulations simply shift a target site of NSAID-induced mucosal injury from the stomach to the more distal intestinal tract.

In children, data are scarce, but preterm neonates appear to be more susceptible to the adverse effects of NSAIDs. For example, 1 in 10 premature infants with a patent ductus arteriosus, who received indomethacin, were found to have intestinal perforation compared with none in surgically treated babies.[85] Overall, perforation has been reported to occur throughout the gastrointestinal tract in premature neonates receiving NSAIDs.[63,65–67,85] Common mechanisms of local prostaglandin depletion seem to underlie gastric and intestinal perforation associated with NSAID therapy.

Strictures. NSAIDs cause strictures in the small intestine and colon in adults after prolonged use, which is not necessarily a consequence of ulceration. Pathologic characteristics range from nonspecific strictures to multiple, thin, and web-like diaphragms that are considered patho-

gnomonic of NSAID use.[86] An apparently low incidence of the condition may be an underestimate as a result of difficulty in diagnosis. There is no report of the NSAID-induced web-like strictures in pediatric patients.

NSAID Enteropathy. NSAID enteropathy may be defined as a disturbance of the small intestinal function associated with NSAID use in the absence of macroscopic pathology such as macroscopic ulceration and bleeding. The underlying alterations are probably diffuse intestinal inflammation and increased mucosal permeability.[87] However, how NSAIDs cause these changes is unknown. Clinical pictures include iron deficiency anemia owing to chronic blood loss, a protein-losing enteropathy, and mild lipid malabsorption. Although as many as 70% of NSAID users are estimated to be at least partially affected by the condition, overt manifestations are uncommon.[87] Recently, measurement of fecal calprotectin, a neutrophil protein, has been suggested as a simple method to diagnose the condition.[88]

Colitis. Chronic use of NSAIDs, usually for 6 months or longer, may cause various forms of colitis, whose symptoms include watery and/or bloody diarrhea. Case reports in adults indicate that eosinophilic, collagenous, pseudomembranous, and nonspecific colitis are associated with NSAID use. Mefenamic and fulfenamic acids are most often implicated as causative NSAIDs, but epidemiologic data are scarce to define drug-specific risks.

In a recent study with a case-crossover design (a median patient age of 35 years old, ranging from 4 months to 89 years),[89] NSAID use within 6 days prior was shown to increase the risk of acute diarrhea by about threefold, although information on concurrent medications, if any, was not given, and the diversity of NSAIDs used made it impossible to analyze drug-specific risks. Interestingly, however, none of their study patients received meclofenamate,[88] which was reported to induce diarrhea as much as 30% in clinical trials.[90]

The mechanism of NSAID-induced colitis is largely unknown, although inhibition of prostaglandin synthesis coupled with relative overproduction of leukotrienes may be a contributing factor. It is clinically characterized by acute diarrhea with or without mucus or blood.

In addition to the de novo colitis, NSAIDs may activate inflammatory bowel disease, especially ulcerative colitis, within a few days of the start of the therapy in some patients.[87,91] The mechanism is not fully understood, but inhibition of the COX by NSAIDs may shift the arachidonic acid metabolism pathway sideways to produce the proinflammatory leukotrienes.

NSAID-induced pathology in the colon is similar to those in the small intestine but less commonly reported. This may be due to a progressively small amount of orally ingested NSAIDs reaching the colon in most patients as a result of nearly complete absorption in the proximal intestinal tract. Indeed, ulcers and strictures (broad based or diaphragms) are seen, if at all, mostly in the right side of the colon.[87,92,93]

ACKNOWLEDGMENT

I thank Ms. Evelyn Rubin for her help in preparing the manuscript.

2. *Radiation Enteritis*

Jan A. J. M. Taminiau, MD, PhD

In children, the use of radiation therapy for abdominal malignancies has diminished in recent years, but some specific applications remain.

Two decades ago, radiotherapy to the abdomen was commonly given for lymphoma, neuroblastoma, rhabdomyosarcoma, teratoma, and Wilms tumor.[1] In the last decade, external radiotherapy has been used postoperatively for Wilms tumor, rarely for Hodgkin disease of the abdomen and Ewing sarcoma of the pelvic bones,[2] and for some complicated malignancies with poor prognosis. In children, irradiation for neuroblastoma is provided by intravenous ^{131}I metaiodobenzylguanidine, which emits β-radiation locally without penetration to surrounding tissues. For rhabdomyosarcoma in the pelvic region,[1] brachytherapy is a treatment in which needles are inserted in the pelvic region for postoperative local irradiation without damaging radiation effects on the surrounding tissues.

Presently, doses of irradiation to the abdomen rarely exceed 20 to 30 Gy and are usually lower, so they do not exceed tolerance of the kidneys, liver, intestine, or other organs. However, radiation to the pelvis for Ewing sarcoma may require a dose up to 60 Gy.[2]

INCIDENCE OF RADIATION ENTERITIS IN CHILDREN

The incidence of radiation enteritis during and after abdominal pelvic radiation therapy varies in adults between 2.5 and 25% and is characterized by reversible abnormalities in small intestinal or anorectal mucosa. Acute damaging effects are mostly reversible, but months to years after irradiation, mucosal changes may develop, and sometimes they are irreversible. In 69 children aged 6 months to 8 years, treated by total or partial irradiation (20–35 Gy) with chemotherapy for Wilms tumor, neuroblastoma, or rhabdomyosarcoma, gastrointestinal symptoms occurred in 74% and diarrhea in 42%. In 55%, a 10% body weight loss was observed in the acute phase. Long-term persistent gastrointestinal symptoms occurred in 36% of children treated in the same institution.[3,4] The majority have some loose stools, which do not interfere with their daily activities.[5]

PATHOPHYSIOLOGY

Gastrointestinal damage depends on the physical characteristics of radiation exposure. The modern megavoltage (MV) linear accelerators use a wave guide to accelerate electrons, bombarding a target at high energy to produce x-rays in the range of 4 to 25 MV. Radioactive atoms have unstable nuclei, which release energy in the process of spontaneous disintegration. Ionizing irradiation with protons (x-rays or γ-rays), electrons, neutrons, or pions interacts with tissues and produces radicals. They damage nuclear deoxyribonucleic acid (DNA), leading to cell death.

The accepted radiation dose unit is 1 Gy or 100 rad (1 rad = 1 cGy).

Today radiation treatment is usually administered in 2 Gy treatment fractions; these regimens were empirically developed, and they do not clearly separate the responses of normal tissues and malignant tumors. For most pediatric tumors, external beam irradiation is used. An exception is pelvic rhabdomyosarcoma, for which brachytherapy uses per operatively placed ^{192}I needles in sheets.[6]

As cells are irradiated with increasing doses, one observes a shoulder in their survival curve; this shoulder reflects the cells' capicity to accumulate sublethal damage, which becomes effective at higher doses, leading to rapid cell death. Between fractions of radiation treatment, however, this accumulated damage may dissipate.[7]

A significant factor determining the response of a cell to radiation is the phase of its division cycle. There is a brief period after mitosis when there is no DNA synthesis (G_1); then there is a DNA synthetic phase (S), followed by a short second phase without DNA synthesis (G_2), followed by cell division (mitosis). Sensitivity to irradiation is most pronounced in the mitotic and G_2 phases, and resistance is most pronounced in the synthesis phase. These findings may explain how chemotherapeutic drugs can alter the sensitivity of cells to irradiation because they act mainly on the synthetic phase of the cell cycle. Chemotherapeutic drugs, at times used in concert with radiation, such as doxorubicin, 5-fluorouracil, and actinomycin D, are also capable of injuring intestinal cells.[8] The tissue perfusion of tumor cells modifies their sensitivity to irradiation. Hypoxic cells are particularly radiation resistant. Usually, but not always, radiation injury is most severe in rapidly dividing cells, which are less differentiated and have a high mitotic activity, like malignant cells. In the intestine, enterocytes are comparable to hematopoietic and tumor cells in the rapidity of their mitotic activity. Therefore, radiation treatment directed at injuring tumor cells is likely to damage enterocytes within the radiation field. The earliest impact of radiation on the gut epithelium occurs in the crypts, where epithelial cells are dividing most rapidly.[9] These cells mature during migration out of the crypts and move to the

villous tips, where they are extruded or go into apoptosis. The whole replacement procedure requires 4 to 6 days in humans for the small intestine, colon, and rectum. After radiation exposure, crypt intestinal epithelial cells go into apoptosis and stop dividing, migrating, and maturing. Repopulation of enterocytes of the villous epithelium is impaired, and villous atrophy is inevitable. Usually, epithelial integrity is maintained, but ulceration may occur. With fractionated radiation dosages, these changes rarely cause symptoms, but for some reason, possibly a variability on individual radiosensitivity, the intestinal epithelial barrier may be destroyed in some patients who develop severe diarrhea, mucosal bleeding, and, rarely, septicemia from bacterial translocation. After discontinuation of radiation treatment, crypts regenerate, and the epithelium repopulates with enterocytes on the muscosal surface; abnormalities in mucosal morphology may persist for longer periods.

It is interesting to note that with exclusion of pancreatic juices from the intestinal lumen, epithelial radiation injury does not develop, but exclusion of biliary secretions has no influence on radiation injury.[10] In the acute phase, pancreatic juices seem to be involved in radiation effects, but their role has not been investigated in the chronic phase.[11,12]

Subepithelial structures in the gut mucosa are less rapidly dividing than epithelial cells, but irradiation of vascular endothelial cells and connective tissue can cause late and permanent changes in the vascular supply to the musosa.

Radiation leads initially in the acute phase to capillary endothelial swelling, capillary leakage, lymphatic leakage, and edema.[13] This damage is followed in the recovery phase by vascular and connective tissue changes, which can progress to obliterative endarteritis and endophlebitis, causing intestinal ischemia, ulcerations, and necrosis.[14] Strictures are caused by progressive fibrosis owing to this vasculopathy.[15] Mucosal surface destruction is secondary to these vascular changes, as are possible motility disorders (Table 8.2-1).[9,16]

This scenario has been turned on its head. The radiation administered to the mouse intestine preferentially damages the endothelial cells of the gut microvasculature. The death of epithelial stem cells might be a secondary event to the demise of endothelial cells. Microvascular endothelial cells express the receptor for basic fibroblast growth factor (bFGF), whereas epithelial stem cells in the crypt do not; systemic administration of bFGF enhances epithelial stem cell survival after irradiation. Irradiation of microvascular endothelial cells generates ceramide, a proapoptotic lipid that facilitates endothelial cell death. bFGF, an endothelial cell mitogen, overrides the ceramide signal. This was supported by a compelling experiment in which mice lacking the gene for acid sphingomyelase, which is required for ceramide production and is highly expressed in endothelium, were protected from radiation-induced destruction of the gut mucosa. This two-compartment model is well known for tumor growth, but gut epithelial cells are highly hypoxia resistant; therefore, this hypothesis has been challenged.[17–19]

Tissue injury at a molecular level has been studied for leukocyte–endothelial cell interactions after radiation-induced tissue injury, in which E (endothelial)-selectin and intercellular adhesion molecule 1 (ICAM-1) are involved in mediating leukocyte sequestration in irradiated normal tissues. In inflammation, leukocyte–endothelial cell interactions are important for the trapping of inflammatory cells into the inflammatory infiltrate.[20] It has been shown that leukocytes roll on irradiated endothelial cells via E-selectin and then are arrested by ICAM-1. Leukocytes have a very slow rolling velocity on E-selectin substrate, suggesting the involvement of additional rolling receptors on the irradiated vasculature. Other potential receptors are P-selectin and L-selectin. Also, the observed radiation-mediated effects on CD31 expression imply a role for CD31 in mediation of leukocyte transmigration into irradiated tissues.[21] In this process, up-regulation of ICAM-1 might also be involved.[22]

This elucidation of specific molecules involved in radiation-induced leukocyte extravasation permits speculation on possible specific targeted therapeutic strategies for patients. The ICAM-1 knockout mice do not exhibit an increase in leukocyte infiltration of the lung after irradiation. This observation identifies ICAM-1 as a possible therapeutic target for the amelioration of radiation-induced leukocyte–endothelial cell interactions.[23] Inhibiting leukocyte ligand binding by inhibiting ICAM-1 on the endothelial surface might reduce leukocyte influx in normal tissues after irradiation. Injection of monoclonal ICAM-1 antibodies into irradiated lungs of mice attenuated infiltration of leukocytes into lung tissue. Theoretically, these antibodies might inhibit endothelial cell surface ICAM-1 and diminish inflammation in normal human tissues after irradiation. Anti-CD31 antibodies might be of therapeutic benefit to block transmigration of leukocytes into irradiated tissues. Glucocorticoids might be effective by inhibiting nuclear factor-κB (NFκB) activation. NFκB is implicated in inducing transcription of E-selectin and ICAM-1 in irradiated endothelium. Leukocyte infiltration of normal tissues after irradiation might be an important factor in the pathogenesis of late radiation damage.

Another important determinant of radiation-induced tissue injury is platelet adherence to the vascular wall and abnormal endothelial cell proliferation, leading to vascu-

TABLE 8.2-1 CLINICAL FINDINGS: RADIATION ENTERITIS IN CHILDREN

lar occlusion. A dose of 2 Gy increases von Willebrand factor release from endothelial cells with increased platelet adhesion to the extracellular matrix; endothelial cells detach from the underlying matrix, leading to platelet adhesion, thrombus formation, and, ultimately, vascular occlusion of the lumen.[24]

A transmembrane glycoprotein thrombomodulin (TM) is located on the luminal surface of endothelial cells and is pivotal in maintaining thrombohemorrhagic balance. TM forms a complex with thrombin and prevents fibrin formation but activates protein C, a major anticoagulant. Radiation causes local TM deficiency, insufficient activation of protein C, and reduced scavenging of thrombin, thus enhancing activation of protease-activated receptor 1, which increases twofold in vascular and intestinal smooth muscle cells in irradiated intestine. This up-regulation has proinflammatory, profibrogenic, and promitogenic effects and might be implicated in radiation-induced vascular sclerosis and in radiation fibrosis of the intestinal wall.[25]

Matrix metalloproteinases (MMP-2, MMP-9 [gelatinases]) are present in the mucosa of the gut, and it has been shown that these metalloproteinases are increased after irradiation in human rectal mucosa.[26] The mucosal extracellular matrix (ECM) is a functionally active scaffolding meshwork that, in addition to maintaining normal tissue stricture, is pivotal in the integration of cellular interactions. MMPs play a central role in regulating the equilibrium between the ECM, synthesis, and breakdown. Up-regulation might signify damage and atrophy of the ECM, although publications are conflicting in their results so far, and protective effects during irradiation might not be excluded.[26]

Immediately after irradiation, the bowel is hyporesponsive to secretagogues, with less inducible nitric oxide synthase derived. Nitric oxide goes parallel with decreased tissue resistance, which makes the epithelium more vulnerable to epithelial translocation. The same first 3-day period, the tissue is less responsive to exogenous 5-hydroxytryptamine (5-HT); simultaneously, the sensitivity of 5-HT_3 and 5-HT_4 receptors was attenuated. The subsequent day, the decreased 5-HT tissue content was normalized, with a higher sensitivity of the tissue to 5-HT owing to up-regulation of 5-HT_3 and 5-HT_4 receptors. The 5-HT–mediated pathways are neural and non-neural, respectively, and in the first days after irradiation diminished colonic water and electrolyte transport was related to hyporesponsiveness of the epithelium and at recovery of diarrhea increased responsiveness the days after. With respect to the above, it might be apparent that a paradox exists. The irradiated epithelial cells secrete less chloride and water, although diarrhea is one of the side effects of radiotherapy. However, secretion, compared to absorption, in the colon is a minor event. It is just sufficient to reserve the microenvironment. It might be conceived that the low-volume secretory processes are surpassed by phenomena of diminished absorption in the colon. It is shown that the Na^+/K^+–adenosine triphosphatase activity is diminished and is related to malabsorptive electrolyte diarrhea.[27,28]

In animals, granisetron (5-HT_3 receptor antagonist) prevented diarrhea and improved colonic motility.[29]

The cell death attributable to radiation of the gut goes parallel with apoptosis. In radiation-induced apoptosis, expression of the tumor suppressor gene *TP53* in the stem cell region is increased. In knockout mice, no apoptosis increase was observed after irradiation of small and large intestine, so *TP53* seems to be mandatory for this apoptosis increase. Also, at the same time, the expression of apoptosis-protecting gene *BCL2* is increased. Animals lacking *BCL2* have increased apoptosis after mucosal irradiation. Probably, a balance of these proapoptotic and protecting genes is involved in radiation damage.[30]

BCL2 is involved in protection of the large intestine, whereas *BCLW*, another physiologic regulator, is an important determinant in protecting the small intestine during irradiation.[31]

Induction of apoptosis measured in human rectal specimens showed increased permeability in a size-dependent fashion for marker molecules in Ussing chambers.[32]

After ionizing radiation, transforming growth factor-β (TGF-β) is increasingly expressed. It is a potent fibrogenic and immunomodulatory cytokine leading to hyperplasia of connective tissue mast cells and leukocyte migration into the intestinal wall. Interestingly, 26 weeks after radiation, only the isoform TGF-β1 remains elevated in vascular endothelial cells, fibroblasts, and smooth muscle cells. It is increased strongly only in areas of persisting radiation-induced injury and is probably related to the development of vascular sclerosis and fibrosis of the serosa and muscularis propria.[33]

Fibroblast growth factors (FGF-2) enhance survival of epithelial cells after injury induced by ionizing radiation. The biologic effects of FGFs are mediated by binding to an activating cell-surface receptor tyrosine kinase. FGF-2 is elevated in small intestine after radiation injury, it is localized to mesenchymal cells surrounding regenerating crypts, and it enhances crypt stem cell survival when it is administered before but not after radiation. With other cytokines or intracellular regulatory molecules in animal models, it has been shown that only when administered before irradiation do they protect epithelial stem cells and enhance recovery, including TGF, tumor necrosis factor (TNF)-α, interleukin (IL)-1, IL-11, prostaglandin E_2 (PGE_2) and misoprostol. Clinical studies are lacking so far, but it is conceivable that some effects might lead to clinical application.[34]

The most abundant gastrointestinal prostaglandin, PGE_2, is probably involved in radiation injury; the biologic activities are mediated through interaction with plasma membrane G protein–coupled receptors, the E-prostanoid (EP) receptors, which are up-regulated in the intestinal mucosa after irradiation.[35]

In rats, growth hormone in low- but not high-dose radiation maintained body weight and growth.[36]

In animals, by gene transfer through a herpes virus as vector, human manganese superoxide dismutase in the small intestine delivered by the luminal route was overexpressed and prevented radiation damage, suggesting a role for oxygen free radicals to initiate cytokine cascades, leading to fibrosis after chronic radiation injury.[37]

EFFECTS OF RADIATION ON MOTILITY

Radiation of the gut does not significantly affect normal migrating motor complexes. It was observed that giant migrating contractions are generated after the first dose of irradiation and continue for the duration of the irradiation period. Afterward, motility returns to normal patterns. These changes in motility pattern occurred in small and large intestine and resulted in rapid propulsion of luminal contents. Although lowered contractile activity in the proximal small intestine was observed, these increased giant migrating contractions overwhelm and increase transit. In animal models, during irradiation in gastrointestinal tissue, changes in tissue and serum levels of various neuroendocrine products were shown in a region-specific manner, including acetylcholinesterase, vasoactive intestinal polypeptide (VIP), substance P (SP), and peptide YY, but no relationship to altered motility was provided. Also, the increased sensitivity to cholinergic stimuli up-regulation of 5-HT_3 and 5-HT_4 receptors suggests a role for serotonin, but relationships are unclear so far.[38]

In human colonic specimens in nerve fibers, SP and VIP were increased in mucosal and circular muscle fibers but were decreased after 6 weeks postirradiation, which might have an influence on inflammation and motility.[39] In animals, increased SP directly after irradiation of the intestine was related to increased contractility and release of proinflammatory mediators such as TNF.[40]

In animal morphometric studies on the intestine after irradiation, the storage function of the irradiated gut is and stays decreased, further supported by persistent increased stress in the proximal part to the affected site.[41] This is supported by observations in the rectum in humans after radiation therapy for prostate cancer in which anorectal function is preserved, although with a decreased storage capacity and rectal compliance.[42–44]

Long-term effects are seen in 11% of patients.[45] Radiation doses in the 1960s and 1970s were up to 40 Gy, but now 20 Gy is rarely exceeded. In pelvic irradiation, long-term effects are more likely to occur in children owing to the application of higher doses.[45] Up-regulation of CD31 expression on endothelial cells, which plays an important role in platelet adherence, disrupting regulation of endothelial cell proliferation, is a focal event, resulting in protrusions into the lumen. Strategies to prevent late radiation reactions should be targeted to radiation-mediated CD31 expression and attempts to prevent leukocyte influx, thrombus formation, and abnormal endothelial cell proliferation. Blocking ICAM-1 could reduce leukocyte influx in irradiated tissues. Because chronic inflammatory processes are important for late radiation effects, prevention and amelioration of inflammatory processes are realistic treatment prospects for childhood malignancies.[23]

MICROSCOPIC ABNORMALITIES IN RADIATION-DAMAGED BOWEL

At the onset of damage to the bowel, reduced mitotic activity is observed under light microscopic examination. The migration of normal mature enterocytes continues, and for a few days, the epithelial villous structure remains intact. Gradually, a lack of migrating enterocytes stretches them out, failing to cover the surface with enterocytes, and a gradual reduction in villus size follows. In the crypt, apoptotic cells are present within 24 hours. Abnormalities increase gradually because radiation is usually administered in 2 Gy/d until the total dose is achieved.

At the electron microscopic level, radiation can cause reduced numbers of microvilli, disrupted tight junctions,[46] dilated endoplasmatic reticulum, and sometimes mitochondrial swelling or fragmentation of internal crystae. Chemotherapy can enhance these effects because methotrexate,[47] actinomycin D, vincristine,[48] and doxorubicin induce comparable effects on the small intestinal epithelium. In addition, hyperemia, edema, and inflammatory infiltration occur, and, occasionally, crypt abscesses are visible. Vascular abnormalities are difficult to discern; they are predominantly responsible for the late effects.[15]

Late effects after radiation to the abdomen are due mainly to vascular injury. The typical lesions are subintimal fibrosis with degeneration of the full thickness of the walls of different-sized vessels in the submucosa; these lesions are distributed irregularly. With the vascular changes, there is ischemic bowel and consequent infarction, atrophy, and fibrosis. The obvious result is fibrosis of the submucosa and muscular layers of the gut, leading, in some cases, to luminal narrowing of the intestine and obstruction.[15]

Intestinal resections within 2 years of irradiation show serosal adhesions and ulcers, but after 8 years, ulcerative strictures are seen in 82%, with damaged vessel walls in 73%, enteritis cystica profunda in 73%, atypical epithelia in 64%, and fistula in 18%. These sequelae suggest a need for careful long-term follow-up of all of these patients.[49]

ACUTE RADIATION ENTERITIS

Early Clinical Symptoms in Children

Symptoms of acute radiation enteritis can develop within hours after the first exposure, but usually they begin during the first to second week, or even after completion of abdominal or pelvic radiotherapy. Some diarrhea is usually noticed; even bloody diarrhea can occur during radiation therapy. Occasionally, nausea, vomiting, abdominal cramps, and abdominal pain may occur. Irradiation to the abdomen in children usually involves the small bowel; pelvic irradiation, which can damage the distal large bowel and ileal loops, is administered relatively infrequently to young patients. When it does occur, proctosigmoiditis produces mucoid discharge, tenesmus, and rectal bleeding, suggesting mucosal ulceration (Table 8.2-2). The clinical picture here resembles acute ulcerative colitis.[50] In a retrospective study, 70.5% of children undergoing abdominal radiation therapy had early symptoms, consisting of severe vomiting or diarrhea that was severe, requiring intravenous fluids, in 30%.[4]

Thoracic radiation can cause acute radiation esophagitis. Symptoms are highly variable, from mild substernal burning to dysphagia and swallowing-induced, angina-like chest pain.[5]

TABLE 8.2-2 MECHANISMS OF RADIATION ENTERITIS

ACUTE RADIATION ENTERITIS
Interruption of enterocyte replacement
Villous atrophy
Disaccharidase deficiency
Occasional mucosal ulceration
CHRONIC RADIATION ENTERITIS
Mainly vascular obliteration
Obliterative endoarteritis
Endophlebitis
Intestinal ischemia
Diffuse chronic mucosal inflammation
Villous atrophy
Progressive fibrosis
LATE EFFECTS OF RADIATION ENTERITIS
Degeneration of vessel walls
Subintimal fibrosis
Ischemic bowel with infarction
Submucosal and muscular atrophy and fibrosis
Ongoing perivascular inflammation
Stricture formation

Mechanisms of Early Clinical Symptoms

In the affected loops, malabsorption is initially due to edema, followed by villous atrophy and osmotic diarrhea, which is the result of a secondary deficiency of brush border enzymes with dietary disaccharide intolerance.[51,52] The affected surface area predicts the extent of clinical symptomatology. Chemotherapy might cause the same disaccharidase deficiency and might enhance the symptomatic impact of radiation. In about 60% of cases, steatorrhea develops during radiation therapy mainly in those receiving concurrent chemotherapy; probably the basis for this fat malabsorption is villous atrophy.[53,54] Chemotherapy alone can cause steatorrhea, and radiation therapy seems to be a potentiating factor. 5-HT_3 receptors might play an important role in radiation-induced nausea and vomiting by direct stimulation of specific receptors on peripheral afferent nerves by free radicals or endotoxins or stimulation of central nervous centers by circulating substances. In fact, 5-HT_3 receptor antagonists are effective in controlling radiation-induced vomiting and nausea.

Diagnosis

Minor symptomatology in the early treatment phase does not justify intensive investigations unless a reduction in therapeutic fraction size or an increase in fraction interval is being considered. Duodenoscopy with mucosal biopsy will identify villous atrophy and an inflammatory lesion. On endoscopic visualization, hyperemia, friability, erosions, and ulcerations may be apparent. When the pelvic region is within the radiation field, sigmoidoscopy might show edema, hyperemia, friability, and ulceration of the rectal mucosa. Isotopic or barium imaging studies are not warranted. Hydrogen breath testing can be used to detect disaccharide intolerance, but many of these children are receiving antibiotics, which negates the usefulness of the test.[12,52]

Treatment

In children, symptoms are usually mild and rarely dictate adjustment of the radiation dose. On occasion, for severe symptoms, radiation treatment must be stopped, the dose decreased, or the interval between doses increased. Symptoms usually abate in a fortnight after cessation of radiation therapy. Treatment should be instituted according to symptomatology and the probable site of injury.[55] Mild diarrhea owing to lactose intolerance diminishes on a lactose-free diet.[53] Nausea and vomiting are sensitive to treatment with 5-HT_3 antagonists.[56] These drugs might also inhibit serotonin-mediated small intestinal dysmotility. A combination of nausea, vomiting, and diarrhea seems to be sensitive to nonsteroidal anti-inflammatory drugs (NSAIDs). Aspirin, ibuprofen,[57] and indomethacin[58] have been helpful in reducing painful cramps, diarrhea, and nausea in adults; they have also been useful in treating radiation-induced esophagitis.[59–61] Cholestyramine, which can improve diarrhea in adults after pelvic irradiation, might be used in children with radiation treatment to the same site.[62,63] Some relief of symptoms during radiation can occur with elemental feedings or total parenteral nutrition,[64–66] but these techniques are usually reserved for children with severe symptoms. Children who develop significant malnutrition should receive aggressive nutritional support given enterally or parenterally.[50] In animals, neither oral arginine nor glutamine had any effect on radiation-induced intestinal injury.[67]

Severe rectal bleeding has been successfully treated with laser therapy,[68] and rectal sucralfate enemas may mitigate radiation proctitis.[59]

For erosive blood loss, 4% formalin solutions applied rectally might have some effect clinically when laser coagulation is not available.

Argon plasma coagulation is suitable for treating hemorrhagic gastrointestinal tract lesions. Ulcers might develop locally, but these are asymptomatic.[69]

Prophylaxis

Radiation delivery to an abdominal tumor sometimes can be modified to diminish gastrointestinal side effects.[70–72] For example, in adults undergoing pelvic irradiation, the volume of small intestine in a pelvic radiation field can be determined by barium studies. If indicated by these studies, the patient can be placed in the prone position for pelvic irradiation to decrease the exposure of normal small intestine.[73] Children requiring pelvic radiation therapy, especially those with previous abdominal surgery and the risk of fixation of the small bowel in the pelvis, should have a similar assessment, and then their radiation fields should be adjusted to a hyperfractionated regimen to minimize late side effects. Also, in adults, use of an elemental diet or parenteral nutrition showed diminished diarrhea and improved nitrogen balance during the acute phase of abdominal radiation treatment.[74–76] NSAIDs given prophylactically may ameliorate acute radiation enteritis.[57]

Topical sucralfate and hydrocortisone, but not mesalazine (5-acetylsalicylic acid), have some preventive effect in radiation proctitis, but this cannot be extrapolated to radiation effects on other usually affected parts of the intestine in children.[77] Amifostine is cytoprotective in adults against radiation mucositis.[78]

Indomethacin reduces the endoscopic manifestations of radiation esophagitis but not the microscopic abnormalities.[58] Exclusion of pancreatic juices in animals can reduce intestinal radiation damage, but antiproteases, such as trypsin inhibitors from soy beans or *Ascaris*, have not been studied in a clinical setting.[11,79]

In children, the appearance of late symptoms can be preceded by gastrointestinal complaints during the early radiation period, but 10 children presenting with ileus 10 years after abdominal radiation had not experienced acute-phase symptoms.[4]

CHRONIC RADIATION ENTERITIS

Eleven percent of children develop a delayed intestinal syndrome consisting of vomiting and diarrhea with a distended abdomen after completion of radiotherapy.[5] Delayed symptoms first appeared within 2 months after completion of radiotherapy. In the French experience, no child developed delayed radiation enteritis without previously having had an early reaction during radiotherapy, but in our experience, only 41% had been asymptomatic during the original radiation treatment. These intestinal lesions are characterized by adhesions and fibrosis, leading in some cases to intestinal obstruction and enteroenteric fistulae steatorrhea, which have been observed in children up to 6 months after completion of radiotherapy. Late and very late symptoms are rare in children; they may be reported at any time after the well-defined period of delayed reactions within 2 months after cessation of radiotherapy.[4,58]

In cases of delayed radiation damage, the extent of bowel involvement is almost always more extended than suspected. In most cases, both small bowel and large bowel are involved. If Ewing sarcoma or rhabdomyosarcoma has been treated with pelvic irradiation, the terminal ileum may suffer from late effects, but, usually, other regions of small bowel and, occasionally, the colon are involved. Increasing pain or a change in pain pattern requires early investigation for obstruction, perforation, abscess formation, or infarction. A recurrent malignancy always must be considered. Minor symptoms should not be overlooked.[80–83]

Pathophysiology of Delayed Reactions

In some children and many adults, mucosal abnormalities such as villous atrophy, abnormal crypts, venous obliteration, and lymphatic ectasias may persist for years because of a combination of epithelial, arteriovenous, and lymphatic obliterative lesions, resulting in vascular and structural dysregulation.[84–86] Subtotal villous atrophy can certainly persist for up to 6 months after radiation therapy. Persisting villous atrophy related to submucosal vascular abnormalities is likely to cause malabsorption if enough irradiated bowel surface area is involved.[87–89] Secondary disaccharidase deficiency with osmotic diarrhea can be a functional sequela of this lesion. Protein-losing enteropathy can occur, with edema and hypoproteinemia owing to permanently dilated lymphatic vessels from obliterative lymphatic lesions.[90–92] Also, bacterial overgrowth with bacterial deconjugation of bile acids can contribute to this malabsorption because the vascular lesions, fibrosis, and stricture formation may cause intestinal stasis with bacterial overgrowth.[93,94]

Deficiency of vitamin B_{12} occurs with long-standing ileal involvement in radiation enteritis, when it might be secondary to bowel stasis with bacterial overgrowth. Rarely, hypocalcemia and vitamin D deficiency occur during chronic mucosal malabsorption.[95] It has to be emphasized that vascular abnormalities without stricturing might cause diarrhea, steatorrhea, nausea, or (sub)clinical signs of deficiencies without obvious alarming symptomatology. Small bowel intestinal obstruction caused by vascular abnormalities after radiation exposure is usually symptomatic owing to strictures and adhesions, with abdominal discomfort, distention of the abdomen in combination with abdominal pain, and sometimes vomiting. Chronic blood loss or massive bleeding owing to radiation ulcers or telangiectasia occurs but very rarely in children. Abdominal abscesses after bowel necrosis and fistulization after pelvic irradiation have been observed in children, but only at laparotomy. Also, septicemia and peritonitis are very rare in children.

Diagnosis

Routine imaging can be helpful, but there are many pitfalls. Strictures and dilatations of the intestine may be detected, but the regions of intestinal wall involved in chronic lesions usually cannot be localized radiologically. Isotope labeling of leukocytes can be used to detect inflammation and abscesses[96,97]; intensive concentrations of isotope suggest an ongoing inflammatory process preceding stricture formation and fibrosis. Also, abnormalities in the vessels of the submucosa are detectable with these scans. Endoscopy is rarely helpful because the involved areas are usually out of reach of the endoscope in children, but small bowel biopsy may show chronic villous atrophy. Malabsorption should be evaluated with fecal fat balance studies. Labeled triglyceride breath tests might be helpful, and in cases of bile acid malabsorption, bile acid breath tests have been used. The Schilling test to assess vitamin B_{12} absorption and the ^{13}C-xylose breath test are helpful in detecting bacterial overgrowth owing to strictures and dilated areas.[98] Occasionally, arteriography may be applied to show arterial stenosis after radiation.

Treatment

Conventional treatment of mild cases of radiation enteritis is supportive. Surgical intervention may be attempted if there is intestinal obstruction, but in children, adhesions, fibrosis, and inflamed bowel loops usually make operative dissection unacceptably hazardous. For reasons that are not yet clear, a diet free of gluten and cow's milk (lactose) and low in fiber and fat content can be very beneficial to symptomatic children.[99] Five children with progressive intestinal dysfunction improved dramatically on such a diet. For undernourished patients not responding to the measures described above, some approaches, used mainly in adults to date, can be attempted.[100] These strategies include a low-fat diet with supplemented medium-chain triglycerides and essential fatty acids and pancreatic enzyme supplements.[101]

If there is fat malabsorption, it is prudent to give supplements of fat-soluble vitamins: A, D, E, and K.

In those rare childhood cases in which terminal ileum has been included in the radiation field and there is watery diarrhea, cholestyramine treatment can be tried. Bacterial overgrowth, which might be anticipated where there is stasis of contents, can be treated with antibiotic regimens.

The management of small intestinal inflammation and proctocolitis has been largely empiric, but a combination of sulfasalazine with prednisone has been effective in a few patients.[102] For proctitis and colitis after pelvic irradiation, anti-inflammatory agents have been of some benefit,[103] and short-chain fatty acid enemas have been used to improve symptomatic radiation proctitis.[104]

Severe bleeding or moderate severe bleeding should be traced by endoscopy and treated locally.

VERY LATE EFFECTS OF RADIATION THERAPY

Gastrointestinal problems can develop in long-term survivors of childhood malignancies exposed to therapeutic abdominal radiation. These complications are very rarely reported, perhaps because, previously, long-term survival was not possible. These late gastrointestinal lesions caused by irradiation may be related to new treatments and new combinations of treatment. Supportive therapies such as blood transfusions can influence the immune apparatus of the gut and induce chronic infections, such as *Candida* esophagitis and cytomegalovirus gastritis and colitis during treatment.[105] New drugs are always appearing for use in childhood cancer, but, so far, no long-term direct gastrointestinal sequelae have been reported in children. Most delayed effects in adults are seen between 6 months and 5 years after irradiation.[106] Later events are called "late event" and beyond 20 years (up to 29 years[107,108]) are designated "very late." In children, these time periods are more difficult to define because of small numbers of cases.[109]

In pediatric cancer patients, benign esophageal stricture formation has been reported in five children directly or 2 years after cessation of radiotherapy.[110] Investigations showed esophageal dysmotility with absent peristalsis in these children.

Symptoms were progressive dysphagia. One child with a total radiation dose of 1,320 cGy responded well to esophageal dilatations, three children with a total dose of 5,400 to 6,800 cGy remained symptomatic after 7 to 50 esophageal dilatations, and one child finally required an esophageal replacement. Some of the children with esophageal strictures after radiotherapy had experienced several disease recurrences of rhabdomyosarcoma or Hodgkin disease.[111–114] Another 21-year-old young man had an esophageal stricture 14 years after radiation therapy for Hodgkin disease.[115] Investigations showed esophageal dysmotility with absent peristalsis in all six children. Fibrosis, dense collagen depositions, and ulcerations without an inflammatory infiltrate are seen in pathologic specimens.[116] Gastric lesions have been reported in adults after a dose of 5,500 cGy or more; atrophic gastritis and ulcers are extremely rare. In children, no gastric lesions have been reported.

Very late effects on the small intestine have presenting symptoms of vomiting, abdominal pain (localized or generalized), constipation,[117] diarrhea, bleeding with or without anemia, anorexia, fatigue, wasting, and rarely chronic hypercholereic metabolic acidosis. These symptoms are mainly the expression of subacute intestinal obstruction; they are intermittent and treatable by operation in most cases. A few patients have a continuum of symptoms after acute radiation enteritis advancing into delayed radiation enteropathy without a latent period. The incidence of clinically significant problems is enhanced by abdominal surgery and possibly radiomimetic chemotherapy. Frequency of late effects depends on the dosage delivered. Overall, there is a 5% incidence of fibrosis after 4,000 to 5,000 cGy and an incidence as high as 36% after 6,000 cGy or more. The late effects are anatomically related to fixed parts of the gut, duodenum, or terminal ileum or loops fixed by adhesions after surgery.[118,119]

More mobile parts of the small intestine seem to recover better from acute radiation enteritis. In the affected regions, diffuse fibrosis of the muscularis propria and fibrosis of the submucosa are detected, along with stenosis and ulceration. Vascular lesions in the submucosa and in the mesentery are characterized by variable myointimal proliferations and media fibrosis. These changes involve small arteries and arterioles and small veins. Some small arteries show an acute vasculitis with heavy infiltration of lymphocytes and neutrophils in the media and adventitia, and variable necrosis of the vessel wall. In late radiation, enteritis fibrosis without an inflammatory infiltrate is common, but focal acute vasculitis distant from ulcerations signifies ongoing fibrosis. Villous atrophy is noticed in all resected specimens, suggesting long-term permanent villous alterations in patients treated with radiation therapy to the abdomen.

The incidence of proctosigmoiditis on long-term follow-up is probably 2 to 5% and dose dependent; above 5,000 cGy, the incidence increases at 1-year follow-up to 18 to 37% and above 6,000 cGy to 37%.[4,5]

Secondary malignancies are extremely rare. One child with Wilms tumor developed colon cancer years after chemotherapy, surgery, and radiation.[120]

Another with Wilms tumor developed hepatocellular carcinoma 16 years after chemotherapy, surgery, and radiation.[120]

From the atom bomb survivors in Japan, a slight increase in carcinomas of the esophagus and colon but not the stomach, small intestine, or rectum was reported 25 years after observation. In adults assessed 30 years after irradiation for benign uterine bleeding with a dose range between 695 and 1,050 cGy, the increased risk of secondary malignancy appears to be related to low- and medium-range dosages of radiation instead of a high dosage.[121]

It seems clear that children who have been treated with abdominal radiation for malignant disease must be observed over their lifetimes for possible complications, including secondary malignancy.[122,123]

ACKNOWLEDGMENT

I am indebted to Dr. F. Oldenburger, pediatric radiotherapist, for his help with the manuscript.

CHAPTER 9

ACUTE DIARRHEA

Stefano Guandalini, MD

DEFINITION AND EPIDEMIOLOGY

Acute diarrhea is the abrupt onset of increased fluid content of the stool above the normal value of approximately 10 mL/kg/d. Usually, this situation implies an increased frequency of bowel movements, which can range from 4 to 5 to more than 20 times per day. The augmented water content of the stools is the result of an imbalance in the function of the small and large intestinal processes involved in the absorption and secretion of electrolytes, organic substrates, and thus water.

Acute-onset diarrheal episodes, most often the result of infections of the gastrointestinal tract, continue to be a major problem for worldwide child health. Although in developed countries, its prevalence and severity have declined, acute diarrhea remains an extremely common and often a severe problem. In developing countries, an average of three episodes per child per year in children below 5 years of age is reported, but there are areas with 6 to 8 episodes per year per child. In these settings, malnutrition is an important additional risk factor for acute and prolonged diarrhea.[1] Childhood mortality associated with diarrhea has constantly but slowly declined during the past two decades, mostly because of the widespread use of oral rehydration solutions (ORSs).[2] A recent review of studies published during the previous 10 years found that global diarrheal disease mortality fell to 2.5 million per year.[3] However, despite this progressive reduction in global diarrheal disease mortality, diarrhea morbidity in published reports from 1990 through 2000 has slightly increased worldwide compared with previous reports.[4] Furthermore, we should not ignore that in countries where the toll of diarrhea is highest, poverty also adds an enormous additional burden, and long-term consequences of the vicious cycle of enteric infections, diarrhea, and malnutrition are devastating.[5]

In the United States, there are 1 to 2 episodes per child per year in children below 5 years of age, with 220,000 hospital admissions (or about 10% of all admissions for children in this age range) and about 400 deaths per year.[6,7] Furthermore, acute diarrhea causes 20% of physician referrals for children below the age of 2 years[8] and 10% for those below the age of 3 years.[9] Throughout the world, the most underprivileged populations are most severely affected. In the United States, the mortality rate among blacks is four times that for whites (32.2 vs 8.2 deaths per 100,000 live births).[10,11] Even though gastrointestinal infections are by far the most common cause of acute diarrhea, the sudden onset of increased stool fluid output can indeed be caused by many different disorders. Table 9-1 lists these potential causes in the approximate order of frequency. Many different pathogens can be responsible for infectious diarrhea. Table 9-2 lists the main agents known to infect the intestine and cause acute diarrhea in children. In a multicenter investigation conducted over a period of 1 year in several European countries, my colleagues and I identified a pathogen in 65.6% of 287 children, most commonly *Rotavirus* (35.1%).[12] The frequency with which a particular pathogen is isolated varies widely between different geographic areas and different age

Giardia lamblia	1–3

groups. For instance, bacteria are generally more common in the first few months of life and then again in school-age children. *Rotavirus*, the single most pervasive cause of infectious diarrhea worldwide, peaks between the ages of 6 and 24 months. In developed countries, intestinal infections are usually sporadic, but outbreaks of foodborne or waterborne infections are well described and continue to occur. Recently, a growing epidemiologic role for Norwalk-like virus has been reported. Norwalk-like virus is now considered to cause an impressive 10% of sporadic cases in developed countries.[13] It should be mentioned that all of the above applies to the general population: in patients with immune disorders, specifically acquired immune deficiency syndrome (AIDS), a much wider array of pathogens is seen. Etiologic diagnosis, not considered necessary in most sporadic cases occurring in immunocompetent children, in subjects with human immunodeficiency virus (HIV) infection is very important for treatment, and it is currently thought that endoscopy is necessary.[14] See Chapter 38, "Infections," for a detailed presentation of individual enteric infections.

It is well accepted that extraintestinal infections (eg, middle ear, lung, and urinary tract infections) can result in acute diarrhea, which is usually mild and self-limited, but the mechanisms for such a relationship are not understood.

Many drugs can induce acute diarrhea as a side effect. Among them, antibiotics have a special place because they frequently cause diarrhea. *Clostridium difficile*[15] may be responsible for many cases of antibiotic-associated diarrhea, but this is not always the case. Indeed, it is thought that in children, the majority of episodes of diarrhea secondary to antibiotic use are not related to *C. difficile*.

The incidence of food allergies has risen during the past decade. Presently, it is assumed that about 3% of all infants are affected by food allergies, of which by far the most common is cow's milk protein allergy (CMPA). A vast array of signs and symptoms are linked to CMPA, but acute diarrhea (typically accompanied by vomiting) is a very common modality of onset. Thus, CMPA should be taken into consideration in the differential diagnosis of acute-onset diarrhea, particularly when the diarrhea fails to resolve within 10 to 14 days.

Although disorders of digestive and absorptive processes are more commonly considered causes of chronic diarrhea or malabsorption syndromes, it is worth remembering that sucrase-isomaltase deficiency may be mistaken for an acute diarrheal illness if the relationship with the intake of sucrose is not detected by accurate history taking. Likewise, lactose intolerance of the older child may not be distinguishable from other forms of diarrhea with an acute onset. In general, the child presenting with acute diarrhea may be showing the early symptoms of a chronic malabsorption syndrome.

In patients treated for cancer by chemotherapy or radiation therapy, acute diarrhea may also ensue as a result of the damage to the intestinal absorptive area. See Chapter 8, "Gastrointestinal Injury," for details.

Several "surgical" conditions (eg, appendicitis[16]) can also present with acute diarrhea as the most obvious clinical sign. This should always be kept in mind when approaching a child with acute-onset diarrhea.

Much rarer disorders resulting in acute diarrhea are niacin deficiency and ingestion of heavy metals.

Finally, it should be noted that despite an aggressive search for the cause of acute diarrhea in children, only in 60 to 70% of cases is it possible to make a diagnosis (usually an intestinal infection). Whatever the cause, typically acute diarrhea in developed countries runs a mild course and resolves, by definition, in less than 14 days. In the previously mentioned study, my colleagues and I found that acute-onset diarrhea lasted a mean of 5.0 ± 2.2 days.[12] Overall, only about 10% of all children had a course more prolonged than 7 days (Figure 9-1).

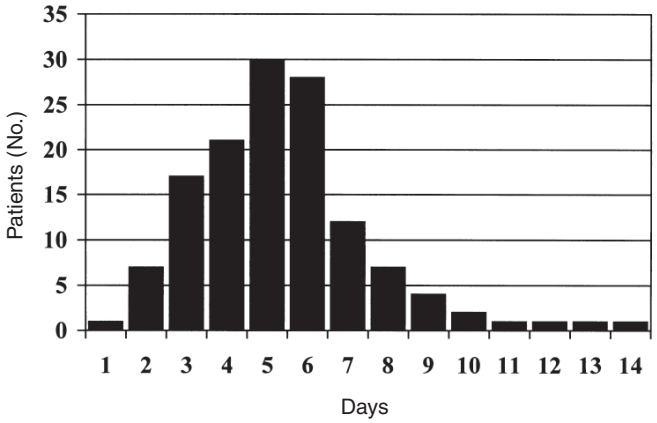

FIGURE 9-1 Bar graph with duration of diarrhea in 456 Italian patients.

PATHOGENESIS

As previously stated, diarrhea results from an imbalance in the intestinal handling of water and electrolytes. Under normal circumstances, the small intestine absorbs large quantities of sodium, chloride, and bicarbonate. It also secretes H^+ ions and, to a lesser extent, bicarbonate and chloride. Water then passively follows the net transport of solutes. The overall absorption of water, sodium, and chloride can therefore be viewed as the result of two opposing unidirectional fluxes of ions, one absorptive and the other secretory. Even though these two processes were once thought to be completely anatomically separated (absorption taking place in the mature epithelial cells lining the villi, whereas secretion is predominantly a crypt process), we now know that they are not, with both absorption and secretion occurring in villi and crypts.[17] Still, the majority of absorption takes place in the villous region, and the bulk of secretion does originate from the crypts. Because the absorptive capacity of the enterocytes quantitatively far exceeds secretory activity, the net result in health is absorption of water and electrolytes.

The basic cellular mechanisms that determine electrolyte absorption and secretion and therefore, when altered, the presence of diarrhea are schematically illustrated in Figure 9-2. The most important ion in drawing net water and nutrient absorption in the gut is sodium. Three different processes of sodium absorption have been described, all driven by Na, K adenosine triphosphatase (ATPase), a basolateral membrane enzyme with a key role in intestinal absorption of ions and nutrients. In fact, Na, K ATPase generates and maintains a Na electrochemical gradient between the gut lumen and the interior of the intestinal epithelial cell, which allows Na to enter the cell downhill along one of the following three paths.

Sodium Absorption Coupled to Nutrients

The entry of glucose and of several groups of amino acids is coupled with high affinity to that of Na throughout the small intestine. A specific carrier called sodium-glucose transporter 1 (SGLT-1) [18] is involved in coupling the entry of glucose (and galactose) across the brush border to that of Na. Furthermore, several, but not all, carriers for different categories of amino acids also couple their entry into the enterocyte with the downhill transport of Na.[19,20] Dipeptide absorption, on the other hand, is not directly coupled to Na absorption but is nevertheless an electrogenic, active process, occurring coupled to the entry of a proton ion (H^+) across the brush border.[21] The existence of the Na-coupled glucose absorption, and its substantial integrity during most acute diarrheal disorders (see below), is considered the pathophysiologic basis for the use of orally administered hydration solutions in children with diarrhea.

Electrogenic, Amyloride-Sensitive Na Absorption

This process allows sodium to enter the cell down its electrochemical gradient, through selective channels, uncoupled to other substrates in the ileum and throughout the colon, where it is preponderant. In the large intestine, electrogenic Na^+ absorption via the epithelial Na^+ channel takes place in the surface epithelium and upper crypts of the distal colon. The cystic fibrosis transmembrane conductance regulator (CFTR) is expressed throughout the colonic epithelium and dominates in the crypts.

It should also be noted that Cl is absorbed throughout the gastrointestinal tract whenever a potential difference is created (serosal side positive) as a result of electrogenic Na absorption through either of the two pathways described above.

Neutral NaCl Absorption

By far the most important process involved in vectorial absorption of Na (and Cl) is the Na-Cl cotransport. This transport process operates throughout the gastrointestinal tract, but it predominates in the small intestine. Transport of the ionic pair NaCl is actually mediated by two coupled antiports; one exchanges Na^+/H^+ (cation

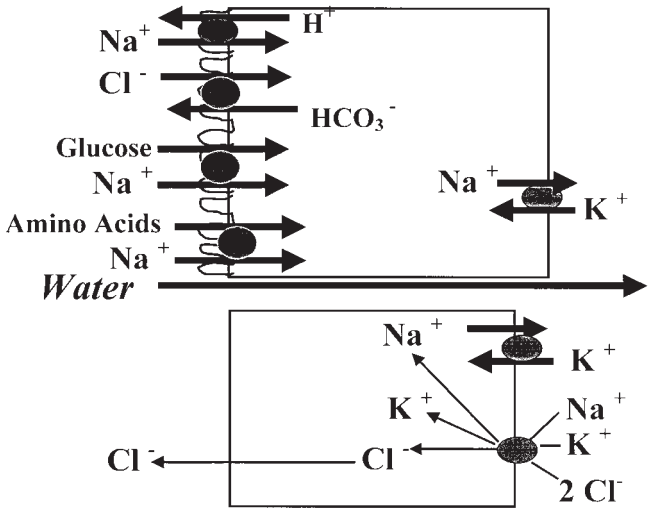

FIGURE 9-2 Main intestinal absorptive/secretory processes for electrolytes. In the villous cell (*top panel*), Na, K adenosine triphosphatase (ATPase) actively extrudes Na in exchange for K, thus maintaining the low intracellular Na concentration, which allows the "downhill" entry of the ionic pair Na-Cl and of the Na-coupled nutrients such as glucose and amino acids. It can also be seen that the entry of the ionic pair Na-Cl is in reality, across most of the intestinal tract, the result of a double antiport, Na being exchanged with H and Cl with HCO_3. In the crypt cell (*bottom panel*), the low Na cell concentration maintained by Na, K ATPase builds a Na gradient between the extracellular compartment and the cell. Energized by this gradient, a carrier in the basolateral membrane (lower part of the figure) couples the flow of one Na, two Cl, and one K from the serosal compartment into the crypt cell. As a result, Cl accumulates above its electrochemical equilibrium and under physiologic circumstances leaks into the lumen across a semipermeable apical membrane. Because absorptive activity in the villous cell quantitatively far exceeds the minor secretion from the crypts (as suggested in the figure by the arrows' sizes), the net result is absorption of electrolytes and nutrients. Water absorption then passively follows, mainly through the intercellular tight junctions.

exchanger), and the other exchanges Cl^-/HCO_3^- (anion exchanger). The Na^+/H^+ antiport operates via specific carriers that have been identified in the past several years and are named the Na-hydrogen exchangers (NHEs). There are six isoforms of NHE (1 to 6)[22]: NHE3 is located in the brush border of the enterocytes and is thought to be the main isoform involved in the transepithelial absorption of Na. The isoform NHE1 is mostly involved in maintaining intracellular pH.[23]

Anion Secretion

Chloride and HCO_3 are the major anions being actively secreted into the gut lumen. Such secretion takes place mainly in the crypts and is electrogenic. As a result, passive diffusion of a cation (usually Na) and water follow.

Overall, the intestinal transport of water and electrolytes is a finely tuned process resulting from the complex interplay of regulatory mechanisms involving the enteric nervous system, cells in the lamina propria, and the epithelial cells. The regulatory agents released and ultimately responsible for the maintenance of this homeostasis include hormone peptides, active amines, arachidonic acid metabolites, and nitric oxide (Table 9-3). Under normal circumstances, such complex interactions eventually act on the intestinal epithelial cells, affecting the described ion transport processes and ultimately resulting in net water and electrolyte absorption. The bulk of absorbed water crosses the intestinal epithelium between the cells (across the tight junctions), following the osmotic gradient generated by the transport of nutrients and electrolytes.

Diarrhea, therefore, is the reversal of this normal net absorptive status to secretion. Such a derangement can be the result of either an osmotic force that acts in the lumen to drive water into the gut or the result of an active secretory state induced in the enterocytes. In the former case, diarrhea is osmolar in nature, as observed after the ingestion of nonabsorbable sugars such as lactulose or of lactose in lactose malabsorbers. In the typical active secretory state, there is enhanced anion secretion mostly by the crypt cell compartment, best exemplified by enterotoxin-induced diarrhea.

These two basic pathogenetic mechanisms are summarized in Figure 9-3. In osmotic diarrhea, the intestinal mucosa cannot digest and/or absorb one or more nutrients. As a consequence, these solutes exert an osmotic force, proportional to their concentration, which drives water, mainly across the leaky tight junctions, into the lumen. Furthermore, as the unabsorbed nutrient is often a carbohydrate, when it reaches the colon it undergoes further digestion by the resident microflora, generating smaller particles and, hence, further contributing to the osmotic drive of water into the lumen. The main features of osmotic diarrhea are described in Figure 9-3. Stool output is proportional to the intake of the unabsorbable substrate and is usually not massive; diarrheal stools promptly regress with discontinuation of the offending nutrient, and the stool ion gap is high, exceeding 100 mOsm/kg. In fact, the fecal osmolality in this circumstance is accounted for not only by the electrolytes but also by the unabsorbed nutrient(s) and their degradation products. The ion gap is obtained by subtracting the concentration of the electrolytes from total osmolality, according to the formula: ion gap = osmolality – [(Na + K) × 2].

In secretory diarrhea, the epithelial cells' ion transport processes are turned into a state of active secretion. This situation can occur as a result of many processes. When dealing with *acute* secretory diarrhea, the most common cause is a bacterial infection of the gut. Several mechanisms may be at work (see Chapter 38).[24] After colonization, enteric pathogens may adhere to or invade the epithelium; they may produce enterotoxins (exotoxins that elicit secretion by increasing an intracellular second messenger) or cyto-

TABLE 9-3 ENDOGENOUS REGULATORS OF INTESTINAL WATER AND ELECTROLYTE TRANSPORT

SOURCE	STIMULATE ABSORPTION	STIMULATE SECRETION

Ion Gap:	≥ 100 mOsm/kg	< 100 mOsm/kg

FIGURE 9-3 Scheme of osmotic and secretory diarrhea. The left panel shows the situation in osmotically induced diarrhea. Undigested or unabsorbed substrates remain in the gut lumen and exert an osmotic force proportional to their concentration that drives fluid into the lumen. In the case of unabsorbed carbohydrates, colonic flora enzymes may partially digest them, thus further contributing to the osmotic load and water flow into the lumen. Secretory diarrhea (*right panel*) is characterized by a state of active secretion of anions by the enterocytes. In vivo, equivalent amounts of cations also passively follow, and the result is net secretion of water and electrolytes. The role of the colon varies according to the cause of the secretion.

toxins. They also may trigger release of cytokines attracting inflammatory cells, which, in turn, contribute to the activated secretion by inducing the release of agents such as prostaglandins or platelet-activating factor. Features of secretory diarrhea, reported in Figure 9-3, are a high purging rate, a lack of response to fasting, and a normal stool ion gap (≤ 100 mOsm/kg), indicating that nutrient absorption is intact. The role of the colon in secretory diarrhea varies with the causes.[25–27] Generally speaking, the colonic mucosa's absorptive capacity is maximized; thus, the large intestine partially compensates for the increased small intestinal water loss. However, there are instances in which the colon is either directly involved in the stimulated secretion (ie, when the secretion is the result of a bacterial infection involving the colon) or, even if not challenged topically by a pathogen, may be put in a secretory state via the enteric nervous system as a result of enterotoxin-stimulated secretion going on in the small intestine.[24]

Three intracellular second messengers (cyclic adenosine monophosphate [cAMP], cyclic guanosine monophosphate [cGMP], and Ca^{++}/protein kinase C) have long been recognized as key mediators of secretion (see Table 9-3). They are activated by physiologic events and by various secretagogues, notably bacterial enterotoxins. Increases in any of these second messengers result in a series of biochemical events that activate protein kinases, which act directly on ion channels, inhibiting NaCl-coupled influx and increasing Cl efflux (Figure 9-4). Enterotoxins elaborated by bacterial pathogens selectively and specifically increase either cAMP (eg, cholera toxin and *Escherichia coli* heat-labile toxin) or cGMP (eg, enterotoxigenic *E. coli* [ETEC], enteroaggregative *E. coli* [EAEC], or *Klebsiella* heat-stable enterotoxin—STa). In the mature villous cells, cAMP and cGMP appear to be equally powerful inhibitors of NaCl entry, whereas cAMP is more potent than cGMP in stimulating anion secretion. In the crypts, several components are involved in the cyclic nucleotide and Ca-dependent electrogenic anion secretion. Na, K ATPase in the basolateral membrane maintains a low intracellular Na concentration, thereby allowing a gradient favorable to Na entry from the extracellular environment. Because of this gradient, one Na, two Cl, and one K flow via a carrier in the basolateral membrane from the serosal fluid into the cell (see Figure 9-4). Whereas Na and K may recycle out of the cell, Cl accumulates in the cell above its electrochemical equilibrium. Protein kinases, activated by these cyclic nucleotides and by Ca, then open Cl channels, allowing anions to leave the cell down a favorable electrochemical gradient. The major Cl channel, sensitive to all of the described second messengers, is the CFTR protein,[28] but other anion channels are also present.

More recently, another mechanism for fluid secretion has been elucidated by studies of the zonula occludens toxin from *Vibrio cholerae*.[29] This toxin loosens tight junctions between small intestinal enterocytes,[30] leading to fluid secretion into the lumen.[31] Although examples of purely osmolar and purely secretory diarrheas do occur, in most acute-onset diarrhea, both mechanisms coexist. For example, in rotaviral enteritis, a serious disruption of absorptive functions occurs as a result of the selective invasion of the mature enterocytes by the invading organisms. In this circumstance, osmolar diarrhea ensues. However, the reduction of absorptive cells in the gut lining also unmasks the secretion in the crypts, and a secretory component is superimposed. Furthermore, the secretory nature of rotavirus diarrhea is also augmented by an enterotoxin, the nonstructural protein NSP4, which acts as a viral enterotoxin to induce diarrhea, causing Ca^{++}-dependent transepithelial Cl

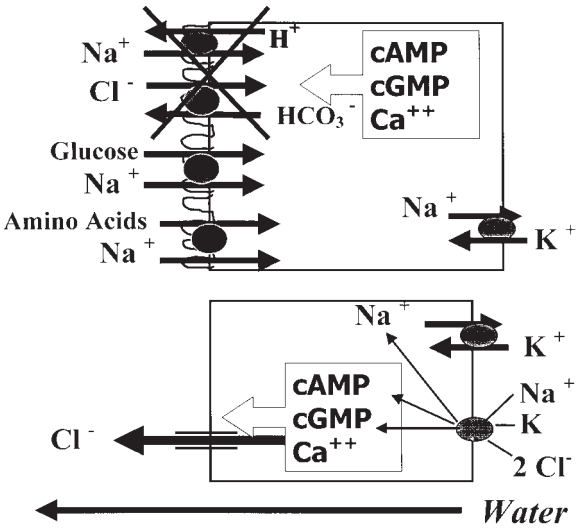

FIGURE 9-4 Secretory changes induced by second messengers. Cyclic adenosine monophosphate (cAMP), cyclic guanosine monophosphate (cGMP), and Ca^{++}/protein kinase C have similar effects. In the mature villous cell (*top panel*), they inhibit the electrically neutral, coupled influx of Na and Cl (which results from the double antiport of Na/H and Cl/HCO_3). In the undifferentiated crypt cell, cAMP, cGMP, and Ca^{++}/protein kinase C act by opening Cl channels (mainly the cystic fibrosis transmembrane conductance regulator) in the luminal membrane. As a consequence, Cl leaves the cell moving down its electrochemical gradient. Because the epithelium cannot secrete only anions, cations (Na) flow across the paracellular pathway, driven by the electrical gradient created by the secretory transport of Cl. Thus, antiabsorptive (mostly but not exclusively in the villous cell) and prosecretory (mostly but not exclusively in the crypt cell) forces combine to shift ions, and with them water, from absorption to secretion.

secretion.[32] Of interest, recently a second example of an enterotoxin-like action by a viral protein has been found, the HIV-1 Tat protein, which acts on ion secretion and on cell proliferation in human intestinal epithelial cells.[33]

Table 9-4 summarizes the main pathogenic mechanisms displayed by the most common agents of infectious diarrhea, along with their predominant site of action within the gut. Chapter 38 contains additional information on the pathogenesis of viral, bacterial, parasitic, and fungal infections.

CLINICAL FEATURES

Acute diarrhea in developed countries is almost invariably a benign, self-limited condition, subsiding within a few days. The clinical presentation and course of illness are dependent on the host and on the infecting organism.

As for the host, age and nutritional status appear to be the most important elements. In fact, the younger the child, the higher is the risk for severe, life-threatening dehydration as a result of the high body water turnover and limited renal compensatory capacity of very young children. Whether younger age also means a risk of running a prolonged course is an unsettled issue. In a series of 453 children, no correlation was found (r = .01, p = not significant) between age at onset and diarrhea duration, but in developing countries, it has been reported that persistent postenteritis diarrhea (PPD) shows a strong inverse correlation with age.[34,35] Nutrition plays an essential role in determining the severity of the diarrheal episode, an effect mediated by several factors, including an altered small intestinal mucosal permeability.[36]

As for the infecting organism, the different pathogenic mechanisms deployed by different infectious agents result in a variable pattern of clinical features (see Table 9-4). Table 9-5 reports clinical features at admission in the previously quoted series of 287 patients.[12] It can be seen that this group of well-nourished children with acute diarrhea from 10 European centers presented mainly with watery or loose stools, often with vomiting and fever. They were mostly in good or fair condition and with either mild or no dehydration in almost 80%. By looking at the clinical features of children grouped according to the pathogen identified, it is evident that these features do vary according to etiology, as one would expect based on the varying pathophysiology. Table 9-6 reports data pooled from our recent series[12] and from a previous series of 154 children,[37] 3 months to 5 years of age. Only patients in whom a single pathogen was identified are reported. When compared with children with either invasive etiology or enterotoxigenic bacteria, it is obvious that patients with rotaviral diarrhea tend to have severe dehydration, vomiting, and watery stools. Fever, crampy abdominal pain, and blood mixed with stools are more common in patients with invasive pathogens such as *Salmonella*, *Shigella*, *Yersinia*, *Campylobacter*, and *Entamoeba histolytica*. The smaller group of children affected by STa-producing ETEC had milder illness, with fecal electrolyte content consistent with a secretory pathogenesis.[38]

In developed countries, diarrhea is basically a self-limited condition. If the proper replenishment of water and electrolytes lost with the stools is provided on an ongoing basis, hydration will be maintained, and the condition will fade within a few days. Sometimes diarrhea fails to subside and undergoes a prolonged course. See Chapter 10, "Persistent Diarrhea," for a detailed presentation of persistent diarrhea. The World Health Organization (WHO) has defined PPD as an episode beginning acutely and lasting for at least 14 days.[39] Between 0 and 1% (in developed countries) and up to 20% (in developing countries) of acute-onset diarrheal episodes run a prolonged course. Table 9-7 lists the main causes leading to the syndrome of PPD. As can be seen, most of the same pathogens that cause acute diarrhea are involved in PPD. Predisposing factors have been described, but by far the most important is a weakened underlying immune status and malnutrition. In fact, PPD, which is frequently seen in association with malnutrition, causes 30 to 40% of all diarrheal deaths in underdeveloped countries.[40,41] In this setting, PPD, in turn, undermines nutritional status, leading to a vicious cycle of diarrhea, malnutrition, and diarrhea.[42] An episode of acute infectious enteritis might evolve into a prolonged course by a variety of mechanisms,[43] including many different morphologic and biochemical abnormalities in the small intestine. In

TABLE 9-4 PATHOGENIC MECHANISMS AND LOCALIZATION OF THE MAIN INTESTINAL PATHOGENS

PREDOMINANT PATHOGENESIS*	SITE OF INFECTION	AGENT	CLINICAL FEATURES
Direct cytopathic effect	Proximal small intestine	*Rotavirus* Enteric-type adenovirus Calicivirus Norwalk-like virus EPEC *Giardia*	Copious watery diarrhea, vomiting, mild to severe dehydration; frequent lactose malabsorption, no hematochezia Course may be severe
Enterotoxigenicity	Small intestine	*Vibrio cholerae* Enterotoxigenic *Escherichia coli* Enteroaggregative *E. coli* *Klebsiella pneumoniae* *Citrobacter freundii* *Cryptosporidium*	Watery diarrhea (can be copious in cholera or ETEC), but usually mild course; no hematochezia
Invasiveness	Distal ileum and colon	*Salmonella* *Shigella* *Yersinia* *Campylobacter* Enteroinvasive *E. coli* *Amoeba*	Dysentery: very frequent stools, cramps, pain, fever, and often hematochezia with white blood cells in stools Variable dehydration Course may be protracted
Cytotoxicity	Colon	*Clostridium difficile* Enterohemorrhagic *E. coli* *Shigella*	Dysentery, abdominal cramps, fever, hematochezia EHEC or *Shigella* may be followed by hemolytic uremic syndrome

EHEC = enterohemorragic *Escherichia coli*; EPEC = enteropathogenic *Escherichia coli*; ETEC = enterotoxigenic *Escherichia coli*.
*Elaboration of various types of enterotoxins affecting ion transport has been demonstrated as an additional virulence factor for almost all of the bacterial pathogens.

some cases, the mucosal villous architecture is almost normal, and in others, continuous or patchy atrophy is seen. Abnormalities of brush border and/or intraluminal digestive enzymes, gut permeability, and/or small bowel intraluminal bacterial flora can be found. In developed countries, the rare occurrence of PPD in otherwise healthy children is most often due to a food protein sensitization. In infants, cow's milk proteins are the most common offending proteins.[44] If acquired during the acute phase of the intestinal infection, this sensitized state might be provoked by increased antigen penetration, secondary to damaged mucosa and increased permeability.

PRINCIPLES OF MANAGEMENT

REHYDRATION

The obvious major risk in acute diarrhea is the loss of water and electrolytes with consequent dehydration and possibly even loss of Na homeostasis. Rehydration or maintenance of hydration is therefore the cornerstone of treatment. Until the mid-1960s, this was accomplished almost exclusively via the intravenous route. Subsequently, the expanded understanding of the pathophysiologic events in intestinal transport processes allowed a dramatic change of approach. In fact, it became apparent that enterotoxigenic bacteria such as *V. cholerae* or ETEC leave intact small intestinal mucosal morphology and absorptive functions. In particular, the glucose-coupled Na influx was found to be fully functional in cholera toxin and other cAMP-induced secretory diarrheas, studied in vitro and in vivo.[45–47] This was later confirmed for the other cyclic nucleotide, cGMP, and its related enterotoxins.[48] Thus, the ongoing absorption of Na and glucose during secretion promotes fluid absorption and allows rehydration to take place in spite of the ongoing fluid loss seen in enterotoxigenic diarrheas. It must be noted that ORSs have been found to be effective even in situations such as rotavirus

enteritis, despite a diffuse damage to the epithelium, which in vitro results in the inhibition of nutrient transport.

These concepts provided the pathophysiologic basis for the WHO-UNICEF–supported and highly successful global program for oral rehydration therapy (ORT). Oral rehydration solutions have proved both safe and effective worldwide in hospital settings and also in the home to prevent dehydration. For more than two decades, the WHO has recommended a standard formulation of glucose-based ORS with 90 mmol/L of sodium and 111 mmol/L of glucose, with a total osmolarity of 311 mmol/L. However, many in vitro and in vivo studies during the 1980s and 1990s had consistently shown that lower concentrations of sodium and glucose enhance solute-induced water absorption and might therefore be superior to the solution with a higher osmolarity, as reviewed in several articles.[49–51]

The ORS originally proposed by the WHO, and so successfully employed over the years in huge numbers of adults and children, might still be preferable for use in areas where the prevalence of cholera is high.[52] In fact, cholera, still a major cause of morbidity and mortality in some parts of the world,[53] is known to induce the highest rates of Na purging, around 90 mmol/L of stools. It should be noticed, however, that when investigated in a controlled trial that compared the two solutions even in children with cholera, they performed equally well.[54] Reduced-osmolarity solutions have concentrations of glucose and Na inferior to those in the WHO solution: glucose ranges between 75 and 100 and Na between 60 and 75 mmol/L, so osmolarity is maintained at 225 to 260 mOsm/L. The use of such ORSs in children of developed countries was originally proposed in 1992 by an ad hoc committee of the European Society of Pediatric Gastroenterology, Hepatology and Nutrition (ESPGHAN).[55] The composition recommended is reported in Table 9-8. Hypo-osmolar ORSs appear to have the additional advantage of allowing a reduced stool output while being just as effective in obtaining and maintaining rehydration and can be safely given throughout the duration of diarrhea, as shown in both developed countries[56] and, more recently, by a large multicenter trial, in developing countries.[57] Indeed, a recent large meta-analysis of all published controlled trials comparing low-osmolarity solutions with standard WHO formulas appearing in the Cochrane Library concluded that "in children admitted to hospital with diarrhoea, reduced osmolarity ORS when compared to WHO standard ORS is associated with fewer unscheduled intravenous fluid infusions, lower stool volume post randomization, and less vomiting. No additional risk of developing hyponatraemia when compared with WHO standard ORS was detected."[58] Thus, the time is probably right for the WHO approach to recommend a global ORS based on a reduced-osmolarity composition.[59]

Studies comparing glucose- versus rice-based ORSs generally show that, although the rice-based ORS tends to reduce stool output during the first 12- to 24-hour periods, both solutions are well accepted and equally efficacious.[60,61]

In a large meta-analysis, ORT was found to provide effective treatment for over 96% of children of developed countries,[62] without need to resort to intravenous rehydration.

In summary, ORT with a glucose-based ORS must be viewed as by far the safest, most physiologic, and most effective way to provide rehydration and maintain hydration in children with acute diarrhea worldwide, as recommended by the WHO, by the ad hoc committee of ESPGHAN,[55,63] and by the American Academy of Pediatrics.[64] Overall, according

ESPGHAN = European Society of Pediatric Gastroenterology, Hepatology and Nutrition; WHO = World Health Organization.

to the WHO, the use of ORT for patients with diarrhea rose during the years 1980 to 1993 from less than 5% to about 50% of all episodes of diarrhea worldwide.[65] Indeed, developed countries remain behind in fully using such effective means of treatment, as shown in both Europe[63] and the United States,[66] where rates of use are disappointingly low.

Refeeding

It has been clear for many years that, when affected by gastroenteritis, breastfed infants should be continued on breast milk without any need for interruption. In fact, breastfeeding not only has a well-known protective effect against the development of enteritis,[67] it also promotes faster recovery and provides improved nutrition.[68] This is even more important in developing countries, where withdrawal of breastfeeding during diarrhea has been shown to have a deleterious effect on the development of dehydration in infants with acute watery diarrhea.[69]

In artificially fed infants, however, the issue is much more controversial. For years, the popular remedy for acute diarrhea has been that of fasting, on the intuitive basis that "gut rest" would be beneficial. This long-held view has been challenged during the past several years to the point that today the evidence in favor of rapid refeeding is overwhelming. In fact, many well-conducted studies have provided evidence that in weaned children not severely dehydrated or acidotic, a rapid return to full feeding after having completed oral rehydration in the first 4 to 6 hours is well tolerated.[70–72] Indeed, ORT itself has a beneficial effect on nutrition by stimulating the child's appetite as a result of the improved water and potassium balance. Furthermore, rapid refeeding after adequate ORT has been shown to allow a faster recovery from the abnormally increased intestinal permeability owing to induced enteritis.[73]

Furthermore, evidence has been provided that even in the United States, delaying reintroduction of normal feeds in diarrheic children may have devastating nutritional effects.[74] The Working Group on Acute Diarrhea of ESPGHAN evaluated in a multicenter study the effect of early versus delayed resumption of full feedings in European children with acute diarrhea.[75] The children were first orally rehydrated with a reduced-osmolality solution, formulated according to the previous recommendations,[55] and were then assigned to either the "gradual" or the "early" refeeding group. Two hundred thirty patients (mean age 14 months) were examined; their profile on entry into study showed no statistically significant difference between the two groups. After 4 hours of ORT, the patients who were "early" fed resumed their normal diet, including lactose-containing formulas, whereas the "late feeders" continued to receive only ORS for 24 hours before returning to normal foods. Weight gain proved significantly greater in patients refed early, not only during the first 1 or 2 days after rehydration but also throughout hospitalization, and persisted as late as at day 14 postenrolment. Most important, the two groups did not differ in the incidence of emesis and watery stools. Of note, by day 5, no patient in either group had lactose intolerance.

Lactose intolerance was once thought to be a major problem in children with diarrhea and a reason to delay refeeding milk-based formulas. In fact, human milk is particularly rich in lactose. In spite of the presence of reducing substances in the stools of infants with diarrhea, it is believed that lactose intolerance is not a concern for the vast majority of patients in developed countries.[76] In the ESPGHAN study, only 3% of the children at admission had signs of lactose malabsorption and none at day 5 postenrolment after receiving a normal, lactose-containing formula.[75] The occurrence of lactose intolerance must not be completely disregarded. Occasionally, and with increased frequency in malnourished children, diarrhea may worsen on reintroduction of milk or "normal" formulas. If fecal pH decreases and more than 0.5 to 1% reducing substances are found in the stools, lactose intolerance should be assumed and a lactose-free formula employed at least temporarily to prevent PPD.[77,78]

There is overwhelming evidence that rapid refeeding for most infants beyond the first 3 months of age is safe and effective in acute diarrhea.[42,68,70–72,79–81] Based on this evidence, including the large meta-analysis by Brown and colleagues of the published trials comparing different refeeding regimens,[82] the ESPGHAN Working Group recommended that "the optimal management of mild-to-moderately dehydrated children in Europe should consist of (A) oral rehydration with ORS over 3 to 4 hours, and (B) rapid reintroduction of normal feeding thereafter."[83,84] These principles are equally applicable to the developing world.

Other Treatments: Antibiotics, Micronutrients, Immunoglobulins, Drugs, and Probiotics

Appropriate management of dehydration, electrolyte status, and nutrition, as outlined above, remain the corner-

stones of therapy. In bacterial enteritis, the decision to treat a child with antibiotics is not easy. Pediatric data on newer antimicrobials, such as the fluoroquinolones, are scanty. Furthermore, enteric bacterial pathogens show increased resistance to standard therapy, antibiotics are variably effective, and their use may prolong the carrier status.

In terms of recommended antimicrobial treatment in the nonimmunocompromised host, enteric bacterial and protozoal pathogens can be grouped as follows: (1) agents for whom antimicrobial therapy is always indicated; the consensus includes in this category only *V. cholerae*, *Shigella*, and *Giardia lamblia*; (2) agents for whom antimicrobial therapy is indicated only in selected circumstance; (3) infections by enteropathogenic *E. coli*, when running a prolonged course; enteroinvasive *E. coli*, based on the serologic, genetic, and pathogenic similarities with *Shigella*; (4) *Yersinia* infections in subjects with sickle cell disease; and (5) *Salmonella* infections in the very young infants, if febrile, or with positive blood culture.[85]

Micronutrient deficiencies found in malnourished children with diarrhea include zinc deficiency. In the past few years, a great deal of interest has been generated by the possible role of zinc supplementation in either the prevention or the treatment of acute diarrhea in developing countries, particularly in India and Bangladesh. In a double-blind, controlled study in Bangladesh, Roy and colleagues showed that the supplementation of 20 mg/d of elemental zinc to malnourished children with acute diarrhea resulted in shorter duration of diarrhea, lesser stool output, better weight gain, and improved zinc serum status.[86] All of these changes were again more evident in initially zinc-deficient subjects. Further evidence was subsequently provided in support of the role of zinc supplementation to prevent and treat acute diarrheal diseases in children of developing countries.[87–90] A meta-analysis of trials of adjunctive zinc supplementation in children with diarrhea showed that zinc reduced the duration of the illness by 24%.[91]

In light of these latest acquisitions, it is conceivable that supplementation of zinc should be implemented for children with acute diarrhea or even more generally to malnourished children living in areas with a high risk of developing diarrhea.[92]

Several articles have documented, either in case series or in small uncontrolled trials, the efficacy of oral or enteral immunoglobulin in the treatment of rotavirus diarrhea.[93–96] Although these data are interesting and may apply to certain patients with severe rotavirus diarrhea (immunocompromised or immunocompetent), it does not appear that the cost-benefit ratio would justify this approach on a widespread basis.

The search for the ideal drug to treat acute diarrhea is certainly not new. Considering the burden of morbidity of this condition, it is obvious that having a safe and effective drug would be beneficial. This quest has, however, been largely unsuccessful, and all current guidelines warn against the use of drugs that may be more harmful than useful. Even the impressive search that has taken place in the past two decades as a result of the increased knowledge on the pathophysiology of intestinal secretion has been disappointing because most of the "newer" antisecretory agents (such as chlorpromazine, loperamide, and octreotide) have a limited effect and/or are not devoid of potentially hazardous side effects, making them not an option for acute diarrhea. Recently, however, a new investigational drug has appeared that does show some promise: the enkephalinase inhibitor Acetorphan (racecadotril).[97–100] This molecule is supposed to maintain higher levels of enkephalins by preventing their breakdown: enkephalins would then act by reducing intracellular levels of the cyclic nucleotides cAMP and cGMP, thus ultimately reducing their role in elicited ion secretion (see the previous section on pathophysiology). The drug, which in vivo has been effective in reducing jejunal secretion stimulated by cholera toxin,[101] has been experimented initially in adults with acute-onset diarrhea (reviewed in Lecomte[100]) and later also in children with acute diarrhea of various etiologies, but mostly owing to *Rotavirus*.[102,103] In both pediatric studies, the drug given at 1.5 mg three times a day significantly reduced the stool output and the duration of diarrhea compared with placebo.

One of the most rapidly expanding areas in the treatment and prevention of diarrheal disease has been the use of "probiotics," a term meant to stress the derivation of these bacteria from healthy, live microflora and their beneficial effect on the host.[104] See Chapter 76.2B, "Probiotics," for more details. The use of several strains of lactic acid bacteria to treat human diseases is not new; indeed, lactobacilli are among the most commonly employed bacterial species used to promote health and counteract intestinal infections. Table 9-9 lists the most thoroughly investigated probiotics. Among them, *Lactobacillus rhamnosus* strain GG (ATCC 53103) is by far the most widely investigated. The capacity of this strain to

transiently colonize the human gut, unlike the strains employed for the production of commonly marketed yogurts, is well established.[105] *Lactobacillus* GG has a number of diverse, potentially beneficial, biologic effects, and in several well-conducted clinical trials, it proved effective in the prevention[106,107] and/or treatment of acute diarrheal disease in children[108,109] and in adults.[110] The effect is definitely most pronounced in rotavirus diarrhea, where a shortening of the duration of the illness,[12,111–113] prevention of PPD,[12] and reduced duration of viral shedding[114] have been documented. Indeed, after many double-blind, placebo-controlled, and randomized investigations have been reported on the efficacy of some strains of *Lactobacillus* in children with acute diarrhea, three recent rigorous meta-analyses have confirmed their safety and effectiveness.[115–117] Some evidence is also starting to mount that probiotics, among them particularly *Lactobacillus* GG, are more beneficial if administered early in the course of the disease.[12,118] Additionally, a meta-analysis found that there could well be a dose-effect pattern (Figure 9-5), with the effect on the duration of diarrhea depending on the dose of probiotic administered.[117] These data are of importance as they point to our need to learn more about the pharmacokinetics of these agents in order to employ them effectively. All of these effects are undoubtedly important in the management of children with acute diarrhea; this modality of treatment therefore shows exciting promise.

Probiotics also appear to be useful in the prevention of nosocomial-acquired infectious diarrhea[119] and of antibiotic-associated diarrhea. A recent meta-analysis of nine published randomized, double-blind, placebo-controlled trials of probiotics suggested that they can be used to prevent antibiotic-associated diarrhea and that both lactobacilli and the yeast *Saccharomyces boulardii* have the potential to be used in this situation.[120]

As more and more candidate probiotics are proposed, it is evident that each one must be studied individually and extensively to prove its efficacy and safety before use in acute diarrhea is recommended.

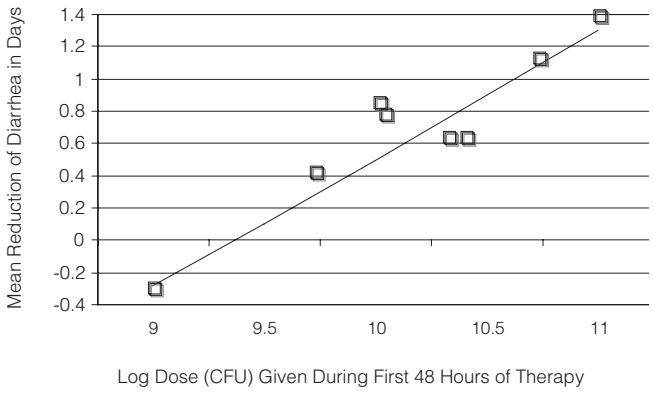

FIGURE 9-5 Dose-effect response between *Lactobacillus* and reduction in duration of diarrhea. A clear dose-effect relationship is apparent from the eight controlled studies that reported diarrhea duration as an outcome. CFU = colony-forming units. CHAPTER 10

PERSISTENT DIARRHEA

Alfredo Guarino, MD
Giulio De Marco, MD

Diarrheal disorders are a major health problem in children worldwide. Studies published in the last 10 years indicate that the global incidence remains unchanged at about 3.2 episodes per child per year, despite a reduction in mortality.[1] Most diarrheal diseases resolve in 1 week, but a small, although consistent, number of cases persist beyond this time. Especially in developing countries, these cases are associated with a high risk of mortality, accounting for most diarrhea-associated fatalities.[2]

A number of definitions have been used for persistent diarrhea, leading to discrepancies in either mortality rates and responsible etiologies in published studies.[3] The World Health Organization (WHO) defines persistent diarrhea as an episode of diarrhea that begins acutely and lasts for 14 days or more.[4] This definition was intended to exclude specific causes of chronic diarrhea such as celiac disease or inflammatory bowel diseases. The difficulties in defining and differentiating diarrhea at its onset and the possibility that a chronic diarrhea may begin acutely support the concept that persistent diarrhea is mainly defined by its duration. In this respect, persistent diarrhea is not different from chronic diarrhea, the conventional duration of which is at least 14 days. However, the term persistent diarrhea is more related to an acute-onset diarrhea that continues behind the expected duration of an infectious diarrhea. Narrowing the spectrum, persistent diarrhea may be defined as protracted and severe diarrhea, that is, diarrhea that persists for more than 2 weeks, leading to nutritional impairment, which may require clinical nutrition.

The definition of persistent diarrhea thus encompasses a wide spectrum of conditions ranging from long-lasting infectious diarrhea to intractable diarrhea, which implies, in its classic definition, a high risk of death.

EPIDEMIOLOGY

The incidence and prevalence of persistent diarrhea show a distinct pattern in developing and industrialized countries. Studies from Asia, Latin America, and Africa support an average incidence of persistent diarrhea as high as 10% of all cases of diarrhea, ranging from 5 to 25% in different settings.[5–7] In light of the burden of infectious diarrhea, persistent diarrhea has a major impact in developing countries. In developed countries, the incidence of chronic diarrhea is inadequately documented. A report from the United Kingdom indicates an incidence of 3 to 5%,[8] but it is likely that this incidence has been reduced in recent years. More importantly, mortality rates associated with persistent diarrhea are dramatically high in developing countries (23–62%) and are responsible for most diarrhea-associated deaths. No data on the general incidence of persistent diarrhea-related fatal outcomes are available in Western countries, but indirect observations suggest a very low mortality rate, with the exception of the so-called intractable diarrhea syndrome. These epidemiologic differences clearly indicate that persistent diarrhea is a distinct disease in developing countries in comparison with developed countries. The concept of two substantially different clinical conditions is supported by studies on primary etiologies and on the risk factors responsible for persistent diarrhea in the two socioenvironmental settings.

PATHOPHYSIOLOGY

The pathophysiologic mechanisms of persistent diarrhea are generally divided into secretory and osmotic, but, in several cases, diarrhea is the result of both mechanisms. Secretory diarrhea is usually associated with large volumes of watery stools and persists even when oral food is withdrawn. In contrast, osmotic diarrhea is dependent on oral feeding, and stool volumes are usually not as massive as in secretory diarrhea.

Secretory Diarrhea

It is characterized by increased electrolyte and water fluxes toward the intestinal lumen, resulting from either the inhibition in neutral NaCl absorption by villous enterocytes or the increase in electrogenic chloride secretion by secretory crypt cells. The classic example of secretory diarrhea is that induced by *Vibrio cholerae* and enterotoxigenic *Escherichia coli*. Cholera toxin produced by *V. cholerae* binds to specific enterocyte membrane receptors activating the adenyl cyclase through the stimulation of an enterocyte G protein. The resulting increase in intracellular cyclic adenosine monophosphate (cAMP), in turn, activates specific signalling proteins, inducing the opening of chloride channels. Intestinal fluid secretion predominantly results from electrogenic chloride secretion through the activation of the cystic fibrosis transmembrane regulator chloride channel, located on the apical membrane of the enterocyte. The

other components of the enterocyte ion secretory machinery are (1) the Na:K:2Cl cotransporter for the electroneutral chloride entrance into the enterocyte; (2) the Na:K pump, which decreases the intracellular Na^+ concentration, determining the driving gradient for further Na^+ inlet; (3) the K^+ selective channel, which enables intracellular K^+, once entered because of coupled Na^+ movement, to return to the extracellular fluid (Figure 10-1).

The stimulation of chloride secretion, in response to cholera or cholera-like toxins, is mediated by the up-regulation of intracellular concentration of mediator cAMP. Other enterotoxins induce intestinal secretion through the activation of cyclic guanosine monophosphate or a rise in intracellular calcium concentration. Recently, another intracellular mediator, nitric oxide, was proposed as a key factor controlling chloride secretion.[9] The classic concept that only bacteria induce secretory diarrhea has now been challenged by the evidence of similar ion secretion pathways induced by viruses and protozoan agents. *Rotavirus*, the most frequent agent of infectious diarrhea, produces a nonstructural protein (NSP4) that stimulates calcium-mediated chloride secretion.[10] Also, human immunodeficiency virus (HIV) induces secretory diarrhea: a protein expressed by HIV, the *trans*-activating transfer factor Tat, acts as an enterotoxin via up-regulation of calcium intracellular concentration.[11] Thus, viruses may induce secretory diarrhea. The protozoon *Cryptosporidium parvum*, a major agent of severe and protracted diarrhea in immunocompromised children,[12] also induces secretory diarrhea through an enterotoxic activity that has been detected in stools and is able to induce chloride secretion through a calcium-mediated pathway.[13] Secretory diarrhea may also be of a noninfectious nature. Several hormones and neurotransmitters have been implicated in intestinal secretion as part of a complex neuroendocrine network that integrates the intestinal response to external stimuli.[14] Electrolyte secretion can be activated by microbial enterotoxins or by other secretagogues of endocrine or nonendocrine origin (Table 10-1). Also, inflammatory cytokines, such as interleukin-1, may exert a direct secretory effect on the enterocyte (see Table 10-1).[15]

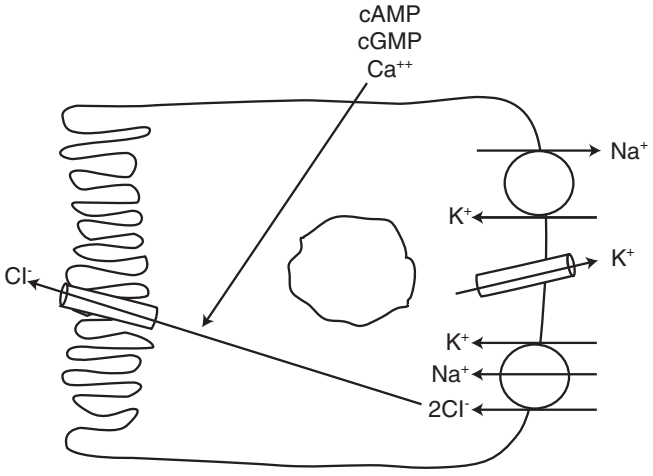

FIGURE 10-1 Components of the secretory machinery in the intestinal epithelial cell. The intestinal crypt cells maintain a secretory tone by a balanced movement of anions and cations through the epithelial monolayer. The Na:K:2Cl cotransporter is responsible for the elecroneutral chloride entrance, from the basolateral membrane, into the enterocyte. The Na:K pump decreases the intracellular Na^+ concentration, indirectly determining a driving gradient for chloride entrance, and the K^+ selective channel enables intracellular K^+ to return to the extracellular fluid. The up-regulation of cyclic adenosine monophosphate (cAMP), cyclic guanosine monophophate (cGMP), or Ca^{2+} induces active chloride secretion of the enterocyte through chloride channels, such as the cystic fibrosis transmembrane regulator, located onto the apical membrane of the enterocyte.

A different mechanism of secretory diarrhea is the inhibition of the electroneutral NaCl-coupled pathway that involves the Na^+-H^+ and the Cl^--HCO_3^- antiporters. Defects in the genes of the Na^+-H^+ and the Cl^--HCO_3^- exchangers are responsible for congenital Na^+ and Cl^- diarrhea, respectively.[16]

Osmotic Diarrhea

Osmotic diarrhea is caused by the presence of nonabsorbed nutrients in the gastrointestinal tract and is generally associated with intestinal damage. The osmotic force driving water into the lumen is provided by nonabsorbed solutes either deriving from food or from injured mucosa. A classic example of osmotic diarrhea is lactose intolerance associated with congenital or acquired lactase deficiency. Lactose, being not absorbed in the small intestine, reaches the colon in its intact form. The colonic microflora ferment the sugar to short-chain organic acids, generating an osmotic load that drives water into the lumen. The ingestion of sugar-containing carbonated fluids exceeding the transport capacity, as well as the ingestion of magnesium salts and sorbitol, both not absorbed, also results in an osmotic load.

In general, osmotic diarrhea occurs whenever digestion and/or absorption are impaired. Reduction or absence of pancreatic enzymes and bile acid disorders are responsible for impaired digestion. Intestinal villi are blunted in overt celiac disease because of antigen-driven immune response. In congenital microvillous atrophy, the functioning absorptive surface is reduced because of a genetic developmental disorder involving the brush border (Figure 10-2). In short-bowel

TABLE 10-1 MAIN FACTORS DETERMINING ELECTROLYTE AND WATER SECRETION

Cyclic adenosine monophosphate dependent
Bacterial enterotoxins: *Vibrio cholerae*, *Escherichia coli* (heat labile), *Shigella*, *Salmonella*, *Campylobacter*, *Pseudomonas*
Hormones: vasoactive intestinal peptide, gastrin, secretin
Anion surfactants: bile acids, ricinoleic acid
Cyclic guanosine monophosphate dependent
Bacterial enterotoxins: *E. coli* (heat stable) enterotoxin, *Klebsiella pneumoniae*, *Citrobacter freundii*, *Yersinia enterocolitica* enterotoxin
Hormones: guanylin
Calcium dependent
Bacterial enterotoxins: *Clostridium*, *Cryptosporidium*
Viral enterotoxins: *Rotavirus* nonstructural protein 4, HIV Tat
Endogenous factors: histamine, interleukin-1β and -8, bradykinin, cholecystokinin
Neurohormones: acetylcholine, serotonin, galanin

HIV Tat = human immunodeficiency virus *trans*-activating transfer factor.

syndrome, surgical removal of a large portion of the intestine does not leave enough of the absorbing intestine. Intestinal absorption depends on an intact epithelium but also on an adequate time for digestion and contact between the nutrients and the absorptive surface. Thus, alterations in intestinal transit times, particularly reductions in small intestinal and whole-gut transit times, may result in impaired nutrient, electrolyte, and water intestinal absorption. Finally, increased gut permeability, secondary to inflammation or cytotoxic agents, is responsible for excessive protein loss, as in protein-losing enteropathies. Infectious agents induce diarrhea with an osmotic mechanism when they are responsible for direct epithelial or mucosal damage, as in the case of enteroadherent or enteropathogenic *E. coli* (Figure 10-3).

However, various pathways generally contribute to persistent diarrhea, interacting with each other and producing a synergic vicious circle. A paradigm of the complex pathophysiology of persistent diarrhea is provided by HIV infection. Chronic diarrhea is considered an acquired immune deficiency syndrome (AIDS)-defining condition in the classification scheme for pediatric HIV infection.[17] Malnutrition can be an early manifestation of HIV infection and is associated with a rapid decrease in the CD4+ cell number and an increased rate of opportunistic infections.[18] A long list of combined dysfunctions of the digestive-absorptive processes is observed in 60 to 80% of children with HIV infection naive to antiretroviral therapy and may involve the intestine, the liver, and the pancreas.[19] Clinical manifestations of the so-called HIV enteropathy may be limited, but iron and lactose malabsorption is very common.[20] Overall, nutrient malabsorption certainly contributes to malnutrition and eventually to wasting, the terminal feature of HIV infection. The pathophysiology of intestinal dysfunction is complex and involves multiple factors. There is little evidence of a role of specific enteric pathogens in HIV-associated intestinal dysfunction, even though *Cryptosporidium* is recognized as specifically responsible for intestinal inflammation and secondary digestive abnormalities in these children.[21] A role of HIV itself has been hypothesized, and recent data showed that Tat protein released by the virus functions both as a viral cytotoxin and an enterotoxin, directly interacting with the enterocyte to impair cell growth and proliferation, as well as ion transport.[11] The role of HIV in intestinal dysfunction is supported by the finding that children shifted to highly active antiretroviral therapy showed a rapid normalization of intestinal function tests, in parallel with a decrease in viral load and an increase in CD4+ cell number.[22] Interestingly, it was also shown that nutritional rehabilitation is effective in the improvement of the immune status, thus supporting the cause-and-effect relationship between malnutrition, intestinal dysfunction, and immune derangement.[23] Thus, HIV-associated intestinal dysfunction, malnutrition, and immune impairment produce a vicious circle and represent the paradigm of the high risk for persistent diarrhea and its high mortality in poor countries, following intestinal infections (Figure 10-4).

RISK FACTORS

Most studies on risk factors for persistent diarrhea have been performed in developing countries. Caloric and proteic malnutrition appears to be the most relevant risk factor for an intestinal infection to evolve into persistent diarrhea. The coexistence of malnutrition in children with infectious diarrhea consistently increases the probability of a protracted duration, with an inverse correlation between nutritional status and the severity of the diarrhea.[24,25] Also, specific micronutrient deficiencies are related to persistent diarrhea. Vitamin A and zinc deficiencies are significantly associated with persistent diarrhea, and clinical trials assessing the efficacy of their supplementation support these observations.[26–31] Infants who are not breastfed are at increased risk of persistent diarrhea, whereas prolonged breastfeeding is a

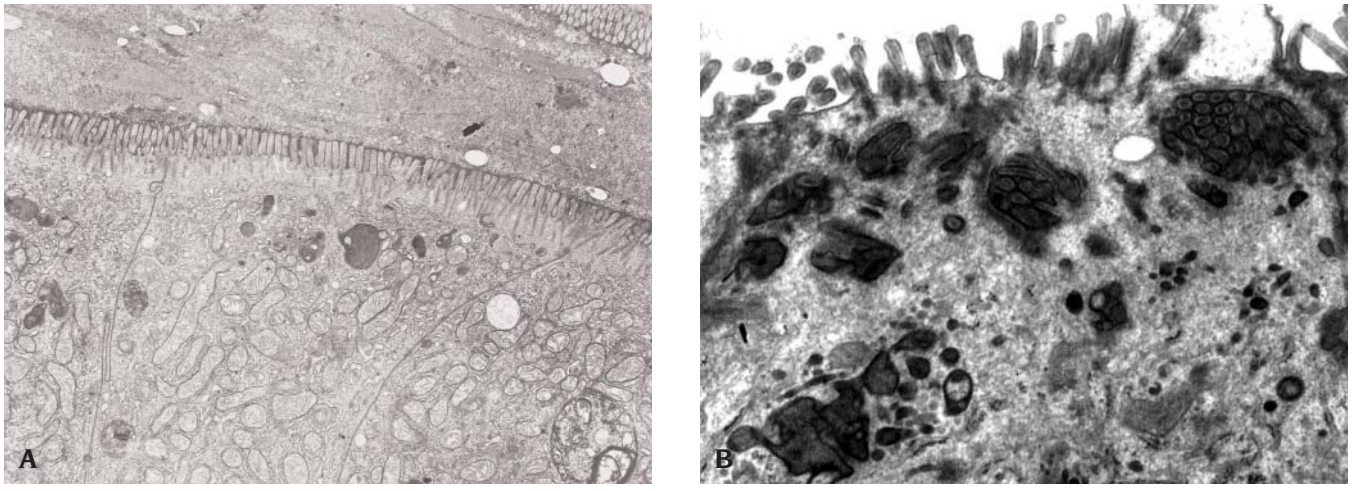

FIGURE 10-2 Ultrastructural evaluation of enterocytes. *A*, Enterocytes show signs of mild, nonspecific damage; microvilli look shorter than normal; cytoplasm is normal with the exception of an increased vacuolization. Courtesy of M. Morroni, Ancona, Italy (transmission electron micrograph, stained with lead citrate). *B*, Microvillous inclusion disease is characterized by loss and disorganization of microvilli of the brush border. In the cytoplasm, secretory granules and inclusion bodies with microvilli are evident. Courtesy of A. Phillips, London, UK (transmission electron micrograph, double stained with lead citrate and uranyl acetate).

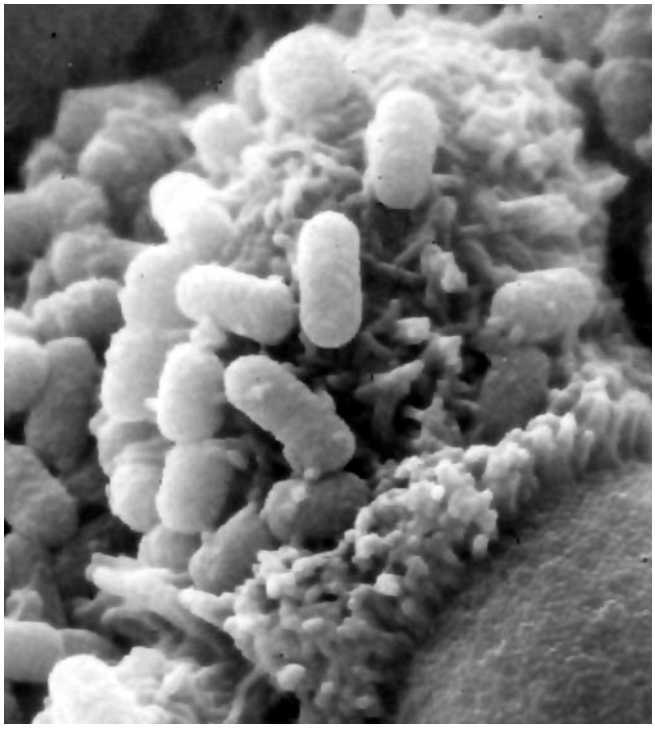

FIGURE 10-3 Enteropathogenic *Escherichia coli* adhesion to intestinal epithelial cells. Adherence is the first stage of enteropathogenic *E. coli*–induced diarrhea. Following that, a number of bacterial proteins are translocated by a type III secretion system, driving the enterocyte effacement, pedestal formation, and intimate bacterial attachment to the host cell. Courtesy of A. Phillips, London, UK (scanning electron micrograph, critically point dried in liquid carbon dioxide and coated with gold-palladium).

protective factor.[25,32] Because malnutrition is also associated with extraintestinal infections, persistent diarrhea is significantly associated with a broad range of health problems, such as pneumonia, urinary tract infections, and anemia.[33] Prior illnesses have also been implicated in triggering protracted diarrhea, and among them, measles carries an increased risk for diarrhea, which may persist as long as 6 months because of its immunosuppressive effect.[34] The major etiology of acquired immunosuppression, the HIV infection, is the leading underlying condition of persistent diarrhea in developing countries, where access to effective antiretroviral therapies is limited or not available.[35] Selected intestinal infections, induced by classic enteropathogenic agents, including *Shigella* and enterotoxigenic *E. coli*, have been implicated as determinants of persistent diarrhea in developing countries.[36,37]

A diarrhea presenting with increased severity at its onset may be associated with an increased risk of long duration, especially when malnutrition is present.[38] Persistent diarrhea is generally more frequent in males, with a male-to-female ratio of 1.2 to 2.6:1 and in the age range of 6 to 24 months.[6,25,36] The age of the mother may also be a determinant of persistent diarrhea, with an increased risk found in children born to younger mothers.[39,40] The use of antibiotics for acute gastroenteritis is not generally recommended and has recently been reported as a specific risk factor for persistent diarrhea.[25]

On the other side, risk factors for persistent diarrhea also exist in developed countries and depend on the specific etiology of persistent diarrhea. For selected genetic diseases such as congenital Na^+ or Cl^- diarrhea, a history of intractable diarrhea in the family may be reported. A family history of fatal diarrhea was identified as a risk factor for the intractable diarrhea syndrome in a population of 32 consecutive children admitted to receive parenteral nutrition.[41] In the same population, the lack of breastfeeding, parental atopy, and early (less than 3 months) onset of symptoms had an increased incidence compared with controls.[41]

ETIOLOGY AND SPECIFIC CLINICAL FEATURES

The overall prevalent etiologic pattern of persistent or chronic diarrhea is substantially different in the two distinct socioenvironmental settings considered. Persistent diarrhea in developing countries has its own epidemiology, risk factors, and, more importantly, a peculiar etiologic pattern, different from that seen in children living in industrialized countries. These differences can be mainly ascribed to the overwhelming rate of intestinal infections observed in developing and transitional countries, where other causes of persistent diarrhea become almost negligible. In addition, diagnostic facilities are not easily accessible in developing countries, raising problems in diagnosing the rare diseases that are responsible for persistent diarrhea in industrialized countries. A list of etiologies of persistent diarrhea is reported in Table 10-2.

Enteric infections are by far the most frequent cause of persistent diarrhea in developing countries. Extensive efforts have been made to identify specific pathogens responsible for persistent diarrhea.[42] The results are scattered through different geographic regions. Consecutive cultures during episodes of persistent diarrhea have shown that the same organism is not always found during prolonged illness, suggesting that sequential infections with the same or a different pathogen may be responsible for prolonged symptoms.[43] Enteroadherent *E. coli* have been specifically implicated in persistent diarrhea (see Figure

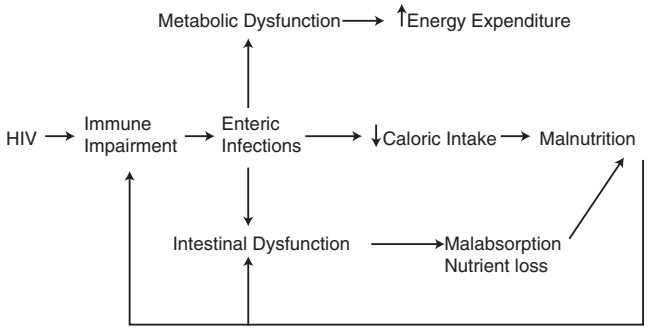

FIGURE 10-4 Pathways of malnutrition in human immunodeficiency virus (HIV)-infected children. A complex interplay exists among several conditions, leading to malnutrition in HIV-infected children. Enteric infections and intestinal dysfunction are major determinants of wasting, an acquired immune deficiency syndrome (AIDS)-defining condition.

TABLE 10-2 CAUSES OF PERSISTENT DIARRHEA

Infections
Bacterial: *Shigella*, *Salmonella*, *Yersinia enterocolitica*, *Escherichia coli*, *Clostridium difficile*, *Campylobacter jejuni*, *Vibrio cholerae*, *Mycobacterium avium* complex
Viral: rotavirus, adenovirus, astrovirus, torovirus, cytomegalovirus, HIV
Parasitic: *Cryptosporidium*, *Giardia*, *Entamoeba histolytica*, *Isospora*, *Strongyloides*
Postenteritis syndrome
Small bowel overgrowth
Tropical sprue
Diarrhea associated with exogenous substances: excessive intake of carbonated fluid, dietetic foods containing sorbitol, mannitol, or xylitol; excessive intake of antacids or laxatives containing lactulose or $Mg(OH)_2$; excessive intake of methylxanthine-containing drinks (cola, tea, coffee)
Abnormal digestive processes: cystic fibrosis, Shwachman-Diamond syndrome, isolated pancreatic enzyme pancreatitis, chronic pancreatitis, Pearson syndrome; trypsin/chymotrypsin, enterokinase deficiency
Disorders of bile acids: chronic cholestasis, use of bile acid sequestrants, primary bile acid malabsorption, terminal ileum resection
Carbohydrate malabsorption: congenital or acquired sucrase-isomaltase deficiency, congenital or acquired lactase deficiency, glucose-galactose malabsorption, fructose malabsorption
Immune-based disorders: food allergy, celiac disease, eosinophilic gastroenteritis, inflammatory bowel disease, autoimmune enteropathy, primary immunodeficiencies
Structural defects: microvillous inclusion disease, tufting enteropathy, phenotypic diarrhea, heparan-sulfate deficiency, $\alpha_2\beta_1$ and $\alpha_6\beta_4$ integrin deficiency, lymphangiectasia
Defects in electrolyte and metabolite transport: congenital chloride diarrhea, congenital sodium diarrhea, acrodermatitis enteropathica, selective folate deficiency, abetalipoproteinemia
Motility disorders: Hirschsprung disease, intestinal pseudo-obstruction (neurogenic and myophatic), thyrotoxicosis
Surgical causes: congenital or acquired short bowel (secondary to stenosis, segmental atresia, malrotation)
Neoplastic diseases: neuroendocrine hormone-producing tumors: VIPoma, APUDomas, mastocytosis

HIV = human immunodeficiency virus.

10-3).[44–46] Less compelling evidence suggests a role for *Shigella*, enterotoxigenic *E. coli*, and *Campylobacter*.[36,37] *Cryptosporidium* was often found in persistent episodes in Bangladesh but not in Peru.[43,47] Fatal diarrhea induced by *Cryptosporidium* was associated with a specific deficiency in interferon-γ production.[48] *Giardia lamblia* shows similar incidence rates in acute and persistent diarrhea. Among viruses, *Rotavirus* has been associated with severe and protracted diarrhea[43,49] and implicated in life-threatening intractable diarrhea syndrome in developed countries.[50] Cytomegalovirus is a possible cause of intractable diarrhea, also in the immunocompetent child.[51] Torovirus has been found in children with persistent diarrhea but may be associated with enteroadherent *E. coli*.[52] Also, astrovirus has recently been associated with persistent diarrhea.[53]

In children with AIDS, opportunistic agents are a major cause of persistent diarrhea. Opportunistic agents are defined as microorganisms that induce diarrhea exclusively or, in unusually severe forms, in target populations, such as immunocompromised children. Enteric cryptosporidiosis is the most frequent cause of severe and protracted diarrhea in HIV-infected children.[12] Infections with *Blastocystis hominis*, *Coccidia*, *Mycobacterium avium*, *Isospora belli*, and *Candida albicans* should be specifically considered in children with AIDS and persistent diarrhea.[54,55] Finally, HIV may be directly responsible for diarrhea and the so-called HIV enteropathy.[11]

In rich countries, persistent infections are directly responsible for a relative minority of persistent diarrhea cases.[41,56,57] However, indirect consequences of enteric infections do play a major role. Postenteritis syndrome is a clinicopathologic condition in which small intestinal mucosal damage persists following acute gastroenteritis. Sensitization to food antigens and secondary disaccharidase deficiency were classically considered to be responsible for postenteritis syndrome. More recent studies have demonstrated that the incidence of disaccharidase deficiency is very low following acute diarrhea.[58,59] Similarly, the role of sensitization to food antigens has a relatively lower incidence than previously thought, and international guidelines discourage the use of hypoallergenic or diluted milk formulas during acute gastroenteritis.[60,61] A third mechanism of postenteritis syndrome is believed to be an infection or reinfection with an enteric pathogen. However, the mechanisms of postenteritis diarrhea remain to be fully clarified.

Small bowel bacterial overgrowth induces persistent diarrhea through multiple mechanisms. In normal conditions, bacterial load in the proximal jejunal fluid does not exceed 10^4 colony forming units (CFU)/mL of aerobic bacteria. An increase over 10^5 CFU/mL in duodenal fluid, or the presence of anaerobic bacterial species that are normally detected only in more distal intestinal segments, is believed to be responsible for severe impairment of digestive and absorptive processes. Diarrhea may be the result of either a direct interaction between a microorganism and the enterocyte or the consequence of deconjugation and dehydroxylation of bile salts and hydroxylation of fatty acids operated by enteric bacteria.

Persistent diarrhea may be the result of maldigestion owing to pancreatic disorders. In most patients with cystic fibrosis, pancreatic insufficiency results in fat and protein malabsorption. In Shwachman syndrome, exocrine pancreatic hypoplasia can be associated with neutropenia, bone changes, and intestinal protein loss. Specific isolated pancreatic enzyme defects result in fat or protein malabsorption. Familial pancreatitis, associated with a mutation in the trypsinogen gene, is associated with chronic pancreatitis, pancreatic insufficiency, and persistent diarrhea.

Liver disorders, such as cholestasis, may lead to a reduction in the bile acid pool with fat malabsorption. Bile acid

loss may be associated with terminal ileum diseases, such as Crohn disease, or with terminal ileum resection. A rare disease is primary bile acid malabsorption attributable to mutations of the ileal bile acid transporter,[62] and neonates and young infants present with fat malabsorption and chronic diarrhea. Long-term use of bile acid binders such as cholestyramine may be responsible for continued bile acid loss in the stools, leading to decreased bile acid pool size.

Increased intraluminal osmolarity and subsequent diarrhea are the end points of excessive sugar-containing carbonated fluid or fruit juice intake, which exceeds the transport capacities of the small intestine in younger infants. Excessive intake of sorbitol, magnesium hydroxide, and lactulose is also responsible for persistent diarrhea. Persistent diarrhea may also be the manifestation of carbohydrate malabsorption because of specific molecular defects. These include lactose intolerance, sucrase-isomaltase deficiency, and congenital glucose-galactose malabsorption. Lactose intolerance is rarely associated with congenital lactase deficiency but is more frequently a consequence of lactase deficiency owing to mucosal damage. A progressive loss of lactase activity, which affects about 80% of the nonwhite population, may be responsible for persistent diarrhea in older children receiving cow's milk.[63]

The extreme severity spectrum of persistent diarrhea includes a number of heterogeneous conditions leading to the so-called intractable diarrhea syndrome. This was originally described as diarrhea lasting more than 2 weeks, with no detectable infectious etiology, starting in the first 3 months of age and loaded with a high mortality rate.[64] More recent definitions reflect the concept that the syndrome, in its typical setting, is the result of a permanent defect in the structure or function of intestine, leading to progressive intestinal failure with the need for parenteral nutrition for survival.[56] The intractable diarrhea syndrome has an evolving etiologic spectrum in which enteric infections and food intolerances have been replaced by more rare congenital conditions (Table 10-3).[41,56,57] The main groups of diseases causing severe and protracted diarrhea include structural enterocyte defects, immune-based disorders, multiple food intolerance, motility disorders, and short gut.[57] This classification is based on the main disorder responsible for diarrhea and has implications for the outcome of the disease.[57] However, the etiology of persistent diarrhea includes a larger number of specific diseases that are herein briefly described.

An increasing number of molecular defects are responsible for a wide variety of electrolyte transport defects. In congenital chloride diarrhea, a mutation in the solute carrier family 26 member 3 gene (*SLC26A3*) leads to severe intestinal Cl^- malabsorption owing to the defect or absence of the Cl^-/ HCO_3^- exchanger.[65] The consequent defect in HCO_3^- secretion leads to metabolic alkalosis and acidification of the intestinal content, with further inhibition of Na^+/H^+ exchanger-dependent Na^+ absorption. Patients with congenital sodium diarrhea show parallel clinical features because of a defective Na^+/H^+ exchanger in all segments of the small and large intestine, the presence of extremely high Na^+ fecal concentration, and severe acidosis.[66]

Structural enterocyte defects, based on specific, yet largely unknown, molecular defects, are responsible for early-onset severe diarrhea.[67] In microvillous inclusion disease, there is a net reduction of the absorptive surface area, associated with massive active secretion of electrolytes in the stools. The ultrastructural hallmark of the disease is the lack of microvilli on the apical enterocyte surface and the presence of secretory granules and membrane-bound inclusions lined by microvilli (see Figure 10-2).[68] Evidence has been obtained that inclusion bodies originate from autophagocytosis of the apical membrane of enterocytes, with engulfing of microvilli.[69] Intestinal epithelial dysplasia (or tufting enteropathy) is relatively more common than microvillous inclusion disease and is characterized by various degrees of morphologic abnormalities mainly localized in the epithelial layer, including disorganization of surface enterocytes with focal crowding and formation of tufts (Figure 10-5).[70] Abnormal laminin and heparan sulfate proteoglycan deposition on the basement membrane have been detected in intestinal epithelia from infants with tufting enteropathy.[71] Also, a defect in the distribution of integrins has been reported.[71] These ubiquitous proteins are involved in cell-cell and cell-matrix interactions and play a crucial role in cell differentiation and tissue development. An abnormal intestinal distribution of $\alpha_2\beta_1$ and $\alpha_6\beta_4$ integrins has been implicated in tufting enteropathy.[72] Congenital heparan sulfate deficiency is an extremely rare disorder,

Gaslini Hospital, Genoa, Italy (hematoxylin and eosin; ×10 original magnification).

with severe enteric albumin loss presenting within the first weeks of life.[73] Heparan sulfate is a glucosaminoglycan component of the basement membrane with multiple roles in the intestine, including restriction of charged macromolecules within the vascular lumen.

Phenotypic diarrhea is characterized by immunodeficiency and facial abnormalities, woolly hair, and intractable diarrhea with a typical familiar pattern (Figure 10-6).[74]

Persistent diarrhea may have an immune or allergic pathogenesis. Cow's milk protein allergy, as well as other food allergies, may determine abnormalities of the small intestinal mucosa. Multiple food intolerance is included in most series of intractable diarrhea syndrome. However, this is usually an exclusion diagnosis based on a relationship between any ingested food and diarrhea. In most cases, multiple food intolerance is not eventually confirmed by oral challenge.

The intestine may be the target of specific autoimmune processes that are responsible for persistent diarrhea and, in more severe cases, for intestinal failure. Autoimmune enteropathy is characterized by the production of antienterocyte antibodies, primarily immunoglobulin G, directed against components of enterocyte brush border or cytoplasm. In association, a cell-mediated autoimmune response is detected with a mucosal T-cell activation.[75] Abnormal immune function, as seen in patients with agammaglobulinemia, isolated immunoglobulin A deficiency, and combined immunodeficiency disorders, can result in persistent diarrhea induced by a wide spectrum of microorganisms, as in AIDS.

Disorders of intestinal motility are an emerging group of intestinal diseases associated with persistent diarrhea. Motility disorders include alterations of the enteric nervous system development and function, such as in Hirschsprung disease, aganglionosis, and chronic intestinal pseudo-obstruction (which encompasses both neurogenic and myogenic forms).[76,77] Recently, alterations of the connective-tissue plexus layer, which roots circular and longitudinal intestinal muscles, have been identified in children with chronic intestinal pseudo-obstruction.[78] Other motility disorders may be secondary to extraintestinal disorders, such as in hyperthyroidism. Motility disorders are associated with either constipation or diarrhea, or both, with the former usually dominating the clinical picture.

Short-gut syndrome is associated with persistent diarrhea. All intestinal abnormalities, such as stenosis, segmental atresia, and malrotation, may require surgical resection. In these conditions, the residual intestine may be insufficient to carry on its normal digestive-absorptive functions. Alternatively, small bowel bacterial overgrowth may be the main mechanism involved in diarrhea, such as in blind loop syndrome.

In rare cases of severe persistent diarrhea, the gastrointestinal symptoms may be the initial manifestation of a mitochondrial disease.[79] Finally, in cases in which a cause of diarrhea is not detected and the clinical course is inconsistent, Munchausen syndrome by proxy should be considered.

FIGURE 10-6 Intractable diarrhea associated with phenotypic abnormalities. *A*, In rare cases, intractable diarrhea may be associated with facial dysmorphism, hypertelorism, and woolly, easily removable hair with trichorexis nodosa. *B*, Jejunal biopsy specimens show total or partial villous atrophy with crypt necrosis and inconstant T-cell activation. All of the patients have defective antibody responses despite normal serum immunoglobulin levels. Courtesy of A. Barabino and C. Marino, G. Gaslini Hospital, Genoa, Italy (hematoxylin and eosin; ×10 original magnification).

The natural history of intractable diarrhea is related to the primary intestinal disease.[57] Food intolerances generally resolve in a few weeks or months, as does autoimmune enteropathy, when appropriate immunosuppression is started. Children with motility disorders show more severe, long-lasting symptoms but a less severe course, whereas those with structural enterocyte defects never recover, undergo a more severe course, generally needing parenteral nutrition, and often become candidates for intestinal transplant.[57] The natural history of short gut encompasses all the outcomes, depending on the length of remaining gut, its function, child age, and management.

APPROACH TO THE CHILD WITH PERSISTENT DIARRHEA

Because of the wide etiologic spectrum of persistent diarrhea in children, medical decisions should be based on diagnostic algorithms that begin with the age of the child, then consider clinical and epidemiologic factors, and always take into account the results of microbiologic investigations.

Specific clues in the family and personal history may provide useful indications. A history of chronic or intractable diarrhea in a relative suggests a genetic disease, particularly if presentation occurred in the first months of life. A family history positive for immune or atopic diseases points toward allergy or autoimmunity.

The presence of polyhydramnios is consistent with congenital chloride or sodium diarrhea. A previous episode of acute gastroenteritis is suggestive of postenteritis syndrome, whereas a history of recent intestinal resection strongly points to short-bowel syndrome or blind loop syndrome. Finally, the association of diarrhea with ingestion of specific foods should always be considered for possible intolerance to one or more food antigens.

Initial clinical examination should include the evaluation of general and nutritional status. It is not rare to face a critical clinical condition with dehydration, marasmus, or kwashiorkor, requiring prompt supportive interventions to stabilize the patient. The presence of eczema or asthma is associated with an allergic disorder, and specific extraintestinal manifestations (eg, arthritis, diabetes, thrombocytopenia) may suggest an autoimmune disease. Specific skin lesions may be suggestive of enteropathic acrodermatitis. Typical facial abnormalities and woolly hair are associated with phenotypic diarrhea (see Figure 10-6).

If the child with persistent diarrhea lives in a developing country or comes from a poor social setting in which the typical risk factors for persistent diarrhea, including malnutrition, are common, an intestinal infection should be suspected. However, in all cases of persistent diarrhea, irrespective of risk factors, the diagnostic approach should include stool cultures and a search for parasites, *Rotavirus*, and other enteric viruses.

The evaluation of nutritional status is crucial to establish the need for rapid intervention. It should start with the evaluation of the weight and height curves and of the weight-for-height index to determine the impact of diarrhea on growth failure. Malnutrition may precede the onset of diarrhea, thus contributing to its long duration, or it could be the consequence of the disease, suggesting the presence of malabsorption. Weight gain is generally impaired before height growth, but, with time, linear growth is also affected, and both parameters may be equally abnormal in the long term. Assessment of nutritional status includes dietary history and biochemical and nutritional investigations. Caloric intake should be quantitatively determined. Biochemical markers include albumin (half-life 20 days), prealbumin (half-life 2 days), retinol binding protein (half-life 12 hours), transferrin (half-life 8 days), serum iron, iron binding capacity, and micronutrient concentrations. The half-life of serum proteins may help distinguishing short- and long-term malnutrition. Assessment of body composition may be performed by measuring midarm circumference and triceps skinfold thickness or, more accurately, by bioelectrical impedance analysis or dual-emission x-ray absorptiometry scans.

The relationship between weight modifications and energy intake should be carefully considered. In infants and children who are apparently thriving or overweight while suffering from chronic diarrhea, a 1-week dietary record may be used to explore the hypothesis that the youngster is being overfed or is drinking excessive amounts of juices or beverages with a high sucrose content. Conversely, a child with persistent diarrhea and suspected malabsorption may be receiving diluted hypocaloric formula or even clear liquids in an effort to reduce diarrhea, and persistent diarrhea may be an indirect consequence of ongoing malnutrition.

Search for etiology may be based on the pathophysiology of diarrhea. Electrolyte concentrations in fecal samples discriminate between secretory and osmotic diarrhea and may provide important information for guiding the subsequent diagnostic approach (Table 10-4). In parallel, assessment of intestinal function has a key role in the diagnostic approach and should be performed in a noninvasive manner (Table 10-5).

Microbiologic investigation of stool samples should include a thorough list of agents and may provide valuable information. A search for proximal intestinal bacterial overgrowth is part of a microbiologic investigation. The breath hydrogen test, after glucose oral load, may identify an abnormal bacterial proliferation in the small bowel. The breath test can also be used for detecting carbohydrate malabsorption.

Diagnostic workup of persistent diarrhea is largely based on the specific diagnostic tools available; however, endoscopy and histology provide essential information. Small intestinal biopsy was effective in detecting a primary intestinal etiology in more than 90% of cases of chronic

diarrhea.[80] Colonoscopy should be performed in all cases of chronic diarrhea in which gross or occult blood is detected in the stools or when an increased frequency of mucoid stools and abdominal pain suggests colonic involvement. Biopsies should be performed at multiple sites, even in a normal-appearing intestine, because at least 5% of apparently normal colons will yield specimens positive for colitis, when a disease characterized by patchy lesions is responsible for the observed symptoms. Histology is important to establish the degree of mucosal involvement, through grading of intestinal damage and the presence of associated abnormalities, such as inflammatory infiltration of the lamina propria. Morphometry provides additional quantitative information on epithelial changes. In selected cases, light microscopy may help identifying specific intracellular agents, such as cytomegalovirus from the presence of large inclusion bodies in infected cells[51] or intracellular parasites. Electron microscopy is indicated in all cases of intractable diarrhea of unknown etiology and is essential to detect microvillous inclusion disease or other cellular ultrastructural abnormalities. Immunohistochemistry allows the study of mucosal immune activation and of other cell types (smooth muscle and neuronal cells and enterocytes), as well as components of the basal membrane. An immunohistologic classification of intractable diarrhea, with prognostic implications, was originally proposed by Cuenod and colleagues.[81] The authors recognized a group of children with severe immune activation and epithelial damage and another group with no mucosal damage and likely affected by inborn defects of enterocyte differentiation.

Imaging has a major role in the diagnostic approach to persistent diarrhea. Preliminary abdominal radiography is useful for detecting gaseous distention, suggestive of a gastrointestinal obstruction. Intramural or biliary gas may be seen in necrotizing enterocolitis or intestinal invagination. Structural abnormalities such as diverticula, malrotation, stenosis, blind loop syndrome, and motility disorders may be appreciated after a barium meal and an entire bowel follow-through examination.

Specific investigations should be carried out when a specific diagnostic suspect is posed. A valuable tool in the diagnosis of bile acid malabsorption is the measure of retention, in the enterohepatic circulation, of the bile acid analogue $^{(75)}$Se-homocholic acid taurine as an index of ileal bile acid absorption.[82] A scintigraphic examination, with labeled octreotide, is indicated in cases of suspected APUD (amine precursor uptake decarboxylation) cell neoplastic diseases.[83] In other diseases, other specific imaging techniques, such as computed tomography or nuclear magnetic resonance imaging, may have an important diagnostic value.

Once infections have been excluded, a schematic flowchart for the approach to the child with persistent diarrhea may be applied. The main etiologies of persistent diarrhea may be investigated, based on the features of diarrhea and their predominant or selective intestinal dysfunction (Figure 10-7). A step-by-step diagnostic approach is important to minimize the invasiveness to the child and the overall costs, while optimizing the yield of the diagnostic workup.

THERAPY

Persistent diarrhea associated with impaired nutritional status should always be considered a serious disease, and therapy should be promptly started. Treatment of persistent diarrhea can be schematically divided into general supportive measures, nutritional rehabilitation, and drug treatment. The latter includes specific therapy targeted to individual etiologies and treatment aimed at counteracting fluid secretion and/or promoting restoration of disrupted intestinal epithelium.

Because death in most instances is caused by dehydration, replacement of fluid and electrolyte losses is the major early intervention. Rehydration is best performed through the oral route with oral rehydration solution (ORS).[60] Recent studies provide data on the efficacy of hypotonic ORSs rather than isotonic solutions.[84,85] The addition of amino acids to glucose-based ORSs, or the substitution of rice gruel or cereal for glucose, has been proposed to create a "super ORS," which may provide advantages over the pure sugar and electrolyte conventional WHO ORS.[86,87] Amylase-resistant starch (pectin), added to an ORS, is not digested and absorbed in the upper bowel but reaches the colon, where bacteria break it down to short-chain fatty acids, having fluid absorptive effects.[88,89] It may be added to ORS to specifically counteract secretory diarrheas.

In malnourished children, nutritional rehabilitation is essential, also when an enteric infection is documented. Exclusion diets are usually administered with the double purpose of overcoming food intolerance, which may be the primary cause of persistent diarrhea or its complication. The sequence of elimination should be graded from less to more restricted diets, that is, cow's milk protein hydrolysate to an amino acid–based formula or vice versa, depending on the severity of the child's conditions. If the latter are severe, it may be convenient to start with amino acid–based feeding formula. Even though a disaccharidase deficiency is no longer recognized as a major cause of persistent diarrhea, hypolactasia is often secondary to intestinal damage and malnutrition, irrespective of its primary etiology. A lactose-free diet should be started in all children with persistent diarrhea and is included in a treatment algorithm designed by the WHO.[90] Lactose is generally withdrawn and replaced by maltodextrins or a combination of other carbohydrates. Sucrose-free formulas are indicated in sucrase-isomaltase deficiency.

A sufficient number of calories should always be provided. Caloric intake may be progressively increased to 50% or more above the Recommended Dietary Allowance for age and sex. In children who do not tolerate high feeding volumes, caloric density may be increased by adding fat

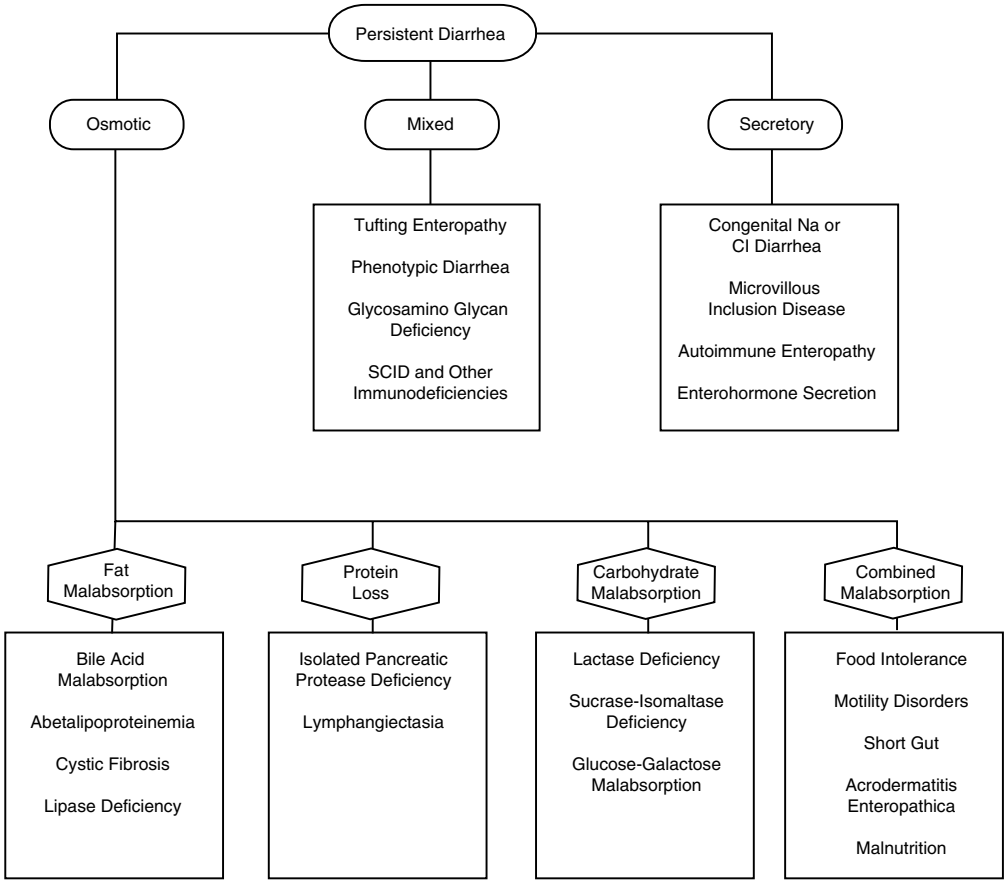

FIGURE 10-7 Scheme of specific etiologies of persistent diarrhea according to its pathophysiology. Assessment of the secretory, osmotic, or mixed mechanism of diarrhea and of predominant nutrient malabsorption may help identify the primary etiology, thereby directing the diagnostic workup through specific investigations. SCID = severe combined immunodeficiency.

or carbohydrate. However, formula osmolality should be checked and the intestinal absorbing capacity should be monitored by digestive function tests. In children with steatorrhea, medium-chain triglycerides may be the main source of lipids because they are easily absorbed.

In several cases, clinical nutrition should be considered; this includes enteral or parenteral nutrition. Enteral nutrition may be performed via a nasogastric or gastrostomy tube and is indicated in a child who is not able to be fed through the oral route either because of primary intestinal diseases or because of extreme weakness. Continuous enteral nutrition is effective in children with a reduced absorptive function. The rationale of continuous enteral nutrition is based on the increased ratio of time to the absorptive surface. A reduced surface functioning for extended time increases daily nutrient absorption. In children with extreme wasting, enteral nutrition may not be sufficient. In such cases, parenteral nutrition may be a life-saving procedure. Parenteral nutrition should be undertaken at an early phase, as soon as other, less invasive, nutritional approaches have been unsuccessfully attempted.

Nutritional rehabilitation has a general beneficial effect on general condition, intestinal function, and immune response. Continuous enteral nutrition was used in children with HIV and intestinal malabsorption and was effective in increasing their body weight while restoring intestinal absorptive function and inducing a rise in CD4 cell number.[23] Micronutrient and vitamin supplementation is part of nutritional rehabilitation and prevents further problems, especially in malnourished children from developing countries.[28,29]

Specific therapy includes anti-infectious drugs and immunosuppression. When a specific infectious agent is detected, specific treatment should be undertaken. In case of bacterial intestinal infection, antibiotic therapy can be administered.

In *Rotavirus*-induced diarrhea, oral administration of human immunoglobulins has been demonstrated to be effective both in immunocompetent and immunocompromised children and should be considered for treatment in severe or protracted diarrhea.[91,92] Human serum immunoglobulins, available in preparations for intravenous use, may be administered through the oral route at a dose of 300 mg/kg of body weight in a single oral dose. The rationale of passive immunotherapy is based on the demonstration of neutralizing antibodies against all viruses of medical importance in the preparations for intravenous use.[91]

Diarrheal diseases are consistently associated with modifications of intestinal microflora. An attempt at modifying intestinal microflora may be worth considering, even when an infectious cause is suspected but not proved. Two distinct strategies are available: the administration of probiotic bacteria and the administration of antibiotics. Large and reliable meta-analyses demonstrated an efficacy of probiotic administration both in the prevention and treatment of acute and protracted diarrhea.[93,94] Alternatively, empiric antibiotic therapy may be undertaken in children with either small bowel bacterial overgrowth or with suspected bacterial diarrhea. A specific indication for persistent diarrhea has been shown for trimethoprim-sulfamethoxazole.[95] Metronidazole is a reasonable alternative for the broad pattern of target agents, including parasites. The so-called bowel cocktail (metronidazole, cholestyramine, and high-dose gentamicin given orally) has been proposed for severe protracted diarrhea of suspected infectious etiology, although conclusive proof of efficacy is lacking.[96]

Specific therapy with immunosuppressive drugs should be considered in selected conditions such as autoimmune enteropathy. Azathioprine, cyclosporine, and tacrolimus have been used in severe protracted diarrhea of immune origin. Autoimmune enteropathy may be successfully controlled by immunosuppression, allowing withdrawal of parenteral nutrition.[57,97]

Treatment may also be directed at modifying specific pathophysiologic processes. Most secretory diarrheas are infectious, but intestinal ion secretion is also a common mechanism of the intractable diarrhea of infancy. In these cases, the use of drugs that are able to modify intestinal ion transport may be considered. Among proabsorptive agents, the enkephalinase inhibitor racecadotril inhibits the breakdown of natural endogenous opiates (enkephalins) by intestinal tissue and has been effective in controlled clinical trials.[98,99] In severe secretory diarrheas, such as in neuroendocrine tumors, microvillous inclusion disease, and enterotoxin-induced severe diarrhea, a trial with somatostatin or its analogue, octreotide, may be considered.[100] Octreotide has been used in diarrhea secondary to neoplastic diseases and in intestinal infections. Subcutaneous administration of octreotide was effective in reducing fecal output in HIV-infected children with severe cryptosporidiosis, and a specific antagonist effect against the enterotoxic activity associated with *Cryptosporidium* has been shown in vitro.[101] Loperamide and chlorpromazine have also been used in children with severe and protracted diarrhea, but they are loaded with several major side effects, particularly in children. Growth hormone has been used as a trophic factor in the short-gut syndrome and may have an additional beneficial effect in secretory diarrhea because it inhibits chloride secretion and promotes sodium absorption through a direct effect on the enterocyte.[102–104] Growth hormone may be an ideal drug in case of severe and protracted diarrhea when both epithelial atrophy and ion secretion are associated.

However, when other attempts have failed, the only option may be parenteral nutrition or surgery, including intestinal transplant.

CONCLUSIONS

Persistent diarrhea is still a major problem worldwide, but with two distinct presentations. In developing and transitional countries, persistent diarrhea is a relatively frequent outcome of intestinal infections and is loaded with a high case-fatality ratio, mainly because of the combined effect of enteric infections, intestinal dysfunction, malnutrition, and immunosuppression. In industrialized countries, the etiologic spectrum of persistent diarrhea is broader, with infections still playing a role, particularly in children with immunosuppression, but with a progressively increasing

number of primary, and usually irreversible, intestinal diseases. Optimal diagnostic approach and general management require advanced knowledge and technology and should be carried on in tertiary care centers or through a close interaction among experts in gastroenterology, nutrition, infectious diseases, and pediatric surgery.

CHAPTER 11

PROTEIN-LOSING ENTEROPATHY

Roy Proujansky, MD

The loss of serum proteins across the gut mucosa can occur in association with a wide variety of gastrointestinal and nongastrointestinal disease states in children. The effect on the patient is largely the result of the balance between excessive enteric protein loss and hepatic protein synthesis, protein distribution, and degradation in the rest of the body. This chapter reviews the relevant aspects of serum protein metabolism and the alterations that occur in a number of disease states.

NORMAL ALBUMIN METABOLISM

Albumin is a water-soluble molecule (molecular weight 65,000) that maintains plasma oncotic pressure and functions as a transport protein for hormones, metals, ions, bilirubin, and a variety of other biologic molecules. Because of the nonselective nature of intestinal protein loss, serum albumin level serves as an indicator of the degree to which abnormal loss of many different proteins may be occurring.

Serum albumin concentration depends on relative rates of synthesis and breakdown and on patterns of tissue distribution. Albumin is synthesized in the liver at a rate of 120 to 200 mg/kg/d in the normal adult, with somewhat higher rates (180–300 mg/kg/d) during the first year of life.[1] The predominant factor affecting albumin synthesis is nutrient intake. Food or protein deprivation is associated with a decrease in albumin synthesis of 50% within 24 hours. Meal-stimulated increases in hepatic albumin synthesis have been demonstrated in vivo using isotopic techniques.[2] Amino acids, especially tryptophan, appear to be essential nutritional requirements.[3,4] Hormonal influences also play a role, with cortisol, thyroid hormone, and insulin stimulating albumin synthesis.[5] Experimentally, hypophysectomy and diabetes may be associated with decreased synthesis that corrects with growth hormone or insulin replacement, respectively.[6,7] A variety of proinflammatory cytokines may also decrease the synthesis of albumin as part of the hepatic "acute-phase response" to inflammation.[8,9]

Approximately one-third of total-body albumin is intravascular. Extravascular albumin is distributed throughout the skin (30–40% of the total extravascular pool), muscle, and viscera. An exchangeable pool of extravascular albumin exists that can be mobilized to conserve serum albumin levels. The exchangeable pool size is 6 to 8 g/kg for children less than 1 year of age and 3 to 4 g/kg in the older child. Malnutrition may decrease the exchangeable pool to one-third of its normal size.

CONTRIBUTION OF THE GASTROINTESTINAL TRACT TO ALBUMIN METABOLISM

Between 6 and 10% of the plasma albumin pool is degraded in a 24-hour period. Loss into the gastrointestinal tract accounts for less than 10% of albumin degradation in healthy subjects. In patients with protein-losing enteropathy, however, albumin catabolic rates are 43% higher than in healthy controls. Much of this albumin loss is at the expense of plasma albumin, with the net effect of increasing the fractional catabolic rate of the plasma pool by a factor of 3. This loss provokes a relatively modest increase in hepatic albumin synthesis (24%), suggesting a limited capacity of the liver to respond to these losses.[10,11]

The site of albumin loss at the mucosal surface is not well characterized. Postulated mechanisms include diffusion between mucosal cells, rupture of lymphatics through the mucosal surface, and leakage of protein across ulcerated mucosa.[12] An immunofluorescent study in a canine model has demonstrated that in the setting of elevated intestinal venous pressure, transmucosal albumin flux occurred exclusively at the villus tip region. At normal venous pressures, no loss was observed.[13] The sites of protein loss attributable to other mechanisms have not been characterized.

METHODS OF DIAGNOSIS OF ENTERIC PROTEIN LOSS

Methods for documenting enteric loss of plasma proteins have evolved to elucidate normal physiologic losses and alterations attributable to various diseases. Techniques employed for these studies involve either the injection of radiolabeled substances and determination of radioactivity in enteric secretions or direct measurement of an endogenous protein in enteric secretions. Ideally, the molecules employed in these techniques should distribute and be metabolized similarly to other plasma proteins; they should not be selectively secreted, digested, or reabsorbed by the gastrointestinal tract. If a radiolabel is employed, it should remain bound to its carrier and, if dissociated within the gastrointestinal tract, should not be reabsorbed.[14] The technique employed must be safe, reproducible, and cost-effective.

Radiolabeled proteins that have been used to determine enteric protein loss have included iodine 131(^{131}I) albumin, chromium 51 (^{51}Cr) albumin, and copper 67 (^{67}Cu) ceruloplasmin. Radioiodinated albumin was initially employed for a variety of physiologic studies of plasma protein distribution and metabolism and thus initially seemed to be a likely candidate for similar studies of enteric protein loss. However, free iodine is actively secreted by the salivary glands and gastric mucosa and is reabsorbed in the intestine, so it is not suitable for these studies. Because chromium is not actively reabsorbed or secreted into the intestine in appreciable quantities, ^{51}Cr-labeled albumin has been used more extensively. The labeled albumin is given as an intravenous injection, and stools are collected for several days and assayed for radioactivity.[15,16] The use of ^{51}Cr albumin has been somewhat limited in the pediatric population because of the need for a several-day stool collection, the requirement that stool not be contaminated by urine, the concern about the use of radioactive agents in young patients, and, in recent years, the unavailability of the radiopharmaceutical. The use of ^{67}Cu ceruloplasmin gives similar results to those obtained with ^{51}Cr albumin, but its use has been limited by its cost and its brief half-life.[14,17] More recently, technetium 99m (^{99m}Tc)-labeled albumin has been used to visualize scintigraphically the sites of gastrointestinal protein loss.[18,19] In these studies, serial imaging following intravenous injection of the ^{99m}Tc-labeled albumin has allowed not only the detection of excessive enteric protein loss but also localization to the stomach, small intestine, or colon. Such discrete localization has the potential to identify surgically correctable lesions in the setting of localized loss and may also facilitate specific diagnosis of etiology based on the affected portion of the gastrointestinal tract.

Studies of enteric protein loss have also employed radiolabeled chemical agents believed to behave metabolically in a fashion similar to that of plasma proteins. ^{131}I polyvinylpyrrolidone has been used for this purpose but has been faulted because of the release of iodine from the carrier molecule and because of variability in the molecular weights of the preparations employed.[20] Iron 59 (^{59}Fe)-labeled iron dextran has also been tried.[21] Chromic chloride 51 ($^{51}CrCl_3$) can be injected intravenously; it can then bind to plasma proteins in vivo to give results similar to those of studies employing injected ^{51}Cr albumin.[22]

In recent years, the measurement of fecal concentrations of α_1-antitrypsin (α_1-AT) has been used more routinely for documentation of intestinal protein loss.[23,24] α_1-AT has a molecular weight similar to that of albumin and is not actively secreted, absorbed, or digested by the gastrointestinal tract. α_1-AT can be detected in the stool following lyophilization, extraction by solubilization, and subsequent immunologic assay, with radial immunodiffusion appearing to be superior to immunonephelometry.[25] Stools can be collected over several days and α_1-AT clearance determined, or fecal concentration of α_1-AT in random single-stool specimens can be compared with control values. Variations in the extraction procedure used have led to differences in the absolute values of α_1-AT concentrations obtained by different investigators, so control values may be different, depending on the method employed.

The concentration of fecal α_1-AT correlates well with enteric protein losses in children with various gastrointestinal disorders.[26,27] This assay has been shown to correlate with disease activity and response to therapy. Clearance of α_1-AT correlates closely with determinations made by the intravenous $^{51}CrCl_3$ technique.[28,29] Spot sample determinations of fecal α_1-AT concentrations agree with measures of α_1-AT clearance done on more prolonged stool collections.[30,31] Thus, the simplicity of this test, combined with its avoidance of radioisotopes, has made the α_1-AT assay very appealing for use in clinical pediatrics. Modifications that may make the assay even easier and less expensive have been suggested.[30,32]

Although the fecal α_1-AT assay has been shown to be useful clinically, assay results should be interpreted carefully. α_1-AT is degraded at a pH of less than 3; therefore, the fecal α_1-AT assay is not reliable for assessing gastric protein loss. Small amounts of blood loss into the gastrointestinal tract will not appreciably alter fecal α_1-AT concentration, but gross hematochezia will.[26] Fecal α_1-AT concentrations may vary during infancy, depending on the age of the patient and the type of feeding.[33,34] The synthesis and secretion of α_1-AT by intestinal epithelial cells, the process of which has been documented,[35] may increase in response to the inflammatory cytokines interleukin-1 and interleukin-6.[36] These findings raise the possibility that measurements of fecal α_1-AT concentrations in the setting of underlying gastrointestinal inflammation may reflect epithelial secretion along with systemic protein loss. In spite of these considerations, the relative ease and reliability of the fecal α_1-AT assay are likely to result in its continued use clinically as the primary method for documenting enteric protein loss.

GASTROINTESTINAL DISEASES ASSOCIATED WITH ENTERIC PROTEIN LOSS

A number of disorders have been associated with excessive enteric protein loss in children. Using a pathophysiologic classification, these disorders can be divided into those owing predominantly to excessive protein loss from intestinal lymphatics and those owing to protein loss across an abnormal or inflamed mucosal surface (Table 11-1). An alternative classification scheme would be a more clinical approach, distinguishing those disorders in which enteric protein loss is the major manifestation of the illness from those in which protein loss is present but is overshadowed by other clinical manifestations of these disorders. Those diseases that are characterized predominantly by a protein-losing state are discussed below, with the focus on the contribution of enteric protein loss to their manifestations.

PRIMARY INTESTINAL LYMPHANGIECTASIA

Intestinal lymphangiectasia is characterized by diffuse or localized ectasia of the enteric lymphatics, often in association with lymphatic abnormalities elsewhere.[14] The patho-

TABLE 11–1 DISEASES ASSOCIATED WITH EXCESSIVE ENTERIC PROTEIN LOSS

LOSS FROM INTESTINAL LYMPHATICS
Primary intestinal lymphangiectasia
Secondary intestinal lymphangiectasia
Cardiac disease
Constrictive pericarditis
Congestive heart failure
Cardiomyopathy
Post–Fontan procedure
Obstructed lymphatics
Malrotation
Lymphoma
Tuberculosis
Sarcoidosis
Radiation therapy and chemotherapy
Retroperitoneal fibrosis or tumor
Arsenic poisoning
LOSS FROM AN ABNORMAL OR INFLAMED MUCOSAL SURFACE
Infection
Invasive bacterial infection (eg, *Salmonella*, *Shigella*)
Parasitic infection (eg, *Giardia*)
Clostridium difficile
Helicobacter pylori
Bacterial overgrowth
Immunologic and inflammatory disorders
Gastric inflammation
Ménétrier disease
Eosinophilic gastroenteritis
Intestinal inflammation
Gluten-sensitive enteropathy
Milk- and soy-induced enteropathy
Common variable immunodeficiency
Tropical sprue
Radiation enteritis
Graft-versus-host disease
Ulcerative jejunitis
Colonic inflammation
Ulcerative colitis
Crohn disease
Hirschsprung disease
Necrotizing enterocolitis
Vasculitic disorders
Systemic lupus erythematosus
Mixed connective tissue disease
Schönlein-Henoch purpura

genesis of these abnormal lymphatic structures is uncertain. Ectatic lymphatics may be located in the mucosa, submucosa, or subserosa, leading to excessive loss of protein and lymphocytes into the gut or the peritoneal cavity. The mechanism of this lymphatic loss is believed to be from rupture of lymphatics across the mucosa, with subsequent leakage of lymph into the bowel lumen. The resulting clinical picture is one of edema (which may be asymmetric), growth failure, and variable gastrointestinal symptoms.

The presentation of primary intestinal lymphangiectasia may occur at any time throughout infancy and childhood. Gastrointestinal symptoms, in decreasing order of frequency, include intermittent diarrhea, nausea, vomiting, and, occasionally, abdominal pain.[37] Steatorrhea may also occur. Some patients may have relatively few gastrointestinal symptoms. Edema may be symmetric and pitting if it is due to the presence of a hypoproteinemic state, or, alternatively, it may be asymmetric and nonpitting if it is due to an underlying lymphatic abnormality of the affected extremity. Lymphedema of an extremity may precede the onset of symptoms owing to gastrointestinal involvement. Lymphatic aberrations may also lead to the development of a chylothorax or chylous ascites, which should be differentiated from pleural effusions or ascites, resulting from hypoproteinemia. Primary intestinal lymphangiectasia may occur as an isolated abnormality or as part of a more generalized syndrome such as Noonan syndrome or Klippel-Trénaunay-Weber syndrome.[38,39] Intestinal lymphangiectasia has also been noted to occur in families[40] and in other syndromatic forms with variable associated features and inheritance patterns.[41,42]

In addition to the loss of albumin, patients with lymphangiectasia may have reduced levels of immunoglobulins and lymphocytes owing to the loss of lymph. Differentiation from a primary immunodeficiency with gastrointestinal disease may be difficult initially. Enteric lymphatic loss results in the predominant loss of T lymphocytes, leading to reduced delayed hypersensitivity skin test responses, prolonged homograft survival, and diminished blast transformation to mitogen stimulation in vitro.[43,44] Additional abnormalities that have been described include hyposplenism,[45] thymic hypoplasia,[46] and neutrophil dysfunction.[47] In spite of these abnormalities, patients with intestinal lymphangiectasia do not appear to be unusually susceptible to infections.

The diagnosis of intestinal lymphangiectasia is suggested by the previously mentioned clinical findings and supported by the presence of hypoproteinemia and lymphocytopenia. Hypocalcemia is also occasionally present and may produce tetany. Steatorrhea may be demonstrable on a fecal fat collection, and fecal α_1-AT excretion may be increased. Barium studies may demonstrate thickening of the jejunal folds, fluid hypersecretion, and nodular or punctate lucencies in the mucosa of the small bowel.[37,48] Lymphangiography, which may be technically difficult to perform, has shown hypoplasia of the peripheral lymphatics in the injected limb, partial or complete absence of the thoracic duct, or, rarely, entry of contrast into the bowel lumen via mesenteric lymphatics.[14] Lymphoscintigraphy using ^{99m}Tc labeling of a microcolloid has been used more recently to localize lymphatic leakage and is technically easier than lymphangiography.[49] It should be recognized that the site and extent of the intestinal lesion vary widely between patients and may sometimes be extremely difficult to document with imaging studies.

Biopsy of the small intestinal mucosa may demonstrate dilated lacteals associated with distortion of the villi if a proximal lesion is present (Figure 11-1). Occasionally, extrusion of Brunner glands into villus tips and detachment of surface epithelium with formation of a subepithelial space may mimic the histologic appearance of lymphangiectasia.[50] Because of the focal nature of some lymphatic abnormalities, a capsule biopsy of the jejunal mucosa may miss the lesion. Endoscopic abnormalities, such as scattered white plaques or the presence of chyle-like substances covering the mucosa, have been observed

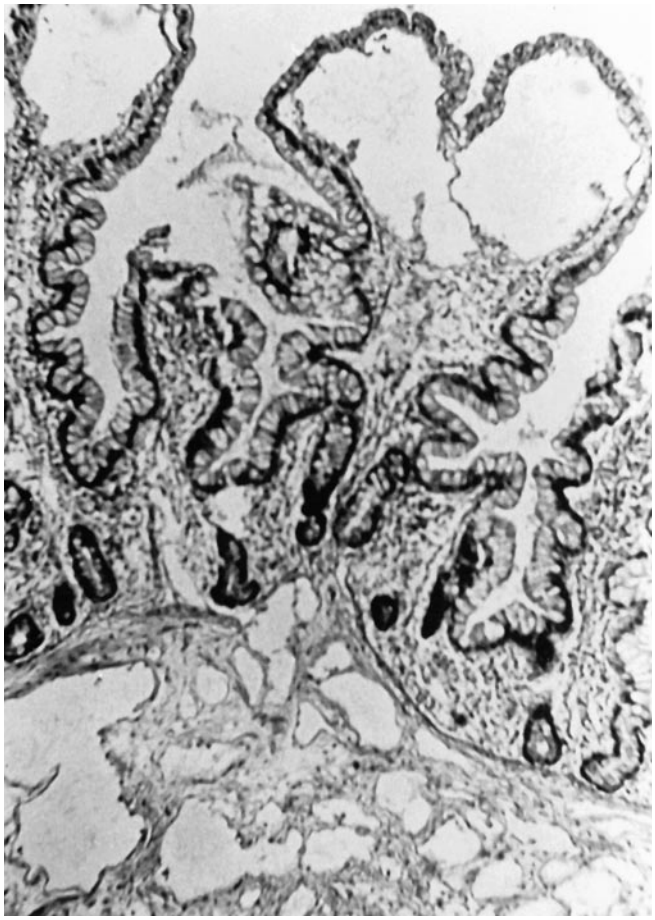

FIGURE 11-1 Microscopic view of intestinal biopsy specimen demonstrating wide villi with dilated lacteals in the mucosa and enlarged submucosal lymphatics.

and have been useful for directing biopsies at the time of endoscopy.[51,52] The endoscopic and histologic findings are less obvious if the patient has been on a low-fat diet. Endoscopic documentation of mucosal lymphangiectasia in patients without compatible symptoms is usually of no clinical significance.[53] Mucosal biopsy is not useful in patients with lymphangiectasia confined to deeper layers of the bowel wall.

The mainstay of treatment for intestinal lymphangiectasia is a low-fat, high-protein, medium-chain ($C_{6:0}$ to $C_{12:0}$) triglyceride (MCT) diet. MCTs are not re-esterified within the intestinal cell and thus bypass the enteric lymphatics and directly enter the portal system. It is believed that the reduction in dietary long-chain fats reduces lymphatic flow and pressure within the lymphatic system and decreases the amount of lymph leakage. This dietary approach can be implemented by the use of special MCT-containing formulas during infancy or by the supplementation of a low-fat diet with MCT oil in older children and adolescents. Using this approach, several authors have reported favorable effects on hypoalbuminemia, gastrointestinal symptoms, and growth.[37,54,55] This improvement may occur in spite of ongoing protein loss. The need for dietary therapy is often permanent, although occasional spontaneous remissions do occur.

Not all patients will respond completely to this dietary approach. Some patients will require additional supplementation with calcium salts and water-soluble forms of fat-soluble vitamins.[56] Low gammaglobulin levels may persist in some patients, but such patients are unlikely to require treatment because of their continuing capacity to generate specific antibodies.

Isolated reports have documented improvement in patients following localized resections of affected portions of the bowel or anastomosis of abnormal lymphatics to venous channels.[37,57] These approaches may be hampered by an inability to demonstrate radiographically such a localized lymphatic abnormality and the tendency for patients with the primary form of lymphangiectasia to have extensive lesions. Surgical shunts have been used in patients with persistent chylothorax or chylous ascites, with variable success.[58,59] The favorable response of patients with congenital chylous ascites to treatment with total parenteral nutrition suggests that this approach may be helpful in certain cases that are resistant to other forms of therapy.[59] Antiplasmin therapy has been found effective in a patient with lymphangiectasia and increased plasma fibrinolytic activity who did not respond to dietary therapy.[60] Octreotide has also shown some efficacy for the treatment of intestinal lymphangiectasia.[61]

SECONDARY INTESTINAL LYMPHANGIECTASIA

In addition to its occurrence as a primary developmental abnormality, lymphangiectasia may occasionally result from lymphatic obstruction or elevated lymphatic pressure. Cardiac lesions such as in congestive heart failure[62] and constrictive pericarditis[63] can increase lymphatic pressure. A protein-losing state has also been documented following the Fontan procedure for complex congenital heart disease.[64] Corticosteroids may have a role in the treatment of this protein-losing enteropathy after a Fontan procedure,[65] and, more recently, heparin therapy has been found efficacious in a few of these cases.[66] This clinical observation is supported by the recent suggestion of a relationship between heparan sulfate and other lamina propria glycosaminoglycans in the pathogenesis of some enteric protein-losing states.[67] Inflammatory processes that cause retroperitoneal lymph node enlargement[68] or fibrosis may lead to obstruction of enteric lymphatics. Chemotherapeutic agents or other toxic substances may directly damage the lymphatic structures.[69,70] Fleisher and colleagues have described a few patients with a steroid-responsive acquired form of intestinal lymphangiectasia with elevated immunoglobulins and sedimentation rates, suggesting an underlying inflammatory etiology.[71]

MÉNÉTRIER DISEASE

Ménétrier disease is a relatively rare disorder characterized by a marked protein-losing gastropathy associated with enlarged and thickened gastric folds in the fundus and the body of the stomach. Most pediatric patients with this dis-

order have been less than 10 years of age, and their illness has usually presented abruptly, with vomiting, abdominal pain, and peripheral edema.[72] Laboratory findings often reveal a mild normochromic normocytic anemia, eosinophilia, and hypoalbuminemia. Excessive protein loss has been demonstrated by the use of ^{51}Cr albumin excretion.[72,73] The typical upper gastrointestinal radiographic appearance has thickened gastric folds in the fundus and body of the stomach, often with antral sparing (Figure 11-2), which has been confirmed endoscopically.[74] Thickened folds have also been shown by ultrasonography.[73] Histologic examination of endoscopic or suction biopsies has shown a hypertrophic mucosa with elongated pits. Occasionally, cystic or polypoid changes and an inflammatory infiltrate have been noted.[72] Several cases of Ménétrier disease in childhood have been associated with histologic or serologic evidence of cytomegalovirus infection.[75–77] An infant with coexistent Ménétrier disease and formula-protein allergy has been described.[78]

The etiology of Ménétrier disease has not been conclusively determined. Theories have suggested the possibility of abnormal regulation of gastric epithelial growth, which might, in some cases, have been triggered by an environmental pathogen such as cytomegalovirus. Transforming growth factor-α (TGF-α), a member of the epidermal growth factor family of peptides, may be important in the pathogenesis of Ménétrier disease. Transgenic mice overexpressing TGF-α have been found to have a gastric lesion resembling Ménétrier disease.[79,80] Increased expression of TGF-α has also been demonstrated in gastric mucosa from patients with Ménétrier disease.[80] Studies such as these may help to further characterize the factors that initiate the abnormal mucosal growth that appears to occur in this disease.

The differential diagnosis of Ménétrier disease in childhood is that of a protein-losing gastropathy associated with thickened gastrointestinal folds. Initially, diagnosis can be facilitated by showing that a protein-losing state is present and that protein loss is primarily from the stomach. Because α_1-AT determinations may be inaccurate when the site of loss is the stomach, modifications of the technique or scintigraphic detection of the site of protein loss may be necessary.[81,82] Radiographically, eosinophilic gastroenteropathy may present in a similar fashion, but it usually involves the antrum and presents a distinctive histologic picture on biopsy.[83] Gastric lymphomas and Zollinger-Ellison syndrome can also produce a similar clinical and radiographic picture, but they are both very rare in children.[74] Thickened gastric folds without discrete polyps have been noted by upper gastrointestinal radiography in Peutz-Jeghers syndrome.[74] A retrospective histologic analysis of cases of Ménétrier disease has recently suggested that patients may be further subclassified on the basis of the degree of glandular hyperplasia and the presence and extent of infiltrating lymphocytes.[84] The distinction between lymphocytic gastritis and hypertrophic gastropathy may be of prognostic and therapeutic significance.

Children with Ménétrier disease usually have a self-limited illness without recurrence or sequelae, unlike adults, in whom the disease is chronic.[85] The chronic form of Ménétrier disease has also been described in a family in which two cases began in childhood.[86] Treatments for the chronic form that have been partially or completely effective include acid suppression, octreotide, and gastrectomy.[87,88] Omeprazole has been highly effective in some patients with this disorder.[89]

ENTERIC PROTEIN LOSS DURING THE COURSE OF OTHER GASTROINTESTINAL DISORDERS

Excessive enteric protein loss is common in several diseases in which symptoms attributable to protein loss are overshadowed by other consequences of the disease process. For the majority of these conditions, protein loss is due to mucosal disruption from a diffuse inflammatory process affecting the mucosa of the stomach, small intestine, or colon, alone or in combination. The following briefly reviews issues related to

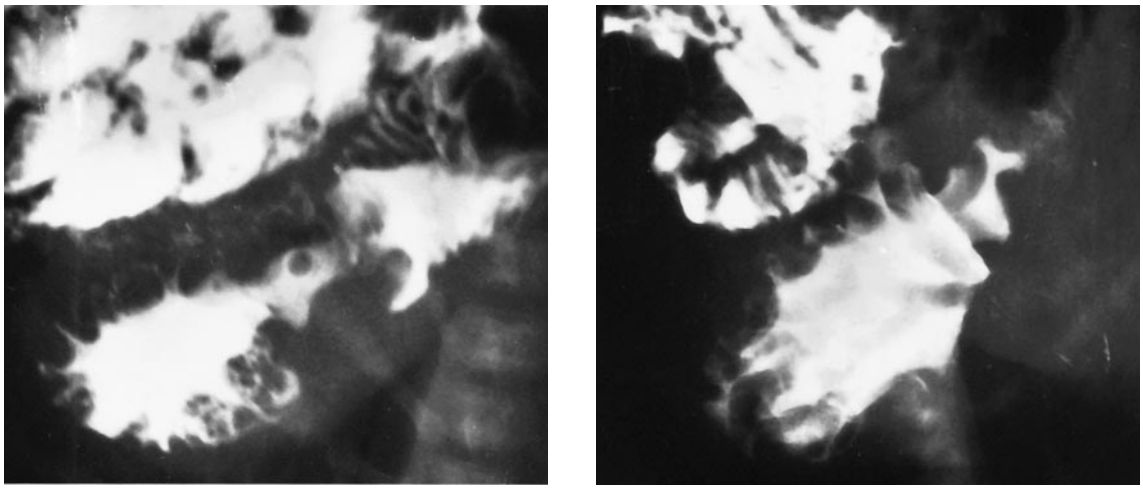

FIGURE 11-2 Upper gastrointestinal radiographs from a patient with Ménétrier disease showing marked thickening of the gastric folds.

protein loss in a number of disorders that are discussed in greater detail elsewhere in this book.

INFECTIONS

Gastrointestinal protein loss during the course of enteric infectious processes has not been extensively evaluated, but such loss can be excessive during the course of infections with *Salmonella*,[12] *Shigella*,[90] *Giardia*,[91] and other parasites.[92] Thomas and colleagues found no difference in fecal α_1-AT excretion between control patients and infants with acute self-limited gastroenteritis.[26]

Excessive gastric protein loss has been observed during the course of *Helicobacter*-associated gastritis.[93] A correlation between *Clostridium difficile* colonization and fecal α_1-AT excretion has also been detected in asymptomatic infants[94] and in symptomatic adults.[95] Excretion of ^{51}Cr albumin can be increased in patients with bacterial overgrowth of the small bowel from blind loop syndrome.[96] A decrease in protein loss was associated with prolonged antibiotic therapy in these latter cases.

INFLAMMATORY AND IMMUNOLOGIC DISORDERS

Hypoalbuminemia is a common occurrence in the course of eosinophilic gastroenteritis and milk- and soy-sensitive enteritis in infants,[26,97–99] In cow's milk– or soy-sensitive subjects, the absence of gastrointestinal symptoms in the presence of profound hypoalbuminemia and edema can be striking. A decrease in the degree of protein loss with treatment has been documented in both of these conditions. Active celiac disease has also been shown to result in increases in fecal α_1-AT.[26,27] This loss of protein not only improves with treatment, but treated celiac patients cannot be distinguished from normal subjects on the basis of fecal α_1-AT excretion. Fecal α_1-AT excretion has been used to monitor the response to gluten withdrawal as well as to monitor compliance in patients on a gluten-free diet.[100]

An elevated concentration of fecal α_1-antitrypsin has been detected in the stools of patients with probable necrotizing enterocolitis[101] and patients with graft-versus-host disease following bone marrow transplant.[102] In each of these cases, the possibility of using serial values to detect the onset and resolution of these conditions has been suggested.

Several studies have revealed increased gastrointestinal protein loss in patients with idiopathic inflammatory bowel disease (ulcerative colitis and Crohn disease).[26,31,103,104] Fecal α_1-AT excretion, fecal α_1-AT clearance, and ^{51}Cr albumin excretion are all increased in patients with inflammatory bowel disease compared with controls. Fecal α_1-AT excretion has been shown to correlate with disease severity and, to some extent, the degree of small bowel involvement but to correlate poorly with the Crohn Disease Activity Index.

Protein-losing enteropathy has been demonstrated in association with common variable immunodeficiency.[105] Thus, because hypogammaglobulinemia can be either the effect or the cause of a protein-losing state, one needs to exercise caution in discerning the etiology of hypogammaglobulinemia associated with hypoalbuminemia and enteric protein loss.

VASCULITIC DISORDERS

Excessive enteric protein loss can be associated with systemic lupus erythematosus either at diagnosis or during the course of the disease.[106] Similarly, protein-losing enteropathy has been observed in other vasculitic conditions, including mixed connective tissue disease[107] and Schönlein-Henoch purpura,[108] and during the course of vasculitis after bone marrow transplant.[109]

METABOLIC DISORDERS

Previously, metabolic disorders have not been considered among those conditions that have protein-losing enteropathy as a common clinical feature. However, improved diagnosis of metabolic disease has allowed a greater understanding of the diverse spectrum of clinical presentation of some of these illnesses. One such example is the recent elucidation of variants of carbohydrate-deficient glycoprotein syndrome.[110,111] These disorders, which may be associated with a significant protein-losing enteropathy, may be responsive to dietary therapy.[110,111] Protein-losing enteropathy has also been seen in cobalamin C deficiency and may be a feature of other underlying metabolic disease.[112]

CONCLUSION

Protein-losing enteropathy occurs in the course of a number of gastrointestinal disorders. Those in which the protein-losing state contributes significantly to clinical manifestations are relatively uncommon in children and can be identified on the basis of clinical, laboratory, radiographic, and endoscopic criteria. Scintigraphic techniques and the measurement of fecal α_1-AT can be used to document protein loss and to potentially localize the site of loss. In addition, these measurements may be useful for following the course or activity of a number of chronic inflammatory conditions during which protein loss occurs.

CHAPTER 12

VOMITING

Judith M. Sondheimer, MD

Vomiting presumably conveys a survival advantage in that it promotes the rapid expulsion of ingested toxins. It is a complex behavior, which in humans is usually composed of three linked activities: nausea, retching, and expulsion of stomach contents. In 1952, Wang and Borison proposed a model for the neurohumoral control of vomiting that has stood up remarkably well to subsequent investigation.[1] These investigators identified two anatomic regions in the medulla controlling vomiting: the chemoreceptor trigger zone (CTZ) and the central vomiting center. The CTZ is located in the area postrema on the floor of the caudal end of the fourth ventricle outside the conventionally defined blood-brain barrier. Receptors in this region are activated by proemetic agents in the circulation or cerebrospinal fluid. It was proposed that efferents from the CTZ project to a central vomiting center from which the motor events of vomiting are initiated via vagal and splanchnic sympathetic efferents. The central vomiting center was thought to be located in the nucleus tractus solitarius and surrounding reticular formation of the medulla just beneath the CTZ. Input from all other sources provoking emesis—gastrointestinal, vestibulo-ocular, and higher cortical afferents—also was said to project to the central vomiting center, which then initiated and coordinated nausea, retching, and expulsion, as well as the preparatory autonomic phenomena (gastrointestinal motor events, salivation, tachypnea, and tachycardia). Ablation studies in animals, which have failed to identify an anatomically discrete central vomiting center, have suggested that the central vomiting center represents the integrated activity of the paraventricular nuclei arrayed along the central neuraxis controlling a myriad of autonomic functions. These nuclei receive input from central and peripheral afferents and together serve as a central pattern generator for the respiratory, cardiac, gastrointestinal, and somatomotor events of vomiting.[2,3]

NAUSEA AND THE GASTROINTESTINAL CORRELATES OF VOMITING

Cineradiographic evaluation of animals after administration of intravenous proemetics has revealed a series of gastrointestinal motor events preceding vomiting (the gastrointestinal motor correlates of vomiting).[4] First, there is an increase in segmental, nonperistaltic activity in the duodenum and small intestine. Gallbladder contraction occurs, and some duodenal contents regurgitate into the stomach. Next, a large-amplitude contraction originating in the mid–small bowel sweeps slowly retrograde over a period of 30 to 60 seconds, filling the gastric antrum with small bowel contents and pancreatobiliary secretions. Gastric motor activity is suppressed. By this means, diluent and buffer are added to any noxious gastric contents. Finally, a series of lesser-amplitude contractions originate in the ileum and propagate the remaining small bowel contents into the colon. Diarrhea often follows vomiting, but studies have not revealed a predictable pattern of colonic motor activity preceding this diarrhea. Just before the onset of retching, gastric contents may reflux into the distal esophagus, suggesting that relaxation of the cardia, crural diaphragm, and lower esophageal sphincter has occurred. The gastrointestinal motor correlates of vomiting are initiated by vagal and sympathetic efferents from the central pattern generator, which also coordinate the other autonomic events occurring at this time, increased salivation, increased respiratory rate, increased heart rate, and pupillary dilation.[4,5] Cholecystokinin (CCK) may be the local mediator of the gastrointestinal motor correlates. Nitric oxide may be the inhibitory mediator of gastric atony.

It is not clear that the motor correlates of vomiting actually produce nausea. Completely coordinated vomiting may occur in the absence of nausea (eg, vomiting caused by increased intracranial pressure). Furthermore, nausea may occur in the absence of vomiting (eg, following a very large meal, in motion-induced nausea, or in gastroparesis). Nausea may simply be a conscious sensation of gastric distention and/or atony. Alternatively, it could be a response to output from the central pattern generator to the cortex.[5]

SOMATOMOTOR EVENTS OF VOMITING

The vomiting act is characterized by cycles of retching followed by forceful expulsion of gastric contents through the mouth. The diaphragms descend and the external intercostal (inspiratory) muscles contract against a closed glottis. The esophagus dilates in response to the negative intrathoracic pressure. The stomach remains atonic, filled with refluxate from the small bowel. Abdominal muscle contractions begin, compressing the stomach and forcing gastric contents into the fundus and lower esophagus. The

fundus of the stomach may herniate into the thorax during this phase, effectively removing the antireflux barrier produced by abdominal pressure on the lower esophageal sphincter. With relaxation of abdominal contraction, strenuous inspiratory effort ceases and the esophagus empties back into the stomach. Several cycles of retching occur, becoming shorter, more rhythmic, and forceful until the esophagus no longer empties between cycles. The last abdominal contraction in the cycle produces expulsion of gastric contents. It occurs early, while the esophagus is still full, and is associated with elevation of the diaphragm producing positive pressure in both the thorax and abdomen. These motor events are accompanied by spinal flexion, wide open mouth, palatal elevation, upper esophageal sphincter relaxation, and forceful ejection of gastric contents.[4]

NEUROHUMORAL CONTROL OF VOMITING

Studies of the area postrema or CTZ in animals who vomit have shown that it contains specific receptors for many neuroactive compounds that can cause vomiting. These include receptors for dopamine (the site of action of apomorphine), acetylcholine, vasopressin, enkephalin, angiotensin, insulin, serotonin, endorphin, substance P, and many others.[6] A common mediator, 3′, 5′-cyclic adenosine monophosphate, may be involved in the excitatory responses of all of these stimulatory peptides because theophylline inhibits the proemetic activity of them all. Receptors of the dopamine D_2 type are present in the highest concentration, explaining the exquisite sensitivity of humans to apomorphine. The efferent output from the CTZ projects to the nearby paraventricular nuclei. Subemetic doses of stimulatory agents may simply produce the gastrointestinal motor correlates of vomiting without expulsion of contents.

Gastrointestinal vagal and sympathetic afferents carry sensory input from the gut to the nucleus tractus solitarius and the other paraventricular nuclei of the central pattern generator. A small number of vagal afferents appear to terminate in the area postrema as well. Stimulation of the central end of the cut vagus provokes a complete vomiting cycle even in the absence of the CTZ, so the role of vagal afferents to the CTZ is unclear. The widespread projections of the visceral afferents in the paraventricular area are consistent with the concept of a central pattern generator rather than a discrete vomiting center. Emesis in response to direct gastrointestinal irritants such as copper sulfate, abdominal radiation, and gastrointestinal dilation is a result of afferent vagal signals to the central pattern generator produced by local release of inflammatory mediators from damaged mucosa, with secondary release of excitatory neurotransmitters, most importantly serotonin from deep mucosal enterochromaffin cells. In motion sickness, afferent input to the central pattern generator from the vestibular organ, visual cortex, and higher cortical centers involved in integration of sensory input is probably more important than gastrointestinal afferent input.[7] Some animal experiments suggest that humoral excitation of the CTZ may play a role in motion sickness (see "Therapy," below). The anticipatory vomiting of cancer chemotherapy is mediated by afferents to the central pattern generator from higher cortical centers, in response to smells, sights, sounds, and feelings associated with chemotherapy.[8] The CTZ is almost certainly involved in intravenously administered chemotherapy, but there is increasing appreciation of the importance of gastrointestinal afferent input to the central pattern generator resulting from drug-induced mucosal damage and intestinal distention.[9] Emesis seen in association with inflammatory bowel disease is stimulated by gastrointestinal afferents in response to the locally produced prostaglandins and distention. The vomiting of pregnancy has been incompletely defined. The CTZ may mediate emesis in early pregnancy in response to luteinizing hormone, progesterone, human chorionic gonadotropin, or androgens, all of which have been reported to be elevated in women with vomiting of pregnancy.[10] The role of vagal afferents from the uterus and emotional adjustment to pregnancy in this condition has not been clarified. Vomiting associated with systemic anaphylaxis is probably mediated by the effects of histamine on the CTZ.

VOMITING SYNDROMES

Regurgitation

Effortless regurgitation of gastric contents is a characteristic symptom of gastroesophageal reflux in infants. It is not clear whether this behavior is centrally or locally controlled or whether it should be considered "vomiting" at all. Most episodes of regurgitation are not associated with nausea; retching is rare; and expulsion is not forceful or complete. When regurgitation of gastric contents causes aspiration, cough, gagging, or peptic injury, a full vomiting reflex with forceful expulsion of gastric contents may occur, probably mediated by afferents from the pharynx and esophagus. Spontaneous relaxation of the lower esophageal sphincter is the major mechanism by which gastroesophageal reflux occurs, with or without regurgitation.[11] Whether other reflex motor activity involving the abdominal or gastric musculature is required to produce regurgitation during reflux is unknown. It is not known why regurgitation is so characteristic of infant reflux compared with that of older children and adults.

Cyclic Vomiting Syndrome

This disorder is characterized by recurrent episodes of nausea and vomiting without an identifiable organic cause. Recent reports indicate that the condition may affect up to 1.9% of schoolchildren.[12] The episodes are of rapid onset, often starting during sleep or early morning. Children may vomit many times per hour, to the point of dehydration. Persisting for hours to days, but rarely more than 72 hours, the episodes are separated by completely symptom-free intervals. The episodes may end spontaneously, may cease after a period of sleep, or may progress to such severe dehydration and electrolyte imbalance that intravenous fluids, sedatives, and antiemetics are required. There are few

residua to most episodes, and the patient suddenly seems better and complains of hunger. For each individual, the pattern of inciting events and the character of the attacks are similar. Stress or minor intercurrent illness is frequently noted at the onset. The symptom-free interval ranges from several weeks to more than a year. A similarity to migraine attacks and even seizures has long been noted, and headaches of various types are present in up to 25% in some series.[13] Migraine headaches may be present in up to 47% of patients, and a family history of migraine is found in 47% of first-degree and 72% of second-degree relatives.[14] A family and personal history of irritable bowel symptoms is seen in 62%.[15] The diagnosis rests on the characteristic history, the normal physical examination, and a meticulous evaluation for other organic diseases causing recurrent episodes of vomiting. A unifying cause has not been determined. Attention has focused on the possibilities of mitochondrial deoxyribonucleic acid (DNA) mutations (because the mother often has a history of migraine), ion channel defects, abnormalities of the hypothalamic-pituitary-adrenal axis, and increased autonomic reactivity.[12] Inflammatory and vasoactive mediators (interleukin-6 and nitric oxide) released from gastric and esophageal mucosa may stimulate the central vomiting center [16].

Important considerations in the differential diagnosis of cyclic vomiting are such disorders as urea cycle defects, disorders of organic acid metabolism, gastric and intestinal motility disorders, central nervous system lesions, familial dysautonomia, obstructive uropathy, obstructive cholangiopathy, familial pancreatitis, intestinal malrotation, duplication, strictures and diverticulae of the intestines, adrenal insufficiency, and diabetes mellitus. All of these disorders may be associated with prolonged symptom-free intervals and normal physical examinations for some time. Peptic disease may cause vomiting, but the emesis is more chronic and less episodic. Diagnostic evaluations should be focused on conditions suggested by history. Symptomatic treatment should be instituted as early as possible after onset of symptoms. Lorazepam, butyrophenones, and benzamides such as metoclopramide and rectal trimethobenzamide have been used with occasional success. Propranolol, phenytoin (Dilantin), and antihistamines (especially cyproheptadine) have been used prophylactically.[17] Drugs commonly used in the treatment of migraine have been effective in treating attacks in some patients, including sumatriptan, amitriptyline, and pizotifen. The immediate initiation of intravenous fluids and nasogastric suction is helpful in some patients. Patient and parent education as to the appropriate treatment and the usual benign nature of the condition is essential. Evaluation and treatment of stress or overt psychiatric disease are also indicated.

Rumination

Rumination is the frequent regurgitation of previously ingested food into the mouth. Regurgitated food may be rechewed and swallowed or voluntarily spit out. Rumination is not accompanied by apparent nausea, retching, or forceful expulsion. It occurs most often in mentally retarded children. The origin of rumination appears to be behavioral in most instances. Because it is so often seen in institutionalized children, it is felt to be a form of self-stimulation. Indeed, rumination is reported to occur in 84% of gorillas held captive in zoos for more than 5 years.[18] The syndrome has been described in cases of child neglect, in neonates during prolonged hospitalization,[19] in children and infants with untreated gastroesophageal reflux,[20] and in older children as an associated symptom of bulimia. Except in infants with gastroesophageal reflux and in bulimic patients, the symptom often responds to increased personal attention, especially during feedings, and mild negative reinforcement.[21] If untreated, it may result in life-threatening inanition. Motility studies in a few adults have shown that rumination is produced by voluntary abdominal muscle contraction associated with a pharyngeal maneuver, which results in reduced upper esophageal pressure.[22] Manometric studies have also shown characteristic simultaneous spike-wave activity in the stomach and duodenum during rumination.[23] Differentiating this symptom from the vomiting and regurgitation associated with gastroesophageal reflux, metabolic disease, and many of the other conditions listed in Table 12-1 may require extensive diagnostic testing. However, the setting of neglect should raise the suspicion of rumination syndrome early in the evaluation.

Bulimia

Bulimia is an eating disorder characterized by recurrent episodes of binge eating followed by purging induced by vomiting, diarrhea, diet, and exercise.[24] Commonly seen in adolescent and young adult females (up to 10% of this age group), it does occur in males[25] and premenarchal females.[26] Patients describe a frightening sensation that they have lost control of themselves during vomiting and a persistent anxiety over body shape and weight. Vomiting may be induced by medications such as ipecac, hypertonic saline, or other emetogenic substances. It may be a result of self-induced gagging. It may also be promoted by forceful abdominal muscle contraction during spontaneous lower esophageal sphincter relaxations associated with belching. This characteristic is sometimes useful in manometrically discriminating the patient with bulimia from the patient with gastroesophageal reflux. These patients often vomit surreptitiously. They often come from dysfunctional families characterized by enmeshment with overly controlling parents. Parental substance abuse is common. Sexual abuse by a family member has been reported in up to 15% of cases.[27] Depression and feelings of helplessness are common. As in anorexia nervosa, complications of purging include malnutrition, electrolyte imbalance, esophageal erosion and bleeding, dental erosion, and dehydration. Gastrointestinal symptoms seen in up to 50% of patients include abdominal pain, constipation, bloating, nausea, and postprandial fullness. Pancreatitis may be falsely indicated by the presence of hyperamylasemia secondary to constant salivary gland stimulation. A careful history is the most important diagnostic tool. In cases in which recurrent vomiting is an admitted symptom of bulimia, antiemetics are of little use. Psychotherapy and antidepressants are the mainstays of therapy.

TABLE 12-1 ANTIEMETIC AND ANTINAUSEA DRUGS WITH INDICATIONS AND POSSIBLE MECHANISMS OF ACTION

CHEMICAL NAME	REPRESENTATIVE BRAND NAME	INDICATION	MECHANISM
ANTIHISTAMINES			
Diphenhydramine Hydroxyzine Dimenhydrinate Promethazine Meclizine	Benadryl Vistaril, Atarax Dramamine Phenergan Antivert	Motion sickness, mild chemotherapy-induced vomiting	Most likely labyrinthine suppression, possibly via anticholinergic effect as well as H_1 receptor antagonism in the central pattern generator
ANTICHOLINERGICS			
Hyoscyamine	Scopolamine Levsin	Prophylaxis of motion sickness	Antimuscarinic effect probably at the level of the labyrinth or central pattern generator
SUBSTITUTED BENZAMIDES			
Metaclopramide	Reglan	Chemotherapy, motility disorders, especially gastroparesis, GER	D_2 receptor blockade at the CTZ and enteric nervous system. In high dose, has 5-HT_3 activity enterically
Trimethobenzamide	Tigan	Often used during vomiting associated with acute gastroenteritis — ? efficacy. May abort some cases of cyclic vomiting	D_2 receptor blockade
Cisapride	Prepulsid	Motility disorders, GER	Enteric acetylcholine release
5-HT_3 RECEPTOR ANTAGONISTS			
Ondansetron Granisetron	Zofran Kytril	Chemotherapy Postoperative nausea and vomiting	5-HT_3 receptor blockade most important at the enteric level, but possibly some effect at the CTZ and central pattern generator
CANNABINOIDS			
Dronabinol Nabilone	Marinol Cesamet	Chemotherapy, but used less and less because of more efficacious drugs and central side effects	Unknown
BENZODIAZEPINES			
Lorazepam Diazepam Midazolam	Ativan Valium Versed	Chemotherapy—especially lorazepam. Preferred because of rapid effect and short duration	These drugs probably act via central GABA inhibition producing sedation and anxiolysis
PHENOTHIAZINES			
Prochlorperazine Chlorpromazine Perphenazine Promethazine	Compazine Thorazine Trilafon Phenergan	Chemotherapy, cyclic vomiting, acute gastritis. Rarely used in pediatrics because of extrapyramidal side effects	D_2 receptor antagonist at CTZ
BUTYROPHENONES			
Droperidol Haloperidole	Inapsine Haldol	Cyclic vomiting, intractable vomiting from acute gastritis, chemotherapy, postoperative nausea and vomiting	D_2 receptor blockade at the CTZ. Central anxiolysis and sedation
Domperidone	Motilium	Chemotherapy, motility disorders especially gastroparesis, GER	D_2 receptor blockade at enteric nervous system
CORTICOSTEROIDS			
Dexamethasone	Decadron	Mild chemotherapy-induced vomiting or in combination with other antiemetics; emesis resulting from increased intracranial pressure	Unknown, possibly decreased enteric prostaglandin synthesis

CTZ = chemoreceptor trigger zone; GABA = γ-aminobutyric acid; GER = gastroesophageal reflux; 5-HT = 5-hydroxytryptamine.

SUPERIOR MESENTERIC ARTERY SYNDROME

See Chapter 36, "The Surgical Abdomen."

VOMITING AND CHEMOTHERAPY

Vomiting is a common complication of cancer chemotherapy, which can be severe enough to produce dehydration, electrolyte imbalance, enhanced drug toxicity, and malnutrition. Other complications include Mallory-Weiss esophageal tears, bone fractures, wound dehiscence, and emotional depression. Delay or discontinuation of necessary cancer therapy may result from any of these complications. Emesis may be immediate, delayed, or anticipatory. Factors influencing the incidence of vomiting include the type, dose, route, and rapidity of administration of the chemotherapy. The patient's propensity to develop motion sickness, motivation for chemotherapy, and age are also relevant considerations, with young patients at higher risk than adult patients. Postpubertal females may have increased risk of chemotherapy-induced emesis in the luteal phase of the menstrual cycle. Combinations of drugs

have an additive effect on nausea and vomiting. On first intravenous exposure, vomiting usually occurs after a latency of about an hour. Vomiting may be brief (acute phase) or may persist for 2 to 5 days (delayed phase). Drugs most likely to produce emesis in pediatric patients include cisplatin, dacarbazine, and nitrogen mustard (> 90% likelihood of vomiting). Highly emetic agents (60 to 90% likelihood of vomiting) include nitrosoureas, actinomycin D, cyclophosphamide, and procarbazine. Less emetogenic drugs (30 to 60% likelihood of vomiting) include L-asparaginase, 5-azacitidine, daunorubicin, 5-fluorouracil, and mitomycin C. Drugs with low emetogenic potential (< 30%) include vinca alkaloids, epipodophylotoxins, oral alkylating agents, bleomycin, isophosphamide, cytosine arabinoside, and thiotepa.[8]

The CTZ is thought to be the most important receptor for intravenously administered chemotherapeutic agents. The receptor in the CTZ most closely associated with chemotherapy-induced vomiting is the dopamine$_2$ receptor, which explains the antiemetic effect of phenothiazines, butyrophenones, domperidone, and metoclopramide, which are all D_2 receptor antagonists. The mechanism by which cannabinoids produce an antiemetic effect is not known, but it may be via an antiadrenergic effect at the CTZ or by inhibition of prostaglandin synthesis. Neurokinin-1 receptor antagonists are antiemetic, acting on the dorsal vagal complex and preventing vagal motoneuron activity. Thus, they may prevent gastric fundic relaxation, an early stage in the vomiting complex.[28] Corticosteroids may interfere with prostaglandin synthesis and are most effective when used in conjunction with other antiemetics. Antihistamines and anticholinergics are relatively ineffective in cancer chemotherapy-induced emesis, but both may suppress output from the central pattern generator. Benzodiazepines have little direct antiemetic effect but are helpful in anticipatory emesis as they reduce anxiety and recall of the events surrounding chemotherapy.[17]

High-dose metoclopramide blocks not only D_2 receptors but also the central and local receptors for serotonin (5-hydroxytryptamine-3 [5-HT_3] receptor). Therapeutic agents with very high specificity for the 5-HT_3 receptor have fewer extrapyramidal effects than metoclopramide and have powerful antiemetic activity in the acute phase of vomiting induced by cisplatin, doxorubicin, cyclophosphamide, and abdominal irradiation. The 5-HT_3 receptor antagonists (ondansetron, ganisetron) used in combination with other standard antiemetics confer an advantage in the prevention of chemotherapy-induced nausea and vomiting in pediatric patients. The combination of a neurokinin receptor antagonist and dexamethasone has been shown specifically to decrease the delayed vomiting phase of chemotherapy with cisplatin.[29] Although it is assumed that the major site of action of the selective serotonin antagonists is the CTZ, a major effect of 5-HT_3 receptor antagonists is at the enteric level, where they block receptors in the peripheral ends of vagal afferents, thus blocking serotonin-stimulated vagal afferent input to the central pattern generator and reducing the perception of emetic stimuli.[8,9,30]

DIAGNOSTIC APPROACH TO THE CHILD WITH VOMITING

Vomiting is a common symptom of many disease states. The differential diagnosis of the child with vomiting varies with the age of the patient. Congenital anatomic, genetic, and metabolic disorders are more commonly seen in the neonatal period, and peptic, infectious, and psychogenic causes are more prominent with increasing age. Feeding intolerance and food refusal behavior, with or without vomiting, are common symptoms of cardiac, renal, pulmonary, metabolic, genetic, and neuromotor disorders; child abuse; and Munchausen syndrome by proxy. The physician must remain alert to the huge differential and not assume that all infants who vomit have gastroesophageal reflux. Serious disease in infancy may be missed by this approach. Suggested screening laboratory evaluation in any child with prolonged or repetitive vomiting includes complete blood count, serum electrolytes, blood urea nitrogen, urinalysis and urine culture, and stool examination for occult blood, leukocytes, and parasites. Specific indications from history and physical examination may result in obtaining other tests, such as upper gastrointestinal series; abdominal ultrasonography, computed tomography or magnetic resonance imaging of the head, tests of liver function, serum amylase, toxicology screen, pregnancy test, serum ammonia, urinary organic acids, urinary catecholamines, urinary porphyrins, and electroencephalography. Endoscopic examination of the esophagus, stomach, and duodenum is sometimes helpful if peptic disease or anatomic abnormality is suspected. Manometric evaluation of the esophagus, stomach, and duodenum is occasionally helpful in defining primary or secondary motor abnormalities causing emesis.

THERAPY

The use of antiemetic agents in infants and children without a clear understanding of the cause of vomiting is not recommended. The use of antiemetic agents is contraindicated in most infants and children with vomiting secondary to gastroenteritis, structural anomalies of the gastrointestinal tract, or surgical emergencies such as pyloric stenosis, acute appendicitis, renal stones, bowel obstruction, or an expanding intracranial lesion. There are only a few situations in which antiemetic agents are indicated and possibly effective. These include motion sickness, postoperative nausea and vomiting, cancer chemotherapy, some cases of cyclic vomiting syndrome, and gastroparesis or other gastrointestinal motility disorders.

Motion Sickness

The neurohumoral stimuli for motion sickness are not known. The traditional view that the vestibular organ is overstimulated in motion sickness is probably not a sufficient explanation. Indeed, in the dog, the area postrema appears necessary to motion-induced emesis, suggesting that circulating compounds may, in part, mediate this condition.[7] Possible mediators known to have receptors in the

CTZ include such stress-related hormones as epinephrine, antidiuretic hormone, adrenocorticotropic hormone, cortisol, growth hormone, and prolactin, all of which can be increased during motion sickness. Some investigators believe that sensory input to the cortex, which conflicts with previous sensory experiences (such as the sensory conflict created by distorting eyeglasses or flight simulators), creates increased input to the central pattern generator, bypassing the CTZ.[7] The most common drugs used for prophylaxis of motion sickness are anticholinergics such as scopolamine (Hyoscine) and antihistamines. Although the activity of these agents may be on muscarinic and histamine receptors in the vestibular apparatus and CTZ, recent work suggests that both drug types block muscarinic receptors in the cortex, pons, and nucleus tractus solitarius.[31] Thus, the effects of these drugs may be to raise the emetic threshold of the central pattern generator for input from the cortex generated by sensory conflict. The combination of scopolamine and D-amphetamine has been used with synergistic effect to combat the symptoms of nausea and vertigo accompanying the weightlessness of space adaptation syndrome. Phenothiazines, substituted benzamides, and other D_2 receptor antagonists are of little benefit in experimentally induced motion sickness. The 5-HT_3 receptor antagonists are also ineffective.[32]

Cancer Chemotherapy

Antinausea and antiemetic therapy for cancer chemotherapy has been discussed in part above. Drugs normally used in pediatric patients include the antihistamines (mild symptoms) benzamides, butyrophenones, and other D_2 receptor antagonists and 5-HT_3 receptor antagonists. Combinations of these drugs with others that facilitate their antiemetic activity—dexamethasone and benzodiazepines—are commonly used. Indications and modes of activity of many of the standard antiemetics are listed in Table 12-1. Recent studies in animals and adults have shown good control of chemotherapy-induced vomiting with opiate agonists (butorphanol) and potentiation of vomiting with the opioid antagonist naloxone. However, the known emetic effect of narcotics in most clinical experience limits the routine use of these agents. Control of anticipatory nausea includes relaxation techniques and anxiolytics such as benzodiazepines in combination with standard medications.[17]

Postoperative Nausea and Vomiting

The importance of controlling postoperative nausea and vomiting (PONV) has increased with the current emphasis on rapid postoperative discharge in the day-surgery setting. The incidence of PONV is reported to be 5% in infants and as high as 50% in children between 6 and 16 years of age.[33] The incidence has decreased with improvements in perioperative hydration, decreased use of preoperative narcotics, attention to speed in operative procedures, effective decompression of the gastrointestinal tract, attention to allaying anxiety and pain, and improved techniques in mask anesthesia to avoid intestinal tract distention.[34] Decreased insistence on taking oral fluids in the first postoperative hours has also decreased vomiting in the day-surgery setting. Despite improvements, PONV remains a problem in pediatrics, especially following tonsillectomy and strabismus surgery. The most commonly used medication for the prevention and treatment of PONV is droperidol, both for its effect on the D_2 receptor in the CTZ and its sedative effects. Experience with 5-HT_3 receptor antagonists, used singly or in combination with droperidol, in both the prevention and treatment of PONV is encouraging, especially after gastrointestinal surgery and other procedures in which gastrointestinal distention is produced, but expense is an important issue. Induction of anesthesia with propofol, a rapidly cleared, lipid-soluble, substituted phenol, has been reported to decrease PONV by 50%, probably because of its very rapid clearance.[31,33,35]

CHAPTER 13

COLIC AND GAS

Shuvo Ghosh, MD
Ronald G. Barr, MDCM, FRCPC

Colic is usually thought of as a symptom, a synonym for acute and unexpected abdominal pain. In children, the term most commonly refers to a syndrome characterized by a self-limited cluster of behaviors in the first 3 months of life, presumed to be secondary to underlying gastrointestinal disturbances and signifying pain in the intestine. Older infants and children are described sometimes as "colicky," implying a predisposition to irritability and gastrointestinal upset.

Neither the presumption that the source is gastrointestinal nor that colic is a painful condition has been proven,[1,2] and our understanding of the etiology, pathophysiology, and treatment of colic is far from complete. However, systematic descriptions of colic and of crying in normal infants have increasingly clarified our understanding of the behaviors that are the core concerns and have led to a revision of the usual interpretation of most complaints of "colic." It is now reasonably clear that all of the behavioral characteristics of crying that constitute the behavioral syndrome of colic are typical of normally developing infants but that they are either more intense or occur more frequently in infants thought to have colic. As a result, most infants who present with this syndrome are otherwise normal infants at the upper end of a continuous spectrum of crying behavior. Although less well established, a small proportion of these infants will continue to have increased crying that persists after the first few months, when colic has subsided in most infants. The clinical challenge is to understand in which infants this typical normative crying pattern may be exacerbated by concurrent pathogenic processes and whether such processes are implicated in persistently crying infants.

DEFINITIONS

Colic refers to a behavioral syndrome occurring during the first 3 months of life. In about 30% of cases, symptoms persist into the fourth and fifth months.[3,4] Crying is the core symptom, but clinicians differ on what other behaviors constitute the syndrome.[5] There are three dimensions around which defining features of colic can be organized (Table 13-1).[6] The first, crying, has age-dependent and diurnal characteristics. Increased crying typically begins about 2 weeks after birth, reaching a peak sometime in the second month, and then declines to baseline levels by about 4 months of age. This crying is not random but tends to cluster in the late afternoon and evening hours. Changes in the amount of evening crying account for most of the developmental pattern of colic. The second defining dimension is the association between crying and several behavioral characteristics. Some of the crying occurs in prolonged bouts that are resistant to soothing, even with feeding. During these bouts, infants may clench their fists, flex their legs over their abdomens, arch their backs, flush, and have an active, grimacing, and ruddy face that is interpreted as a manifestation of pain (a "pain facies"). Other behaviors add to the impression that this crying is gastrointestinal in origin; the abdomen may be hard and distended, and the crying bout may include regurgitation and passing of gas per rectum. The third defining dimension is that the crying bouts are described as "paroxysmal" in that their onset can be sudden and unpredictable, beginning and ending without warning, and seemingly unrelated to other events in the environment.

These clusters of characteristics have been interpreted as features of a distinct clinical syndrome, but because they are qualitative and continuous, it is difficult to determine whether one infant has colic, whereas another does not. By far the most widely used quantitative definition of colic is the one proposed by Wessel and his colleagues known as the "rule of threes."[4] Infants are considered to have colic if they cry for more than 3 hours a day for more than 3 days a week for more than 3 weeks. Because few parents or clinicians are willing to wait 3 weeks before something is done, the third criterion is often dropped (modified Wessel and colleagues' criteria). This definition has provided a useful benchmark for comparing samples across studies in controlled trials of colic, but it has significant limitations in clinical settings. First, the amounts of crying designated by the definition are arbitrary, so there is no obvious reason why an infant who cries slightly less than 3 hours a day should be considered not to have colic, whereas an infant who cries slightly more should be considered to have colic. Second, it takes no account of parents who work hard to calm their infant compared with parents who let their infants "cry it out." Third, the definition does not take account of the quality of crying. Evidence concerning whether there is an acoustically specific colic cry remains controversial,[7–10] but it is clear that differences in the quality of cries contribute to whether an infant is brought to the clinician with a crying complaint.[7]

TABLE 13-1 BEHAVIORAL CHARACTERISTICS OF COLIC SYNDROME

DIMENSION	DEFINING FEATURE
Age dependent	Age dependent: total daily crying tends to increase in the first 2 mo, then decline in months 3 and 4
	Diurnal: crying tends to cluster in the late afternoon and evening
Behavioral	Common: crying occurs in prolonged bouts; some crying bouts are resistant to soothing
	Variable: clenched fists; legs flexed over abdomen; back arched; flushed face and skin; active, grimacing face ("pain facies"); hard, distended abdomen; regurgitation; passing gas (burping, per rectum)
"Paroxysmal"	Bouts can be sudden, begin and end without warning, and be unrelated to environmental events

However, the main reason Wessel and colleagues' definition is not very helpful clinically is the robust evidence that most cases of colic, however defined, represent infants at the upper end of a spectrum of crying in normally developing infants rather than a distinct syndrome indicative of underlying organic disease in the infant or psychopathology in the caregiver. Three lines of evidence support this basic concept of colic. First, all of the phenomena thought to be defining of colic are present in infants without colic, except that they are less in amount, duration, or intensity.[11] For example, an age-dependent and diurnal pattern of crying is typical of most infants in most caregiving settings studied,[12–14] including infants of the !Kung San hunter-gatherers of Botswana[15] and infants in Manali, India.[16] Furthermore, in otherwise well infants born 8 weeks prematurely, the crying curve peaks at about 6 weeks corrected age rather than 6 weeks after birth.[17] The other behaviors associated with crying, including crying after a feed, abdominal distention, and showing a "pain facies," also occur in infants without colic but slightly less frequently.[7] Infants with colic are more likely than controls to have crying bouts that are unsoothable, but their frequency is proportional to their overall amount of crying.[18] In sum, the crying pattern of infants with colic is continuous with, rather than distinct from, that of normal infants. The second line of evidence is that most cases of colic occur in the absence of detectable disease in the infant or the parent. Current estimates from admittedly imperfect data suggest that organic diseases are associated with colic in about 5% of cases (higher in referral settings) (Table 13-2).[2,6,19,20] Similarly, most cases of colic cannot be accounted for by parental inexperience, postpartum depression, or deficient caregiving. There is no difference in crying amounts between firstborn and later-born infants, even though first-time parents bring their infant to the physician with this concern more often.[21] Emotional lability in the third trimester is no different in mothers whose infants later have colic,[22] and they show similar affection, are as interactively sensitive, and hold and soothe their infants more compared with other mothers.[18] The third line of evidence is the remarkably consistent pattern across available follow-up studies showing that the physical and emotional outcomes for the infant with colic in low-risk families do not differ from those of controls.[23,24] However, colic appears to be a risk factor for the mother's emotional state, her confidence as a caregiver, and her perception of her infant, especially in high-risk families.[18,23,25–27]

It has been suspected for some time that a small number of infants who present with an otherwise typical colic syndrome continue to have persistent crying well beyond the first 3 months of life, when most colic has subsided.[26,27] These infants most often have associated prenatal, perinatal, and family risk factors and often manifest associated sleeping and feeding problems and breakdown in the usual mother–infant interaction patterns. Because of these features and the persistent crying, this pattern of early crying has been dubbed the "mother-infant distress syndrome."[28] In addition, however, increased crying and complaints about crying can arise after the first 3 months in infants who did not have colic previously.[29,30] Of the 1 in 16 infants whose crying is at levels consistent with "colic" at the end of 3 months of age, about half also had colic at 6 weeks ("persistent" cases), but the other half had not had colic previously. In summary, what has in the past been called "colic," quite nonspecifically, probably included at least three groups of infants: (1) those with the typical

TABLE 13-2 ORGANIC DISEASES PRESENTING WITH "COLIC-LIKE" SYNDROME

DISEASE STATES	STRENGTH OF EVIDENCE	ESTIMATED PREVALENCE*
Cow's milk protein intolerance	Strong	< 5%
Isolated fructose intolerance	Strong	Rare
Maternal drug effects (especially fluoxetine hydrochoride [Prozac])	Strong	Unknown, changing
Anomalous left coronary artery from the pulmonary artery	Strong	Very rare
Infantile migraine	Moderate	Rare
Reflux esophagitis	Moderate	Rare
"Shaken baby" syndrome	Moderate	Difficult to distinguish cause and effect
Congenital glaucoma	Weak, but suggestive	Rare
CNS abnormalities (especially Chiari type I malformation)	Weak, but suggestive	Rare
Urinary tract infection	Weak	Probably rare
Lactose intolerance	Very weak	Probably not etiologic

CNS = central nervous system.
*In primary care settings.

behavioral syndrome of early increased crying; (2) a subgroup of infants, often with additional risk factors, whose high levels of crying (and feeding and sleeping problems) persist; and (3) a new group of infants with increased crying that develops after the first 3 months. Respecting the developmental nature of these syndromes and their origins, the term *colic* will be reserved for the behavioral syndrome of early increased crying, *caregiver-infant distress syndrome* for later increased crying, and *persistent caregiver-infant distress syndrome* for those who had increased crying both early and later.[29]

An understanding of colic syndrome as a collection of behaviors that normally developing infants do rather than a specific condition that infants have forms the basis for a practical clinical approach to the problem. First, if there is no distinct syndrome, crying complaints need to be addressed regardless of whether they meet definitional criteria for colic syndrome. Second, even if most cases are explained by normal developmental processes, the importance of identifying those cases in which organic disease causes a colic-like syndrome is not diminished (see Table 13-2). Coexistent disease most likely exacerbates the pattern of increased crying that would be present even in the absence of disease. There are two important clinical consequences. First, even successful treatment of a coexisting disease may only reduce, but not eliminate, increased crying, depending on when it is introduced. Second, irrelevant treatment introduced when crying would diminish anyway may be inappropriately interpreted as effective.

NORMAL SPECTRUM OF CRYING AND COLIC

In controlled studies, a number of behavioral characteristics of infants representing the upper end of the crying spectrum with the behavioral syndrome of colic have been described. As a group, these infants do cry for more hours a day than control infants, independent of parental reporting bias.[31] Crying tends to cluster in the evening, but infants who cry more in the evening also tend to cry more during the rest of the day.[32,33] The quantitative increase is due primarily to longer crying bout lengths rather than increased crying frequency,[7] although some infants with colic may cry more frequently as well.[34] In infants who meet Wessel and colleagues' criteria,[4] not only are the daily duration and bout length longer, but also the facial activity is greater when crying. The cries tend to be perceived as more intense, urgent, grating, and sick-sounding, with higher, more variable fundamental frequencies and more dysphonation under some conditions.[7,8,35] In a significant proportion of infants whose parents complain about crying, the quantity of crying (daily duration and bout length) is the same as in infants who do not meet the criteria for colic.[7,31] Nevertheless, the quality of crying may be different, and it tends to be perceived as "sick-sounding" after meals.[7] This is not simply parents being anxious about their infants because it probably reflects acoustic differences in the structure of the cry sound.[10]

There have been occasional reports of differences in the crying pattern in some infants: formula-fed infants[33] or infants who are "switched" from breast to formula feeds[36] may have a "flatter" within the day distribution (more crying in the morning, less in the evening) and/or the age-related peak may occur earlier.[37] Unfortunately, there are no systematic studies of crying characteristics of infants whose colic has been demonstrated to be due to gastrointestinal disease. In case reports, the crying tends to be characterized as severe, the pattern of evening clustering within the day is often absent, there are almost always other symptoms and signs in addition to the increased crying, and the crying often does not resolve by the fourth month of life.[2,6,38–40]

Many of the features of crying behavior in infants with and without colic are understandable in light of the normal organization of infant behavior in the first few months of life. Infant behavior is not organized as a continuum of arousal but rather as a set of discontinuous and distinct modes of behavior reflecting the organism's "behavioral state,"[41,42] of which crying is one. Three important features of behavioral states are that (1) they are self-organizing in the sense that a state is maintained until that pattern of events occurs that results in a shift to another state, (2) they are relatively stable over time (minutes rather than seconds), and (3) a stimulus experienced in one state has a different effect when experienced in another state. In Wolff's classification, the crying state is defined in terms of persistent cry vocalizations (from whimpering to loud screaming), diffuse motor activity or a rigid extended trunk posture, resistance of limbs to passive movement, and a facial crying grimace sometimes accompanied by flushing.[42] Wolff notes that a specific aspect of the behavior of human infants not seen in other animal young is that crying and the accompanying rhythmic limb movements frequently continue after the removal of the offending stimulus.[42] Fussing is conceptualized as a state of transition, characterized by intermittent vocalizations and less intense and nonrhythmic motor activity.[42] Waking activity is characterized by bursts of generalized motor activity and by open eyes. Occasional moaning, grunting, or whimpering can occur, but it is always unsustained.

The features of vocalization, motor behavior, facial expression, and vascular reactivity that characterize crying as a self-organizing state closely parallel the clusters of behavior that are typical of colic but are distinct from the negative vocalizations of common fussing and intermittent crying. Because it is a different state, a soothing stimulus applied to an infant who has just begun to cry but whose crying state is not yet organized is more likely to abort the transition from awake activity to crying than if it were applied after the crying has become sustained. Consequently, crying vocalizations can become incorporated into a behavioral state of the child that is prolonged, self-sustaining, and resistant to soothing. This may explain why the sustained, unresponsive "crying of colic" appears to be distinct from normal crying while at the same time occurring in otherwise well infants. The behavioral state concept also helps to explain why a soothing maneuver successful for the unsustained whimpering of fussiness might fail if initiated after the infant's behavior has become organized into a crying state. In general, the problem of

colic may be the problem of understanding the conditions that provoke or terminate the crying state, not just crying vocalizations.

As with other behavioral states,[42,43] the prevalence and precipitating determinants change over developmental time as a function of physiologic reorganization of the child. As such, the rapid growth and differentiation of the central nervous system during early postnatal life are probably important determinants of colic syndrome. Infant behavioral states other than crying also undergo parallel significant changes during the second to fourth months of life, including periodic organization of sleeping and waking[42,44] and emergence of alert activity.[42,43] These organizational shifts probably reflect periods of increased stability for some states and unstable transitions to other newly emerging states. In particular, increasing stability for the waking states results in fewer disruptions by extrinsic or intrinsic perturbations. The decline in crying following the early peak at 2 months probably represents one manifestation of increasingly stable wakefulness.

The development of cognitive, affective, and motor functions makes maintenance of a stable state of noncrying wakefulness less dependent on environmental factors. For example, during the first 3 months, the infant becomes more responsive to environmental stimuli such as the human voice (compared with nonhuman sounds) and human figures (compared with visual distraction in general).[42] The onset of the social smile at about 6 weeks prolongs infant interaction with caregivers and stabilizes alert waking states. The increase in thumb sucking permitted by newly developed hand control allows the infant to achieve a quiet awake state through coordinated rhythmic motor activity.[45,46] In general, the infant's increasing competence provides more options for self-regulation of state in the second and third months. Thus, the infant's maturing, increasingly stable waking states may explain the spontaneous remission of colicky behavior as a manifestation of normal developmental processes, which most hypotheses postulating pathogenetic factors fail to do.

If changing organization of behavioral states accounts for most of the manifestations of early crying, then one might expect similar nonpathogenic changes in other states as well both in infants with and without colic. This appears to be true for a number of behavioral and physiologic systems. Infants with colic do have lesser amounts of sleep overall,[47–49] which, when adjusted for the "trade-off" with the increased crying, appears to be different only at night.[49,50] However, sleep architecture measured by all-night sleep recordings is no different in infants with and without colic either at 2 months or after colic has resolved at 7 months,[50] implying that this does not represent a disordered physiologic condition. Furthermore, sleeping less in the early weeks does not predict less sleeping in the remainder of the first year, nor is being a "high fusser" or a "high crier" in the first 3 months related to total sleep at 9 months or sleeping through the night.[51] Neither are there any differences for high, middle, or low frequencies in heart rate variability during sleep at 2 or 7 months of age, suggesting that colic syndrome is not associated with an "imbalance" of the sympathetic and parasympathetic autonomic systems.[52] Finally, despite almost twice as much crying and fussing, infants with and without colic show no differences in heart rate, vagal tone, or salivary cortisol secretion to the moderate stress of a mock physical examination.[49] The one apparent difference is that the pattern of diurnal rhythm in salivary cortisol secretion is "flatter" in infants with colic, although the overall daily secretion is the same.[49]

Considering colic as the upper end of a spectrum of otherwise normal crying behavior implies that complaints about crying will also be generated for behavior that does not meet clinical criteria, however defined, for "colic." Amounts of crying are not the only reason that it is brought to attention, in part because crying, whether increased or not, can have different meanings to caregivers. Despite no overall differences in crying, parents of firstborn infants are more likely to bring it to the attention of clinicians.[21] It is clear that some parents are not concerned even in the face of excessive amounts of crying and that the majority of crying complaints do not meet the clinical criteria for colic.[7,34] Often the amounts of crying in these latter infants do not differ significantly from control infants,[7,53] although it remains possible that the quality of the crying could be different, at least in some situations.[10] Interestingly, however, parents of infants with lesser amounts of crying may feel more feelings of anger and nervousness and of being rejected by their infants, whereas those with higher amounts do not.[53] However, infants with higher amounts of crying are more likely to have less optimal behavioral interchanges during feedings and diaper changes when infants are not crying, especially with fathers, than infants who cry less.[54]

PATHOGENESIS

Candidate pathophysiologic determinants should help explain both the early increase in crying and its subsequent decline, the most reliable features of crying in infants both with and without colic.[4,13,14,21,45,55] Second, they should help explain why crying during the day is not random but tends to cluster in the evening hours ("evening colic"). Third, bout length, but not frequency of crying, is amenable to change in normal infants.[14,45] In contrast, infants with colic lack the ability to calm, resist soothing, and have crying episodes that are difficult to terminate after they start.[56] Consequently, the mechanisms underlying colic probably relate to intrinsic or extrinsic proximal factors that tend to maintain rather than initiate crying bouts.

Feeding and Colic

The hypothesis that dietary factors have a significant role in the pathophysiology of colic stems from observations that feeding disruption or lack of calming follows feeding in infants with colic and that crying appears to lessen if the diet is changed to reduce exposure to cow's milk protein. In fact, however, the therapeutic success of a formula change is usually very difficult to distinguish from the normal developmental evolution of crying. The dietary factor most commonly implicated in colic relates to intolerance

to protein components, but plausible mechanisms underlying feeding-colic relationships could implicate both protein and carbohydrate nutrients as well as non-nutrient determinants related to motility, gut hormones, feeding behavior, and their interactions.

Nutrient Determinants

Protein Intolerance. Dietary cow's milk proteins are presumed to act as antigenic stimuli of a gastrointestinal hypersensitivity reaction. If this were true for most infants with colic, then change or modification of the ingested protein to a less antigenic form should reduce the colicky behavior. In breast versus formula comparisons, two contradictory predictions are possible, depending on the operative mechanism. On the one hand, formula-fed infants should develop colic because of the high concentration of potentially antigenic protein. On the other hand, breastfed infants are exposed to lower concentrations of antigenic protein but may be more likely to have colic owing to increased hunger and crying from insufficient milk. In controlled studies, neither prediction has been confirmed. In fact, the prevalence, pattern, and amount of crying associated with colic have been similar in both breast and formula feeders in referred and nonreferred infants.[36,55,57–59] However, if there is an earlier peak and a flatter, within the day pattern of crying,[33,37] this could be, in principle, related to the higher concentration and/or more uniform delivery of potentially antigenic cow's milk proteins.

Most likely, this lack of difference could have occurred because cow's milk protein is passed in breast milk.[60] The most likely and possibly most antigenic cow's milk proteins, β-lactoglobulin and casein, are found in human milk but in concentrations (up to 33 ng/mL) that are much lower than the mg/mL concentrations typical in infant milk-based formula.[61–63] However, potentially antigenic bovine immunoglobulin G (IgG) occurs at comparable levels in human and cow's milk samples, shows marked individual variability between mothers, and tends to be higher in the milk of mothers who report colic symptoms in their infants.[61] Finally, variables such as socioeconomic status, infant care, and attitudinal differences probably covary with the choice of feeding, making it difficult to identify independent effects attributable to diet. Nevertheless, the clinical impression of crying differences in breast- and formula-fed infants is not substantiated when such potential confounders are controlled.[36]

Intolerance to cow's milk protein could be implicated by immunologic or local toxic mechanisms. The quantity of ingested antigen, the relative permeability of the small intestine to dietary protein that is greater in infants with colic,[64] and reduced secretory immunoglobulin A typical of the infant may predispose patients to dietary antigen sensitization. True cow's milk hypersensitivity occurs in recognized clinical syndromes,[33,65,66] but there are only indirect data relating it to colic. Typical manifestations of gastrointestinal hypersensitivity (such as vomiting and diarrhea) are not part of the colic syndrome, colic is rarely encountered in other protein intolerance syndromes,[66] and there appears to be no specific immunologic marker associated with colic symptoms.[33] The incidence of family atopic history and other atopic manifestations is not increased in patients with colic.[24,55,58,67] However, the confusing spectrum of clinical presentations of hypersensitivity reactions,[33,68] the number of potential protein antigens in cow's milk (about 20), the lack of correlation between symptoms and permeability,[64] the possible contributory role of other digestive products (see below), and the variety of possible humoral or local and systemic cellular mechanisms make the confirmation of a specific immunologic relationship to colic very difficult.[6,67] Evidence of increased plasma cell content in the lamina propria of small intestinal mucosa in response to milk challenge has been reported in infants with colic and with other milk protein intolerance syndromes consistent with an immunoglobulin E–mediated hypersensitivity reaction.[69] Both immunologic and toxic mechanisms imply tissue damage in the intestine, for which the evidence is mixed. Both circulating motilin and permeability to human α-lactalbumin are increased in infants with colic, but fecal α_1-antitrypsin, hemoglobin concentrations, and fecal calprotectin levels are not.[64,70–72] The apparent inconsistency could be because motilin levels and permeability may index gut immaturity rather than pathology.[64,70] Evaluation of the role of dietary protein has been improved by increasingly careful reports of controlled diet trials. Conflicting findings and limitations in the designs of these studies continue to hamper their interpretation.[2,73] Evans and colleagues reported no symptomatic improvement in breastfed infants despite a measurable reduction in the presence of cow's milk antigen in breast milk on control days.[67] However, Jakobsson and Lothe and their colleagues did report symptomatic improvement in select subgroups of infants with colic symptoms with elimination of cow's milk from the diet of the infant or mother in formula- and breastfed infants, respectively.[74,75] In three breastfed infants, symptomatic improvement occurred in association with a reduction in detectable β-lactoglobulin in the breast milk.[62] In a subgroup of infants with severe colic dramatically responsive to casein-hydrolyzed formula, Lothe and Lindberg reported a recurrence of significant crying when given a 1-day challenge of bovine whey compared with human albumin protein.[39] A subgroup of referred formula-fed infants had fewer "colic" symptoms on a 1-week soy formula than on a standard cow's milk formula, with about 70% of these infants fulfilling study criteria for intolerance.[76] In a more generalizable but still selected double-blind study of referred breast- and formula-fed infants, a statistically significant and clinically meaningful reduction in crying (> 25%) was reported when the infants were placed on a low-allergen diet, but the improvements were most apparent (although not statistically significant) for the subgroup of breastfed infants younger than 6 weeks of age whose mothers were placed on a severely restricted low-allergen diet.[77] In a small open-label follow-up study, similar results were reported when mothers received amino acid–based supplements to provide sufficient caloric intake.[33] In the most carefully designed triple-crossover

study comparing cow's milk and hydrolyzed casein formulas, Forsyth reported a statistically significant overall reduction in crying and fussing when infants were on hydrolyzed casein formula compared with whole milk and a decrease in colic crying after the first change. However, only 2 of the 17 infants showed the predicted pattern of crying after each formula change, and the level of crying was still high (between 2 and 3 hours per day) even on casein formula.[78] An interesting and still unresolved question is whether the 3-day periods on casein hydrolysate formula in this study were sufficient to permit resolution of the process presumed to be causing the crying. In another small study of formula versus breast milk within the subject, there was a statistically significant but clinically unremarkable reduction in colic attacks with breast milk.[79] Finally, in two small unblinded and uncontrolled but carefully interpreted studies, Estep and Kulczycki described approximately 40% reductions in infant distress behavior in six formula-fed and six breastfed infants with colic who received an amino acid–based formula for 4 to 12 days, and all responded to a subsequent bovine IgG challenges with increased crying.[60] Interestingly, four of the breastfed infants whose mothers simultaneously followed a cow's milk protein elimination diet successfully returned to full breastfeeding after the formula "respite."

Although complicated and controversial, hypersensitivity to cow's milk protein probably does contribute to some cases of colic syndrome. It remains unclear as to whether it represents a specific mechanism for particular cases of colic-like syndrome or a mechanism that exacerbates the otherwise normal increased crying curve in the first few months of life (Figure 13-1). In the two studies in which the incidence of colic was mentioned, responders in diet trials of cow's milk elimination were estimated to account for 1 to 2% of births or 10 to 25% of infants presenting with colic.[76,79] In a prospective epidemiologic study of infants with cow's milk protein intolerance,[80] increased crying occurred in 20 to 40% of infants with cow's milk protein intolerance, but in only 4 of 65 infants (6%) was crying the main symptom. Compared with studies of nondietary constituents, diet studies tend to have smaller, more select samples from referral services, with a greater likelihood of additional symptoms (diarrhea, vomiting, weight loss) and more severe crying.[2] Consequently, formula changes are probably appropriate for a small proportion of infants with colic in primary care settings. It remains a challenge to determine to what extent protein intolerance explains crying problems brought to the physician and how cases in which protein intolerance is a factor may be selected for treatment.

Carbohydrate Intolerance and Intestinal Gas. Intestinal gas has long been considered a putative cause of colic because of the clinical association with abdominal distention, burping, and flatus. Intestinal gas may be derived from air swallowing, diffusion from the blood, and intraluminal production.[81] Air swallowing is the main source of gastric gas, which is predominantly nitrogen and oxygen. Intraluminal production of carbon dioxide derives from the interaction of hydrogen ions and bicarbonate in the small intestine and as a direct or indirect product of bacterial fermentation in the colon. Hydrogen and methane, the other major gastrointestinal gases, are produced by bacterial metabolism in the colon in adults and probably in infants.[81,82] Passive diffusion of gas between blood and lumen is dependent on relative partial pressures of the gases in the two compartments, with the probable result that carbon dioxide enters the stomach, nitrogen enters the small intestine and colon, and oxygen enters the colon. Gas is removed from the intestine through eructation, lumen to blood diffusion with subsequent expiration through the lungs, flatus, and bacterial catabolism in the colon.[81] Obligate air swallowing with sucking is thought to be exacerbated by poor feeding technique or inappropriately sized holes in artificial nipples. Crying itself may result in additional gastric gas, which remains after the crying episode itself has ended.[83] Lying supine may inhibit gas escape if the posteriorly placed gastroesophageal junction is covered by gastric liquid. Gastric accumulation itself may be irrelevant; symptoms could depend on passage of gas through the pylorus.[84]

Colonic gas produced in the gut is probably the major source of abdominal gas. Colonic bacteria use a range of substrates, but dietary carbohydrate (usually lactose) results in the most gas production.[85] Incomplete lactose digestion unassociated with clinical disease has been confirmed by breath hydrogen testing under normal feeding conditions in healthy infants and persists into the third month[82,86]; in fact, some proportion of all dietary carbohydrates is incompletely absorbed.[87] Amounts of colonic gas are influenced by a variety of factors affecting substrate levels and relative composition of bacterial flora and their function.

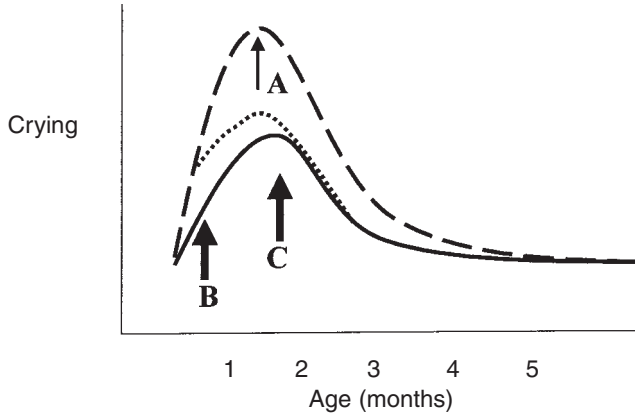

FIGURE 13–1 Probable effects of organic disease on crying pattern. The solid dark line represents the crying pattern in normal infants. If an infant has an organic condition contributing to crying, it will probably exacerbate the crying pattern (*arrow A, dashed line*). If an infant with an organic condition is appropriately treated early (*arrow B*), then the crying may still continue to increase despite appropriate treatment (*dotted line*), "rejoining" the normal crying pattern that would have occurred in the absence of the coexistent organic condition. If an infant without an organic condition is given a therapeutic trial (eg, a formula change) at a given time (*arrow C*), then crying may improve even though the improvement is unrelated to the therapy.

In principle, a primary role for colonic gas secondary to incomplete carbohydrate absorption in colic is attractive because it is consistent with the clinical pattern. The increased substrate absorption occurs at the same ages as the spontaneous reduction in crying. Evening crying could be related to the accumulation of partial, incompletely absorbed carbohydrates from the more frequent daytime feeds. The hypothesis is consistent with postfeed crying because colonic gas would still be present, even with adequate burping. However, the mechanisms by which gas produces distress are unclear. There is no significant postfeed distention in infants with colic,[7] nor is there radiologic evidence of increased intestinal gas volume.[55,83,88] Theoretically, distressing sensations could be related to changes in intestinal gas volume, producing reactive phasic gut contractions rather than a steady state of distention. Alternatively, pain may be related to motility patterns that permit retrograde gas passage from the colon.[89]

Attempts to demonstrate an etiologic role for intestinally derived gas have produced mostly negative results. Two studies have reported increased breath hydrogen excretion before and after feeding in infants whose parents reported a history of colic.[90,91] However, there is no difference in hydrogen production per gram of colonic carbohydrate (lactulose) or in mouth to colon transit,[92] nor do infants with colic differ in regard to stool pH or reducing substances.[93] In normal infants, reduced lactose intake did not reduce crying in a crossover trial.[94] There is a convincing single case of colic owing to fructose malabsorption, but the crying of this infant was severe, prolonged beyond 4 months, and accompanied by diarrhea.[40] Two trials that attempted to modify incomplete lactose absorption with oral lactase or hydrolyzed lactose milk did not reduce crying behavior.[79,95] In a large multicenter controlled trial, simethicone—a surface active agent—was ineffective, even in infants whose parents considered their symptoms to be gas related.[96] The best evidence of a possible etiologic role for incomplete lactose absorption is a randomized double-blind crossover trial that demonstrated a 1-hour reduction in crying when milk formulas were incubated for 24 hours with lactase drops in a small group of 13 infants,[97] keeping open the possibility that lactose absorption could be a factor in a few select infants.

Non-nutrient Determinants

Motility. Theoretically, alterations in intestinal motor activity could predispose the infant to colic as a direct source of abdominal distress or indirectly by affecting the distribution of intraluminal contents (including gas) in the gut. Jorup reported colonic hyperperistalsis, increased rectal pressure, and responsiveness to anticholinergics in dyspeptic infants in whom frequent stools were a prominent symptom.[88] The motility abnormalities were limited to the colon, stimulated by sucking, equally likely with breast or cow's milk, and highly variable from infant to infant. Although the frequent stools make these infants somewhat atypical, Jorup believed that most cases of colic could be accounted for by this mechanism. Newer evidence in favor of motility being implicated is the beneficial effect on colic of dicyclomine hydrochloride.[98,99] Dicyclomine may act centrally or peripherally by decreasing gastrointestinal spasm or by a direct relaxant action on smooth muscle. Unfortunately, its side effects make this drug unsuitable for use for infantile colic. A herbal tea preparation containing a number of antispasmodics (chamomile, fennel, and balm mint) has been reported to reduce colic symptoms in a controlled trial.[100] The picture remains unclear in that there are no documented abnormalities in mouth to cecum transit times in colic.[92] Furthermore, in a well-designed crossover trial to assess modifying gut motility with a fiber-enriched (soy polysaccharide) formula, the special formula reduced neither crying nor mouth to cecum or whole-gut transit.[101]

Gut Hormones. Because prostaglandins affect smooth muscle contraction and gastrointestinal motility, are present in high concentrations in breast milk, and can induce colic and diarrhea symptoms as a side effect of intravenous administration in newborns, they are candidates for proximal mediators of colic symptoms.[102–104] Which of the prostaglandins might be involved and whether the effect is local or systemic are uncertain. Most clinical syndromes in which prostaglandins are implicated involve stimulation of an intestinal secretory process with secondary motility changes. Because diarrhea is not part of the colic syndrome, a role for prostaglandins must be explained by their impact at physiologic dose levels.

A role can be proposed for several classes of hormones and transmitters found in the gut, but direct evidence is sparse. Basal motilin levels are raised in infants with colic independent of the diet, vasoactive intestinal peptide and gastrin levels are normal in colic, and all three levels are raised in other symptomatic gastrointestinal syndromes, suggesting some specificity for the role of motilin.[105] Furthermore, circulating motilin levels are elevated at birth in infants who subsequently develop colic; they are higher in formula-fed infants with colic than in breastfed infants with colic and continue to be higher throughout the first 3 months of life, but they overlap with values in noncolic controls.[70] Raised motilin levels could indicate gut disease or immaturity. By stimulating gastric emptying, small intestinal peristalsis, and shorter transit times, motilin could contribute to perceived intestinal pain or passage of intraluminal stimuli to the colon.

If dysmotility contributes significantly to colic symptoms, endogenous opioids with strong biologic effects on motility and secretion are likely to be implicated. These opioid effects should be considered in conjunction with those of cholecystokinin (CCK), which opposes the effects of opioids under many conditions. Both opioids and CCK have been implicated in the regulation of pain perception and satiety,[106] and these roles may evolve rapidly in early infancy.[107,108] Opioids may affect pain, distress, and ingestive behaviors simultaneously.[109,110] These complicated relationships may be important determinants of the developmental course of early distress behavior in human infants.

At least in infant rats, CCK is sufficient to reduce separation-induced distress vocalizations.[111] However,

CCK does not affect pain threshold in infant rats and does not, contrary to its role in adults, block morphine-induced analgesia.[112] Consequently, to the extent that the crying of infants with colic is exacerbated by separation from the mother and/or by hunger, reduced CCK might be relevant to colic behavior. Interesting evidence of possible CCK involvement in human infants with colic comes from the observation of Lehtonen and colleagues that gallbladder contractility (a function of CCK) was decreased postprandially in infants with colic, in infants who were crying at the time of examination, and in the evening.[113]

Developmental changes in the availability of melatonin and serotonin are also consistent with some of the characteristics of the crying of infants with colic.[114] The diurnal evening increase in circulating serotonin could contribute to intestinal smooth muscle contractions. Furthermore, circulating serotonin levels tend to increase during the first few months of life. Reduction in intestinal cramping could be due to the smooth muscle relaxant action of melatonin. Melatonin is present at birth,[115] after which the levels decline and then increase to develop diurnal evening elevations at about 3 months of age.[114]

Taste-Mediated Calming. Dietary intake is also implicated in proximate mechanisms to recruit physiologic systems to soothe already crying infants. In infant rats, small amounts of sucrose, polycose, corn oil, or milk formula applied to the tongue eliminate separation-induced distress vocalizations, mimicking the effect of opiates, and these responses are blocked by opioid antagonists.[109,110,116,117] In human infants, similar quieting effects have been demonstrated for sucrose and some other carbohydrates.[118–123] The sucrose effect has been shown to be due to the sweetness (or possibly positive hedonic properties) of the taste stimulus.[32,118,122] The calming effect of sucrose is specifically dependent on a normally functioning central opioid system in human infants as well.[120,124,125] The possibility that changes in a central opioid-dependent calming system might be related to early increased crying is suggested by the fact that this sucrose-induced quieting effect is gradually reduced over the first 6 weeks of life, when crying duration tends to increase.[119,126] Furthermore, the longer crying bouts typical of infants with colic implicate a less efficient distress reduction system. Indeed, when the response to sucrose taste was compared in equivalently crying infants with and without colic at 6 weeks, sucrose taste was less effective in infants with colic.[127] Consequently, developmental changes in the availability of such systems to taste stimuli, frequency of feeding, and individual differences in effectiveness may all contribute to differences in the ability to calm between normal and colicky infants. Furthermore, these findings implicate nongastrointestinal central distress reduction systems as contributory to the behavioral manifestations of colic.[128]

Biobehavioral Interactions. Gastrointestinal and behavioral systems may be complementary modulators of crying behavior. Species in which the protein and fat content of breast milk is low demonstrate low sucking rates, frequent feeding at short intervals, and continuous proximity to their source of food ("carrying species"), whereas species with high protein content in breast milk exhibit the opposite behaviors ("caching species").[129] Extrapolating from human breast milk composition, human infant sucking rates are (and caretaking should be) characteristic of carrying species. Small, frequent feeds might, for example, reduce hunger cries, result in less fermentable substrate being delivered to the colon and increased CCK being released, and elicit taste-mediated calming and increased rhythmic sucking. Indeed, !Kung San hunter-gatherers practice close mother-infant contact, constant carrying, upright posture, immediate responsivity, and frequent feeding (approximately four times per hour).[130] These features might all be expected to reduce crying behavior. Interestingly, crying in !Kung San infants also has an early peak and occurs with the same frequency but is about half the duration of crying in Western infants.[45] These findings support the concept that there is an early, maturationally based predisposition to cry but that prolonged crying bouts are amenable to change by biologic and behavioral factors associated with caregiving style.

Caregiving Style. Because colic tends to be unresponsive to maternal interventions, the concept that gastrointestinal factors rather than caregiving style or mother–infant interaction are determinants of colic tends to be accepted. However, systematic observation confirms the common wisdom that caregiving practices such as carrying and rocking are effective in shifting arousal to states of increased visual and auditory alertness and producing persistent soothing effects.[42,56] Psychologically significant interventions (eg, human voice and figures versus nonhuman sounds and visual distraction) become increasingly important as effective soothing agents during the early months.[42] In fact, the diminished effectiveness of sucrose taste at 2 and 4 weeks can be restored if the sucrose is delivered in combination with eye to eye contact from the caregiver.[131] The use of a pacifier to induce an organized rhythmic motor pattern will attenuate the crying state in response to pain[73,132] and reduce spontaneous crying.[42] However, crying owing to hunger is arrested only by gastric filling, not by sucking and swallowing.[42] In general, behaviors and environmental stimuli that involve postural change, repetitiveness, constancy and/or rhythmicity, and close proximity between mother and infant tend to maintain a noncrying state.

In two studies assessing the effects of caretaking in normal infants, crying was reduced by increased carrying and shorter interfeed intervals.[14,133] In the carrying study, crying reduction was substantial, averaging 43% for daily cry/fuss duration or 54% in the evening.[14] However, when increased carrying was tried as a therapy for colic, there was no additional benefit over that of parent counseling itself.[56] In other studies assessing the effect of modifying parental behavior, intensive parental counseling aimed at improving parental responsiveness was reported to reduce crying time by 70%, to the level seen in noncolic controls.[134] That response seemed more rapid than the response to a change of formula,[135] but this observation was not replicated.[136] In

a separate randomized controlled study, empathic interviews and advice to reduce overstimulation were reported to significantly reduce crying behavior.[137] Extensive clinical use has been made of a car-ride simulation device, but a controlled trial did not demonstrate any advantage for this technique over parental advice and reassurance.[136] As with dietary manipulations, trials of behavioral interventions have been subject to conflicting results and serious methodologic limitations, making interpretation of their significance difficult.[2] Furthermore, studied infants tend to manifest only moderately severe crying and are less likely to have been referred.[2] Consequently, firm conclusions about the effectiveness of these interventions and the selection of infants who are likely to benefit from one strategy or the other remain problematic.

Visceral Hyperalgesia and Allodynia

In light of the variety of putative mechanisms, it is clear that colic syndrome is not due to a single pathologic process, and an integrated model of pathogenetic processes is not close at hand. However, a plausible integrative hypothesis for the processes underlying colic phenomenology is that colic behavior reflects visceral hypersensitivity to otherwise innocuous intestinal stimuli, where the hypersensitivity is due to developmental processes and minor insults that alter afferent mechanisms and/or changes in the excitability of central neurons onto which these afferents project. The related concepts of visceral hyperalgesia and allodynia are analogous to mechanisms well described in the skin and possibly implicated in other gastrointestinal syndromes such as nonulcer dyspepsia, recurrent abdominal pain, and irritable bowel syndrome in which evidence of organic disease is absent.[138] Hyperalgesia refers to a reduced pain threshold and/or a greater or longer duration of response to a painful stimulus. Allodynia refers to painful or discomforting experiences owing to stimuli that do not normally produce pain or discomfort. Thus, intestinal distention, reflux of gastric contents, or changes in motility that would not normally be painful or discomforting were sensed as such.

Hypersensitivity of afferent mechanisms can occur owing to changes in the sensitivity of the primary afferent neurons in which noxious stimuli "alter the gain" of the afferent system through the action of chemical mediators that might be activated by inflammation or repeated noxious procedures.[138,139] On the one hand, this altered sensitivity changes the sensory information transmitted to secondary, dorsal horn neurons; on the other hand, it may affect reflex loops that regulate a variety of functions of the enteric nervous and gut effector cell systems, including motility, secretion, and blood flow. Afferent hypersensitivity can also be due to central hyperexcitability in dorsal horn cells. This central hyperexcitability would most likely be responsible for allodynia. These processes could be activated even in young infants. In general, excitatory pathways mature early and continue to mature postnatally. Inhibitory influences develop later. Both local inhibitory interneuronal connections in the substantia gelatinosa and the functional development of descending inhibition from the brainstem are all postnatal events, at least in the rat and probably in humans.[140]

There are a number of reasons why such mechanisms might be germane to the pathogenesis of colic. First, they provide a plausible way of understanding how such apparent discomfort can be expressed in the absence of detectable signs of disease, as is the case for most infants with colic. Second, visceral hyperalgesia and allodynia can persist long after the initial stimulus but can still be transient.[141] This finding is consistent with current evidence that colic does not have persistent effects on health and later development.[23] Third, descending cortical modulation is considered to play an important role in governing the excitability of dorsal horn neurons, especially in regard to pain perception.[138,142] This modulation inhibits excitatory tone so that in its absence, resting activity and responses to various sensory inputs to spinal dorsal horn neurons are increased. Fourth, central hypersensitivity can persist beyond the initiating stimulus (such as inflammation or repetitive noxious stimulation) and can be associated with reduction in thresholds and increases in the receptive field size of the dorsal horn neurons, allowing innocuous stimuli to excite previously unexcitable nociceptive pathways.

Such mechanisms help to explain why many disparate factors described previously (eg, protein intolerance, gas, motility differences) might cause discomfort without any one of them being wholly responsible for the behavioral manifestations of colic syndrome. Of specific interest for infants in general, but especially for those with colic syndrome, is that the maturation of these inhibitory systems is delayed relative to the functional maturity of the afferent systems.[141,143,144] Until these inhibitory systems are fully in place, infants may be predisposed to being more sensitive to otherwise innocuous stimuli. The evening clustering could be a function of the relatively increased density of sensory input to centrally hyperexcitable neurons during daylight hours. The developmental course of colic syndrome, specifically the decline in crying behavior, could be a function of modulation by increasing maturity of local inhibition owing to interneuronal synaptogenesis in the spinal cord and of descending inhibitory systems from the brainstem and cortex as the infant matures. Much less is known about the maturation of cortical pain systems, but the relative delay of inhibitory connections compared with excitatory connections appears to be a general pattern there as well.[140]

MANAGEMENT OF EXCESSIVE CRYING OR COLIC

Our current understanding of the mechanisms for excessive and prolonged crying in infants is incomplete, but the problem demands a well-conceived management strategy. Because of the continuity between the crying of infants with and without colic, the following strategies are suggested for treating all patients with excessive crying, whether or not they meet Wessel and colleagues'[4] or other diagnostic criteria. It frequently falls to the gastroenterologist to provide that management and care, which should be based on the mechanistic concepts outlined above. Early

attention should be directed to the detection of a specific disease and its treatment, while paying attention to the needs of the caregivers and the potential dangers (such as "shaken baby" syndrome) for the infant.

EARLY CRYING EXACERBATED BY SPECIFIC DISEASE PROCESSES

Treatment will depend on whether a specific disease is detected. It is rare for gastroenterologists to see such patients who have not already been considered to have a dietary intolerance or allergy or trial of various diets. By far the most common organic diagnosis is dietary protein intolerance or, more specifically, cow's milk protein intolerance. Clinical clues to this diagnosis include hyperperistalsis immediately after intake of cow's milk, persistent vomiting and/or diarrhea, weight loss, blood in the stool, and the persistence of symptoms beyond the usual peak period of crying. These symptoms favor a clinical trial of removal of milk formula from the child's diet or milk from the diet of a breastfeeding mother with or without temporary substitution of an amino acid–based formula for the infant.[60] Response should be monitored closely. If lactogenesis is carefully maintained, breastfeeding infants temporarily placed on a formula substitute can usually be returned to full breastfeeding.[60] In formula-fed infants, formulas should not be frequently switched, nor should they be changed simply for their placebo effect.[57]

EARLY INCREASED CRYING WITHOUT SPECIFIC ORGANIC DISEASE

Treatment should be focused on reducing the infant's crying and allaying the stress experienced by caregivers. Several of the measures below apply equally to children who also have a specific organic disease. With regard to reducing crying, current evidence supports the following:

1. Crying may be reduced temporarily by various behavioral interventions, but it is not likely to disappear until the infant is mature enough that his or her own regulatory controls on crying become more efficient.
2. Evidence for the effectiveness of medications is adequate only for dicyclomine hydrochloride.[98,99] However, this is no longer recommended for colic because of potentially hazardous side effects. In a single randomized double-blind placebo-controlled trial, the anticholinergic drug cimetropium bromide was used, not to prevent colic but to treat individual colic "crises," defined as inconsolable full-force crying bouts with associated behaviors (legs flexed, closed fists, meteorism) that are unresponsive to behavioral soothing measures.[145] Consequently, whereas the number of bouts were the same, the duration of bouts was reduced from 48 minutes to 17 minutes on average. The only reported side effect was increased sleepiness. Cimetropium bromide is a synthetic derivative of scopolamine, an anticholinergic agent, and its safety in infants has yet to be established. Other treatments for which there is no supportive evidence include alcohol, phenobarbitol, and/or anticholinergic combinations.[146,147] "Gripe water," the active ingredients of which are sodium bicarbonate and alcohol, may increase gastric gas through contact with gastric acid, thus stimulating burping,[148] but its effectiveness remains untested. There is no demonstrable benefit from simethicone, an "antigas" medication.[96]
3. Many commercially available devices (eg, crib shakers, heart sounds) provide stimulation analogous to that provided by more contact time with a caregiver. Temporary soothing is accomplished by anything that provides relatively constant background motion or sound. Many household devices (eg, fish tank aerators) can be used for this purpose. Placing the infant on a clothes washer or drier is contraindicated because of the danger of serious injury from falling off owing to the vibrations.

Reducing the psychological pressure on the caregiver is the most important component of management. Current evidence supports the following strategies:

1. Acknowledge the reality of the concern, regardless of the amount of crying.
2. Provide information for the parents aimed at reducing anxiety and anger at the infant attributable to not knowing basic facts about early crying and colic syndrome. First and foremost, make it clear that crying (a) increases into the second month, (b) is continuous with the behavior of infants with less crying, (c) is a universal behavioral phenomenon in normally developing infants, and (d) is not associated with organic disease (in the absence of other symptoms and signs). To quickly and efficiently provide this information about the normality of early increased crying, the National Center on Shaken Baby Syndrome (<www.dontshake.com>) sponsors educational campaigns on "the period of PURPLE crying." Each of the letters in the word "PURPLE" refers to a property of early crying that increases anxiety and angers caregivers, namely, P for peak pattern, U for unpredictable occurrence of crying bouts (or "crises"), R for resistance to soothing, P for pain-like facial grimace, L for long crying bouts, and E for evening clustering.
3. Suggest that a diary of crying and weight gain be kept.[149] A typical diurnal crying pattern and weight gain argue against underlying organic disease.
4. Determine the sources of pressure on the primary caregivers (eg, "significant other," parents-in-law, friends, or internalized cultural beliefs) and attempt to alleviate them.
5. Provide explicit "boundary" suggestions about inappropriate responses, no matter how problematic the crying. Should it seem too much to handle, it is important to stress that physically shaking the infant is never appropriate. Removing oneself from the infant and having someone to call are important alternative strategies.
6. Regular respite for the primary caregiver is best provided by the significant partner if available, especially for crying periods during the night. Other family members and baby-sitters are useful but must be educated about the "PURPLE" crying characteristics and the importance of

not shaking the infant. The primary caregiver may resist help, believing that the infant needs her in particular.
7. In severe cases, especially if the crying is occurring in the context of a fragile and otherwise challenged family, referral to specialized clinics or services is indicated. The increased crying may unmask caregivers and families with significant issues that need attention, as well as being a useful reason for the family to seek help.

INEFFECTIVE OR UNPROVEN TREATMENT STRATEGIES

Some erroneous assumptions concerning colic, derived from cultural and medical lore, have achieved the status of facts on which ill-advised management may be based:

1. Neither crying and fussing nor colic is more common in breast- or formula-fed infants. Possibly, crying in formula-fed infants peaks earlier than crying in breast-fed infants.[21] Changing from breast milk to formula does not reduce colic.
2. By including sham diaper changes, Wolff showed that wet diapers were not a sufficient cause of infant crying.[43]
3. Leaving the infants to cry out so that they learn to control their crying is not effective. Being responsive to the infant does not "spoil" the infant. The strategy of not responding to a crying infant because the infant would be "spoiled" is based on an operant conditioning/learning paradigm. To leave the infant is difficult and ineffective,[134] and there is no evidence to suggest negative consequences from responding. Indeed, pregnant women who were concerned during pregnancy about "spoiling" with too much physical contact had an increased risk of having an infant with colic.[34] Immediate responsivity and cuddling activate multisensory channels that soothe crying infants; this interaction should be responsive to the infant rather than intrusive.[137] A good functional outcome for the crying infant involves more contact, interaction, and attempts at soothing, not less, even if this increased contact does not eliminate the crying.
4. There is no systematic evidence for, and much evidence against, the proposition that maternal personality or anxiety causes excessive crying.[22,150] However, the presence of an infant with colic in an already fragile family is likely to increase the risk of negative outcomes for the infant and the family.[23,151]
5. One should not discount reports of excessive crying as attributable to bias in reporting by overconcerned or anxious mothers. Of course, maternal anxiety occurs with increased crying and colic, but there is no evidence that maternal reports of increased crying are exaggerated because of anxiety.[22]
6. Increased crying and colic are not more common in firstborns. Crying in the first- and subsequently born babies is identical, but mothers are more likely to bring the problem to a clinician when it occurs in firstborns.[21]
7. Although widely practiced, controlled evidence does not support massage therapy as an effective treatment for colic.[152]
8. To date, available studies on chiropractic spinal manipulation do not demonstrate that the natural course of the change in crying patterns is affected by treatment.[153]

POSTCOLIC CRYING SYNDROMES

The recognition that there is a small proportion (perhaps on the order of 5%[28,30]) of infants who have persistent caregiver-infant distress syndrome, presenting initially with colic and associated risk factors, and that another group with caregiver-infant distress syndrome develops colic-like crying levels after 4 months of age raises additional questions as to the management and approach to later crying problems. We know much less about infants with these conditions. There is at least some evidence that some infants with one or both of these conditions may be associated with carbohydrate malabsorption from fruit juices.[154] These infants, especially those with associated sleeping and feeding problems, may also have a poorer prognosis for later problems with hyperactivity and conduct problems during school years.[155] As with more typical infants with colic, it is difficult to distinguish those with contributory organic conditions from those whose distress reflects otherwise normal individual differences in temperament ("difficult temperament") or a more widely dysfunctional so-called "dysregulation syndrome of infancy."[156] Rational approaches to diagnosis and management for these infants remain a challenge.[157]

SUMMARY

Despite the lack of evidence for a primary etiologic role, the complaint of colic will continue to be considered gastrointestinal in origin until its mechanisms are better understood. Although the dilemma of responding to the distress of the infants and their parents in the absence of demonstrable pathogenesis remains problematic, it is clear that preventing negative secondary consequences such as shaken baby syndrome in the infant and depression or loss of confidence in caregivers is possible and should be considered a positive therapeutic achievement.

CHAPTER 14

ABDOMINAL PAIN

John T. Boyle, MD

ACUTE ABDOMINAL PAIN

Acute abdominal pain is a popular descriptor that has evolved from the seminal definition by Sir Zachary Cope of abdominal pain of recent onset that triggers an urgent need for prompt diagnosis and active treatment.[1] The nature of the pain is usually such that the parent seeks immediate medical evaluation by a general pediatrician or emergency room physician. An acute complaint of abdominal pain precipitates at least 5% of unscheduled pediatric visits.[2] Although most children with acute abdominal pain have self-limiting conditions, the pain may herald a serious medical or surgical emergency. The diverse etiologies include acute surgical emergencies, disorders that will or may require surgical intervention, and specific intra-abdominal, extraintestinal, or systemic medical disorders. Severe acute pain may also present against a background of chronic illness. Most often, the child appears well at presentation, and the abdominal pain is accompanied by multiple complaints and is usually associated with a self-limited disease. The major challenge is to make a timely diagnosis of the acute surgical abdomen. In patients who present with acute abdominal pain to a primary care practice or community emergency room, the frequency of diseases requiring surgical intervention may be as low as 1%.[2] A physician can easily become complacent when dealing with a child with acute pain. It is important to have a consistent approach that addresses key diagnostic categories and gives parents guidelines to recognize warning signs that require re-evaluation. The primary care physician or emergency physician will most often call on the pediatric or general surgeon for consultation when concerned about a particular presentation of acute abdominal pain. There are, however, occasions when, with indefinite symptoms, there may be a tendency to wait for evolution of an acute process, in which case, the pediatric gastroenterologist may become involved in diagnosis and management.

Pathophysiology of Abdominal Pain

Abdominal pain can be perceived by autonomic sensory pathways from the abdominal viscera; somatic sensory pathways from the parietal peritoneum, abdominal wall, or retroperitoneal skeletal muscles; or somatic sensory pathways from extra-abdominal sites that share central projections with sensory pathways from the abdominal wall (referred pain).[3,4] Visceral pain is a dull or aching sensation generally perceived in one of three regions: the periumbilical, epigastric, or suprapubic midline area. Unfortunately, pain and tenderness are not always felt immediately over the site of disease. For example, the initial pain of appendicitis is usually felt in the periumbilical or epigastric areas, whereas pain caused by obstruction of the transverse colon is usually felt in the suprapubic midline area. Somatic pain, in contrast, is usually well localized and intense (often sharp) in character. An intra-abdominal process will manifest somatic pain if an inflammatory process affecting a viscus touches a somatic organ (ie, the anterior parietal peritoneum or abdominal wall). The classic example of referred abdominal pain is the shared central projections of the parietal pleura of the lung and the abdominal wall, such that abdominal pain may be the initial presentation of pneumonia. All three types of pain may be modified by a child's level of tolerance. Psychogenic and environmental factors augment or inhibit the perception of pain to varying degrees in different individuals.

Pain arising from the small intestine, regardless of the etiology, is always felt first and chiefly in the periumbilical or midepigastric area of the abdomen. Because the appendicular nerves are derived from the same thoracic nerves that supply the small intestine, it is not surprising that the pain at the onset of appendicitis is usually felt in the epigastric or umbilical area of the abdomen. The pain of disorders affecting the cecum, ascending colon, and descending colon are characteristically first felt at the actual site of the lesion because of the corresponding short mesocecum or mesocolon. An evolving change in localization of abdominal pain is often significant. Localization of pain in the right iliac fossa some hours after acute epigastric or periumbilical pain is usually due to appendicitis, although, rarely, the same sequence is seen with perforated pyloric or duodenal ulcer or in cases of acute pancreatitis. Radiation of the pain is also frequently helpful in diagnosis. In biliary colic, the pain is frequently referred to the region just under the inferior angle of the right scapula, whereas renal colic may be felt in the testicle on the same side. Testicular pain may also occur with appendicitis. A pelvic abscess, which lies close to the bladder, or an inflamed appendix that irritates the right ureter frequently causes pain on micturition. In many cases of peritonitis, intraperitoneal abscess, or abdominal distention owing to intestinal obstruction, abdominal pain will be caused or increased on inspiration.

Differential Diagnosis

Figure 14-1 divides the differential diagnosis of acute abdominal pain into three categories: (1) conditions requiring acute surgical intervention, (2) conditions that may initially be managed conservatively but will or may eventually require surgical intervention, and (3) specific intra-abdominal, extra-abdominal, and systemic conditions that require medical management. Detailed descriptions of the clinical presentation, diagnosis, and management of the specific disorders associated with acute abdomen are discussed in other chapters. The age of the patient is particularly helpful because the incidence of certain conditions is limited within a particular range of years (Table 14-1). Figure 14-2 presents an algorithm for sequential evaluation of a patient with acute abdominal pain. By thinking and working up selected key diagnoses, rare conditions will not be missed.

Is There Evidence of a Catastrophic Event Requiring Emergency Surgery?

Catastrophic events include acute generalized peritonitis, intestinal infarction, or infarction of the ovaries or testes. Such complications may follow blunt or penetrating abdominal injury, high-grade acute intraluminal intestinal

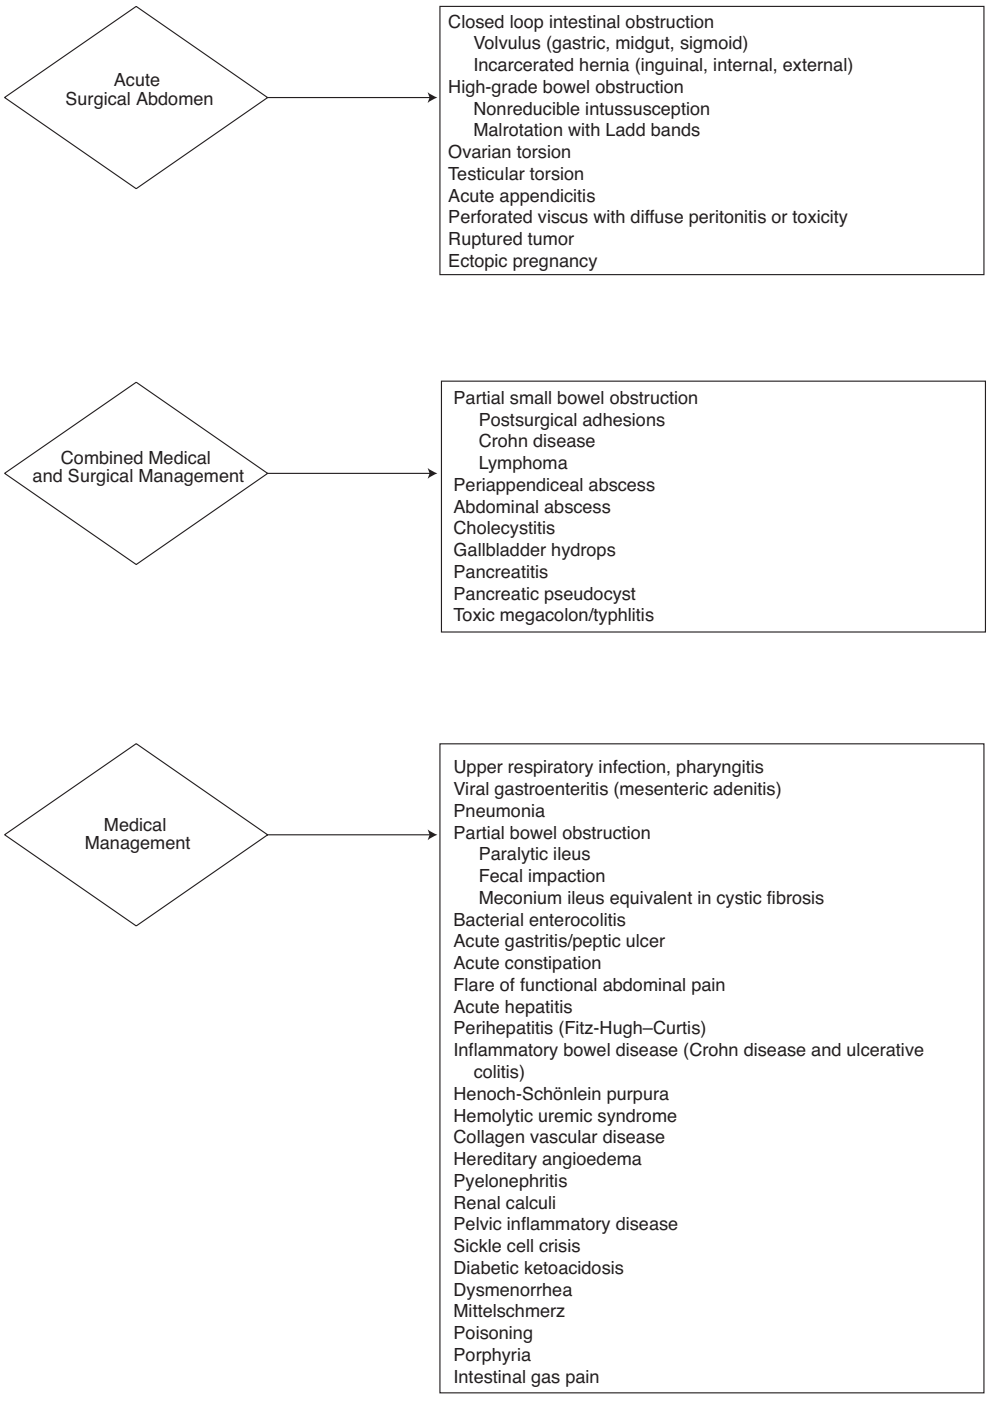

FIGURE 14-1 Differential diagnosis of acute abdominal pain.

TABLE 14-1 PRINCIPAL CAUSES OF ACUTE ABDOMINAL PAIN BASED ON AGE

NEONATE
Necrotizing enterocolitis
Spontaneous gastric perforation
Hirschsprung disease
Meconium ileus
Intestinal atresia or stenosis
Peritonitis owing to gastroschisis or ruptured omphalocele
Traumatic perforation of viscus (difficult birth)
INFANT (< 2 YR)
Colic (< 3 mo)
Acute gastroenteritis or "viral syndrome"
Traumatic perforation of viscus (child abuse)
Intussusception
Incarcerated hernia
Volvulus (malrotation)
Sickling syndromes
SCHOOL AGE (2–13 YR)
Acute gastroenteritis or "viral syndrome"
Urinary tract infection
Appendicitis
Trauma
Constipation
Pneumonia
Sickling syndromes
ADOLESCENT
Acute gastroenteritis or "viral syndrome"
Urinary tract infection
Appendicitis
Trauma
Constipation
Pelvic inflammatory disease
Pneumonia
Mittelschmerz

obstruction (intussusception), closed-loop intestinal obstruction (volvulus or incarcerated hernia), torsion of the ovaries or testes, and perforation secondary to peptic ulcer, intestinal foreign body, gallbladder hydrops, or acute cholecystitis. An obvious "sick" general appearance of a child who presents with acute abdominal pain suggests a late stage of all varieties of acute abdominal disease. A pale, ashen, diaphoretic facial appearance leaves little doubt about a serious abdominal disorder. The signs and symptoms of a catastrophic event can vary according to the time that has elapsed since the acute event has occurred. High fever is unusual in the early stages. An initial stage of generalized, continuous abdominal pain accompanied by prostration, hypothermia, retching, and vomiting is followed by a period in which abdominal pain lessens, vomiting ceases, and temperature and pulse return to normal. Sending patients home or admitting them to a general hospital ward during this "honeymoon phase" can have disastrous consequences because this stage is soon followed by a shock-like picture accompanied by high fever, abdominal distention, gastrointestinal bleeding, and generalized peritoneal signs. Well-known features of peritonitis include abdominal wall rigidity, involuntary guarding, cutaneous hyperesthesia, rebound tenderness, absent bowel sounds, positive psoas or obturator signs, and tenderness on palpation of the anterior or right lateral rectal wall during rectal examination. Rebound tenderness may or may not be a sign of a surgical abdomen. Rebound has also been reported in association with severe gastroenteritis, pneumonia, lead poisoning, and Henoch-Schönlein purpura.[1]

There is no reliable clinical, laboratory, or radiologic test that can distinguish between simple and strangulation obstruction of the small intestine.[5] Abdominal upright or decubitus plain films may show the presence of free air in the peritoneal cavity. A gasless abdomen is not uncommon in closed-loop or strangulating obstruction in which the obstructed loops are fluid filled.[6] Computed tomographic (CT) signs of strangulation include bowel wall thickening with or without target sign, pneumatosis, portal venous gas, mesenteric haziness, fluid, or hemorrhage often associated with ascites and abnormal bowel wall enhancement patterns following intravenous contrast.[7] CT may be oversensitive in diagnosing strangulation because bowel wall thickening, mesenteric haziness, fluid, and ascites are nonspecific findings that may also accompany other inflammatory processes, including appendicitis or Crohn disease.[7]

Does a Diagnosis of Acute Viral Syndrome (Gastroenteritis, Upper Respiratory Infection, Pharyngitis) Make Sense?

An acute viral syndrome is the most common cause of acute abdominal pain in any age group beyond the neonatal period.[2] Think viral syndrome when multiple symptoms, including fever, vomiting, diarrhea, decreased appetite, headache, cough, sore throat, and rhinorrhea, occur simultaneously with onset of crampy, diffuse abdominal pain. The abdomen is soft and nondistended in most cases. Although the child may perceive palpation as uncomfortable, this maneuver does not elicit localized or rebound tenderness. Bowel sounds are normal or hyperactive. Gastroenteritis may present with predominant upper gastrointestinal tract symptoms, including epigastric pain, nausea, and variable vomiting. The pain most often occurs during eating or in the immediate postprandial period. Alternatively, gastroenteritis may present with predominant lower tract symptoms with generalized, periumbilical, or lower abdominal pain associated with diarrhea. The key to diagnosis is that the pain is self-limiting and does not progress or localize.

The differential diagnosis of acute viral syndrome includes bacterial enterocolitis, food poisoning, acute infection with *Helicobacter pylori*, acute pneumonia, pyelonephritis, diabetic ketoacidosis, Henoch-Schönlein purpura, hemolytic uremic syndrome, and angioedema. Bacterial enterocolitis should be suspected by the abrupt onset of fever and diffuse abdominal pain, followed shortly by diarrhea. Small-volume, frequent stools, blood and mucus in the stool, fever greater than 102.5°F, and polymorphonuclear leukocytes in the stool suggest a bacterial rather than a viral etiology. Although the severity of the abdominal pain may simulate appendicitis, palpation of the abdomen elicits diffuse tenderness and no evidence of peritoneal irritation. Common bacterial food poisoning may present with generalized abdominal pain associated with profuse watery diarrhea (*Clostridium perfringens*), or profuse vomiting and generalized abdominal pain, followed by

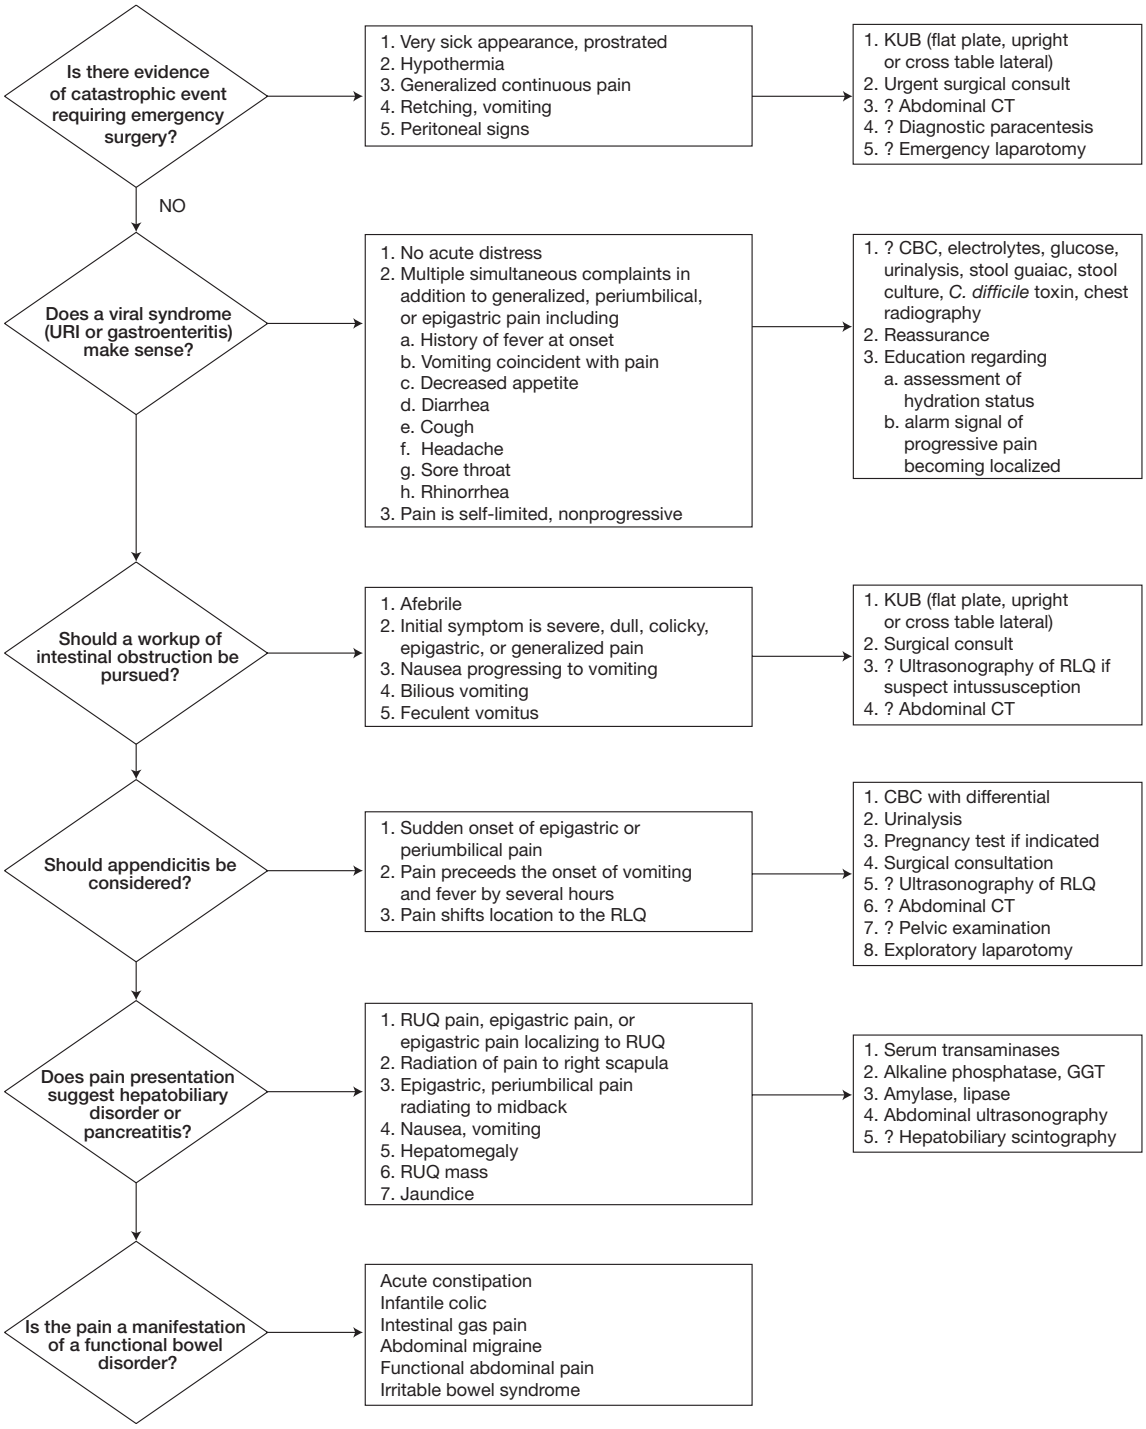

FIGURE 14-2 Approach to the patient with acute abdominal pain. CBC = complete blood count; *C. difficile* = *Clostridium difficile*; CT = computed tomography; GGT = γ-glutamyltransferase; KUB = flat plate of abdomen; RLQ = right lower quadrant; RUQ = right upper quadrant; URI = upper respiratory infection.

diarrhea (*Staphylococcus aureus*). Acute infection with *H. pylori* results in a neutrophilic gastritis with transient hypochlorhydria associated with epigastric abdominal pain and nausea. Pain is rarely severe enough to seek acute evaluation. As a general rule, serologic or stool antigen testing for evidence of *H. pylori* is not indicated in a child presenting with symptoms of viral gastroenteritis. Symptoms and signs of pneumonia are invariably present, including tachypnea out of proportion to fever, grunting respiration, cough, decreased breath sounds, and inspiratory rales. Fever, often accompanied by gastrointestinal symptoms suggestive of viral gastroenteritis, is frequent in the infant with urinary tract infection or pyelonephritis. In older children, fever accompanied by diffuse abdominal or flank pain may be the presenting symptom of pyelonephritis. Frequency, urgency, and dysuria, symptoms of cystitis, may be absent. Abdominal pain accompanied by vomiting may herald the onset of ketoacidosis in diabetes mellitus. There is usually an antecedent history of polydypsia, polyuria, and weight loss. There may be exquisite abdominal tenderness with guarding

and rigidity that may mimic peritonitis. The smell of ketones on the breath and the presence of deep sighing (Kussmaul breathing) reflect the ketoacidosis. In Henoch-Schönlein purpura, diffuse abdominal pain and vomiting with or without hematochezia may precede skin involvement by 1 week or occur 1 week after skin involvement. Diagnosis is suspected by evidence of other organ involvement, including joint pain, hematuria, and proteinuria. Intussusception occurs in 4 to 5% of children with abdominal pain. In hemolytic uremic syndrome, diffuse abdominal pain, vomiting, and hematochezia precede the onset of thrombocytopenia, coagulopathy, and oliguric renal failure by up to several weeks. At times, peritoneal signs may be prominent. Hereditary angioedema occurs in persons born without the ability to synthesize a normally functioning C1 inhibitor. Patients usually present with episodic, localized, nonpitting subcutaneous edema without urticaria, pruritus, or redness. Swelling of the intestinal wall without concurrent subcutaneous edema can lead to intense abdominal pain, sometimes with vomiting or diarrhea.

Acute abdominal pain secondary to acute infection is usually a clinical diagnosis that requires no confirmatory testing. Decision to do tests such as the complete blood count (CBC) with differential, electrolytes, blood urea nitrogen, creatinine, blood glucose, stool guaiac, stool culture, stool for *Clostridium difficile* toxin, urinalysis, or chest radiography should be based on clinical suspicion. The key to management is reassurance and education of the parents about the signs and symptoms of dehydration and the need for re-evaluation if pain progresses or localizes in the following 24 to 36 hours.

Should a Diagnosis of Intestinal Obstruction Be Entertained?

The differential diagnosis of intestinal obstruction includes closed-loop obstruction (volvulus, incarcerated hernia), high-grade or complete intraluminal obstruction (intussusception), partial obstruction (incomplete intussusception, postoperative adhesions, Crohn disease, fecal impaction), and paralytic ileus. Early diagnosis of closed-loop and high-grade intraluminal obstruction is essential to avoid intestinal ischemia. Intestinal obstruction is suggested by a history of episodic, crampy visceral pain and vomiting and is supported by physical signs of abdominal distention, diffuse pressure tenderness, visible peristalsis, and absent or high-pitched bowel sounds. In acute intestinal obstruction, the temperature, as a rule, is normal. Visceral pain is usually present from the onset and frequently comes in bouts and spasms. Frequent bilious emesis, beginning soon after the onset of epigastric pain, suggests high intestinal obstruction (malrotation with Ladd bands). If the obstruction is in the distal small bowel or colon, nausea is constant from the onset, but vomiting is usually a late symptom. In most cases, the character of the vomiting changes with time. First, the stomach contents are expelled, and then yellow-green bilious material appears. The color of the emesis gradually changes to greenish-brown and becomes "feculent" (foul smelling). Feculent vomiting is diagnostic of distal intestinal obstruction.

Causes of intestinal obstruction requiring surgery include intussusception, postoperative adhesions, and incarcerated hernia (inguinal, internal, or external). Intussusception occurs most often in infants aged 6 to 18 months and is usually ileocolic and idiopathic. Intussusception is heralded by episodic crampy abdominal pain often following signs of viral gastroenteritis or upper respiratory illness. Prior abdominal surgery or peritonitis places a child at risk for intestinal obstruction from adhesions. Adhesions can occur relatively early in the postoperative course or months or even years later. Small incarcerated indirect inguinal hernia can easily escape detection if the whole abdomen is not observed and palpated, especially in obese patients. A firm, discrete mass can be palpated at the internal inguinal ring and may or may not extend into the scrotum. The testes may appear dark because of pressure on the spermatic cord causing congestion.

Small bowel obstruction can be diagnosed on an abdominal plain film with the demonstration of dilated loops of small intestine with air-fluid levels and no or little colonic gas, whereas colonic obstruction appears as colonic distention. Typically, in intussusception, no stool or air-fluid levels are seen in the cecum. In suspected obstruction, serial abdominal radiographs reveal progressive bowel distention and disappearance of gas from the distal bowel. Unfortunately, the plain film is diagnostic in only 46 to 80% of cases of small bowel obstruction.[5] The lower percentage probably reflects the radiographic findings at the patient's initial presentation, whereas the higher percentage includes patients who received follow-up studies. Ultrasonography can readily detect distended fluid-filled bowel loops, which certainly suggests the possibility of obstruction, but defining the location, type, and cause of the obstruction is extremely operator dependent. Also, where gaseous distention predominates or if the child resists abdominal compression because of pain, ultrasonography may be technically limited. If the question is to rule out ileocolic intussusception, the sensitivity of abdominal ultrasonography has been reported to be close to 100%, even in relatively inexperienced hands.[8,9] The position of the leading edge can be determined, the presence or absence of a lead point can be ascertained, and the presence or absence of blood flow within the intussusception can be identified with Doppler examination. The presence of flow on Doppler interrogation has been shown to predict radiographic reducibility by barium or air and diminish the danger of perforation during reduction. Abdominal CT has significantly advanced the evaluation of small and large bowel obstruction, especially in the acute situation in which high-grade or possibly strangulating obstruction is being encountered.[7] The abdominal CT diagnosis of small bowel obstruction requires a dilated proximal small bowel and collapsed distal bowel. Although CT may miss low-grade partial small bowel obstruction (eg, secondary to Crohn disease), incomplete obstruction rarely results in strangulation and, therefore, can be managed conservatively, at least initially. The diagnosis of closed-loop obstruction (volvulus or incarcerated hernia) by CT may be difficult to ascertain.

Causes of intestinal obstruction requiring surgery must be distinguished from paralytic ileus, which generally presents with increasing abdominal distention, minimal abdominal pain and tenderness, nausea, and increased frequency of flatus and loose stools. Vomiting is uncommon. Bowel sounds are characteristically diminished or absent. Paralytic ileus may be seen in a number of clinical settings, including hypokalemia, uremia, lead poisoning, drug therapy that interferes with gastrointestinal motor function, postsurgical period, posttraumatic shock, and viral gastroenteritis. Radiographs in a child with paralytic ileus demonstrate multiple, small air-fluid levels throughout the abdomen, but serial films show either no worsening or gradual improvement of the bowel gas pattern. The abdominal CT finding that suggests paralytic ileus is small bowel dilatation associated with a colon that is distended by gas and fluid.[7] Although fecal impaction is a frequent complication of chronic fecal retention, complete obstruction is rare. Partial obstruction from fecal retention responds to a combination of serial enemas and a large volume of polyethylene glycol (PEG) electrolyte solution given by nasogastric tube with or without manual evacuation of the distal rectum under general anesthesia. Distal ileal obstruction syndrome is a complication of cystic fibrosis that may result in partial small bowel obstruction from inspissation of intestinal contents in the distal ileum. The obstruction usually responds to a large volume of PEG electrolyte solution given by nasogastric tube or Gastrografin enemas.

Should Appendicitis Be Considered?

The first symptom of appendicitis is characteristically epigastric or periumbilical pain. The awakening out of sleep by acute abdominal pain in a previously well child is a common presentation of acute appendicitis. The temperature at the onset of acute appendicitis is usually normal but may rise to 100 or 100.5°F within a few hours. Similarly, vomiting usually begins a few hours after the onset of abdominal pain. Frequent vomiting may occur at the onset of acute appendicitis if the distal tip of the appendix distends acutely behind a proximal appendiceal concretion. Diarrhea is not a common symptom associated with uncomplicated appendicitis. Characteristically, over time, the pain shifts to the right lower quadrant. The most reliable sign of acute appendicitis is localized tenderness in the right lower quadrant. In fact, the localization of pain and tenderness on physical examination depends on the anatomic position of the appendix. In the case of the retrocecal appendix, pain may be localized to the lateral abdomen or flank. Alternatively, pain associated with retrocecal appendicitis may never localize. An appendix pointing to the left lower quadrant may present with suprapubic tenderness.

An elevated total white blood cell count (WBC) in the range of 11,000 to 17,000/mm^3 is seen in approximately 80% of patients, but the specificity of leukocytosis for acute appendicitis is poor.[10] It is important to note that a normal WBC and differential should not delay surgical exploration in a child with localized right lower quadrant tenderness. A WBC that is higher than 20,000 mm^3 suggests an acute bacterial infection or intra-abdominal abscess.[11] The plain abdominal radiograph is most often normal in children with appendicitis. Conversly, patients with a right lower quadrant process of any etiology, including appendicitis or gastroenteritis, may present with air-fluid levels in the right lower quadrant, indicative of a localized ileus. Unless the conventional abdominal radiograph reveals a calcified appendicolith (seen in 10% of patients with appendicitis), it is too nonspecific to help in the diagnosis of appendicitis.[12]

Many surgeons now advocate imaging studies to improve diagnostic accuracy and decrease the need for hospital admission to observe patients with suspicion but a lower probability of appendicitis. High-resolution graded compression ultrasonography is an excellent test for detection of acute nonperforated appendicitis.[13] Appendicitis is suspected by visualization of a rigid, noncompressible, aperistaltic, tubular structure in the appropriate location. In children, the sensitivity and specificity of sonography as applied to the diagnosis of appendicitis are very high, reported at 94% and 89%, respectively, with an overall accuracy of 91%.[14] Ultrasound visualization of the appendix must be interpreted in light of the clinical findings. False-negative results may occur for a number of reasons, including a lack of patient cooperation, inadequate compression to displace bowel gas, and operator inexperience. Abdominal CT can also be performed quickly, does not require graded compression, requires less initial experience in interpretation, and is highly accurate in both the diagnosis and exclusion of appendicitis.[15] On CT, an inflamed appendix is fluid filled, often contains a fecolith, and shows "stranding" or inflammatory changes in the periappendiceal fat.[12]

Many cases of appendicitis progress to perforation without the occurrence of vomiting. A large percentage of very young children will have perforated by the time of presentation. Immediately following perforation, abdominal pain may improve, and the temperature may become normal or even subnormal. Within 1 to 2 hours, however, there are usually signs of generalized rather than localized peritonitis accompanied by frequent vomiting, pallor, tachycardia, and fever of 101°F or greater. Secretory diarrhea may be a predominant symptom following a perforated appendix if the inflammatory mass lays against the sigmoid colon. Following appendiceal perforation, the child characteristically prefers to lie still. Any movement usually evokes pain and irritability. Bowel sounds are absent. Following perforation, the diagnostic accuracy of ultrasonography decreases because of guarding and focal ileus. Perforation may be suspected by visualization of asymmetric mural thickening, areas of increased intramural echogenicity, and fluid in the right paracolic gutter with adjacent atonic bowel loops. Abdominal CT is more sensitive, more specific, and less operator dependent for assessing a perforated appendix. CT signs of perforation include periappendiceal phlegmon or abscess.[15]

The differential of right lower quadrant abdominal pain includes Crohn disease, small bowel obstruction, pyelonephritis, renal colic, acute salpingitis (pelvic inflammatory disease), ovarian torsion, dysmenorrhea, ruptured

ovarian cyst, mittelschmerz, typhlitis, ectopic pregnancy, and mesenteric adenitis. Acute onset of Crohn disease should be suspected if there is right lower quadrant mass and diarrhea. Children with urolithiasis rarely present with the excruciating pain of stone passage seen in adults. Colicky pain in the abdomen or flank is more common. Hematuria, either microscopic or macroscopic, occurs in the vast majority of children. The presence of fever greater than 101°F suggests pyelonephritis and salpingitis in addition to a perforated appendix. Urinalysis should be performed in all patients with right lower quadrant abdominal pain, flank pain, or pain radiating into the groin. Pelvic examination with appropriate examinations for sexually transmitted diseases is indicated in an adolescent female who has just completed a menstrual period and presents with lower abdominal pain and fever. The patient may report an increased vaginal discharge or irregular bleeding. A complication of salpingitis that evokes clinical signs of peritonitis and shock is a ruptured tubo-ovarian abscess. Typical primary dysmenorrhea consists of crampy, dull, midline, or generalized lower abdominal pain at the onset of the menstrual period. The pain may coincide with the start of bleeding or precede the bleeding by several hours. Associated symptoms include backache, thigh pain, diarrhea, nausea, vomiting, and headache. Endometriosis must be considered when there is chronic, cyclic, undiagnosed pelvic pain in teenagers. Unilateral abdominal pain at the midpoint of the menstrual cycle (time of ovulation), with or without spotty bleeding for 24 hours, is characteristic of mittelschmerz. Typhlitis should be considered in a neutropenic patient receiving antineoplastic drugs who presents with right lower quadrant abdominal pain, fever, diarrhea, nausea, and vomiting. Localized tenderness may progress rapidly to diffuse signs of peritonitis as a result of intestinal perforation. Urine or serum pregnancy testing should be performed in adolescent females of reproductive age with lower abdominal pain. Mesenteric adenitis is a commonly used term to describe clustering of inflamed lymph nodes in the region of the terminal ileum in patients undergoing appendectomy. Mesenteric adenitis should not be considered a separate diagnosis but rather a sequela of viral or bacterial gastroenteritis.

Does the Pain Presentation Suggest a Hepatobiliary Disorder or Pancreatitis?

Epigastric, right upper quadrant, or initial epigastric pain localizing to the right upper quadrant should suggest hepatobiliary disease, pancreatitis, or, rarely, acute peptic ulcer disease. Screening tests include serum transaminases, alkaline phosphatase, γ-glutamyltransferase, amylase, and lipase, as well as possible abdominal ultrasonography and hepatobiliary scintography.

Hepatobiliary disorders that may present with acute abdominal pain include viral hepatitis, biliary colic, acute calculous cholecystitis, cholangitis, acalculous cholecystitis, gallbladder hydrops, and perihepatitis (Fitz-Hugh–Curtis syndrome). Acute hepatitis is suspected if epigastric or right upper quadrant abdominal pain is accompanied by flu-like symptoms, including low-grade fever, anorexia, nausea, vomiting, malaise, and fatigability associated with palpation of tender hepatomegaly. Clinical manifestations of gallstone disease include biliary colic, acute cholecystitis, and cholangitis. Biliary colic is triggered by a gallstone(s) obstructing the cystic duct. The pain of biliary colic frequently follows a meal and can be localized to the right upper quadrant or epigastric areas. Sustained pain rises to a plateau of intensity over 5 to 20 minutes and gradually resolves over a 1- to 6-hour period. The patient tends to be restless, and the position does not help the pain. Pain lasting longer than 6 hours suggests acute cholecystitis. Cholecystitis implies an chemical inflammatory process within the gallbladder triggered by prolonged obstruction of the cystic duct. Referred pain to the dorsal lumbar back near the right scapula, nausea with some vomiting, and low-grade fever (< 101°F) are common. As inflammation worsens, the pain becomes more generalized in the upper abdomen and is increased by deep inspiration (Murphy sign: production of pain by deep inspiration or cough while the physician's fingers are compressing the abdomen below the right costal margin in the midclavicular line) and jarring movements. A common bile duct stone should be considered if the patient is jaundiced. Cholangitis should be suspected in a patient who has right upper quadrant pain, shaking chills, and a spiking fever greater than 102.5°F. A rigid abdomen or rebound tenderness suggests local perforation or gangrene of the gallbladder. Acute acalculous cholecystitis is acute inflammation of the gallbladder in the absence of stones. It is rare in children but has been associated with systemic illness or enteric infections. Acalculous cholecystitis should be included in the differential of a patient with the simultaneous onset of high fever and pain symptoms suggesting biliary colic. Gallbladder hydrops, or acute noncalculous, noninflammatory distention of the gallbladder, has been associated with Kawasaki disease, Henoch-Schönlein purpura, and scarlet fever. In addition to right upper quadrant pain, the distended gallbladder may be palpated. Perihepatitis is a complication of pelvic inflammatory disease in adolescent females that presents with severe right upper quadrant pain and tenderness produced by inflammation of the liver capsule. Fever may or may not be present. The syndrome has been associated with both *Neisseria gonorrhoeae* and *Chlamydia trachomatis*.

In pancreatitis, onset of pain is usually insidious over several hours. Constant epigastric or upper quadrant pain with or without radiation to the back, which is aggravated when the patient lies down, is an indication to check pancreatic enzymes. The pain may be referred to the left scapula or be generalized in both upper abdominal quadrants. Vomiting may be severe and protracted. A low-grade fever (< 101°F) may be present. The abdomen may be distended but is rarely rigid. Rebound tenderness is rare. Bowel sounds may be decreased.

Is the Acute Abdominal Pain a Manifestation of a Functional Bowel Disorder?

The three main considerations are acute constipation, aerophagia, and flare of functional abdominal pain. Acute

constipation may complicate a viral illness that causes decreased bowel motility and results in dietary changes. Rectal pain produced by anal fissure may be a cause of constipation. Abdominal pain is usually left-sided or suprapubic, antedated by decreased frequency or volume of usual bowel movements for several days. Acute constipation may be accompanied by sensations of urgency, tenesmus, and rectal pain. Abdominal examination may reveal distention or hard feces in a palpable colon.

In emergency rooms, acute constipation is frequently given as a cause of acute abdominal pain after abdominal plain film performed to screen for obstruction is interpreted by the radiologist as showing a moderate or large amount of stool. In fact, abdominal plain film has a low specificity for diagnosing constipation. In the absence of a confirming history and digital rectal examination showing a rectum full of stool, a child with acute abdominal pain should not be treated for acute constipation based on an abdominal radiograph.

Intestinal gas is also overplayed as a cause of acute abdominal pain. In the absence of a history of excessive air swallowing and distention, parents should not be told that acute abdominal pain is the result of intestinal gas. As with constipation, the abdominal plain film has a low specificity for diagnosing excessive intraluminal gas.

A significant percentage of children who present to emergency rooms with acute abdominal pain have a flare of chronic functional abdominal pain, described below. A history of chronic pain, a normal abdominal examination, and the absence of alarm signals suggest a flare of functional abdominal pain. Emergency physicians should reassure the patient and parents regarding normal examination and resist initiating further workup that might confuse management initiated by the patient's primary caregiver or pediatric gastroenterologist.

CHRONIC ABDOMINAL PAIN

Chronic abdominal pain is one of the most commonly encountered symptoms in childhood and adolescence. The definition of "chronic" has evolved from the seminal definition by Apley of recurrent paroxysmal abdominal pain in children between the ages of 4 and 16 years that persists for greater than 3 months duration and affects normal activity.[16] Chronic abdominal pain has been reported to occur in 10 to 15% of children.[17–19] At least as many children experience chronic pain but maintain normal activity and rarely come to the attention of the physician.[17–19]

The Pediatric Rome group has proposed that chronic abdominal pain can be subcategorized based on clinical presentation: (1) isolated paroxysmal abdominal pain, (2) abdominal pain associated with symptoms of dyspepsia, (3) abdominal pain associated with altered bowel pattern, and (4) abdominal migraine.[20] Symptoms of dyspepsia include pain associated with eating, epigastric location of pain, nausea, episodic vomiting, early satiety, occasional heartburn and acid regurgitation, and excessive belching. Symptoms of altered bowel pattern include diarrhea, constipation, or a sense of incomplete evacuation with bowel movements. The differential diagnosis of each subcategory of chronic pain includes a heterogeneous group of anatomic, infectious, noninfectious inflammatory, and biochemical organic disorders. Yet, although the exact prevalence figures are unknown, the most common cause in each subcategory is functional abdominal pain. The modifier "functional" is used in gastroenterology if no specific structural, infectious, inflammatory, or biochemical cause for the abdominal pain can be determined. The vast majority of children classified by Apley as having "recurrent abdominal pain" had functional abdominal pain.

Pathophysiology of Functional Abdominal Pain

There is general agreement that functional pain is genuine and not simply social modeling or imitation of parental pain or a means to avoid an unwanted experience (eg, school phobia or malingering). The etiology and pathogenesis of the pain are unknown. Many physicians conceptualize functional pain as "nonorganic." Yet there is a growing body of evidence that the pain is the result of disordered brain-gut communication involving both the efferent and afferent pathways by which the enteric and central nervous systems communicate. It is not clear whether the different subcategories of functional abdominal pain result from a heterogeneous group of disorders or represent variable expressions of the same disorder. The frequent occurrence of upper and lower bowel symptoms in the same patient (particularly nonulcer dyspepsia and irritable bowel in an adolescent) suggests that the latter scenario may indeed be the case. Although there is no evidence that the etiology of functional pain in children differs from functional pain in adults, the tendency of children to outgrow functional pain suggests that self-limiting developmental factors may be involved in the pathophysiology of pain in children.

The prevailing viewpoint is that the pathogenesis of the functional pain involves the interrelationship between altered gastrointestinal motility and visceral hypersensitivity.[21] Motility disturbances have been described in children, including altered intestinal transit, enhanced rectal contractility to cholinergic agonists, clusters of jejunal pressure activity that coincide with pain, lower rectal compliance, and altered rectal contractile response to a meal.[22–24] Visceral hypersensitivity in children with functional abdominal pain is supported by reports of enhanced awareness of balloon distention in the rectum and pain associated with physiologic stimuli such as the intestinal migrating motor complex.[25,26] A common link among these various motor and sensory phenomena is the autonomic nervous system. In some patients, associated symptoms including headache, dizziness, motion sickness, pallor, temperature intolerance, and nausea suggest a generalized dysfunction of the autonomic nervous system. In fact, abnormalities of sympathetic cardiac, vasomotor, and sudomotor function by autonomic testing have been described in patients with functional pain.[27] In adult studies, there is growing evidence that the initiating factors for autonomic dysfunction are found in the central nervous system, namely, the limbic system and the thalamus. Furthermore, there is increasing

evidence that serotonin (5-hydroxytryptamine [HT]) and its receptors (particularly the 5-HT_3 and 5-HT_4 receptors) play a major role in the pathogenesis of functional pain.[28]

In a child with visceral hypersensitivity, painful sensations may be provoked by physiologic phenomena or concurrent physical and psychological stressful life events. Examples of physiologic phenomena that may trigger pain include postprandial gastric or intestinal distention, gastric emptying, intestinal contractions or the migrating motor complex, intestinal gas, or gastroesophageal reflux. Intraluminal physical stress factors that may trigger pain include aerophagia, simple constipation, lactose intolerance, minor noxious irritants such as spicy foods, *H. pylori* gastritis, celiac disease, or drug therapy. Systemic physical or psychological stress factors may also provoke or reinforce the pain behavior by altering the conscious threshold of gastrointestinal sensory input in the central nervous system. Acute or chronic physical illness may unmask functional pain. Psychological stress factors may include death or separation of a significant family member, physical illness or chronic handicap in parents or a sibling, school problems, altered peer relationships, family financial problems, or a recent geographic move.

The concept of visceral hypersensitivity can be better understood by examining the role of lactose intolerance as a trigger of functional abdominal pain. There does not appear to be a difference in the incidence of lactose intolerance between patients with functional abdominal pain and age-matched patients without pain. Yet Barr and colleagues have reported a qualitative improvement in pain symptoms in 70% of intolerant children treated with a lactose-free diet.[29] They observed that such children lack an awareness of intolerance to lactose because there is no temporal relationship between lactose ingestion and abdominal discomfort. These results suggest that lactose intolerance is not directly the cause of the pain but the trigger that unmasks visceral hypersensitivity (perhaps by luminal distention) in susceptible patients. That lactose is but one provocative stimulus in such patients is supported by observations that a lactose-free diet does not induce complete resolution of the pain or alter the natural history of the condition.[29]

Recently, there has been progress in defining a subgroup of adults with symptoms of irritable bowel syndrome (IBS) developing after an episode of infective gastroenteritis.[30] The role of inflammation in the pathogenesis of functional abdominal pain must also be considered in view of the frequent finding of mild nonspecific histologic inflammatory changes at all levels of the gastrointestinal tract in patients with functional abdominal pain.[31,32] It may be speculated that such mild inflammatory changes that persist after gastroenteritis may be the cause of visceral hypersensitivity or altered intestinal motility. Immune responses alter neural and endocrine function, and, in turn, neural and endocrine activity modifies immunologic function.[33] Activated immunocompetent cells such as monocytes, lymphocytes, macrophages, serotonin-containing enterochromaffin cells, and mast cells that take up residence in the intestinal tract may secrete a repertoire of cytokines and inflammatory mediators that can lead to profound changes in enteric neural function. The main symptoms of postinfective irritable bowel (ie, diarrhea and loose stools) may reflect the prokinetic and secretory effect of 5-HT and inflammatory mediators derived from enterochromaffin cells and lymphocytes.[30] The possibility that some aspect of personality, behavior, coping style, or emotional state influences immune responses may also have implications in functional abdominal pain. The enteric or central nervous system may also modulate intestinal immune responses. Activation of the sympathetic nervous system causes leukocytosis, sequestration of lymphocytes, and inhibition of natural killer cell activity.[33] Sensory neurons also contain a variety of neurotransmitters and neuropeptides that can affect lymphocyte function, including substance P, vasoactive intestinal polypeptide, angiotensin II, calcitonin gene–related peptide, and somatostatin.

There also appears to be a genetic vulnerability because of the high frequency of pain complaints in family members.[16] Recent studies suggest that patients with functional abdominal pain who make their way to a subspecialty setting commonly exhibit "internalizing" behavior characterized by anxiety, mild depression, withdrawal, and low self-esteem.[34,35] Such a behavior profile may be primary and part of the genetic vulnerability of such patients. Alternatively, it has been postulated that such internalizing behavior is fostered within a family structure characterized by maternal depression, enmeshment, overprotectiveness, rigidity, and a lack of conflict resolution.[36] A third possibility is that the internalizing behavior is a common psychological adaptation to both organic and nonorganic chronic conditions.[35] Whether primary or secondary, the behavior pattern of the child and the family structure may both influence how the disorder is experienced and acted on.

The morbidity associated with recurrent abdominal pain is not physical but results from interference in normal school attendance and performance, peer relationships, participation in organizations and sports, and personal and family activities. Liebman found that only 1 of 10 children with functional abdominal pain attended school regularly and that absenteeism was greater than 1 day in 10 in 28% of patients.[37] A common misconception is that pain is the direct cause of the morbidity. In fact, the environmental consequences of the pain probably contribute significantly to the morbidity. Fordyce and colleagues observed that although pain does not originate from its consequences, much pain behavior is accounted for and modified by its consequences.[38] As described below, the usual parental, school, and medical management of recurrent abdominal pain is focused on symptom relief, which reinforces the pain behavior with attention, rest, and medication. This approach fails to reinforce nonpain responses such as normal activity.

Diagnosis of Chronic Abdominal Pain

Because the exact etiology and pathogenesis of the pain are unknown and no specific diagnostic markers exist for any group, functional abdominal pain is too often perceived as a diagnosis of exclusion. Yet it is the clinical presentation, together with a well-structured medical history and physical examination, that usually indicates that functional

abdominal pain is the likely diagnosis in an individual child presenting with chronic abdominal pain. Rather than a shotgun approach to rule out all potential infectious, inflammatory, structural, and biochemical causes of a particular pain presentation, diagnostic evaluation should be driven by an index of suspicion based on pertinent alarm signals in the history and physical examination. In clinical practice, functional abdominal pain should not be a diagnosis of exclusion. Primary care physicians should be able to make a primary diagnosis of functional abdominal pain without resorting to a large battery of biochemical or radiography tests. Management of functional pain is facilitated by early diagnosis, parental education and reassurance, and clear delineation of goals of therapy. The major outcome variable in the management of functional abdominal pain in children is lifestyle, not cure of the pain.

One reason why primary care physicians have difficulty making a positive diagnosis of a functional abdominal pain is that there is rarely a clear distinction between acute and chronic abdominal pain. A parent's decision to consult a physician is usually based on the age of the child, the severity of the pain, and the effects of pain on the child's lifestyle. Primary caregivers must often deal with the evolution of pain from the initial acute presentation to a chronic or recurring problem. A stepwise series of diagnostic studies is often initiated during early stages of the pain when an organic etiology is considered to be more likely. Empiric therapy with nonopioid analgesic medications, antispasmodic and anticholinergic agents, and gastric acid–reducing agents may be tried before time criteria for functional abdominal pain are met. Parents tend to become more frustrated and anxious, particularly if they perceive that a serious disorder is being missed or if the physician implies that the primary factors that influence the perception of pain are cognitive and emotional. Parental uncertainty only increases the stressful environment that provokes or reinforces the pain behavior.

Thus, the concept of functional abdominal pain must be introduced into the differential diagnosis of abdominal pain in children before the 3-month time criteria for duration of pain are met. Functional abdominal pain lacks a symptom-based diagnostic marker. None of the following have been shown to help the physician discriminate between organic, psychosomatic, and functional abdominal pain: frequency of pain; character of pain; location of pain; pain awakening patient at night; associated gastrointestinal symptoms, including anorexia, nausea, episodic vomiting, increased gas, or altered bowel pattern; or associated extraintestinal symptoms, including fatigue, pallor, headache, and arthralgia. Similarly, there is no evidence that anxiety, depression, behavior problems, or recent negative life events discriminate between organic, psychosomatic, and functional abdominal pain. Because there are no prospective studies on natural history or incidence, it cannot be stated that the duration of pain itself, beyond 3 months without an organic diagnosis, supports a diagnosis of functional pain.

Although there are no evidence-based data, clinical experience suggests that subclassifying pain presentations may facilitate the choice of testing by narrowing the differential diagnosis (Figure 14-3). Children with abdominal pain may be subclassified by one of four clinical presentations: (1) abdominal pain associated with symptoms of upper abdominal distress, (2) abdominal pain associated with altered bowel pattern, (3) isolated paroxysmal abdominal pain alone, and (4) cyclical pain syndrome. Cyclical pain refers to episodes of intense acute midline pain lasting several hours to a few days with intervening symptom-free intervals lasting weeks to months. Functional abdominal pain should be presented as the most common cause of all four clinical presentations. The frequent occurrence of upper and lower bowel symptoms in the same patient is not uncommon.

Establishing a Working Diagnosis of Functional Abdominal Pain

The key variables that point toward a functional diagnosis are a normal physical examination, other than abdominal pressure tenderness, and absence of alarm signals for an organic disorder. Even with a normal physical examination, further diagnostic testing is definitely indicated in the presence of the following alarm signals: involuntary weight loss, growth retardation, significant vomiting, significant diarrhea, gastrointestinal blood loss, associated fever, arthritis, rash, symptoms of a psychiatric disorder, or a family history of inflammatory bowel disease. Alarm signals in the physical examination include evidence of linear growth deceleration, localized tenderness in the right upper or lower quadrants, localized fullness or mass effect, hepatomegaly, splenomegaly, spine or costovertebral angle tenderness, perianal fissure, perianal fistula, visible soiling, and guaiac-positive stools. Although a family history of patients with functional pain who consult physicians is more likely to be positive for parental health complaints, including marital discord, psychiatric illness, and past surgery, this cannot be used to discriminate between functional and organic pain.

Diagnostic testing is indicated when alarm signals or abnormal physical findings suggest a possibility of an organic disorder. No studies have evaluated the value of common laboratory tests (CBC, erythrocyte sedimentation rate [ESR], comprehensive metabolic panel, urinalysis, stool parasite analysis) to distinguish between organic and functional pain. Diagnostic testing may also be considered to reassure the parent, patient, or physician that the most likely diagnosis is functional pain. The physician may also need to do testing to rule out organic disease in the patient in whom pain continues to severely affect lifestyle despite a functional diagnosis. Clinical experience suggests that subclassifying pain presentations may facilitate the choice of testing by narrowing the differential diagnosis (see Figure 14-3).

Establishing a working diagnosis of functional pain and initiating conservative therapy before time criteria are achieved does not preclude an ongoing, focused, diagnostic workup. Synonyms of functional pain that may be useful for individualizing diagnosis in a given patient are functional dyspepsia for pain with upper abdominal symptoms, IBS for pain associated with altered bowel pattern, func-

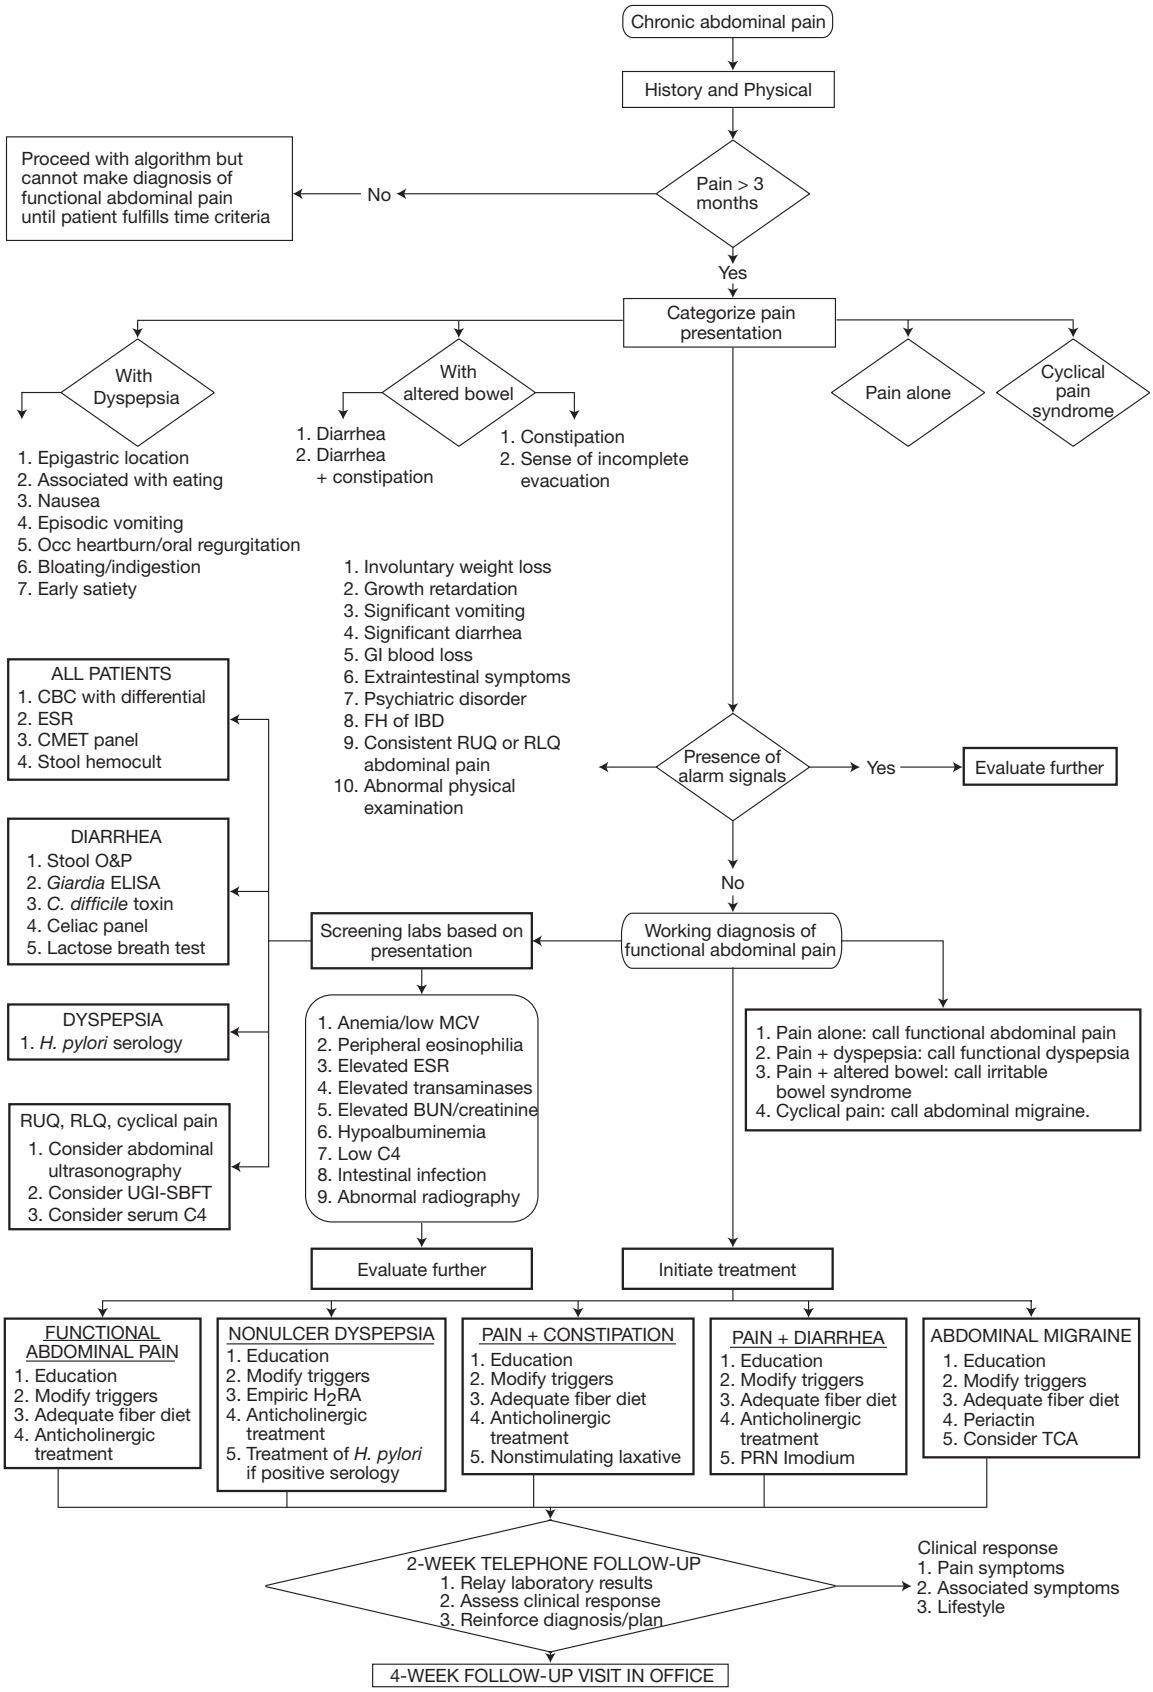

FIGURE 14-3 The author's algorithm for the evaluation and management of chronic abdominal pain. BUN = blood urea nitrogen; CBC = complete blood count; *C. difficile* = *Clostridium difficile*; CMET = comprehensive metabolic panel (Chem 12); ELISA = enzyme-linked immunosorbent assay; ESR = erythrocyte sedimentation rate; FH = family history; GI = gastrointestinal; *H. pylori* = *Helicobacter pylori*; H_2RA= histamine$_2$ receptor antagonist; IBD = inflammatory bowel disease; MCV = mean corpuscular volume; O&P = ovum parasite examination; PRN = as needed; RLQ = right lower quadrant; RUQ = right upper quadrant; TCA = tricyclic antidepressant; UGI-SBFT = upper gastrointestinal small bowel follow-through .

tional abdominal pain for patients with isolated paroxysmal abdominal pain alone, and abdominal migraine for cyclical acute pain episodes. Two of the following features are required for diagnosis of abdominal migraine: (1) a headache during episodes, (2) photophobia during episodes, (3) associated classic unilateral migraine headaches that may or may not be associated with abdominal pain, (4) a family history of migraine, and (5) visual, sensory, or motor aura antedating acute pain.[39,40]

Diagnostic Evaluation Based on Subcategories of Chronic Abdominal Pain

Chronic Abdominal Pain Associated with Symptoms of Dyspepsia. Table 14-2 lists the differential diagnosis in patients with chronic abdominal pain and upper gastrointestinal symptoms. The key to deciding on the extent of initial workup is the presence or absence of significant vomiting. A reasonable focused laboratory evaluation in all patients includes a CBC with differential, ESR, *H. pylori* serology and/or stool antigen, hepatic panel, and pancreatic enzyme measurement. In cases in which recurrent vomiting is a significant part of the history, an upper gastrointestinal series with small bowel follow-through and abdominal ultrasonography should be considered to rule out gastric outlet disorder, malrotation, partial small bowel obstruction, small bowel Crohn disease, gallstones, pancreatic pseudocyst, hydronephrosis secondary to ureteropelvic junction obstruction, and retroperitoneal mass.

Gastroesophageal reflux disease should be suspected when heartburn and acid regurgitation are prominent parts of the history. Gastroparesis following a viral infection may begin within 7 days following resolution of acute viral illness (especially post rotavirus) and lead to chronic epigastric pain associated with persistent nausea and episodic vomiting.[41,42] Diagnosis is confirmed by demonstrating delayed gastric emptying by scintigraphy. Recurrent epigastric or right upper quadrant pain associated with tender hepatomegaly suggests chronic hepatitis. Biliary colic is episodic, severe, constant pain in the right upper quadrant or epigastrium that persists for 20 minutes to 2 hours and that is usually triggered by eating. Choledocholithiasis is confirmed by abdominal ultrasonography. Gallbladder dyskinesia remains a controversial primary diagnosis to explain chronic dyspepsia. Diagnosis should be suspected in patients with protracted symptoms suggesting biliary colic, a positive family history of gallstones, normal abdominal ultrasonography, and hepatobiliary scintigraphy with delayed ejection fraction after cholecystokinin infusion.[43] Dramatic improvement has been reported in children after elective cholecystectomy.[44,45] Experience in adults has been less dramatic, with only 47% of patients becoming completely asymptomatic.[46] Adult norms for ejection fraction have been used to assess pediatric patients. In relapsing pancreatitis, recurrent severe epigastric pain persists for days and may radiate to the back. Endoscopic retrograde cholangiopancreatography is indicated only if there is biochemical or radiologic evidence of recurrent pancreatitis or biliary-type abdominal pain following cholecystectomy. Continuous pain, especially in the context of multisystem complaints, is an alarm signal for possible psychiatric disease. Eating disorder should also be considered in any young patient with significant weight loss.

TABLE 14-2 DIFFERENTIAL DIAGNOSIS OF RECURRENT ABDOMINAL PAIN ASSOCIATED WITH SYMPTOMS OF DYSPEPSIA

Associated with upper gastrointestinal inflammation
Gastroesophageal reflux disease
Peptic ulcer
Helicobacter pylori gastritis
Nonsteroidal anti-inflammatory drug ulcer
Crohn disease
Eosinophilic gastroenteritis
Ménétrier disease
Cytomegalovirus gastritis
Parasitic infection (*Giardia, Blastocystis hominis*)
Varioliform gastritis
Lymphocytic gastritis/celiac disease
Henoch-Schönlein purpura
Motility disorders
Idiopathic gastroparesis
Biliary dyskinesia
Intestinal pseudo-obstruction
Other disorders
Obstructive disorders from Table 14-1
Chronic pancreatitis
Chronic hepatitis
Chronic cholecystitis
Ureteropelvic junction obstruction
Abdominal migraine
Psychiatric disorders

H. pylori gastritis and nonsteroidal anti-inflammatory drugs (NSAIDs) are the most important exogenous factors associated with peptic ulcer in adults. However, in children, clinically significant ulceration occurs infrequently with NSAID use or *H. pylori* gastritis.[31,47] The pathogenic mechanisms distinguishing those individuals at risk have not been identified. A careful history is required to ensure that NSAID consumption is detected in any patient being evaluated for recurrent abdominal pain with dyspepsia. The incidence of *H. pylori* infection in children increases with age, is inversely related to socioeconomic class, and increases in families in which an adult has had either an ulcer or documented *H. pylori* infection.[48] In the absence of peptic ulcer disease, the relationship between *H. pylori* infection and abdominal pain remains unclear. Although there are no evidence-based data to establish a clear link between *H. pylori* gastritis without ulcer and abdominal pain associated with symptoms of upper abdominal distress,[47] most gastroenterologists will treat a symptomatic child who has been identified as *H. pylori* positive. The rationale is that *H. pylori* may act as a physical trigger of functional dyspepsia in selected patients. Some authors have concluded that the most cost-effective approach is to test serologically for *H. pylori* and to treat all infected cases. However, many investigators have pointed out that commercially available serologic assays do not appear to have the necessary sensitivity or specificity to screen pediatric

patient populations.[47] Empiric treatment of *H. pylori* should be considered only in patients with an elevated immunoglobulin (Ig)G antibody and is not recommended for patients with a positive IgM or IgA antibody. It is not unreasonable to avoid antibody testing altogether and consider treatment only in patients with endoscopically proven infection who have not responded to treatment of functional dyspepsia.

Upper endoscopy should be considered in untreated patients with alarm signals, patients who fail to respond to time-limited gastric acid reduction therapy for functional dyspepsia, and patients in whom symptoms recur after attempting to step off seemingly effective therapy. Upper endoscopy is the gold standard to rule out infectious and inflammatory disorders in the upper gastrointestinal tract. Recognizable objective findings by gross endoscopic examination include superficial erosions, ulcer, stricture, antral nodularity associated with *H. pylori* gastritis, gastric rugal hypertrophy associated with Ménétrier disease and cytomegalovirus gastritis, and the small, heaped up, volcanic-like mounds, pocked with a central crater, associated with chronic varioliform gastritis. Objective histologic findings may help to diagnose reflux esophagitis, eosinophilic gastroenteritis, cytomegalovirus gastritis, *H. pylori* gastritis, Crohn disease, and celiac disease. In the absence of gross ulcer or histologic evidence of *H. pylori*, superficial antral gastritis or duodenitis is of questionable clinical significance and should not dissuade a diagnosis of functional dyspepsia. There is no evidence in children that nonspecific superficial antral gastritis or duodenitis progresses to peptic ulcer. A diagnosis of postviral gastroparesis or gallbladder dyskinesia should not be entertained without first ruling out upper gastrointestinal tract inflammation and infection by upper endoscopy.

Chronic Abdominal Pain Associated with Symptoms of Altered Bowel Pattern. Altered bowel pattern may include a change in the frequency and/or consistency of stools (diarrhea or constipation), pain relieved with defecation, straining or urgency, a feeling of incomplete evacuation, passage of mucus, or a feeling of bloating or abdominal distention. Table 14-3 lists the major differential of chronic abdominal pain associated with an altered bowel pattern. The key to deciding on the extent of initial workup is the volume of diarrhea, evidence of gross or occult blood in the stool, and the presence of encopresis. In patients with diarrhea, a focused laboratory evaluation should include a CBC with differential, ESR, stool for *Giardia* antigen, stool for ovum parasites, and stool for *C. difficile* toxin. Alarm signals, including evidence of gastrointestinal bleeding, tenesmus, pain or diarrhea repeatedly wakening the patient from a sound sleep, involuntary weight loss, linear growth deceleration, extraintestinal symptoms (fever, rash, joint pain, recurrent aphthous ulcers), a positive family history of inflammatory bowel disease, iron deficiency anemia, and an elevated ESR are indications to pursue a diagnosis of inflammatory bowel disease by colonoscopy and barium contrast upper gastrointestinal series with small bowel follow-through. Lactose intolerance should be considered as a potential primary etiology of chronic abdominal pain in the presence of diarrhea. A trial of a lactose-free diet or performance of a lactose breath hydrogen test is prudent in children with pain associated with loose bowels, bloating, and increased flatulence. Diarrhea associated with encopresis suggests chronic fecal retention and megacolon. Serologic testing for celiac disease should be considered in patients with pain and an altered bowel pattern, especially in patients with iron deficiency anemia or secondary amenorrhea. Large-volume diarrhea is also an indication to pursue colonoscopy to rule out microscopic inflammation, which may alter colonic motility and absorptive function, including lymphocytic, collagenous, or eosinophilic colitis.[49–51]

TABLE 14-3 DIFFERENTIAL DIAGNOSIS OF RECURRENT ABDOMINAL PAIN ASSOCIATED WITH ALTERED BOWEL PATTERN

Idiopathic inflammatory bowel disorders
Ulcerative colitis
Crohn disease
Microscopic colitis with crypt distortion
Lymphocytic colitis
Collagenous colitis
Infectious disorders
Parasitic (*Giardia*, *Blastocystis hominis*, *Dientamoeba fragilis*)
Bacterial (*Clostridium difficile*, *Yersinia*, *Campylobacter*, tuberculosis)
Lactose intolerance
Complication of constipation (megacolon, encopresis, intermittent sigmoid volvulus)
Drug-induced diarrhea, constipation
Gynecologic disorders
Neoplasia (lymphoma, carcinoma)
Psychiatric disorders

Table 14-4 lists the indications for colonoscopy in children with chronic abdominal pain and an altered bowel pattern. The accuracy of colonoscopy in diagnosing inflammatory conditions of the colon is superior to barium enema because of the direct visualization of the mucosal surface and the ability to obtain biopsy and culture specimens. Intubation of the terminal ileum can also aid in the diagnosis of Crohn disease. Recognizable objective findings by gross examination with a flexible endoscope include edema, erosions, ulceration, pseudomembranes (discrete yellow plaques on the colonic mucosa), and polyps. Subjective gross endoscopic findings, including erythema, increased vascularity, and spontaneous friability,

TABLE 14-4 INDICATIONS FOR COLONOSCOPY IN PATIENTS WITH RECURRENT ABDOMINAL PAIN AND ALTERED BOWEL PATTERN

Evidence of gastrointestinal bleeding
Profuse diarrhea
Involuntary weight loss or growth deceleration
Iron deficiency anemia
Elevated acute-phase reactants (sedimentation rate, C-reactive protein)
Extraintestinal symptoms suggestive of inflammatory bowel disease (fever, rash, joint pains, recurrent aphthous ulceration)

become meaningful only in the context of histology because they are subject to more interobserver variation in interpretation. Objective histologic findings include (1) cryptitis, crypt abscesses, and crypt distortion with branching and dropout, suggesting ulcerative colitis or Crohn disease; (2) noncaseating granuloma specific for Crohn disease; (3) fibrosis and histiocyte proliferation in the submucosa suggesting Crohn disease; and (4) epithelial and intraepithelial lymphocytes or eosinophils with or without subepithelial collagen thickening in lymphocytic colitis, eosinophilic colitis, and collagenous colitis, respectively. Mild superficial increases in interstitial lymphocytes or eosinophils in the absence of crypt distortion or significant diarrhea are nonspecific and should not dissuade the physician from making a positive diagnosis of irritable bowel syndrome.

Chronic Isolated Paroxysmal Abdominal Pain. Table 14-5 lists the major differential of recurrent paroxysmal periumbilical abdominal pain in children. It is often important to try to see the patient during an attack of pain. The Carnett test may help to determine whether pain is arising from the abdominal wall or has an intra-abdominal origin.[52] The site of maximum tenderness is found through palpation. The patient is then asked to cross arms and assume a partial sitting position (crunch), which results in tension of the abdominal wall. If there is greater tenderness on repeat palpation in this position, abdominal wall disorders such as cutaneous nerve entrapment syndromes, abdominal wall hernia, myofascial pain syndromes, rectus sheath hematoma, or costochondritis should be suspected. Discitis, which is an osteomyelitis of the vertebral end plate, may present as a combination of back and abdominal pain.[53] The condition is usually associated with intermittent fever, an elevated peripheral WBC, and an elevated ESR. Unrecognized constipation should be suspected if a left lower quadrant or suprapubic fullness or mass effect is appreciated on abdominal examination and rectal examination reveals evidence of firm stool in the rectal vault or soft stool in a dilated rectal vault with evidence of perianal soiling. Often a history of constipation or encopresis is unknown to the parent. Parasitic infections, particularly *Giardia lamblia*, *Blastocystis hominis*, and *Dientamoeba fragilis*, may present with chronic pain in children in the absence of altered bowel pattern. Alarm signals are also indications to evaluate for Crohn disease or rare disorders such as polyarteritis nodosa, intestinal ischemia, and eosinophilic gastroenteritis, and angioneurotic edema can be indistinguishable from Crohn disease on clinical grounds. Suspicion of polyarteritis nodosa rests on evidence of extraintestinal disease, particularly renal involvement. Mesenteric vein obstruction should be considered in adolescents using oral contraceptives. Clinically, it can present gradually with progressive abdominal pain over a period of weeks. Pneumatosis is usually a late finding. The clinical presentation of eosinophilic gastroenteritis depends on the depth of the infiltration by the eosinophilic process. Submucosal disease can become manifest with abdominal pain and signs of obstruction. Any region of the gastrointestinal tract can be involved. Angioneurotic edema can be heralded by recurrent episodes of pain in the absence of cutaneous or oropharyngeal edema.[54] The family history is usually positive for allergy. Recurrent fever associated with generalized abdominal pain and peritoneal signs suggests the possibility of familial Mediterranean fever. Appendiceal colic is a controversial cause of chronic abdominal pain.[55,56] Appendiceal spasm has been postulated to be caused by inspissated casts of fecal material within the appendix. A number of anecdotal surgical reports have described complete resolution of pain symptoms following elective appendectomy. Appendiceal colic should be suspected in patients with recurrent acute episodes of well-localized abdominal pain and tenderness, most commonly in the right lower quadrant, demonstrated on several examinations. Ureteropelvic junction obstruction is well known to present with recurrent episodes of crampy periumbilical pain, but in all cases reported in the literature to date, the pain has been associated with vomiting.[57] Dull, midline, or generalized lower abdominal pain at the onset of a menstrual period suggests dysmenorrhea. The pain may coincide with the start of bleeding or precede the bleeding by several hours. Gynecologic disorders associated with secondary dysmenorrhea include endometriosis, partially obstructed genital duplications, ectopic pregnancy, and adhesions following pelvic inflammatory disease. Cystic teratoma has been described in prepubertal patients presenting with right or left lower quadrant pain. The vast majority of such patients have a palpable abdominal mass. Benign ovarian cysts in adolescent females do not cause recurrent abdominal pain. Acute intermittent porphyria is a rare disorder characterized by the temporal association of paroxysmal abdominal pain and a wide variety of central nervous system symptoms, including headache, dizziness, weakness, syncope, confusion, memory loss, hallucinations, seizures, and transient blindness.[58] Acute

TABLE 14-5 DIFFERENTIAL OF RECURRENT ABDOMINAL PAIN PRESENTING AS ISOLATED PAROXYSMAL ABDOMINAL PAIN

OBSTRUCTIVE DISORDERS
Crohn disease
Malrotation with or without volvulus
Intussusception with lead point
Postsurgical adhesions
Small bowel lymphoma
Endometriosis
Infection (tuberculosis, *Yersinia*)
Vascular disorders
Eosinophilic gastroenteritis
Angioneurotic edema
APPENDICEAL COLIC
DYSMENORRHEA
MUSCULOSKELETAL DISORDERS
URETEROPELVIC JUNCTION OBSTRUCTION
ABDOMINAL MIGRAINE
ACUTE INTERMITTENT PORPHYRIA
MENTAL DISORDERS (FACTITIOUS DISORDER, CONVERSION REACTION, SOMATIZATION DISORDER, SCHOOL PHOBIA)
FUNCTIONAL ABDOMINAL PAIN

intermittent porphyria is often precipitated by a low intake of carbohydrate or by specific drugs such as barbiturates or sulfonamides.

Focused laboratory evaluation might include CBC with differential and ESR to screen for occult systemic inflammatory condition. Decision to do stool ovum parasite examination is dependent on the incidence of *G. lamblia*, *B. hominis*, and *D. fragilis* within the community. The most valuable diagnostic test in a patient with symptoms suggesting obstruction is an upper gastrointestinal series and small bowel follow-through. Rare conditions such as lymphoma, angioneurotic edema, mesenteric vein thrombosis with ischemia, eosinophilic gastroenteritis, and pseudoobstruction will also be suggested by barium contrast radiography. Abdominal ultrasonography and abdominal CT have low diagnostic yield for picking up appendiceal abnormalities with recurrent right lower abdominal pain. Colonoscopy and ileoscopy should be performed to rule out Crohn disease in such patients if bloodwork or upper gastrointestinal small bowel follow-through suggests the possibility of inflammatory disease. Elective laparoscopy with planned appendectomy should be considered in patients with chronic right lower quadrant pain and negative infectious, inflammatory, and anatomic evaluation. Head CT to rule out intracranial space-occupying lesions should be considered in patients with recurrent abdominal pain and headache.

Treatment of Functional Abdominal Pain

Management of all four presentations of functional abdominal pain begins with a positive diagnosis and explanation of suspected pathophysiology and goals of therapy. Specific treatments include identification and modification of physical and psychological stress factors, dietary modification, drug therapy, and active psychological support. Hospitalization is rarely indicated for patients with functional abdominal pain.

Positive Diagnosis, Explanation of Suspected Pathophysiology, and Goals of Therapy. A positive diagnosis is based on normal physical examination and absence of alarm signals in the history, as described above. Focused laboratory and/or radiograph evaluations are based on subcategorizing pain presentation. It is important to emphasize that functional pain is the most common etiology of chronic abdominal pain in children and that the pain is real. Although the exact etiology and pathogenesis of functional abdominal pain in children are unknown, a substantial body of evidence suggests that it is caused by a disturbance of the autonomic nervous system, which results in altered communication between the gut and the brain. The prevailing viewpoint is that the pathogenesis of the pain involves visceral hypersensitivity and altered conscious awareness of gastrointestinal sensory input, with or without disordered gastrointestinal motility. Many parents and children can conceptualize the pain as a "headache" within the abdomen. Parents and child must be told that the primary goal of treatment is resumption of a normal lifestyle, not eradication of abdominal pain. Goals of treatment include regular school attendance, school performance to the child's ability, participation in desired extracurricular activities, normal weight gain and growth, and a normal sleep pattern. Reassurance that functional pain disorders will not affect future health can have positive therapeutic effects. Many patients lose their symptoms spontaneously after a positive diagnosis, suggesting that allaying the patient's and/or parents' fears may remove a significant stress factor triggering symptoms.

Modify Triggers of Pain. The first goal is to identify, clarify, and possibly reverse physical and psychological stress factors (see above) that may have an important role in the onset, severity, exacerbations, or maintenance of pain. In some cases, painful sensations may be provoked by physiologic phenomena, including postprandial gastric or intestinal distention, gastric emptying, intestinal contractions or the migrating motor complex, intestinal gas, or gastroesophageal reflux. Concurrent physical and psychological stressful life events may also trigger flares of pain. Intraluminal physical stress factors that may trigger pain include aerophagia, simple constipation, lactose intolerance, minor noxious irritants such as spicy foods, *H. pylori* gastritis, celiac disease, or drug therapy. Systemic physical or psychological stress factors may also provoke or reinforce the pain behavior by altering the conscious threshold of gastrointestinal sensory input in the central nervous system. Acute or chronic physical illness may unmask functional pain. Psychological stress factors may include death or separation of a significant family member, physical illness or chronic handicap in parents or a sibling, school problems, altered peer relationships, family financial problems, or a recent geographic move.

Equally important is to reverse environmental reinforcement of the pain behavior. Parents and teachers must be engaged to support the child rather than the pain. Regular school attendance is essential regardless of the continued presence of pain. In many cases, it is helpful for the physician to communicate directly to school officials to explain the nature of the problem. School officials must be encouraged to be responsive to the pain behavior but not to let it disrupt attendance, class activity, or performance expectations. Within the family, less social attention should be directed toward the symptoms. Consultation with a child psychiatrist or psychologist may be indicated when there is concern about maladaptive family coping mechanisms or if attempts at environmental modification do not result in return to a normalized lifestyle.

It is important to address symptoms of mental disorders that may contribute to the pathogenesis of pain symptoms. Failure to treat attention-deficit/hyperactivity, anxiety, or depression will adversely affect pain management. Anxiety may be primary, part of adjustment to an identifiable stress, or associated with panic disorder. Symptoms of anxiety include irritability, exaggerated startle response, poor concentration, worry, hypervigilance, motor restlessness, nervousness, difficulty sleeping, school phobia, fear of separation, and being easily fatigued. Depressive mood is suggested by insomnia, hypersomnia, anorexia, overeat-

ing, low energy, poor concentration, tearfulness, low self-esteem, poor concentration, feelings of hopelessness, and recurrent thoughts of death.

Dietary Modification. The role of dietary modifications in the management of functional pain disorders is not established. Postprandial symptoms in functional dyspepsia may be improved by eating low-fat meals or by ingesting more frequent but smaller meals throughout the day. A high-fiber diet is recommended for both diarrhea-predominant and constipation-predominant irritable bowel and isolated functional pain. The goal for fiber intake in grams is calculated by adding the patient's age + 5. Excessive fiber in the diet may result in increased gas and distention and actually provoke pain. Malabsorption of dietary carbohydrates may act as provocative stimuli in functional abdominal pain. Most often, the patient does not perceive a temporal association between ingestion of a particular sugar and the abdominal pain. Avoidance of excessive intake of milk products (lactose), carbonated beverages (fructose), dietary starches (corn, potatoes, wheat, oats), or sorbitol-containing products (vehicle for oral medication, sugar substitute in gum and candy, ingredient in toothpaste, and a plasticizer in gelatin capsules) is not unreasonable. Confirmation of lactose intolerance by a lactose breath hydrogen test should be considered before recommending prolonged lactase enzyme replacement therapy or commercial milk products that have been pretreated with lactase enzyme. Excessive gas in patients with irritable bowel syndrome can be managed by advising the patient to eat slowly, to avoid chewing gum, and to avoid excessive intake of carbonated beverages, legumes, foods of the cabbage family, and foods or beverages sweetened with aspartame.

Medications. There are no evidence-based data to support antisecretory therapy in pediatric patients with functional dyspepsia. Response rates in controlled clinical trials using antisecretory agents, both H_2 receptor antagonists and proton pump inhibitors, in adults with functional dyspepsia range from 35 to 80% compared with placebo response rates of 30 to 60%.[49] Meta-analyses of these trials suggest that acid reduction therapy is 10 to 30% more effective than placebo in relieving symptoms of ulcer-like (predominant abdominal pain) dyspepsia.[59] Conversely, there is no evidence that symptoms of nausea or bloating are relieved by antisecretory therapy. Given that acid reduction therapy may be beneficial in a subset of patients, it is not unreasonable to treat pediatric patients with ulcer-like dyspepsia with 4 to 6 weeks of an H_2 receptor antagonist. Patients who fail to respond or who relapse with step-down therapy should have upper endoscopy to establish a firm diagnosis of functional dyspepsia. If a firm diagnosis of functional dyspepsia is established by upper endoscopy, it is not unreasonable to continue acid inhibition therapy in patients who initially responded to shot-term empiric treatment but had recurrence of pain symptoms with attempts at step-down therapy. Short-term step-up to a proton pump inhibitor may be tried in patients who previously did not respond to an H_2 blocker. Metoclopramide, the only promotility agent available in the United States, has not been studied in pediatric patients and has only limited testing in adults with functional dyspepsia. It is not unreasonable to treat dysmotility-like dyspepsia (strong component of nausea, early satiety, and bloating) with a time-limited course of metoclopramide, but the high incidence of adverse central nervous system side effects and extrapyramidal symptoms associated with metoclopramide makes it risky for long-term use. As stated above, although *H. pylori*–eradication therapy is not established to be effective in adults with functional dyspepsia, the available data clearly do not rule out the possibility. Thus, most pediatric gastroenterologists still will treat documented *H. pylori* in functional dyspepsia. There are no evidence-based data to support the use of antispasmodic or antinauseant drugs to treat dyspepsia.

There are also no evidence-based data on the effects of pharmacologic therapy in pediatric patients with IBS. Synthetic opioids such as loperamide and diphenoxylate or the bile salt binding agent cholestyramine may be helpful in treating diarrhea associated with IBS. Loperamide is preferred over diphenoxylate because it does not traverse the blood-brain barrier. Fiber supplements such as psyllium, methycellulose, or polycarbophil are effective in treating both constipation and diarrhea, but their value in relief of abdominal pain associated with IBS is controversial. Nonstimulating laxatives such as PEG powder, mineral oil, milk of magnesia, and lactulose are effective adjuncts in treating constipation-predominant IBS. Antispasmodic or anticholinergic agents are commonly used in clinical practice to treat visceral abdominal pain, although efficacy is controversial. Only enteric-coated peppermint oil capsules (with possible smooth muscle–relaxing properties) have been shown to be superior to placebo for reducing functional pain by a randomized, double-blinded control study.[60] The duration of therapy at which time pain response was assessed, however, was only 2 weeks. Excessive gas can be managed by advising the patient to eat slowly, to avoid chewing gum, and to avoid excessive intake of carbonated beverages, legumes, foods of the cabbage family, and foods or beverages sweetened with fructose or sorbitol. Simethicone or activated charcoal may help individual patients.

In uncontrolled, retrospective case series, prophylactic cyproheptadine and propranolol have been reported to reduce the frequency of attacks of abdominal migraine.[61,62]

Although there is a lack of formal randomized, placebo-controlled trials, there has been a recent surge in using antidepressant and psychotropic agents to treat both diarrhea-predominant IBS and functional dyspepsia in adults.[63] Anecdotally, this class of drugs appears to be effective in adults with or without psychiatric abnormalities, especially low-dose tricyclic antidepressants. These drugs may act as "central analgesics" to raise the perception threshold for abdominal pain or down-regulate pain receptors in the intestine. There are as yet no data on treatment of pediatric patients.

There has been a recent surge in the development of novel drugs for IBS in adults, such as 5-HT_3 receptor antagonists and 5-HT_4 agonists aimed at modifying gas-

trointestinal motor activity and restoring normal visceral sensation. A significant beneficial effect of the 5-HT_3 antagonist alosetron has been reported in diarrhea-predominant adult women with IBS.[64] A significant beneficial effect of the 5-HT_4 agonist tegaserod has been reported in constipation-predominant adult women with IBS.[65]

Direct Psychological Support. Consultation with a child psychiatrist or psychologist may be indicated when there is concern about maladaptive family coping mechanisms or if attempts at environmental modification do not result in return to a normalized lifestyle. Referral for psychological treatment can be proposed as part of a multispecialty treatment package to help the patient manage the pain symptoms better. It is critical that the psychologist or psychiatrist initially focus on illness behavior and expand psychotherapeutic treatments as indicated only as the patient or parents begin to see the benefits of referral.

Cognitive behavioral therapies add strategies such as cognitive restructuring to behavioral interventions such as teaching relaxation and behavior management techniques. For example, a therapist would evaluate a patient's cognitive interpretation of bodily sensations and teach how cognition impacts affective experience and behavior. The perception that abdominal pain is a sign of impending physical disease must be countered both to address functional disability and to reassure the family that a functional diagnosis is credible. Attribution styles can also be examined for distortions. Patients are taught to treat their beliefs as hypotheses to be tested rather than accept their beliefs as inherently valid. Cognitive behavioral interventions targeting children's competence in social roles may be a useful adjunct to other medical treatment in reducing illness behavior. In addition, parents are trained to behaviorally reinforce appropriate coping behavior. There are evidence-based data that cognitive behavioral treatment helps to reduce pain and improve functioning. Cognitive behavioral therapy has been compared to standard supportive care of children with functional abdominal pain.[66–68] Both groups demonstrated reductions in pain at 3 months; however, those receiving cognitive behavioral treatment were more likely to be pain free at 6-month (55.6% vs 23.8%) and 12-month follow-up (58.8% vs 36.8%). These findings are very encouraging, although replication by different investigators is still needed.

Hospitalization. Hospitalization is rarely indicated for patients with functional abdominal pain. Fifty percent of patients experience relief of symptoms during hospitalization. However, no data have been presented that the natural history of the pain is affected. Hospitalization does not enhance the fundamental goals of environmental modification. More commonly, it will reinforce pain behavior.

Prognosis of Functional Abdominal Pain in Children

There are no prospective studies of the outcome of any of the various presentations of functional abdominal pain. Once functional abdominal pain is diagnosed, subsequent follow-up rarely identifies an occult organic disorder. Interestingly, pain resolves completely in 30 to 50% of patients by 2 to 6 weeks after diagnosis. This high incidence of early resolution suggests that the child and parent accept reassurance that the pain is not organic and that environmental modification is effective treatment. Nevertheless, more long-term studies suggest that 30 to 50% of children with functional abdominal pain in childhood experience pain as adults, although in 70% of such individuals, the pain does not limit normal activity.[69–71] Thirty percent of patients with functional abdominal pain develop other chronic complaints as adults, including headaches, backaches, and menstrual irregularities. Based on a small number of patients, Apley and Hale have described several factors that adversely influence prognosis for a lasting resolution of pain symptoms during childhood, including male sex, age at onset less than 6 years, a strong history of a "painful family," and greater than 6 months elapsed time from the onset of pain symptoms to an established functional diagnosis.[72]

CHAPTER 15

ABDOMINAL MASSES

Robert H. Squires Jr, MD

Identification of an abdominal mass in a child elicits a barrage of diagnostic considerations that range from benign conditions to life-threatening malignancies. An urgent need arises to establish the diagnosis to provide an accurate prognosis and treatment plan for the child and family.

Approximately 60% of abdominal masses identified by physical examination in childhood are attributable to organomegaly, with the remainder representing anomalies of development, neoplasms, or inflammatory conditions.[1] Important clues to the diagnosis include the age of presentation (Table 15-1) and symptomatic complaints. Conditions associated with pain or gastrointestinal dysfunction generally present to medical attention early in their course, whereas asymptomatic masses may be well tolerated by the host for years before clinical detection. Thus, developmental anomalies such as an omental cyst are usually present in the young infant but may not be recognized for years or decades. The classification of abdominal masses by age at presentation is arbitrary, and overlap is obvious, but the approach is clinically useful.

GENERAL PRINCIPLES

A meticulous physical examination is essential for early detection of an abdominal mass.[2] An individual will never receive more frequent serial abdominal examinations by trained medical personnel than in the early years of life during periodic well-child checks, yet this is an age at which examinations are challenged by the uncooperative or reluctant child. It is estimated that 0.5% of newborn infants have a renal anomaly,[3] yet careful diligence on the part of the examiner is needed to detect an abnormality early. As many abdominal masses are asymptomatic, the examiner's fingers must both feel and "think" of what lies beneath them.

The examination begins with careful inspection. The child must be reassured and comfortable. For the infant or small child, the best examination table may be the mother's lap. The abdomen must be fully exposed. Signs of asymmetry or discomfort are identified. If the child is old enough to specify a sensitive area of the abdomen, the examination should begin some distance away from the area of discomfort and gradually work closer to the area of concern. The initial approach to the abdomen is best with light and then deep palpation of the left lower quadrant. By slowly moving the examining fingers cephalad to the left costal margin, abnormalities of the colon, bladder, kidney, adrenal gland, mesentery, and spleen can be identified. The process is repeated beginning in the right lower quadrant to detect abnormalities of the cecum, ileum, right colon, kidney, adrenal gland, gallbladder, and liver. Beginning the abdominal examination in the lower quadrants allows for the detection of marked enlargement of the liver or spleen, which can be otherwise missed. The rectus muscle can make it difficult to detect a mass in the midline, particularly in the older child. Therefore, a bimanual examination along the midabdomen can detect a subtle fullness. If a mass is identified, the examination should focus on physical characteristics such as tenderness, firmness, mobility, and whether the surface is smooth or irregular.

Radiologic assessment is an essential component of the evaluation of an abdominal mass. A collaborative relationship with a pediatric radiologist is helpful to determine the most productive diagnostic approach.[4] Abdominal radiographs are of limited value when a palpable mass is present but will detect calcification within the mass. Ultrasonography (US) is often the most useful initial test. It has many advantages, particularly in children, including portability of the instrument, absence of ionizing radiation, no requirement for sedation, and the ability to discriminate between a solid or a cystic mass. If the mass involves the urinary system, intravenous pyelography will provide information regarding renal anatomy and function, and voiding cystourethrography will identify abnormalities of the bladder, vesicoureteral reflux, and posterior urethral valves. Radionuclide scintigraphy is of limited value but may be useful to evaluate renal anatomy and function. A Meckel scan can identify gastric mucosa contained within a Meckel diverticulum or an intestinal duplication. Computed tomography (CT) with enteric and intravenous contrast offers superior anatomic detail of an abdominal mass, whether it is in the peritoneal or retroperitoneal space. Although CT technology is noninvasive, many children require intravenous sedation and analgesia to obtain an adequate study, and general anesthesia is occasionally indicated. Magnetic resonance imaging (MRI) is particularly useful in the evaluation of vascular malformations and retroperitoneal tumors that displace, obstruct, or invade important vascular structures.

TABLE 15-1 ABDOMINAL MASSES IN INFANTS AND CHILDREN

- NEONATES
- Retroperitoneal—kidney
  - Hydronephrosis
  - Multicystic dysplastic kidney
  - Autosomal recessive polycystic kidney disease
  - Autosomal dominant polycystic kidney disease
  - Mesoblastic nephroma
  - Renal vein thrombosis
- Retroperitoneal—other
  - Adrenal abscess
  - Fetus in fetu
- Pelvic
  - Hydrometrocolpos
  - Ovarian cyst
- Gastrointestinal
  - Intestinal duplication, malrotation, obstruction
  - Sacrococcygeal teratoma
- INFANTS AND CHILDREN
- Retroperitoneal
  - Wilms tumor
  - Neuroblastoma
  - Pancreatoblastoma
  - Rhabdomyosarcoma
  - Lymphoma
  - Ewing sarcoma
  - Germ cell neoplasm
- Liver—benign solid tumors
  - Adenoma
  - Mesenchymal hamartoma
  - Focal nodular hyperplasia
- Liver—malignant tumors
  - Hepatoblastoma
  - Hepatocellular carcinoma
  - Germ cell neoplasm
  - Angiosarcoma
  - Intrahepatic mesenchymal tumor
  - Embryonal rhabdomyosarcoma
- Liver—vascular lesions
  - Capillary hemangioendothelioma
  - Solitary cavernous hemangioma
- Liver—cystic hepatobiliary disease
  - Choledochal cyst
  - Caroli disease
  - Caroli syndrome
  - Congenital cysts
- Alimentary tract
  - Stomach
    - Carcinoma
    - Leiomyosarcoma
    - Rhabdomyosarcoma
    - Myosarcoma
    - Fibrosarcoma
  - Small bowel
    - Anomalies: duplication, Meckel, malrotation
    - Lymphoma
  - Colon
    - Fecal mass
    - Adenocarcinoma
- Omentum and mesentery
  - Cysts
  - Mesenteric fibromatosis
  - Inflammatory pseudotumor
  - Liposarcoma
  - Leiomyosarcoma
  - Fibrosarcoma
  - Mesothelioma
  - Metastatic tumor
- ADOLESCENTS
- Retroperitoneal
  - Renal cell carcinoma
- Pelvic
  - Hematocolpos
  - Ovarian cyst
  - Teratoma
  - Germ cell tumor
  - Choriocarcinoma
  - Gonadoblastoma
  - Embryonal carcinoma
- Liver
  - Hepatocellular carcinoma

ABDOMINAL MASSES IN THE NEONATAL PERIOD

Detectable masses in neonates likely originate in the genitourinary system.[5] Hydronephrosis and multicystic dysplastic kidney (MDK) make up 50 to 75% of abdominal masses reported in the neonatal period.[1] Physical findings associated with renal masses include isolated anomalies of the external ears or developmental features associated with in utero low urine output such as Potter facies.

RETROPERITONEAL MASSES

Hydronephrosis constitutes 25% of neonatal abdominal masses and is the most common renal mass in the newborn period.[5,6] It occurs as a consequence of a dilated collecting system. Renal damage results from either infection owing to stasis or increased intrapelvic pressure. Obstruction to the urinary tract occurs primarily in three locations: (1) ureteropelvic junction, (2) ureterovesical junction, and (3) bladder outlet or urethra.

Ureteropelvic junction obstruction is a common cause of unilateral hydronephrosis. In the majority of cases, the cause is unknown. However, abnormal angulations, intra-abdominal adhesion, abnormal valve, aberrant vessel, ureteral stenosis, or hypoplasia can be found. Other causes for unilateral hydronephrosis include ureterocele, periureteral diverticulum, and ectopic distal ureteral insertion.[1] When unilateral hydronephrosis is identified, the contralateral kidney is often at increased risk for developmental anomalies, including renal absence and multicystic dysplasia. Other congenital anomalies associated with hydronephrosis include imperforate anus, spinal dysraphism, and congenital heart disease.

Bilateral hydronephrosis suggests distal obstruction and is seen in males with posterior urethral valves. These folds, called the cristae urethralis, are membranes that arise from the verumontanum in males, extend distally to attach to the anterior wall of the urethra, and result in bladder outlet obstruction. Male children will present with a distended bladder, poor urinary stream, dribbling, or urosepsis. Occasionally, the initial presentation will be renal failure, failure to thrive, or urinary ascites. A defined obstructing structural lesion is not the only cause of bilateral hydronephrosis. Myoneural dysfunction, myelomeningocele, and prune-belly syndrome are also associated with two abnormal kidneys.

Regardless of the etiology, physical examination usually reveals a large, rounded and smooth, cystic flank mass or masses. If the obstruction is near the bladder, as seen in ureterovesical junction obstruction, the hydroureter may also be felt. When the obstruction is at or distal to the bladder outlet, as in posterior urethral valves, it is possible to palpate the kidneys, both hydroureters, and the distended bladder. US is the best initial test to evaluate suspected hydronephrosis. If present, a voiding cystourethrogram can be diagnostic for sites of obstruction and for the presence of posterior urethral valves. Diuretic renography using mertiatide (MAG3) with furosemide also allows for reliable diagnosis of obstruction.[7] Intravenous urography is not recommended in the neonate.[8]

Although neonatal hydronephrosis is detected more frequently, many cases appear to resolve spontaneously, which suggests that a structural obstruction may not be present in many neonates.[6,9] If a structural abnormality is suspected, treatment is directed to correct the underlying condition.[10] Appropriate antibiotic therapy for the patient with urosepsis is indicated. Patients with significant compromise of renal function require prompt decompression of the obstructed urinary system. If bilateral hydronephrosis is present, a Foley catheter in the urinary bladder may provide adequate drainage initially. Depending on the site of obstruction, however, percutaneous nephrostomy may be needed to drain the upper tracts.

MDK is the most common form of cystic disease in infants and accounts for 20% of all urinary tract malformations. It is usually sporadic, but, occasionally, an autosomal dominant pattern of inheritance is noted.[11,12] Whereas most tumors involve one kidney, 15% are bilateral. The affected kidney is usually nonfunctional.[13] The vast majority of cases are discovered before the child reaches the second birthday.

The condition usually presents as an asymptomatic flank mass discovered by the physician on routine physical examination or by the caretaker who notices an unusually large abdomen. The kidney contains cysts of variable size throughout the organ, which can be palpated as a multilobulated and immobile cystic mass. Other anomalies associated with MDK include esophageal atresia, imperforate anus, and tracheoesophageal fistula. Respiratory distress and gastric outlet obstruction owing to the large abdominal mass have been described.[14] Examination of the mass by US reveals the diagnostic "grape cluster" pattern. It is important to evaluate the contralateral kidney. If the involved kidney is small or hypoplastic, there is a higher incidence of renal abnormalities of the uninvolved kidney.[15] Although the lesion is not premalignant, treatment usually involves removal of the affected kidney to avoid problems with hypertension, abdominal pain, infection, or mass effect. The outcome is generally good when only one kidney is involved. However, chronic renal insufficiency or renal failure is associated with bilateral disease.[16]

Autosomal recessive polycystic kidney disease (ARPKD), also known as infantile polycystic disease, has an incidence of approximately 1 to 2 per 10,000 births.[5,17] The condition is characterized by bilateral renal enlargement caused by generalized dilation of the collecting tubules and is invariably associated with congenital hepatic fibrosis. A mutation in the *PKHD1* gene, located on the short arm of chromosome 6, is thought to be responsible for this condition.[18] Fibrocystin, a potential receptor protein that acts in collecting duct and biliary differentiation, is the transcription product of the *PKHD1* gene.

Clinicians have traditionally identified four classifications of the condition, based primarily on age and symptoms. Infants with the prenatal form, which is the most severe, are often delivered stillborn as a result of massive cystic kidneys and pulmonary hypoplasia. Potter facies (wide-set eyes, beaked nose, low-set ears, prominent fold arising from the inner canthus), usually associated with renal agenesis, can also be seen in this severe form of ARPKD.[5] The neonatal form of ARPKD is less severe, but the children will develop renal failure months or years later. Hepatic involvement is often minimal. Children with the infantile and juvenile forms of the disease have the onset of renal insufficiency later in life but are more predisposed to develop significant liver disease. In these patients, liver biopsy reveals portal areas to be expanded by an increased number of dilated ductules surrounded by fibrous tissue. The dilated ductules may later become cystic. These original four classifications of ARPKD are now felt to have considerable clinical variability and intrafamilial differences regarding onset of renal insufficiency.[17] Different subtypes can be observed within the same family.[19] However, the age at presentation, development of hypertension, and degree of hepatic involvement are often similar among siblings.

Autosomal dominant polycystic kidney disease (ADPKD), also known as adult polycystic disease, is increasingly recognized in infants.[3] Ultrasonographic features that distinguish it from ARPKD include the presence of renal cysts within the enlarged renal masses. A number of extrarenal anomalies associated with ADPKD include endocardial fibroelastosis, intracerebral vascular anomalies, pyloric stenosis, and hepatic fibrosis. The clinical course is highly variable, with some children asymptomatic whereas others progress early to end-stage renal failure.[20] An ADPKD gene (*PKD1*) has been identified on chromosome 16 and accounts for 85% of the pedigrees.[21] A second gene (*PKD2*), located on chromosome 4, accounts for the remainder. Identification of the gene products structure and function may provide clues to pathogenesis.[22]

Mesoblastic nephroma is the most common renal tumor in the neonatal period.[23] This generally benign tumor has also been called a congenital Wilms tumor, fetal renal hamartoma, or leiomyomatous hamartoma. It presents as a massive flank mass with accompanying hematuria, hypertension, and vomiting and is cured by nephrectomy. Rarely, it presents with atypical features such as polyhydramnios and hypercalcemia.[24] There are reports of metastasis to the brain, skeletal structures, lungs, and heart.[5,25,26] Following nephrectomy, the prognosis is good.[27]

Renal vein thrombosis (RVT) results in infarction of variable amounts of renal parenchyma.[1] Factors that predispose the newborn to develop RVT include hemoconcentration from dehydration, polycythemia, and low perfusion

states with secondary venous congestion, local tissue swelling and hypoxia, and cellular disruption and hemorrhage. Maternal factors that predispose the newborn to RVT include maternal diabetes, toxemia, and the use of medications such as steroids and thiazide diuretics during pregnancy.[28] This condition can occur in utero without any identifiable predisposing illness.[28] In the older patient, RVT is associated with nephrotic syndrome.[29]

Presenting features may include a palpable flank mass, hematuria, thrombocytopenia, and a consumptive coagulopathy.[30] However, this classic presentation is infrequent. More often, the infant presents with minimal symptoms, such as peripheral edema or signs of a hypercoagulable state with thromboses at extrarenal sites.[29] US reveals a swollen kidney with decreased echogenicity, which suggests focal or diffuse disruption of renal parenchyma. Use of Doppler technology can assess flow within the renal vein and will detect the thrombus.[31] Diuretic renography using mertiatide is also used.[32] MRI is an alternative to evaluate the patency of the renal vein, although venography remains the gold standard to diagnose RVT.[33]

Management should focus initially on treatment of the underlying factors that precipitated the RVT. Improved hydration and perfusion may interrupt thrombus progression. Use of anticoagulation therapy such as heparin or streptokinase is not well defined.[29] However, it is likely to be most useful when RVT is associated with inferior vena cava thrombosis, extension of the thrombus to the contralateral renal vein, or evidence of recurrent pulmonary emboli. Thrombectomy may be needed for bilateral RVT.

Other Retroperitoneal (Nonrenal) Masses

Neonatal adrenal abscess is a rare condition that most likely begins with a hemorrhage into the adrenal gland. Signs of adrenal hemorrhage include shock, an abdominal mass, anemia, and prolonged jaundice, but the condition may be deceptively asymptomatic.[34] A differential diagnosis for the physical and radiographic findings in this condition would include lymphatic cyst, neuroblastoma, Wilms tumor, renal duplication, and hydronephrosis. Rarely, an extrapulmonary sequestration of the lung will mimic an adrenal abscess.[35] A delay in diagnosis can be fatal. Treatment involves percutaneous or surgical drainage.

Fetus in fetu is an extremely rare event that occurs in approximately 1 in 500,000 deliveries. The location of the entrapped fetus is most often in the upper abdominal retroperitoneal space, although other extra-abdominal sites have been reported. The mass is usually painless, and the diagnosis is made with either plain radiography revealing a vertebral column and an axial skeleton[36] or prenatal US.[37]

Pelvic Masses

Hydrometrocolpos is a rare condition that presents as a mass in the lower midline of the abdomen.[38] It can be associated with a number of syndromes, such as Bardet-Biedl, McKusick-Kaufman, and oral-facial-digital.[39] The uterus may be palpable as a nodule at the top of the vaginal mass (hydrocolpos), or the uterus itself may be enlarged as well (hydrometrocolpos). An imperforate hymen is the most common cause and is revealed as a bulging hymen detected on physical examination. In the absence of an imperforate hymen, vaginal and cervical stenosis or atresia should be considered in the differential diagnosis. Complicated anatomic problems may need assessment prior to surgical correction attempts, using techniques such as US, cystography, excretory urography, or barium enema.[40]

Cysts and neoplasms are rare in infancy, although the incidence increases throughout childhood. Cystic lesions are usually follicular and likely attributable to ovarian stimulation by maternal hormones.[1] Eighty-five percent of ovarian cystic lesions are benign. Solid lesions are more likely to be malignant. In the newborn, ovarian lesions are displaced out of the pelvis and present as an abdominal mass.

Gastrointestinal Lesions

Intestinal duplication can occur at any level, but the most common site is in the area of the terminal ileum.[41] A typical duplication mass is located on the mesenteric border of the adjoining bowel and is lined with intestinal or gastric mucosa. On palpation, the mass is soft, compressible, and mobile. Symptoms that typically develop include intestinal obstruction, perforation, or hemorrhage.[42] US is the best initial examination and can be diagnostic. Contrast radiography of the intestinal tract and a Meckel scan to identify ectopic gastric mucosa are two additional studies that may provide useful information.[43]

Intestinal distention can also simulate an abdominal mass, especially if there is an anatomic blockage. A volvulus secondary to malrotation can present with bilious vomiting, distention, and a mass. Intussusception, with its classic sausage-shaped mass, is rare in infancy.[44] Other common causes of intestinal obstruction in neonates include meconium ileus and meconium plug. If scybala are palpable on abdominal examination in the newborn or young infant, then Hirschsprung disease should be considered.

Other Neoplasms

Sacrococcygeal teratoma is the most common neoplastic abdominal mass in the neonatal period. It has a large external component and is obvious at birth. The vast majority are benign, but a delay in diagnosis is associated with malignant transformation.[45,46]

ABDOMINAL MASSES IN INFANTS AND OLDER CHILDREN

Retroperitoneal Masses

Nephroblastoma or Wilms tumor is an embryonal renal neoplasm and is the most common childhood abdominal malignancy (Figure 15-1).[23,47,48] The incidence remains fairly constant at 500 cases annually in the United States, which is 8 cases for every 100,000 children less than 15 years of age or an approximate risk of 1 case per 10,000 infants.[23,49] A typical patient is a 4 year old who presents with an asymptomatic abdominal mass discovered by a parent while bathing the child or by a physician as an incidental finding during an abdominal examination.[48,50] Infrequently, a left-sided varicocele owing to tumor com-

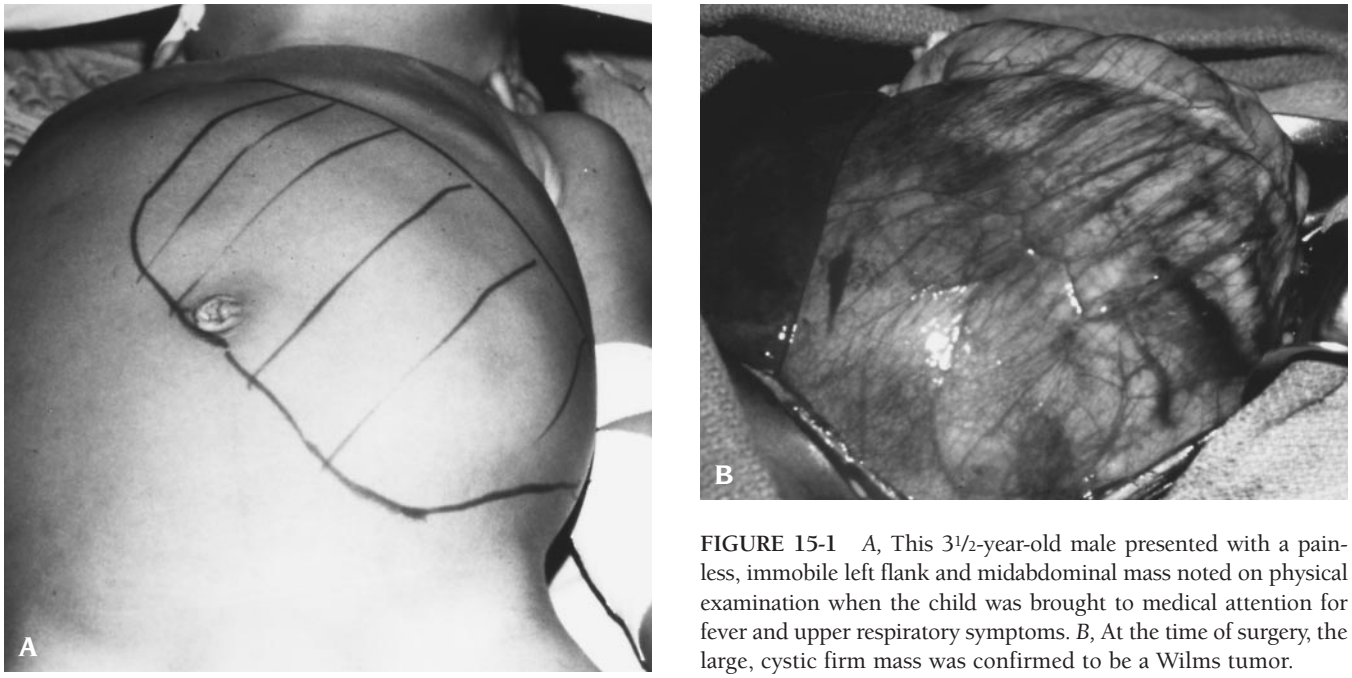

FIGURE 15-1 *A,* This 3½-year-old male presented with a painless, immobile left flank and midabdominal mass noted on physical examination when the child was brought to medical attention for fever and upper respiratory symptoms. *B,* At the time of surgery, the large, cystic firm mass was confirmed to be a Wilms tumor.

pression of the left renal vein may be seen. Malaise, weight loss, and anemia are uncommon presenting signs or symptoms. A large, unrecognized tumor that is ruptured during play may present as an abdominal catastrophe. The incidence of Wilms tumor is increased in children who manifest a variety of extrarenal anomalies, which include aniridia, hemihypertrophy, genitourinary anomalies, neurofibromatosis, Beckwith-Wiedemann syndrome, hypospadias, cryptorchidism, gonadal dysgenesis, and duplication of the renal collecting system.[48] Microscopic hematuria following minimal abdominal trauma should also raise the suspicion of a Wilms tumor.

The cause of Wilms tumor is unknown, but associations with three specific suppressor genes are recognized.[51] Deletions of the short arm of chromosome 11 are thought to set the stage for oncogenesis when certain gene products are not present.[52] The *wt1* gene deletion is associated with aniridia, the *wt2* gene deletion is seen with Wilms tumor and Beckwith-Wiedemann syndrome, and the *wt3* gene deletion is associated with bilateral Wilms tumor.[48]

Physical examination reveals a palpable immobile flank mass with a smooth contour, which is painless unless rupture of the tumor or intraparenchymal hemorrhage has altered the basic nature of the tumor. Evidence of hypertension may be present as a consequence of increased rennin or compression of the vasculature by the tumor.[53] A careful inspection of the eyes, extremities, and external genitalia may provide evidence of the associated findings discussed above.

US identifies the kidney as the origin of the mass and can assess the patency of the inferior vena cava and the presence of renal vein involvement.[48] CT of the chest will identify lung metastasis, which will be present in 8 to 15% of patients with Wilms tumor. MRI may be useful to evaluate for renal vein invasion and to identify contralateral renal involvement.[3]

Treatment involves a combination of surgery, chemotherapy, and radiation.[47] Complete surgical excision is the primary focus of treatment. The tumor must be handled with care during the surgical procedure to prevent rupture. The National Wilms Tumor Study Group reports a 90% survival rate in patients with favorable histology and with disease that is limited to the kidney, which can then be completely excised.[54] This compares with 54% survival rates for patients with distant metastasis or bilateral renal involvement. A number of clinical variants of nephroblastoma, including cystic nephroma and cystic partially differentiated nephroblastoma, are separated from Wilms tumor based on differences in gross and histologic appearance (Figure 15-2).[55] Nephrectomy alone appears to be adequate therapy.

Neuroblastoma is a malignancy involving neural crest cells that arise within the adrenal medulla or anywhere along the chain of sympathetic ganglia from the neck to the pelvis (Figure 15-3).[48,56] This is the most common solid tumor of infancy, and 60 to 75% develop within the abdomen.[57] Approximately 500 new cases are reported each year.[47,58] Half of the cases are diagnosed in patients under 2 years of age, and 90% occur in the first 8 years of life.[57] The tumor is twice as common in boys as in girls.

Clinical presentation is variable and related to the site of the primary tumor. It is often first recognized as an immobile abdominal mass that can be either asymptomatic or painful. Symptoms may include fever, weight loss or failure to gain weight, abdominal pain and distention, and anemia. The tumor may secrete vasoactive intestinal polypeptide or other catecholamines that result in intractable diarrhea and hypokalemia. Less common manifestations include opsoclonus-myoclonus syndrome and Horner syndrome. Neuroblastoma is associated with a number of conditions, including Beckwith-Wiedemann syndrome, Hirschsprung disease, fetal alcohol syndrome, and Waardenburg syndrome.[57]

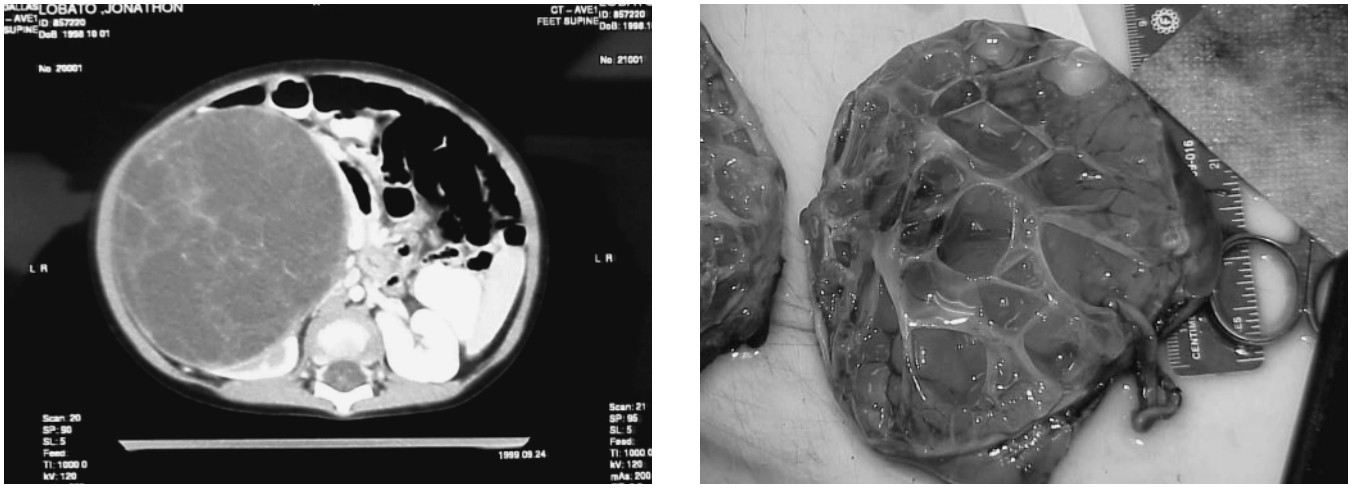

FIGURE 15-2 Cystic nephroma (multilocular cyst of the kidney). The computed tomographic scan on the left reveals a large, thin-walled cystic structure that occupies most of the right midabdomen in this 4-year-old female who presented with a painless abdominal mass. The pathologic specimen on the right is characteristic of a cystic nephroma with thin septa between the multiple cysts.

Because 50 to 75% of patients have advanced disease at the time of presentation, an effort to screen 1-year-old children was initiated with the hope of early detection, but this strategy was not helpful.[59] The tumor disseminates by direct extension, lymphatic involvement, or hematogenous spread. Metastasis to the bone may result in debilitating pain and refusal to walk. Unilateral proptosis with orbital ecchymosis is characteristic of central nervous system involvement. Paraplegia may result if the tumor extends through the spinal foramina. Pulmonary metastases are rare.[47,58]

Treatment is based on the stage of the lesion. The most important independent variables that determine outcomes are age and stage of disease. Infants younger than 1 year of age and no evidence of remote disease (eg, stages I, II, and III) have the best survival rates.[47,58] Primary tumor excision provides the most successful treatment, and survival under these circumstances is good.[56] Other favorable prognostic factors include thoracic location and histology that reflects a high degree of maturation.[50] An elevated serum lactate dehydrogenase, serum ferritin, or neuron-specific enolase is a poor prognostic factor.[57]

Genetic abnormalities are identified in about 80% of tumors, the most common being deletions on chromosome 1.[60,61] As the prognosis has not changed significantly in the last two decades, novel treatment strategies continue to be investigated.[56,58] The molecular biology of neuroblastoma is characterized by somatically acquired genetic events that lead to gene overexpression (oncogenes), gene inactivation (tumor suppressor genes), or alterations in gene expression. New efforts to define risk stratification by a combination of clinical features and biologic factors may lead to more specific treatment strategies.[62]

Pancreatoblastoma is a rare pancreatic tumor that generally affects infants and young children. It presents as a palpable abdominal mass accompanied by abdominal pain, anorexia, vomiting, and weight loss. Jaundice is rare. Elevation of serum α-fetoprotein (AFP) occurs only with liver metastases. Interestingly, almost half of cases reported are in Asians. Complete surgical resection is the treatment most commonly associated with long-term survival.[63,64]

Other tumors can present in the retroperitoneal space. Some are benign mesenchymal tumors such as hemangioma, lymphangioma, and lipoma. Malignant tumors can also occur, with examples including rhabdomyosarcoma, lymphoma, Ewing sarcoma, and germ cell neoplasms.[65] Significant retroperitoneal lymphadenopathy is not detectable on palpation but may be found unexpectedly on radiographic studies and does not always herald malignancy. Enlarged retroperitoneal nodes can be seen in some patients with celiac disease.[66]

Benign Liver Masses

Hepatic adenoma is a rare benign encapsulated tumor derived from hepatic epithelium.[47,67] The finding consti-

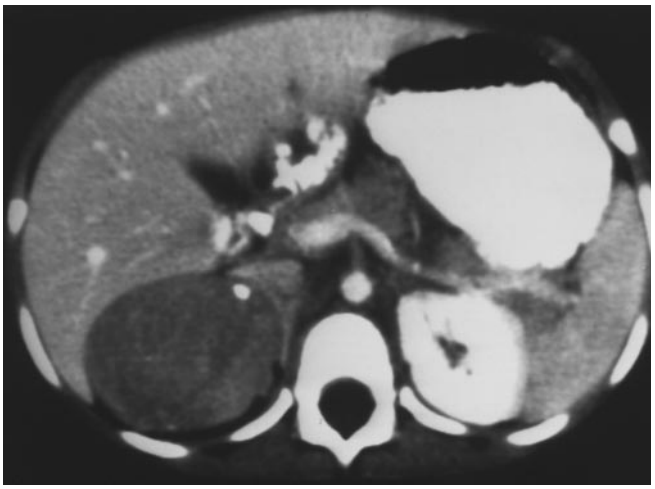

FIGURE 15-3 A computed tomographic (CT) scan of the abdomen was performed on this 18-month-old male child who presented with abdominal pain and fever. Physical examination revealed a painless mass in the right abdomen. The CT scan demonstrated a solid mass above the right kidney that was subsequently found to be a neuroblastoma.

tutes 2 to 5% of all benign tumors in childhood[47] and is commonly seen in adult women during the reproductive years. In a child, the presentation may vary among the following scenarios: (1) an asymptomatic mass noted as an incidental finding on a sonogram, (2) a sudden abdominal crisis secondary to hemorrhage or rupture of the tumor, (3) a finding in a patient with known risk factors for developing the tumor. Spontaneous rupture or hemorrhage occurs in up to 25% of cases.[47] Risk factors associated with adenoma formation include glycogen storage disease types I and III, familial diabetes mellitus, use of birth control pills or androgenic steroids, hereditary tyrosinemia, and adenomatous polyp syndromes.[68,69] Liver tests and AFP levels are usually normal.[69] There are no reports of significant parenchymal insufficiency or portal hypertension associated with these lesions.[70]

Radiographic features on US reveal either hyperechoic or hypoechoic lesions, depending on the fat content of the tumor.[71] Findings on CT will vary depending on the presence or absence of hemorrhage. Sufficient overlap exists between hepatocellular adenoma and hepatocellular carcinoma to prevent a definitive diagnosis based on imaging alone.[72]

Hepatic adenomas, although not malignant, do have some potential for malignant transformation.[67] Factors associated with increased risk for malignancy include lesions greater than 5 cm, glycogen storage disease, and use of oral contraceptives.[47,70] Surgical excision of the adenoma should be considered if the lesions increase in size, if there is a predilection for spontaneous hemorrhage, if premalignant risk factors are present, or if more malignant diagnoses cannot be excluded. A wedge resection or lobectomy is the surgery of choice.

Mesenchymal hamartoma (also called a giant lymphangioma, hamartoma, or bile cell fibroadenoma) is a benign hepatic tumor that results from a developmental anomaly of periportal mesenchyme and contains connective tissue stroma combined with bile ducts, liver cells, and angiomatous components (Figure 15-4).[73,74] It occurs almost exclusively in children less than 2 years of age. Children usually present with abdominal distention, respiratory distress owing to a mass effect, and/or congestive heart failure from arteriovenous shunting. Some children can be asymptomatic.

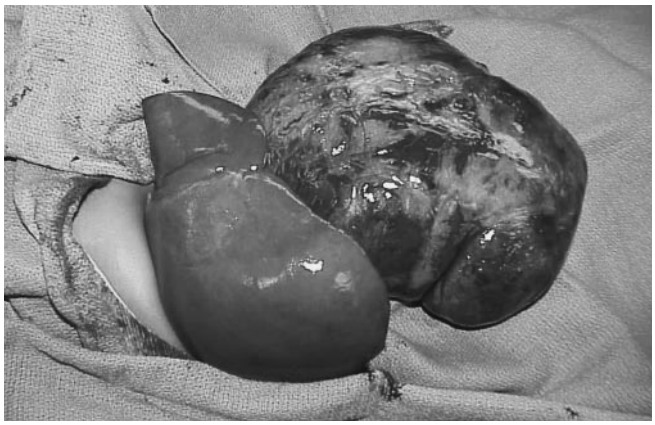

FIGURE 15-4 An 8-month-old child presented with fever, fretfulness, and vomiting. Guarding was noted on abdominal examination and radiographic studies identified a subhepatic mass. The surgical specimen revealed a large mesenchymal hamartoma.

US will often reveal a cystic mass that is contained within the right hepatic lobe. The CT scan defines boundaries of the lesion and helps determine resectability. As some tumors regress spontaneously, a conservative approach has been advocated. However, complete resection with extensive histologic sampling is suggested by some following reports of an apparent association with an undifferentiated embryonal sarcoma, which is highly malignant.[75]

Focal nodular hyperplasia is rare and always benign and usually presents as an asymptomatic incidental finding on a diagnostic study.[76] It occurs most commonly in young women. The lesion likely develops as a consequence of hyperplastic growth in response to altered blood flow in the liver parenchyma adjacent to a preexisting arterial malformation. There is an association with micronodular cirrhosis. Acute abdominal pain may develop owing to torsion or rupture of the lesion with bleeding.[76]

A CT study reveals a large homogeneous, hypodense mass and a low-density central area that corresponds to a scar that is seen in one-third of cases.[77] After intravenous gadolinium administration, lesions are enhanced when compared with normal liver and the central scar becomes hyperintense owing to concentration of the contrast. Calcifications are rare but described. Imaging findings are not specific, and there is overlap with conditions such as fibrolamellar carcinoma; therefore, a biopsy is usually indicated.[47,78] The diagnostic feature is the presence of medium to large thick-walled muscular vessels contained within fibrous bands.

Malignant Liver Masses

Hepatoblastoma (HBL) almost always arises in an otherwise normal liver (Figure 15-5).[79,80] The incidence of HBL is between 0.5 and 1.5 cases per million children.[80] The median age at presentation is 16 months, although cases in adolescents and adults are described. Most patients present with modest symptoms such as weight loss, anorexia, and anemia and a painless mass in the right upper quadrant. The etiology is unknown. There appears to be an increased risk for the development of HBL for patients with Beckwith-Wiedemann syndrome, Meckel diverticulum, diaphragmatic or umbilical hernias, Wilms tumor, fetal alcohol syndrome, familial adenomatous polyposis, and very low birth weight infants.[81,82] Chromosomal abnormalities are reported and involve chromosomes 11, 20, and 8.

Aminotransferase levels are normal in approximately two-thirds of patients with HBL, and most are not icteric. However, all children with HBL show elevations of AFP. Levels of AFP can be used to monitor the course of the disease, but the height of AFP elevation is not related to prognosis.[83] In addition, histology and tumor size have no bearing on the ultimate prognosis. A tumor that is confined to one lobe, usually the right, and is resectable carries a good prognosis. Poor prognostic factors include vascular invasion and distant metastases.[83] Abdominal and chest CT studies are useful to predict resectability.

Complete surgical resectability remains the most important prognostic factor.[84] At the time of diagnosis,

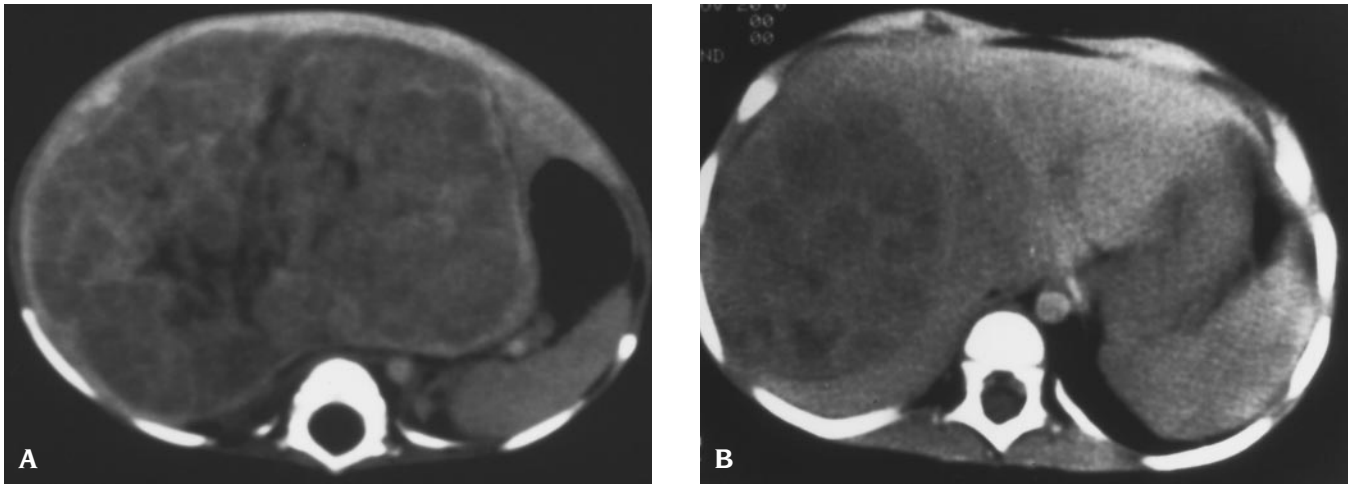

FIGURE 15-5 A 1-year-old male infant presented for routine physical examination and was found to have firm hepatomegaly. A sonogram confirmed an intrahepatic mass, and the α-fetoprotein was elevated. *A,* Computed tomographic scan of the abdomen confirms a large, unresectable hepatoblastoma. *B,* Following chemotherapy, the tumor has dramatically decreased in size.

approximately 50% are resectable, 40% are localized to one lobe but are not resectable, and 10% of the patients have distant metastases, usually to the lung.[83] Antineoplastic agents such as cisplatin and doxorubicin, as dual therapy or in combination with other chemotherapeutic medicines, are used to treat unresectable HBL.[85] Some patients who present with initially unresectable lesions subsequently become candidates for complete surgical excision following chemotherapy. With the current protocols, up to 65 to 75% of patients may be cured.[86] Orthotopic liver transplant is an option for patients whose tumor remains unresectable despite chemotherapy.[87,88]

Hepatocellular carcinoma (HCC) is a rare epithelial neoplasm that occurs primarily in older children and adolescents.[47,89] HCCs account for 0.5 to 2% of all pediatric tumors. Patients with HCC are more likely to present with signs and symptoms such as abdominal pain, fever, anorexia, malaise, and hepatomegaly.[90] The relationship between chronic hepatitis B and the subsequent development of HCC is well established.[90] However, other conditions also place the patient at an increased risk for development of HCC and include hemochromatosis, hepatitis C, α_1-antitrypsin deficiency, hereditary tyrosinemia, porphyria cutanea tarda, glycogen storage disease, and hypercitrullinemia.[91] In adults, the vast majority of patients have well-established cirrhosis at the time of diagnosis of HCC. In children with hepatitis B, however, many only have evidence of inflammation and regeneration and do not have cirrhosis.[92,93] Patients with polymorphisms of the uridine diphosphate–glucuronosyltransferase *UGT1A7* gene may be at increased risk for development of HCC.[94]

CT of the abdomen reveals a large hypodense mass with central areas of low density corresponding to tumor necrosis. After intravenous contrast, HCC appears hyperdense and is accompanied by an enhancing thin rim around the tumor. Vascular invasion of either portal or hepatic vein branches is characteristic and identified by CT in 70% of patients.[92]

Unfortunately, most children present with advanced disease at the time of diagnosis, with metastases to the lung present in up to 40% of cases.[90,93] As with HBL, complete tumor resection remains the only realistic chance for cure.[95] Chemotherapy is reserved for unresectable lesions, when a delay in surgical resection is anticipated, and as adjuvant chemotherapy following surgical resection.[96,97] Liver transplant is a potential alternative for some patients. Unfavorable factors include very large tumor size, positive hepatitis B status, nonfibrolamellar histologic type, and local or metastatic spread.[98]

Other hepatobiliary malignancies may occur in children. Germ cell tumors are reported, and resection is curative.[99] Angiosarcoma is rare, usually occurs in girls between 3 and 5 years of age, and presents with a rapidly expanding mass. These lesions can develop following treatment and apparent cure of hemangioendothelioma. Surgical resection is the only curative therapy.[100] Intrahepatic mesenchymal tumors represent 2% of all malignant mesenchymal tumors in children and 6% of primary hepatic tumors in childhood. Complete resection is needed to cure the disease, and chemotherapy is reserved for more extensive tumors.[101,102] Embryonal rhabdomyosarcomas arise in the extrahepatic biliary tree, and prognosis is dismal because complete resection is seldom possible, chemotherapy is ineffective, and radiation is, at best, palliative (Figure 15-6).[101,102]

VASCULAR LESIONS OF THE LIVER

Capillary hemangioendothelioma is a massive arteriovenous connection, which typically presents as high-output congestive heart failure and hepatomegaly in infants less than 5 months of age.[99,103,104] A bruit is sometimes heard over the epigastrium. Few clinical symptoms are noted in some patients owing to slow growth of the lesion.[105] Anemia and platelet trapping within the tumor may result in the Kasabach-Merritt syndrome. This tumor is associated with other congenital anomalies, including bilateral Wilms tumor, hemihypertrophy, Beckwith-Wiedemann syndrome, and meningomyelocele.[99,106,107]

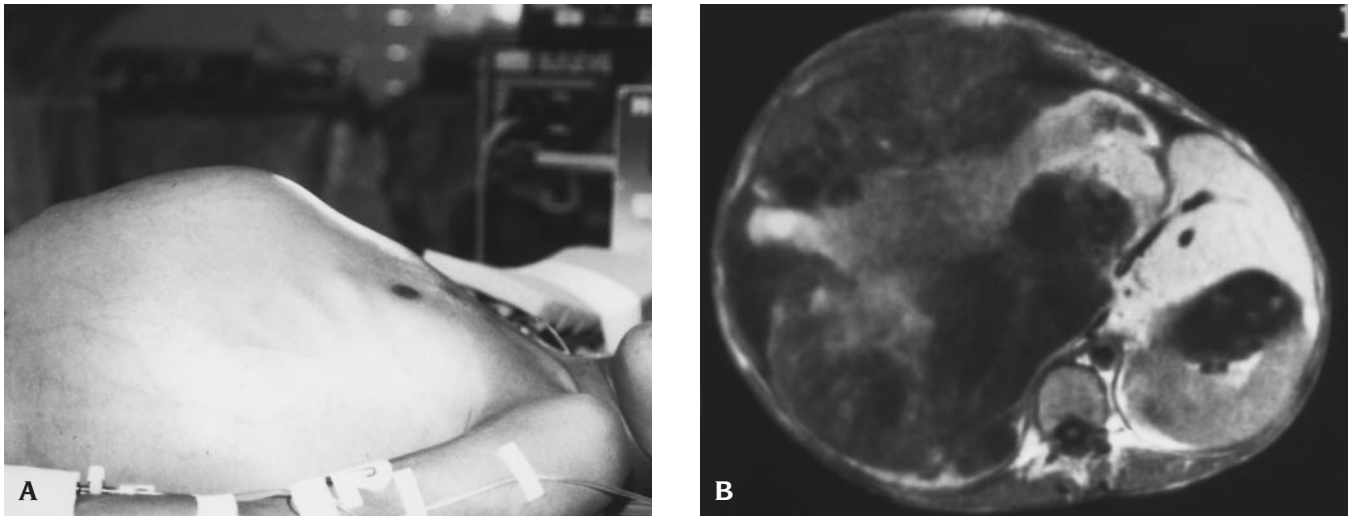

FIGURE 15-6 *A,* This 4-year-old child presented with abdominal distention, anorexia, weight loss, and vomiting. On physical examination, the child had evidence of decreased muscle mass and a hard painless mass in the right upper quadrant. *B,* An abdominal computed tomographic scan demonstrates extensive replacement of hepatic parenchyma by a mass, which was identified as an embryonal sarcoma.

A plain kidney, ureter, bladder film often identifies an enlarged liver shadow, and calcification of the tumor may be present in up to 30% of cases.[105] Doppler analysis of this vascular lesion may show high flow velocities. Specific enhancing characteristics, using helical CT and MRI, allow for the best characterization of hemangioma in most cases.[105]

The natural history of the capillary hemangioendothelioma is spontaneous resolution.[99] Digitalis and diuretics may be needed to support the child in high-output heart failure. Thyroid hormone therapy may be necessary owing to increased catabolism of endogenous thyroid hormone by the hemangioendothelioma. Steroids will elicit a clinical response for some patients, but improvement may take weeks. For severe or recalcitrant cases, treatments include antineoplastic drugs, steroids, and interferon-α, used alone or in combination.[104,108] Complete surgical resection or selective hepatic artery embolization can be lifesaving in some cases.[99] Patients with multifocal lesions are usually not surgical candidates, and they rely on embolization of the tumor or hepatic artery ligation to provide symptomatic relief while awaiting spontaneous resolution.[109] Hepatic transplant is rarely necessary.[110]

Solitary cavernous hemangioma tends to be localized within one lobe, usually the right.[111] Angiography shows a large feeding artery. The risk to the patient is rupture with hemoperitoneum. If the lesion is localized, then surgical excision is preferred. Otherwise, steroids, hepatic artery embolization, or surgical ligation is helpful.[112]

Hepatobiliary Disease

Choledochal cysts present with hepatomegaly and a palpable mass in up to 60% of patients (Figure 15-7).[113] This condition should be considered in any patient with evidence of cholestasis, with or without jaundice. The risk of malignant transformation increases with age, reaching a 12.5% overall risk. Factors that likely play a role in the development of malignancy include intracystic lithiasis, prolonged bile stasis and infection, chronic inflammation, reflux of pancreatic fluid, and genetic factors.[114] Surgical excision is not by itself fully protective against future development of cancer.[115] Liver transplant is considered for extensive intrahepatic cysts.

Caroli disease is a rare malformation consisting of multifocal nonobstructive cystic or saccular dilations of the intrahepatic bile ducts.[116] It may be an isolated finding (type 1, Caroli disease) or associated with congenital hepatic fibrosis (type 2, Caroli syndrome). Symptoms include fever, abdominal pain, jaundice, and hepatosplenomegaly. The median age at onset of symptoms is 5.5 months, whereas the median age at diagnosis is 12 months. Congenital renal mal-

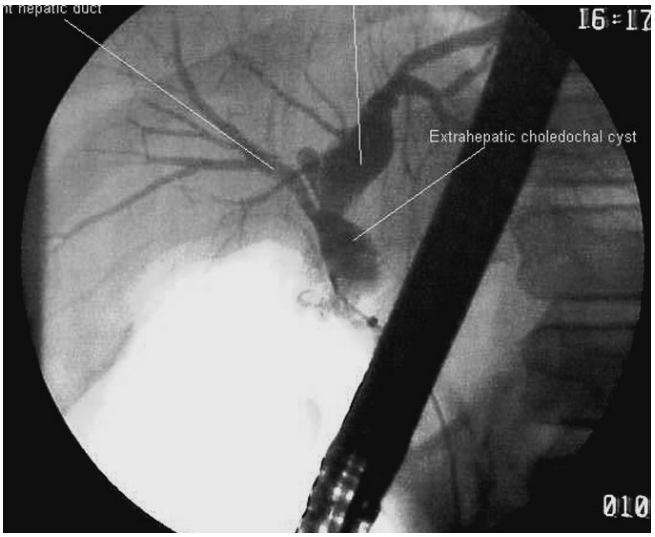

FIGURE 15-7 A 7-year-old female presented with a history of jaundice and abdominal pain for 3 days. History revealed that similar episodes had occurred at least twice in the past. At the time of the visit, she was anicteric with a liver 2.0 cm below the right costal margin. A sonogram suggested a choledochal cyst that was confirmed on endoscopic retrograde cholangiopancreatography. A left lobectomy was performed owing to the involvement of the left intrahepatic bile duct.

formations occur concomitantly in 80% of children and include ARPKD, renal tubular ectasia, and other forms of cystic diseases of the kidneys and pancreas. For children with ADPKD, the liver abnormalities may be diffuse throughout the liver or, less commonly, localized and confined to the left lobe. Prognosis depends on the frequency and severity of cholangitis.[117,118]

Congenital cysts are usually large enough to be detected on physical examination, and abdominal US characterizes the lesion as a cyst. Vague, nonspecific abdominal pain associated with abdominal distention may be the dominant clinical symptoms initially; however, hemorrhage, perforation, or torsion of the cyst can bring the patient to immediate medical attention. Treatment depends on the size and location of the cyst and is usually achieved by complete resection or drainage using a Roux-en-Y intestinal limb.[1]

Masses of the Alimentary Tract

Stomach. Tumors that involve the stomach include leiomyosarcoma, rhabdomyosarcoma, myxosarcoma, teratoma, and fibrosarcoma. Lymphoma is usually associated with post-transplant lymphoproliferative disease. Gastric carcinoma accounts for less than 5% of childhood carcinomas.[39] Presenting symptoms include anorexia, weight loss, hematemesis, and, occasionally, abdominal pain. Upper gastrointestinal contrast radiography or fiberoptic endoscopy usually identifies the lesion. Abdominal CT will demonstrate the extent of the disease and assess nodal involvement.[119]

Small Bowel. Congenital anomalies of the small bowel, which include malrotation, duplication, and Meckel diverticulum, can present in this age group with symptoms that range from vague abdominal pain to pernicious vomiting or intestinal hemorrhage. The most common malignant small bowel tumor is a lymphoma, which accounts for 5 to 10% of all non-Hodgkin lymphomas.[120,121] Patients are rarely asymptomatic and will present with fever, weight loss, altered stool pattern, and an abdominal mass. CT and US are used to evaluate the extent of the disease. A combination of surgery and chemotherapy can obtain a good remission rate for localized primary intestinal lymphoma. Intestinal perforation that complicates intestinal lymphoma in children brings a poor prognosis.[122]

Colon. Scybala, in the constipated child, can be confused for a mass arising from the pelvis or within the left lower quadrant. A careful abdominal and rectal examination will rapidly identify stool in the colon and thus avoid additional expensive and invasive tests. Adenocarcinoma is the most common colon malignancy in children, but only 1% of colon malignancies occur under 30 years of age.[119] Conditions associated with increased risk for colon cancer in children include familial polyposis syndromes and ulcerative colitis. Abdominal CT is needed to assess staging of the tumor.

Masses of the Omentum and Mesentery

Omental and mesenteric cysts likely result as a consequence of obstructed or ectopic lymphatics.[123] The lesions present most often in children and young adults and are often found incidentally, and up to 90% of patients have minimal or no symptoms. When present, symptoms can vary between a vague, nonspecific "pulling" sensation with mild abdominal discomfort and fullness and an acute abdominal crisis resulting from intestinal obstruction, volvulus, or rupture of the cyst. An abdominal mass is not always palpable but, when present, is a soft, thin-walled, freely mobile mass that is typically located within the mesentery near the terminal ileum (Figure 15-8).

Abdominal CT and US will demarcate the extent of the cyst. Omental cysts should be completely resected, but recurrences are reported.[122]

Mesenteric fibromatosis is a rare benign intra-abdominal tumor that has an aggressive tendency to infiltrate surrounding structures.[124,125] It is often associated with Gardner syndrome, previous trauma, or prolonged estrogen intake but can occur as a primary condition in the absence of predisposing factors. Possible presenting complaints include abdominal pain, a nontender abdominal mass, weight loss, or evidence of intestinal obstruction or perforation. The condition represents 12% of the soft tissue tumors in children. Spontaneous regression occurs in less than 20% of cases and most likely occurs in congenital cases. Cytogenetic analysis may improve the classification of disease in the future.[126,127]

FIGURE 15-8 A 12-year-old female presented with chronic, intermittent abdominal pain that would occasionally awaken her at night. Nonbilious, nonbloody emesis occurred two to three times per week. Abdominal examination suggested a mass in the right lower quadrant and a sonogram demonstrated a cystic lesion. The surgical specimen confirmed a large mesenteric cyst on the mesenteric border of the terminal ileum.

Complete surgical resection is the treatment of choice, but complete resection may not be possible, and local recurrence is not uncommon. Clinical features that favor the likelihood of recurrence following resection include (1) presentation at an age greater than 5 years, (2) incomplete surgical resection, (3) dermoid present on an extremity, (4) microscopic evidence of tumor at the resection margins, (5) mitotic index of 5 or more per 10 high-power fields, and (6) areas of necrosis and inflammation within the tumor. [125]

Peritoneal metastases are associated with a wide variety of primary diagnoses and will have a mass-like appearance on abdominal CT.[128] Primary tumors are rare and generally include liposarcoma, leiomyosarcoma, fibrosarcoma, and mesothelioma.[129]

Inflammatory conditions can present as an abdominal mass; examples include an abscess from a ruptured appendix or Meckel diverticulum, pelvic inflammatory disease, or Crohn disease. The mass is usually tender and sometimes fluctuant and can be identified on abdominal or rectal examination. Abdominal US and contrast-enhanced CT are useful if more definition of the mass is required. An inflammatory pseudotumor is a firm, painless, well-circumscribed, nonencapsulated mass that commonly adheres to and infiltrates surrounding viscera.[130] The etiology is obscure, but such pseudotumors are associated with an inflammatory response in conditions such as Hodgkin disease, Castleman disease, and peptic ulcer disease. There are no reports of malignant change. Multiple local recurrences may plague the patient following initial surgical resection.

MASSES IN ADOLESCENTS

Many of the conditions previously described may occur in adolescents. However, some occur more commonly in this age group. Hematocolpos may not become evident until the onset of menses, when the female patient presents with no menstrual bleeding, constipation, difficulty voiding, or recurrent urinary tract infections.[1] Ovarian cysts and tumors can present as an asymptomatic abdominal mass, or the patient may complain of a dull, poorly localized discomfort. Occasionally, an abdominal crisis brings the child to medical attention as a consequence of ovarian torsion (Figure 15-9). Over 85% of cystic ovarian lesions are benign, and a teratoma (dermoid) is the most common cystic lesion. Physiologic follicular cysts occur in 12- to 14-year-old adolescents. If surgery is needed, enucleation of the cyst will preserve ovarian tissue.[1] Overall, 17% of ovarian masses in children are malignant.[1] A solid lesion noted on pelvic US should be a warning sign that a malignant lesion may be present. Potential malignant ovarian tumors include germ cell tumor, dysgerminoma, choriocarcinoma, gonadoblastoma, endodermal sinus tumor, and embryonal carcinoma (Figure 15-10). Approximately 20% of malignant ovarian tumors involve epithelial tumors (serous and mucinous cystadenocarcinoma), mesenchymal tumors (androblastoma, granulosa cell tumor), and stromal tumors. Because most ovarian lesions are benign, ovary-sparing operations should be performed whenever feasible.[131] Renal cell carcinoma occurs at a mean age of 14 years, and patients will present with flank pain and gross hematuria.[132,133] Survival is 60% in those patients with complete resection because these tumors are resistant to chemotherapy. Prognosis is poor with metastatic disease.

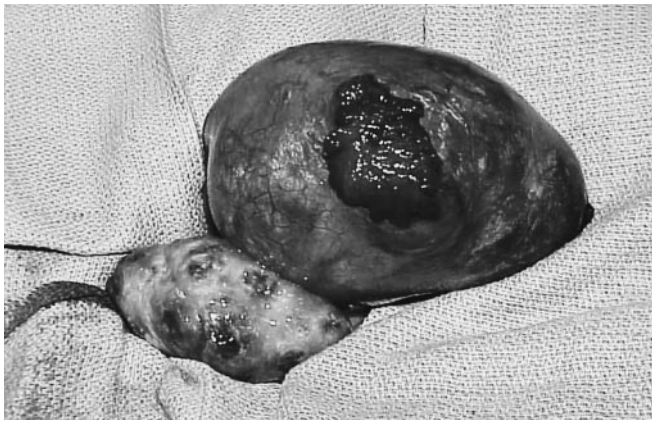

FIGURE 15-9 A 13-year-old female presented to the emergency room with sudden, intense left lower quadrant pain. An ultrasound examination suggested an ovarian mass. This surgical specimen is an ovarian torsion. The fimbria on the tubal portion can be seen.

FIGURE 15-10 This large ovarian teratoma was delivered from the abdomen of a 15-year-old female who presented with acute lower abdominal pain and vomiting. A mass arising from the pelvis was noted on physical examination.

CHAPTER 16

GASTROINTESTINAL BLEEDING

1. *Upper Gastrointestinal Bleeding*

Mark A. Gilger, MD

Upper gastrointestinal (UGI) bleeding in children is an unusual but potentially serious problem. Hematemesis is always a frightening ordeal for the patient and parents. Fortunately, it is rarely life threatening and usually stops. Although the causes of UGI bleeding have remained unchanged, the treatment, such as the use of octreotide and endoscopic therapy, has improved. UGI bleeding is considered a "red flag" sign of possible peptic injury and always warrants further investigation.[1] The purpose of this chapter is to outline a rational approach to children with UGI bleeding and discuss diagnostic and therapeutic interventions.

EPIDEMIOLOGY

UGI bleeding is uncommon in children. Using the Pediatric Endoscopy Database System–Clinical Outcomes Research Initiative (PEDS-CORI), Bancroft and colleagues found that hematemesis accounts for only about 5% (327 of 6,337) of indications for upper endoscopy in children.[2] In children hospitalized in the intensive care unit, UGI bleeding is considerably more common, with an incidence ranging from 6 to 25%.[3,4] However, even in this critically ill population, life-threatening UGI bleeding occurred in only 0.4% of children.[5]

DEFINITIONS

UGI bleeding refers to bleeding occurring above the ligament of Treitz. Hematemesis indicates vomiting with frank red blood and generally denotes a more rapidly bleeding lesion. Coffee ground emesis is secondary to the coagulative effect of gastric acid on blood. It is usually slower and from a more benign bleeding source. Melena refers to black, tarry stools. The dark black color is probably caused by hematin, the oxidative product of heme produced by intestinal bacteria. Melena can be produced by relatively small volumes of blood (50–100 mL) in the stomach. Melena may persist for 3 to 5 days and thus cannot be used as an indication of ongoing bleeding.[6] In general, most UGI bleeding in children is benign and stops without intervention.

IS IT BLOOD?

There are a variety of important considerations in a child with suspected UGI bleeding. The first is to determine if the suspicious material, whether seen in emesis or stool, actually contains blood. In children, many common beverages and foods may give the appearance of blood if vomited. For example, red food coloring, as found in Jello, Kool Aid, and other red foods, such as tomatoes and strawberries, may give the appearance of blood in emesis. UGI bleeding also may cause melanotic stools. Once again, foods such as spinach and licorice and certain medications such as bismuth and iron may cause the stool to appear black.

Determination of blood in gastric contents is best accomplished using a bedside technique to detect hemoglobin (ie, Gastroccult, SmithKline Diagnostics, Inc, San Jose, CA). Fecal material can also be tested for the presence of hemoglobin (ie, Hemoccult, SmithKline Diagnostics).[7] The principle in both products is based on the oxidation of guaiac by hydrogen peroxide to a blue quinone compound. Guaiac is a colorless compound that turns blue when placed in contact with substances that have peroxidase activity and are then exposed to hydrogen peroxide. The paper is impregnated with guaiac, a natural resin extracted from the wood of *Guaiacum officinale*. If the fecal material contains blood, the peroxidase activity of the heme portion of hemoglobin will catalyze the oxidation of guaiaconic acid when hydrogen peroxide (the developer) is placed on the paper. The test is simple and convenient but has limitations. The guaiac oxidation reaction is not specific for blood but rather for peroxidase activity. Many foods, such as red meat and certain vegetables (melons, grapes, radishes, turnips, cauliflower, and broccoli), contain enough peroxidase activity to cause a positive guaiac reaction.[7,8] Fortunately, plant peroxidases are relatively unstable and, despite the potential, rarely cause a false-positive reaction.[7] Iron no longer produces a false-positive Hemoccult reaction.[7]

IS THE BLEEDING GASTROINTESTINAL?

UGI bleeding is often manifest as blood per os. There are a variety of potential nongastrointestinal bleeding sources above the ligament of Treitz. For example, epistaxis, blood-tinged sputum, and oropharyngeal bleeding (ie, tonsils, adenoids, tongue, and gingivitis) will all produce blood per os. In some cases, the source is obvious, such as with epistaxis or visible injury to the oropharyngeal mucosa. However, the bleeding source could be the lungs or upper airway. It must be recognized that sputum is often poorly expectorated in young children, leading to the assumption that the bleeding is gastrointestinal. Pharyngeal bleeding may be difficult to identify with routine inspection of the oral cavity. Arteriovenous malformations of the tongue and posterior pharynx must be considered, as well as bleeding from the salivary glands.

APPROACH TO UGI BLEEDING

The initial evaluation of any child with gastrointestinal bleeding must include a brief history followed by a rapid assessment of the physical condition, with particular attention to the vital signs and the patient's level of consciousness (Figure 16.1-1). If the bleeding is severe, therapy may need to begin before the location of the bleeding can be ascertained. Significant gastrointestinal bleeding will be initially manifest by tachycardia, whereas hypotension occurs later, an ominous signal of impending cardiovascular collapse. Immediate therapy is aimed at correction of volume loss and anemia, which should include aggressive fluid and blood resuscitation. If the patient remains unstable after receiving a blood transfusion of approximately 85 mL/kg or greater, emergency exploratory surgery is indicated. Surgical consultation is mandatory in any case of severe UGI bleeding. Sources such as varices, ulcers penetrating into an artery, or mucosal tears into arterial vasculature must be considered in severe UGI bleeding in children. Careful attention must be paid to the child's fluid volume status. Be aware that overexpansion of blood volume may worsen variceal bleeding.

Once the child is hemodynamically stable, further evaluation can proceed in a controlled manner (see Figure 16.1-1). Initial laboratory evaluation should generally include a complete blood count with platelets and reticulocyte count, a protime and partial thromboplastin time, and a blood type and crossmatch (Table 16.1-1). Additional laboratories to assess liver function (alanine aminotransferase, aspartate aminotransferase, and albumin) and kidney function (blood urea nitrogen and creatinine) may prove useful. For example, abnormal liver enzymes and a low albumin or an elevated protime can be an indication of chronic liver disease. An elevated blood urea nitrogen can be an indication of UGI bleeding because azotemia may be the result of intestinal absorption of the blood and hypovolemia.[9,10]

Gastric aspiration is a simple, useful indicator of UGI bleeding. A bloody aspirate indicates active bleeding, usually gastric or esophageal. A clear aspirate does not eliminate a duodenal bleeding source. In a national survey of

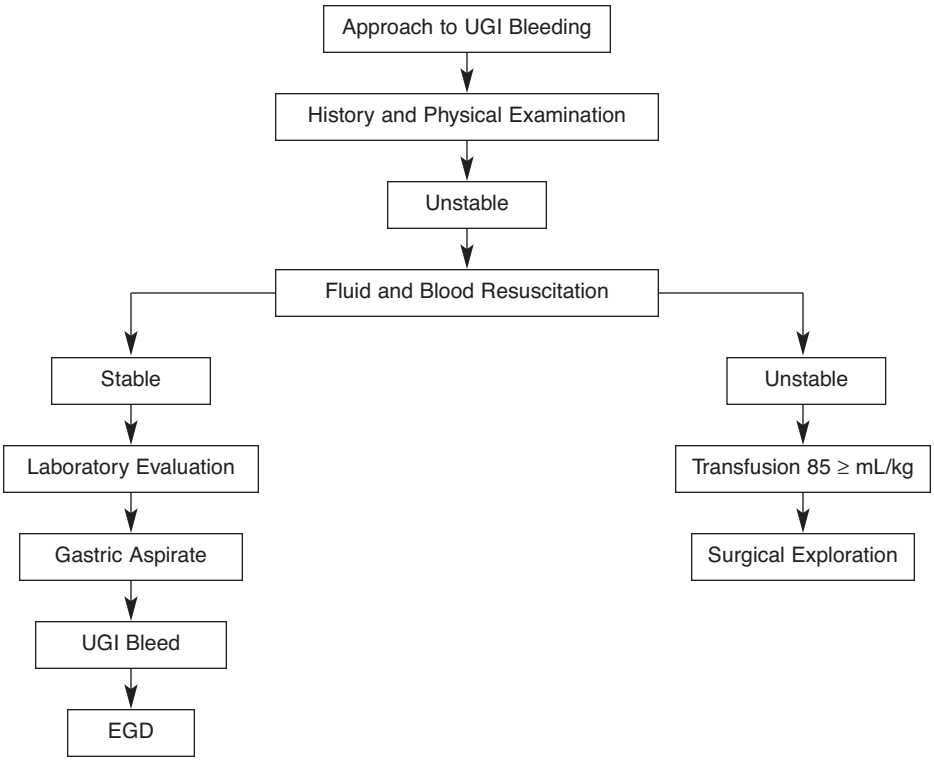

FIGURE 16.1-1 An approach to the diagnosis and treatment of upper gastrointestinal (UGI) bleeding in children, emphasizing initial stabilization followed by a controlled diagnostic evaluation. Adapted from references 13 to 17, 43, 63, and 86. EGD = esophagogastroduodenoscopy.

TABLE 16.1-1 COMMON LABORATORY STUDIES USEFUL IN THE EVALUATION OF UPPER GASTROINTESTINAL BLEEDING IN CHILDREN

Complete blood count with differential
Reticulocyte count
Protime and partial thromboplastin time
Blood type and crossmatch
Alanine aminotransferase, aspartate aminotransferase, albumin
Blood urea nitrogen, creatinine

UGI bleeding in adults, Gilbert and colleagues reported that a bleeding source was identified in 16% of patients with a negative gastric aspirate.[11] Iced saline lavage is no longer recommended. It has been shown to be ineffective in slowing UGI bleeding in animal models and has the theoretic potential of causing hypothermia and electrolyte abnormalities in infants.[12]

After the rapid assessment of vital signs, a thorough physical examination can reveal stigmata of underlying disease, suggesting a source of bleeding (see Figure 16.1-1). For example, a variety of dermatologic lesions are similar to those seen in the gastrointestinal tract. Skin findings such as a caput medusa, spider angiomata, and jaundice may indicate liver dysfunction. Other dermatologic findings, such as hemangioma and telangiectasia, may be indicative of lesions in the gastrointestinal tract. Cutaneous palpable purpuras are suggestive of Henoch-Schönlein purpura. Other physical findings, such as hepatosplenomegaly, may indicate cirrhosis.

ETIOLOGY BY AGE GROUP

UGI bleeding in children is best considered by age because certain causes are unique to particular age groups. Table 16.1-2 lists the potential etiologies of UGI bleeding in children by age group.[13–22]

NEONATE

Hematemesis in the first few days of life is suggestive of swallowed maternal blood.[23] Fortunately, maternal blood can be differentiated from that of a newborn using the Apt test for fetal hemoglobin.[23] The test can be performed using emesis or stool. One milliliter of emesis is mixed with 5 mL of water. The mixture is centrifuged to produce a clear, pink supernatant. One milliliter of supernatant is added to 4 mL of 1% sodium hydroxide. After 2 minutes, if the solution remains pink, it is fetal hemoglobin, whereas a yellow-brown color indicates maternal hemoglobin A.

The well newborn may present with hematemesis with or without other manifestations of bleeding, such as epistaxis or easy bruising. In this scenario, hemorrhagic disease of the newborn secondary to vitamin K deficiency must be considered.[24] This problem is easily remedied by the intramuscular or intravenous administration of vitamin K. Failure to correct the bleeding should be followed by laboratory evaluation to assess for other bleeding disorders, such as clotting factor deficiencies, von Willebrand's disease, and other bleeding diatheses.[25] Vitamin K deficiency can also be the result of underlying fat malabsorption, such as cystic fibrosis and cholestatic syndromes, although these problems are rare in the neonatal period. In the breastfed infant, maternal blood can be ingested from a cracked or irritated breast. Sensitivity to dietary proteins, especially milk and soy, can be manifest as hematemesis, although it more commonly presents as streaks of blood and mucus in the stool.[26] Unusual causes of UGI bleeding in this age group include milk-protein sensitivity,[18,19] hypertrophic pyloric stenosis,[20] and anatomic deformities such as a web of the stomach and duodenum.[21,22]

Significant UGI bleeding in the neonate is usually associated with critical illness, such as shock. The neonatal gut is highly susceptible to mucosal injury during the relative intestinal ischemia produced by shock. Stress gastritis and ulcers of the stomach and duodenum can result and are potential causes of significant UGI bleeding (see Table 16.1-2).

INFANT

Stress gastritis and ulceration with secondary UGI bleeding are well recognized in the critically ill infant.[3–5] Although fairly common, clinically significant bleeding is unusual, with estimates ranging between 0.4% and 2% of children.[3,4]

Acid-peptic disease, such as esophagitis, gastritis, and ulcer, although uncommon, does occur and can cause UGI bleeding in this age group.[27] The bleeding is generally minor. Hematemesis is rarely the only manifestation and is usually accompanied by irritability with feeding, feeding refusal, and regurgitation.[27]

TABLE 16.1-2 ETIOLOGIES OF UPPER GASTROINTESTINAL BLEEDING IN CHILDREN BY AGE GROUP, IN RELATIVE ORDER OF FREQUENCY

NEWBORN	INFANT	CHILD–ADOLESCENT
Swallowed maternal blood	Stress gastritis or ulcer	Mallory-Weiss tear
Vitamin K deficiency	Acid-peptic disease	Acid-peptic disease
Stress gastritis or ulcer	Mallory-Weiss tear	Varices
Acid-peptic disease	Vascular anomaly	Caustic ingestion
Vascular anomaly	Gastrointestinal duplications	Vasculitis (Henoch-Schönlein purpura)
Coagulopathy	Gastric/esophageal varices	Crohn disease
Milk-protein sensitivity	Duodenal/gastric webs	Bowel obstruction
	Bowel obstruction	Dieulafoy lesion, hemobilia

Adapted from references 3 to 5, 13 to 17, 43, and 63.

Vascular anomalies often appear on the skin and soft tissue during infancy. They can be divided into tumors and vascular malformations. Hemangiomas are the most common tumor, being found in 4 to 12% of white infants (Table 16.1-3).[28,29] Fortunately, vascular anomalies of the gastrointestinal tract are considerably less common, although the exact prevalence is unknown.[28] Symptomatic hemangiomas of the gut are rare, but when they do occur, they are commonly associated with skin lesions. The gastrointestinal bleeding can be significant, even requiring transfusion (Figure 16.1-2).[28] Most hemangiomas require no treatment and will spontaneously regress with time. In severe, multifocal, or large hemangiomatous lesions, treatment with prednisone may be useful. Lesions that do not respond to corticosteriods may be treated with interferon alfa-2b.[30]

Mechanical obstruction of the UGI tract can be a cause of hematemesis in this age group. Bleeding may be caused by mucosal injury from the mechanical shearing forces, such as Mallory-Weiss syndrome or gastric prolapse.[31–34] Anatomic abnormalities, such as duplication cysts, can cause UGI bleeding. Duplications containing gastric mucosa can ulcerate and bleed. Antral duplications have been reported to cause hypergastrinemia with ulceration and bleeding.[35] Obstructive lesions such as hypertrophic pyloric stenosis,[20] duodenal web,[21] and antral web[22] have all been reported as causing UGI bleeding in infants.

Children and Adolescents

Vomiting is common in children, usually the result of infection. It should come as no surprise that the consequence of forceful vomiting, such as a Mallory-Weiss tear, is likely the most common cause of minor UGI bleeding in children (see Table 16.1-2). Peptic mucosal injury, such as esophagitis, gastritis, and ulceration, may result in UGI bleeding. Although erosive esophagitis is actually quite common, being reported in 34.6% of neurologically normal children undergoing upper endoscopy,[36] secondary UGI bleeding is not nearly so frequent. As in adults, a variety of nonsteroidal anti-inflammatory medications, such as aspirin, ibuprofen, naproxen, and ketorolac, can cause gastric mucosal injury, resulting in UGI bleeding.[37–39] Gastric infection with *Helicobacter pylori* can result in peptic ulceration with bleeding.[40] Rare cases of mucosa-associated lymphoid tissue lymphoma (MALToma) have occurred secondary to *H. pylori* infection, which may also result in UGI bleeding.[17]

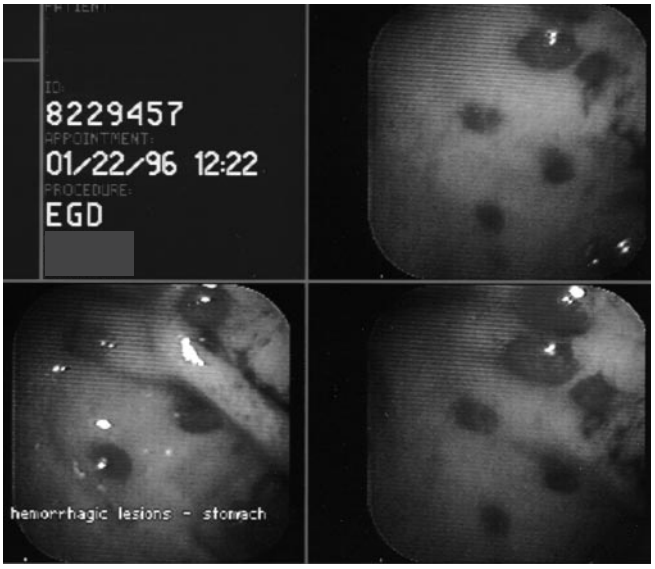

FIGURE 16.1-2 Multiple hemangiomas seen in the stomach of a 3-month-old girl with hematemesis.

Variceal bleeding is the most common cause of severe UGI bleeding in children.[41] Most variceal bleeding is esophageal, secondary to the high-pressure, turbulent flow in the thin-walled superficial vessels of the distal esophagus.[42] Acute variceal bleeding in children stops spontaneously in about 50% of patients, with rebleeding found in 40%.[43] The lifelong risk of variceal bleeding appears to be about 50%.[43,44] The clinical presentation is usually either hematemesis or melena. In some children, nonspecific abdominal pain may precede variceal bleeding for up to 48 hours.[45]

Ingestion of foreign bodies and caustics has the potential to cause UGI bleeding.[13,46] In general, bleeding from a foreign body implies that either a sharp object (eg, safety pin, needle, razor) has been ingested, causing a mucosal tear, or the ingested object is chronic and has caused an ulcer.[46,47] Bleeding caused by a caustic ingestion is usually a late sign of the ingestion, which has caused a stricture.

Vascular anomalies are a rare cause of UGI bleeding (see Tables 16.1-2 and 16.1-3). Minor UGI bleeding has been found with gastric hemangioma and Dieulafoy lesions.[48] Very rare but massive UGI bleeding has been noted with an aortoesophageal fistula.[49]

A variety of other causes of UGI bleeding have been reported in children. These include gastric or duodenal vasculitis, such as Henoch-Schönlein purpura,[50] Munchausen syndrome by proxy,[51] pharyngeal leeches,[52] ruptured pancreatic pseudocyst,[53] and bleeding from gastric polyps in children with Menkes disease.[54] Certain gastric tumors have the potential to ulcerate and bleed, such as leiomyosarcoma and teratoma.[55] Crohn disease with UGI involvement must be considered as a cause of UGI bleeding in this age group.[13,56,57]

DIAGNOSIS

Radiographic Studies

In general, radiographic studies have a limited role in the diagnosis of UGI bleeding. A plain x-ray film is useful in identifying unsuspected foreign bodies, with free air sug-

gesting bowel perforation and bowel obstruction. Barium studies are of little value because they cannot detect superficial mucosal lesions and can obscure the mucosa during endoscopy. Abdominal ultrasonography is useful in the assessment of portal hypertension or if large vascular anomalies are suspected.[17] Doppler flow can identify evidence of cirrhosis and portal blood flow dynamics.

Angiography

In cases of massive UGI bleeding, angiography offers an alternative to endoscopy for both diagnosis and treatment. The rule of thumb is that the bleeding must be at least 0.5 mL/min to be detected by angiography.[58] Hemobilia is a very unusual although appropriate indication for angiography over upper endoscopy.[17] Angiography also provides a therapeutic approach, such as the placement of "coils" for embolization of the bleeding vessel.[59,60] Transjugular intrahepatic portosystemic shunts offer an alternative to surgical therapy in some children with variceal bleeding. Experience is still limited in children, but this angiographic technique holds promise.[61]

Nuclear Medicine

Technetium-labeled bleeding scans and sulfur colloid scans are helpful in the diagnosis of obscure bleeding in the small bowel. However, in UGI bleeding, upper endoscopy is far superior for evaluation of bleeding above the ligament of Treitz.

Endoscopy

Esophagogastroduodenoscopy (EGD) is the preferred method to evaluate the UGI tract for a source of bleeding. Hematemesis is considered a "red flag" sign and is an indication for early EGD.[1] EGD is generally indicated for assessment of acute UGI bleeding requiring transfusion or unexplained recurrent bleeding.[17] EGD can determine the source of the bleeding in 90% of cases.[13] EGD is particularly useful in the diagnosis of mucosal lesions such as gastritis, esophagitis, peptic ulcers, and Mallory-Weiss tears. In a recent review of 6,337 EGDs using the PEDS-CORI database, Bancroft and colleagues found that 20% had esophageal inflammation, 17% had gastric mucosal abnormalities, 6% had peptic ulcers, 6% had varices, 2% had Mallory-Weiss tears, and 8% had nonspecific mucosal abnormalities.[2] This differs somewhat from the reports of others, such as Cox and Ament, who reported that 20% of children undergoing EGD had duodenal ulcer, 18% had gastric ulcer, 15% had esophagitis, 13% had gastritis, and 10% had varices.[62] It is important to recognize that most UGI bleeding in children stops spontaneously; thus, emergency endoscopy is indicated only when the findings will influence a clinical decision, such as the need for medical or surgical therapy.[13] EGD is contraindicated if the patient is clinically unstable, such as in shock, hypovolemia, myocardial ischemia, or profound anemia.[13,17]

TREATMENT

The initial goal in the treatment of any child with UGI bleeding is to provide hemodynamic stability, such as adequate oxygen delivery, fluid and blood resuscitation, and correction of any coagulopathy or metabolic or electrolyte abnormality (see Figure 16.1-1). It is only after the patient has been appropriately stabilized that medical and endoscopic treatment can begin.

Medical Therapy

Table 16.1-4 lists the medications useful for treatment of UGI bleeding.[63] Treatment consists of either acid suppression or vasoactive agents. Initial treatment for suspected acid-peptic disease is appropriate because this is a common cause of UGI bleeding in children.[63–69]

In children with severe UGI bleeding, medications to reduce splanchnic blood flow, such as octreotide and vasopressin, can be useful. Although both drugs are generally well tolerated in children, octreotide is the drug of choice because it is effective and has minimal side effects.[42,43]

Endoscopic Therapy

A variety of endoscopic therapies are available for the treatment of UGI bleeding. These include electrocoagulation (heater probe, monopolar probe, and bipolar electocoagulation [BICAP] probe[70]), laser photocoagulation,[71] argon plasma coagulation,[72] injection of epinephrine and sclerosants,[73] band ligation,[48] and mechanical clipping.[74] Unfortunately, there is little published experience with these techniques in children. As a result, which approach is best remains unknown. The argon plasma coagulator is an attractive tool because it fits through small pediatric endoscopes and has a controlled depth of penetration.[72] Laser therapy is commonly applied in adults, but there is a significant learning curve and high potential for full-thickness wall injury.[13,71] Injection therapy is appealing because it is easily performed, is inexpensive, and uses a sclerotherapy needle, all of which are familiar to the pediatric endoscopist. The combination of injection (ie, epinephrine) and BICAP is likely the most commonly performed endoscopic treatment of UGI bleeding in children, although no data exist. In this technique, the bleeding is extinguished with injection of 1:10,000 epinephrine followed by BICAP (Figure 16.1-3).

Endoscopic treatment of esophageal varices includes either injection sclerotherapy or variceal banding. Injection sclerotherapy has been used for the treatment of

variceal hemorrhage for over 40 years, even in children.[75] Control of bleeding is achieved in over 90% of cases.[76,77] Varices are eradicated in over 80% of cases.[43,77] Although simple and attractive, complications after sclerotherapy are common, such as strictures, recurrence of the varices, and recurrent bleeding.[43] Variceal banding is a considerably more recent development, first introduced in 1989 as an adaptation of the treatment for hemorrhoids (Figure 16.1-4).[78] In meta-analysis studies in adult patients, there is no difference between sclerotherapy and banding in the control of bleeding or mortality.[79] Although there are no comparative studies between sclerotherapy and banding in children, there is an increasing body of literature to suggest that banding is the preferred method in children.[43,80–82] Banding appears to be much better tolerated in children compared with sclerotherapy, with less retrosternal pain and no fever.[43,79] Banding equipment has not yet been adapted for use in infants and small children because the banding device remains too large. Although variceal banding is effective in controlling bleeding, rebleeding occurs in up to 80% of patients.[83,84]

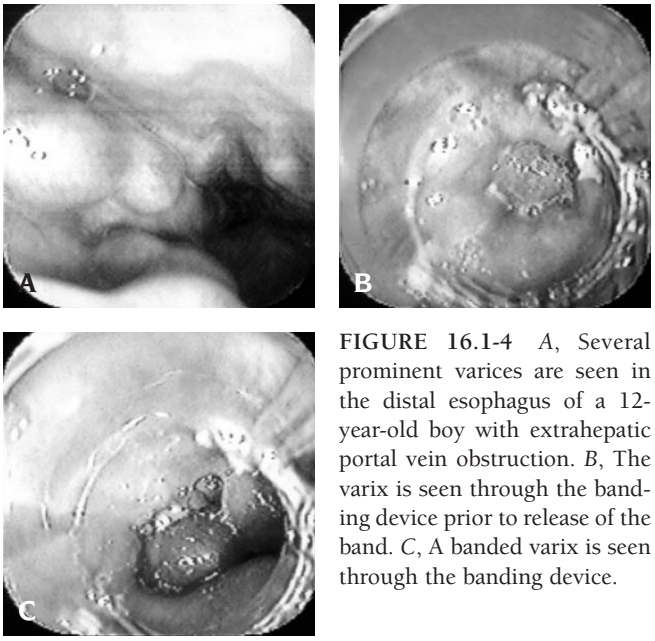

FIGURE 16.1-4 *A*, Several prominent varices are seen in the distal esophagus of a 12-year-old boy with extrahepatic portal vein obstruction. *B*, The varix is seen through the banding device prior to release of the band. *C*, A banded varix is seen through the banding device.

Surgery

In any situation in which the risk of bleeding is high, surgical consultation should always be obtained prior to the interventional technique (see Figure 16.1-1). Exploratory laparotomy is reserved for uncontrollable bleeding. In general, surgery is most common with a posterior duodenal ulcer with arterial bleeding, bowel perforation with bleeding, and gastroesophageal varices.[17] In a review of a 45-year experience with 43 children requiring surgery for peptic ulcer disease and secondary UGI bleeding, Arazow and colleagues found that 38 were in the era before histamine receptor antagonists.[85] They found that only two children in the "proton pump inhibitor era" required surgery, one for bleeding and one for obstruction.

Surgical intervention for gastroesophageal varices requires a portosystemic shunting procedure, such as a mesocaval shunt, distal splenorenal shunt, or central portocaval shunt.[86] The esophageal transection and devascularization, or Sugiura procedure, is a rare but potentially lifesaving surgery for bleeding esophageal varices.[87] de Ville de Goyet and colleagues reported a portal revascularization surgery for extrahepatic venous obstruction.[88] In this surgery, the superior mesenteric vein is connected to the left hepatic vein bypassing the portal venous obstruction. It has been successful in seven children to date. In children in whom the left intrahepatic vein is patent and accessible, this surgery is a unique treatment option.

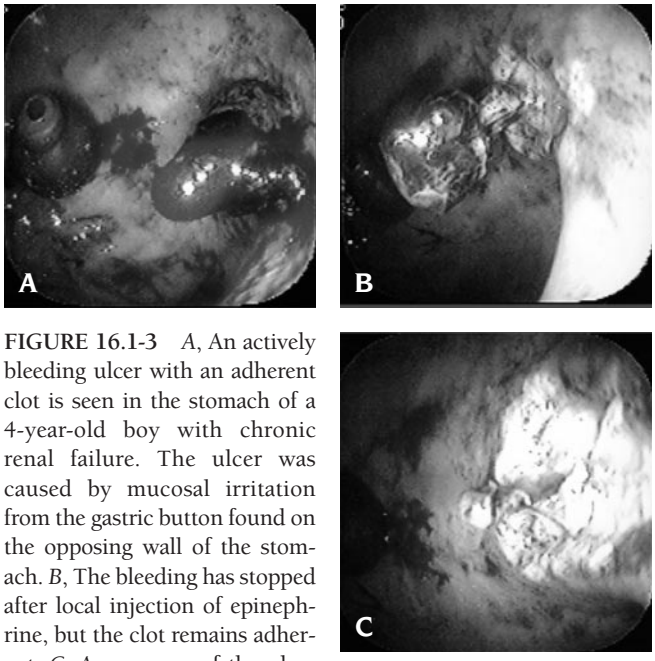

FIGURE 16.1-3 *A*, An actively bleeding ulcer with an adherent clot is seen in the stomach of a 4-year-old boy with chronic renal failure. The ulcer was caused by mucosal irritation from the gastric button found on the opposing wall of the stomach. *B*, The bleeding has stopped after local injection of epinephrine, but the clot remains adherent. *C*, Appearance of the ulcer base after coagulation with a bipolar electrocoagulation probe and removal of the clot.

CONCLUSIONS

UGI bleeding in children is an unusual but occasionally devastating problem. Fortunately, it is rarely life threatening in children and usually stops spontaneously. Treatment options, such as the use of octreotide and endoscopic therapy, have markedly improved. However, even though new medications and exciting interventional techniques exist, one must first do no harm.

2. Lower Gastrointestinal Bleeding

Dominique Turck, MD
Laurent Michaud, MD

Lower gastrointestinal (LGI) bleeding is defined as bleeding with an origin distal to the ligament of Treitz. Although the passage of blood rectally in a child is very alarming to parents and is therefore promptly brought to the physician's attention, blood losses are usually mild to moderate and self-limited. The clinical presentation of LGI bleeding depends mainly on the rate and quantity of blood loss and may range from stools positive for fecal occult blood test to a life-threatening hemorrhage presenting with profound shock.

LGI bleeding can be revealed in four ways: (1) hematochezia, that is, the passage of bright red blood per rectum, either isolated or mixed with stools, indicating an origin low in the gastrointestinal tract, most commonly the colon. However, this finding is less reliable in infants, given their relatively shorter intestinal transit time. Owing to the quantity and cathartic action of blood through the intestine, massive upper gastrointestinal bleeding may present with hematochezia; (2) melena, that is, the passage per rectum of black, tarry, and foul-smelling stools, indicating a source of bleeding from above the ileocecal valve. Melena can also be seen in cases of bleeding from the proximal large bowel provided that the colonic transit time is slow; (3) occult gastrointestinal bleeding, with symptoms limited to pallor or fatigue, detected by discovery of iron deficiency or iron deficiency anemia or by testing for the presence of fecal blood; and (4) symptoms of severe blood loss such as malaise, tachycardia, or even profound shock without any objective sign of bleeding.

Proper history taking and thorough physical examination are of paramount importance to help differentiate the numerous diagnostic possibilities of LGI bleeding in children. The spectrum of disease to be considered is very different from that of adults. The pediatrician should never rush toward diagnostic workup at the expense of basic care of the child. Caution is necessary for the use of diagnostic tests, especially in very young children. The main parameters to take into account for the differential diagnosis are (1) age, because many causes of LGI bleeding are specific to certain age groups; (2) location of the bleeding in relation to the characteristics of the stools; (3) amount of blood passed; and (4) condition of the patient, that is, the presence or absence of associated symptoms and physical signs.

The objectives of this chapter are to review the nature of bleeding and the initial assessment, history taking, physical examination, and diagnostic investigations to be performed in a child presenting with LGI bleeding. The main specific causes of LGI bleeding are reviewed by age from birth to adolescence. Rare causes, occult LGI bleeding, and LGI bleeding in developing countries are also presented. Specific treatment of the various underlying causes of LGI bleeding is beyond the scope of this chapter.

NATURE OF BLEEDING

Is It Blood?

Many substances ingested by children, either foods or medicines, may cause the stool to appear bloody or dark or to test positive for the presence of blood.[1] A red or purple tinge to the stools can mimic hematochezia, especially in cases of concomitant diarrhea, because of the ingestion of artificial food colorings used in drinks, breakfast cereals, syrup medications, and gelatin desserts or of tomato skins, peach skins, and beets. Melena may be confused with dark- or black-colored stools owing to iron preparations, bismuth subsalicylate, spinach, dark chocolate, purple grapes and grape juice, blueberries, and cranberries.[2]

The history will help determine if it is truly blood that has been passed, but if questions remain as to the nature of the red streaks or the black discoloration, stool analysis can rapidly bring the answer. Fecal occult blood testing has been shown as an efficient screening aid for detecting gastrointestinal blood loss.[3] However, fecal blood testing devices may lack specificity or sensitivity. False-positive results can be due to the ingestion of red meat or peroxidase-containing fruits and vegetables such as tomato, cherry, turnip, broccoli, radish, cantaloupe, or cauliflower. False-negative results can be observed in case of ingestion of large doses of vitamin C or, because of a dry stool sample, outdated reagents or the prior conversion of hemoglobin to porphyrin by the intestinal microbiota of the child.[3]

Is It Blood from the Child?

Ingestion of maternal blood at delivery or from a fissured nipple during breastfeeding can result in melena in an otherwise healthy-appearing baby. Blood can be identified as of maternal origin by means of the Apt-Downey test of a stool sample. The Apt-Downey test differentiates maternal from fetal hemoglobin by their different colorimetric responses to denaturation with sodium hydroxide.[4] Factitious reporting of LGI bleeding or addition of blood to stool samples has been described in Munchausen syndrome by proxy.[5,6] This factitious illness alleged by a parent, usually the mother, should be suspected when extensive testing yields no cause in an otherwise healthy child whose clinical examination is repeatedly normal.

Is It Blood from the Gastrointestinal Tract?

Blood exogenous to the gastrointestinal tract is a possible cause of pseudo-LGI bleeding. Swallowed blood postadenoidectomy or post-tonsillectomy, or from epistaxis or traumatic nasopharyngeal lesions owing to the passage of a nasogastric tube, may, in cases of vigorous bleeding, be the cause of melena. In a pubertal female patient with apparent hematochezia, the onset of menarche should be considered. Hematuria may also be mistaken for hematochezia.

Is It Blood from the Lower Gastrointestinal Tract?

As mentioned above, hematochezia may be seen in cases of severe upper gastrointestinal bleeding, whereas melena may be secondary to LGI bleeding. The presence of hyperactive bowel sounds is suggestive of upper gastrointestinal bleeding. The placement of a nasogastric tube and aspiration and blood testing of gastric contents are of great help to determine the location of gastrointestinal bleeding, especially in patients with hemodynamic instability and in the absence of frank hematemesis. The presence of esophageal varices is not a contraindication to the use of this test. A gastric aspirate negative for blood is very much in favor of bleeding originating from beyond the ligament of Treitz in the small bowel or colon. However, a bleeding duodenal ulcer or hemobilia (hemorrhage into the biliary tract) cannot be completely ruled out if no reflux of blood occurs from the duodenum to the stomach. In case of doubt, esogastroduodenoscopy will enable recognition of the bleeding source from the upper gastrointestinal tract.

INITIAL ASSESSMENT

The most important step in the initial management of a child with LGI bleeding is the rapid assessment of the degree of volume loss and the initiation of fluid resuscitation if needed. Therefore, hemodynamics is the initial focal point. Vital signs are taken, and the child's skin and mucous membranes are inspected for pallor and signs of shock. If the child looks healthy and has no past history of disease that could lead to LGI bleeding, and if blood loss is minor and hemodynamic condition is unquestionably normal, admission to hospital is not necessary, and a diagnostic workup can be performed on an outpatient basis. However, close follow-up is necessary in cases of worsening or recurrence of bleeding.

Tachycardia is a very sensitive indicator of severe blood loss, whereas slow capillary refill and hypotension are ominous signs of hypovolemia and shock. Symptoms of hemodynamic instability should prompt urgent placement of two large-bore intravenous catheters and may lead to transferring the patient to the intensive care unit. Supplemental oxygen is provided if necessary. Blood is drawn for a complete blood count (hemoglobin, hematocrit, platelet count), clotting studies, and routine chemistry. Blood typing and crossmatching should also be performed so that transfusion can be given without delay if needed.

HISTORY

Family History

A first-degree relative history of allergy, inflammatory bowel disease, familial adenomatous polyposis, hereditary hemorrhagic telangiectasia, Ehlers-Danlos syndrome, or bleeding disorders is strongly suggestive of the same disease in the presenting child.

Child History

Omphalitis, sepsis, and umbilical catheterization in the neonatal period should be sought because of the risk of portal vein cavernoma and secondary portal hypertension, as well as abdominal surgery, especially resection of the small bowel and/or right colon in the neonatal period or early infancy, previous episodes of bleeding from the gastrointestinal tract or other site, hematologic abnormalities, and liver disease.

Attendance at a day-care center is associated with a higher risk for bacterial or viral gastrointestinal infection, whereas recent travel to an endemic area is suggestive of amebiasis. Recent use of antibiotics is a risk factor for antibiotic-associated diarrhea and pseudomembranous colitis.[7] Exposure to contaminated foods (chicken, eggs, unpasteurized milk) enhances the risk for outbreaks of bacterial gastrointestinal infection.

The occurrence of LGI bleeding soon after weaning and introduction of cow's milk or soy protein formula in the diet strongly suggests the occurrence of cow's milk or soy protein allergy.

Age at Onset of LGI Bleeding

Age is a very important component of the history for finding the most common causes of LGI bleeding. However, some causes of LGI bleeding can be seen in different age groups, such as malrotation with midgut volvulus, allergic proctocolitis, intussusception, Meckel diverticulum, lymphonodular hyperplasia (LNH), or Henoch-Schönlein purpura. Anal fissure and infectious colitis can even be observed in any age group, from birth to adolescence. Table 16.2-1 shows the main causes of LGI bleeding in relation to age.

Characteristics of LGI Bleeding

A careful analysis of the aspect of the hemorrhage passed per rectum will help to localize the site of bleeding in the LGI tract. The amount of blood (ie, streaks, drops, teaspoonful, cupful) is often difficult to determine precisely and is overestimated by the parents because of their anxiety. Hematochezia limited to the outside of the stools or spots of red blood coating the stools or found in the diaper, on the toilet tissue, or in the toilet bowl imply bleeding from an anal or rectal origin. Hematochezia mixed through the stool suggests a colonic source for the bleeding located higher than the rectum, whereas hematochezia mixed with mucus and loose stools suggests colitis. Maroon-colored stools are strongly suggestive of a vigorous hemorrhage arising from the distal small bowel. Currant jelly stools are potentially indicative of ischemic bowel lesions, such as those seen in cases of intussusception or midgut volvulus. In case of

TABLE 16.2-1 PRINCIPAL CAUSES OF LOWER GASTROINTESTINAL BLEEDING IN RELATION TO AGE

NEWBORN (BIRTH–1 MO)	INFANT (1 MO–2 YR)	PRESCHOOL AGE (2–5 YR)	SCHOOL AGE (> 5 YR)
Necrotizing enterocolitis	Anal fissure	Anal fissure	Anal fissure
Malrotation with volvulus	Infectious colitis	Infectious colitis	Infectious colitis
Allergic proctocolitis	Allergic proctocolitis	Polyp	Polyp
Hirschsprung disease enterocolitis	Intussusception	Meckel diverticulum	Henoch-Schönlein purpura
Hemorrhagic disease of the newborn	Meckel diverticulum	Henoch-Schönlein purpura	Inflammatory bowel disease
	Lymphonodular hyperplasia	Hemolytic uremic syndrome	
	Malrotation with volvulus	Lymphonodular hyperplasia	
	Hirschsprung disease enterocolitis		
	Intestinal duplication.		

melena, special attention should be given to the darkness of the stools: in general, the more proximal the hemorrhage is in the gastrointestinal tract, the darker the stool.

Symptoms Associated with LGI Bleeding

Selective questioning should also point to the presence of concomitant transit abnormalities (constipation or diarrhea) and association with abdominal and/or anorectal pain to help the physician narrow down possible causes of LGI bleeding. Table 16.2-2 shows the main associated gastrointestinal symptoms in relation to the underlying causes of LGI bleeding.

PHYSICAL EXAMINATION

Findings in the physical examination are very helpful in elucidating the cause of the LGI bleeding. Failure to examine properly the anus, perineal area, and rectum, as well as the skin and mucous membranes, will result in missing many obvious causes of LGI bleeding and performing unnecessary tests. Main physical findings in relation to the underlying diseases are shown in Table 16.2-3. Fever suggests the presence of an infectious disease or inflammatory disorder. Carefully assessing growth is necessary because failure to thrive may be suggestive of an underlying chronic disease such as Hirschsprung disease or inflammatory bowel disease.

DIAGNOSTIC INVESTIGATIONS

The main advantages and potential disadvantages of the various diagnostic investigations available for children with LGI hemorrhage are reviewed below. The specific diagnostic investigations allowing diagnosis of the main causes of LGI bleeding in children are listed in Table 16.2-4.

Laboratory Investigation

Laboratory tests must be individually tailored to the patient's history, associated symptoms, and physical signs.[2] Complete blood count, clotting studies, and routine chemistry are performed unless history taking and physical examination allow the cause of LGI bleeding in the patient to be determined without doubt. Hypereosinophilia is very suggestive of allergy or parasitic infection. The presence of iron deficiency anemia suggests a history of chronic blood loss. Determination of erythrocyte sedimentation rate and/or C-reactive protein is useful when infectious colitis or an inflammatory disorder is considered for the cause of LGI bleeding. Liver function tests are necessary when liver disease and portal hypertension are suspected to be responsible for LGI bleeding. Renal function should be assessed and urine analysis performed when an underlying renal disease is suspected. The determination of the ratio of blood urea nitrogen to creatinine has been proposed by some authors to help localize the origin and importance of gastrointestinal bleeding.[8] A high ratio of blood urea nitrogen to creatinine would be in favor of upper gastrointestinal bleeding. However, this measurement has not been confirmed on a routine basis as a valuable tool in the clinical setting.

In cases of bloody diarrhea, stool culture and stool examination for virus, ova and parasites, and *Clostridium difficile* toxin are necessary.

TABLE 16.2-2 PRINCIPAL ASSOCIATED GASTROINTESTINAL SYMPTOMS IN RELATION TO THE UNDERLYING CAUSE(S) OF LOWER GASTROINTESTINAL BLEEDING

AMOUNT OF BLOOD LOSS	APPEARANCE OF BLEEDING	CHARACTERISTICS OF STOOLS	PAIN	UNDERLYING DISEASE
Small	Red	Hard	Yes (anorectal)	Anal fissure
Small to moderate	Red	Loose	Variable (abdominal)	Allergic proctocolitis, infectious colitis, hemolytic uremic syndrome, IBD
Small to moderate	Red	Normal, coated with blood	No	Polyp
Moderate	Red to tarry	Normal	Yes (abdominal)	Henoch-Schönlein purpura
Moderate	Red to tarry, currant jelly	Normal	Yes (abdominal)	Intussusception
Moderate	Red to tarry	Loose	Yes (abdominal)	Hirschsprung disease enterocolitis
Large	Red to tarry	Normal	No	Meckel diverticulum, angiodysplasia

IBD = inflammatory bowel disease.

TABLE 16.2-3 PRINCIPAL PHYSICAL FINDINGS IN RELATION TO THE UNDERLYING CAUSE(S) OF LOWER GASTROINTESTINAL BLEEDING

LOCATION	PHYSICAL FINDING	UNDERLYING DISEASE
Abdomen	Hepatosplenomegaly, ascites, dilated venous channels on the abdomen, caput medusa	Portal hypertension
	Abdominal mass	Intussusception, IBD, intestinal duplication
Perineal area	Anal fissure	Constipation, Crohn disease
	Skin tag, fistula, abscess	Crohn disease, chronic granulomatous disease, immunodeficiency syndromes
	Hemorrhoids, rectal varicosities	Portal hypertension, constipation (adolescent)
	Rectal mass at digital rectal examination	Polyp
Skin and mucous membranes	Eczema	Food allergy
	Purpura	Henoch-Schönlein purpura, hemorrhagic disease, hemolytic uremic syndrome
	Jaundice, palmar erythema, spider angioma	Liver cirrhosis
	Digital clubbing	Liver cirrhosis, IBD
	Pyoderma gangrenosum	Ulcerative colitis
	Erythema nodosum	Crohn disease
	Telangiectasia	Hereditary hemorrhagic telangiectasia
	Soft tissue tumor (skull, mandible)	Gardner syndrome
	Café au lait spots	Turcot syndrome
	Pigmentation of the lips, buccal mucosa, face	Peutz-Jeghers syndrome
	Alopecia, onychodystrophy, hyperpigmentation	Cronkhite-Canada syndrome
	Breast hypertrophy	Cowden disease
	Bluish soft nodules	Blue rubber bleb nevus syndrome
	Soft tissue hypertrophy	Klippel-Trénaunay syndrome
Eye	Iritis	IBD
Joint	Arthritis	Henoch-Schönlein purpura, IBD
Growth	Failure to thrive	IBD, Hirschsprung disease
	Very short stature, webbed neck, widespread nipples	Turner syndrome

IBD = inflammatory bowel disease.

Radiographic Examination

If the patient's history and physical examination are suggestive of either an obstructive or ischemic underlying process, plain supine and upright films of the abdomen are urgently indicated to look for air-fluid levels, dilated loops of bowel, or pneumoperitoneum. Barium enema has absolutely no role in the initial evaluation of a patient with hematochezia or melena and will delay any further endoscopic or scintigraphic evaluation. Indication for barium enema is limited to the very few situations when other attempts have failed to localize any potential source of bleeding.

Ultrasonography

Ultrasound examination of the abdomen is very useful in the emergency setting, when an acute abdominal disorder with obstruction and/or ischemia is suspected, or when an abdominal mass is present. In cases of intussusception diagnosed by abdominal ultrasonography, most radiologists favor the use of air rather than barium enema to confirm the diagnosis and reduce intussusception.

Anoscopy

This is the first-step examination when the child presents with hematochezia suggestive of anal or rectal origin, as detailed above. It allows a prompt diagnosis of anal fissure or hemorrhoids. It should be emphasized that the presence of an anal lesion does not exclude a more proximal lesion that may be responsible for LGI bleeding.

Proctosigmoidoscopy

Proctosigmoidoscopy is the first procedure to consider in children with hematochezia suspected of rectosigmoid origin, as detailed above, because it can identify the source of bleeding with much more accuracy and specificity than barium enema.[9] Proctosigmoidoscopy is helpful for the detection of anal fissure, hemorrhoids, polyp, colitis, and inflammatory bowel disease.[10] Biopsy specimens can be harvested during the procedure.

Colonoscopy

Colonoscopy is indicated when proctosigmoidoscopy fails to find the cause for LGI bleeding, as well as in patients with melena after an upper tract lesion has been ruled out by a negative nasogastric aspirate and/or upper endoscopy and when examination of the terminal ileum is necessary or polypectomy has to be performed. Proper preparation of the colon is very important to allow satisfactory examination of the mucosa. Colonoscopy is unnecessary in children with an acute-onset bloody diarrhea, in whom infections should be ruled out with the appropriate stool specimens and cultures, and is contraindicated in children with suspected intestinal obstruction or ischemia.[2] Other contraindications for colonoscopy include fulminant colitis or toxic megacolon, suspicion of perforation or peritonitis, pneumatosis intestinalis, and suspicion of intussusception. Colonoscopy offers the opportunity to provide direct access to biopsies, polypectomy, and coagulation of bleeding lesions.

TABLE 16.2-4 DIAGNOSTIC INVESTIGATIONS TO BE PERFORMED FOR IDENTIFYING THE MAIN CAUSES OF LOWER GASTROINTESTINAL BLEEDING IN CHILDREN

DISEASE	DIAGNOSTIC INVESTIGATION(S)
Newborn period: birth to 1 mo	
Necrotizing enterocolitis	Physical examination, plain radiographs of the abdomen
Malrotation with midgut volvulus	Plain radiographs of the abdomen, ultrasonography, upper gastrointestinal series, barium enema
Allergic proctocolitis	Diet history taking, exclusion of the allergen(s) from the diet, skin prick tests, total IgE and RAST, proctosigmoidoscopy
Hirschsprung disease enterocolitis	Barium enema, rectal manometry, rectal biopsies
Hemorrhagic disease of the newborn	Clotting studies
Infancy: 1 mo to 2 yr	
Anal fissure	Physical examination, anoscopy
Infectious colitis	Stool culture, stool examination for virus, ova, and parasites
Intussusception	Ultrasonography
Meckel diverticulum	Radionuclide scanning, exploratory laparoscopy or laparotomy
Lymphonodular hyperplasia	Proctosigmoidoscopy, biopsy, barium enema
Intestinal duplication	Ultrasonography, CT, upper gastrointestinal series, barium enema
Preschool age (2–5 yr)	
Polyps	Proctosigmoidoscopy, colonoscopy
Henoch-Schönlein syndrome	Physical examination
Hemolytic uremic syndrome	Complete blood count (anemia, thrombopenia, schizocytes), renal function (renal insufficiency)
School age (> 5 yr)	
Inflammatory bowel disease	Ultrasonography, small bowel follow-through or CT, esogastroduodenoscopy, colonoscopy, biopsy
Vascular causes	
Hemorrhoids	Physical examination, anoscopy
Angiodysplasia	Colonoscopy, angiography
Dieulafoy lesion	Colonoscopy, angiography
Telangiectasias	Colonoscopy
Miscellaneous	
Diversion colitis	Proctosigmoidoscopy, biopsy
Jejuno- or ileocolic perianastomotic ulceration	Barium enema, proctosigmoidoscopy, biopsy
Neoplasia	Colonoscopy, biopsy
Solitary rectal ulcer syndrome	Proctosigmoidoscopy, biopsy

CT = computed tomography; Ig = immunoglobulin; RAST = radioallergosorbent test.

Enteroscopy

Advances in instrumentation have allowed endoscopic evaluation of part or all of the small intestine. Recent introduction of long enteroscopes allowed endoscopic investigation of the small bowel to localize sites of occult bleeding between the ligament of Treitz and the ileocecal valve. For now, only a few models are in limited use.

Capsule Endoscopy

Obscure gastrointestinal bleeding, either occult or overt, is certainly the most frequent indication for capsule endoscopy. Despite some drawbacks, capsule endoscopy is a big step forward in the diagnosis of obscure gastrointestinal bleeding of presumed small bowel origin.[11] In a study of adult patients with LGI bleeding and negative colonoscopy and gastroscopy, capsule endoscopy was superior to enteroscopy in the identification of bleeding abnormalities in the small intestine (68% vs 32%). Capsule endoscopy was safe and well tolerated.[12] The wireless capsule can make diagnoses beyond the reach of enteroscopes.

Radionuclide Scanning

Abdominal scintigraphy with technetium (Tc) 99m pertechnetate (Meckel scan), which rapidly binds to the gastric mucosa, has been very useful in making the diagnosis of heterotopic gastric mucosa contained in Meckel diverticulum or in intestinal duplication in children, with an 85 to 90% sensitivity. The Tc 99m pertechnetate red blood cell scan (bleeding scan) requires that a sample of the patient's own red cells be labeled with Tc 99m pertechnetate and reinjected into the bloodstream. The site of bleeding can be visualized provided that the bleeding rate is 0.5 mL/min or higher.[13]

Angiography

An ongoing bleeding rate of 0.5 mL/min or greater is also needed for angiography to identify the bleeding source accurately through the visualization of luminal extravasation. Angiography can identify a potential bleeding site in 50% of children.[14] Angiography also offers the benefit of local therapy infusion of vasopressin or selective arterial embolization in tertiary centers with the technical expertise to perform supraselective catheterization. Angiography may cause very serious complications such as arterial spasm, arterial thrombosis, contrast reactions, and acute renal failure. It should therefore be limited to the very few patients with active LGI bleeding and negative esogastroduodenoscopy and colonoscopy. The introduction of bleeding scans using pertechnetate has markedly decreased the role of angiography as a primary test in severe LGI bleeding.

Intraoperative Endoscopy: Laparoscopy

Intraoperative endoscopy was the only available method of total gastrointestinal tract examination.[15] The two main indications for intraoperative endoscopy were the localization of unknown sites of gastrointestinal bleeding and the search for small bowel hamartomatous polyps of the Peutz-Jeghers syndrome for polypectomy and/or segmental resection. Enterotomy should be avoided as often as possible to limit the incidence of wound infection complications. Laparoscopy has been proposed for the definitive diagnosis and treatment of gastrointestinal bleeding of obscure origin in children negative for gastroscopy, colonoscopy, and Tc 99m pertechnetate scan.[16]

The development of capsule endoscopy in the near future will more than likely reduce dramatically the indication for intraoperative endoscopy and laparoscopy.

SPECIFIC CAUSES OF LGI BLEEDING

Age is the first parameter to take into account to find the cause of LGI bleeding in the neonatal period, as well as in infancy, childhood, and adolescence. However, some causes of LGI bleeding can be encountered in at least two or even more different age groups. An algorithm for managing LGI bleeding in children is shown in Figure 16.2-1.

Newborn Period (Birth to 1 Month)

Necrotizing Enterocolitis. Necrotizing enterocolitis results from a loss of the protective mucosal barrier of the intestine damaged by ischemia, thus allowing bacteria of the intestinal microbiota to invade the bowel wall and possibly enter the bloodstream.[17] It is the first diagnosis to rule out in a neonate presenting with rectal bleeding (see Chapter 42, "Necrotizing Enterocolitis"). Necrotizing enterocolitis is associated with prematurity, low birth weight, asphyxia, and sepsis, all of which predispose the infant to intestinal ischemia. Affected infants usually have an average birth weight of 1,500 g and a mean age of 30 to 32 weeks. However, up to 10% of all cases of necrotizing enterocolitis occur in full-term infants.[18]

Symptoms include systemic instability with hypothermia, apnea, bradycardia, and lethargy, associated with

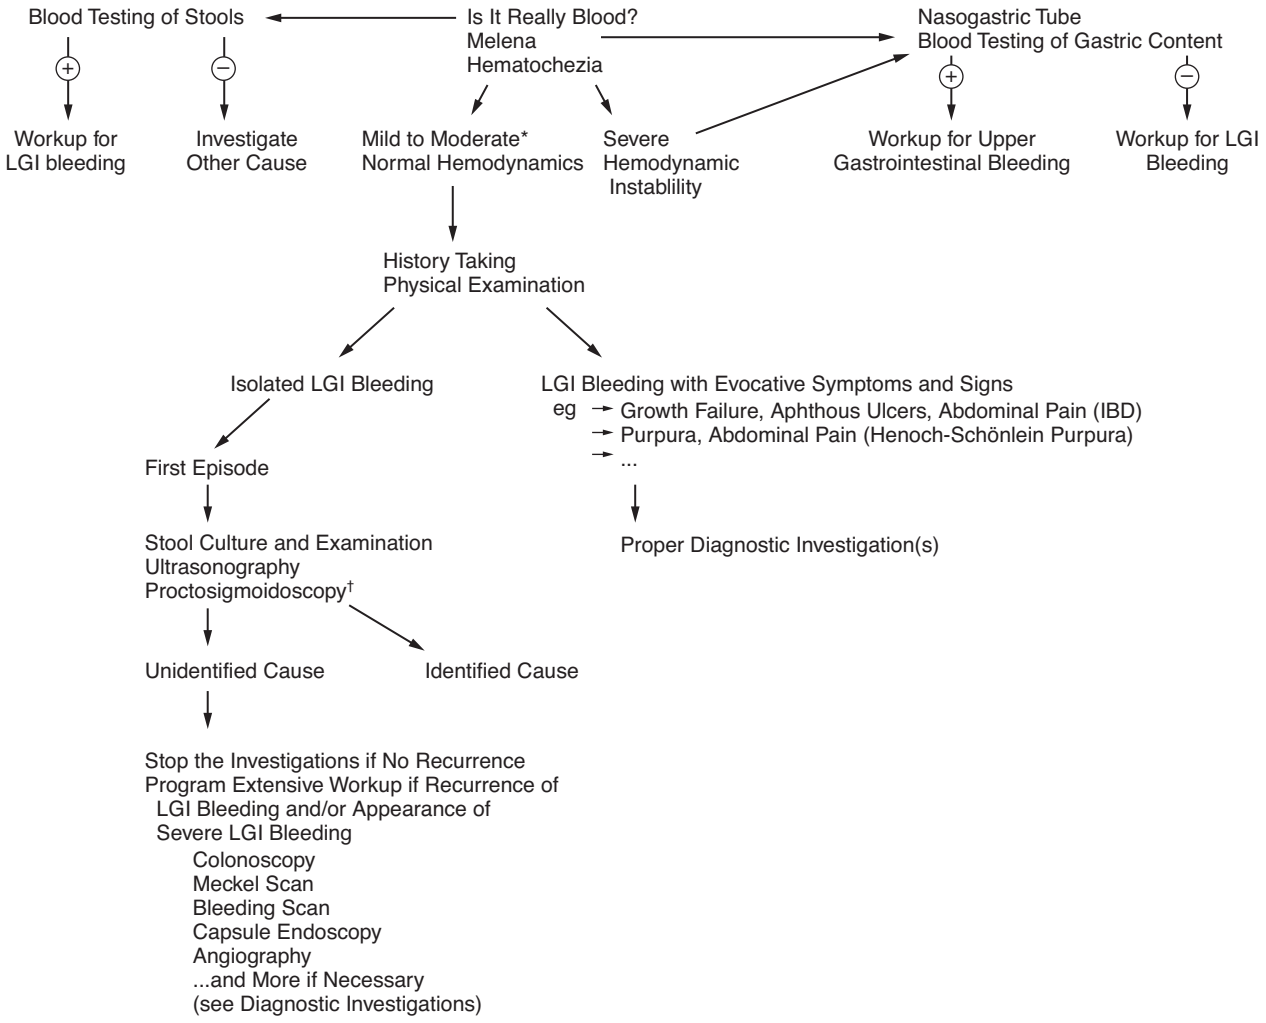

FIGURE 16.2-1 Algorithm for managing lower gastrointestinal (LGI) bleeding in children. IBD = inflammatory bowel disease. *In case of doubt, nasogastric intubation for blood testing of gastric content performed without any delay. †In the absence of symptoms and signs suggestive of obstruction or ischemia.

abdominal distention, feeding intolerance, increased gastric residuals, bilious vomiting, and bloody stools.[19] Physical examination may reveal decreased bowel sounds, abdominal tenderness, and erythema of the abdominal wall. Proctosigmoidoscopy or colonoscopy is absolutely contraindicated in this context to avoid any risk of subsequent iatrogenic perforation. Radiologic examination of the abdomen may show dilated bowel loops, bowel wall thickening, pneumatosis intestinalis (ie, gas in the bowel wall—the hallmark radiologic finding of the disease), or even pneumoperitoneum in cases of intestinal perforation. Medical and/or surgical management depends on the severity and/or course of the disease.

Malrotation with Volvulus. Malrotation with midgut volvulus is most commonly seen in the neonatal period, with an incidence of 1 case in 6,000 live births,[20] and constitutes a surgical emergency. Symptoms are suggestive of bowel obstruction and include bilious vomiting, pain, and abdominal distention. Melena can be associated and results from mucosal injury secondary to ischemia of the volvulized bowel.[1] Depending on the clinical situation, the child may undergo surgery directly. Otherwise, a definitive diagnosis can be made by a barium enema localizing the cecum either in the right upper or left upper abdominal quadrant. An upper gastrointestinal series can also show that the duodenum does not cross the midline and that the remainder of the small intestine lies to the right of the midline. Doppler ultrasonography is of great interest for the diagnosis of midgut volvulus by showing clockwise rotation of the superior mesenteric vein around the superior mesenteric artery ("whirlpool" sign).[21] Once the diagnosis is made, prompt surgical correction is performed to prevent necrosis of the small intestine.

Allergic Proctocolitis. Food-induced proctocolitis usually occurs in the first few weeks or months of life and is most often secondary to cow's milk or soy protein hypersensitivity. Infants usually have occult or gross blood in their stools with or without mucous stool or diarrhea.[22] Aside from occasional apparent pain on defecation and eczema in a few cases, infants with food-induced proctocolitis generally appear healthy and have normal weight gain. No single laboratory or biochemical test is either sensitive or specific enough to be diagnostic of allergic colitis (see Chapter 44, "Enteropathy"). A positive family history is helpful. Diagnosis of allergic colitis can be established by the response to elimination of cow's milk or soy protein through the use of an extensively hydrolyzed formula and standardized rechallenge.[22] When some doubt remains as to the presence of food allergy, proctosigmoidoscopy in conjunction with the evaluation of multiple mucosal biopsy specimens may be helpful for diagnosis. Focal erythema and hemorrhagic erosions are frequently seen at endoscopy. Biopsies show an infiltration of the mucosa and lamina propria with eosinophils. By 1 year of age, the infants usually tolerate an unrestricted diet, and the long-term prognosis is excellent.

Proctocolitis related to cow's milk protein allergy may also occur in exclusively breastfed infants because of sensitization to cow's milk proteins entering into the mother's milk. Evolution after exclusion from the maternal diet of the protein is usually simple.[23] Sensitization to other trophallergens via mother's milk (eg, egg, fish, peanuts) has also been described.

Hirschsprung Disease Enterocolitis. The typical pattern of presentation for Hirschsprung disease is severe constipation, abdominal distention, vomiting, and feeding intolerance in a young male infant, usually under the age of 3 to 6 months. However, 10 to 30% of patients with Hirschsprung disease present with LGI bleeding from enterocolitis, manifested as occult blood-positive or frankly bloody stools, associated with fever, abdominal distention, and sepsis (see Chapter 46, "Hypomotility Disorders").[24]

Hemorrhagic Disease of the Newborn. Hematochezia or melena may be a manifestation of a hemorrhagic disease of the newborn, starting usually between 2 and 5 to 7 days of life and is often associated with bleeding from other origin, that is, mucocutaneous or urinary. Prolonged prothrombin time can be observed in relation to vitamin K deficiency resulting from failure to administer vitamin K at birth, maternal treatment with phenobarbital or phenytoin, and untreated fat malabsorption (cystic fibrosis). Severe bacterial sepsis can lead to disseminated intravascular hemolysis and cause upper gastrointestinal and/or LGI bleeding. Patients with a specific clotting disorder (hemophilia A and B, von Willebrand disease, idiopathic thrombocytopenic purpura) are also prone to gastrointestinal bleeding. However, spontaneous bleeding from the LGI tract is unusual in this situation, and an underlying bleeding source is identified in most cases.[25]

Severe esogastroduodenitis and/or gastroduodenal ulcer can also be observed in patients with maternal and/or neonatal stress and can lead to hematochezia or melena. In case of doubt, in particular in a neonate presenting with pallor and a shock-like appearance, the placement of a nasogastric tube can easily point to bleeding from the upper gastrointestinal tract.

Infancy (1 Month to 2 Years)

Anal Fissure. Anal fissure is probably the most common cause of LGI bleeding in infants and young children, although statistics concerning the actual incidence of this condition are impossible to obtain because most cases go unreported. Streaks of bright red blood on the surface of otherwise formed stools or spots of red blood in the diaper or on the toilet tissue are very suggestive. Anal fissure results from a superficial tear of the squamous lining of the anal canal, which is usually caused by the passage of hard, large stools.[2] The fissure is often located in the midline (6 and 12 o'clock). In most cases, anal fissure is secondary to constipation (see Chapter 46.1, "Idiopathic Constipation").[26] Because defecation may be very painful, the child usually reacts by withholding stools, thereby increasing

constipation and creating a vicious cycle. Diagnosis is made on the patient's history and thorough inspection of the anal canal. Treatment usually consists of stool softeners associated with topical analgesic ointments.

Painless anal fissure is very suggestive of Crohn disease, especially when deep and eccentric to the midline, and is associated with perineal lesions (fistula, skin tags). However, Crohn disease is very rare in infancy and mainly concerns children over 8 to 10 years of age, as well as adolescents (see Chapter 41.1, "Crohn Disease"). It should be kept in mind that regardless of the age group, anal fissure may be the result of sexual abuse, especially in boys.[27] Careful questioning is necessary to exclude this possibility.[1] Other causes of perineal disease that may lead to bleeding include chronic granulomatous disease and immunodeficiency syndromes.

Infectious Colitis. Any enteroinvasive infection is capable of disrupting mucosal integrity, resulting in LGI hemorrhage (see Chapter 9, "Acute Diarrhea," and Chapter 38, "Infections"). Bacterial pathogens causing infectious enterocolitis are numerous and include *Salmonella*, *Shigella*, *Campylobacter jejuni*, *Yersinia enterocolitica*, and *Escherichia coli* (especially the O157:17 variant). Frankly bloody mucous diarrhea occurs most commonly, with or without abdominal pain and fever. Stool cultures and stool examination for ova and parasites are necessary not only in cases of bloody diarrhea but also when the child exhibits unexplained prolonged LGI bleeding without diarrhea. *Entamoeba histolytica* is the most important parasitic pathogen. When routine stool parasitic examinations are negative, proctosigmoidoscopy with tissue biopsy may be required to make a proper diagnosis. Amebiasis presenting as rectal bleeding without diarrhea has been described in childhood.[28] In the older child, *Y. enterocolitica* may mimic the presentation of inflammatory bowel disease. Pseudomembranous colitis owing to *C. difficile* infection is mainly observed during the use of antibiotics or up to 3 to 4 weeks after the treatment has ceased. It should be remembered that this condition may occur without known ingestion of antibiotics. Patients commonly have watery diarrhea with blood and mucus and may experience fever and abdominal pain. Acute hemorrhagic colitis owing to *Klebsiella oxytoca* has been described after the use of oral or parenteral ampicillin, amoxicillin, or cephalosporin.[29] *Aeromonas hydrophilia* has also been implicated in gastrointestinal bleeding.[30] About 25% of the patients infected with *A. hydrophilia* develop diarrhea with blood and mucus that can last up to 1 month. Although the presentation of the LGI bleeding is rarely associated with significant hemodynamic changes, bleeding may be massive in patients with underlying coagulopathy or immunocompromised status.

Rotavirus and Norwalk virus may cause mild bloody diarrhea, but they are generally not responsible for overt blood losses in the stool. Cytomegalovirus is a possible cause of significant LGI hemorrhage and is prominent in immunocompromised patients, especially those infected with human immunodeficiency virus (see Chapter 39, "Gastrointestinal Manifestations of Immunodeficiency").[31]

Intussusception. Intussusception usually occurs in patients 4 to 10 months of age, with 65% of cases occurring before 1 year and 80% by 2 years of age.[1] Intussusception is often idiopathic or associated with lymphoid hyperplasia of the terminal ileum. The majority of cases occur in the region of the ileocecal valve, and no lead point can be precisely identified. In older children, a lead point, including polyp, Meckel diverticulum, intestinal duplication, or neoplasm, especially lymphoma, is more likely to be found. Intussusception may also be a complication of Henoch-Schönlein purpura, cystic fibrosis, and Peutz-Jeghers syndrome.

A previously healthy, well-nourished infant typically presents with episodes of colicky abdominal pain and vomiting, followed by passage of "currant jelly stool," representing a mixture of blood, mucoid exudate, and stool. However, intussusception should be considered in the differential diagnosis of children passing any type of bloody stool.[32] Clinical examination may reveal a palpable sausage-shaped abdominal mass. The presence of LGI bleeding suggests that venous congestion with ischemia has already occurred in the affected area of the bowel. Such bowel compromise is usually seen only after 6 to 12 hours of symptoms of colicky abdominal pain and vomiting. The child may then pass a normal stool and show marked improvement. However, pain reappears shortly thereafter, lasts a couple of minutes, and recurs at regular intervals. Eventually, the infant will become pale and apathetic.

Diagnosis is confirmed by abdominal ultrasonography. The triad of vomiting, abdominal pain, and bloody stools is not consistently present, especially in infants below 4 months of age. The intussusception is ileocolic in location in 80 to 90% of cases, although ileoileal intussusception may also occur on an idiopathic basis. Hydrostatic or pneumatic enema techniques allow reduction of the intussusception in 80% of cases.[20]

Meckel Diverticulum. Meckel diverticulum is an anomalous remnant of the vitelline duct present in the terminal 100 cm of the ileum that results from incomplete obliteration of the omphalomesenteric duct. It is the most common congenital abnormality of the gastrointestinal tract, with an incidence ranging from 1 to 4% and a male-to-female ratio of 2:1.[33,34] Approximately 50% of the diverticula contain heterotopic tissue, with gastric mucosa being by far the most common type. A few diverticula contain pancreatic tissue. Most cases of Meckel diverticulum are fully asymptomatic and are found incidentally at the time of surgery or autopsy.[35] Among patients with complications, 60% are less than 2 years of age.[1]

The typical presentation of Meckel diverticulum in childhood is LGI bleeding resulting from the ulceration of adjacent ileal mucosa by acid-secreting heterotopic gastric mucosa contained in the diverticulum.[33] LGI bleeding is often brisk and painless and may present as self-limited recurrent bleeding in an otherwise healthy child or life-threatening acute massive lower hemorrhage. Meckel diverticulum represents the most common cause of significant LGI bleeding in infants and young children. Provided that gastric mucosa is present, the diagnosis of Meckel

diverticulum can be made with an 85 to 90% sensitivity by a radionuclide Tc 99m pertechnetate scan showing the presence of heterotopic gastric mucosa in the right lower quadrant of the abdomen.[36] It has recently been shown that in many patients, the inflamed Meckel diverticulum can be identified on abdominal ultrasonography or Doppler ultrasonography.[37] False-positive results of Tc 99m pertechnetate scintigraphy have been reported in patients with intussusception, hydronephrosis, arteriovenous malformation, and inflammatory bowel disease. If obtaining a technetium 99m pertechnetate scan or any other diagnostic procedure is going to incur a significant delay, with ongoing bleeding in the patient, exploratory laparotomy remains the only way to confirm a suspected Meckel diverticulum. Laparoscopy can be an alternative diagnostic and therapeutic modality of choice to exploratory laparotomy in patients suspected of Meckel diverticulum.[38]

Locations of heterotopic gastric mucosa other than Meckel diverticulum may be found anywhere in the gastrointestinal tract, from the tongue to the rectum, but are extremely rare in children, especially in the hindgut. However, bleeding from gastric heterotopia in the rectum has been described during infancy, as well as obstruction with recurrent intussusception responsible for episodes of hematochezia.[15,39] The treatment of choice is surgical excision.

Lymphonodular Hyperplasia. LNH of the colon is characterized by multiple yellowish nodules that are enlarged lymphoid follicles. The appearance of LNH is readily seen on either an upper gastrointestinal series or a barium enema, as well as endoscopically and microscopically on biopsy. LNH is a common intestinal phenomenon observed in children below the age of 10 years undergoing investigational studies of the intestinal tract. Two retrospective studies showed that LNH of the colon was present in 14% and 33% of children undergoing colonoscopy, respectively.[40,41] Thus, LNH is a common endoscopic bystander on the mucosa of the lower gastrointestinal tract.

The etiology of LNH remains unknown. Some studies attempting to correlate specific gastrointestinal symptoms with the presence of LNH have been inconclusive, prompting several authors to conclude that LNH is a normal finding in children.[42,43] LNH is nowadays thought to be an allergic response to parasites, yeasts, food antigens, or other unknown antigenic stimulants.[40] If detected on the colon, it seems more suggestive of gastrointestinal food allergy.[41,44] Food allergy should be investigated properly in this situation: a history of allergy in the patient and the patient's family, immunoglobulin (Ig)E levels, skinprick tests, and radioallergosorbent test. Regardless of their etiology, hyperplastic lymphoid nodules disrupt the normal mucosal architecture, which leads to mucosal thinning. Ulceration may occur over the follicles and lead to hematochezia.[45] LNH is therefore primarily associated in childhood with abdominal pain and hematochezia.[46] The only syndromic association appears to be IgA deficiency with giardiasis and chronic diarrhea. Lymphoma associated with LNH has been reported in adults, but in children, LNH is a nonmalignant process.[47] LNH probably represents a normal response of lymphoid tissue in children to a variety of stimulations, which accounts for its frequent identification. LNH resorbs slowly as the child enters adolescence, similarly to the resorption of adenoid and tonsillar tissues seen in the same period. Hence, LNH becomes a very unlikely source of LGI bleeding in older children, those over the age of 7 years.[46]

Intestinal Duplication. Intestinal duplication is most often found in the small bowel. Similar to Meckel diverticulum, duplication of the bowel often contains ectopic gastric mucosa, which may result in local peptic ulceration and LGI bleeding.[48,49] Bleeding may also be due to stasis and bacterial overgrowth causing subsequent local ulceration or to ischemic necrosis of the bowel secondary to intussusception or enlargement of the duplication.[50] Rectal bleeding and proctalgia have been reported in a child with a diverticular rectal duplication with heterotopic gastric mucosa.[48] However, clinical presentation of duplication of the bowel as an abdominal mass or intestinal obstruction is more common than LGI bleeding. Ultrasonography or computed tomography may suggest the diagnosis, but only laparotomy is definitive. Treatment is surgical resection of the affected segment, thus avoiding complications described with other digestive duplications: infection, ulceration, bleeding, or malignant changes during later life. A recent advance has been laparoscope-assisted resection of intestinal duplication cysts.[51]

Other main causes of LGI bleeding in infants from 1 month to 2 years of age are allergic proctocolitis, malrotation with volvulus, and Hirschsprung disease enterocolitis (see Table 16.2-1).

Preschool Age (2 to 5 Years)

Polyps. Polyps of the colon and rectum in children do not carry the serious implications of polyps in adults, with the exception of familial polyposis coli, in which there is a very high risk of malignant change before 20 years of age or even during late childhood or adolescence (see Chapter 45, "Intestinal Tumors"). Intestinal polyps represent the most frequent cause of significant LGI bleeding after 2 years of age, usually presenting with isolated, recurrent, and painless hematochezia, small in amount, and no hemodynamic change.

Juvenile polyps account for more than 95% of all polyps found in children. They are hamartomatous and have very low, if any, malignant potential.[52,53] However, it has recently been emphasized that careful histologic examination of juvenile polyps should be performed because of an increased incidence of potential malignant changes in children presenting with multiple polyps and polyps located in the ascending colon.[54] The vast majority of juvenile polyps are solitary (five polyps or less in the entire large bowel) and mainly occur in the left side of the colon, with a predominance in the rectosigmoid area. However, they may occur throughout the colon. If rectosigmoidoscopy fails to demonstrate the presence of polyps, colonoscopy should be performed thereafter. Recurrent or

multiple juvenile polyps can be seen in juvenile polyposis coli or generalized juvenile polyposis. Juvenile polyposis coli refers to multiple juvenile polyps found only in the colon, whereas in generalized polyposis coli, polyps are found throughout the gastrointestinal tract. Juvenile polyposis coli and generalized polyposis coli have been shown to be associated with adenomas, thus raising the question of possible malignant change.[54] Peutz-Jeghers syndrome is a condition inherited as autosomal dominant and characterized by hamartomatous gastrointestinal polyps and abnormal brown pigmentation of the lips, oral mucosa, and skin. Abdominal pain owing to mechanical blockage or intussusception is the most common symptom. Almost all patients have small intestinal polyps, but some also have polyps in the colon, which may cause hematochezia. Cowden disease and Cronkhite-Canada syndrome are extremely rare and are characterized by the presence of hamartomatous and/or inflammatory polyps.

Adenomatous polyps, the common type in adults, are much less frequent than juvenile polyps, but they represent a premalignant condition. They are found in familial polyposis coli, Gardner syndrome, and Turcot syndrome. Total colectomy is necessary before adulthood. LGI bleeding is rarely seen as a complication of colonoscopy following polypectomy (see Chapter 67.3, "Ileocolonoscopy and Enteroscopy").[55] Bleeding may occur immediately or may be delayed for more than 2 weeks after the procedure. A vast majority of postpolypectomy bleeding cases resolve spontaneously without requiring blood transfusion or further intervention.

Henoch-Schönlein Purpura. Henoch-Schönlein purpura primarily involves the skin, gastrointestinal tract, joints, and kidney. The peak age at onset ranges from 3 to 7 years. The typical clinical picture is characterized by an urticarial rash on the buttocks and lower extremities, followed by large joint arthralgia and papular purpuric lesions. Gastrointestinal manifestations occur in 45 to 75% of cases and include vomiting, colicky abdominal pain, melena, and/or bloody stools resulting from diffuse mucosal hemorrhage.[56] Intussusception associated with Henoch-Schönlein purpura can also cause melena or hematochezia. In up to 15% of patients, gastrointestinal bleeding and other gastrointestinal symptoms precede the appearance of skin lesions by as many as 7 to 10 days.[56] Urinalysis is necessary to check for blood and/or albumin. Forty percent of patients may have recurrence of any of the symptoms within 6 weeks of the initial onset of the disease. Recurrence is more common in older patients.

A variety of systemic vasculitides can precipitate gastrointestinal hemorrhage but are rarely observed in children: polyarteritis nodosa, Churg-Strauss syndrome, or systemic lupus erythematosus.[57–59] Vascular inflammation leads to mucosal ischemia and ulceration, resulting in abdominal pain and/or gastrointestinal bleeding.

Hemolytic Uremic Syndrome. Hemolytic uremic syndrome is characterized by microangiopathic hemolytic anemia, thrombocytopenia, and acute renal failure. Symptoms of acute hemorrhagic colitis with abdominal pain, vomiting, fever, and bloody diarrhea precede the illness in approximately 50% of cases. LGI bleeding results from small vessel occlusion and mucosal ischemia of the intestine. Infection with *E. coli* O157:H7, an enterohemorrhagic *E. coli* that produces verotoxin, is considered the most important causative event in both sporadic and epidemic cases of hemolytic uremic syndrome.[60] Intussusception and colonic perforation have rarely been described.[61] Systemic involvement may involve the liver and the pancreas (pancreatitis).[61] Gastrointestinal manifestations of hemolytic uremic syndrome resolve, usually without sequelae. Prognosis depends on the severity of renal involvement. The severity of the gastrointestinal prodrome reflects the severity of the extraintestinal acute microangiopathic process and the resulting renal long-term outcome.[62]

Other main causes of LGI bleeding in children from 2 to 5 years of age are anal fissure, infectious colitis, Meckel diverticulum, and LNH (see Table 16.2-1).

School Age (Above 5 Years)

Inflammatory Bowel Disease. Approximately 25% of all new cases of inflammatory bowel disease in the population occur in individuals younger than 20 years of age.[63] In this population, rectal bleeding and/or bloody diarrhea are present at diagnosis in 90 to 95% of patients with ulcerative colitis and 25% of patients with Crohn disease (see Chapter 41, "Inflammatory Bowel Disease").[64] Rectal bleeding as an isolated presenting feature is very unusual in Crohn disease as opposed to ulcerative colitis. Acute major LGI bleeding is uncommon in adult patients with inflammatory bowel disease.[65] To our knowledge, no pediatric data are available. Profuse bleeding leading to shock and requirement for blood transfusion seems to be very rare in children and adolescents with inflammatory bowel disease, apart from very severe attacks of ulcerative colitis.

Other main causes of LGI bleeding in children from 5 years of age to adolescence are anal fissure, infectious colitis, polyps, and Henoch-Schönlein purpura (see Table 16.2-1).

RARE CAUSES

Many rare causes of LGI bleeding have been reported in children. They can be arbitrarily classified as from vascular and miscellaneous origin (Table 16.2-5).

Vascular Abnormalities

Hemorrhoids: Colonic and Anorectal Varices. Hemorrhoids are very unusual in children. If present, portal hypertension should be suspected.[66] Varices most commonly occur in the esophagus and stomach in patients with portal hypertension, with less frequent involvement of the small intestine and rarely of the colon. However, a prospective study has shown that one-third of the children with portal hypertension had hemorrhoids or anorectal varices that were most often totally asymptomatic. The incidence of both hemorrhoids and anorectal varices was twofold

TABLE 16.2-5 RARE CAUSES OF LOWER GASTROINTESTINAL BLEEDING IN CHILDREN

Neoplasia
Graft-versus-host disease
Solitary rectal ulcer syndrome
Traumatic rectal lesions

higher in case of extrahepatic than in intrahepatic disease.[67] Hemorrhoidal bleeding usually presents with bleeding on defecation. The hemorrhoidal bleeding may be significant, but in the absence of bleeding diathesis, it rarely causes hemodynamically compromising hemorrhage. The presence of rectal, perirectal, and colonic varices can be successfully assessed by endoscopic ultrasonography. Treatment is advised only for symptomatic patients, and injection sclerotherapy is satisfactory for the majority.[66]

Angiodysplasia. There is little experience of angiodysplasia of the colon in the pediatric population. Identification of vascular lesions can be made either endoscopically or angiographically. The endoscopic appearance of angiodysplasia (or vascular ectasias) has been described as flat or slightly raised lesions that range from 2 to 10 mm in diameter and are red in color. In children, intestinal perforation has also been reported.[68] The severity of bleeding can vary in the same patient at different times. Most bleeding episodes stop spontaneously. The probability of recurrent hemorrhage is unpredictable, and approximately 50% of patients will rebleed. A recent study clearly showed in children that colonoscopy found an apparently normal mucosa in half of the patients and a vascular anomaly in the other half, the nature and the extent of which could not be detailed. Mesenteric arteriography detected all cases of angiodysplasia.[69]

The diagnosis is usually not considered in children, which leads to a significant delay in diagnosis, as was true in a pediatric series of nine patients.[68] Unlike in the elderly and the cases reported in the literature, the left hemicolon was the most frequently involved area.[68]

A variety of modalities have been described to treat angiodysplasia colonoscopically, with the most widely accepted techniques involving some degree of thermal ablation, but surgical resection remains the first-line therapeutic modality.

Dieulafoy Lesion. Dieulafoy lesion is a very unusual cause of gastrointestinal hemorrhage in children.[70] Among Dieulafoy lesions, 80% are located in the stomach, with the majority of the remaining 20% located in the duodenum.[71,72] However, cases describing similar lesions located in the more distal small bowel and the colon have been reported. Pathologically, these lesions are characterized by a congenitally abnormal enlarged arteriole running within the submucosa. The diagnosis is most often made because of massive and recurrent bleeding.[73] The endoscopic diagnosis is difficult unless the procedure is performed during active bleeding. In adults, the descriptive reports of colonic and small bowel Dieulafoy lesions are mainly based on angiographic descriptions of a documented bleeding site. Therapy with injection techniques, coagulative therapy, and banding can all be efficient in stopping bleeding. If unsuccessful, embolization therapy or surgery should be considered.

Telangiectasias. In the autosomal dominant condition of hereditary hemorrhagic telangiectasia (Osler-Weber-Rendu disease), gastrointestinal hemorrhage is very unusual before typical skin and mucous lesions are noticeable. The most common presenting sign is epistaxis, which is reported in 78 to 96% of cases.[74] Approximately 80% of patients have a family history of bleeding. A few cases of telangiectasias of the colon have been described in patients with Turner syndrome.

Connective tissue disorders, especially Ehlers-Danlos syndrome type IV (ecchymotic) and pseudoxanthoma elasticum, are associated with intestinal bleeding as a consequence of fragile vascular epithelium.[75]

Other Vascular Lesions. A variety of vascular lesions may be found either in isolation or in association with systemic diseases. These lesions include angioma, hamartoma, hemangioma, hemangioendothelioma, and blue rubber bleb nevus.

Blue rubber bleb nevus syndrome, or Bean syndrome, is a rare systemic disorder characterized by cutaneous and gastrointestinal vascular malformations that lead from occult blood loss with severe anemia and iron deficiency to overt life-threatening gastrointestinal bleeding. Blue rubber bleb nevus syndrome belongs to the group of vascular venous malformations. It occurs sporadically most of the time but can be inherited as an autosomal dominant disease. Patients with blue rubber bleb nevus syndrome present with typical skin lesions, with some lesions having a rubber-like appearance.[76] Bluish, soft, compressible skin nodules, especially noticeable on the soles of the feet and the palms of the hands, are pathognomonic of the syndrome. In the absence of massive bleeding, a conservative treatment using endoscopic laser coagulation or bipolar electrocoagulation will be sufficient. Resections are otherwise necessary, but additional lesions may subsequently develop.[77]

A complex malformation known as the Klippel-Trénaunay syndrome is a capillary-lymphaticovenous malformation that results in limb hypertrophy and can extend into the pelvis and colon, resulting in hematochezia.

Miscellaneous

Diversion Colitis. Whatever the underlying reason, surgical isolation of colonic mucosa from the normal fecal stream may provoke inflammation and ulceration. Theories to explain diversion colitis include bacterial overgrowth, the use of antibiotics, the presence of intraluminal toxins, and, more importantly, diminished production of local short-chain fatty acid leading to impaired colonocyte metabolism. Reported symptoms include rectal bleeding, mucoid discharge, tenesmus, and abdominal pain.[78] Massive hemorrhage has also been reported. Endoscopic and histologic findings may be indistinguishable from inflammatory bowel disease.[79] Biopsies usually show nonspecific acute and chronic inflammation and/or nodular hyperplasia.[80] The presumed pathogenic mechanism of local short-chain fatty acid deficiency is supported by the resolution of symptoms and gross injury following administration of short-chain fatty acid enema.[78] However, other authors were unable to reproduce similar results.[81] Restoration of normal fecal flow results in complete resolution of diversion colitis.

Jejuno- or Ileocolic Perianastomotic Ulceration. This is a pediatric entity following ileocolic or jejunocolic anastomosis after intestinal resection in infancy and early childhood that may occur many years after surgery.[82] Gross or occult rectal bleeding, with or without abdominal pain and diarrhea, has been described. The cause of anastomotic ulceration remains unknown.[83] Bacterial overgrowth, blind loop formation, and ischemia have all been considered a possible mechanism, but there is no evidence confirming any of these hypotheses. Perianastomotic ulceration is likely to reflect a process of chronic inflammation and repair. Surgical resection has been necessary in most of the published cases.[82]

Neoplasia. Gastrointestinal tumors revealed by LGI bleeding are very uncommon in children. Carcinoma of the colon and rectum has been reported in patients of all pediatric age groups, and the youngest known living patient was 9 months old at the time of diagnosis.[84] Abdominal pain and vomiting were the main revealing symptoms, associated with frank rectal bleeding or melena. Familial adenomatous polyposis syndromes represent premalignant conditions and are obvious risk factors for the occurrence of adenocarcinoma of the colon and rectum, as well as ulcerative colitis after 10 years of the disease.

Leiomyoma of the colon is rarely found in the pediatric population and can be revealed by LGI bleeding.[85] Histologic differentiation from leiomyosarcoma may be difficult. Gastrointestinal stromal cell tumors are considered visceral sarcomas arising from the gastrointestinal tract, and there is evidence to suggest that they originate from the interstitial cells of Cajal. Cases of rectal and colonic stromal cell tumors have been reported.[86] A case of bloody diarrhea has been described in a single patient with colonic ulcerations related to fatal histiocytosis X.[87]

Graft-versus-Host Disease. Enteric graft-versus-host disease, in both its acute and less common chronic form, may rarely present in children with hemodynamically significant LGI hemorrhage. Bleeding may be exacerbated by an associated coagulopathy.

Solitary Rectal Ulcer Syndrome. Solitary rectal ulcer syndrome is a benign chronic ulcerative disease that is very unusual in childhood.[88] Symptoms include dyschezia, tenesmus, mucous discharge, pain located in the perineal area, rectal prolapse, and rectal bleeding. Most patients present with mild rectal bleeding, although major gastrointestinal blood loss requiring multiple transfusion has been reported.[89] A relationship between solitary rectal ulcer syndrome and chronic constipation is often reported. The postulated mechanism seems to be excessive straining efforts during which high intra-abdominal pressure forces the anterior rectal mucosa firmly into the contracting puborectalis muscle. The anterior rectal mucosa is frequently forced into the anal canal and, as a consequence, becomes strangulated, causing congestion, edema, and ulceration. Rectoscopy may show a unique superficial ulcer with an exudative base, which may vary in diameter from 5 mm to 5 cm. Histopathologic diagnosis of solitary rectal ulcer is based on the fibromuscular obliteration of the lamina propria stroma with misorientation of smooth muscle cells.[88]

Traumatic Rectal Lesions. Rectal prolapse per se, most often secondary to constipation, may cause rectal bleeding. A foreign body inserted into the rectum is a very rare cause of LGI bleeding in children. Sexual abuse should then be ruled out.

OCCULT LGI BLEEDING

Large amounts of blood can be lost into the gastrointestinal tract and remain occult. In most cases, occult LGI bleeding is revealed by symptoms limited to pallor or fatigue or failure to thrive. It is further detected by discovery of iron deficiency or iron deficiency anemia and is confirmed by repeated positive testing for the presence of fecal blood. A very careful history taking and thorough physical examination is of crucial importance to resolve adequately the differential diagnosis of the patient. In the absence of any clinical clue, that is, associated symptom and/or physical finding suggesting a precise cause for LGI bleeding, esogastroduodenoscopy and colonoscopy are performed. If endoscopy fails to identify a source of bleeding, abdominal scintigraphy with Tc 99m pertechnetate or Tc 99m pertechnetate red blood cell scan and angiography will not be helpful because in cases of occult LGI bleeding, the bleeding rate is very unlikely to be 0.5 mL/min or higher.

Ultrasonography and small bowel follow-through or computed tomography may help to find abnormalities suggestive of Crohn disease, especially in adolescents presenting with occult LGI bleeding and an elevated erythrocyte sedimentation rate or C-reactive protein. Preliminary data in adults strongly suggest that capsule endoscopy is a very promising tool for adequate diagnosis of obscure LGI bleeding of presumed small bowel origin.

LGI BLEEDING IN DEVELOPING COUNTRIES

The profile of recurrent LGI bleeding in children has been reported by several authors in developing countries, especially from India. Colonic polyps were the most common lesion (50%), followed by amebic colitis (25%), solitary rectal ulcer (10%), and polyposis syndrome (13%).[90] Sigmoidoscopy alone could establish the diagnosis in almost all cases. Juvenile polyps were by far (90–95%) the main cause of colonic polyps, most often located in the rectosigmoid region.[91] Rare cases of ulcerative colitis, tuberculous colitis, and allergic colitis have also been described.[92] In children of school age (mean age 7 years), colitis and colorectal polyps were reported to represent 42% and 41% of all cases of LGI bleeding, respectively, in an Indian tertiary university hospital.[93] The causes of colitis were mainly infectious (60%), pseudomembranous (15%), and allergic (11%). The authors concluded that the spectrum of LGI bleeding was similar to that of developed countries.

CONCLUSION

The causes of LGI are numerous and depend strongly on the age of the child. Anal fissure secondary to constipation, intussusception, Meckel diverticulum, juvenile polyps, and inflammatory bowel disease is most commonly found in the pediatric age. The pediatrician should always keep in mind the importance of adopting a rational approach for the differential diagnosis of LGI bleeding. It should be reemphasized that adequate history taking and detailed clinical examination are two essential steps before performing any diagnostic investigation.

CHAPTER 17

GROWTH FAILURE

Conor Doherty, MB, BS, MRCP, DTM&H

Growth failure and malnutrition are inextricably linked. The relationship between the two can be illustrated in many ways, from cocausal to cyclic, and analyzed on many levels, from the molecular to the epidemiologic. Growth failure is the principal manifestation of malnutrition in childhood, and chronic diseases of the gastrointestinal tract and digestive system frequently lead to both malnutrition and impairment of growth.

Growth and nutritional status can be assessed in six principal ways:

1. Anthropometry: measurement of the dimensions of the body and/or its parts
2. Clinical examination: detection of abnormalities associated with specific nutrient deficiencies
3. Biochemistry: measurement of circulating or tissue levels of nutrients; their carriers, precursors, or metabolites; and markers of inflammation and growth
4. Body composition: eg, assessment of fat and fat-free mass, bone density
5. Dietary assessment: prospective and retrospective food intake measurements
6. Functional tests: eg, muscle strength; cardiac, visual, and nerve function.

Each assessment has a normal range and reference standards, but no single assessment provides a single index. The assessments need to be considered together to completely describe the growth and nutritional status of the child.

The aim of this chapter is to focus on the basic biology of growth, how to measure it, the factors that may disturb it, and the manifestations of growth failure. This is followed by a review of the regulation of growth during the main phases of early life: intrauterine, infancy, childhood, and puberty.

Growth failure and malnutrition are common in developing countries, and many seminal studies of the relationship between the two have been undertaken there. We have focused much of this chapter on data obtained from this part of the world. However, the general principles involved in understanding the factors that regulate and impair growth, particularly dietary factors, are equally applicable to children who suffer malnutrition from insufficient nutrients in the developing world as they are to those in the developed world who do not grow optimally because of gastrointestinal disease.

MEASUREMENT OF GROWTH

Measurements

Growth is an increase in the mass and dimensions of the body and comprises ponderal and linear components. To assess growth, we must be able to measure both components accurately. Standardization of techniques and calibration of equipment ensure accurate and reliable measurements.

Ponderal growth is assessed by measuring change in weight. Instruments include the balance beam scale and the electronic scale. Ideally, the child should be measured naked in the early morning. In general, ponderal growth measurements are more accurate than linear measurements because the techniques employed are easier, but whichever scales are used, they must be calibrated regularly. Other measures of ponderal growth that are commonly assessed include skinfold thickness and mid–upper arm circumference (MUAC). Skinfold thickness is generally measured in the triceps and subscapular areas. Calipers are held perpendicular to the skin, and the skinfold is pinched and elevated with the free hand. The caliper jaws are opened, closed over the skinfold, and released, and the measurement is recorded. MUAC and subscapular skinfold thickness are both assessed with the left arm hanging down and the elbow extended at a point midway between the olecranon and the acromion. MUAC is measured with a narrow, nonstretching tape applying only light pressure to the arm to avoid biting into the tissue. Skinfold thickness is most commonly used to assess subcutaneous fat as an index of total-body fat. Subcutaneous fat, however, varies between body sites[1] and can form a variable proportion of total-body fat. Thus, combinations of measures of two skinfold thicknesses from different sites or one skinfold thickness with arm circumference measurement (as "arm fat area") have been used to improve correlation with total-body fat,[2] but

this correlation varies between 0.4 and 0.9 and is particularly poor in preschool children. MUAC encompasses not only fat but also muscle and bone. It is a sensitive indicator of malnutrition, particularly when combined with height. It is a useful tool for community nutritional assessment of preschool children because it remains relatively constant between 2 and 5 years of age and is therefore age independent during that time.

Linear growth is more difficult to measure accurately and is assessed either as supine length or standing height. Supine length is best assessed in children less than 2 years using a baby board with supports for the head and feet. An assistant is required who holds the baby's head in firm contact with the headboard so that the line between the center of the ear hole and the lower border of the eye socket (Frankfort plane) is vertical. The measurer then straightens the child's legs by gripping the ankles and takes the reading. The standing height of children over 2 years is measured using a stadiometer. The child should be in his/her bare feet with heels together and buttocks and shoulder blades against the stadiometer, looking straight ahead, with a headboard resting at right angles against the highest point of the head. The measurer should ensure that the Frankfort plane is horizontal and apply gentle pressure to the mastoid process to extend the head, checking that the heels have not lifted off the baseboard.[3] Assessing height accurately in the 2- to 3-year age group is difficult, and to obtain accurate measurements, it is appropriate to measure supine length even in children up to 5 years old. The US National Center for Health Statistics (NCHS) reference data, however, are based on length to 2 years old and height above this age. Because length is 0.5 to 1.5 cm greater than height, it is recommended that if the former is measured over 2 years old and the NCHS reference is used, then 1.0 cm should be subtracted. Length or height should be reported to the nearest 0.1 cm, but it should be remembered that the measurement error is nearly 0.5 cm. The rate of change of height (velocity) has been promoted as a better expression of linear growth than height alone,[4] but an inherent lack of precision in estimating velocity may limit its reliability in assessing growth in short children.[5]

Assessing body proportions by measuring subischial leg length, as a derivative of sitting height, or knemometric length (distance between knee and heel) has been employed to measure long bone growth and its contribution to total linear growth. However, these measurements are more technically difficult than length or height assessment, and their relationship to total linear growth is not clear because different parts of the skeleton appear to grow at different rates and times.[6] Assessing body proportions is useful, however, when assessing linear growth in children who cannot stand.

Indices and Reference Populations

Growth is measured using a combination of height, weight, age, sex, and other anthropometric variables, including MUAC. Single anthropometric measurements, however, are uninterpretable, and indices (eg, weight for height) are combinations of measurements that allow growth data to be compared within and between groups (eg, a single weight is meaningless unless related to a child's height or age). In turn, growth indices must be related to a reference population for meaningful interpretation. The World Health Organization (WHO) has endorsed the use of that population defined by the NCHS as a reference.[7] However, the use of references based on a population of infants and children from one country to assess the growth of children in another country (eg, a developing country) has proved controversial. Differences in the genetic potential for growth are often quoted as a rationale for having country- or region-specific growth references. However, although genetic differences do exist, environmental factors have the larger effect on the potential for growth. Martorell, who looked at the heights of school-age children from different socioeconomic groups in different countries, demonstrated this (Figure 17-1).[8]

The WHO has acknowledged that reference data will be used as standards and recommends that care be taken to choose references that resemble standards.[7] It further acknowledges that because the mean heights of young children of many affluent populations differ little among ethnic groups, it should be possible to construct a standard that reflects the growth potential of all children throughout the world. The WHO chose the 1977 NCHS reference because the population on which it was based lived in a healthy environment, was well nourished, and had probably met its full growth potential. As a standard, its limitations must be recognized. The growth curves were originally constructed in 1975 from four sources. The 0- to 23-month data of recumbent lengths came from the Fels Research Institute Longitudinal Study of 1923 to 1975. The infants

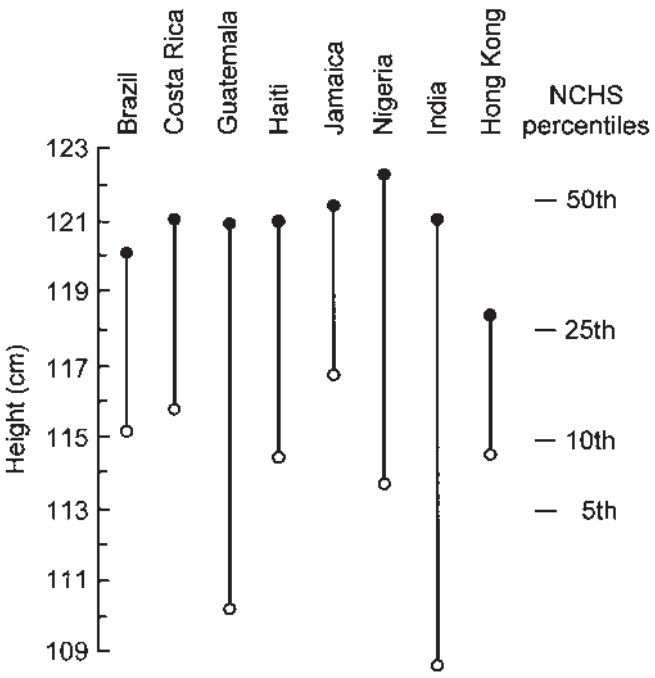

FIGURE 17-1 Mean heights of 7-year-old boys of high (●) and low (○) socioeconomic status in representative countries. Reproduced with permission from Martorell R.[8] NCHS = National Center for Health Statistics.

included in this data set were predominantly formula-fed and were from a relatively restricted genetic, socioeconomic, and geographic background. The 2- to 18-year-old data of standing heights came from three US surveys from 1960 to 1975. Across most populations, there is little difference in mean growth in height or in the distribution around the mean, but the inclusion of both healthy and sick, breast- and formula-fed infants in this reference should be remembered, particularly when comparing individuals or particular groups against the reference, for example, breastfed infants (see below). With these limitations in mind, NCHS data should perhaps be used as a tool to identify children at risk of malnutrition rather than as a standard to be attained or as a means to label children as malnourished.[9] An expert committee of the WHO has recommended the development of a new reference for infants and children, which will be a complex and costly undertaking.[10] The Centers for Disease Control and Prevention (CDC) recently published new childhood growth percentiles to replace the 1977 NCHS percentiles in the United States to provide a more up-to-date reference.[11] The new CDC percentiles may better represent current growth patterns but may still misdiagnose the normalcy of growth in young exclusively breastfed infants.[12]

Nutritional status can be assessed at specific time points by employing one or more anthropometric indices and comparing them against a reference. This can de done in one of three ways: as a deviation from the median of the reference expressed as standard deviation (SD) scores, as a percentile of the reference population, or as a percentage of the median reference value. For the analysis of data, SD or z-scores are recommended because they lend themselves to easy mathematical manipulation and statistical analysis.[9]

Growth, however, is expressed as rate of change in weight, height, and any other anthropometric variable (velocity) and can be assessed only by comparing indices over time against the reference population. In assessing individual children, it must be emphasized that plotting a child's weight and height over time allows assessment of the child's own growth curve in relation to a reference population. Indices examined at one time point without reference to earlier recordings make it impossible to determine whether the child is following steadily along a growth percentile, moving downward, or catching up.

Commonly used derived indices include weight for height, weight for age, and height for age. Deficits in different indices reflect different underlying processes and can indicate different causation. Weight can be lost and gained quickly in response to environmental insults, whereas height cannot be lost. "Wasting" and "stunting" are terms coined to reflect these different processes. Wasting is a deficit in weight for height and results either from a failure to gain weight or from weight loss. It can develop rapidly and be reversed rapidly and reflects a process occurring in the relatively recent past.

Body mass index (BMI), calculated as weight (kg)/height^2 (m), is commonly used as a "fatness" index in adults and has recently been recommended as an indicator of nutritional status in children after infancy.[7] The median values of BMI in children vary markedly throughout childhood, particularly in the first year of life and at puberty. BMI has been noted recently to be different in normal Chinese and Caucasian infants.[13] In the United Kingdom, boys attain 16% and 45% of their adult height and weight, respectively, between the age of 12 years and adulthood, resulting in a large change in median BMI from 16 to 21 years.[14] This additional weight is predominantly composed of muscle and bone rather than fat and is therefore relatively unaffected by the factors that determine fat accretion (food intake, disease). Children with a BMI z-score < –2 or > +2 are generally considered undernourished and overnourished (obese), respectively.

Stunting is a deficit in height for age and signifies slowing of skeletal growth. In general, it reflects a chronic process. The prevalence of nutritional deficits varies with age, and low weight for height often peaks in the second year of life, whereas low height for age starts earlier and decreases by 3 years. Interpretation of these indices must take into account age. Thus, a low height for age among 1 year olds reflects current health and nutrition, whereas among 6 year olds, it suggests a past problem but may also indicate concurrent stunting in the same population among younger children. Weight for age encompasses both weight for height and height for age. As an index of nutritional status, it has limitations; for example, a child with a low weight for age could be stunted and have a relatively normal weight for height.[15] In younger children, low weight for age may reflect the prevalence of low weight for height but in older age groups is more likely to be associated with a low height for age (Figure 17-2).

One of the major uses of derived growth indices is to predict subsequent health problems, especially morbidity, mortality, intellectual development, work capacity, reproductive performance, and risk of chronic disease. However, prediction does not necessarily indicate causation. There

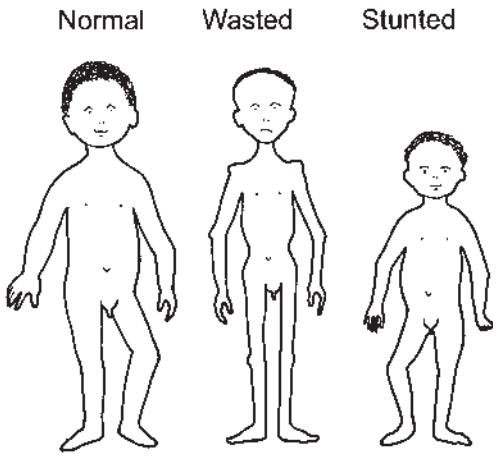

FIGURE 17-2 Comparison of a normal, a wasted, and a stunted child, all aged 1 year. Reproduced with permission from Waterlow JC.[15]

was a strong exponential association between weight for age and mortality rates in a meta-analysis of six longitudinal studies of children, but its capacity to predict death was low.[16] Its predictive value was highest in populations with high morbidity and mortality, indicating that malnutrition increases case-fatality rates rather than the incidence of disease. Weight for height is a better index of acute risk than weight for age and therefore of more value in identifying children who need nutritional treatment.[17] A cutoff of < 70% of the reference median is commonly used as an indicator for admission to hospital in developing countries to treat severe malnutrition.

UNICEF employs the terms "underweight," "wasted," and "stunted" to describe types of childhood malnutrition. It defines children as being moderate/severely underweight, wasted, or stunted as those > 2 SD below the reference (NCHS) median weight for age, weight for height, and height for age, respectively. Using these definitions, 28% and 32% of under 5 year olds in developing countries are currently estimated to be moderate/severely underweight or stunted. Almost half of all malnourished children live in South Asia, where the prevalence of moderate/severely underweight children is 48% (Figure 17-3).[18]

Combinations of indices can also give clues to causation. In areas of low prevalence of nutritional deprivation, where stunting occurs and weight for height is maintained, endocrine causes or skeletal dysplasias, as opposed to chronic disease, in which weight for height is often also low, are commonly responsible.

GROWTH: INFANCY, CHILDHOOD, AND PUBERTY MODEL

Linear growth is a complex process occurring in three distinct phases: infancy, childhood, and puberty.[19] The infancy phase is a continuation of the high fetal growth rate, with a rapid decline to 3 years of age. The onset of the childhood phase is heralded by an abrupt increase in linear growth rate and thereafter continues with a lower, more slowly decelerating velocity. A third distinct phase occurs at puberty before linear growth ceases and adulthood is reached. These three phases contribute differently to overall linear growth. Maximal rate of growth occurs during the infancy phase, but the slower but longer childhood phase is responsible for two-thirds of postnatal linear growth. The pubertal phase is associated with a second increase in growth velocity but is relatively short-lived and contributes least to the overall sum of linear growth.

The control of the infancy phase is poorly understood but is primarily a function of the intrauterine environment and postnatal nutrition. The onset of the childhood phase, normally in the second half of the first postnatal year, is influenced by the action of growth hormone (GH), which particularly regulates long bone growth in the legs. GH continues its influence throughout childhood and adolescence, but sex steroid secretion during puberty superimposes a further spurt in linear growth on the decelerating childhood phase. The etiology and reversibility of stunting are best considered with reference to the infancy, childhood, and puberty model (Figure 17-4). Changes in onset and duration of these phases and the effect of nutritional insults and interventions during them can best be understood within this context.

Ponderal Growth and Changes in Body Composition during Infancy and Childhood

Body composition can be assessed in a number of ways but is best viewed as a "two-component" model that consists of fat mass and fat-free (or lean body) mass. Human beings are among the fattest of mammals,[20] and the high level of fatness in infancy is particularly striking. The principal function of body fat is believed to be insulation, but high

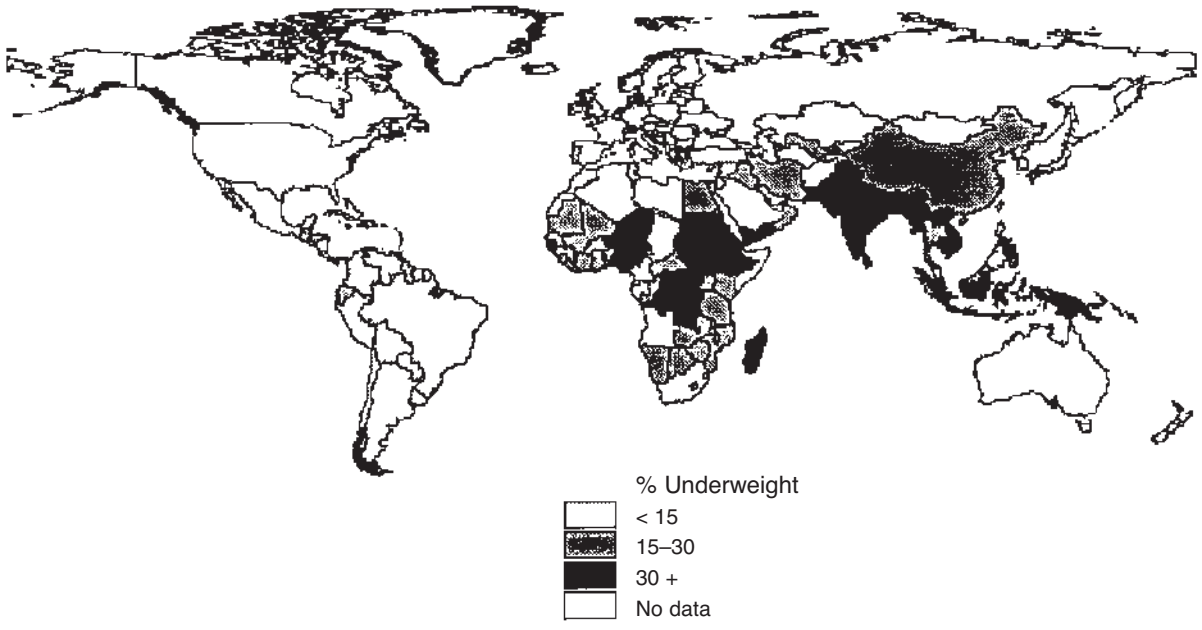

FIGURE 17-3 World map of underweight children. Reproduced with permission from UNICEF.[18]

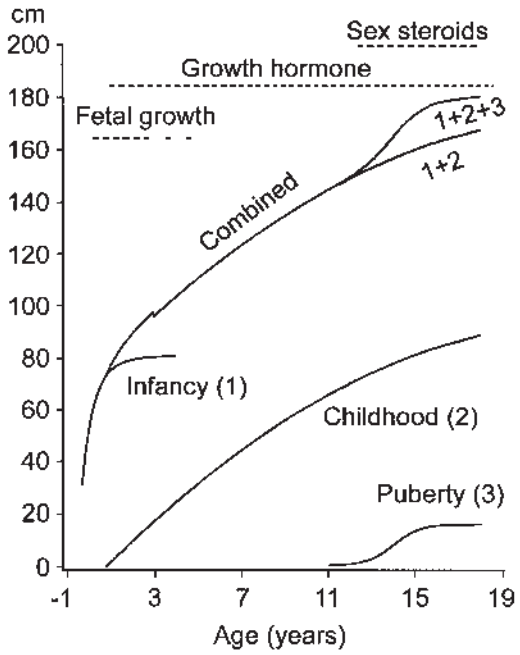

FIGURE 17-4 The infancy, childhood, and puberty model of growth. Reproduced with permission from Karlberg J.[19]

fatness in infancy probably evolved as an energy reserve to meet the relatively high energy demands of the large human brain and the risk of inadequate feeding, particularly around the time of weaning.[20] This underlines the importance of adequate ponderal growth for a variety of physiologic and biochemical functions and the adverse effects of inadequate ponderal growth (such as stunting). Epidemiologic studies in developing countries have consistently shown that inadequate growth and energy reserves (as indicated by weight or height) represent an important independent factor risk for morbidity and mortality[21] and contribute between 56 and 83% to infectious disease mortality in childhood.[16]

Typical changes in the body composition of children throughout early life can be summarized using the concept of the "reference child."[22] In the last trimester of gestation, appreciable quantities of lipid are deposited such that the reference child is born with around 14% of body weight as fat. Body fat continues to increase to about 25% of body weight at 6 months of age and then falls to a nadir of around 13% in boys and 16% in girls in late childhood. Intergender differences in body composition are present in childhood, with girls typically slightly fatter than boys. These gender differences become more pronounced during adolescence. Between the ages of 10 and 20 years, boys typically gain 33 kg of fat-free mass, but girls gain only 16 kg, and the difference between the sexes in body fat percentage therefore becomes more pronounced as they get older (Figure 17-5). Undernutrition is typically associated with depletion of both fat-free mass and fat mass. Overnutrition/obesity is associated with increased fat-free mass and increased fat mass.[22]

There is substantial variability in body composition at all ages, and secular trends in body composition have occurred. Modern children are considerably fatter than the reference child, but the general age-related changes noted above are still present.[23] These age-related changes in body fatness probably reflect changes in the need for an energy reserve of adipose tissue. Changes in body composition result from changes in the balance of lipogenesis and lipolysis. Regulation of this balance throughout childhood is complex and not fully understood but probably depends on the balance between the actions of insulin, GH, and insulin-like growth factor (IGF)-1 and IGF -2.[24]

Ponderal growth has a genetic component. Evidence for this includes the concordance between body size and composition of monozygotic twins, even when reared separately.[22] However, environmental influences are also important determinants of ponderal growth. Adiposity depends on energy balance, which is the difference between energy intake and total energy expenditure (made up of resting energy expenditure, diet-induced thermogenesis, and energy expended on physical activity). A positive energy balance promotes fat gain, but in developed countries, increases in energy intake may not be the principal cause of the secular trends toward increasing fatness that have been observed recently.[25] Rather, these have probably resulted from a reduction in energy expenditure secondary to reduced habitual physical activity in childhood, even in infancy. In developed countries, there is little evidence of a relationship between dietary composition and body composition, and the latter seems to vary largely independently of the former.[24]

However, inadequate food intake is the principal cause of inadequate ponderal growth in developing countries, and in undernourished patients, inadequate energy and protein intake make a major contribution to abnormalities in body composition and to inadequate ponderal growth—hence the increased risks of morbidity and mortality noted above.[21]

One dietary factor that seems increasingly important for ponderal growth in developing countries is parental feeding style (PFS). PFS shows substantial variation between and within developing countries, and this is strongly related to ponderal growth.[26] In particular, more "laissez-faire" PFS can predispose to inadequate food

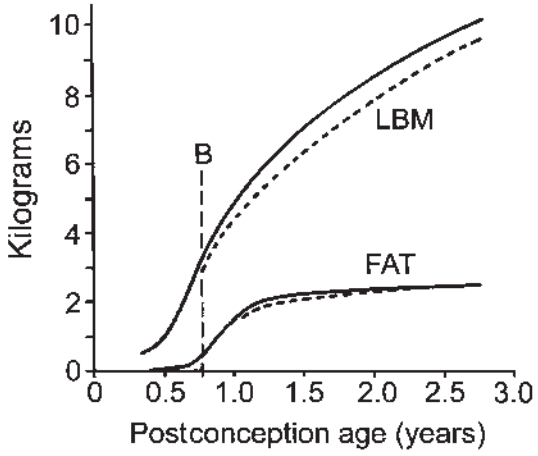

FIGURE 17-5 Average values for lean body mass (LBM) and fat in fetus and infant. Boys —; girls - - -. Reproduced with permission from Forbes GB. Human body composition. New York: Springer-Verlag; 1987.

intake and hence compromise ponderal growth. It is of note that interventions that promote more supportive and responsive feeding styles appear to have had some success in improving ponderal growth in developing countries. In developed countries, an overly controlling PFS might predispose children to obesity by impairing their innate capacity to regulate energy intake.[27]

Prenatal Influences

Intrauterine growth has a significant influence on postnatal growth and must be considered in the assessment of growth during infancy. Birth size is a reflection of gestational age, with those born prematurely, but with an appropriate weight for gestation, usually demonstrating normal postnatal growth. Infants with a low weight for gestational age are termed small for dates or intrauterine growth retarded (IUGR). The relative degree of retardation of linear and ponderal growth can suggest causation. Those infants with length affected less than weight usually have a good postnatal growth prognosis and reflect a short-term insult to intrauterine growth in late pregnancy (eg, placental insufficiency). Those with length and weight equally affected, however, reflect a more chronic process, and the prognosis for optimal postnatal growth is much poorer. Thus, chronic fetal undernutrition, chronic maternal illness or malnutrition, toxin ingestion (eg, alcohol, tobacco), or genetic abnormalities can lead to proportionally small babies.

GH secretion is high during fetal life but does not influence the linear growth of the fetus. GH-deficient children are only 1 to 2 cm shorter on average than normal infants at birth.[28] GH receptors are present in cartilage but may be immature. Whether this small discrepancy in linear growth is a result of this immaturity or a secondary metabolic action of fetal GH remains to be established. Anencephalic and athyroid fetuses do not demonstrate growth retardation, indicating that both pituitary GH and thyroid hormone are not vital determinants of intrauterine growth.[29] Placental factors (eg, lactogen and somatomedins) may well influence intrauterine growth and need further study. Placental size and function clearly influence birth weight.

The incidence of low birth weight (< 2,500 g) in 1995 was 15.3% or 21.3 million newborns worldwide, of which 20.4 million were born in developing countries.[30] IUGR, defined as birth weight below the 10th percentile of the birth weight for gestational age reference curve,[10] in developing countries alone represents 30 million newborn infants per year or 23.8% of births. IUGR is associated with increased mortality, and the strength of the association is greatest in the neonatal period but also extends postneonatally. Infants weighing 2,000 to 2,499 g were approximately 4 and 10 times more likely to die in the neonatal period and 2 and 4 times more likely to die in the postneonatal period than those born weighing 2,500 to 2,999 g and 3,000 to 3,499 g, respectively.[31] IUGR babies can demonstrate catch-up growth postnatally. Data from developed countries indicate that partial catch-up growth can occur by 2 years of age and thereafter maintain that achieved place in the growth distribution until adulthood. Achieved adult sizes are, on average, 5 cm shorter and 5 kg lighter than controls.[32] In developing countries, where the postnatal environment might be less favorable, the effect of IUGR is similar in absolute terms. The influence of BMI at birth for growth-retarded children on subsequent catch-up growth is unclear. However, birth length and predicted target height (a function of midparental heights indicating genetic potential) influence catch-up growth and explained half of the variation in catch-up growth in one study.[33] The effect of birth length predominated up to 2 years of age; thereafter, target height dominated up to 8 years. Pubertal catch-up growth in these children was small and was not influenced by fetal experience. Overall, the difference in final height of these children was primarily attributable to the difference in the magnitude of catch-up growth during the first 6 months of life, confirming that this is the critical period for catch-up growth.

Thrifty Phenotype (Barker) Hypothesis

IUGR is increasingly recognized as a major determinant of some chronic adult diseases, in addition to its effect on growth and early mortality. Recognition of the long-term adverse effects of the intrauterine and early infantile environment on later disease susceptibility has led to the formulation of the thrifty phenotype (Barker) hypothesis.[34–36] This proposes that impaired fetal and early infantile growth affects susceptibility to chronic adult degenerative disease.

Birth weight is a relatively easily obtained index of growth for use in epidemiologic studies, yet it is a crude measure of the quality of the intrauterine environment. Associations between low birth weight and later hypertension, ischemic heart disease, and non–insulin-dependent diabetes in adulthood have been reported from retrospective studies, mainly in developed countries.[37–39] Low weight at age 1 year has also been associated with an increase in the prevalence of non–insulin-dependent diabetes or impaired glucose tolerance in adult life.[37] Prospective studies are now in progress, and early results from developing countries suggest a link between low birth weight and the development of insulin resistance,[40] which could account for some of these reported findings. However, much remains to be clarified, particularly which aspects of the uterine or early infantile environment are related to later disease susceptibility[41] and which nutritional or metabolic mechanisms explain these associations.[42] Birth weight could be a proxy for other factors that are more difficult to measure directly. Other characteristics of size at birth (eg, degree and distribution of adiposity, birth length, and rate of postnatal growth) may be more important.

Animal models have generated further insights into these associations.[43,44] The offspring of rat dams fed low-protein diets during pregnancy demonstrated permanent changes in hepatic enzyme activity and insulin and glucagon sensitivity. Continuation of the protein restriction postnatally was associated with increased longevity compared to the offspring of dams that were solely protein restricted during pregnancy (ie, catch-up growth reduced longevity).

A recent epidemiologic follow-up study of Finnish men with detailed anthropometric records has shown that the highest risk of coronary artery disease mortality occurred

in boys born thin at birth but who demonstrated ponderal catch-up growth in childhood.[45] Ponderal growth can be generated with relative ease in the malnourished child. Linear growth is more difficult to induce and requires a more prolonged intervention, and few malnourished infants in developing countries reach their full linear growth potential. Improving a child's ponderal growth in an environment of high infant mortality owing to infectious disease will reduce that child's risk of morbidity and mortality owing to infectious disease and thus is desirable. It is difficult to assess the effect on subsequent mortality and morbidity of improving a child's ponderal growth in an environment of already low infant mortality. What is clear is that further thought and study are needed into the long-term effects of nutritional interventions in infancy in growth-retarded children.

Prevention of IUGR has proved difficult, and a systematic review of 126 randomized controlled trials evaluating 36 interventions demonstrated that most did not have any effect. Cessation of smoking, balanced protein/energy supplementation, and antimalarial chemoprophylaxis were found most likely to be beneficial.[46] Near-normal fetal growth rates can occur in even severe maternal malnutrition, indicating that factors regulating placental and fetal growth are robust and resistant up to 36 weeks gestation. This is reflected in the similarity of mean birth weights at 36 weeks across populations. At 34 to 36 weeks of gestation, fetal growth slows owing to space constraints within the uterus; thereafter, maternal malnutrition can have a marked effect on birth weight.

Dietary supplementation of mothers during pregnancy might therefore be expected to reverse IUGR. A meta-analysis of controlled clinical trials, however, demonstrated only modest increases in maternal weight gain and fetal growth.[46] Targeting of specific populations of women has proved more encouraging. Rural Gambian women have low weight gain in pregnancy, lose body fat, and have a high ratio of fetal weight to total weight gain in pregnancy, particularly during the wet season. High-energy groundnut biscuit supplementation (4.3 MJ/d) for 82 days significantly increased weight gain during pregnancy (by 580 g) and birth weight (by 136 g) and significantly reduced odds ratios for stillbirths and all deaths up to 28 days postpartum. This was achieved through a reduction in the number of babies who were small for their dates rather than born preterm.[47]

Maternal height and prepregnancy weight are also important determinants of birth size,[46] but their effects could, in large part, be due to an intergenerational effect of maternal birth size. Recent data from Guatemala demonstrated that maternal birth size was a significant predictor of child's birth size; for every 100 g increase in maternal birth weight, there was a 29 g increase in the child's birth weight, and for every 1 cm increase in mother's birth length, the child's birth length increased by 0.2 cm.[48]

Infancy Phase of the Infancy, Childbirth, and Puberty Model

Infant birth size is linked to that of the mother rather than that of the father, whose influence on growth becomes more apparent with time. If there is a large disparity between the size of the father and that of the mother, then the likelihood increases that the baby's growth will cross growth reference percentiles either up or down. Approximately two-thirds of normal children cross percentiles in the first 18 months of life. By the age of 2 years, growth "converges to the mean," genetic potential predominates as its principal determinant, and the percentile trajectory leading to midparental height is achieved.

The infancy phase of growth represents a continuation of the fetal phase with a rapid deceleration of growth until 3 years of age, when the childhood phase of growth predominates. Growth during infancy may continue to be influenced by the same factors that determined growth in utero, with nutrition being a preeminent factor. Human milk has long been recognized as the optimal food for babies, and complementary feeding is generally recommended as starting at around 6 months.[7] Longitudinal studies of infant growth in developing countries indicate that stunting occurs between the ages of 4 months and 2 years (see below), coinciding with the transition from breastfeeding to complementary foods. The energy density of weaning foods has therefore been proposed as a factor in the etiology of stunting.

The timing of this transition has recently been questioned[49] and is of considerable importance, particularly in developing countries. The increased risk of disease associated with the introduction of microbially contaminated solid foods must be balanced against the risk of malnutrition from prolonged exclusive breastfeeding—"the weanling's dilemma."[50] For a sound recommendation as to the optimal timing of complementary feeding, an understanding of the growth of breastfed babies is required.

The common observation of apparent growth faltering of breastfed babies beginning at 3 to 4 months is based on the use of reference growth curves that were constructed from data from predominantly formula-fed infants. Breastfed babies have a differently shaped growth curve and gain less weight in the second half of the first year of life than formula-fed babies do. Gaining less weight, however, does not necessarily imply that breastfed infants are not meeting their energy or nutrient requirements. Studies confirm that breastfed infants have significantly lower energy intakes than formula-fed infants do,[51] but this is not due to inadequate maternal milk production. Breastfed babies regulate their own milk intake[52] and may not consume all of the milk in the breast during a feed. Despite lower energy intakes and weight gain, babies exclusively breastfed to 4 to 6 months of age have similar motor development and lower rates of infection than those who are formula-fed.[53] Thus, NCHS growth curves may reflect the "overfeeding" of formula-fed babies rather than the "underfeeding" of those exclusively breastfed, and the growth of breastfed babies in developing countries may be more appropriately compared with that of breastfed babies of affluent populations.

The weight gain of breastfed babies in developing countries is similar to that of breastfed babies from more affluent populations[54] to 6 months of age, although attained weight differs owing to differences in birth weights. Ponderal

growth faltering thereafter occurs at 6 months in those predominantly but not exclusively breastfed and at 9 months in those exclusively breastfed to 6 months.[55] Linear growth, however, is poorer, and breastfed babies from developing countries are generally shorter than those from developed countries. Infant linear growth is not exclusively a function of nutrition, and when maternal height was controlled for, the difference in length between Honduran and American breastfed babies disappeared.[56]

It seems, therefore, that the growth rate of breastfed infants in developing countries is similar to that of breastfed infants of more affluent populations. Introduction of complementary feeds before 6 months did not influence infant growth in a pooled sample of 453 breastfed babies from six industrialized countries.[57] Even if growth faltering occurs, complementary feeding may not improve growth. The introduction of hygienic precooked complementary food at 4 months of age did not improve growth before 6 months of age in a study of breastfed babies of low-income primiparous mothers in Honduras.[58] The provision of a zinc-fortified complementary food between 4 and 12 months of age to infants of urban slum dwellers in India produced only a modest increase in weight gain, between 6 and 9 months only, and no significant effect on length gain. The prevalence of dysentery and fever was increased in the supplemented group, and breastfeeding decreased.[59] The study, of course, was not designed to examine for these outcomes if complementary foods were delayed until 6 months of age; thus, one cannot conclude from this study that exclusive breastfeeding for 2 more months (beyond 4 months of age) would have any benefit.

The timing of the introduction of complementary feeds, however, cannot be made on consideration of dietary intakes and growth alone. Infant morbidity, mortality, and development, as well as maternal considerations (eg, nutritional impact and length of lactational amenorrhea), must all be included. It may well be that the optimal age of transition varies between populations. In affluent populations, the benefit-to-risk ratio for complementary feeding at a particular age will differ from that of a population in a developed country owing to the lower risk of contaminated complementary feeds. The report of an expert consultation for the WHO recently pointed to the paucity of good data to resolve this issue. They concluded that exclusive breastfeeding to 6 months confers benefit to the infant and to the mother but can lead to iron deficiency anemia; insufficient data precluded the assessment of other potential risks of exclusive breastfeeding such as growth faltering, particularly in populations with severe maternal malnutrition and IUGR. They made a population-based recommendation of exclusive breastfeeding for 6 months, with introduction of complementary foods and continued breastfeeding thereafter.[60]

Childhood Phase

Linear growth velocity rapidly decelerates during the first year of life and is a product of the declining influence of the infancy phase and the onset of the childhood phase of growth. That contribution owing to the infancy phase ceases by 3 years of age. This deceleration is not constant, and the onset of the childhood phase between 6 and 12 months of age is defined by an abrupt and temporary increase before continuing to decelerate. The onset of the childhood phase represents that time when GH begins to influence linear growth (Figure 17-6).[61] In children with isolated GH deficiency, this abrupt onset is lost.[28] Long bone growth is particularly dependent on GH and makes up the majority of growth in the childhood phase compared with the infancy phase, when truncal growth accounts for the majority of linear growth.[61]

The trigger for the onset of the childhood phase is not understood. In Swedish children, it is independent of social class, age at cessation of breastfeeding, and midparental height, but it is influenced by growth rate immediately prior to onset.[62] The age at onset of the childhood phase will influence attained height subsequently; growth between 6 months and 3 years of age is negatively related to the age at onset.[61] Later onset at the childhood phase is common in populations of children with disturbed growth patterns (eg, malnourished children from developing countries or children with a chronic disease such as celiac disease).[63] This delay in the onset of the childhood phase causes growth faltering and has been proposed as a determining factor in attainment of final height, particularly in developing countries.[64] The reasons behind this delay in onset remain to be identified, but because the incidence of faltering clearly reflects socioeconomic conditions, it seems that environmental factors are more important than genetic factors. This view is supported by the observation that the growth rates of affluent members of society in these same

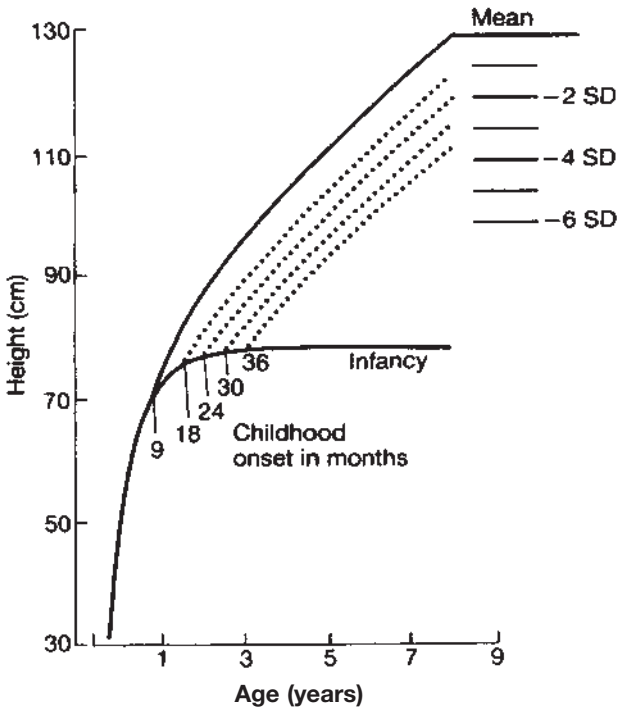

FIGURE 17-6 The effect of late onset of the childhood phase of growth on subsequent linear growth assuming normal action of the infancy component. Normal action of the childhood phase (–) and delayed onset as specified (····). Reproduced with permission from Karlberg J.[61]

developing countries do not falter or show delayed onset of the childhood phase. This phase, especially the first 6 months, is the critical phase for catch-up growth.[33]

Seasonality is an influence on weight gain from the first year of life, reflecting changes in food availability. In the second year of life, seasonality, for the first time, affects linear growth, which fluctuates more in those populations with a delayed onset of the childhood component.[62] As the effect of the infancy phase disappears in the third year, growth trajectory becomes more stable until puberty. This slower but longer phase is responsible for two-thirds of postnatal growth.

Puberty Phase

Puberty is the final phase of growth and development. It is marked by a period of accelerated linear growth accompanied by sexual maturation, as first described by Tanner.[65] At the end of this phase, physical sexual maturity is achieved, and adult stature and body proportions are attained.

The onset of puberty is marked by an increase in the frequency of pulsatile gonadotropin-releasing hormone (Gn-RH) secretion by the hypothalamus. The neuroendocrine control of this event is unclear but may be related to reduced sensitivity of the hypothalamic "pulse generator" to an inhibitory autofeedback mechanism.[66] Gn-RH induces release of the gonadotropins luteinizing hormone (LH) and follicle-stimulating hormone (FSH) from the anterior pituitary gland, also in a pulsatile fashion. During the early stages of puberty, increased pulsatile LH secretion occurs at night only. The adult pattern of intermittent release of pulses every 60 to 120 minutes is established later in puberty. The gonadotropins stimulate the gonads to produce the sex steroids. In the male, LH acts on the Leydig cells of the testis to stimulate testosterone secretion, whereas FSH acts on the seminiferous tubules and Sertoli cells. This results in spermatogenesis and maintenance of the Sertoli cells. In the female, LH and FSH act in concert to develop the ovarian follicles, resulting in estrogen secretion and ovulation.[67]

The adolescent growth spurt is a consequence of the combined action of the sex steroids and GH. GH is secreted by the pituitary somatotrophs in a pulsatile fashion, under the regulation of growth hormone–releasing hormone (GH-RH) and somatostatin. It is postulated that GH-RH controls the amplitude of the GH peak, whereas somatostatin controls its frequency and duration.[68] During puberty, in both sexes, there is a strong positive correlation between levels of gonadal steroids and levels of GH and IGF-1, suggesting that the sex steroids have a regulatory role in growth during this period. In boys, peak height velocity occurs relatively late in puberty, when testosterone levels have risen to approximately adult levels. IGF-1 levels are also maximal at this time. In girls, increased GH secretion occurs earlier in puberty, with maximum concentrations correlating with peak height velocity. Enhanced GH concentrations during puberty in both sexes reflect increased pulse amplitude rather than an increase in the frequency of pulses. The mechanism by which the sex steroids mediate GH secretion is unclear but may involve alteration of the secretory dynamics of GH-RH and somatostatin and/or the responsiveness of the pituitary somatotrophs.

In girls, the first physical sign of puberty is breast budding (Tanner stage B2). The adolescent growth spurt starts around the same time, and peak height velocity is a relatively early event within the pubertal phase (usually occurring around stage B2–3). By the time secondary sexual development is complete, growth rate has slowed considerably.[69] Menarche typically occurs toward the end of the growth spurt. Age at menarche is negatively correlated with height increase postmenarche. In boys, the first physical sign of puberty is testicular enlargement (Tanner stage G2). Onset of puberty in boys occurs less than 1 year after girls. However, the adolescent growth spurt starts much later, at around Tanner stage G3 (when penile growth begins), with peak height velocity occurring at stage G4, with considerable growth potential left after secondary sexual development is complete.[65]

Sexual dimorphism in height is attributable to three factors: boys are slightly taller than girls during the childhood phase of growth; the adolescent growth spurt begins 2 years earlier in girls; hence, boys have an additional 2 years of childhood growth; and the adolescent growth spurt is more intense in boys (mean peak height velocity 10 cm/yr at age 14 years) than in girls (mean peak height velocity 8 cm/yr at age 12 years).[70] Thus, the male adolescent growth spurt contributes more to adult stature than does that of the female.

Extensive changes in body morphology occur during the adolescent growth phase. Leg length increases first, but overall growth is due more to an increase in trunk length, so that the ratio of trunk to leg length increases during puberty.[65] Before puberty, boys and girls have similar body fat distribution. During puberty, fat deposition is less in boys but more truncal in distribution, and their increase in weight during puberty is largely due to an increase in lean body mass.[71]

Within developed countries, there is a secular trend toward earlier maturity and greater adult stature, reflecting favorable socioeconomic conditions. A similar trend is seen within developing countries, where children are stratified according to socioeconomic status (ie, children from privileged groups tend to be taller and mature earlier than their less privileged peers). A similar trend has also been observed in children of immigrants to the United States.[72]

Intercountry adoption of children from developing to industrialized countries has provided valuable data on environmental influences on growth and maturation. Linear growth improves, but final height is compromised by earlier stunting and/or low birth weight, indicating the importance of the fetal and infantile growth phases. Catch-up growth is often cut short by early pubertal onset, particularly in girls, resulting in short final height, despite a normal pubertal growth spurt.[73] Thus, whereas the potential for pubertal growth is unaffected by early malnutrition, the realization of full genetic potential may well be. Malnourished male rats given access to unrestricted feeding had accelerated hypothalamic and testicular maturation. This effect was seen only in those refed before weaning,

perhaps indicating a critical period of hypothalamic sensitivity to changes in nutrition.[74]

In the United Kingdom, the construction of new growth charts in 1990 using cross-sectional data from a variety of sources enabled comparison with current growth standards dating from 1966.[75] Both boys and girls, at all ages, were taller and heavier in 1990. They were also heavier, although the weight differences were more marked in girls. In boys, peak height velocity was reached 6 months earlier at 13.5 years.

Obesity in prepubertal children is associated with increased growth velocity, advanced skeletal maturity, and early onset of puberty. However, obese children rarely become tall adults because obesity affects the timing rather than the magnitude of growth. Obese boys are taller than their thin peers before and during the early stages of puberty.[71] However, these height differences are lost as puberty progresses, and final heights are similar. In the Amsterdam Growth and Health Study, adolescents of both sexes who progressed rapidly through puberty were found to be more obese (BMI and skinfold thickness) than their more slowly maturing peers.[76]

Whereas obesity accelerates linear growth and advances sexual maturity, undernutrition slows growth and delays puberty. Menarche is not dependent on attained body weight in a well-nourished population.[77] However, anorexia nervosa of postpubertal onset is associated with secondary amenorrhea and in prepubertal onset with growth retardation and delayed puberty.[78] Abnormal and highly variable levels of GH, gonadotropins, and sex steroids were found in 19 cases, of which 17 had delayed puberty. Endocrine function failed to normalize after weight gain.[79]

Stunting

Stunting results from growth failure in childhood, which is commonly nutritional in origin. UNICEF estimates that 40% of the world population under age 5 years (226 million) is moderately or severely stunted. As a marker of deprivation, stunting also predicts other functional consequences of severe nutritional insults early in life. Cognitive deficits, decreased work ability, increased morbidity, and increased obstetric risks have all been associated with stunting. Stunted rural Guatemalan children had lower literacy scores, had completed fewer years at school, and scored less well in tests of intellectual function than their peers who had grown normally.[80] Adult height predicted the work capacity of Colombian sugar cane cutters[81]; shorter women with smaller pelvic sizes are at a greater risk of obstetric complications.[82,83]

Stunting is a chronic process, and it may take many months of suboptimal growth before it occurs. The degree of stunting is a product of the severity, timing, and duration of the nutritional insult. If a normal 12-month-old child stops growing completely, then he will take 6 months to fall below the –2 z-score for height for age (ie, to become stunted), whereas a 36-month-old child will take 13 months to do the same (Figure 17-7). Equally, that same 12-month-old child will take 42 months to become stunted if he reduces his growth rate to 70% of normal as opposed to stopping growing completely.[84] Stunting results from a chronic insult, and, equally, catch-up growth will have to be prolonged to reverse it; the older and the more stunted a child, then the longer that he will have to grow at an accelerated rate before full catch-up growth is achieved. In the environment in which the vast majority of stunted children reside, this is usually impossible.

In a study from Pakistan, between 75 and 83% of children were stunted by 24 months of age.[85] The stunting process (defined as height-for-age z-scores) started at 6 months of age and continued to 18 months of age, whereas weight-for-length z-scores increased from a baseline of –1 to 0 at 24 months (Figure 17-8). Other studies have found that length attained at 3 years is highly related to adult height but is independent of subsequent linear growth (ie, that early growth retardation is not reversed later).[86]

The requirement for dietary energy is highest in the first year of life, when growth velocities are high but stomach volumes are low. Yet commonly used weaning foods in many countries with a high prevalence of stunting are bulky and have energy densities too low to support optimal growth (Figure 17-9). Infections, especially gastrointestinal, are common in areas of poverty and illiteracy and contribute to malnutrition, which makes children more susceptible to further infections. This cycle of poor nutrition and infection in this critical phase of growth leads to stunting.

The relative contribution of diarrheal disease and inadequate diet to the commonly observed growth failure of children in developing countries remains uncertain.[87] At an individual level,[88] diarrheal episodes cause short-term faltering in both ponderal and linear growth, yet whether these children then catch up and whether their long-term growth failure is due to inadequate food intake or recurrent diarrhea is controversial. Malnourished rural Bangladeshi children grew equally well in the three monthly intervals in which a diarrheal episode of at least 10 days occurred at the beginning of the interval compared with an interval with no diar-

rhea.[89] In contrast, intervals with at least 10 days of diarrhea occurring in the last 45 days were associated with significantly lower weight gain than those with diarrhea-free intervals. These children were free of diarrhea for over 90% of the time but gained weight only to 74% of the NCHS median during diarrhea-free periods. The authors concluded that these children were malnourished owing to poor food intake rather than diarrhea. A review focusing on evidence of causality concluded that malnutrition was likely to predispose to diarrhea but that there was no conclusive evidence to support the hypothesis that diarrhea is a major cause of permanent growth faltering in whole communities.[90]

Recent application of noninvasive tests of mucosal integrity (eg, dual sugar intestinal permeability test) has permitted the study of the relationship between growth and mucosal injury. In The Gambia, 119 rural infants aged 2 to 15 months had their growth and intestinal permeability assessed monthly until 15 months of age, during which time diarrheal morbidity was also recorded.[91] All were breastfed until 3 to 4 months of age, during which time their growth approximated to the 50th NCHS percentile. By 14 months, both height and weight had fallen to the 5th percentile. Intestinal permeability was strongly related to mean monthly weight and length gain and predicted 39% and 43% of the observed faltering in weight and length, respectively. Intestinal permeability values were abnormal during 76% of the study period, yet the infants had diarrhea for only 7.3% of time. The intestinal mucosal histology of these children was abnormal for most of the time, and the authors concluded that this was more likely due to gastrointestinal infection than to malnutrition. Both decreased nutrient absorption and increased permeability of the mucosal barrier (allowing translocation of microorganisms, endotoxins, and food proteins causing both a local and a systemic inflammatory response) were postulated to contribute to poor growth. In The Gambia, intestinal permeability values improved with age but never reached values seen in similar age children in the United Kingdom. One hypothesis is that the permeability of the intestine is "set" early in life,[92] and the failure of nutritional interventions to correct growth faltering in subjects with early and severe malnutrition may reflect a failure to reverse this enteropathy, once established. This, of course, remains only speculation at this time. Suboptimal intestinal repair after injury was also demonstrated in 20 Gambian infants with persistent diarrhea and malnutrition who had no significant improvement in intestinal permeability 1 month into rehabilitation.[93] Intestinal biopsies demonstrate partial to subtotal villous atrophy, moderate to severe crypt hyperplasia, and marked infiltration of activated intraepithelial lymphocytes. The enteropathy associated with malnutrition has long been recognized; however, only recently has this been appreciated to be a cause and a consequence of malnutrition.

REVERSIBILITY OF WASTING AND STUNTING

Ponderal catch-up growth is relatively easy to achieve in malnourished children through appropriate dietary rehabilitation and can be spectacular (Figure 17-10). Rates of 10 to 20 g/kg/d can be generated—up to 10 times the normal rate of gain in the under 2-year-old age group.[88] The optimal macro- and micronutrient content of rehabilitation diets has long been debated. Not only must preexisting deficiencies be corrected, but energy, protein, and micronutrient content must match the potential for rapid growth; if any one constituent is limiting, growth may falter. Recent WHO recommendations summarize the requirements for energy, protein, potassium, sodium, zinc,

and copper, as well as other minerals and water- and fat-soluble vitamins.[94] The exact requirements of severely malnourished children for many of the micronutrients in particular and when to administer them remain to be clarified. Overzealous[95] or inappropriate timing of supplementation[96] can have potentially fatal consequences for severely debilitated, immunocompromised, septic children. Linear growth is dependent on lean tissue deposition, and the proportion of lean to fat tissue deposited is determined by both the macro- and the micronutrient content of the diet. Adequate dietary protein is necessary for protein deposition, but if it accounts for over 15% of total dietary energy, it will not increase protein deposition further and can be harmful. Zinc supplementation has been shown to increase the proportion of lean tissue deposited,[97] and in children recovering from severe protein-energy malnutrition, it improves ponderal growth[98] and immune function.[99] However, zinc supplementation of growth-retarded and presumed zinc-deficient children has had mixed effects on the promotion of linear catch-up growth. This probably reflects both the diversity of populations in which zinc supplementation was employed in terms of age, degrees of growth retardation, dietary intake, bioavailability of zinc and other growth-limiting nutrients, and the study design.

Examination of both ponderal and linear growth after a nutritional insult can throw light on the relationship between the two. The growth of 369 Jamaican children recovering from severe malnutrition (95% had a weight-for-age z-score < 60% of the NCHS median and/or nutritional edema) was retrospectively examined over a 31-day period. Only a subgroup (29%) demonstrated catch-up in height-for-age z-scores over this period, and they were the children who were most stunted at the onset. Most children did not demonstrate linear growth until they had achieved 85% of expected weight for length.[100] This suggests a threshold for length gain, but even severely malnourished children can gain in length early in rehabilitation; Figure 17-11 demonstrates weight-for-height z-scores of 141 severely malnourished Bangladeshi children plotted for six time points during rehabilitation against subsequent linear growth.[101]

Longitudinal follow-up studies commonly report residual growth failure after severe malnutrition.[102] What appears to limit subsequent linear growth is the severity and duration of the original insult, at what age it occurred, and the nature of the nutritional macro- and micronutrient rehabilitation employed. Ponderal growth reflects the recent health and nutritional status of the child, whereas linear growth reflects longer-term health and must have a

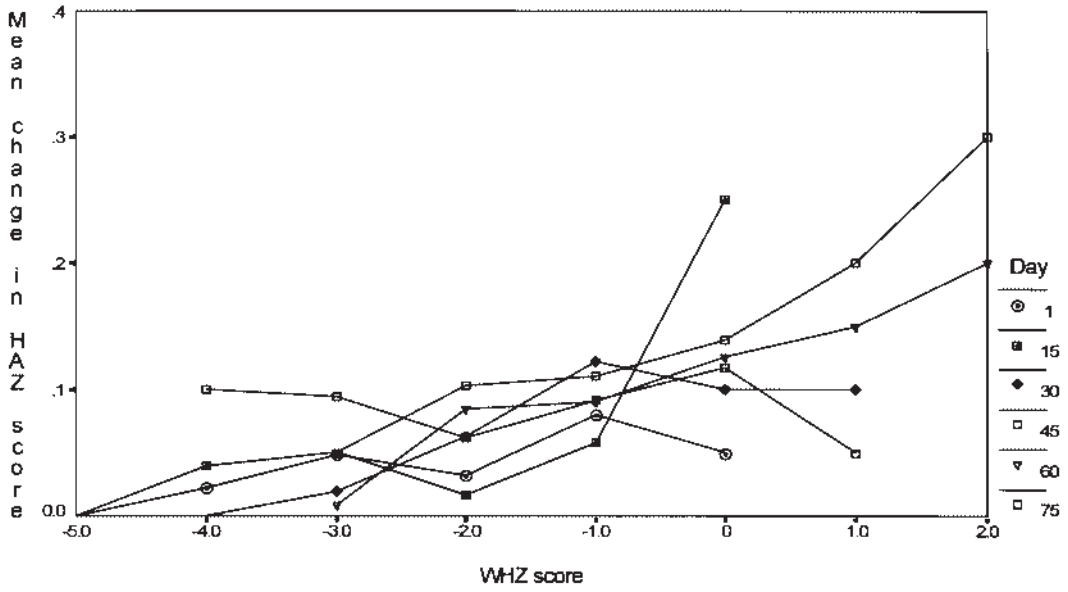

FIGURE 17-11 Linear growth of severely malnourished children. Reproduced with permission from Doherty CP et al.[102]

more sustained optimal environment to occur normally. In general, babies are born with the same mean length between and within populations of diverse socioeconomic backgrounds. The process of stunting seems to occur between the ages of 6 and 18 to 24 months and is associated with a delay in the onset of the childhood phase of growth. If a child in a developing country survives the critical growth period up to 2 years of age, then locally available foods with adequate energy density and the development of the child's immunity to environmental pathogens should allow the child to continue to grow at a normal velocity thereafter. The child will often remain at that baseline level of stunting, however, and demonstrate only marginal catch-up growth. The ability to catch-up linear growth has been demonstrated in studies of children adopted into better socioeconomic conditions.[103] Even this catch-up growth in later childhood is incomplete, and the effect on pubertal timing and final adult stature is not clear. The vast majority of children in developing countries stunted at 2 years of age will be left with a degree of stunting until adulthood.[84]

Nutritional interventions in the critical period[104] of the first 2 years of life, however, can generate catch-up growth and reverse stunting. In Guatemala, a study of food supplementation demonstrated a differential effect at different ages, with only those under 3 years of age demonstrating catch-up growth, and the linear growth of those 3 to 7 years of age did not benefit.[104] The effect of nutritional interventions on stunted adolescents, their age and duration of menarche, and their final attained height are not known.

The potential for catch-up growth will depend on the environment (eg, dietary macro- and micronutrient supply), patterns of morbidity, and the predetermined height potential for that individual child. Height potential is genetically predetermined and normally reflects parental heights in well-nourished populations. Comparing height potential for individual populations across the world, it is clear that differences are primarily due to environmental factors rather than genetic factors. However, stunted children are frequently born to stunted parents. Therefore, the parental heights in this situation are not a useful guide to potential. Animal experiments demonstrate that the progeny of rats that have been nutritionally restricted are small, and even when their offspring have been adequately nourished, it will take three generations or more for them to attain their true height potential.[105] Thus, it will probably take several generations of an optimal nutritional environment for the offspring of stunted parents to attain full genetic height potential. This process of environmental regulation of genetic potential is not clearly understood.

Age at menarche determines the length of the childhood phase of growth and therefore the potential period for catch-up growth. Menarche is frequently delayed in poorly nourished populations,[106] but the degree of this delay and thus the potential for catch-up have declined historically because diet and nutritional status have improved. In certain populations, this delay has been sufficient to allow significant catch-up growth.[107]

CONCLUSIONS

Studies from developing countries provide important observations concerning the relationship between malnutrition and growth failure. These observations are directly applicable to the developed world, especially to children with chronic gastrointestinal disease. The critical period for linear growth is under 2 years of age, and significant nutritional insults before this age are likely to have profound and long-term effects on growth. Ponderal catch-up growth is relatively easy to achieve, but nutritional interventions designed to promote linear growth must be initiated early and be sustained. Even then, potential catch-up may be limited by maternal malnutrition and intergenerational effects. An understanding of the infancy, childhood, and puberty model

of linear growth and the relative contributions of each phase of growth underlie this. Stunting is not a benign adaptation to chronic nutritional insufficiency but has serious consequences in terms of general and reproductive health, school performance and intelligence, and adult work capacity.

CHAPTER 18

MALNUTRITION

Stephen John Allen, MBChB, MRCP (UK) Paeds, DTM&H, MD

Malnutrition is closely associated with poverty in all regions of the world.[1] It makes an enormous contribution to child morbidity and mortality in the half of the world's population that lives on less than $2 (US)/d. The wide-ranging and severe abnormalities of the gastrointestinal system that occur in severely malnourished children are well known. In addition, "tropical" or "environmental" enteropathy occurs in most children living in developing countries and may be an important cause of growth faltering. Recent studies have given new insights into the pathogenesis of the enteropathy associated with malnutrition that raise the prospects for specific interventions for prevention and management.

MALNUTRITION: A MAJOR PUBLIC HEALTH PROBLEM IN THE THIRD MILLENNIUM

The 2002 *World Health Report* focuses on identifying risks to health as the key to prevention.[1] One-fifth of the global disease burden can be attributed to the combined effects of protein-energy and micronutrient deficiency. Underweight is the most important risk factor globally for disease, with most of the burden occurring in developing countries with high mortality rates (Figure 18-1). In these countries, underweight accounts for 12.6% of all deaths in males and 13.4% in females, with an estimated 3.4 million deaths in 2000 (1.8 million in Africa and 1.2 million in Asia). The disease burden attributable to underweight is even greater than that caused by other major risk factors, such as unsafe sex, which captures the burden attributable to human immunodeficiency virus (HIV)/acquired immune deficiency syndrome (AIDS).

Malnutrition is most common among children aged younger than 5 years; the World Health Organization (WHO) estimates that in 1998, 168 million children (27% of all children under 5 years) were at least moderately underweight (defined as a weight for age z- [WAZ] score of < –2 compared with National Center for Health Statistics [NCHS] standards).[2] In prospective community studies in developing countries, 56% of all deaths in children under 5 years were associated with malnutrition.[3] Weight for age has a direct relationship with child mortality that is independent of secular and socioeconomic factors.[4] A central maxim of preventive medicine, that "a large number of people exposed to a small risk may generate many more cases than a small number exposed to a high risk,"[5] is well illustrated by malnutrition. Although the risk of mortality rises progressively with worsening nutritional status, it is important to note that over 80% of malnutrition-associated deaths occur in children with mild to moderate malnutrition because these greatly outnumber severely malnourished children.[3]

Underweight children are at increased risk of dying from common infectious illnesses such as diarrhea and pneumo-

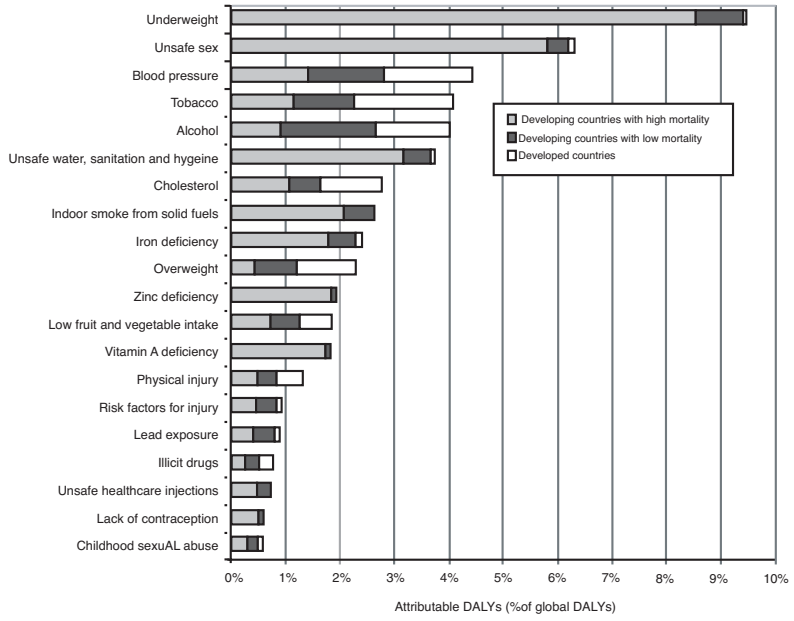

FIGURE 18-1 Underweight (weight-for-age z-score < –2) is the most important risk factor for the global burden of disease (assessed as lost disability-adjusted life years [DALYs]).[1] Reproduced with permission from the World Health Organization.[1]

nia,[6] and malnutrition is particularly common in children attending clinics and hospitals serving economically deprived populations. Underweight increased susceptibility to several major infections in a large series of children under 5 years admitted to hospitals in The Gambia.[7] Mean admission WAZ score in children with a primary diagnosis of malnutrition was 3.8 lower than that in community controls but was also between 1.4 and 2.5 lower for those with a primary diagnosis of malaria, severe malaria, pneumonia, meningitis, or gastroenteritis. Overall, case fatality rose progressively with decreasing WAZ score—from 7.2% for a WAZ score > –2 to 22.7% for a WAZ score < –4—and this relationship was seen in all of these disease categories (Figure 18-2). Weight deficits were too great to be accounted for by dehydration or anorexia during an acute illness.

A further study of 1,264 children admitted to a hospital in The Gambia specifically identified wasting as a major risk factor for mortality. Severe wasting (weight-for-height z- [WHZ] score < –3) was present in 13.1% of admissions, with the greatest frequency in 1 year olds, of which 1 in 4 were severely wasted. Case fatality was increased 3.5-fold (95% confidence interval 1.6–7.6) in severely wasted children compared with better nourished children (WHZ score > –2). Severe stunting (height-for-age z-score < –2) was present in 9.7% of admissions but was not associated with mortality (S. Allen, unpublished data, 2000). Case fatality for severe malnutrition remains high and may even reach 60%.[8] These data highlight the fact that wasting is common in children with a primary diagnosis other than severe malnutrition, and this often goes unrecognized. Specific nutritional support in these children may reduce case fatality.

The longer-term outcome after treatment of severe malnutrition is also usually poor. Mortality during follow-up was 2.3% in Bangladesh,[9] 8% in Tanzania,[10] 18% in Niger,[11] 19% in Zaire,[12] 32% in The Gambia,[13] and 36% in Kenya.[14] In survivors, the recurrence of wasting after discharge is variable, but stunting usually persists and morbidity is high. The marked variability in the reported mortality rates may reflect differences in the adequacy of nutritional rehabilitation before discharge, the education of caregivers during admission, and the length and completeness of follow-up. Furthermore, mortality may be reduced in studies in which children were followed up frequently at home for the purposes of recording outcome.

HISTORICAL PERSPECTIVE

The development of instruments to acquire per oral biopsies of the small intestine in the 1950s led to several classic studies of gut structure and function in malnutrition. However, marked differences in patient groups and study designs make comparisons between studies difficult. Most patients were young children (mostly aged 1–3 years), but the classification of malnutrition and the mix of the major types varied between studies. Classifications of nutritional deficiency are generally complicated because they combine anthropometry with clinical signs.[15] Early studies used the term "marasmus" to describe severe wasting but without edema (Figure 18-3). Kwashiorkor was used less consistently; it denoted the presence of nutritional edema in children who were usually underweight and may, or may not, have had the classic clinical signs initially described in Ghanaian children by Williams,[16] such as dermatosis, hair changes, apathy, and irritability (Figure 18-4). Marasmic kwashiorkor was used for children with edema who were severely underweight. Investigations were done in children with varying severity of malnutrition ("mild" kwashiorkor) and at different stages of rehabilitation.

This terminology was summarized in the Wellcome classification.[17] In a later classification, Waterlow emphasized the importance of distinguishing wasting, expressed as low weight for height and signifying acute malnutrition, from

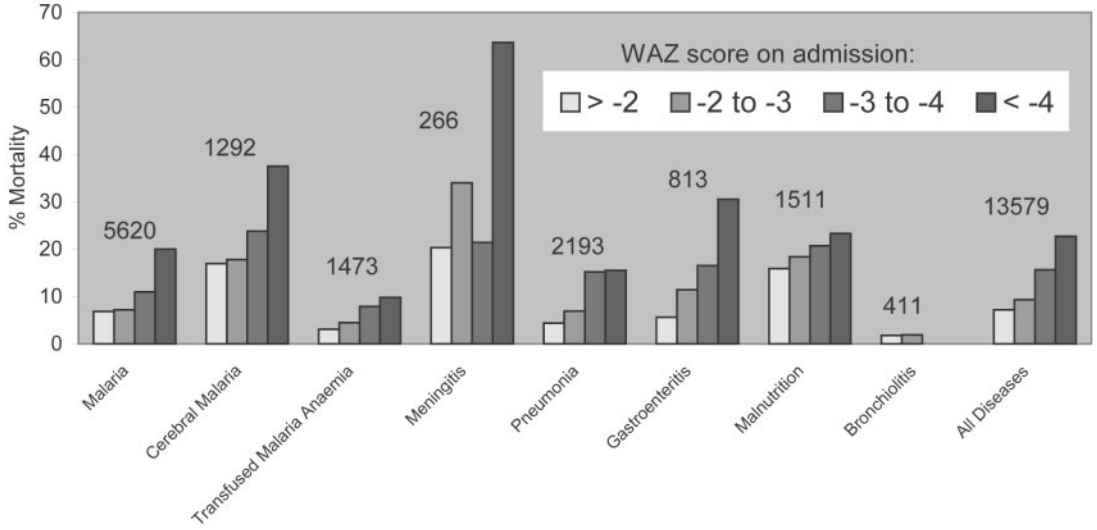

FIGURE 18-2 Low weight-for-age z-score (WAZ) was associated with increased case fatality in children admitted to hospitals in The Gambia. Underweight was common, and this relationship with mortality was seen in several major diseases, as well as in those with a primary diagnosis of malnutrition. The number of children with each diagnosis is shown in the figure. Adapted from Mann WD-C et al,[7] with permission from Blackwell Publishing.

FIGURE 18-3 A severely wasted West African child who presented in 2001 with hypoglycemia, hypothermia, and dehydration.

stunting, a sign of chronic malnutrition and reflected in low height for age.[18] In more recent studies, the term protein-energy malnutrition (PEM) has been used to encompass the interrelated features of deficiency in carbohydrates, proteins, and fat, as well as vitamins, minerals, and trace elements.

In most case series, serum albumin was low or very low, and anemia was common. Micronutrient deficiencies were usually not assessed but will have differed between study populations. Researchers usually determined whether findings in malnourished children were abnormal by comparison with controls, but the choice of control group varied between studies. Some recruited children living in the same environment as the index cases, often hospital controls, who themselves may have had environmental enteropathy and moderate malnutrition. Others chose well-nourished local controls or children from developed countries.

In considering the causes of malnutrition, Bellamy highlights the complex interrelationships among infections, poor nutrient intake, and proximal causes at the household level (Figure 18-5).[19] When searching for causes of gut abnormalities in malnourished children, researchers often try to differentiate the effects of infection, especially diarrhea, from PEM per se. However, this is almost impossible to do. In addition to pneumonia and malaria, either acute or persistent diarrhea is extremely frequent in case series of malnourished children. A wide variety of bacteria and parasites are isolated from stools, but a specific organism is not identified in many children. A further difficulty is that the detection of infections is highly dependent on the methods used, which is particularly important for gut organisms such as *Giardia lamblia*, for which routine diagnostic methods are unreliable.[20] Also, attributing pathology in the gut to specific organisms isolated from stools is complicated because the same organisms are often isolated from healthy controls without diarrhea.

It is clear that effective prevention of malnutrition is likely to require multifaceted approaches that deal with several interconnected socioeconomic, public health, and disease-specific factors. The large mucosal surface area, with a high turnover rate, and the production of large amounts of fluids and enzymes make the gastrointestinal tract particularly susceptible to nutrient deficiency. However, the specific cause(s) of gut abnormalities in malnourished children remain poorly understood. In this review, emphasis is placed on those abnormalities that may be targets for therapeutic interventions either to prevent malnutrition or to improve its outcome.

MALABSORPTION

Prompted by the frequent occurrence of diarrhea and reports of steatorrhea, markedly reduced absorption of various nutrients has been demonstrated in malnourished

FIGURE 18-4 A West African child with marasmic kwashiorkor who presented in 1999.

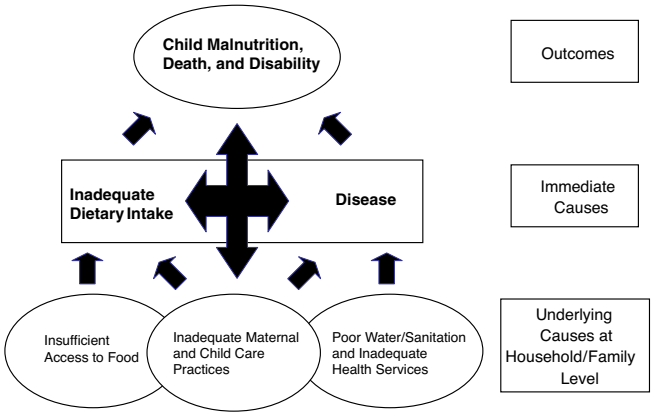

FIGURE 18-5 The vicious cycle of malnutrition, inadequate dietary intake, and disease (mostly infection) is related to underlying causes at the household and family level. Adapted from Bellamy C.[19]

children and the implications for the design of rehabilitation diets have been much debated.

Carbohydrates

Intolerance of lactose is the most consistently reported problem. Stool chromatography in 24 South African children with kwashiorkor and 3 with marasmus revealed lactose in all but 2.[21] A carbohydrate-free diet reduced stool weight and stool lactic acid content markedly in most children, including 8 children with intestinal pathogens in the stools. Reintroduction of milk increased stool output and lactic acid markedly in some children. Carbohydrate tolerance tests in a few children showed impaired lactose absorption. Lactose intolerance was also demonstrated in 14 of 17 Ethiopian boys with kwashiorkor, apparently without diarrhea[22]; 5 of 10 South African children with kwashiorkor tested after 3 weeks of hospital treatment[23]; 8 of 10 malnourished Jamaican infants, 4 of whom had edema but none had severe diarrhea[24]; 39 of 100 malnourished Indian children, of whom 7 had kwashiorkor but none had enteropathogens isolated[25]; and 21 of 43 Brazilian children with a range of nutritional deficiency.[26] Intolerant children often developed acid stools (pH < 4) and abdominal symptoms during challenge tests.[25] Flat lactose tolerance tests were also common in marasmic Brazilian children.[27] Lactose maldigestion also correlated with poor growth in breastfed Gambian infants living in the community.[28]

Malabsorption of other sugars is more varied. Glucose and galactose malabsorption occurred in about half of the Ethiopian[22] and South African children.[23] All of the Indian children[25] malabsorbed glucose, but only 1 of 20 Brazilian children did.[26] Sucrose malabsorption varied from 24 to 60% of cases.[22,24–26] Absorption of all sugars improved with clinical recovery. In the Jamaican series, absorption had increased after 6 to 16 weeks of treatment,[24] and all but 4 of the Indian children had normal sugar absorption after 3 months of nutritional rehabilitation.[25]

In keeping with these observations, variable deficiencies of mucosal disaccharidases have been reported. Half of a series of malnourished South African children had lactase deficiency, especially those with giardiasis, but sucrase and maltase levels were mostly normal.[29] Lactase, maltase, and sucrase activity was low in Ugandan children with mild to moderate kwashiorkor, with lower enzyme activity in those with more severe mucosal atrophy.[30] Disaccharidase deficiency persisted at 1 year after recovery. Lactose intolerance and lactase deficiency persisted in Ugandan children reassessed between 4 and 10 years after recovery from kwashiorkor.[31] However, mucosal histology was similar to that in adult hospital controls, and other disaccharidases were normal. Therefore, whether lactose intolerance was due to long-term mucosal damage or reflected the normal reduction of lactase activity with age in the population was unclear. Lactose-induced diarrhea in children with kwashiorkor did not significantly reduce absorption of nitrogen or fat, allowing continued milk feeding.[21]

Although sugar intolerance may be demonstrated during challenge tests and disaccharidases are shown to be deficient, lower intakes of sugar in milk feeds may be tolerated well without troublesome diarrhea.[23]

Nitrogen

Increased nitrogen losses from the gut are related to both malnutrition and gut infection. Holemans and Lambrechts studied 26 South African children with either kwashiorkor or chronic malnutrition, most of whom had hookworm infection.[32] Although the proportion of nitrogen intake excreted in stools (mean 20%) was higher than in European infants, nearly all children had adequate nitrogen retention of about 50% of dietary intake. A further study confirmed high rates of nitrogen absorption in children with kwashiorkor on milk feeds.[33] In underweight Guatemalan children with edema and a heavy burden of gut pathogens,[34] markedly decreased nitrogen absorption was correlated with the degree of protein depletion as assessed by urinary creatinine-to-height ratio. Nitrogen absorption improved rapidly with clinical recovery. Four Guatemalan children with marasmic kwashiorkor studied during the late stages of recovery absorbed about 80% of ingested nitrogen, and absorption was proportional to intake, although the children remained protein depleted.[35] However, in this study, absorption fell markedly during episodes of diarrhea.

Fat

Variable decreases in dietary fat absorption have been reported, even in children without macroscopic steatorrhea, and absorption improved slowly only during recovery. Average fat absorption was 81.8% in malnourished South African children (compared with 95% in normal children),[32] and malabsorption occurred in between 30 and 100% of malnourished children from Mexico City,[36] India,[25] and Guatemala.[34] The mean increase in plasma triglycerides after an oral margarine load was significantly lower in underweight Brazilian children than in controls.[26] In the late stages of recovery from marasmic kwashiorkor, fat absorption varied from 32 to 89% in Guatemalan children[35] and improved gradually with clinical recovery in a

Mexican series.[36] Fat absorption did not appear to be affected by episodes of diarrhea.[25,35]

Vitamin B_{12}

Initial observations of markedly reduced vitamin B_{12} absorption that was slow to improve with clinical recovery[34] were confirmed in a study of Guatemalan children with severe PEM.[37] At both admission and convalescence, absorption was reduced further in children with diarrhea. Absorption was not improved by giving intrinsic factor, suggesting mucosal dysfunction in the terminal ileum in PEM that is slow to recover, although metabolism of administered vitamin B_{12} by bacteria in the upper gut is an alternative explanation.

THE LIVER IN MALNUTRITION

The fatty infiltration in the liver in kwashiorkor is well known. Autopsies and biopsies of 10 Ugandan children showed a progression of fatty infiltration of hepatocyes beginning at the periphery of lobules and progressing to centrolobular areas.[38] In some cases, fat infiltration was so severe that the liver appeared pale yellow and normal hepatocyes could not be differentiated on microscopy. There was moderate periportal and peripheral pericellular fibrosis and cellular infiltration in the portal areas. The infiltration was mainly of lymphocytes, but eosinophils, macrophages, and neutrophils were also present. With clinical improvement, fat retreated initially from the centrolobular region, but the fibrosis persisted. More irregular patterns of fat infiltration were seen in children with concomitant severe infection,[39] and typical cases of kwashiorkor also occurred without any fatty infiltration of the liver.[38]

Abdominal ultrasonography in Jamaican children showed that hepatic steatosis was greater in children with edematous malnutrition than in those with marasmus, but all malnourished children had more hepatic fat than healthy controls did.[40] The extent of steatosis was not correlated with liver size, and fat was slow to be mobilized from the liver during recovery. Ultrasound examinations in Indian children also confirmed the presence of liver fat in malnourished children without edema.[41] The degree of hepatic steatosis was not associated with the severity of malnutrition or serum transaminases and improved in most cases with weight gain. Compared with biopsies from recovered children, autopsy specimens obtained immediately after death in Jamaican children showed several ultrastructural abnormalities, including decreased peroxisomes, consistent with increased susceptibility to free radical damage.[42]

Impairment of hepatic synthesis in malnourished children is evident by low plasma albumin. Reduced hepatic synthesis may be an important risk factor for mortality; a prolonged prothrombin time was present in 8 of 11 Nigerian children with kwashiorkor who died compared with 4 of 29 survivors.[43] One mechanism may be through decreased production of antibacterial substances such as transferrin and fibronectin, which were reduced in Nigerian children with kwashiorkor and marasmus compared with those in well-nourished local controls.[44] Aflatoxins are found frequently in kwashiorkor, and the known effects of aflatoxins in animal models raise the possibility that they contribute to liver dysfunction in malnutrition.[45]

PANCREAS AND BILE ACIDS

The extremely high rate of protein synthesis by pancreatic acinar cells in the production of digestive enzymes makes them especially susceptible to nutritional deficiency. In keeping with a general atrophy of exocrine glands,[39] children from East and Central Africa who died with kwashiorkor had a small pancreas owing to marked atrophy of the acinar cells, which had a reduced number of enzyme secretory granules. Intercalated ducts, secreting sodium- and bicarbonate-rich fluid, were relatively well preserved, but there was a generalized fibrosis.[38,39,46] Trowell and colleagues considered atrophy of the pancreatic acinar cells to be both a more constant and persistent lesion in kwashiorkor than fatty infiltration of the liver.[39] Pancreatic atrophy was common and associated with a fatty liver in Jamaican children with kwashiorkor but also occurred in marasmic children who had little liver fat.[47] Electron microscopy revealed atrophy of acinar cells with few zymogen granules and disorganization of the endoplasmic reticulum. Pancreatic fibrosis was mild in kwashiorkor and uncommon in marasmus. A further study reported ultrastructural damage of all cell types with changes in B cells, consistent with low insulin secretion.[48] Serum immunoreactive trypsinogen, a marker of either acinar cell damage or ductal obstruction, was correlated with wasting but not stunting in aboriginal children.[49] Pancreatic atrophy appeared to improve quickly with refeeding.[39]

These histologic findings correlate well with studies of pancreatic enzyme production in severely malnourished children. Pancreatic enzymes were low in Hungarian children with nutritional edema after the siege of Budapest (c. 1944).[50] Decreased amylase, trypsin, and lipase were reported in children with severe malnutrition, some with nutritional edema, in Mexico City.[51] In kwashiorkor, amylase and lipase were markedly reduced in Ugandan children,[46] and, in addition to these enzymes, trypsin and chymotrypsin were decreased in Egyptian[52] and South Africa children.[53] Production of enzymes improved promptly and to normal levels with clinical recovery.[46,49,51,53] South African children with marasmus had decreased amylase and chymotrypsin production.[53] In this study, the volume of pancreatic juice and pH in both kwashiorkor and marasmus were variable, but average values were similar to those in better nourished local controls, suggesting less impairment of the function of pancreatic ductules.

Deficiency of conjugated bile acids was the main cause of fat maldigestion, assessed by micellar lipid content of duodenal fluid, in underweight Guatemalan children with edema.[54,55] The concentration of conjugated bile acids in the duodenum was especially low in malnourished children with diarrhea. Free bile acids were increased in both cases and controls. Lipase activity was reduced but sufficient for normal lipolytic activity ($> 75 \times 10^3$ U/mL), and total pancreatic enzyme output was only mildly reduced. Micellar

lipid content and lipase activity normalized with clinical recovery, and conjugated bile acids increased to levels seen in the controls, although they remained low in children with diarrhea. Free bile acids remained high during recovery, especially in children with diarrhea. Some of the cases in this study had increased bacterial colonization of the upper gut, which may have contributed to conjugated bile acid deficiency (see below).[56] Increased free bile acids have also been reported in South African children with kwashiorkor.[57]

It is clear that several factors contribute to malabsorption, and these are likely to vary in different settings. Decreased conjugated bile acids, as a consequence of bacterial colonization of the upper gut, may be more important than deficiency of pancreatic lipase in fat malabsorption in kwashiorkor. Given the marked variability in findings between studies, it is clear that dietary rehabilitation needs to be tailored to individual children, especially those with diarrhea. However, digestion and absorption of carbohydrates, nitrogen, and fat appear to be sufficient for nutritional rehabilitation.[33,36] Milk-based diets are appropriate for most children, and the WHO has produced detailed feeding guidelines.[58] Despite decreased nutrient absorption, it is important to note that diets low in protein, fat, and sodium and high in carbohydrates are recommended during initial treatment. Dietary intake is increased during the rehabilitation phase of management, a time when absorption of many nutrients is improving.

STOMACH

Gastric histology in five South African children with kwashiorkor showed variable degrees of abnormality, including mucosal atrophy, reduced goblet cells, and increased inflammatory infiltrate in the lamina propria composed of lymphocytes, polymorphonuclear leukocytes, eosinophils, and plasma cells.[59] Abnormalities were still present 1 year later in one child after clinical recovery. Biopsies of the gastric fundus in 14 Indonesian children with a range of nutritional deficiency showed variable degrees of atrophy and chronic gastritis compared with the biopsies of healthy controls living in metropolitan Jakarta.[60]

Basal acid output was low in malnourished South African[59] and Indonesian children,[60] and 26 of 34 (76%) Bangladeshi children, mostly with marasmic kwashiorkor, had baseline hypochlorhydria.[61] Hypochlorhydria persisted despite stimulation with histamine in 4 of 20 (20%) of the South African children[59] and despite betazole stimulation in 8 (24%) of the Bangladeshi children.[61] Both basal and stimulated acid concentration had not improved at follow-up despite a marked increase in nutritional status and increased gastric juice volume.[61] In the South African cases, acid output increased only when clinical recovery from kwashiorkor and anemia was complete.[59] In some studies, hypochlorhydria was also common in children recruited as controls.[60,61] Similarly, an intubation study of Gambian infants living in rural villages reported that 4 of 29 (14%) had hypochlorhydria (gastric pH > 4).[62]

Impairment of the gastric acid barrier appears to be a common finding in children living in poverty, not only those with frank malnutrition. Clearly, it is now known that *Helicobacter pylori* infection is extremely common in young children in developing countries.[63] In a large cohort of Gambian infants, colonization determined by the urea breath test was present in 19% at age 3 months and in 84% by 30 months.[64] Also in Gambian studies, acquisition of *H. pylori* was associated with hypochlorhydria, assessed noninvasively by urine acid output following a test feed.[65] *H. pylori* may play an important role in compromising the gastric acid barrier and allowing bacterial contamination of the intestine.

SMALL INTESTINE

HISTOLOGY

Compared with findings in developed countries, studies of kwashiorkor in Uganda,[30,39,66] Kenya,[67] South Africa,[30,68,69] and Guatemala[70] reported enteropathy in all cases with a wide range of abnormalities. Typically, the intestinal wall is thin, with a smooth, atrophic mucous membrane ("tissue paper intestine").[39] Villi tend to be convoluted and ridged rather than fingerlike. Villous atrophy reduces mucosal thickness (mean crypt-to-villus ratio 1.0; normal 0.2),[30] and there may be complete villous atrophy. The brush border is irregular, and narrow and mucosal cells may be irregular or cuboidal, with irregular and displaced nuclei. Intraepithelial lymphocytes are increased. There is frequent branching of crypts. The cellular infiltrate in the lamina propria is markedly increased and consists of lymphocytes, plasma cells, eosinophils, and polymorphonuclear leukocytes.

In South African children already established on a high-protein diet, accumulation of lipid droplets within epithelial cells was prominent.[68] Electron microscopy showed variable distribution of fat—as particles enclosed by smooth endoplasmic reticulum and Golgi vesicles and as chylomicrons in intercellular spaces or in vesicles within lamina propria macrophages. Mitochondria, endoplasmic reticulum, and lysosomes appeared normal. However, in another series of South African children who were studied before starting treatment, abnormalities of epithelial cells included poorly developed microvilli, sparse endoplasmic reticulum, irregular nuclei, and disorganized cytoplasmic organelles but no accumulation of lipid.[69] Crypt cells were immature with increased mitosis, suggesting a rapid turnover. These abnormalities were consistent with impaired absorptive function. Plasma cells in the lamina propria appeared inactive. The discrepancies in findings between the two studies may have been due to biopsies being taken at different stages of management.

In children with marasmus, abnormalities of mucosal architecture similar to those in kwashiorkor are seen, again with a wide range of severity. Brunser and colleagues reported near-normal mucosal architecture except for a thinner mucosa and, at variance with kwashiorkor, reduced mitotic counts.[71] In contrast, Algerian children had thin mucosae with shortened or absent villi indistinguishable from celiac disease.[72] Studies of moderately to severely underweight Brazilian children, some with persistent diar-

rhea, reported variable shortening of villi from near-normal to subtotal villous atrophy, but all patients had increased inflammatory cell infiltrate.[26,27] Features on electron microscopy were also variable but included shortened, branched, or absent microvilli; increased intraepithelial lysosomes; irregular nuclei; and degenerative, detaching epithelial cells from the upper half of the villi—the latter associated with giardiasis.[27,73] Other epithelial cells had only minor abnormalities. Lamina propria plasma cells appeared inactive in about half of the patients. Barbezat and colleagues reported that mucosal atrophy in 3 South African children with marasmus was of a severity similar to that in 13 children with kwashiorkor and 1 with marasmic kwashiorkor,[29] whereas other authors consider mucosal lesions to be milder in marasmus than in kwashiorkor.[34,71]

Sullivan and colleagues performed detailed computerized image analysis of mucosal biopsies from 40 malnourished Gambian children with chronic diarrhea, mostly with marasmus and marasmic kwashiorkor.[74] Many had gut infections, especially with *G. lamblia*. Villi varied from normal height to absent, but nearly all biopsies revealed crypt hypertrophy and lymphocytic infiltration of the lamina propria. Intraepithelial lymphocytes were increased, especially in the crypt epithelium. The marked range of abnormalities detected is summarized in Figure 18-6A, and a typical mucosal specimen showing well-preserved villi is shown in Figure 18-6B and an atrophic mucosa in Figure 18-6C. The degree of mucosal abnormality did not correlate with nutritional status or the presence of *G. lamblia* or *Strongyloides stercoralis*, but it was difficult to distinguish the effects on the mucosa of PEM from those of diarrhea.

In kwashiorkor, improved mucosal cell ultrastructure occurring after only 48 hours of intensive supportive treatment is consistent with a rapid increase in cell protein synthesis.[69] However, repeat biopsies following clinical recovery of kwashiorkor tend to show no or minimal improvement in mucosal appearances, even up to 1 year later.[30] Schneider and Viteri reported a progressive increase in mucosal and brush border thickness and epithelial cell height as nutritional recovery progressed, but crypt mitotic activity and the degree and composition of the cellular infiltrate in the lamina propria remained unchanged.[70]

Similarly, a common finding in studies of marasmus is the persistence of the mucosal lesion. The atrophic mucosa reported in the Algerian children persisted mostly unchanged when biopsies were repeated at 3 months despite marked clinical improvement.[72] After 3 to 4 weeks of inpatient treatment, there was little change in villous volume in the majority (16; 70%) of Gambian children in whom diarrhea had resolved, weight gain was good, and mean crypt cell volume had increased.[75] Villous epithelial volume had actually decreased in three children, two of whom had failed to improve clinically. Further follow-up at 1 year after discharge in a small number of children revealed that most had diarrhea and mucosal architecture was worse than at admission. In the much longer term, between 4 and 10 years after kwashiorkor, complete recovery of the brush border and reduction in inflammatory infiltrate, at least to that seen in local controls, were observed.[31]

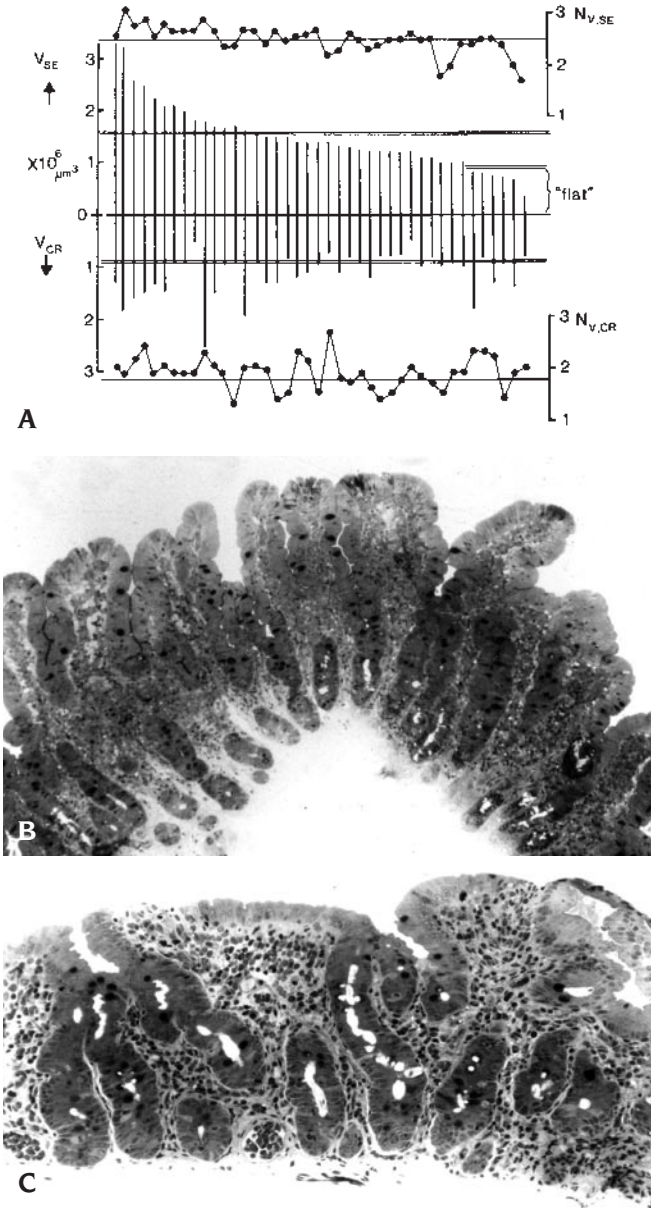

FIGURE 18-6 *A*, A marked range of enteropathy was observed in malnourished Gambian children. Mucosal morphometry for 40 Gambian children with persistent diarrhea and malnutrition displayed in descending order of villous (surface) epithelial volumes (V_{SE}), together with their corresponding crypt epithelial volumes (V_{CR}, left axis). *Horizontal lines* represent lower reference range for control villi and upper reference ranges for flat (celiac sprue) mucosae and control crypts. N_{VSE} refers to the numbers (log transformed) of intraepithelial lymphocytes in surface epithelium (upper) and N_{VCR} crypt epithelium (lower, right axis), and *horizontal lines* represent upper reference ranges. The final specimen in the series is from a child with kwashiorkor. Adapted from Sullivan PB et al[74] and reproduced with permission from Lippincott Williams & Wilkins. *B*, Mucosal biopsy from a child with marasmus. The villi are well preserved, but there is crypt hyperplasia and an increased inflammatory infiltrate. Dark areas at the tips of villi are fat globules. Specimen fixed in formaldehyde and stained with toluidine blue; ×100 original magnification. Reproduced with permission from Dr. P. B. Sullivan. *C*, Atrophic mucosa with intense inflammatory infiltrate and loss of surface epithelial cells in a child with marasmic kwashiorkor. Specimen fixed in formaldehyde and stained with toluidine blue; ×100 original magnification. Reproduced with permission from Dr. P. B. Sullivan.

Given the long-term persistence of mucosal abnormalities following marasmus, it is not surprising that significant enteropathy also occurs in mildly to moderately malnourished children living in the community. Histologic evidence of environmental enteropathy was found in infants with mostly mild to moderate malnutrition living in a Brazilian slum when compared with eight hospital controls from middle-class families.[76] Twenty-nine (73%) of the slum-dwellers had varying degrees of villous atrophy and increased inflammatory infiltrate in the lamina propria, with severe lesions in some children. Mucosal biopsies from stillborn fetuses in Southern India[77] and African neonates[30] had normal appearances with fingerlike villi. Therefore, environmental enteropathy appears to be an acquired lesion, the timing of its onset coinciding with weaning and possibly bacterial colonization of the upper gut (see below).

Immunohistochemistry

A recent study of Gambian children with nutritional status ranging from normal to severely underweight used immunohistochemical techniques to characterize the mucosal inflammatory response.[78] Although most children had diarrhea, stool pathogens were infrequent. However, giardiasis may have been underestimated based on stool microscopy alone. All children were HIV antibody negative. Age-matched children living in the United Kingdom investigated for vomiting or possible enteropathy but shown to have no gastroenterologic disorder were used as controls.

All of the Gambian children, regardless of nutritional status, had increased mucosal permeability, crypt hyperplastic villous atrophy, and increased intraepithelial lymphocytes—the latter with an increased proportion of γδ cells and within the range characteristic of celiac disease (Figure

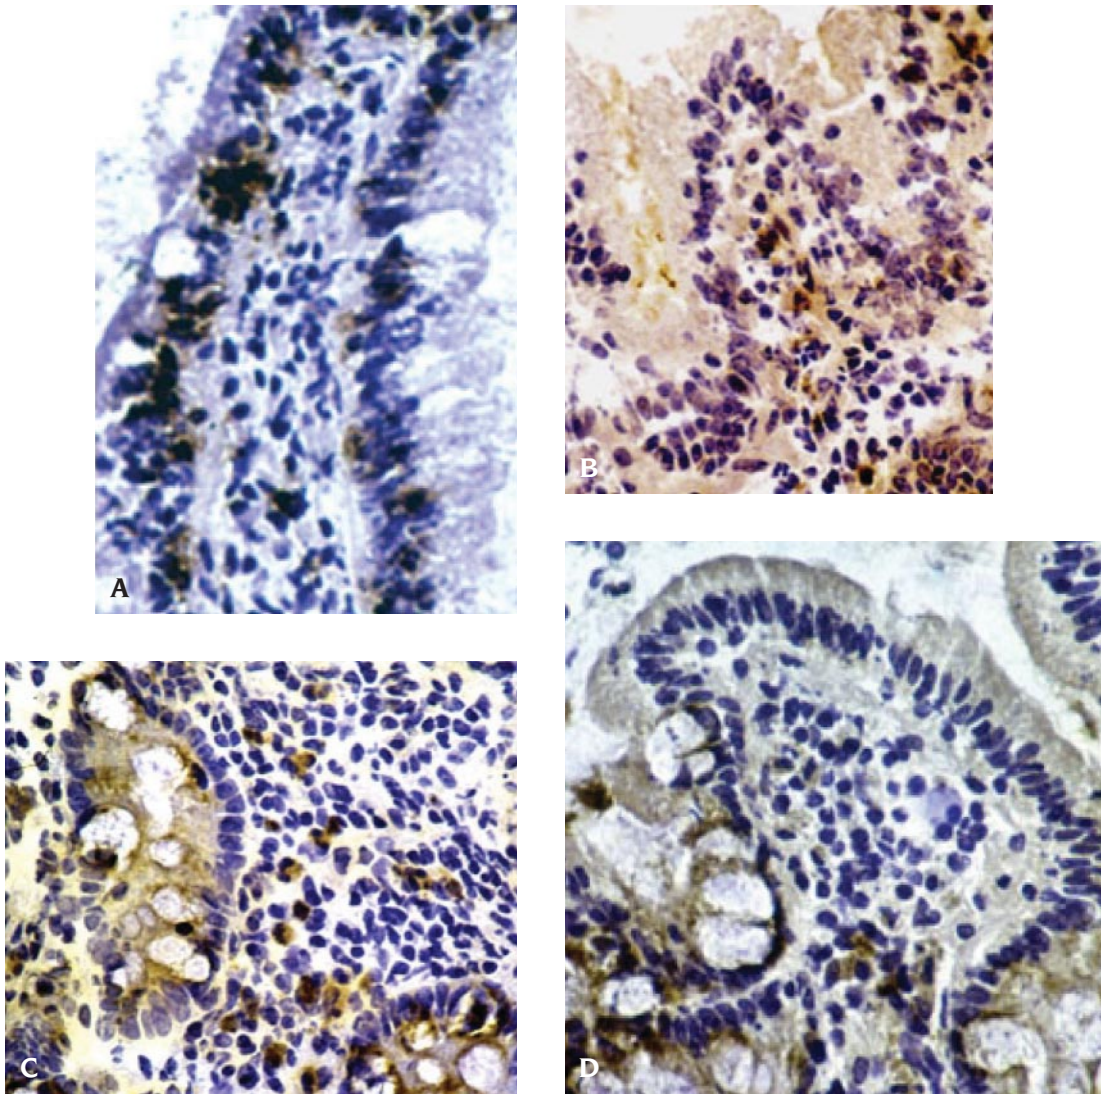

FIGURE 18-7 Immunohistochemistry of mucosal specimens from Gambian children.[78] Reproduced with permission from Lippincott Williams & Wilkins. *A*, High density of γδ intraepithelial lymphocytes despite normal villous architecture in a marasmic child. *B*, Tumor necrosis factor-α immunoreactive cells within the lamina propria in a marasmic child. *C*, Transforming growth factor (TGF)-β+ cells in the lamina propria of a child with failure to thrive but not marasmus. TGF-β expression is also seen in the epithelium. *D*, Contrasting reduction of mucosal and epithelial TGF-β+ cell density in a marasmic child.

18-7A). There was no correlation between permeability, morphometric indices of small bowel architecture, or number of intraepithelial lymphocytes and nutritional status.

Although a wide variation was observed, compared with the UK controls, the median density of cells in the lamina propria in the Gambian children was 4 to 5 times higher for CD3+ and 15 to 30 times higher for CD25+ cells. Activation of the epithelium was evidenced by increased expression of perforin by cytotoxic lymphocytes and human leukocyte antigen (HLA)-DR by crypt cells. The numbers of B cells were increased two- to threefold compared with the UK controls, with an even greater increase in mature B cells. The density of mucosal cytokine-immunoreactive cells was greater in Gambian than in UK children for both proinflammatory (interferon [IFN]-γ and tumor necrosis factor-α) (Figure 18-7B) and putative regulatory (interleukin-10, transforming growth factor [TGF]-β) cytokines (Figure 18-7C). However, the density of TGF-β–producing cells fell as nutritional status worsened, whereas that of proinflammatory cytokine-producing cells remained unchanged (Figure 18-7D). These findings suggest a chronic cell-mediated enteropathy, similar to that in celiac disease, that did not appear to be caused by specific gut pathogens.

The presence of an enteropathy in Gambian children of different nutritional states, with a shift toward greater proinflammatory responses in the most malnourished, suggests that the enteropathy of severe malnutrition may be a continuum of that seen in "tropical" or "environmental" enteropathy.

These findings in Gambian children are broadly similar to the findings of a study of Zambian and black and white South African adults investigated for dyspepsia but without other systemic or gastrointestinal illness.[79] Living conditions for the Zambians were considered to be worse than those for the South Africans. Mean body mass index and serum albumin was significantly lower in the Zambians than in the South Africans, but none were overtly malnourished. In mucosal biopsies, compared with the South Africans, the Zambians had significantly decreased villous height, increased crypt depth, and increased crypt mitotic count. Increased mucosal T-cell activation in the Zambians was evidenced by increased numbers of cells expressing CD69 and HLA-DR.

Intestinal Permeability: Severe Malnutrition

Markedly reduced absorption of D-xylose, consistent with reduced mucosal surface area, was observed in malnourished South African,[80] Indian,[25] Ethiopian,[22] Guatemalan,[34] and Brazilian[26] children. Absorption improved with clinical recovery.

Differential absorption of different-sized sugar molecules to assess simultaneously mucosal surface area and leakiness has been used extensively in studies of malnourished children in both community and hospital settings. Several studies of Gambian children have shown that decreased surface area and increased leakiness are associated with worsening nutritional status. Behrens and colleagues reported a mean (± 2 SD) urinary lactulose-to-mannitol (L:M) ratio of 1.3 (0.2–13) in repeated tests done in children with marasmus compared with 0.42 (0.2–1.4) in well children living in an urban environment.[81] L:M ratios were even higher in 15 children with chronic diarrhea (2.85 [0.2–10.4]). Ratios improved with weight gain and recovery from diarrhea. In the malnourished children with persistent diarrhea reported by Sullivan and colleagues, the mean (± SD) L:M ratio on admission was 0.66 (± 0.36).[82] Mannitol absorption improved slowly but progressively during treatment, suggesting some increase in mucosal surface area, but a marked increased recovery of lactulose after treatment for 3 to 4 weeks suggested persistence of abnormal mucosal leakiness.

Brewster and colleagues studied 149 Malawian children with kwashiorkor on admission and during inpatient rehabilitation, of whom one-third were likely to have had HIV infection.[83] Lactulose-to-rhamnose ratios were much higher on admission (geometric mean 0.17 [95% CI 0.15–0.20]) than those in hospital controls (0.07 [0.06–0.09]) because of decreased rhamnose absorption in the cases. Abnormal permeability was associated with oliguria, sepsis, diarrhea, wasting, young age, and death during admission. In logistic regression analysis, diarrhea and death were associated independently with both decreased absorption and increased leakiness, whereas wasting was associated with decreased absorption only. The association between increased permeability and death suggested that sepsis may have been caused by translocated bacteria from the gut. In survivors, permeability improved little despite clinical recovery and, 3 to 4 weeks later, remained higher than that of local controls, suggesting impaired intestinal cell renewal after enteric infection and malnutrition.

Permeability of the mucosa to nondegraded proteins, assessed by permeability of jejunal explants to horseradish peroxidase in Algerian children with marasmus, marasmic kwashiorkor, and kwashiorkor, was markedly increased on admission.[72] Permeability was lower during clinical recovery but remained abnormal. This finding is consistent with the increased serum antibodies to several food proteins in malnutrition, but whether immune responses to food antigens are involved in the pathogenesis of enteropathy remains unclear.[84]

Intestinal Permeability: Community Studies

In keeping with histologic evidence of enteropathy, noninvasive tests of mucosal permeability are frequently abnormal in children living in the community. D-Xylose absorption was markedly decreased in infants living in a Brazilian slum, most of whom were moderately underweight.[76] Lunn reported that the mean (SD) L:M ratio in infants living in Gambian villages was 0.38 (0.30) compared with 0.12 (0.09) in matched UK control infants.[85] Tests were repeated frequently during the first year of life in 119 infants and correlated with growth. By UK standards, L:M ratios in the Gambian infants were abnormal in 76% of tests. In regression analysis, abnormal L:M ratios accounted for about 40% of growth faltering for both weight and length gains.

A recent study of gut permeability in older children and adults in The Gambia showed that mannitol recovery was always at least half of expected UK values and did not improve with age.[86] However, lactulose recovery improved progressively to fall into the UK range from the age of 10 years. L:M ratios showed within-subject correlation over time, suggesting long-term persistence of enteropathy within individuals. A significant correlation between both L:M ratio and lactulose recovery and height for age z-score was present during both childhood and adult life, suggesting that enteropathy may adversely affect growth both in childhood and during puberty.

LARGE INTESTINE

Sigmoidoscopy in South African children with kwashiorkor showed increased vascularity of the rectal mucosa.[87] On microscopy, there was mild atrophy of epithelial cells, which had a flattened surface and displaced nuclei. Goblet cells were numerous in crypts but reduced on the luminal surface. Polymorphonuclear leukocytes were noticeable in the surface epithelium, and the number of plasma cells increased throughout the lamina propria. The numbers of lymphocytes and macrophages appeared normal. Mucosal histology returned to normal in most cases after 3 to 4 weeks of treatment, although the plasma cell infiltration persisted. In a study of 16 moderately to severely underweight Brazilian infants, colitis was present in 10, and, of these, only 6 had an enteropathogen isolated from the stools.[73] As with inflammation in the small bowel, colitis appears to be a feature of PEM even in the absence of gut infection and is likely to contribute to diarrhea.

GASTROINTESTINAL FLORA

Increased numbers of a wide variety of bacteria in gastric juice have been reported in malnourished Indonesian,[88] Brazilian,[89] and Bangladeshi children.[61] Large numbers of bacteria were found in 13 children with marasmic kwashiorkor living in poor areas of Guatemala City, but 3 of 4 normal controls also had high numbers of streptococci in gastric juice.[56] Bacterial overgrowth was associated with increased gastric pH in underweight Brazilian children with chronic diarrhea (57% had pH > 4), but, interestingly, hypochlorhydria was equally common in better nourished breastfed controls who did not have increased gastric microbial contamination.[89] Similarly, gram-negative bacterial colonization of gastric juice (> 100 colony-forming units/mL) was associated with reduced gastric acid output and increased pH in the Bangladeshi series, but colonization was not observed in any of 20 controls despite hypochlorhydria in many. [61] This suggests that other factors, in addition to gastric pH, determine susceptibility to bacterial colonization of the stomach. In malnourished children, the numbers of microorganisms fell with clinical recovery.[56,89]

In addition to bacterial contamination, large numbers of *Candida* sp (up to 10^9/mL) in gastric juice were found in malnourished Australian aboriginal and Indonesian children[90] and in malnourished Guatemalan children with diarrhea.[56] Whether yeasts contribute to the gut changes in malnutrition remains unclear.

Increased bacterial colonization of the small bowel has been reported frequently in malnourished children, and, as in gastric juice, a wide variety of organisms have been isolated. However, several authors have noted that similar bacterial colonization also occurs in children living in the same environment as malnourished children. In a series of hospitalized, underweight Brazilian children,[73] 11 of 16 had > 10^4 bacterial colonies/mL in jejunal aspirates, including enteropathogenic strains of *Escherichia coli*, *Proteus*, *Enterobacter*, *Pseudomonas*, and *Klebsiella*. Bacterial colonization was associated with a mucus-fibrinoid pseudomembrane over the luminal surface but not with other mucosal abnormalities. In the later study of mostly moderately underweight infants living in a Brazilian slum, colonization of jejunal juice with colonic flora varied from 10^2 to 10^9 colonies/mL, with 5 of 40 children having > 10^4/mL.[76] In the Guatemalan series,[56] apart from greater numbers of *Enterobacteriaceae* in the cases, bacterial colonization of the small bowel was similar in cases and controls. Between 10^3 and 10^7 bacteria/mL, mainly streptococci, were present in three of four controls. In Gambian children with a range of nutritional deficiency, 22 of 25 had > 10^5/mL facultative anaerobes in jejunal juice, with some children having counts > 10^{10}/mL.[91] Most children were colonized with three to four types of organisms, mainly *E. coli,* bacteroides, and enterococci, and counts were higher in those with chronic diarrhea. Although no controls were tested in this study of hospitalized children, the findings can be compared with those of a later study carried out in 37 young Gambian children living in rural villages.[62] About half of these infants had > 10^5 organisms/mL in jejunal juice.

Omoike and Abiodun, working in Benin City, Nigeria, reported mean bacterial counts ranging between 10^3 and 10^9/mL among 30 malnourished children.[92] A wide range of organisms was identified, including *Enterobacteriaceae*, *Bacteroides*, and *Candida*. In contrast to the previous studies, bacterial counts were significantly lower in 11 well-nourished hospital controls, in 2 of whom duodenal juice was sterile, who lived in the same socioeconomic environment. In underweight Australian aboriginal children with chronic diarrhea, mean small intestinal bacterial counts were 5×10^6/mL in those receiving antibiotics and 2×10^6/mL in those not receiving antibiotics compared with 2×10^3/mL in Caucasian controls.[93] Bacteria were of the oral and fecal type, but anaerobes were rarely isolated. In the Indonesian series, the mean microbial count was 7.8×10^7/mL, consisting mainly of gram-positive cocci, enterobacteria, and streptococci, with gram-negative organisms also identified in many children.[88] In the series of Australian and Indonesian children, there was marked contamination of intestinal aspirates with *Candida* species (10^4 to 10^8/mL) compared with Caucasian controls.[90] In the studies in Australia and Indonesia, less microbial contamination of the gut in the controls may have been explained by better living conditions in this group.

Applying the new molecular methods[94] to complement the findings of existing studies and better define the intestinal microflora in both malnourished and healthy children in developing countries is a priority. The marked increased bacterial contamination of the upper gut in malnourished children is likely to contribute to malabsorption, for example, through the deconjugation of bile salts. In addition, loss of immune tolerance to intestinal bacteria is implicated in the pathogenesis of the T cell–mediated enteropathy of inflammatory bowel disease.[95] More research is needed on the role of bacterial contamination of the gut in causing environmental enteropathy and the enteropathy in severely malnourished children.

MICRONUTRIENT DEFICIENCY

The role of two key micronutrients, vitamin A and zinc, in childhood malnutrition, morbidity, and mortality has been reviewed.[96,97] Both are an essential part of the nutritional rehabilitation of severely malnourished children.[58]

Vitamin A

Although there is good evidence that vitamin A supplementation reduces child mortality in some situations, its effect on specific infections, including diarrhea, is less clear.[96,98] Based on vitamin A's role in maintaining mucosal integrity and an observation in Gambian infants that mucosal integrity is least impaired at times of the year when dietary vitamin A is abundant,[99] randomized intervention studies were done in 144 hospitalized and 80 rural infants in India.[100] Infants living in the community had significantly lower L:M ratios after vitamin A supplementation (16,700 IU weekly for 8 weeks) than those receiving placebo, although the differences were small. Infants hospitalized with diarrhea or respiratory infections received 200,000 IU of vitamin A, either at admission or discharge, or placebo. The mean L:M ratio fell in all groups but was significantly lower at 10 and 30 days following discharge in the treated groups. Data on the absorption of the individual sugars were not reported.

Vitamin A supplementation during pregnancy and at delivery of HIV-positive South African mothers did not affect L:M ratios in non–HIV-infected infants.[101] However, among infants who themselves acquired HIV infection, those of supplemented mothers maintained significantly lower L:M ratios over the first 14 weeks of life compared with those of unsupplemented mothers. This effect was due to increased absorption of lactulose in the infants of the control mothers, whereas mannitol absorption in the two groups was similar. The authors concluded that the effect of vitamin A in reducing mucosal permeability may help to counter growth faltering in HIV-infected infants.

Zinc

Like vitamin A, zinc is considered essential for normal immune function and protection against infections.[102] Zinc supplementation prevents episodes of diarrhea and reduces the duration and severity of acute and persistent diarrhea, with some evidence of a greater beneficial effect in malnourished children.[97,103]

Roy and colleagues studied the effects of zinc supplementation (5 mg/kg/d elemental zinc for 2 weeks) on intestinal integrity in Bangladeshi children with acute and persistent diarrhea.[104] Many children had low serum vitamin A, and all received vitamin A supplements. Although mannitol absorption remained unchanged, supplementation reduced lactulose absorption in both conditions. The effects were greatest in the most undernourished children and those with hypozincemia at recruitment.

In a randomized community study of 110 Gambian children aged 0.5 to 2.3 years, zinc supplementation (70 mg twice weekly for 1.25 years) resulted in a small increase in mid–upper arm circumference but no difference in weight gain.[105] Although the mean L:M ratios were not affected by the supplement, lactulose absorption was significantly decreased in the supplemented group.

Supplementation with both vitamin A and zinc appears to have beneficial effects on the integrity of the intestinal mucosa in children. However, further studies are needed to determine the clinical importance of these effects.

CONCLUSIONS

Malnutrition remains a public health problem of enormous importance. In economically poor countries, growth faltering is the norm, and underweight is the leading risk factor for morbidity and mortality. Severe malnutrition is common in children admitted to hospital, and many of these children have severe abnormalities of the gastrointestinal system, including a severe enteropathy. Despite detailed WHO management guidelines, case fatality often remains high, and translocation of bacteria from the gut through a leaky mucosa may contribute to deaths from sepsis. The persistence of the enteropathy in many of the survivors is likely to contribute significantly to their poor longer-term outcome. However, the greatest impact on child survival will be achieved by targeting mild to moderate malnutrition in children living in the community. Both histologic studies of intestinal mucosa and the measurement of mucosal permeability reveal that significant enteropathy, sufficient to impair growth, is common in apparently normal children living in the community. This environmental enteropathy may be a continuum of that seen in severely malnourished children.

Specific interventions to prevent or ameliorate enteropathy in children living in the community and to heal the gut in malnourished children are an urgent priority. Initial research suggesting that the enteropathy in Gambian children with a range of nutritional status is mediated by T cells needs to be confirmed in other locations.[78] However, this exciting finding may present new opportunities for specific interventions. In keeping with approaches to other T cell–mediated enteropathies, interventions to prevent or modify the gut bacterial overgrowth that is common in children in developing countries should be explored.

Interventions to prevent growth faltering in "normal" children living in the community will have the greatest impact on child survival. A group of leading international

experts met in Washington, DC, in 1971 under the auspices of the Committee on International Nutrition Programs and addressed a specific question: "Are there now sufficient data to justify efforts to ameliorate or prevent subclinical malabsorption as one approach to the global problem of malnutrition?"[106] We now know more about the global burden of malnutrition but are only beginning to understand the cause(s) of environmental enteropathy. The tantalizing question as to whether specific interventions to prevent or improve gut function in children living in poor circumstances in economically poor countries would improve growth and decrease morbidity and mortality remains unanswered.

ACKNOWLEDGMENT

Many thanks to Dr. Peter Sullivan for reviewing the manuscript.

CHAPTER 19

OBESITY

Alison G. Hoppin, MD

At the beginning of the twenty-first century, poverty and undernutrition have worsened in some countries, whereas overnutrition and obesity have reached epidemic levels in many others.[1,2] Currently, the increasing trend in obesity makes it the most important nutritional problem globally, and the associated medical problems account for substantial morbidity, mortality, and health care costs. The notion of "nutrition transition" has been developed to describe the unique changes in diet and energy balance that accompany patterns of economic and technological development.[3,4] Understanding the mechanisms causing obesity and associated medical problems in developed countries is essential to reverse the worldwide trend.

DEFINITION

Any definition of obesity is useful only if it predicts medical disability or complications. Because most medical complications of obesity are associated with body fat and not muscle mass, measures of obesity represent an attempt to estimate the adipose compartment. At present, there is no precise clinically practical method to measure body fat, so most methods rely on measurements of body weight as a surrogate for adiposity. Such methods are imperfect because they may misclassify a patient with an unusual proportion of fat to lean body mass, but they are inexpensive and practical for use in the clinical setting and in epidemiologic studies.

Traditionally in the United States, obesity has been defined as weight for height above the 90th percentile on the National Center for Health Statistics (NCHS) growth charts or excess weight above 120% of the median for weight given the child's age, height, and gender. More recently, the body mass index (BMI), defined as the weight of the child in kilograms divided by the height in meters squared (kg/m^2), has been established as a useful standard measure of adiposity. Although BMI does not directly measure body fat, it is typically used to evaluate adiposity in adults and has been recognized as a useful predictor of adiposity in children and adolescents, which, in turn, also predicts risks for present or future medical complications of obesity.[5] BMI in children is correlated not only with other predictors of body fat but also with blood pressure,[6,7] lipid levels,[8,9] and insulin levels.[10]

Like height and weight, BMI is not constant during childhood and adolescence, and it differs by gender. BMI growth charts are a useful way to track an individual against established standards for clinical purposes. BMI also depends on pubertal stage, reflecting disproportionate gains in fat-free compared with fat mass.[11] In addition, there is some evidence that BMI varies with ethnicity.[12] Therefore, research studies involving BMI in children should consider not only age and gender but also pubertal stage and ethnicity.

In 2000, the Centers for Disease Control and Prevention (CDC) established new growth charts using data from the NCHS in collaboration with the National Center for Chronic Disease Prevention and Health Promotion.[13] These growth charts do not include data from the past decade because of the sharp rise in BMI during that period. Recognizing that the BMI of children and adolescents tends to predict obesity and related complications in adulthood, the CDC has also suggested specific nomenclature for the pediatric age group: subjects above the 85th percentile are considered "at risk for overweight" and those above the 95th percentile are considered "overweight."[5] Use of the term "overweight" rather than "obese" reflects the fact that the weight status of the adolescent may still improve before he or she reaches adulthood; thus, the overweight adolescent may not face the medical risks conferred by the term "obesity" in adulthood.

Most industrialized countries and countries in economic transition are experiencing a trend toward increasing obesity but at different rates, so creating definitions appropriate for international use is challenging but important. Using data from six large data sets in various countries, an International Obesity Task Force (IOTF) agreed on standard cutoff points to identify degrees of overweight among children and adolescents in both developed and developing countries.[14] Like the CDC charts, these data provide age- and gender-specific cutoff points for children aged 2 to 18 years. The 85th percentile on the IOTF standard charts, which defines children and adolescents "at risk for overweight," also corresponds to a BMI of 25 kg/m^2 by age 18, the adult definition of overweight. The 95th percentile on the standard chart, defining children and adolescents as overweight, corresponds to about 30 kg/m^2 by age 18 years, the standard adult definition of obesity.

EPIDEMIOLOGY

Relevance and Significance

Presently, 1 in 5 children in the United States is at risk for overweight, and 14% of children and adolescents in the United States are overweight (above the 85th and 95th percentiles for age and gender, respectively, based on the new CDC standards). Since the 1960s, the prevalence of obesity in children and adolescents has tripled.[15] Similar but more gradual trends are seen worldwide. Determining the specific causes of this rapid increase in rates of obesity is clearly essential, yet remarkably complex. Both genetic and environmental factors have been shown to contribute significantly to this problem. In general, genetic factors explain a large part of the variation of body weight within a given population in a common environment, whereas environmental factors tend to explain changes in obesity over time in that population. The study of Pima Indians provides an important example of the interaction between environmental and genetic factors.[16] The Pima Indians who live in the southwestern United States are predisposed to obesity and diabetes, and these traits assort in patterns indicating genetic inheritance. The genetically similar Pima living as subsistence farmers in Mexico are substantially less obese. Genetic factors clearly explain a large part of the obesity among Pima Indians in this country, whereas environmental factors explain the dramatic difference in rates of obesity between the two Pima populations.

Epidemiologists have used cohort studies and case-control designs to determine which environmental factors may contribute to obesity. Such studies have pointed to dietary trends, sedentary lifestyle, decreases in structured physical activity, psychosocial stressors, and cultural trends as likely contributors to the obesity epidemic.[3] A number of dietary factors have been proposed to play important roles. These include the easy availability, high caloric content, and strong marketing techniques of the fast-food industry; general trends toward consumption of foods that are highly processed and contain high carbohydrates and/or total calories (including sugary beverages); and decreased consumption of fiber and low-density foods. Other factors include decreases in structured physical activity, particularly for children, and decreasing lifestyle activity (occupations and transportation require less movement than in the past) and increasing sedentary activities (particularly television viewing and computer use). However, it is important to note that, to date, no single factor among these has been shown to play a pivotal role in the increasing prevalence of obesity.

Obesity and Related Complications

A large body of evidence supports an association between obesity and important risk factors for cardiac disease and type 2 diabetes. Hyperinsulinemia, dyslipidemia, obesity, and hypertension often cluster together and are termed the "metabolic syndrome," "syndrome X," or "insulin resistance syndrome."[17,18] More recently, these findings have also been shown to be closely associated with nonalcoholic fatty liver disease (NAFLD), such that fatty infiltration of the liver is now often considered part of the metabolic syndrome.[19]

The mechanisms underlying the association between these endocrine abnormalities and disease affecting diverse organ systems are the subject of ongoing research. There is support for the concept that an increased ratio of visceral to subcutaneous adipose tissue, perhaps acting through adipocyte-derived hormones such as resistin and leptin and through substrates such as circulating fats, leads to insulin resistance and high circulating levels of insulin.[20,21] Many adults with obesity display all of the elements of the metabolic syndrome, but there are some striking exceptions even among those with severe obesity. For example, a multicenter study using clamp techniques in a group of obese adults showed that 26% of participants aged 18 to 85 years with a BMI > 25 kg/m^2 and 60% of those with a BMI > 35 kg/m^2 were insulin resistant. The frequency of hyperinsulinemia was 41% in participants with a BMI > 25 kg/m^2 and 77% in participants with a BMI > 35 kg/m^2.[22]

Similar clustering patterns have been found in children. Studies in children have shown a relationship among fasting insulin and lipids,[23,24] blood pressure,[25–28] weight,[29] and BMI.[30–32] As in adults, body fat distribution is also correlated with cardiovascular risk factors.[33,34] Berenson and colleagues showed that blood pressure, lipid levels, and BMI were positively correlated with aortic and coronary atherosclerosis at autopsy in both children and adults (2–34 years), suggesting that the metabolic syndrome starts before adulthood.[35] Using data from the Bogalusa study of cardiovascular risk factors, Tershakovec and colleagues showed that the expression of the hypercholesterolemia in children precedes the expression of increased body fat and that insulin and blood pressure subsequently rise as the children grow older and body fat increases.[36,37]

Although there are many similarities between the findings of the metabolic syndrome in children and adults, it is important to recognize that children have a different hormonal milieu than adults, especially during puberty. All children become more insulin resistant at the time of puberty compared with either before or after puberty.[38] Increased body fat and BMI correlate strongly with fasting insulin levels and insulin resistance and have been proposed as potential mediators of the pubertal changes in insulin resistance.[39–42] However, insulin resistance can also occur during puberty in the absence of changes in BMI, coinciding with a period of rapid growth during puberty.[40]

In addition to hyperinsulinemia associated with the metabolic syndrome, frank type 2 diabetes is becoming increasingly common in children. The Third National Health and Nutrition Examination Survey (NHANES III) estimated a prevalence rate of 0.13% for type 2 diabetes and of 1.76% for impaired glucose tolerance among a representative sample of US adolescents.[43] Obesity increases the risk for diabetes substantially: in a study of obese adolescents, 4% had silent type 2 diabetes and 25% had impaired glucose tolerance.[44] The prevalence of type 2 diabetes is particularly high in children of non-European origins.[43] It has been estimated to be 3.6% among adolescent North American Indians[45] and 5.9% among Pima Indian adolescents.[46] In Ohio, type 2 diabetes accounted for 33% of all cases of diabetes among African American and Cau-

casian adolescents, representing a 10-fold increase in the incidence of type 2 diabetes this past decade in Cincinnati.[47] Risk factors for type 2 diabetes include obesity, a family history of diabetes, female gender, acanthosis nigricans, and nonwhite ethnicity.

NAFLD represents a spectrum of liver disease associated with obesity in children and adults.[48,49] Microscopic analysis of fatty liver disease reveals either accumulation of fat alone (steatosis) or fat accompanied by inflammation and fibrosis (steatohepatitis); the latter findings are generally termed nonalcoholic steatohepatitis (NASH). Up to 75% of adults with obesity have NAFLD,[19] and these rates are even higher in patients with severe obesity. Only a minority of patients with steatosis develop progressive liver disease, but the incidence of severe NASH is increasing in parallel with increasing rates of obesity. Obesity and diabetes are the strongest predictors of fibrosis on biopsy, and fibrosis and ballooning degeneration are the strongest predictors of disease progression.[50] NASH has become one of the most common causes of cirrhosis and liver failure and is the third leading indication for liver transplant in adults. Strauss and colleagues estimated that 10% of obese adolescents living in the United States may have NAFLD,[49] whereas other authors have estimated rates up to 25% among children and adolescents evaluated in obesity programs.[48,50–52] Although rare, several cases of cirrhosis associated with NASH in obese children have been described.[19,53,54]

Liver biopsies are considered the gold standard to evaluate NAFLD and are typically performed when liver enzymes are elevated and when the history and serologic testing exclude other common causes of aminotransferase elevation, such as viral hepatitis and alcohol-related hepatitis. Because liver biopsy is costly and is associated with appreciable morbidity, many gastroenterologists biopsy the liver in patients with suspected NAFLD only when alanine transaminase (ALT) levels are persistently at least twice the upper limits of normal.[55] NAFLD is frequently associated with mild (two- to threefold) elevations in aminotransferases, particularly ALT, but these measures are not good predictors of disease severity.[53,54,56] Liver imaging is a more sensitive way to detect fatty liver but also does not predict disease severity. A strong correlation has been shown between ALT > 30 U/L and fatty liver on ultrasonography among obese children,[57] and in a recent study of obese children and hepatic magnetic resonance imaging, all subjects (n = 7/7) with a low fat fraction (≤ 18%) had normal ALT values, but 92% (n = 12/13) of the subjects with a high fat fraction (> 18%) had elevated ALT values.[58]

Although NAFLD is strongly associated with obesity, it appears that this relationship may depend on insulin resistance rather than on the obesity itself. The prevalence of elevated ALT increases with BMI, but this relationship is independently associated with measures of insulin resistance and not with degree of obesity.[50,59] For example, increased insulin levels are associated with elevated ALT levels in obese children,[60] obese adults,[59,61] and lean adults with evidence of insulin resistance.[62] Indeed, animals and humans with lipodystrophy exhibit severe insulin resistance and steatohepatitis despite a paucity of subcutaneous fat.

Epidemiologic observations thus suggest that the pathogenesis of NAFLD involves insulin resistance. Recent laboratory investigations suggest that inflammatory cytokines may, in turn, be important determinants of the observed insulin resistance. Tumor necrosis factor-α (TNF-α) is known to mediate insulin resistance through Jun N-terminal kinase pathways, and animals without TNF-α activity are protected from insulin resistance.[63] Furthermore, treatment of ob/ob(–/–) mice with anti–TNF-α antibodies reverses both steatosis and steatohepatitis, suggesting that TNF-α may be an important stimulator of fat deposition and hepatic inflammation.[64] Clamp studies have suggested that insulin resistance in muscle and liver increases the delivery of free fatty acids to the liver and contributes to the development of steatosis. Identifying the molecular mechanisms underlying steatohepatitis and explaining its association with insulin signaling dysfunction will be helpful in developing specific treatments for NAFLD.

No good treatments for NAFLD have been established to date, but investigators have explored several possible targets. Weight loss is usually recommended,[19,65] but the efficacy of this approach is difficult to measure with intervention studies because of the difficulty achieving significant and sustained weight loss in a study population. Nonetheless, the association between obesity and NAFLD provides some justification for this approach. In addition, there is some evidence that obesity can potentiate other insults to the liver, such as alcohol and hepatitis C virus infection, suggesting that weight control and resolution of steatosis may make the liver less susceptible to such insults.[66] Gastric weight loss surgery is the most reliable way to achieve long-term weight control, and one study suggests that this approach is effective in reducing hepatic steatosis.[67] It remains unclear, however, how this type of rapid weight loss affects the inflammatory component of NAFLD. Indeed, rapid weight loss owing to caloric restriction can itself cause steatohepatitis, raising the question as to whether weight loss surgery might exacerbate steatohepatitis in some cases. Other treatments have been explored that attempt to reduce the production of oxidized lipids that are thought to induce inflammation; these include antioxidants such as vitamin E[68,69] and the lipid-lowering agent atorvastatin[70]; both showed some promise in small uncontrolled trials.[68–70] Most such trials are limited by small sample size, nonrandomized design, and/or a lack of histologic outcomes. Currently, large randomized trials are in progress to evaluate the effects of insulin-sensitizing medications (thiazolidinediones and metformin) in the treatment of fatty liver disease.

Other consequences of obesity seen in childhood are sleep apnea, cholelithiasis, pseudotumor cerebri, gastroesophageal reflux disease, polycystic ovary disease, and orthopedic problems, including Blount disease and slipped capital femoral epiphysis (Table 19-1). Sleep apnea can cause significant hypoxia, heart strain, and reduced daytime functioning and is probably underdiagnosed in pediatric populations. Screening for these and other medical problems is discussed in the medical assess-

TABLE 19-1 PREVALENCE OF DISEASES ASSOCIATED WITH OBESITY IN CHILDREN

DISEASE	PREVALENCE (%)	STUDY POPULATION
ENDOCRINE		
Type 2 diabetes	0.13	Community, 10–19 yr; n = 2,867[204]
Fasting blood sugar > 110 mg/dL	1.76	
Impaired glucose tolerance	21–25	Obesity clinic, 4–18 yr; n = 167[42]
Polycystic ovaries	45 of oligomenorrheic girls 9 of girls with regular menses	Community, all ninth grade girls (n = 2,249)[205]
GASTROINTESTINAL		
Gallstones	0.6	Pediatric inpatients[175]
Fatty liver (elevated aminotransferases)	10	Community, obese, 12–18 yr (n = 332)[206]
Fatty liver (elevated aminotransferases)	20	Obesity clinic, 2–18 yr (n = 72)[207]
GERD	22	Community, 14–17 yr (n = 449)[208]
Constipation	25	Obesity clinic, 2–18 yr (n = 80)[209]
Encopresis	15	
ORTHOPEDIC		
SCFE	0.01 (50–6% of patients are obese)	Community[210]
Blount disease	Prevalence not well established	
RESPIRATORY		
Sleep apnea	1.6 (4.5-fold higher risk if obese)	Community; children[211]
Sleep apnea	5	Obesity clinic[212]
Asthma	8.9 nonobese 14.9 obese	Community[213]

GERD = gastroesophageal reflux disease; SCFE = slipped capital femoral epiphysis.

ment section below. In addition to these complications, obesity in adults is associated with debilitating or life-threatening degenerative problems (axial arthritis and cardiovascular and cerebrovascular disease),[71,72] as well as with increased risk of certain neoplasias (breast, ovarian, prostate, and colon cancers).[73]

TRACKING

"Tracking" describes the risk for a disease state persisting over time. In the case of obesity, there is a moderate risk of childhood obesity persisting into adulthood, and that risk increases if the child stays overweight as he grows older (Figure 19-1). Moreover, the child's risk for obesity in adulthood also depends on the weight status of his parents. Whitaker and colleagues showed that the rate of obesity in adulthood ranged from 8% for children aged 1 and 2 years old without obese parents to 79% for adolescents aged 10 to 14 years old with at least one obese parent.[74] Before 3 years of age, the primary predictor of obesity in adulthood was the parents' obesity status, and the child's obesity status was not an important indicator of the risk of adult obesity. In contrast, after 7 years of age, the child's own obesity status became the more important predictor of his risk for obesity in adulthood.

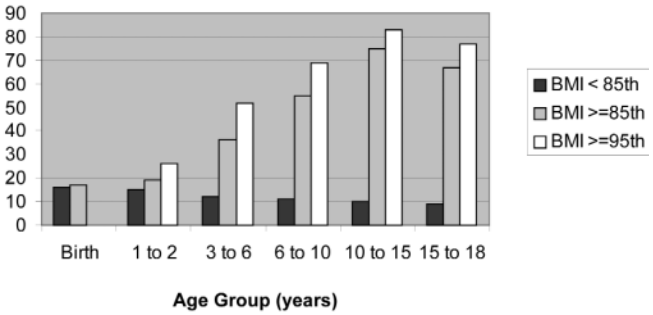

FIGURE 19-1 Percentage of children who will become obese adults. Adapted from Whitaker WC et al.[74] BMI = body mass index.

Obesity in childhood thus confers a higher risk of obesity in adulthood. Moreover, adults who were obese in childhood have a greater risk of morbidity and mortality, independent of their BMI in adulthood, family history of cardiovascular diseases or cancer, and smoking.[75,76] In the Harvard Growth Study, overweight adolescents were shown to have an increased risk for developing obesity-related medical problems in adulthood, including cardiovascular disease and diabetes, compared with adults with a more recent onset of obesity.[75] Likewise, Sinaiko and colleagues showed that weight gain during childhood and adolescence predicts cardiovascular risk in young adults.[30]

HERITABLE FACTORS

Studies of twins and adoptees provide useful estimates of the role of heritable factors in determining an individual's body weight (see Bouchard's 1997 summary of relevant articles on heritability[77]). Adoption studies tend to generate the lowest heritability estimates (30%), whereas twin studies provide the highest heritability estimates (70%). The variability in these estimates of heritability depends in part on definitions of obesity: more severe obesity tends to have a greater heritability factor than lesser variations in BMI.[78] Observations of a genetic contribution to obesity gave rise to the "thrifty genotype hypothesis," which posits that genes predisposing the individual to energy conservation were preserved as a survival characteristic in former times of famine but become a liability in environments with plentiful food and low required physical activity.[79] Possible mechanisms through which genetic polymorphisms can translate to differences in body weight regulation are discussed below.

Fetal Programming

Hales and Barker showed that poor fetal growth is associated with an increased risk for type 2 diabetes and other elements of the metabolic syndrome and proposed that poor nutrition early in life imprints permanent changes in glucose and insulin metabolism.[80] Interestingly, many more recent studies have also shown clear associations between high birth weight and later obesity,[81,82] suggesting that newborns at both ends of the weight spectrum are at risk for obesity-associated disease. This concept of "fetal programming" has now been supported by numerous studies in other human populations and in animals.[83] The hypothesis has also been extended to include the possibility that postgestational influences can participate to create a lifelong metabolic phenotype.[84] For example, a study of adults in Finland showed that the development of type 2 diabetes mellitus was associated with the combination of low birth weight followed by accelerated gain in height and weight during childhood and with high maternal BMI.[85] Similarly, a study of adults in England showed that accelerated weight gain in early childhood added to the effect of low birth weight on the risk of high blood pressure in adulthood.[86] Indeed, populations in transition from conditions of low to high nutrition may be at the greatest risk for such obesity-related complications because of the combination of fetal undernutrition and childhood overnutrition.[87]

A few studies specifically address whether the observed associations between birth weight and future risks for obesity can be directly related to the intrauterine environment rather than to genetics, distinguishing the concept of a "thrifty phenotype" from that of the "thrifty genotype." In a study of the effects of wartime famine in the Netherlands, infants exposed to famine in utero had higher rates of obesity and diabetes in adulthood compared with a genetically similar cohort not exposed to famine, and this effect was largely independent of birth weight.[88] Furthermore, the timing of the famine exposure during gestation appeared to have important effects because fetuses exposed to famine during the first trimester of gestation were more severely affected than those exposed later in gestation. These observations are strongly supported by animal studies, which also demonstrate lasting effects of intrauterine and postpartum nutrition.[89] The mechanisms underlying the observed associations, including the contributions of maternal hyperglycemia, insulinemia, and postnatal growth to the development of later complications, are an important subject for future studies.

BIOLOGY

Regulation of Body Weight

Both animals and humans have a strong tendency to maintain a stable body weight over time owing to a close but sometimes imperfect matching of energy intake with energy expenditure. Animal studies in which energy intake is manipulated reveal powerful influences from homeostatic mechanisms defending body weight.[90] Similarly, the poor long-term results of weight reduction therapies in humans (about 95% of adults regain all weight after dieting) suggest that there are mechanisms that defend a highly individualized "set point" for body weight. When an individual has a heritable or acquired susceptibility to positive energy balance, superimposed on these native homeostatic mechanisms, he or she has a tendency to become obese.

Animal models of obesity have been invaluable in establishing an understanding of the complex mechanisms regulating body weight. Our growing understanding of these pathways is likely to lead to better-targeted interventions, both pharmacologic and behavioral. This is an area of vigorous ongoing research; the major elements of the pathways as we currently understand them are outlined below.

Afferent Pathways. Circulating insulin, which reflects recent nutrient intake and metabolic demands, is an important regulator of nutrient partitioning in peripheral tissues and also communicates to centers regulating appetite in the brain. Peptides (such as cholecystokinin) secreted by the gastrointestinal tract in response to intraluminal nutrients and plasma concentrations of the macronutrients themselves also provide independent signals to the central nervous system, affecting short-term appetite and satiety.[91]

Ghrelin is a peptide secreted by the stomach that is an important short-term mediator of appetite. Its name is derived from its ability to stimulate growth hormone release from the pituitary, but it also stimulates appetite through specific receptors in the ventromedial hypothalamus. Ghrelin is released from the stomach during periods of fasting and is suppressed by nutrient administration.[92] The specific stimulants of ghrelin release are not clear, but volumetric stretching of the stomach wall has no effect. A recent report shows that ghrelin is suppressed in humans who lose weight after gastric bypass surgery but not in the setting of weight loss through caloric restriction.[93] These findings suggest that ghrelin may be the mechanism for the appetite-suppressing effect and high success rates of gastric weight loss surgery but are yet to be confirmed.

Leptin is an important regulator of body fat, first identified in 1994 through studies of the leptin-deficient obese mouse.[94] It is produced primarily in adipose tissue and provides feedback to specific receptors in the ventromedial hypothalamus, an important center for regulation of appetite and energy expenditure. The leptin signal decreases appetite, increases both voluntary and resting energy expenditure, permits fertility,[95] and even activates central "reward" pathways that may, in turn, affect appetitive behavior.[96] The leptin-deficient animal or human therefore has hyperphagia and decreased thermogenesis and physical activity, all of which are reversible by leptin administration.

The central mechanisms through which leptin exerts these diverse effects have been partly elucidated through studies in other animal models. Animals with defects in the leptin receptor (the diabetes mouse and Zucker rat) predictably have phenotypes indistinguishable from leptin deficiency itself.

Central Nervous System. The leptin signal activates a network of regulatory neuropeptides in the central nervous system. The anatomy of this network is the subject of

ongoing research, but many important elements have been described. Some of the pathways are orexigenic (favoring energy intake), whereas others are anorexigenic (inhibiting energy intake). In general, leptin-generated signals tend to inhibit the orexigenic pathways and to stimulate the anorexigenic pathways, thus decreasing appetite. The network also participates in leptin's effects on the reproductive system and energy expenditure (Figure 19-2).

The melanocortin pathway is among the most important links downstream of leptin. Leptin appears to directly increase expression of the pro-opiomelanocortin (POMC) gene, which is cleaved by prohormone convertase to α-melanocyte stimulating hormone (α-MSH),[97] as well as β-endorphin. α-MSH, in turn, stimulates the melanocortin-4 (MC4) receptor,[98] a potent inhibitory influence on the lateral hypothalamus. Meanwhile, leptin also directly inhibits the expression of agouti-related protein, which opposes α-MSH action at the melanocortin receptors.[98] The melanocortin pathway appears to be a particularly important regulator of body weight homeostasis because it exhibits less redundancy than other leptin-related pathways; an interruption in the melanocortin pathway can produce severe obesity, as seen in the agouti yellow mouse.

Leptin also decreases appetite through melanocortin-independent pathways. It inhibits the expression of the orexigenic agent neuropeptide Y, while increasing expression of cocaine- and amphetamine-related transcript (CART). In addition to decreasing appetite, CART has actions on the paraventricular nucleus of the hypothalamus and spinal sympathetic preganglionic neurons, where it affects energy expenditure via the autonomic nervous system (see Figure 19-2).[99]

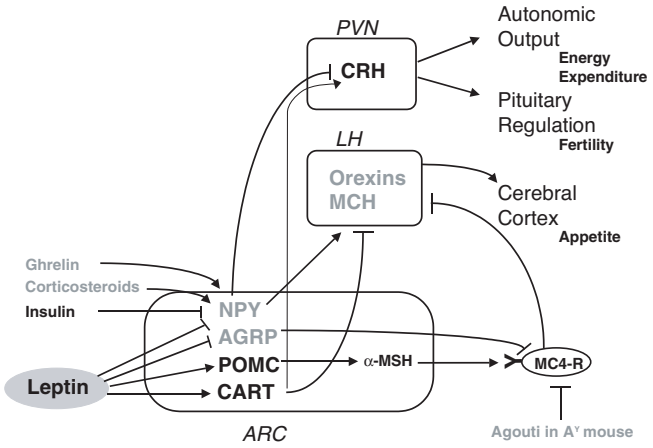

FIGURE 19-2 Central nervous system pathways regulating appetite and energy metabolism. Leptin positively regulates pro-opiomelanocortin (POMC) while negatively regulating agouti-related protein (AGRP)-releasing neurons in the arcuate nucleus (ARC) of the hypothalamus. POMC is a precursor of α-melanocyte-stimulating hormone (α-MSH), which is an antagonist at the MC4 receptor (MC4-R). AGRP and agouti protein are antagonists at MC4-R. The MC4-R pathway negatively regulates appetite, perhaps acting through appetite-stimulating neuropeptides in the lateral hypothalamus (LH), including melanin-concentrating hormone (MCH) and the orexins. Meanwhile, leptin has some actions that are independent of the POMC pathway, including negatively regulating neuropeptide Y (NPY), which is itself a potent appetite stimulant. Ghrelin also appears to act to stimulate appetite through the NPY pathway.[203] NPY also influences autonomic and pituitary output through the paraventricular nucleus (PVN), acting in part through corticotropin-releasing hormone (CRH).

Efferent Pathways. This leptin-responsive network of neuropeptides in the hypothalamus acts on effector pathways in the cerebral cortex, pituitary-adrenal axis, and autonomic nervous system. Most signals regulating appetite and satiety meet in the nucleus tractus solitarius in the medulla, where they are further modulated by afferent signals from the autonomic nervous system. The pituitary-adrenal axis mediates leptin's effects on fertility and likely also affects energy expenditure. Indeed, adrenalectomy prevents the development of obesity in most animal models.[100]

Efferent signals to regulate energy expenditure are integrated in the locus ceruleus, from which the sympathetic nervous system stimulates lipolysis in white adipose tissue and mediates processes that facilitate voluntary energy expenditure and heat generation. Genetically engineered animal models have clarified some elements of these effector pathways. Animals in which uncoupling protein-1 in brown adipose tissue is knocked out have increased body fat, decreased cold tolerance, and decreased thermogenic response to food,[101] but the related peptides, uncoupling protein-2 and -3, which are more widely expressed, are more likely to be relevant to human adiposity.[102] A knockout of the β_3-adrenergic receptor has a similar phenotype, suggesting that elements of the sympathetic nervous system are involved in increasing energy expenditure to match energy intake.[103] Parasympathetic efferent signals through the vagus nerve increase insulin secretion in the pancreatic β cells and may be a mechanism for the hyperinsulinemia in some groups of obese people.[20]

In addition to these autonomic processes, energy expenditure has a "voluntary" component (5–50% of total energy expenditure, depending on the level of exercise)[104] and a component of "fidgeting," or nonexercise activity thermogenesis (NEAT). NEAT has been proposed as a genetically determined system of protection from obesity and may also be mediated by the sympathetic nervous system.[105]

Genetics of Obesity

Exploration of the genetic determinants of body weight can be done in several ways, each offering different insight and limitations. Candidate gene approaches focus on specific genes and pathways that previous studies have shown are likely to be important in producing a phenotype. Each of the neurohormones described above, as well as their receptors and the enzymes responsible for processing, can be considered a candidate gene with potential importance in the regulation of body weight. Association studies use a case-control design to assess the association between variations in genotype and obesity phenotype. This technique lends itself to testing of several polymorphisms in candidate genes within a population; however, it is also prone to substantial false-positive and false-negative results,

depending on the sample size. Such studies are therefore most reliable if similar gene associations can be demonstrated in several different populations. Linkage studies rely on genome-wide scans of large populations to assess the strength of the association between variations in a genomic locus and the phenotype. This technique does not rely on a priori assumptions about the biologic significance of a particular gene and is therefore important in identifying new areas for inquiry. However, it also has relatively low sensitivity and can easily overlook linkages that are common contributors to less extreme phenotypes (eg, common genes predisposing the individual to moderate degrees of obesity). A complete list of published linkages to obesity phenotypes is summarized yearly.[106]

Candidate Genes. Any of the genes encoding a component of the mechanism for regulating body weight homeostasis, including those mentioned above, could be considered a candidate gene for a predisposition or resistance to obesity. Specific mutations in a few of these genes have been shown to cause obesity in rare kindreds. Mutations with strong effects were found in the leptin gene,[107] the leptin receptor gene,[108] the POMC gene,[109] the prohormone convertase gene (*PCSK1*),[110] and the MC4 receptor gene (*MC4R*).[111] The latter is the most common gene in which specific mutations cause obesity, but it is still very rare (27 mutations in 68 individuals published by 2001).[106]

Association studies have analyzed many other candidate genes from the afferent and efferent pathways mentioned above in genetically similar populations (siblings, twins, or kindreds). By 2001, polymorphisms linked to 58 candidate genes had been shown to have some association with obesity phenotypes,[106] including ghrelin,[112] peroxisome proliferation-activated receptor-γ,[113] uncoupling proteins,[114] and the β_3-adrenoreceptor genes.[115]

Linkage studies in large populations have identified many chromosomal loci with associations to a variety of obesity-related phenotypes, including BMI, leptin levels, fat distribution, and hyperlipidemia.[36] Such loci have been identified as of the 2001 gene map update,[106] some of which appear to represent the chromosomal regions of previously identified candidate genes such as the leptin or MC4 receptors. For many other regions or quantitative trait loci, the biologic mechanisms for the apparent linkage with obesity phenotypes remain unclear.

Mendelian Disorders. A number of human genetic syndromes displaying mendelian patterns of transmission and whose phenotype includes obesity have been identified and catalogued in the Online Mendelian Inheritance in Man (OMIM) database.[116] Twenty-five of these syndromes have been mapped to one or more chromosomal locations. The most common syndrome with severe obesity is Prader-Willi syndrome (short stature, hyperphagia, hypogonadotropic hypogonadism, cognitive defecits), which is mapped to chromosome 15q 11-13, a region containing several candidate genes for which a mechanistic explanation for the Prader-Willi phenotype is being sought.[106] The Bardet-Biedl syndrome requires a mutation at one of six loci plus an additional mutation in a second locus[117] and includes polydactyly and retinopathy. Alström syndrome (obesity, retinopathy, and deafness; no cognitive deficits)[118] and Cohen syndrome (hypotonia, retinopathy, and cognitive deficits)[119] have been mapped to one location each, but no obvious candidate genes have been identified as yet.[106] Each of these syndromes has characteristic findings as outlined in Table 19-2 and in the OMIM database[116] and can usually be distinguished from common obesity by a careful medical history and physical examination (see Table 19-2).

EVALUATION

Medical Assessment

The initial step for the assessment of the overweight child is to exclude potential associated syndromes or endocrinopathies and to diagnose possible associated complications, as summarized in Table 19-1. Several syndromes associated with obesity should be considered, including the mendelian syndromes mentioned above. Obesity may also accompany the more common, easily recognizable syndromes of trisomy 21 and Turner. In most cases, these syndromes can be distinguished on the basis of their unique features (listed in Table 19-2 and detailed in some excellent recent reviews[120–122]), and specific laboratory testing is valuable for confirmation but not for screening. The assessment of medical conditions related to overweight (see Table 19-1) has also been summarized elsewhere.[123]

The value of screening laboratory testing has been debated[124] but can be useful to establish whether there is dyslipidemia, steatohepatitis, or evidence of glucose intolerance, particularly because specific treatments for some of these disorders are increasingly considered.[67,68] Blood testing should be done in a fasting state if practicable. Thyroid stimulating hormone, hemoglobin A_{1C}, total cholesterol, very-low-density lipoprotein, low-density lipoprotein, high-density lipoprotein, aspartate aminotransferase, and alanine aminotransferase have been recommended to screen for possible hypothyroidism, diabetes, dyslipidemia, and steatohepatitis, respectively. Fasting glucose and insulin levels will provide information on carbohydrate metabolism and insulin resistance and may predict a risk for diabetes. Specific guidelines to screen for type 2 diabetes in overweight children have been developed (Table 19-3) but are also controversial because of the large number of adolescents fitting the screening criteria (currently about 2.5 million in the United States) and the relatively low yield of the suggested screening tests.[125]

Further laboratory testing may be useful in selected cases but can be expensive, and some tests are not readily available. Sleep studies can and should be performed if there are strong clinical symptoms of sleep apnea, and radiographic evaluation is necessary when slipped capital femoral epiphysis or Blount disease is suspected. Indirect calorimetry can be used to predict the energy deficit necessary for weight loss.[126] This might be useful when poor compliance or an eating disorder is suspected and at times may be useful to provide concrete caloric goals to support dietary changes. Bone age may be

TABLE 19-2 CHARACTERISTICS OF THE MAJOR SYNDROMES ASSOCIATED WITH OBESITY

SYNDROME	COGNITIVE DEFICIT	OBESITY	FEATURES
Albright[122]	Mild	Variable (general) Early onset	Neuroendocrine anomalies Normal or short Skin hyperpigmentation/vitiligo Polydactyly Bone fibrous dysplasia Precocious puberty
Alström[214]	None	Moderate (central) Onset age 2–5 yr	Retinitis pigmentosa Deafness Neuroendocrine anomalies Normal or short stature Normal or hypogonadism
Bardet-Biedl[121]	Moderate	Moderate (central) Onset age 1–2 yr	Normal or short stature Hypotonia Compulsive behavior Retinitis Heart anomalies Polydactyly Renal dysfunction Hypogonadism
Carpenter[215]	Mild	Central	Acrocephaly Polydactyly Syndactyly Short stature Flat nasal bridge High arched palate Heart anomalies Hypogonadism

POMC mutation[109] (autosomal dominant)	None	Early onset	Red hair ACTH deficiency Hyperphagia
Prader-Willi[216]	Mild to moderate	Moderate to severe (generalized) Onset 1–3 yr	Short stature Hypotonia Almond-shaped eyes V-shaped mouth Neuroendocrine anomalies Compulsive behavior High arched palate Hypogonadism

ACTH = adrenocorticotropic hormone; POMC = pro-opiomelanocortin.

helpful in supporting the diagnosis of an endocrinopathy. Consultations with specialists in sleep disorders, neurology, otorhinolaryngology, pulmonology/allergy, endocrinology, genetics, ophthalmology, and surgery may be necessary to manage specific complications.

The medical history should include assessment of concomitant medical diseases for their potential to contribute to weight gain (such as a history of significant head trauma or hypothalamic dysfunction) and to identify barriers to treatment (factors limiting mobility or ability to be physically active). A variety of drugs used for the treatment of psychiatric disease, epilepsy, diabetes, and migraines are associated with weight gain. Identifying these as a likely trigger of weight gain may prompt consideration of alternate drugs (Table 19-4).

Nutritional Assessment

Nutritional evaluation should include, at a minimum, anthropometric measurements and a history of the onset of obesity, as well as of weight loss attempts. Periods of adiposity rebound and potential triggers for excess weight gain should be identified. A family history of obesity and related medical problems should be evaluated to help establish the genetic factors underlying the weight disorder and the potential future medical risks. Assessing dietary intake by recalled food frequency helps to identify diet

TABLE 19–3 AMERICAN DIABETES ASSOCIATION GUIDELINES FOR THE ASSESSMENT OF TYPE 2 DIABETES IN CHILDREN WITH OVERWEIGHT OR OBESITY

Children and adolescents should undergo specific testing for diabetes if they are

Overweight, as defined by
1. BMI > 85th percentile for age and sex, or
2. Weight for height > 85th percentile, or
3. Weight > 120% of ideal (50th percentile) for height,

and have at least two of the following risk factors:
1. Have a family history of type 2 diabetes in first- and second-degree relatives
2. Belong to one of the following specific race/ethnic groups
   - American Indians
   - African Americans
   - Hispanic Americans
   - Asians/South Pacific Islanders
3. Have one or more of the following signs of insulin resistance or conditions associated with insulin resistance:
   - Acanthosis nigricans
   - Hypertension
   - Dyslipidemia
   - Polycystic ovary syndrome

Testing should consist of either
1. Fasting plasma glucose (8-h fast) or
2. Oral glucose tolerance test (blood glucose level 2 h postchallenge)

Further study is called for to determine the predictive value of hemoglobin A_{1C} and fasting insulin levels in determining risks for type 2 diabetes in children.

Adapted from the American Diabetes Association.[47]

composition but, in most cases, does not provide a good estimate of energy intake because underreporting of food intake by obese subjects is well described.[127] In particular, estimating the proportion of each macronutrient and fiber in the diet may help identify targets for dietary change if the diet is particularly skewed toward fat or energy-dense foods. In addition, the diet recall may be useful to assess the diet for deficiencies in micronutrients, particularly calcium and vitamins A and E, β-carotene, folic acid, and other B vitamins; excessive energy intake does not always mean adequate intake of micronutrients.

To identify possible areas for intervention, the amount and type of dairy products, fruits, vegetables, and legumes should be evaluated, and particular attention should be given to the consumption of sugary beverages, including juices and soda. Excessive consumption of sugary beverages has been associated with excess weight gain and increased rate of obesity[128] and is an important early target for dietary change. Similarly, the frequency of use of fast-food restaurants and of other restaurant meals should be examined because these meals often contain excessive caloric content and set appropriate portion standards. The diet history should also explore usual meal patterns, with attention to whether there is regular skipping of meals, binge pattern of eating, and the social context of meals, particularly if there are routine family dinners. Each of these factors may become a target for intervention to establish regular meal-based eating patterns.

Finally, the potential role of exercise and sedentary behaviors should be evaluated, with particular attention to determining the frequency of television and computer use. Several studies have suggested specific causal effects of television viewing on obesity,[129] and the American Academy of Pediatrics recommends limiting television viewing to 1 or 2 hours per day.[130] Assessment and encouragement of lifestyle exercise, in the form of outdoor play or regular walking (eg, walking to school), are as important as assessing structured exercise (eg, participation in sports programs).

Behavioral Assessment

The psychosocial complications of obesity are often subjective and difficult to measure in a standard fashion but undoubtedly represent one of the greatest burdens of obesity in children and adolescents. In many cases, psychosocial issues are best understood as consequences of the disease, brought on by feelings of discouragement and criticism by family, peers, or self. In other instances, the psychological issues precede or exacerbate the obesity. Regardless of the causality, it is important to acknowledge and assess these behavioral and psychological issues in each individual to best target treatment.

Depressive symptoms,[131,132] anxiety,[133,134] binge-eating disorder,[135–138] decreased self-esteem,[139–141] and problems with social interactions[142,143] have generally been found more frequently in obese children and adolescents than in their lean peers. Negative psychosocial associations also persist into early adulthood, when obesity is associated with lower educational attainment and household income and lower rates of marriage, independent of baseline education and aptitude.[144,145] Many of these problems can be attributed to the widespread and culturally entrenched bias against obese individuals in our society.[145,146]

Optimal assessment of the psychosocial issues contributing to and stemming from obesity in a particular patient has not been established and varies greatly between centers and providers. Whether or not standardized instruments are used, some effort should be made to assess mood, motivation, school and social performance, self-image, and eating attitudes and behaviors. It is also important to assess

TABLE 19-4 SELECTED DRUGS ASSOCIATED WITH WEIGHT GAIN

DRUGS WITH WEIGHT GAIN POTENTIAL	ALTERNATIVES WITH LESS POTENTIAL FOR WEIGHT GAIN
Atypical antipsychotics[217,218]	
Clozapine ++++ (gain 4–12 kg)	Quetiapine
Olanzapine ++++	Ziprasidone
Risperidone ++	
Mood stablizers[219,220]	
Divalproex sodium +++	Lamotrigine (weight neutral)
Lithium +++ (10 kg over 6–10 yr)	Adjunctive topiramate (6% of weight lost at 1 yr)
Tricyclic antidepressants[219,221]	
Amitriptyline ++	Desipramine
Imipramine ++	Nortriptyline
Monoamine oxidase inhibitors[219,222]	
Phenelzine > isocarboxazide	Tranylcypromine
Selective serotonin reuptake inhibitors[223]	
Paroxetine ++ (3.6% gain at 6 mo; 25% of patients gained more than 7% of body weight)	Fluoxetine
Sertraline +	
Atypical antidepressants[224]	Buproprion (weight loss)
Anticonvulsants[225]	
Valproate +++ 10–60% of patients gain weight; average gain 8–20 kg[226]	Zonisamide
	Topiramate (weight loss)[227]; 50% lose > 5 lb
Carbamazepine ++ 15 kg/3 mo	
Gabapentin ++ (23% gained > 10% of weight)	
Antidiabetic agents	
Insulin +++ (average 4 kg over 10 yr)[228]	Metformin (2–3 kg weight loss over 6 mo)[229]
Thiazolidinediones ++ (2–5 kg gain)[229]	

+ = mild weight gain potential; ++++ = very strong weight gain potential.

these issues in parents or close caretakers of the patient because factors such as motivation, mood disorders, and eating disorders in a parent will have a substantial impact on the child's attitudes, behaviors, and ability to respond to treatment.[143] The family's financial resources and level of cognitive stimulation in the household also predict the development of obesity[147] and may also affect the family's ability to respond to treatment. A "stages of change" model may be helpful in establishing the readiness of the patient and family for making lifestyle changes (Table 19-5). If the patient or family is in an early stage of change (precontemplation or contemplation), efforts should be focused on helping them forward into the next stage, perhaps using motivational interviewing techniques.

TREATMENT

Nutritional Therapy

Long-term studies of nutrition and exercise interventions for prevention of pediatric obesity are sparse and generally inconclusive. However, studies with short and moderate lengths of follow-up have shown benefits from a variety of "lifestyle" interventions, including nutrition education (in 3- to 9-year-old schoolchildren),[148] exercise, and measures to decrease sedentary activity.[149] All of these interventions have some effects in specific settings, although similar interventions in different settings failed to show an effect.[150–152] These studies are the subject of several recent reviews.[153–155] Most such studies target a school-based population and do not include the family in the intervention. The interpretation of such studies is hampered by high attrition rates, lack of standardization in definitions of obesity and treatment techniques, and limited generalizability.

There is better information available about treatment interventions for preadolescents and adolescents with established obesity, but the majority of studies still do not provide long-term data, and many issues, such as optimal macronutrient composition of diets and strategies to change food preference, have not been adequately studied. A few studies have suggested that structured exercise increases weight loss compared to diet alone,[156,157] and treatments focusing on increasing lifestyle exercise and reducing sedentary behaviors have also shown beneficial effects.[158–160] In general, regimens that combine hypocaloric diets with exercise and behavior modification have been particularly effective.[159–161] Epstein and colleagues have shown a medically significant long-term effect of an 8-month family-based behavioral intervention for families with children 6 to 11 years old. The improvement persisted 10 years after the intervention was completed.[162] The design of this study supports the conclusion that the behavioral intervention was a critical component of the success.

Typically, dietary recommendations for adults and children with obesity have consisted of reduction in dietary fat and energy intake as a balanced, hypocaloric diet. Recommendations have been developed by the American Academy of Nutrition as summarized in the handbook *Pediatric Nutrition*[163] and are similar to those supported by other governmental agencies, as described in a recent review.[164] The goal of the intervention is to reach a healthy weight without affecting linear growth. Specific recommendations include limiting beverages and foods with high caloric density and

TABLE 19-5 STAGES OF CHANGE

Precontemplation
Unaware of, denies, or minimizes the problem
Needs: encouragement to re-evaluate current behavior; encouragement of self-exploration, NOT action; provide information, personalizing the risks
Contemplation
Aware of the problem; ambivalent about change
Needs: gentle confrontation, information and rationale for change, clarification of any misinformation
Preparation
Has decided to make change, plans to do so within the next month, or is gathering information
Needs: assistance in identifying and overcoming obstacles, assistance to identify social supports, encouragement to take small initial steps
Action
Plan is in progress; attitudinal and behavioral changes have begun
Needs: tools and techniques to implement goals; positive reinforcement; support to deal with obstacles and losses, focusing on long-term benefits
Maintenance/relapse
Action maintained over 6 months (maintenance) or return to old habits (relapse)
Needs: self-monitoring tools for successful maintenance, feedback, and encouragement; stress management; use of support systems

Adapted from Prochaska J et al.[230]

low nutritional value, including sugary beverages and full-fat or low-fat baked goods and candies, and encouraging whole grains, fruits, and vegetables. Simple behavioral measures such as meal planning and label reading during grocery shopping are also generally encouraged to support the implementation of these nutrition guidelines.

The "traffic-light diet" provides a structured, balanced, hypocaloric diet in a simple format and has been used effectively for preadolescent[157,162] and preschool children.[165] It uses a simple color-coding scheme to categorize foods into categories for free consumption (low-density foods, "green"), moderate consumption (moderate-density and protein-containing foods, "yellow"), and very limited consumption (foods with high caloric density and/or with high sugar or fat content, "red"). The prescribed caloric content of the diet is generally between 900 and 1,300 kcal daily.

The protein-sparing modified fast (PSMF) diet provides high-quality lean protein while strictly limiting total calories. It has been used to treat severe obesity in a variety of settings, including hospitalized patients and school-based interventions. This diet has been effectively used in settings in which short-term weight loss is medically necessary, but there are no data to suggest that the diet reliably improves obesity in the long term. The principles of this diet are described in Table 19-6 and have been reviewed elsewhere, with sample menus.[166,167] Typically, patients start with a hypocaloric diet for 2 weeks before the PSMF diet is started (1,200 kcal/d); the PSMF diet continues for about 12 weeks (600–800 kcal/d) and is followed by a maintenance diet (balanced, 1,200 kcal/d). Of note, Figueroa-Colon and colleagues reported an 11.2 kg weight loss after 10 weeks of a PSMF diet, which was substantially more than that achieved by less restrictive measures, but by 15 months follow-up, the weight loss achieved by the two groups was similar.[168] Potential complications of the diet include protein losses, hypokalemia, inadequate calcium intake, cholelithiasis, and intravascular volume depletion with orthostatic hypotension.

Although the caloric content of a diet has been shown to relate to treatment success at 1 year,[169] to date, there is little evidence to suggest that alterations in specific macronutrients yield long-term weight reduction. A variety of popular diets have arisen around alterations of specific macronutrients, with or without limitations on total caloric intake. Many of these show good short-term weight loss, but whether these diets achieve long-term effects on obesity is unclear because no adequate long-term studies (with 5 or more years of follow-up) of these diets in representative adult or pediatric populations have been published. Freedman and colleagues reviewed the available evidence of benefits and risk associated with popular diets in adults.[170] Diets that specifically limit fat intake, which were popularized by Dean Ornish, were the subject of a recent review of studies with 6 to 18 months follow-up.[171] The authors of that review concluded that fat-restricted diets are no better than calorie-restricted diets in achieving long-term weight loss in overweight or obese people.

Several dietary approaches have focused on limiting carbohydrates, with (as in the "Zone" diet) or without (as in the Atkins diet) restrictions on fat intake. Careful analysis reveals that in the short term, low-carbohydrate diets cause a greater loss of body water than body fat. If the diet

TABLE 19-6 PROTEIN-SPARING MODIFIED FAST DIET

High-protein, hypocaloric diet for 12 wk
600–800 kcal
Protein 2 g/kg/d (maximum 100 g/d; approximately 50% of calories)
13–20 oz/d lean meat or substitute
Fat approximately 30–40% of calories
Carbohydrate 10–20% calories
As low-starch vegetables, may include one fruit
Ad libitum: tea, bouillion, pickles, spices, mustard
2 L of water per day
Supplements
Multivitamin with minerals
Elemental calcium supplement to meet the recommended daily intake
Monitor serum potassium and supplement as needed
Maintenance diet (36 wk)
Balanced macronutrients
1,200 kcal/d

Adapted from Suskind RM et al.[166]

is maintained in the long term, it results in the loss of body fat. There are few long-term data regarding the overall efficacy of these low-carbohydrate diets. High-fat, low-carbohydrate diets such as the Atkins diet are nutritionally inadequate and require supplementation of calcium and water-soluble vitamins.[170]

Caution should be used when considering the results of studies such as these that focus on adult populations because there is compelling evidence that at least some "lifestyle" approaches to obesity are substantially more effective in children than they are in adults.[172] Some dietary approaches might prove to have long-term results in children even if none can be demonstrated for adults. Diets that include a low glycemic index/load approach or higher consumption of calcium are currently under investigation[128,173] and will require long-term study before any useful conclusions can be drawn. A trial of increasing the fiber content of a hypocaloric diet in children yielded no better short-term results than a hypocaloric diet alone.[174] Medical guidance is important because there are ongoing concerns about medical complications, including dyslipidemias arising from the use of some popular diets and from the use of dietary supplements for weight loss, including in children. As many as 80% of children using unsupervised diets from popular magazines had medical problems resulting from these diets.[164]

As rates of obesity rise, obese children represent an increasing proportion of hospital inpatients.[175] Whether or not the child is hospitalized for an obesity-related condition such as gallstones, diabetes, sleep apnea, or orthopedic problems, nutritional needs must be considered. It is particularly important to recognize that the obesity is a chronic problem and will not resolve by attempting weight loss acutely during the inpatient stay. Moreover, acute severe caloric restriction is inappropriate and can lead to metabolic problems, including refeeding syndrome, despite the child's adequate energy stores. Guidelines for nutritional care of the obese adult inpatients have been developed,[176] but this issue has not been examined in children. It may be appropriate to prescribe a modest reduction in caloric intake, guided by indirect calorimetry or by calculations based on adjusted body weights and using a stress factor that is appropriate to the child's condition. The inpatient stay may also present an opportunity for nutritional education and for engaging the patient and family in a therapeutic plan to address the obesity beyond the hospital stay.

Behavior Therapy

As discussed above, some interventions in childhood have demonstrated long-term improvement of obesity with 5[177] or 10 years[162] of follow up; thus, children appear to have a more consistent and durable response to therapy than adults in the same family[172] or adult populations in general. The importance of including behavior therapy in the treatment of obesity in children has been demonstrated, at least in a family-based setting.[178] Although many interventions use combinations of dietary, exercise, and behavioral interventions, it is notable that the few studies with long-term results have had a rigorous and structured behavioral component.[161]

Commonly used techniques include self-monitoring of food intake and weight, modeling, positive reinforcement (praise), contingency management (certain behaviors are paired with predictable, reinforcing responses), and stimulus control (learning to avoid situations that are cues to overeat). Some studies have tested specific elements of these behavioral techniques. These have shown superiority of family-based over patient-focused treatment,[162] of gradual behavioral treatment (eight sessions over 15 weeks) over rapid behavioral treatment (eight sessions over 4 weeks),[179] of positive reinforcement over restrictive or critical approaches,[170] and of frequent (daily) over less frequent (weekly) positive reinforcement.[180] The value of problem-solving techniques has not been consistently shown.[181,182] Thus, there is ample evidence to support the use of behavioral modification techniques in the treatment and possibly the prevention of obesity in children. Behavior therapy should be thought of as a tool to achieve long-term changes in diet and exercise. In contrast, there are few data to support the use of behavior "micromanaging" techniques such as the rate of eating and bite size.

Weight Loss Drugs

Many of the drugs used for the treatment of obesity in adults in the past are characterized by unproven claims, highly variable efficacy, or dangerous side effects. Nonetheless, the incomplete but growing understanding of the mechanisms underlying the homeostatic control of body weight and the increased rigor applied to clinical drug trials hold promise for the development and use of pharmacologic agents to treat this chronic disease. In the short term, drugs can be important for a patient whose medical condition requires acute weight loss. Drugs may also have a role in treating the chronic component of obesity. Modification of the environmental and societal pressures contributing to obesity should be thought of as an important ultimate goal, but the use of drugs to promote weight loss may keep an individual patient engaged in the "lifestyle" component of treatment and might even change some of the consumer pressures that contribute to our obesity-promoting environment. Thus, pharmacotherapy for obesity is not at odds with lifestyle-changing approaches. As increasingly specific drugs are developed, efficacy and safety improve, and pharmacotherapy may ultimately be an essential tool to treat an otherwise refractory and devastating disease. Whether pharmacologic treatment is cost-effective depends in large part on whether it prevents the medical complications of obesity and associated costs of medical care.

Current options for the pharmacologic treatment of obesity are limited but may have some clinical utility. In general, the drugs demonstrate only modest efficacy but minimal side effects. Sibutramine (Meridia) and orlistat (Xenical) are the two drugs approved by the US Food and Drug Administration (FDA) for treating obesity in adults for periods of up to 1 year. Both demonstrate only modest efficacy but also have few side effects. Weight regain typically occurs on discontinuation of the medication. Concurrent efforts to reduce energy intake and increase exercise are important. Long-term studies (up to 5 years) of these drugs in adults are in

progress. Based on current literature, the modest weight loss achieved by the use of currently available drugs in conjunction with reduced calorie diets is probably not adequate to treat individuals with severe life-threatening complications of obesity, but the drugs may be considered to boost weight loss, assist weight loss maintenance, and reinforce lifestyle change. Whether phenotypic or genotypic analysis can be used to select for patients who respond relatively well to these agents is a subject for future study.

Sibutramine is an appetite suppressant that has been the subject of extensive clinical trials and was approved by the FDA for use in adults with obesity in conjunction with a dietary regimen. It is an inhibitor of both norepinephrine and serotonin and also weakly inhibits dopamine reuptake. At doses of 10 or 15 mg daily, combined with a reduced-calorie diet, modest weight loss is achieved in most patients (loss of 5 to 8% of baseline weight compared with 1 to 4% of weight on placebo),[183–185] but the range of weight loss varies greatly. Weight loss is sustained for most patients as long as the drug is continued (observation periods up to 3 years reported)[186] but generally is regained after the drug is discontinued. Side effects include modest increases in blood pressure (2 mm Hg average) and heart rate, dry mouth, constipation, and insomnia. Most side effects are transient and lead to discontinuation of the drug in about 5% of patients.[186] Importantly, no evidence of valvular heart disease such as that associated with fenfluramine treatment has been found in rigorous studies. Metabolic abnormalities associated with obesity, including hyperlipidemia and insulin resistance, tend to improve commensurate with weight loss.

Orlistat acts by inhibiting gastrointestinal lipases, reducing fat digestion and absorption by about 30%. Predictably, its side effects are related to fat malabsorption, consisting of steatorrhea when high-fat meals are taken, and decreases in serum levels of fat-soluble vitamins, primarily vitamin D.[160] Daily administration of a multivitamin is therefore recommended. Modest weight loss (3.2% more than placebo) is generally achieved,[187] and sustained use partially prevents weight regain during a second year of treatment.[188]

The safety and effectiveness of weight loss drugs in adolescents and children have not been established. A randomized trial of sibutramine in adolescents with concurrent behavioral therapy demonstrated significantly more weight loss than placebo (7.8 vs 3.2 kg). Adverse effects were similar to those seen in adults and prompted reduction or discontinuation of medication in more than one-third of subjects.[189] Large multicenter randomized placebo-controlled trials of sibutramine and orlistat in adolescents are in progress and will provide better assessment of the safety and efficacy of these drugs in adolescents.

Metformin improves insulin sensitivity and also promotes modest weight loss in adults.[190] In contrast to other antihyperglycemic agents, metformin does not increase insulin secretion but decreases hepatic glucose production and improves insulin sensitivity in both diabetic and nondiabetic adults.[191] Small open-label trials of metformin have suggested that it may be useful in ameliorating psychotropic drug–induced weight gain in children.[192] A small randomized trial of metformin in adolescents with hyperinsulinemia and a family history of diabetes showed improved glucose tolerance and a modest decrease in BMI.[193] Larger trials of metformin in adolescents are in progress, as is a small trial of ephedrine and caffeine. Careful review of these results will be necessary before pharmacotherapy outside of clinical trials can be recommended in adolescents or children.

Phentermine, diethylproprion, phendimetrazine, and benzphetamine are noradrenergic agents with appetite-suppressant effects but are studied and approved for short-term use only in adults (generally 12 weeks or less).[183] The latter two drugs are considered to have some potential for abuse and are listed in Schedule III of the US Drug Enforcement Agency.[183] The use of any agent with only short-term goals for weight loss in children and adolescents, particularly one with any potential for abuse, is highly questionable.

Dietary "supplements" or herbal medicines are popular, and consumers spend more than 1 billion dollars on these products annually in the United States.[194] However, they are unregulated and relatively untested. The commonly used herbal supplements are listed in Table 19-7. Supplements that could be used with caution in adults include conjugated linoleic acid, ginseng, chromium, hydroxycitric acid, dehydroepiandrosterone, hydroxymethylbutyrate, chitosan, and St. John's wort, but there is little evidence of the effectiveness of these drugs. Substances that have questionable safety and should be discouraged include Ephedra (or *ma huang*), horsetail, herbal laxatives, and some forms of caffeine and fiber.[195,196] To the best of our knowledge, there are no well-designed studies of dietary supplements and weight loss in children, and no supplements for weight loss can be recommended or even considered with caution.

Weight Loss Surgery

Over the past 15 years, surgically induced weight loss has emerged as an important option for adults with severe obesity. In contrast to poor long-term success rates for nonsurgical treatments of obesity, surgical approaches generally produce durable and substantial weight loss. Over 80% of patients lose at least half of their excess body weight during the first year.[197] Weight generally stabilizes 12 to 24 months after surgery, and 10 to 20% of patients regain a significant portion of the lost weight. If a patient maintains weight loss for 5 years, there is an excellent likelihood that the weight loss will persist for at least 14 years.[198] Studies have shown improvement or resolution of many of the medical complications of obesity, including diabetes mellitus, hypercholesterolemia, and obstructive sleep apnea.[199]

The jejunoileal bypass was an early surgical procedure for weight loss and caused global malabsorption. It caused frequent and unacceptable side effects, including intractable diarrhea, nutrient deficiencies, kidney stones, and hepatic failure. The two most common operations performed today are the Roux-en-Y gastric bypass and vertical banded gastroplasty (Figure 19-3), both of which reduce the gastric capacity to restrict caloric intake. In contrast to the jejunoileal bypass, these operations do not cause sig-

TABLE 19-7 DIETARY SUPPLEMENTS FOR WEIGHT LOSS[194–196]

DIETARY SUPPLEMENT	OTHER NAMES	MECHANISM	EFFECTIVENESS	SAFETY
Ephedra alkaloids	*Ma huang* Norepinephrine	Thermogenic	Yes, only in combination with caffeine	Unsafe (hypertension, palpitation, tachycardia, stroke, seizures, death)

nificant malabsorption, and their safety profile is substantially better. The mechanism through which these operations cause weight loss is not fully understood, although recent studies suggest that it may suppress gastric production of ghrelin, thereby reducing appetite.[93] About 10% of patients have important complications of these procedures, which include anastomotic strictures, incisional hernias, and gallstone formation requiring cholecystectomy. Anastomotic leaks, staple line disruptions, and dumping syndrome can occur but have been reduced to 1 to 2% each by modifications in surgical technique.[200] Although protein-calorie malabsorption is rare, malabsorption of selected micronutrients, particularly iron and vitamin B_{12}, is common and requires postoperative monitoring and treatment.

Gastric restrictive procedures for weight loss are thus an appropriate treatment option for adults with medically significant obesity, but there is still significant uncertainty regarding optimal patient selection. To date, no psychological or physiologic factors have been defined that will determine which patients are most likely to suffer weight regain after surgery (approximately 20% of patients regain most or all of their lost weight) or to suffer medical or psychological complications of surgery. Similarly, there are limited data on the outcomes of weight loss surgery in adolescent patients, but a few series have been published,[201,202] and these suggest that short- and long-term outcomes and complications in adolescents are probably similar to those seen in adults. Weight loss surgery may therefore be appropriate in selected severely obese adolescents. Given the limited data available on outcomes in this age group, these procedures should probably be limited to patients who have exhausted other management approaches and have significant medical complications of their obesity. To optimize long-term outcomes, any concomitant psychiatric disorders should be carefully assessed and under good control before surgery, and measures should be taken to ensure long-term follow-up for medical, surgical, and nutritional issues, ideally in the setting of a multidisciplinary obesity treatment center with substantial experience in surgical treatment of obesity.

Future Directions

With the exception of surgery, current treatments for established obesity have disappointing long-term outcomes. However, research is likely to lead to advances in several important arenas. Perhaps most importantly, public recognition of the obesity problem should lead to public education and public programs designed to prevent obesity during childhood. Such population-wide approaches are more likely to be effective than treatment approaches targeting individual patients with resource-intensive and weakly effective therapies. However, the identification of which preventive strategies will be most effective is important before they can be implemented widely. Second, improved

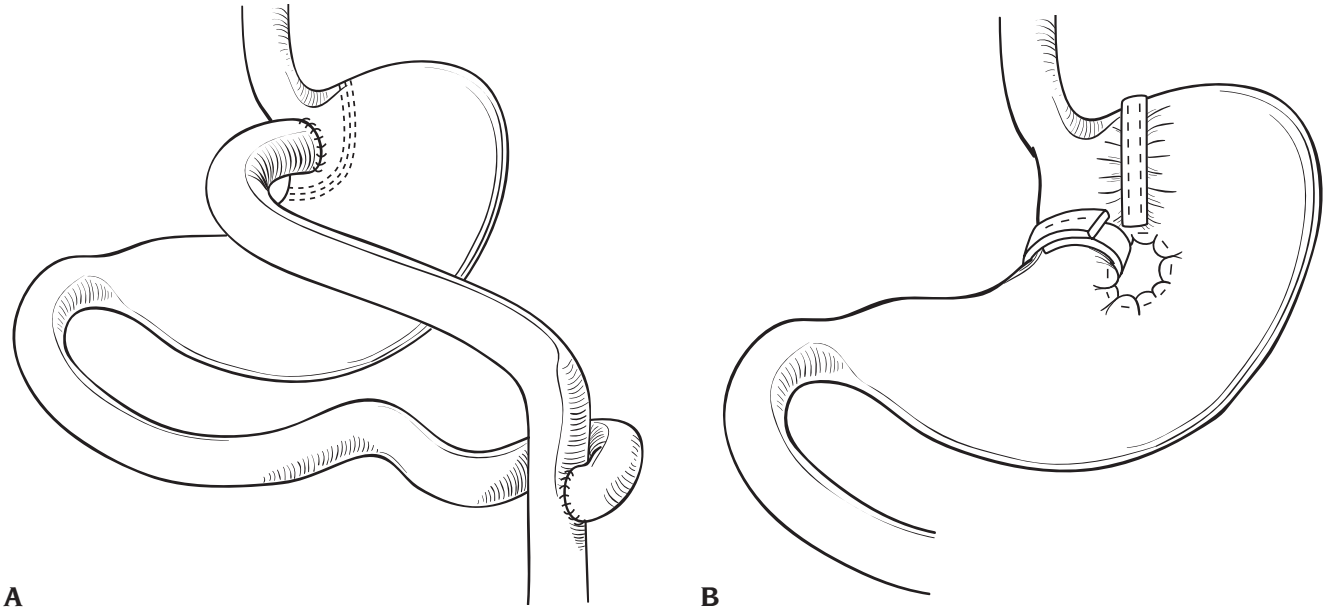

FIGURE 19-3 Gastric restrictive surgery for weight loss. *A*,Vertical banded gastroplasty; *B*, Roux-en-Y gastric bypass.

understanding of the genetic determinants and neural pathways underlying the homeostatic control of body weight is likely to lead to pharmacologic interventions that are more specific and therefore safer and more effective. Third, rigorously scientific and detailed analysis of specific environmental factors contributing to obesity, including issues of diet composition and meal patterns, may lead to more focused dietary and behavioral interventions to treat obesity. Finally, education of the public and health care community to recognize and reverse the commonly held bias against obese individuals should help to minimize the stigma and therefore much of the psychological burden associated with the disease.

CHAPTER 20

MUNCHAUSEN SYNDROME BY PROXY: FACTITIOUS DISORDER BY PROXY

Jay A. Perman, MD
Margarete Parrish, MSW, PhD

The syndrome now classified as a "factitious disorder by proxy"[1] (FDP) has historically been known as "Munchausen syndrome by proxy." Originally described in 1951 by Richard Asher,[2] the syndrome entails deliberate falsification of one's medical history and symptoms for the purpose of justifying extensive medical evaluations, invasive procedures, prolonged medical observations, and treatment. The objective of the behavior is to assume the role of being seriously ill.[1] Asher named the remarkable constellation of behaviors and objectives "Munchausen syndrome" after the legendary eighteenth century German baron who was renowned for his outrageous and utterly fabricated stories.

Following Asher's description of the syndrome, those adults and children meeting the criteria were increasingly recognized and reported.[3,4] In 1977, British pediatrician Roy Meadow expanded on the existing conceptualization with his reporting of two cases of Munchausen by proxy, entailing deliberate parental falsification of a child's medical circumstances.[5] Thus, the condition's relevance to general pediatricians and pediatric subspecialists expanded into the realms of child maltreatment.

In cases of FDP, rather than falsifying their own medical circumstances, adult caregivers deliberately feign or exaggerate the symptoms of another. The victim is typically a preschool-age child and often preverbal; the perpetrators are usually parents, most frequently mothers.[1] The perpetrator's motivation, which is a need to occupy a sick role, distinguishes FDP from malingering, in which secondary gains, either financial or legal, are typically relevant.[1] Although secondary gains and malingering may coexist alongside FDP, the motivations vary dramatically, with other motivations being secondary to those of FDP.[6] The perpetrator's behavior is not better explained by another mental disorder, such as a delusional disorder (somatic type) or a shared psychotic disorder ("folie à deux"). With FDP, a child's medical or psychiatric history and illness are intentionally fabricated, exacerbated, or induced by the perpetrator for the purpose of achieving a sick role vicariously or "by proxy." In some cases, hospitalization is an objective, which can become a way of life.[7]

FEATURES

The majority of cases of FDP involve gastrointestinal (GI), genitourinary, or central nervous system symptoms.[8,9] The type and severity of the symptoms produced depend primarily on the intellectual and medical sophistication of the adult. Feigned psychiatric symptoms are more rare.[1] Cases involving psychiatric FDP are typically much more complicated to uncover than their medical counterparts.[6]

Perpetrators often possess some level of nursing, medical, or other health professional training or experience, which allows them some familiarity with medical environments and equipment.[1,8,9] In these cases, it is important to recognize that a child's health is potentially jeopardized, thus justifying the term "perpetrator" as it applies to the adult in question. FDP is a psychiatric condition that applies to the perpetrator rather than to the pediatric patient. For the child, issues of medical and emotional abuse or maltreatment apply.

The typical presentation of FDP is complex, and assessment poses medical, psychiatric, and ethical challenges. Some warning signs of FDP are provided in Table 20-1. The parent is often very articulate, with educational and socioeconomic advantages. She or he usually appears to have a profound attachment to the child and is possibly eager to appear to be an "ideal" parent. The nonperpetrating parent often appears uninvolved, if not invisible, or may be physically absent.[1,8,9] The children have frequently been repeatedly admitted to multiple institutions during their early childhood with various complex conditions.[10] As they grow older, the children may actually collaborate in the production of symptoms.[1] Having spent childhood in an environment in which sickness was viewed as normal, if not desirable, a child's need for parental approval and attention may motivate such behavioral and emotional distortions. The urge to protect a parent may also play a part in this collusion. Children of FDP perpetrators typically have been conditioned to perceive themselves in a sick or even disabled role.[5] They are at risk of developing self-mutilation behaviors and factitious disorders later in life and eventually becoming FDP perpetrators as parents.[6,11,12]

Despite the FDP perpetrator's apparent devoted concern, she or he often manifests an incongruent disregard for the severity of the medical implications of the child's symptoms.[9,11] Parents with FDP frequently present with significant comorbid histories of depression, somatoform disorders, and personality disorders (particularly narcissistic and borderline). They may report having suffered childhood abuse.[1,8,9,13–16] Such reports must be interpreted cautiously because they may also be fabrications. Confirmation would necessitate documentation, which is rarely available, regardless of FDP.

SPECIFIC MANIFESTATIONS

FDP involves many health risks, including death. Cases often involve multiple signs and symptoms, thus complicating their assessment. GI and other manifestations of FDP are listed in Table 20-2.

With younger children, especially infants, seizures, cyanosis, and apnea-like symptoms are common; patterns involving diarrhea, vomiting, inability to walk, and limb paralysis seem more likely to emerge in toddlers.[7] Cases involving apnea, cyanosis, and seizures carry the greatest risks of mortality.[17,18]

Presentations may be further complicated by comorbid conditions such as failure to thrive or developmental disabilities.[19–21] Commonly encountered FDP-generated GI symptoms include factitious gastrointestinal hemorrhages, fabricated reports of emesis, and deliberately contaminated central venous lines. Examples of specific GI diagnoses commonly noted in children who have subsequently been recognized as victims of FDP are listed in Table 20-3,[22] along with examples of mechanisms of deception.

Children often present with symptoms that are incongruent with their general health; experienced specialists respond with comments such as "I have never seen a case quite like this one." The FDP parent's response to expressions of professional concern is typically one of obsequious vigilance, ostensibly on the child's behalf. The parent may praise and sympathize with a perplexed physician or appear eager to assist equally perplexed nurses or technicians. Parents with FDP frequently refute any improvement in their child's health and appear ready to imply that the physician or professional teams are remiss in having failed to recognize the severity of their child's circumstances. When faced with professional reluctance to escalate medical management, FDP parents are apt to transfer to another care provider. Discharges against medical advice among children with FDP parents are more frequent than they are among the general pediatric population.[9,18,19]

Symptoms provided by an FDP parent far exceed some embellishment or even falsification of a child's medical history by an overanxious parent in search of additional medical attention for their child. At the core of FDP, the perpetrator is engaged in such behavior as intentionally contaminating specimens, sabotaging a central line, poisoning food and beverages, withholding food, surreptitiously injecting insulin, pumping air into a gastrostomy tube, and possibly smothering or suffocating a child.[12,16,17,19] The purposefulness of the behavior is consistent. The objective is to attain a sick role (by proxy) by means of the child's (induced) medical status. Rosenberg used the phrase "disorder of empathy" in describing the mothers with FDP.[15]

TABLE 20-1 WARNING SIGNS OF FACTITIOUS DISORDER BY PROXY

Persistent recurrent illnesses that are unexplained or prolonged
Clinical signs are incongruent with a child's general health status
Signs or symptoms are extraordinarily rare, prompting such comments as "I've never seen anything quite like this before" from experienced clinicians
Repeated hospitalizations and evaluations have failed to provide a conclusive diagnosis or etiology
Noteworthy signs or symptoms do not recur when perpetrator is absent
Perpetrator is often hypervigilant, insisting on participating in procedures or bringing food or medicine from home, often refusing to leave the hospital
Perpetrator appears comfortable or pleased about being around medical environments, sometimes forming unusually close relations with staff
Perpetrator welcomes even invasive or painful diagnostic or surgical procedures
Perpetrator's concern for prognosis is incongruent with severity of symptoms
Clinical symptoms do not respond to treatment as anticipated
Families in which sudden deaths have occurred during childhood
Child's nonperpetrating parent is absent or rarely evident during treatment
Perpetrator has had some medical or nursing training or describes experiences with a similar condition in the past
Perpetrator's anxiety increases with child's medical improvement
Prior medical records that could confirm or preclude diagnostic impressions are reported missing by the perpetrator
Perpetrator becomes defensive or hostile if the information she/he provides is questioned or proven inaccurate

The medical professional's primary responsibility is to protect the well-being and rights of the child. A failure to diagnose or sustain an assessment of FDP raises issues of child abuse and a risk of fatality. Although FDP parents are unlikely to intend to murder, misjudgments may result in fatal interventions in pursuit of medical attention.[9] Additionally, medically abused children may lack the physical stamina or resilience to endure continued maltreatment. Tragically, the literature reflects a heightened sudden death rate among older siblings of children with FDP parents.

RESPONSE AND TREATMENT

The obscure motivation behind FDP behavior makes recognition and response particularly difficult. Recognition of FDP requires astute clinical skills and some common sense, along with considerable willingness to undertake a particularly unpleasant task. When a child's illness is sufficiently extraordinary as to bewilder the most experienced professional, and all reasonable measures taken have proven ineffective, close consideration of a child's environment is indicated. When a child's symptoms are evident only in the presence of the perpetrator, medical suspicions should be alerted. Especially when the perpetrator's anxiety level over the child's symptoms appears considerably less than that of the staff, physicians need to be particularly mindful of FDP. At such times, all staff should be reminded to document specific empiric observations rather than

reports of symptoms given by the perpetrator or the child. Self-reports and parental reports should be noted as such.

An FDP assessment necessarily entails acknowledgment by the medical professional(s) of having (albeit unknowingly) possibly contributed to behavior that endangered a child. Professional resistance to consider FDP is often further complicated by a reluctance to "pathologize," either psychiatrically or criminally, a person who has a child who is possibly genuinely ill. Professionals may also be reluctant to acknowledge the gullibility of the staff in their previous interactions with the perpetrator. Turmoil often already surrounds the child's treatment, and this element often intensifies on the articulation of suspicions of FDP. The staff may find itself "split" as regards the suspected FDP. The perpetrator's capacity to endear herself or himself to staff can potentially confound a timely response, in which a child's well-being is at stake and likely to suffer needlessly. Therefore, when FDP is suspected, the swiftest possible response to confirm or preclude the diagnosis is crucial.[6,16–18]

Even following admission, symptoms often continue to be fabricated.[15] Therefore, when FDP is suspected, all biologic specimens should be protected. The reliability of all apparent findings should be established (eg, is the blood actually that of the child?). Biologic specimens taken when the child is symptomatic should be saved for further investigation (eg, toxicologic). In cases in which a child has diarrhea, the possibility of laxative abuse must be evaluated. Phenophtalein is a frequently used laxative in cases of FDP, and its presence in the stool can be detected by the appearance of a pink color when alkanized to pH 8.5.[21] Stool levels of magnesium and sulfate may also be useful in detecting the abuse of laxatives.[21] All laboratory findings must be carefully documented.

Covert videotaping in hospital rooms has been used, but the practice remains highly controversial for ethical and legal reasons. Covert videotaping should not be used without first obtaining carefully considered legal advice.[23–25] Once FDP is detected, existing interdisciplinary support systems should be applied. Resources such as a hospital's child protection team, or its equivalent, are useful venues for discussions of the assessment and treatment plan. Ideally, such a team comprises professionals from various disciplines with expertise in areas related to child maltreatment.

Premature confrontation of FDP perpetrators or challenges made without sufficient documentation or staff cohesion can result in a detrimental crisis that is best avoided. Physicians and other medical staff must be well organized and solidly prepared to address the unpleasant tasks at hand.

When confronted with the medical and legal implications, the perpetrator typically will disclaim awareness of the medical problem's origin or any element of fabrication. The perpetrator's response to implied or overt accusations is often dramatic. Denial and projection of blame are frequent defensive maneuvers. Lawsuits are sometimes threatened in response to such inferences. Immediate discharges from medical care against medical advice are frequent consequences of confrontation.[8,11,18,25,26] The continued insistence on denying the fabrication of symptoms may reach a near-delusional level. Some perpetrators, however, may be sufficiently familiar with the existing literature to respond to accusations of FDP with spontaneous admissions, along with allusions to their behavior as a "cry for help" on their own part.[7,23,27] The legal incentives for such behavior are both clear and ominous. Dynamically, such admissions carry with them little or no indication of the perpetrator's capacity to distinguish between his or her own needs and the well-being of the child. Clinically, such admissions are not to be mistaken for sufficient evidence of

TABLE 20-2 SIGNS AND SYMPTOMS OF FACTITIOUS DISORDER (MUNCHAUSEN SYNDROME) BY PROXY

GASTROINTESTINAL
Abdominal pain (unexplained)
Anorexia
Diarrhea
Biochemical derangement
Failure to thrive
Hematemesis
Rectal bleeding
Vomiting (sometimes feculent)
Recurrent central line infections
OTHER
Allergies
Apnea, recurrent
Ataxia
Cardiorespiratory arrest
Coma, recurrent
Dehydration: hypernatremia
Diabetes or hypoglycemia
Mental status changes
Near-miss sudden infant death syndrome
Respiratory depression
Sepsis (often polymicrobial); joint and soft tissue infections
Upper respiratory tract bleeding
Urinary tract infection

TABLE 20-3 GASTROINTESINTAL DIAGNOSES FREQUENTLY CONFOUNDED BY FACTITIOUS DISORDER BY PROXY

PRESENTING DIAGNOSIS	METHOD OF FABRICATION
Colitis	Laxatives[8,17,21]
Cystic fibrosis	Altered, contaminated sweat tests and fecal fat analysis[21]
Diarrhea (intractable)	Laxatives Phenophtalein poisoning; salt poisoning[8,13,21]
Failure to thrive	Withholding of food, fluids[8,21]
Gastrointestinal hemorrhages (otherwise unexplained)	Patient's blood withdrawn from Broviac catheter; exogenous sources of blood (usually the perpetrators); warfarin poisoning[12,21,26]
Rectovesical fistula	Altered urine specimens[5]
Seizures/apnea secondary to gastroesophageal reflux	Asphyxiation (manual) Phenothiazine poisoning Salt poisoning Imipramine poisoning[8,14,21] Perpetrator's fabricated report
Vomiting (with or without altered sensorium)	Emetic poisoning Salt poisoning, injecting air into a gastrostomy[11,18] tube[8,12,25]

diminished risk of continued harm to the child or the presence of empathy on the part of the perpetrator.

After the disclosure of medical suspicions of FDP, the secondary gains associated with the condition are no longer reliably available to the perpetrators. The abrupt loss of medical attention and sympathetic regard has been associated with precipitous relocations to new areas in which the FDP patterns may be repeated for a new "audience" of health professionals. When relocation is not an option, the loss of such gains has also been associated with the perpetrator avoiding medical attention altogether, thus placing the child at continued risk from failure to seek appropriate care.[27,28] The rates of recidivism among perpetrators of FDP are noteworthy, even among relatively mild forms of the condition.[6,14]

CHILD ABUSE AND PROTECTION CONSIDERATIONS

The diagnosis of FDP is an Axis I condition according to the multiaxial classifications found in the American Psychiatric Association's *Diagnostic and Statistical Manual, Fourth Edition-Text Revision* (*DSM-IV-TR*).[1] Axis I conditions are those clinical disorders that are generally considered the primary focus of mental health treatment.

Along with the psychiatric implications of FDP, the realities of having inflicted deliberate harm on a child remain a criminal consideration. Although FDP represents a significant Axis I mental disorder, it also entails intentional harm inflicted by a caregiver on a child and thus meets the criteria for child maltreatment established by the laws established by the 1974 Child Abuse and Prevention Act, which applies to all 50 states.[29–31] Accordingly, mentally competent adults must be held accountable for their behavior, particularly behavior that entails medical harm to a child. The primary goal of both short- and long-term treatment must first address the protection of the child from further harm. The existing literature strongly documents the continued vulnerability of children who remain with FDP parents following an established diagnosis and Child Protective Services (CPS) involvement.[9]

Physicians are strongly encouraged to use existing expertise for support, collaboration, and guidance in such difficult decisions. Existing child protection teams and clinical social workers within the medial or CPS systems are the most likely sources of information on local or regional resources and protocols. The importance of careful collection and documentation of data pertaining to FDP cannot be underestimated. Perpetrators' fabrications are often so compelling and so complex that CPS agencies and courts rely heavily on the documentation provided by physicians.[15,17,24] An overview of ideal management recommendations is provided in Table 20-4.

Sadly, the recidivism rate found with cases of FDP, along with the absence of a recognized or effective treatment modality other than removal from the perpetrator, further underscores the necessity of placing the child elsewhere throughout any evaluation and intervention. The existing literature strongly documents children's continued vulnerability to harm when left in the care of FDP perpetrators, even following an established diagnosis and CPS involvement.[6,9,13,26,30,31] Thus, the disruption of an already traumatized child's family life necessarily remains a primary element of intervention. Such decisions are always difficult, but they are made even more poignant in cases involving a child who has reason to perceive himself or herself as medically fragile and a perpetrator who continues to insist on his or her innocence and parental devotion. Degrees of risk and safety must be carefully assessed. The severity of medical and emotional consequences must be carefully considered. The presence of comorbid psychiatric conditions on the perpetrator's part needs careful consideration, along with histories of prior episodes of relocation following extensive medical treatment elsewhere.[11,31,32]

Ongoing clinical considerations for the perpetrator entail attention to both the FDP and the other comorbid Axis I psychiatric conditions, including depression, substance abuse (including prescriptions), and Axis II personality disorders. According to the *DSM-IV-TR*, the personality disorders generally reflect inflexible, maladaptive patterns of perceiving and relating to the world.[1] Patterns of behavior, inner experiences, and impulse control that define Axis II conditions far exceed personality traits and are associated with significant distress and impaired levels of functioning.[1] Axis II conditions are typically associated with problematic ego functions such as impulse control and frustration tolerance. Object relations and object constancy may be problematic, making fulfilling the role of a parent challenging. The specific Axis II conditions most frequently associated with perpetrators of FDP are borderline and narcissistic personality disorders.[8,9,14,15,27] Characteristic and distorted defense mechanisms are generally relevant to Axis II personality disorders. For example, such defenses as denial, splitting, and projection are characteristically overused.[1] Long-term psychotherapy is gen-

TABLE 20-4 MANAGEMENT RECOMMENDATIONS FOLLOWING THE ASSESSMENT OF FACTITIOUS DISORDER BY PROXY (FDP)

Removal of the child from the care of the perpetrator and placement in a situation in which his/her safety is ensured. Placement with relatives is not necessarily a sufficient assurance of safety. Therapeutic foster care is indicated.
Separation of the child from the perpetrator should continue at least until the perpetrator has received a full psychiatric evaluation and a comprehensive social history has been obtained.
Primary pediatric medical care for the child should be coordinated by a practitioner specifically knowledgeable about FDP, who is also familiar with the case.
Comprehensive medical and psychosocial evaluations of siblings.
Long-term psychotherapy for both the perpetrator and the child provided by clinicians familiar with FDP. The perpetrator's partner should be included in therapy, as should siblings.
Ongoing monitoring of the child's medical, developmental, and psychosocial progress should be coordinated between providers of medical and psychosocial care, as well as coordinators of foster care arrangements.
If family reunification is eventually indicated, supervision should continue, with arrangements made through the courts for monitoring to continue regardless of relocation.

erally considered indicated for the Axis II conditions, but the literature generally lacks conclusive material about the successful clinical models suited to FDP in conjunction with Axis II conditions.[29,32] In fact, the literature suggests that fabrications of illness persist indefinitely.[12,14,33,34]

In cases involving court-mandated therapy for perpetrators, the capacity to deceive even experienced clinicians is well documented.[6,12,14,34] Adherence to psychotherapy is often superficial and frequently terminated prematurely by the perpetrator. For such reasons, treatment plans (particularly those entailing reunification) may necessitate having contingencies in place when treatment can be circumvented by the perpetrator.

The longer-term clinical implications for the child of an FDP perpetrator necessitate well-organized collaborative care efforts on the part of physicians, mental health professionals, and CPS and legal professionals. For physicians who continue to provide medical care to the child, ongoing issues of trust and realistic expectations will be crucial. Particularly in cases that necessitate removal from the family of origin and placement with others, physicians are urged to be mindful of issues of bereavement, loss, and stigma associated with such experiences, especially during childhood. Clearly, aspects of medical expertise must be combined with considerable compassion and exquisite sensitivity to children who have sustained such bewildering medical and emotional trauma.

Further research is clearly needed to explore the long-term implications for the children of FDP perpetrators. Longitudinal data are needed to clarify lifetime patterns of responses to determine whether the condition predicts replication in subsequent generations and how and whether children remember and resolve such trauma perpetrated by caregivers.

CHAPTER 21

DISORDERS OF THE ORAL CAVITY

Stephen Porter, MD, PhD, FDS RCS, FDS RCSE

The oral cavity is the most accessible part of the gastrointestinal tract, and lesions of the oral mucosa may be important manifestations of systemic disease. Such lesions may be a direct diagnostic marker of a disorder elsewhere in the gastrointestinal tract (eg, oral lesions of Crohn disease) or may be a manifestation of a systemic disturbance, such as malabsorption or immunodeficiency. This chapter considers the more common disorders that arise in the mouths of children and discusses the impact of gastrointestinal disease on the mouth.

ORAL DISEASE OF CHILDHOOD

A wide range of congenital disorders can give rise to defects of tooth structure, form, and number (Table 21-1). This chapter focuses on the more common primary disorders of tooth structure.

Primary Disorders of Enamel Formation

Amelogenesis Imperfecta. Amelogenesis imperfecta comprises a group of disorders characterized by defects of enamel, inherited in an autosomal dominant or recessive pattern.[1,2] Some are inherited in an X-linked recessive pattern.[3] The classification of this disorder is complex, but three basic types of defect occur:

- *Hypocalcified type.* This is the most common form of amelogenesis imperfecta. The enamel of newly erupted teeth is of normal thickness but is soft and rapidly lost through attrition. This disorder may be inherited in an autosomal dominant or recessive manner.
- *Hypomaturation type.* The enamel is of normal thickness but has a mottled, brown-yellow or white appearance. The enamel is not as soft as that of the hypocalcified type but can still chip off. This type of amelogenesis imperfecta includes an autosomal recessive pigmented form and an X-linked recessive form.
- *Hypoplastic type.* The enamel is of reduced thickness in some or all areas of the crowns of the teeth. There are thus variable degrees of pitting, grooving, and roughness of the enamel surface. This group includes autosomal dominant, smooth, and rough or pitted forms, as well as an autosomal recessive form in which there is almost total absence and an X-linked recessive form.

Occasionally, amelogenesis imperfecta may be a feature of other congenital disorders (eg, in amelocerebrohypohidrotic, enamel-renal, trichodento-osseous, and amelo-onychohypohidrotic syndromes).[4]

Children with amelogenesis imperfecta require evaluation and management by specialists in pediatric dentistry,[5,6] together with other relevant specialists (eg, in clinical genetics).

Primary Disorders of Dentine Formation

Dentine Dysplasia. In this autosomal dominant disorder, the crowns of the deciduous and/or permanent teeth are of a generally normal shape but have an amber or opalescent appearance owing to abnormal dentinal structure. In dentine dysplasia type I (radicular dentine dysplasia), there is obliteration of the pulp chambers, short or absent roots, and resultant tooth mobility and migration. In type II disease (coronal dentine dysplasia, pulpal dysplasia), the disease is not as severe as that of type I and tends to affect the deciduous dentition more than the permanent dentition, and the root structure may be unaffected. A third type of dentinal dysplasia may be accompanied by sclerotic bones.[1,4]

Dentinogenesis Imperfecta. This is probably the most well known of the primary dentinal disorders, probably as a consequence of its potentially profound clinical presentation, there being early loss of the overlying enamel.[1] At least three types of disease are known:

- *Dentinogenesis imperfecta Shields type II (opalescent dentine).* In this, the deciduous and permanent teeth have a blue-gray or translucent amber appearance, and there is

a tendency for the enamel to shear off the underlying dentine. The crowns are bulbous and have a pronounced cervical constriction. The roots are short and rounded, and the pulp chambers may become rapidly obliterated.

- *Dentinogenesis imperfecta Shields type III (brandywine dentine)*. The dentinal defects are similar to those of type II, but there are also "shell teeth," characterized by an abnormally large pulp chamber. This type of dentinogenesis imperfecta is named after the residents of an area of southern Maryland, in whom it was first observed.
- *Osteogenesis imperfecta with dentinogenesis imperfecta*. Dentinogenesis imperfecta can be a feature of type IB, IIIB, or IVB osteogenesis imperfecta, Ehlers-Danlos syndrome type II, Goldblatt's syndrome, Schimke immuno-osseous dysplasia and skeletal dysplasia, and rootless teeth.[7]

Defects of Tooth Shape and Size

Abnormal tooth shape may arise as a consequence of primary disease of the enamel or dentine (see above) but may be acquired local or systemic disease. Early periapical infection of a deciduous tooth can result in abnormal crown formation of the permanent tooth ("Turner's tooth").[8]

Congenital syphilis affects the teeth in which calcification occurs in the first year of life—hence typically the permanent incisors and first molars. The incisors have a screwdriver shape, a notching of the incisal edge, and/or a depression on the labial surface of the crown. The first molars may be bud-shaped and reduced to the size of the adjacent second permanent molar. The normal mesiodistal convexity of the crown may be reduced, and there may be enamel hypoplasia.[9–13]

Other defects of tooth size and shape are detailed in Table 21-2 and in the relevant sections of this text. Other defects of eruption are listed in Table 21-3.

Ectodermal Dysplasia

The ectodermal dysplasias (EDs) comprise a large group of genetically determined disorders, clinically characterized by alterations of two or more ectodermally derived structures, giving rise to a wide variety of defects of the skin, nail, hair, or sweat glands.[14]

There are multiple congenitally missing primary teeth, coronoid primary incisors, with moderately to severely taurodontic second primary molars. Supernumerary cusps may also occur. The permanent teeth are always reduced in number (hypodontia), and the crown shape of any present teeth is usually abnormal; in particular, the permanent incisal crowns are often conical or pointed, whereas the permanent molar crowns have a reduced diameter. The absence of teeth results in an underdevelopment of the alveolar processes and hence a reduction in the lower third of the face height and lip protuberance, the latter causing dry, cracked, and fissured lips.[14–17]

ED typically encompasses a spectrum of ectodermal abnormalities, and those patients with anhidrotic forms may be liable to heat intolerance, which may give rise to episodes of hyperthermia, eventually leading to cerebral damage. Indeed, death owing to hyperthermia is possible but uncommon.[18] Sparse blonde hair, including a reduced density of eyebrow and eyelash hair, is common in ED. The nails may also appear dystrophic and brittle. The periocular skin may show a fine wrinkling with hyperpigmentation. As the salivary glands are ectodermally derived, patients may have varying degrees of salivary gland aplasia, xerostomia, and an increased liability to dental caries.[19]

Early pediatric dentistry affords the child the opportunity to develop normal forms of speech, chewing, and swallowing; normal facial support; improved temporomandibular joint function; and improved self-esteem.[20,21] When a child with ED reaches his or her early teens, orthodontic treatment may be indicated, together with definitive restorative dental care—possibly including endosseous implants.[22]

Other Causes of Hypodontia

Hypodontia can be a feature of a number of other disorders (see Table 21-1).[8,23,24] In addition, it may arise as an isolated anomaly affecting one or more teeth. Commonly missing teeth are the permanent upper lateral incisors, third molars, and second premolars. Hypodontia may be a feature of cleft palate.

TABLE 21-2 DISORDERS OF TOOTH SHAPE AND SIZE

DISORDER	COMMENTS
Dilaceration	A bend in the root or crown of a tooth. Usually affects the permanent incisors. Arises as a consequence of childhood trauma to teeth.
Connation (double teeth)	Teeth joined together. More common in the deciduous than in permanent dentition. May represent fusion or partial development (germination) of teeth.
Macrodontia	Abnormally enlarged teeth. Uncommon but usually affects all of the dentition.
Microdontia	Abnormally small teeth. Uncommon.
Taurodontism	Not a true defect of tooth shape. A radiologic feature characterized by an enlarged pulp chamber, long crown, and short roots.
Prominent tubercles or cusps	A variety of defects may occur.
Enamel cleft	Small cleft in the enamel crown in the cervical region.
Disorders of tooth number and eruption	
Reduced tooth number	

Hyperdontia

Additional teeth are usually smaller than the normal dentition and are termed supernumerary, although when in the midline (usually of the maxillary teeth), they are termed mesiodens.[23,24] Occasionally, supernumerary teeth do not erupt but manifest as a malocclusion. Additional teeth of normal shape and size are termed supplemental and are much less common than supernumerary teeth (see Table 21-1).

Both supernumerary and supplemental teeth can cause delayed or failed eruption of adjacent teeth and, when unerupted, may cause resorption of adjacent roots.

Delayed Eruption of Teeth

The eruption of teeth is usually due to local factors such as malocclusion but may rarely reflect systemic (including gastrointestinal) disease.[8,25]

Acquired Disorders of Teeth

Dental Caries (Decay) and Sequelae. Dental decay is caused by destruction of the dental hard tissues by metabolic acids of dental plaque.[26–31] It initially manifests as areas of white decalcification of enamel, with later destruction of the enamel and dentine. Early decay is asymptomatic, although later disease, when there is involvement of the dentine, gives rise to short-term localized pain in response to hot, cold, and sweet foods. Unchecked decay eventually results in severe pulpal inflammation and death and possibly inflammation of the apical areas of the periodontium (periapical periodontitis).

Periapical periodontitis will give rise to local long-standing pain, usually in response to hot and cold foods and particularly with occlusal pressure. The affected tooth may be slightly elevated, and there may be formation of a sinus that drains from the gingivae at the level of the apex of the tooth. Periapical infection can give rise to periapical abscess formation ("gum boil") and cellulitis, the latter occasionally causing pyrexia and malaise, as well as facial swelling. Other possible sequelae of a periapical abscess include periapical (radicular) cyst formation or, rarely, discharge of a sinus onto the skin.

Dental caries is liable to arise in children who maintain poor oral hygiene and/or have a diet comprising frequent sweet foods. The decay tends to arise in the fissures of premolars and molars, although it can arise interdentally between any teeth.

Factors that predispose individuals to plaque accumulation (eg, malocclusion, enamel anomalies, inability to achieve effective tooth cleaning, frequent sticky foods) increase the liability to dental caries. In addition, xerostomia owing to salivary gland disease or local radiotherapy greatly increases the risk of caries development.

Rampant Caries. Rampant caries is characterized by almost immediate decay of erupting teeth. It typically affects the upper incisors, although almost all of the deciduous dentition can be affected. Rampant caries is due to the frequent use of sugary drinks in bottles or soother.[32] Rarely, rampant caries may be a feature of children with salivary gland aplasia (eg, as in some forms of ED).[19] Of interest, rampant caries can be a feature of methamphetamine and/or cocaine abuse.[33,34]

Other Causes of Loss of Dental Hard Tissue

Dental Erosion. Erosion is the consequence of dietary acidic destruction of enamel. The erosion is usually due to the frequent use of low-sugar (but acidic) soft drinks[35–37] and is thus more likely in adolescents than in young children. Erosion can be a feature of children and adults who

suck and eat large amounts of citrus fruits.[38] It has been observed that some,[39] but not all,[40] examined groups of athletes may be at risk of dental erosion, presumably through the frequent use of diet-type soft drinks. Almost any tooth surface can be affected, but, typically, the palatal aspects of the upper anterior teeth become thinned and smooth.

Although much less common than diet-related disease, erosion can be caused by gastroesopharyngeal reflux disease.[41–46] The posterior teeth and the palatal aspects of the upper anterior teeth of the permanent and, rarely, the deciduous dentitions can be affected. Erosion may also arise in bulimia nervosa (see later also).[47–49]

Attrition. Attrition is the loss of dental hard tissues as a consequence of mastication. Attrition is a normal feature of the late deciduous dentition and is particularly noticeable on the incisors and canines. Severe attrition of the permanent dentition in childhood is uncommon but may arise with severe malocclusion and may be a feature of Rett syndrome.[50]

Abrasion. Abrasion is the loss of dental hard tissues owing to frictional damage by foreign hard substances, typically a toothbrush. It is uncommon in children. Abrasion typically gives rise to concavities within the dentine (and to a lesser extent the enamel) of the cervical margins of teeth.

Dental Discoloration and Staining

The teeth can be extrinsically or, more rarely, intrinsically stained (Table 21-4).

Most discoloration of teeth in childhood is due to dental caries. Enamel decalcified by dental decay can become stained with foodstuffs, and caries that arrests takes on a black appearance. Teeth that become nonvital, typically owing to trauma, may take on a darkened color because of the pigments associated with pulpal necrosis, whereas internal resorption of the dentine can produce pink spots on the crowns of affected teeth.[8]

Systemic tetracycline therapy in the years of crown development can give rise to gray, yellow, or brown pigmentation of the teeth. The degree and color of tooth discoloration will depend on the dose, duration, and type of tetracycline prescribed. Fluorosis causes variable degrees of tooth discoloration, which are detailed later. Other, albeit uncommon, causes of intrinsic pigmentation of the teeth include congenital erythropoietic porphyria,[51,52] hemolytic disease of the newborn, and hyperbilirubinemia owing to rare disease such as biliary atresia. Chlorhexidine gluconate mouthrinse and gel cause brown extrinsic staining of the teeth. The stain can be easily removed by professional dental cleaning and can be prevented by application of chlorhexidine immediately following regular tooth cleaning because the chlorhexidine stains the pellicle that forms on teeth within a few minutes after tooth cleaning.[53]

GINGIVAL AND PERIODONTAL DISEASE IN CHILDHOOD

Most gingival disease in childhood is plaque-related gingival inflammation (gingivitis); however, a wide range of congenital disorders can give rise to gingival and periodontal manifestations. Gingival and periodontal disease in childhood most commonly manifests as swelling (Table 21-5), accelerated periodontal destruction (Table 21-6), and/or ulceration (Table 21-7).

Nonspecific Gingivitis

Acute. Acute nonspecific gingivitis is due to inflammation secondary to local accumulation of plaque. Signs of acute gingivitis develop within 7 to 10 days of plaque accumulation and initially arise on the interdental papillae before spreading to the adjacent free gingival margins. Rarely, there may be involvement of the free and attached gingivae. Acute gingivitis initially manifests as redness and swelling of the affected gingivae; later there is gingival bleeding that may arise with tooth cleaning and eventually will occur during eating. Patients with severe acute gingivitis may have oral malodor and complain of dysgeusia and awaking from sleep to find blood on the pillow owing to drooling of bloody saliva. Unlike acute necrotizing ulcerative gingivitis (ANUG), there is no tissue destruction.[54–57]

Chronic. Chronic nonspecific gingivitis arises as a sequela to long-standing mild acute gingivitis. The gingivae become variably enlarged and fibrous, and there is often some associated acute gingivitis.

Management of Nonspecific Gingivitis. Improvement in oral hygiene is the mainstay of treatment of both acute and chronic nonspecific gingivitis. Surgical reduction of any hyperplastic tissue (eg, by gingivectomy) may be required for the treatment of long-standing chronic gingivitis.

Acute Necrotizing Ulcerative Gingivitis

ANUG (acute ulcerative gingivitis, Vincent gingivitis) is a common disorder of adulthood but can arise in children, particularly those who are malnourished or immunocompromised, for example, with human immunodeficiency virus (HIV) disease. ANUG is characterized by notable, painful, necrotic gingival ulceration and edema with bleeding and malodor. The ulceration typically commences

interdentally but, in severe disease, may extend to cause ulceration of all marginal areas. The tissue destruction results in irreversible flattening of the interdental papillae. Involvement can be localized or generalized.

Patients may complain of an abnormal, sometimes metallic, taste (dysgeusia) and oral malodor. Periodontal destruction is rare, although in severe malnourishment, an ANUG-like disorder (termed noma) can cause ulceration and destruction of the periodontium and adjacent tissues and sometimes perforation of the facial tissues, fistula formation, and eventual orofacial disfigurement. In severe ANUG, there may be cervical lymphadenopathy, pyrexia, and, rarely, malaise.

Poor oral hygiene is the most common cause of ANUG, although viral lymphopenia (particularly upper respiratory virus infections) and, less commonly, immunodeficiency associated with undiagnosed or poorly controlled diabetes mellitus, leukemia, HIV disease, profound malnutrition, and other severe immunocompromised states can be contributing etiologic factors.

There is unlikely to be a specific causative micoorganism, but ANUG is typically associated with *Borrelia vincentii*, fusiform bacteria, *Treponema denticola*, and other gingival spirochetes.

For the management of ANUG, oral hygiene must be improved. Where possible, supragingival deposits and tissue debris should be removed immediately, but subgingival cleaning may be possible until there has been some resolution of the acute disease. Chlorhexidine gel and/or sodium perborate mouthrinses may be helpful, although significant evidence that these topical agents are effective is lacking. Systemic metronidazole (typically 200 mg three times daily for 3 days) or phenoxymethylpenicillin (250 mg four times daily for 5 days) is indicated when the disease is severe and/or there is lymphadenopathy or pyrexia. Appropriate referral (eg, to endocrinology or infectious diseases specialists) may also be warranted.[55,56]

SECONDARY IMMUNODEFICIENCIES
Malnutrition
Diabetes mellitus
Crohn disease
HIV disease
OTHER ACQUIRED CAUSES
Vitamin C deficiency

HIV = human immunodeficiency virus.

Hereditary Gingival Fibromatosis

Hereditary gingival fibromatosis is usually inherited as an autosomal dominant or recessive disorder, although sporadic disease can occur. There is fibrous enlargement affecting many or all gingivae, particularly the free gingiva about the smooth surfaces of the teeth. The disease manifests in early childhood, sometimes causing delayed or partial eruption of teeth. Gingival fibromatosis can be a feature of a spectrum of rare syndromes that usually includes deafness, learning disability, and hypertrichosis. Similar gingival enlargement may be seen in a number of rare conditions (see Table 21-5).

Surgical reduction by gingivectomy or gingivoplasty is usually required to improve esthetics and permit better oral hygiene maintenance. Surgery is more effective postpuberty, when recurrence is unlikely.[57,58]

Other Congenital Causes of Gingival Enlargement

Genodermatoses. Sturge-Weber syndrome can give rise to hemangioma of the gingiva, usually the maxillary gingiva of one side. There is usually an extensive orofacial hemangioma that roughly follows the distribution of one or more of the divisions of the trigeminal nerve and extends into the parietal and occipital lobes of the brain. The maxillary gingivae are often involved, the affected tissue being enlarged, boggy, and purple or blue colored, often covering the crowns of several teeth. The eruption and form of the involved teeth are variably affected. Because epilepsy is a common accompaniment, there may also be phenytoin-induced gingival enlargement. Sturge-Weber syndrome may also include epilepsy, learning disability, hemiplegia, and glaucoma.[59,60]

Tuberous sclerosis may give rise to multiple fibrous enlargements of the gingivae,[61] whereas neurofibromatosis (usually type 1) may give rise to variable numbers of gingival neurofibromas (as well as occasional pigmentation).[62] Cowden disease causes multiple gingival fibrous swellings.[63]

Orofacial Granulomatosis. Orofacial granulomatosis and Crohn disease in childhood may give rise to localized or generalized gingival enlargement. The swelling is diffuse and salmon pink in color, often with a granular surface, and affects the free and attached gingivae. The other oral manifestations of orofacial granulomatosis are discussed later.

Drug-Induced Gingival Enlargement. Gingival enlargement commonly arises with long-term phenytoin, cyclosporine, and calcium channel blockers.[57,58] The gingival enlargement usually commences interdentally and affects both the labial and the lingual/palatal aspects. The enlargement is most likely in patients who do not maintain good plaque control and in those receiving high-dose regimens. The enlargement associated with phenytoin is fibrous in quality, whereas that associated with cyclosporine and calcium channel blockers is softer and more erythematous. Surgical reduction followed by the maintainance of good plaque control is the mainstay of treatment of drug-induced gingival enlargement.

Lipoid proteinosis
Hypoplasminogenemia

HIV = human immunodeficiency virus.

Periodontal Disease in Childhood. Periodontitis—loss of periodontal attachment—is uncommon in childhood but, when present, is usually associated with poor plaque control. Periodontitis manifests as increased tooth mobility and migration and is usually accompanied by features of acute and/or chronic gingivitis. Some loss of alveolar bone may be observed radiographically.

Aggressive periodontitis—periodontal destruction in excess of that expected irrespective of the levels of plaque—is likewise uncommon in childhood and usually reflects an underlying primary defect of phagocyte number or function, deficiency of cathepsin C (as in Papillon-Lefèvre syndrome), a structural defect of cementum (eg, hypophosphatasia) or connective tissue of the periodontium (eg, Ehlers-Danlos syndrome type VIII), or HIV disease (see Table 21-6)

The management of periodontitis of childhood is principally directed toward reducing the infection with *Actinobacillus actinomycetemcomitans* and other periodon-

topathic bacteria by thorough subgingival mechanical cleaning, subgingival antimicrobial agents, intermittent use of systemic tetracyclines (typically doxycycline), and, when indicated, periodontal surgery and perhaps orthodontic movement of malaligned teeth.

Oral Mucosal Disease in Childhood

Oral mucosal disease in childhood principally encompasses lesions that manifest as ulcers, white or red patches, or pigmentation.[8]

Oral Mucosal Ulceration in Childhood. The causes of oral and gingival ulceration in childhood are summarized in Table 21-7.

Traumatic Ulceration. Traumatic ulceration in childhood tends to be due to physical trauma, for example, injury from a toothbrush or orthodontic appliance or accidents in the home or during play. The ulcers are usually solitary, arise at the site of trauma, and heal within about a week of removal of the cause. Traumatic ulceration of the gingivae, lips, or labial frena may be suggestive of physical abuse, particularly when accompanied by facial bruising, laceration, and bite marks.[8,64–66]

Radiotherapy to the mouth or chemotherapy can give rise to oral mucositis. The mucosa becomes red, painful, necrotic, and ulcerated. The cause of mucositis remains unclear; it may simply reflect damage to the basal cells of the epithelium or infection with gram-negative bacteria.[67] There is no specific treatment for oral mucositis, although the use of ice pops during radiotherapy or chemotherapy may lessen the severity of the ulceration, as may good plaque control.[67] Combination topical antifungal/antibacterial regimens (eg, polymyxin, tobramycin, and amphotericin) would seem to be of limited benefit in the treatment of oral mucositis.[68,69]

Infectious Causes of Mouth Ulcers in Childhood. Viral infections most commonly cause mouth ulcers in childhood. Details of these and other possible infections giving rise to oral mucosal ulceration are summarized in Table 21-7.

Recurrent Aphthous Stomatitis. The most common form of nontraumatic ulceration affecting the oral mucosa is recurrent aphthous stomatitis (RAS).[70,71] This condition is characterized by the presence of one or more oral ulcers, which heal within days or sometimes weeks, only to reappear at regular intervals. The associated constitutional effects may vary from minor discomfort from the ulcers themselves to, more rarely, a severely incapacitating illness caused by persistent oral ulceration. The overall prevalence of the condition is 20 to 30%, and it has been estimated that 30% of affected individuals have their first attack of ulceration by the age of 14 years, with 10% having ulcers before the age of 10 years. An associated family history has been demonstrated in 24 to 46% of cases, with a very high incidence in patients whose parents both suffered from the condition.[70] Furthermore, in a study carried out on twins, a 90% concordance between identical twins was found, in contrast to a 57% concordance between nonidentical twins.[72]

RAS may be subdivided into three distinct groups, largely on the basis of the clinical appearance and history of the individual lesions. All three types of RAS may be seen in children and are referred to as minor aphthous ulceration, major aphthous ulceration, and herpetiform ulceration.

Minor aphthous ulcers account for 80% of the total and are most common in patients between 10 and 40 years of age.[70] Ulcers of this type characteristically affect the nonkeratinized oral mucosa of the lips, cheeks, vestibule, and margins of the tongue. The hard palate, gingivae, and dorsum of the tongue are typically unaffected. The appearance of a painful ulcer is frequently preceded by a prodromal phase of 1 to 3 days, during which the patient may complain of a burning or pricking sensation accompanied by a degree of paresthesia at the site of future ulceration. The ulcers, which may occur alone or in groups of three or four during a single episode, usually last between 10 and 14 days but reach a maximum size at 4 to 5 days. Healing is complete, with no residual scarring, but recurrent episodes of ulceration tend to occur regularly at 1- to 4-month intervals. Individual ulcers are shallow, surrounded by an area of reddened mucosa, and vary in shape depending on the site.[73]

In major aphthous ulceration, the ulcers are much larger and more longer lasting than those seen in minor aphthous ulceration. They may appear singly or up to three or four at a time, are very painful, and give rise to extensive tissue destruction. Both keratinized and nonkeratinized oral mucosa may be affected, including the dorsum of the tongue and the oropharynx. Herpetiform ulcers occur with a frequency similar to that of major aphthous ulcers and may also affect the keratinized and nonkeratinized oral mucosa, typically of the floor of the mouth, lateral borders, and ventral surface of the tongue.[70–74] At the outset of an episode of ulceration, numerous discrete ulcers, approximately 1 to 2 mm in diameter, appear. These may later coalesce to form a single, large, painful lesion with a serpiginous outline. The ulcers usually heal within 10 days without mucosal scarring, although recurrent episodes of ulceration may supervene within days. Repeated attacks of this type may give rise to severe dysphagia.

There are no distinguishing histopathologic features. Microscopy reveals an appearance similar to that seen in cases of traumatic ulceration of the oral mucosa.[73] The epithelium shows no diagnostic features, and the underlying connective tissue is infiltrated with inflammatory cells, predominantly lymphocytes and plasma cells.

The precise etiology of RAS is not known. Although there are occasional family patterns of involvement, inheritance does not follow any mendelian patterns, and no particular human leukocyte antigen (HLA) haplotype is associated with RAS.[70,71] An infectious etiology also seems unlikely because patients do not have a raised frequency of past or present herpetic infections and associations with *Helicobacter pylori* have not been proven.[75–80] There are tenuous associations between RAS and psychological

stress, and no consistent pattern has been demonstrated between episodes of RAS and the menstrual cycle. No significant immunologic defects have been consistently detected in patients with RAS.[70,71]

Associations between RAS and gastrointestinal disease are tenuous. Certainly, a small number of patients with undiagnosed, or poorly managed, gluten-sensitive enteropathy (GSE) may have oral signs. Usually, up to 66% have superficial oral ulcers similar to those of RAS[81]; however, patients with RAS do not have a significantly increased likelihood of having clinical, serologic, or small bowel features of GSE, and the introduction of a gluten-free diet does not cause resolution of RAS.[82–89] Up to 20% of patients with RAS may have a hematinic deficiency, usually iron.[71,90] An underlying cause for these deficiencies is rarely found, and replacement therapy infrequently produces any cessation of RAS.[91,92]

A systematic review of the management of RAS is available (Table 21-8).[93] The investigation of patients with possible RAS should be focused on excluding other causes of acute bouts of ulceration (see Table 21-7), in particular the exclusion of an underlying hematologic or gastrointestinal disorder.[70,71]

All patients should be advised to use an oral hygiene procedure that is as atraumatic as possible, and all dental appliances should fit well and not damage tissue. The correction of any hematinic deficiency is of limited benefit unless the cause is corrected.[92] Topical corticosteroids remain the mainstay of RAS treatment in most countries, although there are few well-controlled studies of their precise efficacy.[93] A wide range of different topical corticosteroids may reduce symptoms.

Benzydamine hydrochloride mouthwash is of no more benefit on ulcer healing than placebo[94]; nevertheless, it (or lidocaine gel) can produce transient relief of pain.

Chlorhexidine used as a 0.2% w/w mouthrinse or 1% gel can reduce the duration of ulcers and increase the number of ulcer-free days.[95–98] Topical tetracyclines (eg, chlortetracycline, and tetracycline) may reduce healing times and/or reduce the associated pain of RAS,[99–102] but they may cause dysgeusia, oral candidiasis, and a burning-like sensation of the pharynx and are not suitable for young children, who might ingest them, with resultant tooth staining.

A variety of other topical agents have been suggested to be of some benefit in the management of RAS, but the supportive data are quite sparse. There have been several studies of the efficacy of amlexanox in the management of RAS, including one detailed randomized controlled study, suggesting that the 5% paste may significantly reduce the pain and time of healing of ulceration of RAS. [103–105]

Systemic immunosuppression is rarely warranted in view of the limited efficacy of topical agents and the sometimes profound pain and/or long-standing ulceration. However, although a variety of such agents have been proposed to be clinically useful, there is little supportive evidence.[93]

Thalidomide remains the most effective agent for the management of RAS, producing a remission in almost 50% of treated patients in one randomized controlled trial.[106] Open and double-blind studies of patients with HIV-related oral ulceration and in non–HIV-related RAS and several case studies confirm that thalidomide is of some clinical benefit.[106–114] Thalidomide gives rise to mild adverse side effects (particularly somnolence) in up to 75% of treated patients, and polyneuropathy can arise in about 5%. Clearly, the risk of teratogenicity also limits the clinical application of thalidomide in the management of RAS.

SYSTEMIC THERAPIES†
Systemic corticosteroids
Corticosteroid-sparing agents

*This is the only corticosteroid licensed for local oral application.
†Rarely warranted.

Behçet Disease. Behçet disease is clinically characterized by recurrent oral and genital ulceration together with a spectrum of cutaneous, ocular, neurologic, and other systemic manifestations. Although very uncommon in childhood, almost all affected children will have RAS-like oral ulceration.[115] The ulcers are clinically and histologically indistinguishable from those seen in RAS, and all three types of RAS may be seen in this closely related condition. The local management of oral ulceration in this condition is similar to that for RAS; however, as with adults, systemic therapies, including thalidomide, are often required.[116]

White Patches of the Oral Mucosa in Childhood. The causes of white patches of the oral mucosa in childhood are summarized, reflecting a wide spectrum of possible pathologies (Table 21-9).[81,117] In general, it is possible to consider white patches as being adherent and nonadherent, solitary and multiple. Common causes of oral white patch in children include material alba (food debris) and acute pseudomembranous candidiasis, although a variety of other disorders can manifest as white lesions of the mouth.

Infectious Causes of Oral Mucosal White Patches. ***Acute* Pseudomembranous *Candidiasis*.** The most common fungal infections seen in the oral cavity in children are caused by *Candida albicans*, which is commensal in the mouths of up to 70% of the general population.[118] Candidiasis may present in a variety of clinical forms but is, in all cases, an opportunistic infection caused by a change in the local or systemic host response. Although *C. albicans* remains the most common fungal commensal of the

mouth, there is arising frequency of non-*albicans Candida* species in the oral cavity, particularly in patients with HIV disease or poorly controlled diabetes mellitus or those receiving iatrogenic immunosuppression. In addition, these patient groups may be liable to carry and transmit azole-resistant fungal infections.[119–121]

Acute pseudomembranous candidiasis (thrush) may occur in the newborn but more typically occurs in children receiving broad-spectrum antibiotics or systemic corticosteroids or in those with some primary or secondary immunodeficiency states (eg, HIV disease). It manifests clinically as asymptomatic soft, creamy yellow areas raised above the surrounding mucosa, which leave a red bleeding surface when wiped off. The lesions may be multiple or a confluent mass and may affect all mucosal surfaces, particularly the soft and hard palate, tongue, and vestibule.

Diagnosis is usually based on the clinical picture and history, although, rarely, it can be confirmed by taking a smear of the material; a Gram or periodic acid–Schiff stain of the preparation reveals the typical branching hyphae of *Candida*. Depending on the severity and the underlying cause of the candidiasis, topical and/or systemic antifungal agents may be required, although the principal aim of management must be to find the underlying cause.[117,118]

Chronic Mucocutaneous Candidiasis. Chronic mucocutaneous candidiasis (CMC) is a group of rare immunodeficiencies characterized clinically by recurrent and/or persistent candidal infection of the skin and mucosae. At least four types of CMC have been described: diffuse CMC, sporadic CMC, candidiasis endocrinopathy syndrome, and late-onset CMC. Children with CMC can have widespread and/or recurrent oral pseudomembranous candidiasis, angular cheilitis, and chronic hyperplastic candidiasis. Children with hypoparathyroidism as part of candidiasis endocrinopathy syndrome may have enamel hypoplasia. Antifungal therapy is often difficult in CMC in view of the potential for the azole resistance of *Candida* to develop. Detailed discussions of CMC can be found elsewhere.[122,123]

Keratosis owing to smokeless tobacco
Carcinoma (very rare)
Multiple
Traumatic keratosis
Lichen planus
Oral hairy leukoplakia
Chronic mucocutaneous candidiasis
Others

Other Types of Candidal Infection. ***Acute Atrophic Candidiasis.*** Acute atrophic candidiasis is very occasionally seen in children and is the result of candidal overgrowth in patients being treated with broad-spectrum antibiotics or with immunosuppressive drugs. The mucosa is typically sore, inflamed, and sensitive to hot and spicy foods. Therapy with topical nystatin (eg, pastilles) or amphotericin may be warranted, but signs and symptoms usually resolve on cessation of the causative treatment.[117,118]

Chronic Atrophic Candidiasis. Chronic atrophic candidiasis, which has also been termed denture-associated candidiasis, is characterized by a red, inflamed mucosa and is precisely limited to the area covered by a well-fitting (usually upper) denture. The condition is often seen in children who are wearing a removable orthodontic appliance, with the area of inflammation confined to the mucosa covered by the acrylic base plate. Diagnosis is usually easily made from the clinical picture. Microbial culture for fungal infection is not warranted unless the child is immunocompromised, when non-*albicans Candida* species are most likely to occur. Treatment usually simply requires improving the hygiene of the appliance together with the application of antifungal gel (eg, miconazole) to the fitting surface of the appliance, as well as the administration of topical nystatin or amphotericin; systemic antifungal agents are rarely warranted.[117,118]

Angular Cheilitis. Angular cheilitis (stomatitis) presents as reddened folds at the corners of the mouth. Occasionally, there is ulceration. The lesions are usually colonized by *C. albicans* and/or *Staphylococcus aureus*. Although most commonly associated with a reduction in vertical face height in adult denture wearers, angular cheilitis in children may reflect the presence of an iron deficiency, neutropenia, malnutrition, or cell-mediated immunodeficiency, particularly HIV disease. Angular (and median) cheilitis may accompany the labial enlargement of Crohn disease and orofacial granulomatosis. The diagnosis is usually based on the clinical picture and history; microbiologic studies are usually neither warranted nor helpful. Miconazole gel is usually of some benefit in the treatment of angular cheilitis, although, of course, the underlying cause must be identified and corrected.[117,118]

Oral Hairy Leukoplakia. Oral hairy leukoplakia manifests as an adherent asymptomatic bilateral white patch on the lateral borders and dorsum of the tongue and sometimes the floor of the mouth. Caused by Epstein-Barr virus, this lesion almost always arises in immunosuppressed patients, typically those with HIV disease and individuals receiving long-term corticosteroids (including inhalers) or other immunosuppressants. Although caused by Epstein-Barr virus, it does not warrant any antiherpes intervention. The signs often wax and wane and may resolve if the immunosuppression lessens. This lesion is not potentially malignant.[124,125]

Potentially Malignant and Malignant Disease of the Mouth in Childhood

Oral squamous cell carcinoma is the most common malignant disease of the mouth. Although rare in children, it can still arise and may manifest as a solitary white patch (leukoplakia), speckled area, or ulcer. Any adherent white patch that does not appear to be due to trauma should be examined histopathologically to exclude the, albeit rare, possibility of malignancy.[126]

Human Papillomavirus Infection. Human papillomavirus manifests as warts or cauliflower-like white squamous papillomas. The lips, palate, and gums are the most commonly affected sites. The lesions are usually solitary and small, although in immunocompromised children (eg, those with HIV disease and iatrogenic immunosuppression), they can be multiple.[127] Heck disease (focal epithelial hyperplasia) presents as multiple white papular lesions. Most human papillomavirus infection of the mouth in children is not sexually associated. The lesions can be removed surgically or with cryotherapy, although topical interferon-β may be an alternative therapy.[128,129]

Lichen Planus. Oral lichen planus is common, affecting 1 to 2% of most populations. It typically arises in middle to late life and has a slight female predominance; nevertheless, disease can occasionally arise in children and young adults. Oral lichen planus gives rise to white patches that typically arise bilaterally on the buccal mucosa, dorsum of the tongue, and/or labial and buccal aspects of the gingival. The white lesions are generally asymptomatic, although patients occasionally report a roughness or dryness of the affected mucosal surfaces. Erosions and/or ulceration can arise within the white patches, giving rise to erosive and ulcerative lichen planus, respectively; these lesions can be notably painful, with symptoms being profound with hot, spicy, or acidic foods.[130]

Although lichen planus can be occasionally caused by drug therapy (eg, β-blockers, sulfonylureas[131]), oral lichen planus in children tends to be idiopathic. Rarely, oral lichen planus will be a complication of chronic graft-versus-host disease.

Unlike most other white patches of the oral mucosa, lichen planus does not give rise to solitary lesions; however, it is often advantageous to confirm the clinical diagnosis by histopathologic examination of lesional tissue.

Oral lichen planus only warrants treatment when lesions are erosive, ulcerative, or bullous, when topical corticosteroids are the mainstays of therapy (see Table 21-8).[130,132] Although there are no data, topical tacrolimus may be of benefit for the treatment of symptomatic oral lichen planus in children recalcitrant to topical corticosteroids.[133] Systemic immunosuppressive therapy is rarely warranted for the treatment of oral lichen planus in children or adults. The white lesions of oral lichen planus rarely resolve. It remains unclear if oral lichen planus has a malignant potential; however, in view of the related controversy,[130,134] careful lifelong clinical follow-up is advisable.

White Sponge Nevus. White sponge nevus is a rare autosomal dominant disorder of otherwise well children and adults. It gives rise to bilateral adherent white or gray thickened patches. Similar lesions may occur on the anal or vaginal mucosa. It is generally asymptomatic but may require histopathologic examination to exclude lichen planus.[135]

Oral Mucosal Pigmentation. Oral mucosal pigmentation in childhood is usually racial in origin, although a number of local and systemic disorders may give rise to various pigmented areas in the mouth.[8] Children may have localized nevi, which manifest as localized areas of hypermelanotic or blue pigmentation. Malignant melanoma is rare in the mouths of children[136]; however, when there is any doubt as to the cause of hypermelanotic lesions, histopathologic examination of lesional tissue should always be undertaken.

Amalgam tattoos are more common in adults but may arise in children, presenting as areas of blue macules or, less commonly, papules on the gingivae, floor of the mouth, or buccal mucosa. These lesions are harmless and asymptomatic.

Kaposi sarcoma is the most common oral malignancy of HIV in childhood. It manifests as a blue, red, or purple macule, papule, nodule, or ulcer, usually of the hard palate and/or gingivae. These tumors can be locally destructive and often reflect more widespread systemic involvement of the human herpesvirus 8–associated tumor; however, they may regress with effective highly active antiretroviral therapy (HAART). Similar, but less extensive, Kaposi sarcoma can occur in the mouths of children receiving long-term iatrogenic immunosuppressive therapy.[137]

Addisonian pigmentation manifests as diffuse hypermelanotic pigmentation of the buccal mucosa. More extensive pigmentation can occur but is uncommon. Other causes of oral mucosal pigmentation are indicated in Table 21-10.

Other Oral Mucosal Disorders in Childhood

Ankyloglossia (Tongue-tie). Ankylogossia is common, manifesting as an exaggerated lingual frenum that may limit the ability to protrude the tongue. It does not usually cause difficulties with speech development, although it can limit the ability to clean food debris and plaque from the teeth, gums, and vestibules of the mouth. Ankyloglossia requires simple surgical care.[8]

Abnormal Labial Frenum. The frenum of the upper or, less commonly, lower lip can be exaggerated, giving rise to a diastema (space) between the related central incisors. Children may have difficulty maintining good plaque control at this site. Surgical reduction, together with orthodontic care, will correct this common problem.[8]

Salivary Gland Disease in Childhood

Other than mumps, salivary gland disease in childhood is uncommon. Salivary gland disease may manifest as localized swelling (Table 21-11) and/or xerostomia (Table 21-12).[138]

TABLE 21-10 ORAL MUCOSAL AND GINGIVAL PIGMENTATION IN CHILDHOOD

GENERALIZED
Racial
Addison disease
Drugs (eg, minocycline)
Albright syndrome
Central cyanosis
Neurofibromatosis
Hemochromatosis
Incontinentia pigementi
Chronic hepatic disease (affects gingivae mainly)

HIV = human immunodeficiency virus.

Mumps (Epidemic Parotitis). Mumps is an acute generalized paramyxovirus infection of children and young adults. Mumps typically affects the major salivary glands, although involvement of other structures can occur, including the pancreas, testis, ovaries, brain, breast, liver, joints, and heart.[139]

Mumps is transmitted via the droplet route and has an incubation time of approximately 14 to 18 days. Patients manifest with initial pyrexia, chills, and facial pain. The parotid glands are typically bilaterally enlarged, although this may initially be unilateral. There is often swelling of the submandibular glands together with lymphadenopathy, giving rise to profound facial and neck swelling. Rarely, sublingual swelling may be so profound as to cause elevation of the tongue, dysphagia, and dysarthria. The salivary swelling tends to diminish after approximately 4 to 5 days and may precede more complicated aspects of illness.

Orchitis may develop approximately 4 to 5 days after the onset of parotitis. Typically, only one testicle is affected, and, occasionally, there can be bilateral involvement. Orchitis tends to arise in postpubertal boys and rarely gives rise to serious, long-standing disease.

TABLE 21-11 SALIVARY GLAND SWELLING IN CHILDHOOD

Mumps
Recurrent parotitis of childhood
Sjögren syndrome and related disorders
Acute suppurative sialadenitis
Duct obstruction (uncommon in children)
Sarcoidosis
Cystic fibrosis
Sialosis (rare—eg, with bulimia nervosa)
HIV disease
Hepatitis C virus disease
Mucoceles

HIV = human immunodeficiency virus.

Mumps can give rise to a lymphocytic or viral meningitis. This again commences a few days after the development of parotitis, although it can occur in the absence of salivary gland disease. Other neurologic manifestations include retrobulbar neuritis and encephalitis. Deafness is possible but rare. Pancreatic infection may give rise to mild upper abdominal pain, but acute and long-term complications are unusual. Likewise, although cardiac, hepatic, and joint infections can occur, they are rare and do not generally cause notable complications.

The diagnosis of mumps is typically based on the clinical picture; however, it may be confirmed by detection of viral-specific immunoglobulins G and A. Viral culture is possible but generally unnecessary because serologic methods are highly sensitive.

There is no specific treatment for mumps; analgesia and appropriate fluid intake are the mainstays of therapy. It has been suggested that corticosteroids may be effective for profound parotitis, but, generally, these are not required unless the patients have other systemic symptoms, such as orchitis. Mumps can generally be prevented with appropriate vaccination (mumps/measles/rubella).

HIV Salivary Gland Disease. Salivary gland disease can arise in 4 to 8% of adults and children with HIV infection. The salivary gland disease of HIV infection manifests as swelling and/or xerostomia and reflects underlying bacterial sialadenitis, intraparotid lymphadenopathy, primary or metastatic non-Hodgkin lymphoma, or Kaposi sarcoma.[138,140]

The specific disorder HIV salivary gland disease (HIV-SGD) gives rise to recurrent and/or persistent major salivary gland enlargement and xerostomia. The parotids are most frequently affected; often there is profound bilateral enlargement. Salivary gland disease tends to arise in late HIV infection, although, occasionally, it can be the first manifestation of HIV disease. It may be associated with HLA-DR5 and is part of a more generalized disorder

TABLE 21-12 CAUSES OF LONG-STANDING XEROSTOMIA IN CHILDHOOD

Sjögren syndrome and related disorders
Sarcoidosis
Cystic fibrosis
HIV disease
Hepatitis C virus disease
Drugs
Anticholinergics
Antihistamines
Tricyclic antidepressants
Serotonin reuptake
Sympathomimetics
Phenothiazines
Occasional cytotoxic drugs
Radiation of the head and neck
(when the salivary glands lie within the field of radiation)
Chronic graft-versus-host disease
Dehydration (hypercalcemia, diabetes mellitus)
Anxiety
Depression
Salivary gland agenesis

HIV = human immunodeficiency virus.

termed diffuse infiltrated lymphocytosis syndrome, which is characterized by CD8+ T-cell infiltration of the lungs, salivary glands, and lacrimal glands.[138,140]

The clinical picture of HIV-SGD mimics that of Sjögren syndrome; however, there are distinct histopathologic and serologic differences between the two disorders. Patients with HIV-SGD generally do not have anti-Ro or anti-La antibodies, but they do have hypergammaglobulinemia.

The diagnosis of HIV-SGD is similar to that of Sjögren syndrome. Fine-needle aspiration biopsy may be particularly useful because it allows rapid exclusion of malignancy.[141]

There is little information regarding the specific management of HIV-SGD. The clinical signs of HIV-SGD are usually nonprogressive; hence, therapy is indicated only if there is notable cosmetic deformity or xerostomia. HAART will, at least in the short term, cause resolution of the swelling of HIV-SGD. Less practical, suggested therapies are repeated aspiration, tetracycline sclerosis, or surgical removal of an enlarged gland.[142] External radiation may cause transient improvement, although there are no data on the effectiveness for affected children.[143] Xerostomia independent of HIV-SGD may arise in HIV infection as a consequence of some nucleoside analog HIV reverse transcriptase inhibitors or protease inhibitors (see below).[144]

Hepatitis C Virus Infection. Although there are no data specific to children, it would be expected that hepatitis C virus (HCV) infection would give rise to HCV-related sialadenitis, which manifests as salivary gland enlargement and xerostomia. The histopathologic features of HCV-associated sialadenitis are similar to those of Sjögren syndrome, although the two disorders are etiologically distinct.[138]

Suppurative Sialadenitis (Suppurative Parotitis). Acute suppurative sialadenitis is an uncommon disorder characterized by painful swelling, usually of parotid glands (suppurative parotitis), purulent discharge from the duct of the affected gland, associated dysgeusia, and cervical lymphadenopathy. When disease is severe, there may be accompanying pyrexia, malaise, and a risk of abscess formation and parapharyngeal space infection, including Ludwig angina.

Acute suppurative sialadenitis can arise in childhood (prematurity being a possible risk factor), and sialadenitis can occur in newborns.[145] The highest incidence of childhood disease seems to arise in children aged 3 to 6 years of age.[146] Aseptic sialadenitis has been observed in preterm children receiving long-term orogastric tube feeding. Immunodeficiency and concurrent illness may predispose children to suppurative parotitis.

The causative organism of acute suppurative sialadenitis is often not found. Although facultative anaerobes, particularly *S. aureus* and *Streptococcus viridans*,[147,148] have frequently been reported to be of etiologic significance, a wide range of other bacteria have been implicated.

The diagnosis of acute suppurative sialadenitis is based on the history and clinical picture. Microbiologic culture of pus, under both aerobic and anaerobic conditions, may reveal likely causative agents, although specific relevant tests may be useful if a particular infection seems likely. Additional investigations such as sialography and scintigraphy are rarely warranted, although ultrasonography can be useful, particularly because abscess formation is likely, as can magnetic resonance imaging.

Effective hydration and antibiotics are the mainstays of therapy of uncomplicated acute suppurative sialadenitis.[149] Typically employed antibiotic therapies are antistaphylococcal penicillins (eg, flucloxacillin, amoxicillin, or amoxicillin-clavulanate), cephalosporins, or clindamycin, although the precise choice of antibiotic will often depend on any likely causative organism that is identified. Other alternatives may include flurithromycin. Intraductal injection of antibiotics is unlikely to be of practical benefit. Surgical drainage should be considered if there is a lack of clinical improvement after 3 to 5 days of antibiotic therapy, any unlikely facial nerve involvement, any involvement of deep fascial spaces, or abscess formation within the parenchyma of the gland.[149] Superficial parotidectomy may be required if disease becomes recurrent or chronic.[149,150]

Recurrent Parotitis of Childhood. Recurrent parotitis of childhood (juvenile recurrent parotitis) gives rise to recurrent parotid inflammation, usually associated with nonobstructive sialectasia of the parotid gland. Recurrent parotitis can arise at any age, but the usual age at onset is 3 to 6 years. The disease is characterized by localized pain and swelling, which may last up to 14 days. Fever and overlying erythema are common, and occasionally white mucopus can be expressed from the parotid duct. Recurrent parotitis of childhood tends to be unilateral rather than bilateral. The number of attacks varies from 1 to 5 per year, but some patients may have up to 20 episodes of swelling per year. The frequency of recurrence tends to peak between 5 and 7 years of age, and up to 90% of patients have resolution of disease by puberty.

Sialography and ultrasonography reveal sialectasia. This feature can also be observed in nonaffected glands of the opposite side.

The precise etiology of recurrent parotitis of childhood is unknown. There is no evidence that viral infection underlies this disorder. Analgesia is the mainstay of therapy. Antibiotics do not shorten attacks. In general, the disease tends to resolve, and there is no need for profound surgical intervention.[151]

Long-standing Xerostomia (Dry Mouth). Long-standing xerostomia gives rise to a range of disorders of the oral hard and soft tissues (Table 21-13). Xerostomia can give rise to dysarthria and dysphagia. The oral dryness leads to retention of food on the teeth, mucosa, and gingiva and thus increases the frequency of caries (particularly cervical disease) and acute gingivitis. There is an increased liability to candidal infection, notably acute pseudomembranous candidiasis, and median rhomboid glossitis, chronic atrophic candidiasis (denture-associated stomatitis), and angular cheilitis. Long-standing xerostomia increases the liability to acute suppurative parotitis (see above). The poor salivary output can lead to dysgeusia and loss of taste; many affected persons report that most foodstuffs taste "cardboard-like."[138]

TABLE 21-13 CLINICAL FEATURES OF LONG-STANDING XEROSTOMIA

SYMPTOMS
Oral dryness
Dysarthria
Dysphagia
Loss of taste (often blunting of taste of all foods)
SIGNS
Dryness of the oral mucosa
Variable lack of saliva
Depapillation, redness, and crenation of the dorsum of tongue (scrotal tongue)
Loss of upper denture retention
Increased liability to gingivitis
Increased liability to dental decay (eg, cervical caries)
Increased liability to bacterial sialadenitis (usually of the parotid glands)

Xerostomia is more common in adults than in children; however, children are clearly more likely to manifest the features of salivary gland agenesis than adults and can also be liable to the common causes of acquired salivary gland dysfunction disease.

Salivary Gland Agenesis. Agenesis of one or more of the major salivary glands is extremely uncommon. There can be variation in the number of absent salivary glands and hence varying severity of the associated xerostomia. Lack of saliva predisposes the patient to dental caries, gingival inflammation, candidiasis, and acute suppurative sialadenitis, although, in children, rampant dental caries may be the only initial sign of underlying salivary agenesis.

The precise incidence of major salivary gland agenesis is difficult to establish owing to the asymptomatic nature of many affected individuals. Familial clustering of salivary gland agenesis has occasionally been reported. Salivary gland aplasia may occur in isolation or be associated with other ectodermal defects, in particular lacrimal apparatus abnormalities. Associations with hypohidrotic ED and lacrimal-auriclodentodigital and ectodactyly-ED syndromes have been reported.[152]

Radiotherapy-Associated Salivary Gland Dysfunction. Brachytherapy of head and neck malignancies can cause profound xerostomia and salivary gland acinar destruction when the radiotherapy is directed through the major salivary glands. The degree of xerostomia clearly reflects the duration and dose of radiotherapy. The xerostomia is irreversible and thus can greatly affect the quality of life of affected children.[138] In adults, orally administered pilocarpine may lessen the severity of radiotherapy-induced xerostomia; however, there are no studies of the effectiveness of this cholinergic agent in children with radiotherapy-associated xerostomia. As a consequence, the treatment of long-term oral dryness in children is not specifically directed to enhancing cholinergic stimulation of the salivary glands.[138]

Sjögren Syndrome. Sjögren syndrome is characterized by xerostomia and xerophthalmia owing to profound lymphocytic infiltrate into the salivary and lacrimal glands.[153] Sjögren syndrome can be classified as primary disease, of which there are only symptoms and signs affecting the eye and mouth, and secondary Sjögren syndrome, in which there is xerostomia, xerophthalmia, and associated connective tissue disorder, most frequently rheumatoid arthritis or systemic lupus erythematosus.

Although possibly the second most common connective tissue disorder in adults, Sjögren syndrome is an uncommon disorder of childhood. The etiology of Sjögren syndrome remains unknown. A viral etiology—human retrovirus 5—was proposed but now seems unlikely; nevertheless, a viral basis cannot be excluded because the salivary features of human T lymphotropic virus 1, HCV, and HIV infection mimic those of Sjögren syndrome. To date, there is no evidence of a strong genetic basis for Sjögren syndrome. The pathogenesis of Sjögren syndrome is discussed in detail elsewhere.[154] The investigation of Sjögren syndrome centers on a series of clinical, radiologic, and immunologic tests,[154] of which the histopathologic examination of labial gland tissue and the detection of serum anti-Ro and/or anti-La antibodies are cardinal. The management of the oral complications of Sjögren syndrome is similar to that outlined in Table 21-14.[138] In addition, pilocarpine and other similar agents (eg, cevimeline) may enhance salivary flow. At present, no immunologically based approach has been successful for the treatment of Sjögren syndrome other than perhaps hydroxychloroquine. All children with confirmed Sjögren syndrome will require lifelong specialist follow-up to ensure the early detection of possible non-Hodgkin lymphoma, particularly mucosa-associated lymphoid tissue lymphoma.

MINOR SALIVARY GLAND DISEASE OF CHILDHOOD: MUCOCELES

Mucoceles are common, presenting as single blue or translucent sessile swellings on the lower lip. The swelling may rupture to release a viscid salty mucus. Mucoceles occur in both genders and in all age groups, and the peak age of incidence is between 10 and 29 years. They are rare in infants, although they can occur in neonates. The lateral

TABLE 21-14 MANAGEMENT OF LONG-STANDING XEROSTOMIA

THERAPY	COMMENTS
SALIVARY SUBSTITUTES	
Nonsynthetic agents	Sips of water; convenient but of limited benefit. Soft drinks should be avoided in view of the risk of caries or dental erosion.
Synthetic agents	A variety of sprays, mouthrinses, and gels are available; no one agent is better than another; benefit can be transient.
SALIVARY STIMULANTS (SALOGOGUES)	
Nonspecific	Nonsucrose confectionary can be of benefit, but there may still be a risk of dental erosion. Sorbitol-containing pastilles may be helpful.
Specific	Pilocarpine (and possibly cevimeline) may be of application, but there are no detailed studies of their application in children with long-standing xerostomia.
Oral hygiene care and dietary advice	Minimized risk of caries and gingivitis
Fluoride supplements	Reduces risk of caries

aspect of the lower lip is the most common site of recurrence of mucoceles, but other common sites include the floor of the mouth and ventrum of the tongue. The majority of mucoceles are extravasation type, in which duct damage causes pooling of mucus in the adjacent connective tissue. Retention mucoceles, the less common variant, arise after partial or complete obstruction of the excretory duct (eg, a sialolith), leading to retention of glandular secretions and dilation of the duct. Extravasation mucoceles may be more frequent in young patients, whereas retention mucoceles may occur most often in middle to late life.

Some mucoceles may resolve spontaneously, but large, recurrent, or unsightly mucoceles often require surgical excision or are removed by laser or cryotherapy. Other therapies of less well-proven efficacy include intralesional corticosteroid injections and γ-linolenic acid (oil of evening primrose).[155]

ORAL ASPECTS OF GASTROINTESTINAL DISEASE OF CHILDHOOD

Dietary and Related Disease

Dental caries is the most common diet-related disease of the mouth.[27] The clinical aspects of dental caries are detailed previously and are also reviewed elsewhere.[28–31] Although the prevalence of dental caries may be falling in some communities (particularly in areas of water fluoridation), erosion of the dentition in childhood, as a consequence of the increasing consumption of low-sugar, low-pH carbonated drinks. The details of dental erosion are discussed above and are reviewed elsewhere.[156,157]

Malnutrition. Malnutrition gives rise to gingival and oral mucosal disease but seems to have little impact on tooth structure or eruption.[158] Profound malnutrition in childhood, particularly in areas of political unrest and economic poverty, such as some African states,[159–161] gives rise to severe ANUG (see previously) and later necrotic ulceration and loss of orofacial skin and muscles, when the descriptive term noma or cancrum oris is applied.

Vitamin C Deficiency. Profound vitamin C deficiency may give rise to gingival enlargement. In addition, the gingivae are friable and bleed easily, often spontaneously.[162] Although appropriate vitamin C supplements will resolve these gingival lesions, there is no evidence that vitamin C supplementation is of clinical benefit in the management of plaque-related gingival or periodontal disease.[163]

Hematinic Deficiencies. Anemia secondary to any hematinic deficiencies gives rise to superficial ulceration of the nonkeratinized (mobile) oral mucosa. Deficiencies of iron, vitamin B_{12}, and folate also predispose the patient to angular stomatitis (cheilitis) and glossitis, the latter manifesting as a sore, erythematous, and smooth tongue.[8] Vitamin B_{12} deficiency rarely gives rise to linear erythematous patches of the dorsum of the tongue, sometimes termed Moeller glossitis. Vitamin B_{12} deficiency, sometimes in the absence of anemia, may cause lingual dysesthesia. It has been suggested that deficiencies of vitamin B_1, B_2, and B_6 give rise to angular stomatitis and/or oral dysesthesia; however, much of these data is unsubstantiated.[164] Longstanding iron deficiency in CMC may give rise to a glossitis and postcricoid webbing akin to Paterson–Brown Kelly (Plummer-Vinson) syndrome in late childhood.[123]

Zinc Deficiency. Zinc deficiency in acrodermatitis enteropathica may cause oral mucosal ulceration and angular stomatitis, but, in general, zinc deficiency does not give rise to oral disease. A link between erythema migrans (geographic tongue) and zinc deficiency is controversial; certainly, there are no data showing that children with erythema migrans are zinc deficient or benefit from zinc supplementation.[165]

Hypocalcemia. The hypocalcemia of GSE may give rise to hypocalcification of the deciduous and permanent dentitions, manifesting as areas of whiteness and brown staining of enamel.[166,167] In mild hypocalcemia, the crown shape is not affected, although when there is severe hypocalcemia, there may be pitting of the enamel.[168,169] The hypocalcified enamel is particularly liable to dental caries. Hypocalcemia secondary to autoimmune hypoparathyroidism in candidiasis endocrinopathy syndrome may also give rise to enamel hypoplasia, usually of the permanent dentition.[123,170,171]

Fluorosis. Excess fluoride intake, either as a consequence of drinking water with a naturally high fluoride concentration (greater than 0.03–0.04 ppm; eg, in certain areas of Southeast Asia and South and North America)[172] or following excess ingestion of fluoride supplements (eg, in toothpaste or fluoride tablets), will cause some staining of the enamel of developing teeth.[173,174] Fluorosis most commonly affects the permanent dentition, although in areas where there is endemic fluorosis, the deciduous teeth will also be affected. Mild fluorosis presents as chalky white patches of the enamel of otherwise normal teeth, more severe disease manifests with intrinsic brown staining of the enamel, and severe fluorosis gives rise to brown pitting, mottling, and brittleness of the enamel. As expected, the enamel associated with fluorosis is less liable to dental caries than normal enamel, although in severe fluorosis, the pitting and mottling can lead to unusual patterns of dental decay, for example, on the smooth surfaces of teeth. Other causes of intrinsic staining of the teeth in childhood have been discussed.

Anorexia and Bulimia Nervosa. As a consequence of resultant anemia, patients with long-standing anorexia nervosa or bulimia nervosa often develop oral mucosal ulceration.[175] In bulimia nervosa, the trauma of a patient's finger scraping over the palate may cause traumatic ulceration, palatal petechiae, and, rarely, necrotizing sialometaplasia.[138]

The acidic reflux of bulimia nervosa causes erosion of the deciduous and permanent dentition. The erosion particularly affects the posterior teeth and the palatal aspects of the upper anterior teeth; both the deciduous and the permanent dentitions can be affected.[42,176,177] The reflux of the acidic gastric contents may cause painless bilateral enlargement of the parotids without xerostomia, sometimes termed sialosis.[178,179]

Tylosis. Tylosis gives rise to extensive areas of leukoplakias of the oral mucosa. However, in contrast to the esophageal disease of tylosis, the oral lesions are not potentially malignant.[180]

Disease of the Small Bowel and Related Structures

Gluten-Sensitive Enteropathy. A minority of children (probably about 3%) with undiagnosed or poorly controlled GSE can develop superficial oral ulceration, usually of the nonkeratinized oral mucosa,[181,182] although up to 60% of patients with GSE can have some symptoms (see previously). As discussed previously, it has been suggested that RAS may reflect undiagnosed GSE, but supportive data are lacking; for example, few patients with RAS have histopathologic or immunologic features suggestive of GSE and few have resolution of the ulceration of RAS following instigation of a gluten-free diet. Additional oral features of GSE in childhood include glossitis and angular stomatitis secondary to hematinic deficiencies and enamel hypoplasia as a consequence of long-standing hypocalcemia.[167–169,183,184] Children with dermatitis herpetiformis may have the dental defects of GSE.[185] Chronic bullous disease of childhood may also give rise to vesiculobullous disease of the mouth, although it is rarely associated with gastrointestinal lesions.[186–188] Long-standing dapsone therapy for dermatitis herpetiformis can cause methemoglobinemia, which manifests as blue pigmentation of the tongue.

Cystic Fibrosis. Tetracycline staining of the teeth is the most likely oral feature of cystic fibrosis. As discussed previously, the degree of staining depends on the age at which therapy was given, the duration of treatment, and the type of tetracycline provided. The staining can vary in color from yellow to gray and may range from mild banding to profound discoloration of the complete enamel surface.[189,190] The tetracycline staining does not influence the risk of dental caries, although, interestingly, the areas of tetracycline deposition will fluoresce under ultraviolet light. Minocycline causes profound melanotic hyperpigmentation of the oral mucosa, which can mimic addisonian pigmentation.[191,192] Cystic fibrosis rarely gives rise to other oral lesions. Enlargement of the submandibular, but not the parotid, glands has been reported, and although sialochemical changes do occur, there is no evidence that patients develop profound xerostomia.[193] One report suggested that patients with cystic fibrosis may be liable to calculus formation, but this has never been fully substantiated.[194] Patients may have oral malodor, a predisposition to mouth breathing, and anterior open-bite.[190] Central cyanosis will give rise to blueness of the oral mucosa and gingiva. Some pancreatic supplements may cause oral mucosal ulceration, and a low-fat, high-carbohydrate diet potentially increases the liability to dental caries. Vitamin K deficiency may predispose the child to spontaneous gingival bleeding.

Peutz-Jeghers Syndrome. Peutz-Jeghers syndrome rarely gives rise to oral features per se. There is, however, notable circumoral melanosis manifesting as discrete brown to bluish black macules. Almost all patients have lesions on the lips, particularly the lower lip.[195,196]

Large Bowel Disease

Ulcerative Colitis. There are few detailed descriptions of the oral manifestations of ulcerative colitis in childhood. Oral pyostomatitis vegetans is probably more likely in ulcerative colitis than in Crohn disease and manifests as multiple small, ragged, superficial pustules and ulcers or fissures of the reflected mucosa of the lips (usually upper), soft palate, and buccal mucosa. The course of the oral pyostomatitis vegetans may follow that of the bowel disease.[197–207] Other oral manifestations of ulcerative colitis include superficial ulceration related to hematinic deficiency. There are no reports of oral pyodermia gangrenosum in children with ulcerative colitis, although oral pemphigus vulgaris developed in one child with inflammatory bowel disease.[208] Children will be liable to corticosteroid-induced acute pseudomembranous candidiasis and immunosuppression-related oral hairy leukoplakia (see previously).

Gardner Syndrome. Gardner syndrome commonly affects the mouth, with up to 69% of patients, usually by adolescence, having clinical or radiologic evidence of oral lesions.[209–215] Multiple odontomes and/or supernumerary teeth are common, causing delayed or failed eruption of the permanent teeth, resulting in malocclusion and dentigerous cyst formation. Osteomas occur on the mandible and maxilla.

Crohn Disease and Orofacial Granulomatosis. A detailed review of the oral features of Crohn disease and the differentiation of Crohn disease from orofacial granulomatosis may be found elsewhere.[216–218] For the purposes of this chapter, the two disorders are regarded as almost synonymous. In Crohn disease, oral lesions can predate the more common ileal disease.

Crohn disease may give rise to persistent and/or recurrent lip swelling of one (typically the lower) or both lips. The persistent enlargement may give rise to angular stomatitis and median fissuring, both features presumably being exacerbated by any accompanying iron or vitamin B_{12} deficiency. In early disease, the epithelium of the swelling lip may tear, giving rise to a ragged appearance. The buccal mucosa can become swollen, giving rise to a cobblestoned appearance.[218–223]

Affected children may develop ragged, deep ulcers, particularly of the labial vestibules, although similar lesions can occur on other mobile oral mucosal surfaces. The ulcers may have a rolled margin and/or be associated with mucosal tags. Crohn disease may also give rise to superficial oral mucosal ulceration secondary to hematinic deficiencies. Pyostomatitis vegetans and epidermolysis bullosa acquisita are rare possible oral features of Crohn disease in childhood.

Oral mucosal tags rarely occur in the mouth, and fistula formation in the mouth is possible but has rarely been reported in childhood Crohn disease.

The gingivae, particularly the attached tissues, can become enlarged. This swelling is unrelated to plaque-related gingival disease. There have been reports of periodontal destruction in a small number of patients with Crohn disease, the exact cause of which remains unclear but is unrelated to the gingival features of Crohn disease.[224]

Some child patients with Crohn disease may have a fissured tongue, and, rarely, patients may develop a lower motoneuron palsy of the facial nerve. The term Melkersson-Rosenthal syndrome is sometimes applied to the combination of orofacial swelling, facial nerve palsy, fissured tongue, and mucosal swelling.[225]

Taste abnormalities have been described in adults with Crohn disease, but it is unclear if this is likely in children.

Other potential oral features of Crohn disease include acute pseudomembranous candidiasis secondary to prednisolone therapy and Epstein-Barr virus–induced oral hairy leukoplakia in long-standing immunosuppressive therapy.[124]

Orofacial granulomatosis may, in some instances, represent an intolerance to food additives; hence, appropriate patch testing and elimination diets may occasionally be helpful in the management of some affected patients.[226–228] However, immunosuppressive regimens similar to those of ileal Crohn disease are probably the mainstays of treatment of orofacial granulomatosis. Systemic thalidomide can cause resolution of all of the oral features of orofacial granulomatosis,[229] but relapse may occur on cessation of therapy.

Hepatic Disease

Kernicterus can cause intrinsic yellow staining of the teeth,[8,230,231] although in erythropoietic porphyria, the teeth can be stained orange or red.[51,52] The hyperbilirubinemia and hyperbiliverdinemia of biliary atresia may give rise to yellow or green pigmentation of the gingival margins.[232,233] Severe primary biliary cirrhosis may give rise to spontaneous gingival bleeding. In addition, primary biliary cirrhosis may be associated with secondary Sjögren syndrome with resultant xerostomia.[234]

Penicillamine therapy in primary biliary cirrhosis may cause a lichenoid drug reaction in the mouth that is clinically identical to idiopathic lichen planus. Long-term cyclosporine therapy following liver transplant commonly gives rise to gingival enlargement. The degree of enlargement does not always correlate with cyclosporine dose or plasma levels and may not relate to the patient's oral hygiene status.[235] Median rhomboid glossitis and oral hairy leukoplakia can also arise with long-term cyclosporine (and probably tacrolimus therapy). Aspects of viral hepatitis are discussed above.

CHAPTER 22

CONGENITAL ANOMALIES

Jonathan E. Teitelbaum, MD

Congenital anomalies of the mouth and esophagus are relatively common. The majority of these anomalies are readily apparent at birth or, in many cases, can be appreciated on prenatal ultrasonography. Increasing knowledge of the embryologic events that result in the normal development of these structures has led to the identification of various genes and gene products that help to orchestrate these events. With that, there has been a rapid advancement in identifying various genetic mutations that result in abnormalities of development and subsequent syndromic and nonsyndromic presentations.

These malformations are associated with various clinical presentations. Whereas some allow patients to be asymptomatic, others can cause difficulties in feeding or articulation or life-threatening respiratory difficulties. More complex malformations often require multidisciplinary teams, including surgeons (general, otolaryngologic, orthodontic), gastroenterologists, speech pathologists, and geneticists.

FACIAL CLEFTS (CLEFT LIPS AND PALATES)

Oral clefts are among the most common of all birth defects, second only to clubfoot. Cleft lip with or without cleft palate (CL[P]) occurs with an incidence of 1 in 500 to 1 in 2,500 in different populations based on ethnic group, geographic location, and socioeconomic conditions.[1] The highest incidence is among Native Americans (3.6 in 1,000 live births), whereas among blacks, it is less (0.3 in 1,000 live births). Whites have an incidence of 1 in 1,000 live births. Defects are unilateral in 80%.[2]

Isolated cleft palate (CP) occurs in approximately 1 in 2,000 live births, and there is little to no racial preponderance.[2] CL(P) is more common in boys, whereas CP is seen more commonly in girls. The cause is likely multifactorial disruption of embryologic morphogenesis.[2] Higher birth order may also be a risk factor for CL(P) and CP. However, studies are not conclusive and may be confounded by other factors, such as advanced maternal or paternal age or increased exposure to teratogens, which, in themselves, may be risk factors.[3]

The risk of having subsequent children with clefts is different for those with CL(P) from those with CP. When both parents are unaffected and have an affected child, the risk of recurrence is 4.4% for CL(P) and 2.5% for CP. If one parent is affected, the risk is increased to 15.8% for CL(P) and 14.9% for CP. If two children are affected and the parents are unaffected, the risk for a third child is 9% for CL(P) and 1% for CP.[2] Concordance among monozygotic twins ranges between 40 and 60%, whereas it is 5% among dizygotic twins. The lack of 100% concordance rates among monozygotic twins argues against genetic events alone being responsible for the clefting phenotype.[4]

Cleft lip is a unilateral or bilateral gap in the upper lip and jaw, which form during the third to seventh week of embryologic development.[1] The incisive foramen divides the hard palate into a primary and secondary palate. The primary palate lies anterior to the incisive foramen and includes the bony premaxilla, mucoperiostal covering, and incisor teeth. The secondary palate is posterior to the incisive foramen and is composed of the horizontal plates of the maxilla and palatine bone. The remaining dentition arrives from the secondary palate. Primary palate formation begins at 4 to 5 weeks gestation with the fusion of the paired median nasal prominences. This marks the separation of the oral and nasal cavities. Ultimately, the median nasal prominences give rise to the dental arch, incisor teeth, and philtrum of the upper lip. Formation of the secondary palate (hard and soft) begins at approximately the seventh week of gestation. The posterior maxillary prominences form palatal shelves, which rotate inferiorly and medially to fuse with the vomer in the midline. Anterior to posterior palatal closure occurs in a zipper-like fashion. At 9 weeks gestation, the hard palate fuses with the septum to complete the separation of the oral and nasal cavities. The soft palate is composed of five paired muscles: tensor veli palatini, levator veli palatini, palatoglossus, palatopharyngeus, and musculus uvulae. Midline approximation of the soft palatal musculature marks the completion of palatogenesis at approximately 12 weeks gestation.[2]

The multifactorial inheritance model is currently the most widely accepted theory of nonsyndromic clefts. In this model, the risk of developing a given anomaly is determined by the presence of either genetic or environmental liabilities. Each liability occurs in a normal distribution within the population. The accumulation of multiple small liabilities eventually reaches a threshold, beyond which a defect occurs. Variable penetrance of the phenotype for many genes results in nonmendelian inheritance patterns.

An estimated 300 syndromes include CL(P) in their phenotype; however, syndromic clefts account for only 30% of CL(P).[1] The proportion of patients with CP who

are syndromic versus nonsyndromic remains unresolved, with estimates varying widely, between 15 and 80%.[1] Approximately 25% of syndromic clefts are associated with Stickler syndrome, whereas another 15% are associated with velocardiofacial syndrome.[2] The most common malformations in association with clefts are found in the central nervous system and the skeletal system, followed by the urogenital and cardiovascular systems.[5] Various syndromes associated with CP (Table 22-1) and CL(P) (Table 22-2) have been described.

Defects in the *PVRL1* gene (chromosome 11q23) result in abnormal formation of nectin 1, a cell-cell adhesion molecule expressed in the developing face and palate that is essential for fusion of the medial edge epithelia. A 50% reduction in the amount of nectin 1 appears to be a risk factor for nonsyndromic CL(P) in patients on Margarita Island and Venezuela.[1] A similar gene, *OFC3*, on chromosome 19q13 has also been implicated in nonsyndromic CL(P) based on genetic linkage studies. Other candidate genes include *OFC1* (6p24.3), *OFC2* (2p13), *TP63* (3q27), *MSX1*(4p16.1), *TGFA* (2p13), *TBX22*,[1] *PGD1* (1p36),[6] methylenetetrahydrofolate reductase (1q36),[6] and *TGFalpha* (2p13).[6]

The role of teratogens in the formation of clefts has been supported by studies suggesting causation associated with maternal exposure to corticosteroids, phenytoin, valproic acid,[4] thalidomide,[4] alcohol,[4] cigarettes,[4] dioxin,[4] or retinoic acid; maternal diabetes mellitus; maternal hormone imbalance; and maternal vitamin deficiency. However, there is no consensus that any particular teratogen or environmental factor is implicated in most clefts.[1] Folic acid may have a protective effect to reduce the risk of clefting.[6]

Prenatal diagnosis allows for early parental counseling. Current technology can detect CL(P) at gestational week 15 because the soft tissues of the fetal face become distinct to transabdominal ultrasonography.[5] During the second trimester, ultrasonography detects less than 20% of cases of isolated CL(P) and far fewer cases of isolated CP.[5] However, syndromic CL(P) is detected at 38%, perhaps because a more detailed scan is undertaken given the associated anomalies, or because these clefts are larger and more readily visualized. Optimum timing for diagnosis is regarded as 20 to 22 weeks gestation. The ability to see the defect is influenced by the position of the fetus, position of an overlying hand or umbilical cord, maternal obesity, multiple pregnancies, oligohydramnios, and the experience of the technician. The use of transvaginal ultrasonography and three-dimensional ultrasonography also increases the sensitivity and specificity of the test.[2]

Initial evaluation of a patient with CP should include prenatal care, birth history, teratogen exposure, and a family history of clefting or syndromes. A multidisciplinary team is often helpful in assessing the family's medical and psychosocial needs. The cleft team should consist of a surgeon, otologist, audiologist, dentist (orthodontist or oral surgeon), social worker, geneticist, pediatrician, nutritionist, and speech pathologist. Breastfeeding is possible in some patients with a short or narrow cleft. Infants with larger clefts can rarely generate adequate suction for traditional breast- or bottle feeding. Various specialized nipples have been created to facilitate feeding. Feeding typically takes longer, and frequent burping may be required in these infants because they often swallow large amounts of air. Infants should be weighed on a weekly basis initially to ensure adequate intake.[2]

Palatal clefting disrupts all layers of the normal palate architecture, including mucosa, muscle, and bone. The muscles of the soft palate must wrap anteriorly and insert

on the cleft margin or the posterior palate. Aberrant tensor veli palatini insertion results in eustachian tube dysfunction, so nearly all CP patients will have chronic otitis media requiring myringotomy tube placement. Abnormal insertion of the levator veli palatini results in loss of normal velopharyngeal competence.[2]

CP may be classified as primary or secondary, complete or incomplete, unilateral or bilateral, or submucous. Primary CP results in incomplete closure of the hard palate anterior to the incisive foramen, whereas secondary CP results in a midline defect posterior to the incisive foramen. Secondary clefts appear to be distinct genetic entities, unrelated to cleft lip but often associated with Pierre Robin sequence (PRS). Complete CP involves the primary secondary and soft palate and is usually associated with cleft lip. Submucous CP results from inadequate development of the muscles of the soft palate without disruption of the mucosa. They can characteristically include a bifid uvula, dehiscence of the central palatal musculature (may be palpable or result in bluish discoloration in the midline, termed a zona pellucida), and loss of the posterior nasal spine.[2]

Presurgical orthopedic techniques are used to modify the shape of the cleft deformity before definitive cleft repair. These increase the ease of the primary repair, normalize facial growth, and prevent alveolar collapse. Active techniques include finger massage, lip taping and strapping, and oral prosthetics. Passive techniques are aimed at inhibiting tongue protrusion between the palatal shelves by using oral obturators. Although these techniques have been shown to effectively narrow the distance between alveolar segments, no differences in esthetic outcome, need for revision surgery, or improvement in feeding have been prospectively demonstrated.[2]

Palatoplasty aims to separate the oral and nasal cavities and restore velopharyngeal competence. An aggressive approach must be balanced with the risk of maxillary growth disturbance.[2]

Although 90% of patients with a cleft lip have repair between 3 and 6 months of age,[7] the timing of CP repair is controversial. Proponents of early CP repair (3–6 months) believe that early velopharyngeal competence is critical to normal speech development. Proponents of late palatal repair (2–15 years) believe that the risk of iatrogenic disruption of palatal growth and midfacial hypoplasia outweighs the risk of speech abnormalities. Clefts delayed for more than 2 years generally require obturation to overcome velopharyngeal incompetence and allow normal speech development. Oral obturators placed prior to 2 years are often poorly tolerated. The lack of clear evidence supporting early versus late repair has led to a compromise in which most surgeons perform repair from 12 to 24 months.[2] Recently, experience with neonatal cleft lip and palate repair has been described as safe, although long-term follow-up is not yet available.[8] The risks of repair include bleeding, infection, wound breakdown, palatal fistula, inhibition of maxillary growth, and velopharyngeal incompetence.[2] A description of the various surgical techniques used in palatal repair is beyond the scope of this text.

The emergence of the deciduous teeth is disrupted by the clefting process. The mean emergence age of the cleft side upper deciduous lateral incisor is delayed by 8 months when an alveolar cleft is present and by 13 months when an alveolar and palatal cleft is present. However, if early orthopedic plates are used, the lower incisors emerge earlier than normal. The emergence of the deciduous primary molar is also delayed in patients with clefts.[7] Also, children with cleft lip and/or palate were found to be at risk for dental caries, with the highest incidence found in the teeth adjacent to the oral cleft.

Special consideration should be given to advising the parent to provide breast milk to infants with CP. This is based on a study by Paradise and colleagues, who evaluated 315 infants with CP. Freedom from effusion in one or both ears at one or more visits was found in 2.7% of those fed cow's milk or soy formula exclusively and 32% of those fed with breast milk exclusively or in part for varying periods.[9] General growth patterns of children with clefts do not differ significantly from those without clefts.[7]

PIERRE ROBIN SEQUENCE

Pierre Robin, a French stomatologist, described the association of micrognathia and glossoptosis (posterior displacement of the tongue into the pharynx) in 1923 and added CP in a 1934 report. This triad is now known as the Pierre Robin sequence, with the word sequence being used to reflect the series of events leading to the clinical phenotype. The significant respiratory symptoms associated with PRS distinguish it from simple CP. An estimate on the incidence varies from 1 in 2,000 to 1 in 30,000.[10] Mortality ranges from 2.2 to 26%, with the cause of death typically related to obstructive apnea and failure to thrive.[11]

The initiating event appears to be mandibular deficiency. In early development, the retroposition of the mandible results in maintaining the tongue in a high position within the nasopharynx. Tongue position prevents the medial growth and fusion of the palatal shelves, and a resultant U-shaped cleft occurs.[10] The degree of the defects results in marked clinical heterogeneity.

The nature of the mandibular hypoplasia is heterogeneous and includes positional malformations in which the mandible has normal growth potential, but external factors, such as oligohydramnios, multiple births, or uterine anomalies, prevent full development; intrinsic mandibular hypoplasia in which there is reduced growth potential, such as is seen with genetic syndromes; neurologic or neuromuscular abnormalities in which abnormal mandibular movement prevents tongue descent, as seen with myotonic dystrophy and arthrogryposis; and connective tissue disorders.[10]

Approximately 20 to 40% of affected individuals are classified as having nonsyndromic PRS. These patients have normal growth potential and development if airway and feeding problems are prevented.[10] The majority of cases are therefore associated with various recognized syndromes (Table 22-3), the most common of which include Stickler syndrome (34%), velocardiofacial syndrome

(11%), fetal alcohol syndrome (10%), and Treacher Collins syndrome (5%).[12]

At birth, patients with PRS have marked anteroposterior mandibular deficiency. The base of the nose is often flattened, and a palatal cleft is present. The possibility for mandibular catch-up growth is related to the etiology of the PRS. When mandibular deficiency is due to positioning, the micrognathia will likely self-correct. However, syndromic PRS often involves altered mandibular growth potential, and correction is less likely.[10] Hearing levels in patients with PRS revealed 83% to have bilateral conductive hearing loss, whereas 60% of CP patients (with or without cleft lip) had hearing loss. All patients with hearing loss had middle ear effusion.[13]

Airway obstruction is multifactorial, involving both anatomic and neuromuscular components. Neuromuscular impairment of the genioglossus and other pharyngeal muscles predisposes PRS patients to airway collapse. Mechanical obstruction is the result of the retroposition of the mandible and diminished anterior traction on the tongue. The airway obstruction may lead to associated cor pulmonale, failure to thrive, and cerebral impairment owing to hypoxia.[10] A study by Sher and colleagues using nasopharyngoscopy found that 59% of the obstruction was the result of posterior movement of the tongue contacting the posterior pharyngeal wall.[14]

If the airway compromise is due to glossoptosis, then positioning has been the mainstay of treatment. Patients are placed in the prone position so as to rely on gravity to displace the tongue anteriorly. However, this maneuver does not allow for easy observation of signs of respiratory distress should airway obstruction occur. For this reason, some have advocated the use of a weighted wire to bring the tongue forward.[10]

The use of a nasopharygeal airway has been described, with good results. The tube should have an internal diameter of 3.0 to 3.5 mm and can be advanced to 8 mm until good air movement is observed. Typically, a single tube is sufficient. Gavage feedings through a nasogastric tube are recommended when this tube is in place.[10] A study of 22 neonates treated with nasopharyngeal airway and nasogastric feeding demonstrated this approach to be safe and allowed for improved growth, development, and parental bonding.[15]

The use of a tongue to lip adhesion or glossopexy was also designed to relieve abnormal tongue positioning. In this procedure, the tongue is sutured in place in a more anterior position. Although this can alleviate upper airway obstruction, there is a significant failure rate. In addition, complications include tongue laceration, wound infection, dehiscence, injury to the Wharton duct, and scar formation of the lip, chin, and mouth.[10] A study by LeBlanc and colleagues suggests that this procedure does not adversely affect speech when compared with affected patients who did not undergo glossopexy.[16]

The use of mandibular distraction osteogenesis has been described as a definitive structural resolution of the micrognathia with correction of the hard and soft tissues. The technique is technically demanding and requires good compliance from the parents. Tracheostomy would be a final alternative for those patients who do not respond to nonsurgical measures. Other procedures described include subperiosteal release of the floor of the mouth and hyomandibulopexy.[10]

Feeding difficulties have been reported to be due to poor tongue mobility or poor muscle coordination during swallowing. This leads to poor suck and poor bolus propagation. A recent study revealed over 50% of patients to have temporary feeding problems that resolved by 1 year of life, whereas almost 25% have chronic feeding problems. Overall, 40% required some form of enteral tube feeding.[11] Electromyography during bottle feeding revealed incoordination between oral and pharyngeal phases of swallowing. Esophageal motility studies revealed increased lower esophageal sphincter mean resting pressure and incomplete or asynchronous lower esophageal sphincter relaxation; simultaneous contractions, multipeaked waves, and very-high-amplitude waves along the esophageal body; and increased mean upper esophageal sphincter resting pressure and asynchronous upper esophageal sphincter relaxation.[17]

A separate study by Abadie and colleagues evaluated 66 neonates with isolated PRS. These authors hypothesized that PRS is the result of brainstem dysfunction that causes poor mandibular growth owing to impaired oral motility in utero. They evaluated the patients with esophageal manometry, laryngoscopy, and Holter-electrocardiography recording. They also graded the degree of clefting, glossoptosis, and retrognathia. They found that 98% had feeding difficulty within the first week of life and 81% had problems for the first 3 months of life. Transient solid food dysphagia was present in 18 to 60%, depending on the severity of their PRS. Manometric abnormalities were present, as previously described. Acute life-threatening events were present in 30% overall, with higher proportions seen in more severely affected individuals. Vagal overactivity was demonstrated in 59%.[18]

Early failure to thrive is seen relatively commonly and is often multifactorial. Factors implicated in poor weight gain include feeding difficulties, syndrome-related hypoxemia, respiratory insufficiency, increased caloric demand,

prematurity, and related operations. In addition, gastroesophageal reflux and respiratory infections may contribute. Full catch-up growth in height and weight typically occurs during early childhood.[11]

A mild variant of the PRS has been described in which there is mild retrognathia and a high arched palate. These patients were noted to share manometric abnormalities with classic PRS and presented with early feeding resistance.[19]

PSEUDOPALATAL CLEFTS

Some patients have marked lateral hard palate swellings. These are typically associated with a high arched palate and median furrow. Careful examination reveals an intact palate, despite the misleading appearance of a cleft. Such pseudopalatal clefts are common in patients with Apert syndrome and have been described in Crouzon disease as well. No treatment is indicated.[20]

EPULIS

The first case of congenital epulis was reported in 1871. This rare benign soft tissue tumor occurs eight times more frequently in females than males and three times more often in the maxilla than in the mandible. The tumor is most commonly at the lateral alveolar ridge, where the lateral incisor or canine teeth erupt. The tumors are multiple in 10%. The histogenesis remains controversial, with proposed origins as odontogenic, fibroblastic, histiocytic, myogenic, and neurogenic. Congenital lesions can present as masses protruding from the mouth and can prevent nutrition and partially restrict respiration. Clinically, one may see occasional spontaneous regression and lack of postnatal tumor growth.[21]

EPIGNATHUS TERATOMAS

Epignathus teratomas are rare congenital malformations giving rise to oropharyngeal tumors. They are classified as mature teratoma. The estimated incidence for all mature teratomas is 1 in 4,000 live births, and at least 2% are oropharyngeal. The lesions do not appear to be familial in nature; however, there is a female predominance of 3:1 over males.[22] Epignathus teratomas occur more frequently in children of young mothers and can be associated with polyhydramnios owing to swallowing difficulty. Prenatal detection of these tumors has rarely been reported.[22] Placental edema owing to fetal cardiac decompensation based on the vascular nature of the tumors has been described as preeclampsia.[23]

The clinical presentation is based on the size and location of the tumor. Large tumors can result in early neonatal asphyxia. Computed tomography (CT) and magnetic resonance imaging (MRI) allow preoperative assessment of the tumor. Intracranial extension should be suspected in the event of sphenoid dehiscence.[23]

Histologically, they are composed of various tissues of ecto-, endo-, and mesodermal origin. The site of origin appears to be the craniopharyngeal canal. The implantation of the base can be single or multiple. The majority of these tumors have their point of attachment at the base of the skull in the posterior region of the nasopharynx. The tumors can be multiple and are associated with other malformations in 6% of cases. CP is the most common associated anomaly; however, bifid tongues and noses have been described. Differential diagnosis usually includes rhabdomyosarcoma of the tongue, retinoblastoma, nasal glioma, heterotopic thyroid, cystic lymphangioma, nasoethmoid meningoencephalocele, sphenoid meningoencephalocele, and giant epulis.[23]

Treatment consists of early and total surgical resection using an oral approach. Malignant degeneration has never been described in association with epignathus teratomas. Recurrence has not been reported.[23]

RANULA

A cyst-like swelling in the mouth floor, ranula, has been described since the days of Hippocrates. They are unilateral and unilocular and confined to the sublingual space, causing no discomfort. Their origin is typically due to mucus extravasation from the sublingual salivary gland that results in a pseudocyst. This condition is rare in the neonatal period but has been detected antenatally on ultrasonography.[24]

The ranula is characterized by a translucent blue color reflecting the viscous mucus contained within and the vascular congestion of the overlying mucosa. They are typically soft and slow to enlarge. Traumatic rupture is common, but with healing of the roofing mucosa, recurrences develop. Larger cysts may cause tongue displacement and result in difficulty with mastication, swallowing, and speech. Treatment initially can involve marsupialization and packing of the cystic lumen with gauze. Maintaining the packing for at least 10 days promotes fibrosis and sealing of the leaking salivary duct. Recurrences can be treated with a more extensive intraoral excision of the culpable sublingual salivary gland.[25]

NATAL AND NEONATAL TEETH

Natal teeth are those observable in the oral cavity at birth, whereas neonatal teeth are those that erupt during the first month of life. The reported incidence is somewhat varied, but among larger studies, the range is between 1 in 1,118 and 1 in 30,000. Overall, there does not appear to be a gender predilection, although some studies suggest that the incidence may be slightly higher among females.[26]

The etiology of early eruption is unknown, although it has been related to several factors, including superficial position of the germ, infection or malnutrition, febrile states, eruption accelerated by febrile incidents or hormonal stimulation, hereditary transmission of an autosomal dominant gene, osteoblastic activity within the germ area related to the remodeling phenomenon, and hypovitaminosis. At times, premature eruption is described in which an immature rootless tooth exfoliates within a short time. This phenomenon, in distinction to early eruption, has been designated "expulsive Capdepont follicle," may result from trauma to the alveolar margin at delivery, and

is associated with gingival inflammation. Natal and neonatal teeth owing to early eruption have been related to various syndromes, including Hallermann-Streiff, Ellis-van Creveld, craniofacial dysostosis, multiple steatocystoma, congenital pachyonychia, and Sotos.[26]

Clinically, the teeth may be conical or may be normal in size and shape and opaque yellow-brown in color. They can be classified as mature or immature based on their structure and development. Histologically, most of the crowns are covered with hypoplastic enamel of varying degree and severity. In addition, they often have absence of root formation, ample and vascularized pulp, and irregular dentin formation and lack cementum formation. These teeth can be differentiated from cysts of the dental lamina and Bohn nodules by radiographic examination.[26]

Radiographic verification of the relationship of the tooth and adjacent structures, nearby teeth, and the presence or absence of a germ in the primary tooth area allows one to determine if the tooth belongs to the normal dentition. Indeed, most natal and neonatal teeth are primary teeth of the normal dentition (95%) and not supernumerary teeth. The teeth are usually in the region of the lower incisors (85%) and double in 61% of the cases.[26]

Treatment depends in part on the tooth's implantation, degree of mobility, difficulty sucking or breastfeeding, possibility of traumatic injury, and whether the tooth is part of the normal dentition or supernumerary. If the tooth is part of the normal dentition and well implanted, it should be left in the arch to avoid loss of space and collapse of the developing mandibular arch, which could lead to future malocclusion. Removal should be considered only if there is difficulty in feeding or they are highly mobile, with risk of aspiration. However, it should be noted that, to date, there are no reports of aspiration of a natal or neonatal tooth. If indicated, extraction is relatively easy and can be accomplished with forceps or even the fingers; however, some experts caution that they should not be removed prior to day 10 of life owing to risk of hemorrhage. This risk, however, is lessened if vitamin K is administered prior to extraction, as is typically performed as part of immediate neonatal care.[26]

TONGUE LESIONS

Tongue development begins at 3 to 4 weeks gestation from the first three to four brachial arches.[27] Specifically, the tongue arises from four swellings (median tongue bud, two lateral tongue buds, and hypobranchial eminence), which merge to form the tongue.[27] Pediatric tongue lesions represent 2.4% of all pediatric oral and maxillofacial tumors. Most lesions are benign and include various local neoplastic solid tumors, cysts, polyps, benign neoplasms, and diffuse hypertrophy. Anterior lesions do not typically obstruct the aerodigestive tract and are typically asymptomatic. Posterior lesions may present with acute respiratory distress or dysphagia. Excision of these lesions may hamper function owing to injury to superficial lingual nerves. Diffuse lesions can present with chronic protrusion, respiratory distress, dysphagia, dysarthria, or salivation. Surgical repair aims at preserving motility, taste, and cosmetic appearance.[28]

Osseous christomas are lesions composed of normal bone mass within the soft tissue. When present in the tongue, they are typically posterior near the foramen cecum. Patients' ages range between 5 and 73 years, with an increased frequency in the third and fourth decades. A female predominance has been observed. The origin is thought to be ossified remnants of brachial arches. They may appear as densely calcified masses on plain film and noncontrast CT. Differential diagnosis includes extraskeletal osteosarcoma and chondrosarcoma, which are both less likely in a pediatric population. Treatment is via surgical excision. No recurrences or malignant transformations have been reported.[28]

Hamartomas represent benign tumor-like proliferation of a tissue in its usual anatomic location. Fewer than 15 cases of lingual hamartomas have been reported, although some may have been mischaracterized as mesenchymomas. Lingual hamartomas occur in more than 50% of the orofaciodigital syndromes.[28] Airway obstruction can be a problem with large lesions. Treatment is local resection.

Lingual teratomas occur at the foramen cecum, where the embryologic tongue buds converge. Grossly, they are typically encapsulated, cystic, solid, or multiloculated masses that may contain hair, skin, cartilage, or mucous membrane tissue. The cause is unknown but thought to be secondary to entrapment of embryologic epithelial cells along the lines of closure for the first and second branchial arch or the differentiation of multipotential cells sequestered during closure of the anterior neuropore.[28]

Aglossia is likely due to a lack of development of the lateral lingual swellings of the mandibular arch. This is an extremely rare anomaly, with only a few reports existing among living children.[27] This typically occurs in association with other malformations and has been associated with aglossia-adactylia syndrome and Goldenhar syndrome, in which one can see partial aglossia. In surviving patients, swallowing may improve after several months.[27]

Microglossia is a not so rare malformation, often associated with other congenital syndromes (Table 22-4).[27] Clinical difficulties depend on the degree of microglossia and associated findings. Patients may have some difficulty with articulation.

Tongue hemihypertrophy or hemiatrophy is usually associated with auricular, mandibular, and maxillary hypoplasia. Affected patients have less developed musculature of the soft palate and tongue on the affected side. Parotic gland aplasia or hypoplasia may also be an associated anomaly. Parry-Romberg syndrome and congenital hemifacial hyperplasia are syndromes associated with this anomaly.[27]

Macroglossia is defined as a resting tongue that protrudes beyond the teeth or alveolar ridge. Sequelae owing to macroglossia include articulation errors, particularly in pronouncing consonants requiring the tongue tip to approximate the alveolar ridge or roof of the mouth (ie, s, z, sh, t, d, and n). One may also develop an anterior open bite, prognathism, increased ramus to body angle, and flattening of the alveolar ridge. Deglutition issues may also arise and result in failure to thrive owing to inadequate intake. Airway obstruction may be a further complication and may lead to pulmonary hypertension and cor pulmonale. Acute respiratory distress owing to sudden respiratory obstruction has also been described.[29]

Lymphangioma is the most common etiology of macroglossia in children. It can be apparent at birth 60% of the time, with 95% becoming symptomatic by 2 years of life. The lymphangioma shares a common embryologic origin with cystic hygroma because both arise from lymphatic tissue rests derived from the primitive jugular sac. They typically involve the anterior two-thirds of the tongue. There is a coincident cystic hygroma in 7%. Grossly, it appears as a nodular swelling on the dorsum of the tongue or a water-filled blister. Discoloration of the tongue is due to blue-red vascular blebs deep within the vesicles. Increasing size can result from inflammation or trauma with hemorrhage into the lymphatic spaces. Recurrence after resection is common and arises from residual unremoved tissue.[29]

There are multiple syndromes associated with macroglossia (Table 22-5). Neonatal hypothyroidism, cretinism, has been associated with macroglossia. Here the tongue is enlarged owing to myocyte hypertrophy and myxedematous tissue deposition. The tongue is smooth and symmetrically enlarged. Treatment involves controlling the underlying endocrine condition, typically by the use of exogenous thyroid hormone.[29]

Beckwith-Wiedemann syndrome, described in 1964, also causes macroglossia. This is thought to have autosomal dominant inheritance with variable penetrance and occurs at an incidence of 1 in 13,500 live births.[30] Associated features include exomphalos, gigantism, facial flame nevus, ear lobe anomalies, mild microcephaly, prominent occiput, maxillary hypoplasia, and short orbital floor. Macroglossia is present in 95% of affected individuals. Hypoglycemia is also a prominent feature owing to pancreatic cell hyperplasia.

Hemangiomas, congenital vascular malformations, may present as macroglossia. Histologically, one sees endothelium-lined vascular spaces. Therapy includes systemic and intralesional steroids and laser excision.[29] Rhabdomyosarcoma of the tongue causes macroglossia and accounts for 20% of head and neck rhabdomyosarcomas. Chemotherapy affords a 70% 3-year survival rate.[29] Neurofibromatosis may be associated with macroglossia when affected individuals develop neurofibromas in the tongue. They are typically unilateral and slow growing. Early surgical excision is recommended prior to spread to the floor of the mouth, thus allowing for total excision.[29] Pseudomacroglossia can be seen in those instances in which there is a small mandible (eg, Down syndrome, PRS).[29]

Treatment of macroglossia with surgical excision is based on the effects on feeding, dentition, speech, and airway compromise. Initially, the patient may achieve benefit from nursing in the prone position or feeding through a nasogastric tube. Management involves a multidisciplinary team of an otolaryngologist, a speech therapist, and an orthodontist. Goals include the restoration of the size and shape of the tongue, preservation of function, and correction of dental arch anomalies. Typically, surgery is performed by 4 to 7 months to avoid maxillofacial deformities and speech defects.[29]

Long tongue has rarely been described in which affected persons have an extremely lengthy tongue with extreme mobility. This has been documented in Ehlers-Danlos syndrome.[27] There do not appear to be any clinical manifestations.

Accessory tongue is a very rare malformation in which the tongue is attached to the tonsil or a process arising from one side of the base of the tongue.[27]

Cleft of bifid tongue has been described with Goldenhar syndrome, orofaciodigital syndrome types I and II, CP lateral synechiae syndrome, and focal dermal hypoplasia.[27]

Lingual thyroid occurs when thyroid gland elements persist in the area of the foramen cecum. This is typically along the midline, immediately posterior to the foramen cecum and resting on a broad base. The color varies from red to purple.[27] The lingual thyroid mass usually increases in size as the child ages owing to the effect of thyroid-stimulating hormone on this marginally functioning thyroid. Common presenting symptoms are dysphagia, dysphonia, dyspnea, and, occasionally, pain. A thyroid scan is required to determine the amount of active thyroid tissue because this may be the patient's only functioning thyroid tissue. Management considerations include functional,

metabolic, and cosmetic factors. Euthyroid, asymptomatic patients can be followed carefully over time. Patients with abnormalities in their thyroid function can be managed with hormone therapy; otherwise, surgical resection is warranted. There is an increased frequency of thyroid carcinoma in lingual thyroid tissue.[20]

Other syndromes with associated tongue anomalies include Melkersson-Rosenthal syndrome, in which one-third of affected individuals have a folded tongue; Coffin-Lowry syndrome, in which patients have been observed to have a deep central lingual groove and thickened lips; Riley-Day syndrome, in which one observes decreased numbers of fungiform and circumvallate papillae; and Klippel-Trénaunay-Weber syndrome, in which there may be angiomatosis of the tongue.[27]

Ankyloglossia, tongue-tie, is a congenital anomaly characterized by an abnormally short lingual frenulum, which may restrict tongue tip mobility. Incidence figures reported in the literature vary from 0.02 to 4.8%, and there is a male-to-female ratio of 3 to 1.[31] Ankyloglossia occurs most frequently as an isolated anatomic variation. An increased prevalence has been noted among children of mothers who abused cocaine.[31] It may also be associated with various syndromes, including Opitz syndrome, orofaciodigital syndrome, and X-linked CP. The long-term outcome of ankyloglossia is unknown because there are no long-term studies; however, some authors postulate that the short frenulum can elongate spontaneously, with progressive stretching and thinning with use.[31] This might account for the perception that this disorder is more common among children than adults. Sequelae from ankyloglossia are debated; some feel that it is rarely symptomatic, whereas others state that it results in infant feeding difficulties, speech disorders, and mechanical and social difficulties.[31] Surveys report that the majority of lactation consultants feel that ankyloglossia can hamper breastfeeding and result in sore nipples, poor latching on and sucking mechanics, poor infant weight gain, and early weaning.[31] This is, in part, supported by a recent prospective study in which 36 infants with ankyloglossia were compared with normal controls. Although both groups were able to successfully breastfeed for at least 2 months, the affected group reported more frequent nipple pain and difficulty latching on (25% vs 3% for controls).[32] There does not appear to be a problem with affected infants' ability to bottle feed, although this should not be used as an argument to avoid breastfeeding attempts.[31]

Speech sounds that may be affected by tongue tip mobility include lingual sounds and sibilants such as t, d, z, s, th, n, and l. Although ankyloglossia can be a cause of articulation problems and effortful speech, it is not a cause of speech delay.[31]

Additional problems reported by older children and adults include difficulty in intraoral toilet (lip licking and sweeping away oral debris), cuts under the tongue, creation of a diasthesis between the lower central incisors, and poorly fitting dentures. Social difficulties may also occur, including playing a wind instrument, licking ice cream, and "French kissing."[31]

Diagnosis is based on physical examination in which the frenulum is abnormally short and inserts onto the tongue at or near the tongue tip. The tongue may appear notched or heart-shaped on protrusion. Protrusion is limited and may not extend beyond the lower lip. Hazelbaker, a lactation consultant, devised an assessment tool for lingual frenulum function to be used on neonates. Based on a scoring of seven lingual movements from 0 to 2, low scorers are recommended to undergo frenotomy.[33] However, despite this and other more complex measuring scales, there appears to be no way to predict, based on examination, those children who are likely to have problems related to ankyloglossia.[31]

The timing of surgical correction is controversial. Some feel that given the rare incidence of complications, it is warranted to wait until such complications develop, whereas others feel that prophylactic treatment is warranted, especially in light of the minimal surgical risks.[31] Additional considerations with respect to timing include the fact that delayed repair beyond 1 year of age often requires general surgery, whereas younger children tolerate the procedure in a clinic setting. Frenotomy, clipping of the frenulum, is rapid and easy and is best suited for infants. The discomfort is brief and minor and may not warrant anesthesia. In children over age 1 year, frenuloplasty is preferred. Here the frenulum is released via sequential cuts, as is done with frenotomy, and then the resultant wound is closed with a suture. As with frenotomy, antibiotics are not required, and rare postoperative pain can be managed with acetaminophen. Improvements in breastfeeding are often immediate, given that that was the source of the feeding problem. Similarly, articulation improves in 75% of patients postoperatively among patients with ankyloglossia-related problems. Complications of repair include infection, excessive bleeding, recurrent ankyloglossia owing to scarring, new speech disorder, and glossoptosis.[31]

CYSTIC HYGROMA

Cystic hygromas are congenital malformations of the lymphatic system. They are characterized by single or multiple fluid-filled lesions occurring at sites of lymphatic-venous connections. They typically develop between the late first trimester and early second trimester. The incidence of cystic hygroma is unknown; however, rates as high as 1 in 100 have been reported.[34]

The lymphatic system develops at the end of the fifth week as endothelium grows out from the venous system. Six lymphatic sacs, two jugular sacs draining the head, neck, and arms; two iliac sacs draining the legs and lower trunk; and two sacs draining the gut (the retroperitoneal sac and the cisterna chili), develop in close proximity to the body's large veins. Through centrifugal extension and branching, the lymphatic vessels arise from these sacs. The right and left thoracic ducts connect with the venous system at the junction of the internal jugular and subclavian veins at the end of the sixth week of gestation.[34]

The anatomic distribution and severity of lymphatic vessel anomalies vary with the underlying disorder. They

range in size from that of a small pouch to giant extensions along the length of the body. They tend to infiltrate tissue planes, including the tongue and the floor of the mouth. This can lead to life-threatening airway compromise. Owing to their large size and tissue involvement, endotracheal intubation may be difficult, and tracheotomy is necessary to secure the airway. They are either smooth or irregular in contour, the latter suggesting a multilocular fluid collection. Hygroma spaces are lined by endothelial cells and contain serous lymphatic fluid. They are typically located in the posterior neck. Numerous syndromes have been associated with cystic hygromas (Table 22-6), as well as exposure to alcohol, aminopterin, and trimethadone.[34]

Prenatal diagnosis can ensure that the appropriate surgical personnel are in the delivery room and thus offer the best chance for a good outcome.[35] Indeed, operating while the patient remains on placental support and ex utero intrapartum treatment have been described.[36,37] Before excision is attempted, the extent of the lesion and its relationship to surrounding structures must be considered. For superficial lesions, ultrasonography with or without Doppler may help define the lesion. For more complex lesions, CT and MRI have proven useful. Complete excision is the treatment of choice. However, because their extension can be marked and their involvement of vital structures and nerves is common, removal may not be possible. Postoperative complications of recurrence, wound seroma, infection, and nerve damage occur in 30% or more of cases. If the lesion is only partially resected, recurrence rates approach 100%.[34] Nonsurgical treatment with either bleomycin or OK-432 (lyophilized incubation mixture of group A *Streptococcus pyogenes*) has shown some efficacy.[34]

ESOPHAGEAL DUPLICATION

Congenital duplications may arise along the length of the gastrointestinal system. Although midgut duplications are the most common, foregut duplications (esophagus, stomach, and parts 1 and 2 of the duodenum) account for approximately one-third.[38] Among the foregut duplications, esophageal duplications are the most common. The duplications may appear as cysts, diverticulae, and tubular malformations, all of which are thought to have a similar embryologic origin. Gastric mucosa is frequently observed within the wall of the duplication irrespective of their site of origin.[39]

Esophageal duplications are often identified on chest radiograph and barium esophagogram as posterior mediastinal masses.[39] Duplication cysts may be difficult to distinguish from bronchogenic cysts, which can also cause external compression of the esophagus. Vertebral anomalies are concomitantly found in approximately 50% of cases.[38] Many of these are associated with intraspinal abnormalities. This association is best explained embryologically by the split notochord syndrome. The notochord, present from the third week of gestation, may split, allowing endodermal gut to herniate through the gap, resulting in a cyst or fistula. The cyst may interfere with anterior fusion of the vertebral mesoderm, accounting for the vertebral anomalies.[38]

The most common presenting symptom of an esophageal duplication cyst within neonates is respiratory distress owing to the enlarging cyst pressing on the adjacent lungs and airways. Among older children, dysphagia is a more common complaint. Smaller cysts may remain asymptomatic for years and be noted incidentally on chest radiography. Older children may develop massive gastrointestinal or bronchial hemorrhage and spinal meningitis because the wall of the duplication erodes owing to production of acid from the gastric lining of the duplication.

Diagnosis is usually accomplished radiographically as a mass on a chest radiograph or as a compressing mass on contrast esophagogram. Communicating lesions can also be noted to fill with contrast. Chest CT or MRI is helpful in further defining the lesion.

Management is best accomplished via surgical excision of the duplication. However, excision is not always possible, particularly if the esophagus and duplication share a common wall for any distance. Excision of the bulk of the duplication with stripping of the mucosa on the esophageal wall is an option for those cysts that are unresectable. Recently, resection via minimal access surgery has been described.[40]

ESOPHAGEAL STENOSIS

Congenital esophageal stenosis is defined as an intrinsic stenosis caused by a congenital malformation of the esophageal wall that is not necessarily present at birth. The etiology is classified as tracheobronchial rest (TBR),

membranous diaphragm (MD), and segmental hypertrophy of the muscularis and diffuse fibrosis of the submucosa. The stenosis owing to TBR is the most common and MD is the least common.[41] The overall incidence of esophageal stenosis is estimated at 1 in 25,000 to 50,000 live births, with the incidence of other congenital anomalies associated with congenital esophageal stenosis ranging from 17 to 33%.[42] Symptoms vary with the location and severity of the stenosis. High esophageal lesions typically present with respiratory symptoms, whereas lower lesions present with vomiting. The majority present with the introduction of solids and signs and symptoms of dysphagia.[41]

Esophagograms are helpful in making the diagnosis, and confirmation by endoscopy is diagnostic. When strictures are identified, congenital lesions must be differentiated from acid-related strictures and from compression of the esophagus from external structures such as vascular rings. The majority of cases attributable to TBR are in the distal portions of the esophagus, whereas fibromuscular stenosis (FMS) and MD occur more commonly in the middle third. FMS is classically 1 to 4 cm in length, has a smooth wall with an hourglass configuration, is located at the junction of the middle and lower thirds of the esophagus, and results in only partial obstruction of the esophageal lumen. TBR is typically found within 3 cm of the gastric cardia and often results in high-grade obstruction. MD is more common in the midesophagus.[41]

Segmental stenosis attributable to TBR and FMS can be associated with esophageal atresia and tracheoesophageal fistula (TEF) and accounts for up to one-third of reported cases. TBR, like esophageal atresia, is due to abnormal separation of the foregut into the trachea and esophagus, which occurs at day 25 of gestation. This accounts for their frequent association. MD is likely a form of "partial" esophageal atresia,[41] although case reports of complete obstruction of the esophagus by an intraluminal mucosal diaphragm have been described.[43]

Treatment of congenital esophageal stenosis is typically via excision with end-to-end reanastomosis. If this is in proximity to the lower esophageal sphincter, an accompanying fundoplication should be performed. Some controversy, however, exists as to whether some of these lesions, particularly those with FMS, can be treated by dilatation. Dilatations are not always successful, and there is a risk of perforation. Esophageal webs (MD) may be more amenable to simple dilatation.[41] There have also been reports of treatment of MD with endoscopic laser division.[44]

ESOPHAGEAL ATRESIA

The first reported case of esophageal atresia was an autopsy finding by Durston in 1670. Shortly thereafter, in 1697, Thomas Gibson provided the first clinical description of a TEF.[45] The first successful staged repair was reported in 1939 by Laven and Ladd.[45] Haight reported the first successful primary anastomosis with fistula ligation in 1941.[45] Prior to these reports, esophageal atresia was a uniformly fatal congenital anomaly.

The exact cause remains unknown. Kluth and colleagues used the scanning electron microscope in chick embryos and proposed that the trachea and esophagus normally develop and separate by formation of cranial ventral and dorsal folds in the foregut. Excessive ventral invagination of the ventral pharyngoesophageal fold is thought to be the underlying defect.[46] Developmental disorders of circulation have also been proposed. Genes of the HOXD group have also been linked to these malformations.[45]

Overall, the incidence of esophageal atresia is 1 in 3,000 to 1 in 4,000 live births, with the highest rate among whites.[47] There is a 0.5 to 2% risk of recurrence among siblings of an affected child. Prolonged maternal use of contraceptive pills and exposure to progesterone and estrogen during pregnancy have been implicated as teratogens. Esophageal atresia with TEF takes a number of forms (Figure 22-1); the most common anomaly, accounting for 85% of cases, comprises a blind-ending esophageal pouch with a fistula from the trachea to the distal esophagus.

Approximately 50 to 70% have associated anomalies, including cardiac (11–49%), genitourinary (24%), gastrointestinal (24%), and skeletal (13%). Approximately 10% of patients are classified within the VACTERL association in which three or more of the following anomalies are found: vertebral, anorectal, cardiac, TEF, and renal and radial limb anomalies. Driver and colleagues reported the associated anomalies in 134 patents with esophageal atresia with or without TEF. Of these, 31 had gastrointestinal anomalies, including anorectal malformation (52%), duodenal atresia (19%), malrotation (13%), jejunoileal atresia (10%), duplication (3%), and hiatal hernia (3%).[48] Mee and colleagues identified 119 infants with congenital cardiac anomalies of 554 patients with esophageal atresia. The most common included atrial septal defect (ASD) (8%), ventricular septal defect (VSD) (28%), tetralogy of Fallot (13%), and patent ductus arteriosus (PDA) (13%).[49] Other associations have been noted.[45] Syndromes associated with esophageal atresia and TEF are listed in Table 22-7.

The proximal blind esophageal pouch is typically hypertrophied and has a good blood supply. It is adherent to the trachea, which often has more muscle than cartilage, and thus results in tracheomalacia. The distal pouch is narrow and small; fistulae typically open into the trachea near the carina. The gastroesophageal sphincter is typically incompetent, and the vagus nerve is often defective, accounting for improper peristalsis.[45]

The diagnosis is suspected if there is evidence of polyhydramnios and a smaller than usual gastric bubble. Together these findings have a positive predictive value of 56%.[50] Prenatal ultrasonography may also demonstrate an anechoic structure in the fetal neck, representing the upper pouch. After birth, newborns are typically mucusy and require frequent suctioning. With feeding, there may be coughing, vomiting, and cyanosis. If a distal fistula is present, one may see progressive abdominal distention because the stomach and intestines fill with air introduced from the trachea. With a delay in diagnosis, the patients may develop pneumonitis.
