CHAPTER 50

DISORDERS OF THE BILIARY TRACT

1. *Disorders of the Intrahepatic Ducts*

David A. Piccoli, MD
Pierre Russo, MD

EMBRYOLOGY OF THE INTRAHEPATIC DUCTS

The development of the intrahepatic biliary tree begins between the fifth and ninth week postfertilization. The biliary epithelium is believed to arise from precursor bipotential hepatoblasts that can differentiate into either hepatocytes or biliary epithelial cells.[1] Genes and gene products regulating this process have been recently identified. *HNF1*β is required for the development of interlobular bile ducts and arteries in mice, and mutant mice lacking *HNF1*β in the liver have a paucity of intrahepatic bile ducts and absence of hepatic arteries.[2] *HNF6* is believed to regulate the expression of *HNF1*β and is required for the development of the gallbladder and extrahepatic ducts.[3]

Differences in cytokeratin (CR) expression between hepatoblasts and biliary epithelial cells have been used to illustrate the development of intrahepatic bile ducts. Precursor hepatoblasts express CK 7, 8, 18, and 19; mature hepatocytes express CK 8 and 18 but not 19, whereas biliary epithelium expresses CK 8, 18, 19, and 20.[4] Around weeks 6 to 7, a prominent rim of CK19-positive cells forms along the outer boundary of the developing portal tracts, forming the so-called ductal plate.[5,6] During the next few weeks, the rim becomes a continuous double-layered saccular sleeve around each portal tract. Remodeling of the ductal plate, starting around week 12, results in the formation of discrete tubular spaces incorporated more centrally into the portal mesenchyme, with loss of excess epithelial elements (Figure 50.1-1). This process is believed to proceed from the hepatic hilum, extending centrifugally toward the periphery of the liver. It appears to continue into the first month of life ex utero. A delicate balance between cell proliferation and apoptosis appears to be a key element of this process.[7] The most cranial portions of the hepatic ducts, themselves derived from the cephalic portion of the hepatic diverticulum, would appear to be in direct continu-

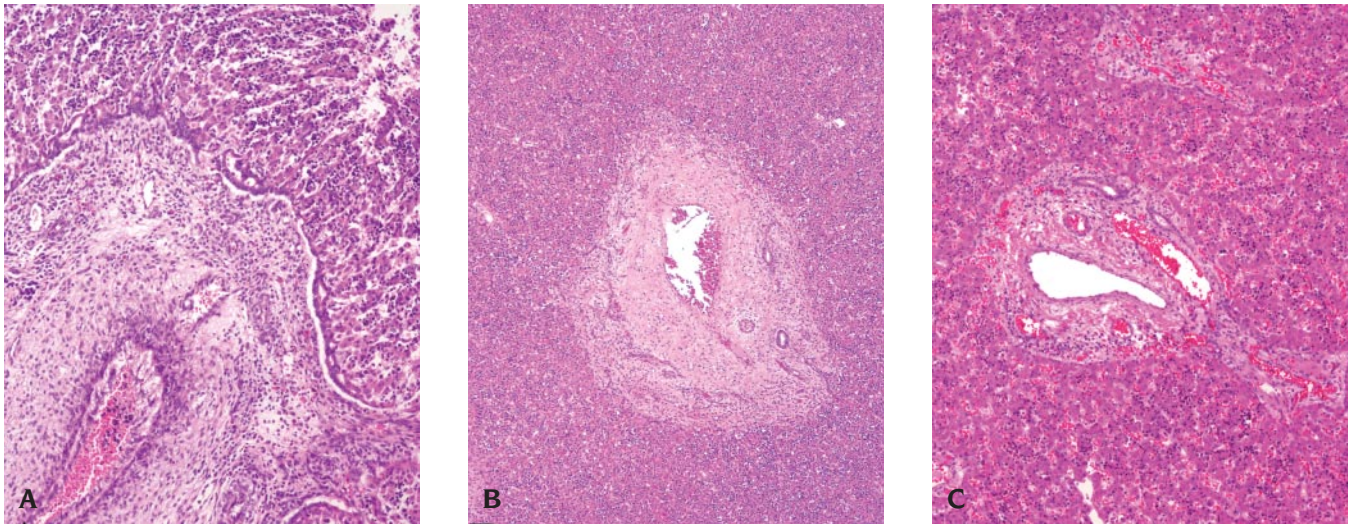

FIGURE 50.1-1 Development of the bile duct as illustrated in fetuses of different ages. *A*, Ten-week-old fetus. The portal vein is in the center of the portal tract. The ductal plate consists of a double-layered saccular sleeve that surrounds the portal tract. *B*, Sixteen weeks. Short segments of the ductal plate become tubules, which are incorporated toward the center of the portal tract. The ductal plate has become discontinuous. *C*, Twenty-five weeks. The ductal plate has largely involuted (hematoxylin and eosin; ×100 original magnification).

ity with converging ductules at the hepatic hilum, which, in turn, are continuous with the ductal plate.[7]

Persistence of the ductal plate in the postnatal liver, appearing as an excessive number of irregular, biliary structures at the site of the original ductal plate and accompanied by an increase in portal tract fibrous tissue, creates a lesion known as the ductal plate malformation (DPM),[8] biliary dysgenesis,[9] or congenital hepatic fibrosis[10] (Figure 50.1-2). The prominent duct elements should not be confused with the proliferating duct elements commonly seen as a response to a variety of hepatic insults, including mechanical obstruction. Jorgenson[8] recognized the similarity between these portal tracts and those seen in fetal life and coined the term "ductal plate malformation" to signify that the lesion represents an arrest in the development of normal portal tract and bile duct structures or, as characterized by Desmet,[11] a disruption of the normal "remodeling" of the embryonic bile duct and portal tract structures into their mature forms. The relevance of this lesion to cystic bile ducts lies in the fact that the abnormal ducts have a propensity to become dilated. This lesion is found in combination with renal abnormalities (usually cysts) in a number of heritable conditions in which there is actual or potential cystic dilatation of the biliary ducts. In addition to these heritable disorders, Desmet has suggested that persistence of the ductal plate can also be associated with extrahepatic biliary atresia,[11] which is not heritable and is not associated with renal disease.

The intrahepatic tree in humans can be divided into large bile ducts (300–800 μm), which include hepatic, segmental, and area ducts, which have associated mucous peribiliary glands, and small bile ducts (< 300 μm), which are not associated with peribiliary glands and include conducting and terminal (or interlobular) bile ducts.[12] Interlobular bile ducts link with intralobular canaliculi via bile ductules or canals of Hering, although the exact anatomy remains unclear. The biliary epithelia of small and large bile ducts express different enzymes and membrane proteins, suggesting that they represent distinct subpopulations.[13] Possible differences in disease susceptibility and responses to injury between epithelia of small and large bile ducts may explain why certain diseases preferentially target smaller bile ducts (primary biliary cirrhosis, graft-versus-host disease), whereas others (sclerosing cholangitis) are primarily directed at larger ducts.[14,15]

INTRAHEPATIC BILE DUCT CYSTIC CONDITIONS

Cystic diseases of the intrahepatic bile ducts present a wide range of disorders. They include both sporadically occurring and heritable conditions and extend from lesions typically discovered incidentally to frank malignancies. A classification scheme is presented in Table 50.1-1. Heritable cystic disease of bile ducts is also referred to as fibrocystic, or fibropolycystic, disease, reflecting the portal fibrosis and DPM that is the histologic hallmark of most of these disorders. The distinction between communicating and noncommunicating cysts is clinically significant because when duct cysts communicate with the biliary tree, they have a greater likelihood of causing clinical disease. Communicating duct cysts can be associated with cholangitis, stone formation, and (relatively uncommonly) neoplasia. Noncommunicating duct cysts are usually asymptomatic but, if sufficiently large, may present as an abdominal mass or biliary obstruction.

SOLITARY CYSTS

Solitary bile duct cysts are generally unilocular cysts lined by a single layer of cuboidal or columnar epithelium (Figure 50.1-3). They tend to present in the fourth to sixth decade with symptoms of fullness or a mass. They are rare in the pediatric age group, 31 having been diagnosed in 63 years at the Boston Children's Hospital.[16] They have been reported in newborns, including a case presenting as a con-

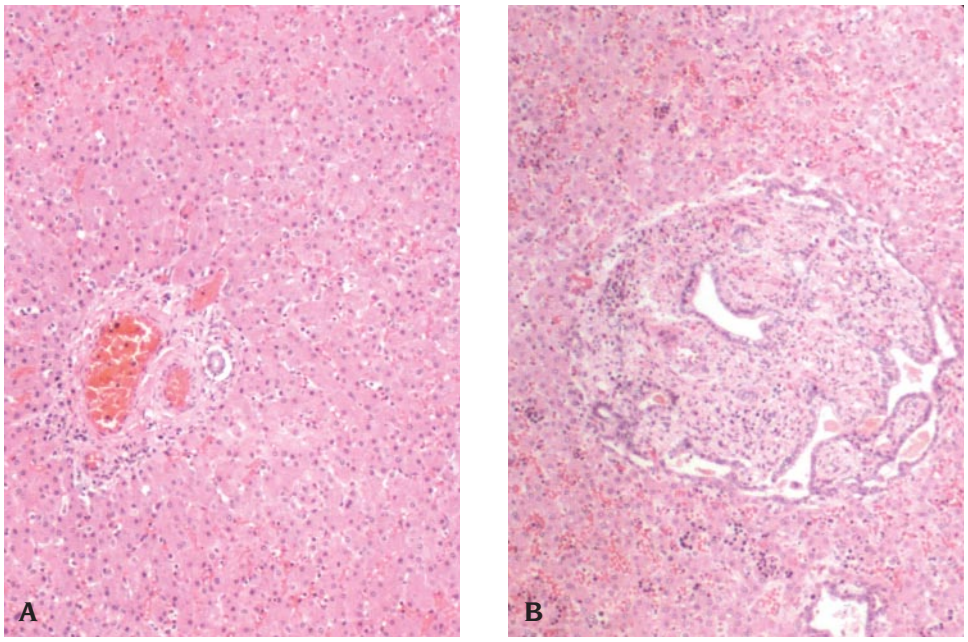

FIGURE 50.1-2 Congenital hepatic fibrosis (CHF). The left panel shows a normal portal tract from a newborn term infant. The right panel, taken at the same magnification, illustrates the hepatic histologic features from a 9-day-old infant with CHF and autosomal recessive polycystic kidney disease. The portal tract is expanded and fibrotic, and there is a proliferation of irregularly dilated biliary structures at the portal tract–lobular interface, a pattern known as "ductal plate malformation" (hematoxylin and eosin; ×100 original magnification).

TABLE 50.1-1 CLASSIFICATION OF HEPATIC CYSTS OF DUCTAL ORIGIN

SOLITARY NONPARASITIC CYSTS
Solitary bile duct cyst
Ciliated hepatic foregut cyst
Peribiliary cyst
Hepatobiliary cystadenoma
HERITABLE HEPATIC CYSTS—FIBROCYSTIC DISEASE
Communicating cysts
Congenital hepatic fibrosis (CHF)
CHF in association with
Autosomal recessive polycystic kidney disease
Nephronophthisis
Malformation syndromes (see Table 50.1-2)
Phosphomannose isomerase deficiency
Caroli syndrome
Noncommunicating cysts
Autosomal dominant polycystic kidney disease
Isolated polycystic liver disease (chromosome 19p13.2-13.1)

genital diaphragmatic hernia.[17] The main differential diagnosis is with autosomal dominant polycystic disease. Imaging studies in the latter would show multiple cysts in the liver and kidney. The cystic structures of Caroli disease are usually part of a more diffuse involvement of the biliary tree (vide infra). In contrast, mesenchymal hamartomas, which are more common in the pediatric age group, have a more complex structure, with multiple cysts and a solid component. Ciliated hepatic foregut cysts, so named because of their alleged origin from the embryonic foregut, are characterized by a lining of ciliated pseudostratified columnar epithelium resting on a basement membrane and surrounded by smooth muscle bundles.[18] They seem to occur more commonly in males in the fourth to fifth decade. Peribiliary cysts are derived from dilatation of the peribiliary glands located in the hilum and large portal areas. They have been reported primarily as findings in autopsy or hepatectomy specimens and have been associated with a variety of liver disorders.[19] They have not been reported in childhood. Hepatobiliary cystadenomas are benign multilocular cystic neoplasms that tend to occur in middle-age women but have been reported in patients from 2 to 87 years of age.[20] They usually occur in the liver but may also arise within the extrahepatic biliary tree and gallbladder. They are lined by a flattened, occasionally papillary, mucin-producing columnar epithelium. In females, the cysts are surrounded by dense mesenchymal tissue resembling ovarian stroma. Its malignant counterpart, the biliary cystadenocarcinoma, has not been reported in children.

HERITABLE INTRAHEPATIC CYSTIC DISEASE

The major heritable conditions characterized by intrahepatic bile duct cysts are congenital hepatic fibrosis (CHF), autosomal recessive polycystic kidney disease (ARPKD), and autosomal dominant polycystic kidney disease (ADPKD). There are also a number of heritable malformation syndromes characterized by potential bile duct cysts and renal disease. The DPM is seen in essentially all of these disorders (least commonly in ADPKD). Whenever the DPM is the basis for the cysts, the cysts communicate proximally and distally with the biliary tree. Renal cysts of tubular origin or other renal developmental lesions are typically present in most of these conditions. It is of note that the renal lesions tend to be dissimilar in the different clinical conditions.

CONGENITAL HEPATIC FIBROSIS

The term "congenital hepatic fibrosis" was coined by Kerr and colleagues[10] and is essentially defined by a characteristic hepatopathology, resulting in portal hypertension and an increased risk of ascending cholangitis. CHF is associated with a wide spectrum of disorders, the most frequent of which is ARPKD, but can also be an isolated condition.

The relationship of ARPKD to CHF is still somewhat controversial. Some investigators maintain that ARPKD and CHF represent a single disorder, whereas others suggest that they are distinct entities with overlapping hepatic histologic features.[5] The hepatic histomorphology in both lesions is essentially similar and is characterized by the DPM. The renal lesions, which also consist of tubular cysts in both, classically differ markedly in both pathology and clinical severity. In newborn patients with ARPKD, the renal lesions are diffuse and prominent clinically, whereas in patients who exhibit the clinical picture of CHF, the renal lesions are often not as evident in early life and are minor. Recently, a gene (*PKHD1*) that maps to the 6p21 locus and encodes a large, receptor-like protein, fibrocystin, has been identified as the site of mutations resulting in ARPKD.[21,22] The identification of this gene will prove to be valuable in the delineation of these two identities.

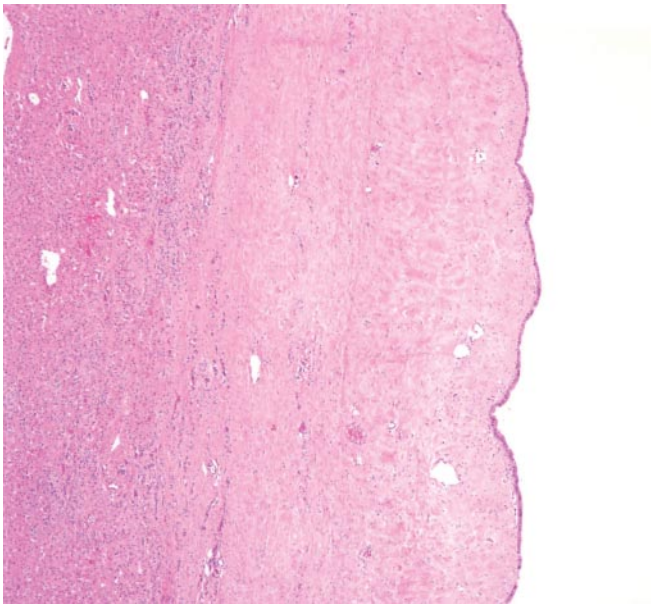

FIGURE 50.1-3 Hepatic cyst. Solitary hepatic cyst from a 9-year-old female. The cyst lining consists of a low cuboidal epithelium resting on a thick fibrous wall. Liver parenchyma can be noted toward the left of the picture (hematoxylin and eosin; ×40 original magnification).

Clinical Findings

A considerable range of clinical presentations is observed in patients with CHF. Most patients present with portal hypertension in the first decades of life. Some patients present with cholangitis, whereas other patients are discovered only incidentally at autopsy (latent CHF).[23] The precise pathogenesis of the portal hypertension is unknown but is thought to be associated with the hepatic fibrosis and/or portal vein abnormalities. Hematemesis or melena is the presenting sign in 30 to 70% of patients from pediatric and mixed population studies.[24,25] In children, the age for presentation of hematemesis may be as early as the first year of life,[26] but it usually ranges from 5 to 13 years. Firm or hard hepatomegaly is present in nearly all patients, often with a prominent left lobe, and this is usually one of the presenting findings. Splenomegaly occurs in the majority, accompanied by hypersplenism with thrombocytopenia. Splenic pressure is elevated, and naturally occurring splenorenal or gastrorenal shunts are occasionally documented. Portal vein abnormalities, characteristically duplication of the intrahepatic branches, are common.[24,27] This is in contrast to histologic descriptions of hypoplastic portal vein branches by others.[5] Occasionally, portal vein thrombosis or cavernous transformation of the portal vein is documented. Renal lesions, when present, appear to be minimal and of little clinical significance. An appearance similar to medullary sponge kidney has been described.[28] Cases of renal insufficiency described in association with CHF may, in fact, represent "late-onset" ARPKD.[29]

Pathology

The cut surface of the liver is speckled with irregular, whitish areas of fibrosis. The characteristic lesion is the DPM, and parenchymal disease is usually absent. The degree of fibrosis is variable, from enlarged portal tracts to broad bands of connective tissue linking portal tracts. It is usually diffuse but occasionally confined to one lobe or even one segment of a lobe.[30,31] Because the lesion may not be equally prominent throughout the liver, needle biopsies may be unreliable in establishing the diagnosis. Although Jorgensen found an increase in the average diameter of bile ducts in patients with CHF compared with those in controls,[8] the exact incidence of gross cysts is not established, nor is it clear whether the incidence of cysts increases with age.[24] Dilatation of bile ducts becomes clinically significant when associated with either cholangitis or malignancy. Cholangitis may be occult, acute, or chronic in nature and contributes significantly to both the morbidity and mortality of CHF. Calculi may form in the dilated ducts, initiating or complicating preexisting cholangitis. Cholangiocarcinoma is an uncommon but serious complication of CHF,[32] and premalignant changes may be observed in the epithelium of cystically dilated ducts. Cholangiocarcinoma may also be found in association with choledochal cysts or dilated intrahepatic ducts in the absence of DPM.

Visceral abnormalities in addition to those in the liver and kidney, described in single or small groups of patients, include congenital heart disease,[33] pulmonary hypertension and arteriovenous fistulae,[34,35] berry aneurysms,[36,37] and osteochondrodysplasia.[38] It is unclear whether these anomalies are intrinsic to the basic disease or coincidental. A syndrome of intestinal lymphangiectasia and protein-losing enteropathy in association with CHF, as described by Pedersen and Tygstrup[39] and by Pelletier and colleagues,[40] has now been demonstrated to be phosphomannose isomerase deficiency[41] (vide infra).

Therapy for CHF

Portosystemic shunting has been the treatment of choice because there is a low incidence of postoperative encephalopathy or hyperammonemia.[24] Prospective trials of other alternative approaches, such as sclerotherapy, banding, or pharmacologic management of varices, are not yet available. Nevertheless, the presence of spontaneous portosystemic shunts in some children suggests that sclerotherapy or banding may be beneficial if either can be shown to hasten the development of hemodynamically significant shunts without surgery. If surgery is selected as the treatment for portal hypertension, the type of shunt should be carefully chosen to prevent the limitation of options for either hepatic or renal transplant in later life.

Prolonged cholangitis is a major complication and has been responsible for hepatic failure and death. Therefore, unexplained fever or serologic evidence of inflammation in the absence of fever warrants a diagnostic liver biopsy and aspirate for culture.[42] Manipulation of the extrahepatic biliary tree carries an increased risk of infection in patients with abnormal ducts or bile stasis.[43] In cases of refractory cholangitis, surgical management and external or internal drainage may be necessary to resolve the hepatobiliary infection. In patients with stasis and refractory cholangitis, a choleretic agent may significantly augment therapy. Ursodeoxycholic acid therapy and prophylactic antibiotic administration have not been adequately studied in CHF-related cholangitis but may have a role in selected patients.

Prognosis for CHF

In general, the prognosis for those older children who present with CHF is good. The limitations are those imposed by complications of the disease, namely portal hypertension, cholangitis, and, occasionally, renal or hepatic failure. Chronic renal failure is most common in patients with a presentation in infancy. As noted, portal hypertension is usually successfully managed and rarely complicated by hepatic encephalopathy. Ascending cholangitis with sepsis and hepatic failure is a major cause of death in most series.[24,25,44] In those patients with chronic cholangitis and/or progressive hepatic dysfunction, liver transplant may prove to be the optimal therapy. Occasionally, patients have received combined renal and hepatic transplants for multiorgan failure.

CHF-Nephronophthisis

In this heritable group of disorders, there is a combination of hepatic lesions with some similarity to CHF with severe tubulointerstitial renal disease.[45–47] Its relation to the previously discussed disorders is not clear because the renal

lesions differ considerably from those seen in the previously discussed disorders, and even the hepatic lesion sometimes does not show a completely typical DPM. These conditions are nonetheless discussed in this chapter given the combination of heredity and the simultaneous presence of renal and liver disease with DPM-like features. The renal lesions are quite different from those of CHF and ARPKD and are characterized by interstitial inflammation and fibrosis with tubular atrophy, cyst formation, and secondary glomerulosclerosis (nephronophthisis). There is usually progressive renal failure with uremia by 20 years of age. The hepatic lesion has features consistent with DPM, although the bile ducts may not feature the characteristic profiles of those in typical DPM, and portal inflammation has been noted in some instances. Morphometric studies by Landing and colleagues on the biliary profiles and portal tracts in some of these diseases suggested heterogeneity in expression and development.[48] These disorders bear some similarities to renal-retinal syndrome (Senior-Loken syndrome), which is characterized by nephronophthisis and retinitis pigmentosa or retinal aplasia. Recent studies have demonstrated significant genetic heterogeneity in Senior-Loken syndrome. The syndrome has been associated with homozygous mutations in the *NPHP1*[49] and *NPHP4*[50] genes. *NPHP1* and *NPHP4* code for nephrocystin and nephroretinin, highly conserved proteins important in cell-cell and cell-matrix recognition.[51] Some patients have also been mapped to a locus on 3q22, overlapping the *NPHP3* locus.[52] Most of these patients do not seem to have liver involvement. It is currently unknown whether the patients with CHF nephronophthisis described in the past, before gene defects in cases of familial nephronophthisis were identified, have similar gene abnormalities.

PHOSPHOMANNOSE ISOMERASE DEFICIENCY

Phosphomannose isomerase deficiency, a disorder of glycosylation, has been associated with DPM and a protein-losing enteropathy.[41,53,54] Kidney disease has not been described in affected patients. Disease appears to result from hypoglycosylation of a number of serum and glycoproteins and suggests a metabolic anomaly leading to the development of the DPM. Phosphomannose isomerase deficiency is particularly interesting in light of the work of Terada and colleagues, who have highlighted cell-matrix interaction and the role of glycoproteins during development of the human intrahepatic biliary system.[55]

CHF AND MALFORMATION SYNDROMES

CHF accompanies a considerable number of malformation syndromes, usually in combination with cystic, dysplastic kidneys (Table 50.1-2). The pathogenetic implications of this coexistence of renal and hepatic cysts in these malformation syndromes and their relationship to ADPKD and ARPKD are not clear, particularly because the renal disease varies considerably in character among the various conditions. Although the literature is replete with descriptions of syndromes with developmental liver lesions, in many reports, the liver findings are poorly defined, often superficially described as "liver fibrosis," "increased bile ducts," or "liver cysts," and lack adequate histologic analysis. Therefore, the syndromes briefly discussed here are those in which there is reasonable evidence that DPM frequently accompanies the other malformations.

Meckel-Gruber syndrome is a recessively inherited lethal condition characterized by a central nervous system malformation, usually an occipital meningoencephalocele, bilaterally large multicystic kidneys, CHF, and polydactyly.[56] There is considerable heterogeneity in clinical findings, and at least three different gene loci have been identified: *MKS1* on 17q, *MKS2* on 11q, and *MKS3* on 8q.[57] Sergi and colleagues reviewed the liver sections of 30 fetuses with Meckel syndrome and found that DPM was a constant anomaly.[58] Two kinds of hepatic lesions were observed: 23 cases showed mainly a cystic dilatation of primitive biliary structures with little portal fibrosis, whereas 7 cases showed mainly rings of interrupted curved lumina around a central fibrovascular axis and pronounced portal fibrosis.

Jeune syndrome (asphyxiating thoracic dystrophy) is a rare autosomal recessive skeletal dysplasia that often leads to respiratory insufficiency because of a severely constricted thoracic cage. Renal disease, pancreatic insufficiency, and abnormalities of the retina, nails, and dental defects are also described.[59] Cystic lesions occur in the kidney and pancreas, whereas the liver changes are mostly characterized by DPM with progressive fibrosis.[60] Clinically significant liver dysfunction may not be apparent in the majority of patients who die in early life, although, among patients who survive beyond infancy, the liver fibrosis seems to be progressive.[61,62] Yerian and colleagues have described abnormalities of intrahepatic portal veins and vascular shunts in the resected liver of an older child who underwent transplant.[60]

Ivemark syndrome (renal-pancreatic-hepatic dysplasia) is one of the two syndromes described by Ivemark. One is usually sporadic and is characterized by asplenia

with visceroatrial heterotaxy but no liver disease.[63] The other syndrome is characterized by dysplastic changes involving the kidneys and liver and pancreatic ducts and, frequently, polysplenia.[64] The liver lesions appear to be consistent with DPM. An autosomal recessive mode of inheritance has been proposed.[64] However, because similar renal, hepatic, and pancreatic abnormalities occur in other syndromes, including trisomy 9, Meckel, Jeune, Saldino-Noonan, and Elejalde types of chondrodysplasia, and glutaricaciduria type II, cases of renal-hepatic-pancreatic dysplasia do not necessarily constitute a homogeneous group.[65,66]

AUTOSOMAL RECESSIVE POLYCYSTIC KIDNEY DISEASE

ARPKD encompasses a spectrum of clinical and pathologic manifestations; however, the two invariant features are DPM and fusiform dilatation of the renal collecting ducts. The renal lesion, when identified in infancy, is characterized by radially arranged tubular cysts occupying most of the large externally smooth renal mass with widely spaced glomeruli (Figure 50.1-4). The longer patients survive, the less characteristic the renal lesions become because the cysts become more rounded, and in some cases with survival beyond the neonatal period, it may be difficult on examination of biopsies to correctly classify the lesion.[67] Using linkage analysis in families with an affected child, prenatal diagnosis became possible.[68]

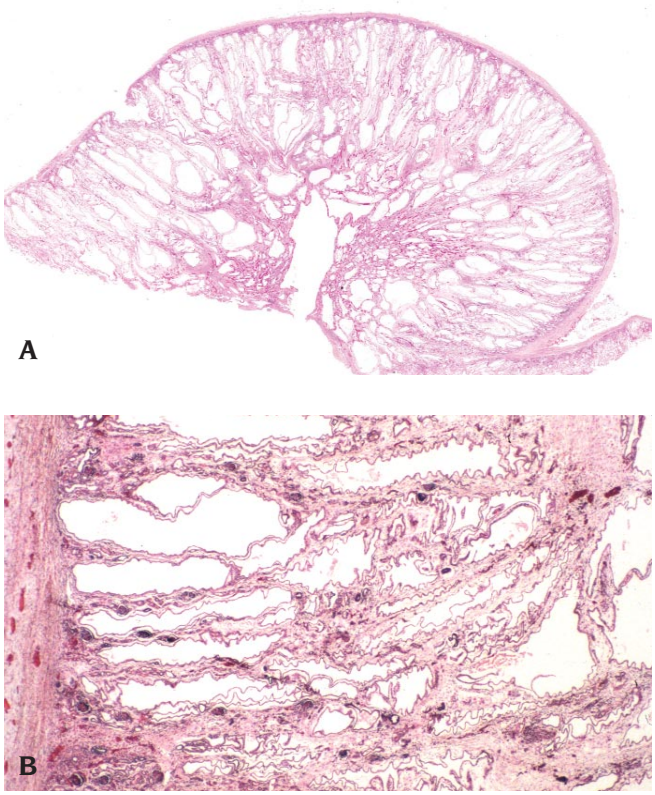

FIGURE 50.1-4 Autosomal recessive polycystic kidney disease. *A*, Low-power microphotograph of the kidney with diffuse fusiform dilatation of tubular segments in a radial arrangement. There is little residual normal parenchyma. *B*, Higher-power view. A few glomerular structures are seen between the dilated tubules and in the subcapsular area to the left of the picture (hematoxylin and eosin; whole mount section).

The renal disease may vary from a lethal perinatal disease to an incidental finding in older children. It has been estimated that 30 to 50% of infants affected with ARPKD will die in the perinatal period,[69] although recent studies suggest a better long-term prognosis.[70] In the infantile form, the kidneys are enlarged and severely dysfunctional. They may be palpable on examination, and an abdominal radiograph will demonstrate bilaterally enlarged kidneys. Excretory urography may only poorly visualize the collecting system. The nephrogram (characteristic of the neonatal presentation) demonstrates a radiolucent mottled parenchyma owing to the cystic changes of the nephrons. Many infants with ARPKD will develop uremia and chronic renal failure. Respiratory distress occurs from compression exerted by the enlarged kidneys, fluid retention, congestive heart failure, concomitant pulmonary hypoplasia, or pneumonia. Progressive renal failure and hypertension may occur over the first few weeks or months of life. Mortality is high in these patients. Patients who survive infancy may develop slowly progressive renal insufficiency and portal hypertension.[29]

The pathogenesis of the renal lesion is at least partially understood. It is tempting to speculate that closely related etiopathogeneses are responsible for both hepatic duct and renal tubular dilatation. Were this so, important insights regarding bile duct development and function might be gained. A variety of animal models have been developed to investigate the mechanisms of cystogenesis in the kidneys. These models have resulted in the speculation that abnormalities in epithelial cell growth, extracellular matrix composition, and fluid secretion are important in cyst formation.[71] Normal renal tubular absorptive epithelia can become cystic if (1) hyperplasia, localized to a distinct nephron segment, requires accommodation of an increased cell mass; (2) secretion, rather than absorption, leads to net accumulation of intratubular fluid; or (3) extracellular matrix abnormalities alter the epithelial microenvironment with resultant abnormal epithelial hyperplasia and secretory activity.[71] Evidence from several studies has suggested the role of the epidermal growth factor-α (EGFR) and transforming growth factor-α receptor axis in promoting epithelial hyperplasia and subsequent renal cyst formation in murine and human ADPKD and ARPKD.[72] Furthermore, similar abnormalities of EGFR expression have been suggested to mediate biliary epithelial hyperplasia and ductal ectasia in a mouse model.[73,74] An inhibitor of tyrosine EGFR tyrosine kinase activity has been shown to markedly reduce collecting tubule cystic lesions, improve renal function, decrease biliary epithelial abnormalities, and improve life span in a mouse model of ARPKD.[75] A murine model of ARPKD, characterized by a mutation in the mouse *cpk* gene, suggests that an inactivating mutation in the *cpk* allele interferes with normal tubular epithelial differentiation in the liver and kidney.[76] This rat model was a critical development in the identification of the *PKHD1* gene.

LIVER DISEASE IN ARPKD

The hepatic lesion is relatively uniform, and grossly visible cysts are uncommon. There is portal tract fibrous enlargement with numerous biliary profiles, as in CHF. Normal interlobular ducts in the center of the tracts are often missing.[5] As in CHF, the bile ducts are in continuity with the rest of the biliary system (communicating cystic disease). The precise incidence of portal hypertension in ARPKD is unclear and may be less than in CHF, although this may reflect the fact that children with ARPKD often die earlier in life. With increasing age of the patients, grossly visible cysts may become more frequent, and an increase in portal fibrosis may be noted.[77] CHF and its attendant complications appear to be a significant cause of mortality and morbidity in older children who have undergone renal transplant.[78] In addition to the renal and hepatic findings, pancreatic fibrosis with duct dilatation or proliferation has been reported occasionally in ARPKD.[79] Interestingly, the *PKHD1* gene has been found to be expressed in the pancreas, as well as in the liver and kidney.[21]

PKHD1 and Fibrocystin/Polyductin in ARPKD

Genetic linkage studies of families with ARPKD allowed the mapping of the disease locus to the 6p21-cen region of chromosome 6.[80] This allowed prenatal diagnosis to be available for siblings of probands.[68] Subsequent studies demonstrated that the clinically diverse presentations of ARPKD, including the severe renal perinatal form, mapped to the same region of chromosome 6,[81] suggesting that mutations in a single gene are responsible for the varied clinical presentations and classifications of fibropolycystic disease. Of the different rodent models of ARPKD, only one rat model with similar manifestations to ARPKD, the Pck rat, mapped to a region syntenic to chromosome 6 in the human, and this model was used to localize and identify the human disease gene.[21] Independently, and using different strategies, Ward and colleagues[21] and Onuchic and colleagues[22] identified the gene *PKHD1*, which encodes a large receptor-like protein. The gene is extremely large, encompassing 67 coding exons spanning more than 469 kb of genomic deoxyribonucleic acid (DNA), and the human transcript is approximately 16 kb. The gene was expressed in the fetal kidney and in the adult kidney and pancreas, with lesser levels seen in the liver.[21,22] The massive protein encoded by *PKHD1*, termed by the authors fibrocystin[21] and polyductin,[22] was predicted to contain 4,074 amino acids with a molecular weight of at least 447 kD.[21,22] This protein has limited homology with other known protein domains but no homology with the polycystins of ADPKD.[22] In 11 of 14 studied kindreds, Ward and colleagues found 6 truncating and 12 missense mutations, with the majority of patients being compound heterozygotes.[21] In a patient group of 25 individuals, Onuchic and colleagues identified potentially pathologic variants in 21 (42%) of the 50 chromosomes, and there was some evidence supporting a genotype-phenotype correlation, with truncating mutations possibly being correlated with more severe manifestations.[22] Bergmann and colleagues[82] and Rosetti and colleagues[83] reported further results of extensive screening for *PKHD1* mutations in ARPKD. In 90 patients, the mutation detection rate was 61%, and 45% of mutations were predicted to truncate the protein. The likelihood of mutation detection was higher for severely affected patients (85%) than for those with moderate ARPKD (41.9%) or for CHF with Caroli disease (32.1%).[83] In both studies, the type of mutation was somewhat correlated with the phenotype, with patients carrying two or one truncating mutation generally having more severe and earlier-onset disease. Except in cases of consanguinity, most patients with two identified mutations were compound heterozygotes.[82,83] The large size of the gene and the widespread location of mutations have, however, limited the applicability of mutation screening for many patients.

AUTOSOMAL DOMINANT POLYCYSTIC KIDNEY DISEASE

ADPKD is the most common hereditary kidney disorder, with a frequency estimated to be from 1 in 400 to 1 in 1,000 individuals worldwide.[84] In contrast, ARPKD is less common, with an incidence in the range of 1 in 6,000 to 1 in 40,000. Although the disease is clinically manifest primarily in adults, it can be anatomically identified even in fetal life. It is important to recognize for its genetic implications, even though the functional significance of the finding is not apparent until beyond childhood. The hepatic lesions are primarily duct cysts, which are readily demonstrated ultrasonographically. Cysts increase in size from childhood until 40 to 50 years of age (Figure 50.1-5). They are recognized and are perhaps present at an earlier age in women than in men. Commonly, the cysts in this condition are dilated ductal elements, which are not shown to communicate with the distal biliary tree and do not contain bile. However, there may also be portal tract lesions consistent with the (communicating) DPM in a smaller percentage of patients.[85] The

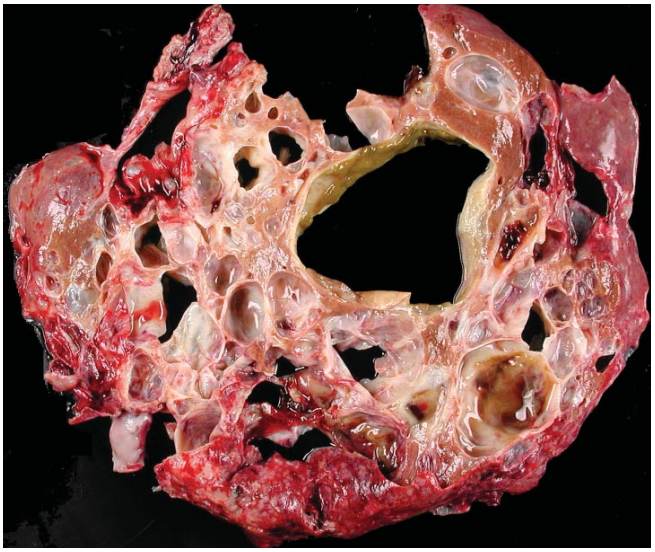

FIGURE 50.1-5 Polycystic liver disease. Hepatectomy specimen at transplant from a 37-year-old male. Photograph courtesy of Dr. Emma Furth, Hospital of the University of Pennsylvania.

significance of the association of communicating (DPM) and noncommunicating lesions for understanding the pathogenesis of the polycystic disease is unclear. Some authors consider the cysts in ADPKD the result of progressive dilatation of von Meyenburg complexes,[86] and Desmet has suggested that the cysts might become separated and noncommunicating as a result of kinks and strictures caused by the strangulating hyaline fibrosis that surrounds them.[5] The hepatic lesions in ADPKD have been thought to be insignificant clinically. However, as more patients with ADPKD survive for longer periods, it has become clear that a significant number of deaths result from hepatic complications.[87] Hepatic complications include infection of the cysts, cholangiocarcinoma, portal hypertension, and pressure effects owing to the cysts.

The renal lesion consists of cysts that appear to arise from multiple areas along the nephron and increase in size with age, eventuating in the kidneys and becoming large cystic reniform masses with inadequate numbers of functioning nephrons.[88]

Cysts may also be found in other organs, including the spleen, pancreas, thyroid, ovary, endometrium, seminal vesicles, and epididymis. Arterial aneurysms are present in up to 30% of cases.[89]

PKD1, PKD2, and the Polycystins

ADPKD results from mutations in one of at least three distinct genetic loci. Mutations in *PKD1*, mapped to chromosome 16p13.3, are responsible for the 85 to 90% of ADPKD in whites,[90,91] and prenatal diagnosis is thus possible. A second ADPKD gene, *PKD2*, has been localized to chromosome 4q13-4q23, and the mutant gene has been identified.[92] The products of *PKD1* and *PKD2* are polycystin 1 and polycystin 2, which have been hypothesized to be part of a common biologic pathway because mutations in these genes produce identical clinical manifestations. However, the onset of renal disease in polycystic kidney disease (PKD) type 2 occurs later in life than in PKD1. The genetic mechanism of disease in ADPKD seems to be a loss of heterozygosity caused by somatic mutations in the wild-type allele in renal epithelial cells. This "two-hit" hypothesis explains the focal nature of ADPKD in that cysts arise from only about 1% of the total nephrons in the kidney.[93] There is also evidence for a third locus for ADPKD, termed PKD3.[94]

ISOLATED HEPATIC POLYCYSTIC DISEASE

A number of reports derived from studies of medicolegal autopsies and occasional families suggested that a polycystic liver disease (PLD) might exist that occurs in the absence of renal disease and is dominantly inherited. Nevertheless, it has been uncertain whether such patients represent a discrete entity or patients with ADPKD, in whom renal cysts were overlooked or were inconspicuous. A study of over 30,000 medicolegal autopsies from Finland identified 22 cases with polycystic disease either of the liver or the kidneys. In only one case were cysts present in both organs, leading the authors to conclude that polycystic disease of the liver and polycystic disease of the kidney were separate entities.[95] Strong genetic evidence that adult PLD is an entity distinct from either PKD1 or PKD2 was presented by Pirson and colleagues, who traced the disorder through three generations of a family and excluded the presence of kidney cysts and linkage of the disease to the genetic markers of PKD1 and PKD2.[96] The genetically distinct nature of isolated PLD is further supported by the finding of Reynolds and colleagues that the causative gene in two large families with PLD mapped to 19p13.2-p13.[97] A Finnish study achieved similar results and also suggested the possibility of a second locus.[98] Drenth and colleagues narrowed the linkage assignment of the PLD locus on 19p and detected a heterozygous mutation at the *PRKCSH* gene.[99] Li and colleagues identified the product of the *PRKCSH* gene as a highly conserved ubiquitous protein that is likely important in signal transduction.[100] Cysts in patients with PLD are believed to arise from dilatation of biliary microhamatomas (von Meyenburg complexes) and from peribiliary glands, as in ADPKD, suggesting that the hepatic cysts in both conditions have a similar pathogenesis.[101] The development of hepatic cysts in PLD appears to be age dependent and rare in childhood, coming to medical attention usually because of symptoms owing to mass effect or from complications such as hemorrhage, infection, or rupture. A relatively higher prevalence of mitral valve abnormalities was also found in patients with PLD.[101]

CAROLI SYNDROME AND CAROLI DISEASE

Caroli disease is a congenital dilatation of the larger intrahepatic bile ducts. Caroli described two variants.[102] One is characterized by pure ductal ectasia without other hepatic pathology, for which the term "Caroli disease" has been proposed. The other variant is a combined type in which Caroli disease is associated with the lesions of CHF, for which the term "Caroli syndrome" has been proposed.[11] Communicating duct cysts occur in both variants. The first variant is very rare and is not known to be heritable. The nature of the second variant, Caroli syndrome, is currently controversial. It is not clear whether Caroli syndrome represents a separate entity from CHF, a variant of it, or a mere radiologic appearance in a variety of biliary disorders. Caroli syndrome has been associated with ADPKD.[103] It has been postulated that Caroli disease represents developmental arrest at the level of the larger intrahepatic bile ducts, whereas Caroli syndrome involves the entire intrahepatic biliary tree such that smaller interlobular ducts are affected (Figure 50.1-6).[6] The mode of inheritance of Caroli syndrome has been reported to be autosomal recessive, although a recent report of a Japanese family suggests an autosomal dominant form of inheritance.[104]

The relationship between Caroli disease and choledochal cyst is also controversial. According to Todani and colleagues, the type V choledochal cyst (intrahepatic cysts) is similar to the appearance of Caroli disease, and they consider the two synonymous.[105] However, those cases described as choledochal cysts in association with

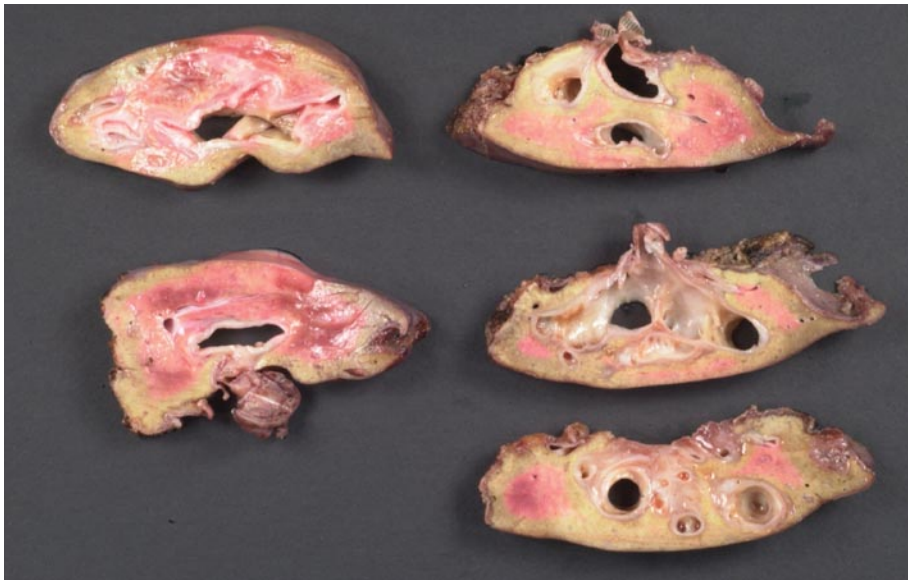

FIGURE 50.1-6 Caroli disease. Extensive intrahepatic bile duct dilatation involving primarily the left lobe of the liver, as illustrated by multiple sections from a partial hepatectomy specimen from a 9-year-old female.

CHF probably have a different pattern of inheritance and, thus, a different etiology and are considered to be a different entity by some authors.[84] Caroli disease typically becomes symptomatic in adults. Patients with Caroli syndrome may present earlier in life owing to the associated liver and renal abnormalities. The duct ectasias in both conditions predispose the patient to bile stasis and repeated attacks of cholangitis and complications such as intrahepatic lithiasis, biliary abscess, sepsis, amyloidosis, and cholangiocarcinoma (Figure 50.1-7).

BILE DUCT PAUCITY

A decrease in the number of ducts (paucity) is one of the most significant abnormalities of the intralobular bile ducts in children.[106] Bile duct paucity can only be defined histologically. In patients at or beyond 37 weeks of gestational age, paucity is present when histologic examination demonstrates that the ratio of ducts to portal tracts is less than 0.9 (Figure 50.1-8). In determining this ratio, it should be kept in mind that (1) bile ductules should not be included in the counting, (2) counts must involve sufficient portal tracts to be representative of the liver as a whole, and (3) this ratio is not applicable in premature infants.[107] The standard for the number of portal tracts required is 20, although some authors suggest that as few as 5 portal tracts may be sufficient.[53,107] Because 20 portal tracts are obtainable only on an operative wedge biopsy, it is commonly necessary to make, or at least strongly suggest, the diagnosis of paucity with a smaller sample number.

Because there is little precise knowledge of the factors that influence the development, viability, and maintenance of the intrahepatic bile ducts, it is not possible to formulate a genuinely coherent classification of the duct paucity conditions. For example, in some situations, there is an active destruction of previously existing ducts. In others, paucity is associated with a primary disease. For this reason, the disorders outlined in Table 50.1-3 are more a list of conditions than a true classification. Furthermore, for a number of the primary disorders in the table, the incidence of paucity is so low as to perhaps be coincidental.

TABLE 50.1-3 DISORDERS ASSOCIATED WITH BILE DUCT PAUCITY IN CHILDREN

SYNDROMIC BILE DUCT PAUCITY—ALAGILLE SYNDROME
NONSYNDROMIC BILE DUCT PAUCITY
Metabolic and genetic disorders
α_1-Antitrypsin deficiency
Cystic fibrosis (rare)
Peroxisomal disorders (rare)
Progressive familial intrahepatic cholestasis (rare)
Trisomy 21 (rare)
Prune-belly syndrome (rare)
Infection
Congenital cytomegalovirus infection (rare)
Congenital syphilis (rare)
Congenital rubella (rare)
Inflammatory and immune disorders
Graft-versus-host disease
Chronic hepatic allograft rejection
Sclerosing cholangitis
Sarcoidosis (rare)
Other
Drug- or antibiotic-associated vanishing bile duct syndrome
Familial idiopathic adulthood ductopenia
Biliary atresia (late)
Panhypopituitarism (rare)
Idiopathic

SYNDROMIC BILE DUCT PAUCITY (ALAGILLE SYNDROME)

Syndromic bile duct paucity, now referred to as Alagille syndrome (AGS), is defined by dominantly inherited bile duct paucity in conjunction with specific extrahepatic findings. It is a diagnosis that has both genetic and prognostic implications.[108–120] Also known as Watson-Alagille syndrome, arteriohepatic dysplasia, syndromic intrahepatic biliary hypoplasia, intrahepatic biliary atresia, intrahepatic biliary dysgenesis, and syndromic paucity of the interlobular bile ducts, it is recognized as an important and relatively common cause of neonatal jaundice and cholestasis in older children. AGS is caused by mutations in the human gene *Jagged1* (*JAG1*), which is mapped to chromosome 20p12.[121,122] This gene encodes a ligand for the Notch signaling pathway, which is involved in cell fate determination.

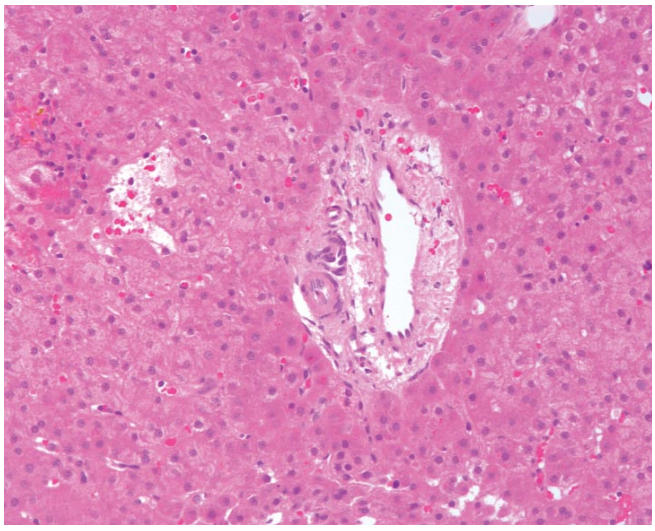

FIGURE 50.1-8 Alagille syndrome. Liver biopsy from a 1-year-old male. Bile ducts are absent from the portal tracts (hematoxylin and eosin; ×200 original magnification).

DEFINITION

AGS is characterized by a marked reduction in the number of interlobular bile ducts and cholestasis, occurring in association with cardiovascular, skeletal, ocular, facial, renal, pancreatic, and neurodevelopmental abnormalities. These occur with variable frequency, and early in infancy, the duct paucity may be absent.

The condition was recognized independently by Watson and Miller[110] and by Alagille and colleagues.[108,109] It is a familial disease with a wide variability in its clinical spectrum, even within individual pedigrees. The list of abnormalities associated with the syndrome has steadily increased since the initial descriptions, but the principal manifestations have remained essentially unchanged (Table 50.1-4).

GENETICS OF AGS

The prevalence of AGS has been reported to be 1 per 100,000 births.[123] This certainly underestimates the true frequency because many symptomatic patients with cardiac disease and mildly affected individuals are not included. There is an equal gender incidence. The family

history is positive for related clinical features in at least 15 to 23% of pedigrees,[109,112,117] although this underestimates the number of family members with subclinical forms of the disease or with mutations in *JAG1*. Pedigree analysis in families with multiple affected members demonstrated an autosomal dominant pattern of inheritance, with low penetrance and a great variability of expression.[109,112,117,124–127] For probands with an identified mutation in *JAG1*, mutational analysis of the family members has recently demonstrated that 56 to 70% are new mutations, not present in either parent.[128,129]

A small number of patients have been reported to have cytogenetically visible deletions of chromosome 20. These visible deletions, however, are rare, occurring in 2 to 7% of patients.[128–130] A translocation that segregates concordantly with three affected family members confirmed the location of the Alagille gene region at 20p12.[131] Rare cytologically invisible microdeletions have been identified.[132] The multiple reports of 20p deletions led to the incorrect hypothesis that AGS is a contiguous gene deletion syndrome. In 1997, two groups, Li and colleagues and Oda and colleagues, reported that AGS is due to a single gene defect in *JAG1*.[121,122] *JAG1* encodes a cell-surface protein that functions as a ligand for the Notch transmembrane receptor. The Notch pathway has been well studied in *Drosophila melanogaster* and *Caenorhabditis elegans*.[133] The system is highly evolutionarily conserved. The Notch pathway is present in many cell types during development, where it serves to regulate cell fate decisions. The name was derived from the notched wing appearance seen in *D. melanogaster* mutants. The multiple manifestations of AGS in humans suggest that Jagged and Notch interactions are critical for normal embryogenesis of the heart, kidney, eye, face, skeleton, and other organs affected in AGS.[134,135] Multiple Notch receptors and ligands have been identified in humans. Defects in *Notch3* have been identified as the cause of cerebral autosomal dominant arteriopathy with subcortical infarcts and leukoencephalopathy (CADASIL) syndrome.[136] Mutations in another Notch pathway ligand, delta-like 3 (*DLL3*), have been linked to the skeletal disorder spondylocostal dysostosis.[137] The other Notch receptors and ligands have not, as yet, been linked to specific clinical syndromes in humans.

JAG1 encodes a protein with a large extracellular domain, a transmembrane domain, and a smaller intracellular portion. Several regions of the protein are similar in all species studied. Mutations in the gene, however, have not been confined to those regions. A large number of mutations in *JAG1* have now been reported[121,122,128,129,138,139] and are found in approximately 70% of individuals by current techniques.[140] Of these, approximately 4% are gene deletion, 49% are protein truncating frameshift or nonsense mutations, 9% are splice-site mutations, and 9% are missense mutations. In 30%, no mutation was identified.[141] The relatively low percentage of missense mutations is interesting. Although there does not appear to be any phenotypic difference between patients with total gene deletion and those with isolated defects, it is possible that missense mutations might cause milder variants of AGS or perhaps even single-organ abnormalities. Abnormalities in *JAG1* could theoretically cause disease by either of two mechanisms. It appears that having only one normal copy of *JAG1* (haploinsufficiency) is not sufficient for normal embryogenesis in humans. The alternative theory, a dominant negative effect caused by abnormal protein, is not supported by the presence of disease in humans with a total gene deletion. The role of *JAG1* in human embryogenesis is not understood, but studies are under way to assess its role in hepatic and cardiac development.[134,135,142]

Gene testing for AGS is currently available on a research basis. Evaluation by fluorescent in situ hybridization (FISH) for deletions at 20p12 is more widely available but is likely to identify only about 5% of mutations causing AGS. A negative result may be misleading. Molecular testing is available in several centers but is difficult owing to the large size of the gene and the lack of significant mutational hot spots. The majority of mutations identified to date are unique and scattered widely across the gene. In addition, current evaluations cannot identify a mutation in approximately 30% of clearly affected probands.[129] When a defect can be identified in a proband, however, it is then easy and useful to identify relatives who are minimally affected yet carry a significant risk to their offspring. Also, it can help to reassure parents of patients with de novo mutations. Prenatal testing is available but only if the mutation is identified in the proband. Testing has also aided in the diagnosis of AGS for patients with minor or atypical manifestations. Given the relatively large number of patients in whom no mutation has yet been identified, it remains possible that other Notch/ligand gene defects or other unrelated genes may account for some patients diagnosed clinically as having AGS. The similarities between AGS with the 22q contiguous gene deletion syndromes are instructive in that the features of heart disease, posterior embryotoxon, and butterfly vertebrae are common to both disorders.[143] A FISH analysis for 22q deletions should be completed in all patients with potentially overlapping syndromes, particularly if liver disease and duct paucity are not prominent features.

Histopathology of the Liver in AGS

There are numerous publications describing the histopathologic features of the liver in AGS.[106,111,112,117,118,144–149] Although Alagille based his original diagnosis of the syndrome on a bile duct to portal tract ratio less than 0.5,[111]

the presence and extent of bile duct paucity vary, largely as a result of the different ages of the patients at the time of biopsy.[112,117,118,149] There is ample evidence that the number of bile ducts may at first be normal in infants with AGS and that paucity develops with time.[112,144,148,149] Studies of serial liver biopsies have demonstrated that in up to 50% of initial biopsies of patients with AGS less than 6 months or 1 year of age, the bile duct to portal tract ratio is normal, with paucity observed in 90% of those older than 1 year of age.[117,118] The overall frequency of bile duct paucity in AGS also varies with the criteria used in establishing the diagnosis, being a requirement for diagnosis in older studies, whereas in more recent ones, which rely on nonhepatic manifestations and the presence of *JAG1* mutations, paucity is identified in 80 to 85% of patients.[140]

Proliferation of bile ducts has been reported in early biopsies of patients with AGS,[146,150] mimicking extrahepatic biliary obstruction, a diagnostic difficulty compounded by abnormal cholangiograms that fail to visualize the hypoplastic extrahepatic biliary tree.[117,148] Diagnostic confusion with extrahepatic biliary atresia has resulted in Kasai portoenterostomies being performed, with variable results in mortality and progression of disease. Evidence of bile duct damage may be inferred by the findings of a piling up of the epithelium, nuclear pyknosis and pleomorphism, epithelial vacuolization, lymphocytic infiltration of the biliary epithelium, and peribiliary fibrosis. Other morphologic changes observed in early infancy include hepatocellular giant cell transformation with extramedullary hematopoiesis (neonatal giant cell hepatitis) and intralobular cholestasis. Portal spaces are usually not expanded but may contain a mild mononuclear inflammatory infiltrate. A reduction in the number of portal spaces, as observed by Hadchouel and colleagues,[147] may reflect an abnormal vasculature.

Hepatectomy specimens obtained at transplant are typically nodular but variably cholestatic. Late histologic changes include portal expansion and fibrosis, with bridging in approximately 50% of patients and cirrhosis in up to one-quarter.[117] The fibrosis has been observed by Hashida and Yunis to be more severe at the hilum.[149] Paucity of bile ducts is by then usually well established, and there is prominent lobular cholestasis. Bile ductular proliferation at that late stage is uncommon and may indicate a concomitant process, such as cholangitis.[151] Edema of the portal spaces, with dilatation of the lymphatics and veins, has been noted.[149] Other changes noted include hepatocellular degeneration and "pseudoxanthomatous" transformation, pseudorosette formations, increased hepatocellular copper, and sinusoidal fibrosis.[144] Electron microscopic observation of bile pigment accumulation in the Golgi apparatus, in concert with normal-appearing canaliculi, was reported as distinctive ultrastructural features in AGS,[152] although its significance has been disputed by others.[153]

Narrowing and hypoplasia of the extrahepatic biliary tree have been observed by cholangiography in both autopsy and hepatectomy specimens[111,144,146,149,151] and decreased filling of intrahepatic branches by endoscopic retrograde cholangiopancreatography.[154]

Hepatocellular carcinomas have been reported with AGS in children as young as 4 years of age,[155–160] as well as later in life.[161,162] Familial occurrence of hepatocellular carcinomas has also been observed,[162] with three of four siblings affected in one family.[163] Nodular hyperplasia, in some cases involving an entire lobe, has been reported in a few cases.[164,165] The significance of reported associations with thyroid cancer[166] and colonic polyposis[167] awaits further studies.

Renal Histomorphology in AGS

A variety of developmental and acquired renal abnormalities have been reported in AGS,[111,117,118,120,168–176] some leading to renal insufficiency, either early in infancy or later. These include medullary and cortical cysts,[171,174,175] renal hypoplasia,[169] ureteropelvic obstruction and bifid ureters, and renal artery stenoses.[176] The most frequently reported and most characteristic finding is deposition of lipids in the glomerular mesangium and basement membranes, resulting in a membranoproliferative pattern.[170–172] Lipid in the glomeruli can be demonstrated by histochemical stains on frozen sections or by electron microscopy.[171] According to Habib and colleagues, the glomerular lipidosis does not appear to be related either to the age of the patients or the degree of hypercholesterolemia but rather to the severity of cholestasis.[170]

Clinical Manifestations of AGS

AGS usually presents in the first 3 months of life in symptomatic patients. It is one of the more common etiologies of cholestasis and jaundice in the neonatal period and must be distinguished from biliary atresia and nonsyndromic bile duct paucity. In older children, AGS may present as a chronic hepatic disease. It is common for an adult to be diagnosed only after recognition of AGS in a severely affected child. The diagnosis is made when characteristic or compatible liver histology is accompanied by the major extrahepatic findings of the syndrome: chronic cholestasis, characteristic facies, cardiac murmur, vertebral anomalies, and posterior embryotoxon.

The extreme variability of the clinical manifestations and the incomplete penetrance of the syndrome obscure the diagnosis. Some patients demonstrate progressive pruritus, cirrhosis, or liver failure, resulting in liver transplant. Others have few or no symptoms and remain undiagnosed as adults.

Although most patients present with hepatic manifestations, the associated cardiac disease generally accounts for the majority of the early mortality.[111,112,117]

Hepatic Manifestations. The majority of symptomatic patients present in infancy and will have manifestations of hepatic disease ranging from mild cholestasis and pruritus to progressive liver failure. The severity of the disease in the parent is of no prognostic value as to severity in relatives or in subsequent children.[125] The degree of hepatic disease does not correlate with the severity of the other systemic manifestations, such as cardiac disease.

Hepatomegaly, with a firm or normal consistency, is recognized in nearly all patients.[61] Splenomegaly is rare

in infancy but appears in one-third to two-thirds by the second decade.[111,112]

The most common laboratory abnormalities are elevations of serum bile aids, conjugated bilirubin, alkaline phosphatase, and γ-glutamyl transpeptidase, which suggest a defect in biliary excretion in excess of the abnormalities in hepatic metabolism or synthesis. There are elevations of the serum aminotransferases, up to 10-fold, which may persist throughout childhood. However, in general, metabolic regulation of transamination, urea synthesis, glucose homeostasis, and protein synthesis is well maintained.

Jaundice is present in the majority of symptomatic patients and presents as a conjugated hyperbilirubinemia in the neonatal period. In half of these infants, it is persistent, resolving only in later childhood. Jaundice commonly is noted during intercurrent illnesses, but the magnitude of the hyperbilirubinemia is minor compared with the degree of cholestasis. Cholestasis is manifest by pruritus and elevations in serum bile acid concentrations. This pruritus is among the most severe in any chronic liver disease. It is rarely present before 3 to 5 months of age[111,112] but is seen in nearly all symptomatic children by the third year of life, even in those who are anicteric.[111,112]

The presence of severe cholestasis results in the formation of xanthomas, characteristically on the extensor surfaces of the fingers, the palmar creases, nape of the neck, popliteal fossa, and buttocks and around inguinal trauma sites. The lesions persist throughout childhood but may gradually disappear after 10 years of age.[177] The timing for the formation of xanthomas relates to the severity of the cholestasis and correlates with a serum cholesterol greater than 500 mg/dL. Hypercholesterolemia and hypertriglyceridemia may be profound, reaching levels exceeding 1,000 mg/mL and 2,000 mg/mL, respectively, with the expected abnormalities in lipoproteinemia. The incidence of atheromata is unknown, but they have been reported as early as 4 years of age in a child found at autopsy to have extensive aortic and endocardial fat deposition.[112]

Hepatic synthetic function is usually well preserved. Serum albumin and ammonia are typically normal, as is the prothrombin time (with adequate vitamin K supplementation). Nevertheless, progression to cirrhosis and hepatic failure, initially reported to be uncommon, is recognized in approximately 20% of patients with AGS.

Malnutrition and Growth Failure. Diminished bile salt excretion and low intraluminal bile salt concentrations result in ineffective solubilization and absorption of dietary lipid, essential fatty acids, and fat-soluble vitamins. The deficiency of fat-soluble vitamins has profound systemic effects. Coagulopathy (vitamin K deficiency), rickets (vitamin D deficiency), retinopathy (vitamin E and A deficiency), and a peripheral neuropathy and myopathy (vitamin E deficiency) may occur.[178]

Growth failure is a common feature (50–90%) during childhood with delayed pubertal development. This is thought to be the result of caloric deprivation from fat malabsorption, the intrinsic vertebral and skeletal abnormalities, and perhaps a secondary abnormality in endocrine function as demonstrated by elevated growth hormone levels with diminished somatomedin production.[179] Ponderal and linear growth is commonly delayed in the first 3 years of life, and this growth failure is due, at least in part, to significant acute and chronic wasting.[180] Patients with growth failure appear to be insensitive to exogenous growth hormone.[179]

Cardiovascular Manifestations. A wide range of cardiovascular abnormalities have been reported in patients with syndromic paucity.[111,117,181,182] An audible murmur is present at some time in 97% of patients.[117] The most common lesions are pulmonary artery stenoses at various sites in the proximal and distal tree, commonly at bifurcations. The entire pulmonary vascular tree may be hypoplastic, either alone or in association with other cardiovascular lesions. Among these, tetralogy of Fallot (TOF) is the most common (7–12%). Other lesions include truncus arteriosus, secundum atrial septal defect, patent ductus arteriosus, ventriculoseptal defects, and pulmonary atresia. Systemic vascular anomalies, including coarctation of the aorta, renal artery stenosis, and small carotid arteries, occur sporadically.[182] Although the majority of cardiac and vascular lesions are of no hemodynamic consequence, significant lesions do occur and in some series have been the predominant cause of early death.[111,112,117] In a large series of patients, Emerick and others demonstrated that only cardiac disease predicted increased mortality in AGS patients.[117] Many patients with intracardiac structural defects have concomitant pulmonic or peripheral pulmonic stenosis, and there is increased mortality following cardiac surgery for these lesions. Survival of AGS patients with TOF was 66% and with TOF with pulmonary atresia was only 25%.[117] In a recent, large study, McElhinney and colleagues reported the cardiac manifestions of 200 patients with a *JAG1* mutation or clinical AGS (or both), predominantly evaluated by cardiologists and/or by echocardiography.[182] A total of 187 subjects (94%) had evidence of cardiovascular involvement.[182] Of the 150 patients with anomalies characterized by imaging, right-sided anomalies were present in 123 and left-sided anomalies in 22, with both in 12.[182] The most common abnormality was stenosis or hyposplasia of the branch pulmonary arteries in 76%. TOF was seen in 23 (12% of all patients) and was accompanied by pulmonary atresia in one-third, a frequency higher than that seen in non-AGS TOF. The majority of patients with TOF-pulmonary atresia died early on. There was no clear difference in the cardiac disease seen in patients in whom a *JAG1* mutation was or was not identified.[182] Although, in general, genotype-phenotype correlations are rare with *JAG1* mutations, Eldadah and colleagues reported a large kindred with autosomal dominant TOF with reduced penetrance correlated with a missense mutation in *JAG1*.[183] Nine of 11 mutation carriers manifested cardiac disease, including TOF, pulmonic atresia, pulmonic stenosis, and absent pulmonary valve, yet none of the affected individuals met the diagnostic criteria for AGS.

Cardiac disease may also account in part for the increased post–liver transplant mortality seen in some series. Accordingly, it is advisable to seek formal diagnosis for any murmur

in a patient with hepatic disease. Doppler echocardiography is usually sufficient in structural cardiac disease, but cardiac catheterization or digital subtraction arteriography may be necessary for diagnosis in some cases.[184]

Recently, patients with congenital cardiac disease but without apparent AGS have been evaluated by molecular techniques for mutations in *JAG1*. Patients with nonsyndromic TOF patients at one cardiac center were found to have unsuspected defects in *JAG1*.[185] Other lesions, such as multigenerational peripheral pulmonic stenosis without apparent AGS, have also been demonstrated to have defects in *JAG1* by mutational analysis.[185] Loomes and others have shown that the expression of *JAG1* in the developing mammalian heart correlates with the cardiovascular disease seen in AGS.[142] The similarity of the severe cardiac disease, particularly TOF, to other genetic syndromes such as 22q deletion is not yet understood.

Characteristic Facies. Characteristic facies are described in the original reports of syndromic bile duct paucity. These consist of a prominent forehead, moderate hypertelorism with deep-set eyes, a small pointed chin, and a saddle or straight nose that, in profile, may be in the same plane as the forehead (Figure 50.1-9).[111] The facies may be present at birth but, in general, become more obvious with increasing age. The usefulness of the facies as a major criterion for diagnosis of AGS has been challenged because of interobserver differences. It has been suggested that these facies are a common result of early and chronic cholestasis,[186] but the constellation of findings and the finding of typical facies in asymptomatic parents may be striking. In a recent study, clinical dysmorphologists were able to distinguish via photographs infants and children with AGS from others with liver disease with a high degree of sensitivity and specificity.[187] Identification of facies in adults was less accurate. Kamath and colleagues have emphasized that the facies change over time and that the characteristic facies of an adult do not, in fact, directly resemble the facies in childhood but do resemble other adults with the gene defect.[187] With time, the chin becomes more prominent and the forehead becomes less dominant, resulting in a face with a predominant lower portion in contrast to the upper prominence of early childhood (Figure 50.1-10). Identification of these adults, who commonly have minimal signs and symptoms of AGS, would help hepatologists in the evaluation of adults with idiopathic cardiac, hepatic, or renal disease. Further evidence that *JAG1* mutations are directly involved in the development of characteristic facies include the demonstration of *JAG1* expression in the facial structures of developing mouse and human embryos[134,135] and the presence of characteristic facies in subjects with no history or evidence of clincal liver disease or cholestasis.

Vertebral and Musculoskeletal Abnormalities. Vertebral abnormalities are described in the initial reports of this syndrome.[109] The most characteristic finding is the sagittal cleft or butterfly vertebrae (Figure 50.1-11). This relatively uncommon anomaly may occur in normal individuals. The affected vertebral bodies are split sagittally into paired hemivertebrae owing to a failure of the fusion of the anterior arches of the vertebrae. Generally, these are asymptomatic and of no structural significance. The mildly affected vertebrae will have a central lucency. A fully affected vertebrae will have a pair of separate triangular hemivertebrae whose apices face each other like the wings of a butterfly. Although these abnormalities are present from birth, they are often unrecognized at the time of evaluation for neonatal hepatitis, only to be identified on spine films taken later. Other associated skeletal abnormalities include an abnormal narrowing of the adjusted interpeduncular space in the lumbar spine in half of the patients,[109,188] a pointed anterior process of C1, spina bifida occulta,[189] fusion of the adjacent vertebrae, hemivertebrae, and the presence of a bony connection between ribs.[110] The fingers may seem short, with short distal phalanges, broad thumbs, and fifth finger clinodactyly. A characteristic supernumerary digital flexion crease has been reported in 35% of AGS subjects compared with 1% of the general population.[190] Markedly decreased bone density and pathologic fractures are com-

FIGURE 50.1-10 Typical facial characteristics of an adult with Alagille syndrome.

monly seen in patients with AGS and significant cholestasis. This may be due to a combination of fat and calcium malabsorption, vitamin D and K deficiency, magnesium[191] or zinc deficiency, copper excess, or chronic malnutrition.

Ocular Abnormalities. A large and varied number of abnormalities have been described in AGS, including abnormalities of the cornea, iris, retina, and optic disk. A few of the findings are secondary to chronic vitamin deficiencies. Of the primary ocular abnormalities, posterior embryotoxon is the most important diagnostically. Posterior embryotoxon is a prominent, centrally positioned Schwalbe ring (or line), at the point where the corneal endothelium and the uveal trabecular meshwork join (Figure 50.1-12). Posterior embryotoxon occurs in up to 89% of patients with AGS,[111] but it also occurs in 8 to 15% of

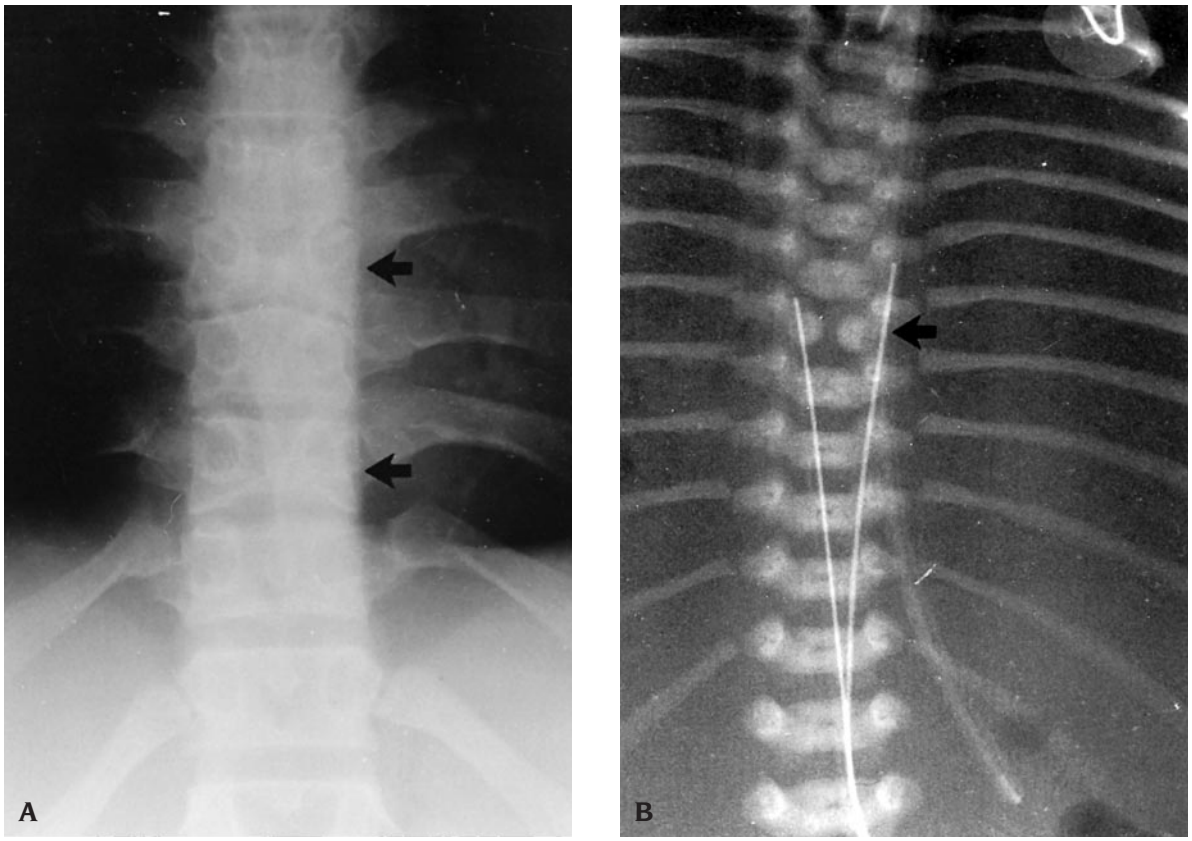

FIGURE 50.1-11 *A*, Multiple butterfly vertebrae (*arrows*) in an adolescent with Alagille syndrome. *B*, Fully affected vertebrae (*arrow*) with separate triangular vertebrae in a neonate with severe congenital heart disease and Alagille syndrome.

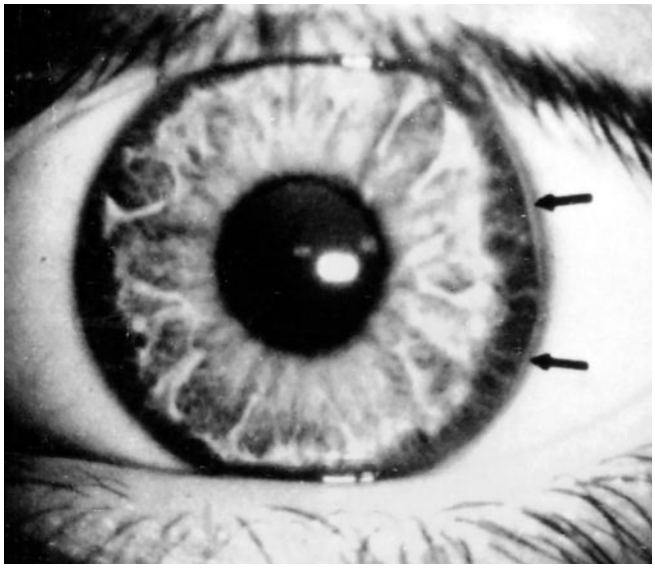

FIGURE 50.1-12 Posterior embryotoxon (*arrow*), prominent Schwalbe line.

normal eyes when evaluated by an ophthalmologist. Posterior embryotoxon can be part of an anterior chamber malformation syndrome. These malformations fall into three groups of peripheral and central abnormalities. Many of these abnormalities have now been reported in AGS. The Axenfeld anomaly is a prominent Schwalbe ring with attached iris strands. In general, about 50% of normal patients with this anomaly develop glaucoma, and glaucoma has been reported likewise in AGS.[192] The Rieger anomaly (primary mesodermal dysgenesis) is a prominent Schwalbe ring with attached iris strands and hypoplastic anterior iris stroma. This autosomal dominant inherited malformation has also been demonstrated in a patient with AGS.[193] Nischal found ultrasonographic evidence of optic disk drusen in at least one eye in 95% and bilateral disk drusen in 80% of patients with AGS but in none of the non-AGS liver patients they studied. This is markedly higher than the incidence in the normal population (0.3–2%), suggesting that this ophthalmologic sign may be an extremely useful diagnostic tool.[194] A peculiar mosaic pattern of iris stromal hypoplasia is present in many patients.[195] In addition, microcornea, keratoconus, congenital macular dystrophy, shallow anterior chambers, exotropia, ectopic pupil, band keratopathy, choroidal folds, and anomalous optic disks have been reported.[196,197] Other ocular findings, including retinal pigmentary changes, are identified in many patients with cholestasis but are not specific for the syndrome and are attributed to fat-soluble vitamin deficiencies.

Central and Peripheral Nervous System Abnormalities. Significant mental retardation (IQ less than 80) is a prominent feature in the initial reports of syndromic paucity.[109,115] More recent estimates are lower, perhaps owing to earlier recognition of the syndrome, the identification of less severely affected individuals, or more aggressive nutritional management. Although only 2% of children had mild mental retardation in one series, 16% had delays in gross motor skills.[117] Current studies emphasize the impact of chronic liver disease on brain development regardless of etiology[198,199] and focus on the role of vitamin E therapy and aggressive nutritional management with intervention programs to optimize outcome. No controlled trials are yet available to fully evaluate these claims. Abnormal visual, auditory, and somatosensory evoked potentials have been noted in AGS patients. These were not explained solely on the basis of fat-soluble vitamin deficiency. Visual evoked potentials returned to normal following resolution of the cholestasis with transplant. Dystonia and tremor associated with elevated whole-blood manganese levels and symmetric hyperintense basal ganglia magnetic resonance signals were seen in one patient with AGS.[200] This resolved following transplant. The possibility exists that neurologic findings in AGS are due to a combination of genetic and vascular abnormalities, chronic nutritional depletion, specific fat-soluble vitamin deficiencies, and toxins accumulated owing to deficient hepatic excretion and chronic cholestasis. A recent report details a family with dominantly inherited deafness, associated with congenital cardiac disease (including TOF) and posterior embryotoxon, without other features of AGS.[201] Affected individuals in this family had a missense mutation of *JAG1*, which segregated with the disease.

Intracranial bleeding has more recently been recognized to be a feature of AGS.[116,117] It occurs in up to 14% of patients and is a significant cause of morbidity and mortality. There is no pattern to the site of bleeding, which varies from epidural to subarachnoid to intraparenchymal. It may be associated with coagulopathy, although most patients had minimal or no abnormalities in clotting. Minor head trauma, to a degree unlikely to cause bleeding, was a factor in a minority of cases. Most were apparently spontaneous bleeds. A prospective study of magnetic resonance angiography was unable to identify any abnormalities, including one small aneurysm that resulted in a fatal subarachnoid hemorrhage (D. A. Piccoli, unpublished data, 1998). The data suggest that a central nervous system vasculopathy may be an intrinsic part of the multisystem abnormalities seen in AGS. Vascular abnormalities have been reported in other organs, including the kidneys and the lungs of patients with AGS. Furthermore, another Notch-related disorder in humans, CADASIL, is a dominantly inherited stroke disorder owing to defects in human *Notch3*. The occurrence and severity of strokes in AGS are not seen in other forms of pediatric liver diseases and thus should be considered as a primary complication of AGS. Careful correction of coagulopathy and observation after head trauma may decrease morbidity and mortality in some cases, but prediction or prevention of intracranial hemorrhage is not currently possible. Moyamoya syndrome, another form of vasculopathy, has been reported in children with AGS.[202] In addition, Lykavieris and colleagues reported a striking frequency of significant bleeding seen in 38 of 174 AGS patients not in liver failure who experienced a total of 49 significant events.[203] Although severe cholestasis was present in most, the majority of patients had normal coagulation and platelet studies. It is unclear if this bleeding tendency is a

pleiotrophic consequence of cholestasis or a primary genetic defect in vascular integrity or hemostasis. In this study, however, eight patients died secondary to the bleeding, half following a surgical episode.

Diagnosis: Clinical Criteria

The specific diagnosis of AGS can be established only by the clinical phenotype. Alagille and colleagues proposed diagnostic criteria for this disorder based on the presence of five major abnormalities. In addition to proper hepatic histopathology, the major criteria are chronic cholestasis, characteristic facies, cardiac murmur, vertebral abnormalities, and posterior embryotoxon.[111] The frequency of these abnormalities compiled from several large series is shown in Table 50.1-5.[111,112,117–119]

Because nearly all patients with significant bile duct paucity will manifest some degree of chronic cholestasis, Alagille and colleagues recommend the use of the other four criteria (facies, murmur, vertebral anomalies, and posterior embryotoxon) to define the syndrome.[111] In 36% of patients, all four features were present. Another 52% had three of the four features, and 12% had only two. Based on these data, Alagille and colleagues recommended that the diagnosis be made with cholestasis and two of the other four abnormalities. The need for more accurate criteria is emphasized by the 8 to 15% frequency of embryotoxon in the general population, the subjective nature of facies assessment, the potential difficulties in assigning a pathologic basis to a mild systolic flow murmur, and the incidence of cardiac disease in biliary atresia (10%), congenital rubella, and deletions of 22q. Furthermore, these data are derived only from significantly affected individuals, who, in the majority of cases, are the affected proband in a family. It is clear from recent genetic studies that family members carrying a mutation in *JAG1* may have few, if any, overt signs of AGS. When tested, most relatives of AGS patients with even isolated manifestations have the mutation.[141] Thus, patients with isolated cardiac disease or apparently nonsyndromic paucity may have mutations in *JAG1*. Although the diagnosis of AGS in a proband should not be established on the basis of fewer than three clinical criteria, it can be suggested. Molecular testing should help to further define these mildly affected patients and their relatives.

In the majority of patients, the hepatic manifestations of the disease dominate the clinical picture. Patients may present with neonatal hepatitis, jaundice, pruritus, cholestasis, or cardiac disease or may be identified as asymptomatic siblings (or parents). The syndrome must be distinguished from other etiologies of neonatal hepatitis and from extrahepatic obstructions such as biliary atresia. The usual evaluation will include an initial laboratory evaluation to identify other etiologies, followed by a sonogram, nuclear scintiscan, liver biopsy, and possibly operative cholangiogram.

An infant with AGS will usually have an elevated conjugated bilirubin and moderately elevated levels of the aminotransferases. The γ-glutamyl transpeptidase, alkaline phosphatase, serum bile acids, and cholesterol may be dramatically elevated, but none of these findings aid in the discrimination of syndromic bile duct paucity from biliary atresia or other causes of extrahepatic obstruction.

Although there is no evidence of mechanical extrahepatic obstruction in AGS, differentiation from biliary atresia can be difficult.[110,111,117,204] Ultrasound examination may

TABLE 50.1-5 CLINICAL MANIFESTATIONS OF ALAGILLE SYNDROME

SYSTEM	FINDINGS
Hepatic	Duct paucity, cholestasis, neonatal hepatitis, fibrosis, cirrhosis, portal hypertension, liver failure, hepatocellular carcinoma, nodular hamartoma
Cardiac	Murmur, pulmonic valvular stenosis, tetralogy of Fallot, pulmonary atresia, truncus arteriosus, ventricular septal defect complex, ventricular septal defect, atrial septal defect, anomalous venous return
Vascular	Peripheral pulmonic stenosis, pulmonic outflow stenosis, coarctation, patent ductus arteriosus, renal artery stenosis, middle aorta syndrome, moyamoya
Skeletal	Butterfly vertebrae, shortened interpedicular distance, shortened phalanges, short stature, spina bifida occulta, fusion of adjacent vertebrae, absent twelfth rib, shortened distal ulna and radius, clubbing, pathologic fractures, osteopenia, rickets
Ocular	Posterior embryotoxon, Axenfeld anomaly, Rieger anomaly, shallow anterior chamber, cataracts, strabismus, exotropia, ectopic pupil, optic disk drusen, iris stromal hypoplasia, band keratopathy, glaucoma, microcornea, keratoconus, congenital macular dystrophy, anomalous optic disks, fundic hyperpigmentation, pigmentary retinopathy, night blindness
Facial/cranial	Characteristic pediatric "particular facies," adult "particular facies," sinus abnormalities, chronic sinusitis, thinned cortical bones, deafness, large ears, high-pitched voice, macrocephaly
Renal	Neonatal renal insufficiency, adult renal failure, solitary, ectopic, or horseshoe kidney, bifid pelvis, duplicated ureter, small kidney, cystic and multicystic kidney, dysplastic kidney, infantile renal tubular acidosis, juvenile nephronophthisis, lipidosis, tubulointerstitial nephropathy, interstitial fibrosis
Central nervous system	Intracranial epidural, subdural, subarachnoid, and intraparenchymal bleeding; stroke; vascular malformation; mental retardation; developmental delay; school dysfunction; abnormal visual, auditory, and somatosensory evoked potentials
Cutaneous	Jaundice, xanthomata, pruritus, thickened, lichenified hands and feet
Growth disorders	Failure to thrive, fat-soluble vitamin deficiency, protein-calorie malnutrition, short stature
Pancreatic	Exocrine insufficiency, diabetes mellitus, pancreatic fibrosis
Other	Tracheal and bronchial stenosis, jejunal atresia, ileal atresia, malrotation, microcolon, otitis media, extrahepatic malignancies

Adapted from references 111, 117, 119, 120, and 149.

not identify the extrahepatic tree owing to diminished gallbladder size, and it is rarely diagnostic. Studies that may demonstrate patency of the extrahepatic biliary tree include technetium 99m disopropyl iminodiacetic acid (DISIDA) and similar scintiscans, radiologic cholangiography via either endoscopic retrograde cholangiopancreatography, percutaneous transhepatic cholangiography, gallbladder cholangiography, or operative cholangiography. A technetium-labeled scintiscan may show excretion into the duodenum in 39% of patients with AGS but in the remainder will not demonstrate communication (as is also seen in biliary atresia).[117]

In addition to the usefulness of DISIDA scintigraphy in the diagnosis of AGS in the neonatal period, there may be a characteristic pattern of excretion of tracer. Distinct retention of tracer in the periphery with central clearing in a young adult has been reported.[205] Studies have suggested that tracer excretion is uncommon in early infancy but may be demonstrable in the same patient later in childhood. In adults, tracer excretion is more common, and the pattern typically involves central clearing. This parallels the clinical progression of severe cholestasis seen in many patients with AGS and suggests that major ducts become the site of functional excretion in AGS.

The liver biopsy is the most useful preoperative study for the discrimination of syndromic bile duct paucity from extrahepatic biliary atresia. However, difficulties in histologic diagnosis may arise early in infancy because bile ductule proliferation may obscure duct paucity or because some ducts may, in fact, be present early in life. In very young infants in whom the percutaneous liver biopsy is not diagnostic, it may be helpful to delay exploration for 1 to 2 weeks and repeat the biopsy (while recognizing that the success of therapy for extrahepatic biliary atresia is correlated with surgery before 60 days of life).[206] If laparotomy is undertaken, an operative wedge biopsy should be obtained. An intraoperative cholangiogram performed by an experienced surgeon must be attempted and carefully interpreted prior to the construction of a portoenterostomy. The extrahepatic bile ducts are anatomically normal and patent in AGS but may be so narrow that operative cholangiography will fail to identify a patent system. Because operative cholangiography alone may result in an incorrect diagnosis of biliary atresia in up to 20% of cases,[117,204] a careful preoperative search should have been performed for the syndromic features. Hepatoportoenterostomy is inappropriate in AGS and may increase morbidity.[111,204] The correct diagnosis is also important for the genetic implications.

In older children, striking abnormalities are seen in fasting bile acid levels, serum lipids, γ-glutamyltransferase, and alkaline phosphatase. Bile acids in severe disease may be elevated 100-fold. The conjugated bilirubin is commonly moderately elevated. The magnitude of the hyperbilirubinemia is usually less than that of the bile acid elevation, and jaundice may disappear during childhood despite persistently elevated bile acids. Most patients have elevated triglyceride and cholesterol, which, in severe cases, may be from 1,000 to 2,000 mg/dL. Moderate elevations of the aminotransferases are common, although to lesser values than the γ-glutamyltransferase. In the majority of patients, the hepatic synthetic and metabolic functions are normal. Prothrombin time following parenteral vitamin K is usually normal. There may be deficiencies in substances requiring bile acids for absorption, such as vitamins A, D, E, and K, and essential fats.

Treatment

Infants with intrahepatic cholestasis may have significant fat malabsorption. Because half of the calories in infant formulas may be from fat, this defect contributes significantly to overall caloric deprivation. Medium-chain triglycerides are hydrolyzed and absorbed in the absence of bile salt micelle formation and thus are a significant caloric additive. Optimal diets include increased amounts of medium-chain triglycerides added to the diet and optimization of the carbohydrate and protein intake. Essential fatty acids may also be malabsorbed, resulting in clinically evident deficiency. This has resulted in acral lesions resembling porphyria, which have responded to parenteral supplementation of essential fatty acids.

Fat-soluble vitamin deficiency is present to a variable degree in most patients with bile duct paucity. Oral or parenteral supplementation is necessary for prevention of vitamin deficiencies. Further exacerbation of these deficiencies may be caused by therapy for cholestasis, such as phenobarbital or cholestyramine. Oral or intramuscular vitamin K will correct the coagulopathy in most patients, and its failure to do so may herald significant synthetic dysfunction. Aggressive therapy should be maintained in patients with clinical bleeding or evidence of significant hypersplenism. Rickets is seen in patients unless supplemented with oral or intramuscular vitamin D. Vitamin D absorption may be enhanced by administration of d-γ-tocopherol polyethylene glycol-1000 succinate (TPGS).[207] Early evidence of elevated serum alkaline phosphatase may be obscured, and serum levels of vitamin D should be checked at frequent intervals.

Deficiency of vitamins E and A may result in significant neurologic abnormalities, including cerebellar ataxia, peripheral neuropathy, abnormalities of extraocular movement, and retinopathy.[120,149,178,208] Vitamin E has been the most difficult to adequately supplement, although TPGS-soluble preparations are widely available. The TPGS is significantly more effective than other oral preparations and has been demonstrated to be effective in reversing neurologic damage in some patients.[209] The serum vitamin E level must be corrected for the serum lipid level in children with marked cholestasis. Vitamin A levels also should be monitored and oral or intramuscular replacement given as indicated. However, measurement of liver concentrations of vitamin A provides a more accurate indication of vitamin A status because serum levels of retinol and plasma retinol binding protein are still normal when hepatic stores of vitamin A are depleted.

Pruritus is the most significant symptom for many patients with chronic cholestasis. Antihistamines may give some relief, and care should be taken to keep the skin

hydrated with emollients. Fingernails must be trimmed. Cholestyramine may improve pruritus in children who can be convinced to take sufficient amounts, but some children will develop a severe acidosis on this therapy.[210] Colesevelam is less well studied but may have some advantages over cholestyramine. Phenobarbital appears to have little effect on either jaundice or on pruritus, although it has proven effective in enhancing bile salt–independent bile formation. Ultraviolet therapy may give temporary relief of pruritus in some cases.[211] Rifampin, which inhibits uptake of bile acids into the hepatocyte, appears to provide significant relief of pruritus in approximately half of patients.[212,213] Ursodeoxycholic acid, a potent choleretic, may have a dramatic effect in reducing symptomatic cholestasis, although, in some patients, it appears to exacerbate pruritus. In other cholestatic diseases, such as sclerosing cholangitis and primary biliary cirrhosis, ursodeoxycholic acid has been demonstrated to improve biochemical parameters and symptoms and may possibly retard disease progression. Naltrexone, an opioid antagonist, has also been useful in some cases.[214] Emerick and Whitington treated nine patients with extreme cholestasis and pruritus with partial external biliary diversion and demonstrated a dramatic decrease in pruritus scores, mean serum bile salt levels, and serum cholesterol.[215] Surgical ileal exclusion has not been well studied in AGS but may provide a more cosmetically appealing alternative to external diversion.

Prognosis

The outcome of syndromic bile duct paucity is highly variable and is most directly related to the severity of the hepatic and the cardiac lesions, with mortality predominantly attributable to these two organs. Complex congenital cardiac disease is a major cause of early mortality, although hepatic complications account for most of the later morbidity and mortality. These data are reflected in a follow-up study that reported a mortality rate of 26% (21 in 80) in 10 years, with only four deaths attributable to hepatic disease (portal hypertension in two and hepatic failure in two).[111] In another series, the predicted probability of survival to 20 years of age for all patients was 75%.[117] The probability of survival to age 20 was 80% for patients who did not require liver transplant and 60% in those who underwent transplant. Hepatic transplant may be required for chronic liver failure, portal hypertension, or severe intractable pruritus. Survival following transplant has varied significantly in different studies, from 45 to 100%.[60,61,116,117,156–158,216–218] Transplant does appear to have a higher risk for patients with AGS, owing in part to the severity of cardiopulmonary disease. Caution should be taken when considering relatives as potential donors for living-related transplant because unsuspected disease in the parent has thwarted donation.[219]

NONSYNDROMIC BILE DUCT PAUCITY

Nonsyndromic bile duct paucity is the term used to designate all instances of paucity except those occurring in AGS. It includes all nonsyndromic cases either with or without an associated primary disease. Thus defined, it covers such a great range of disorders that it is inappropriate to talk of a prognosis for nonsyndromic paucity generally. In some of these disorders, bile duct paucity is a characteristic feature (chronic allograft rejection) or a well-recognized association (α_1-antitrypsin deficiency) or outcome (biliary atresia). In others, bile duct paucity is an unusual and only infrequently reported finding. Most cases of nonsyndromic paucity are acquired, owing to either infections, immune-mediated injury (primary sclerosing cholangitis, primary biliary cirrhosis), or drugs and toxins, or in the setting of graft-versus-host disease (GVHD) or chronic allograft rejection. In those cases associated with a primary disorder, the principal determinant of outcome is usually the primary disease itself. In reviewing reports of supposed nonsyndromic paucity, it should also be kept in mind that there has been an inappropriate tendency to identify progressive intrahepatic cholestasis with paucity in the absence of histologic proof of paucity.

Only a few series of nonsyndromic cases have been published (earlier series of paucity probably include both syndromic and nonsyndromic cases because the syndrome has only relatively recently been recognized). Kahn and colleagues[220] and Alagille[221] have reported series based on histologic criteria. In the series of Kahn and colleagues, of l7 patients with nonsyndromic paucity, 9 were associated with well-defined primary diseases, including Down syndrome, hypopituitarism, cystic fibrosis, α_1-antitrypsin deficiency, cytomegalovirus (CMV) infection, and Ivemark syndrome. (In addition to these, other disorders, including congenital rubella, chromosomal abnormalities, GVHD, rejection of allograft livers, primary sclerosing cholangitis, and possibly Zellweger syndrome, have also been associated with paucity.[222]) In the remaining 8 cases in the series of Kahn and colleagues, the paucity was apparently primary or idiopathic (ie, not associated with any defined disease). The nonsyndromic cases had the clinical and general histopathologic picture of neonatal hepatitis. One of the most striking features in their series was that all of the nonsyndromic patients had paucity before the age of 90 days, whereas syndromic cases did not have paucity before 90 days of age. Their nonsyndromic cases also differed from their syndromic cases in that there was more portal fibrosis and less portal inflammation in the nonsyndromic cases. The clinical course of the patients with nonsyndromic paucity without underlying disease was not outlined in detail, but progressive liver disease was uncommon. Several aspects of this series deserve comment. Most authors have seen histologic paucity in occasional AGS patients before the age of 90 days, so this cannot be taken as an absolute criterion. It should also be noted that this study was conducted using needle biopsy specimens, and there is some lack of agreement as to how many portal tracts must be evaluated to obtain a statistically accurate estimate of bile duct numbers. As previously mentioned, in evaluating liver biopsies for paucity, it must be recognized, as pointed out by Kahn and colleagues, that in premature infants, a ratio of bile duct to portal tracts less than 0.9 may be normal.[107]

Alagille described 24 patients with nonsyndromic paucity who were classified into two groups: group I presented in the first few weeks of life with cholestasis, whereas group II presented later.[221] The groups differ histologically, with group I having portal inflammation, giant cell change, and minimal fibrosis and group II having more portal fibrosis and inflammation in relation to paucity. The outcome of these two groups is highly variable as half developed biliary cirrhosis and 38% died from hepatic failure. About one-third are anicteric, with only biochemical evidence of hepatic disease. Rubella was identified in one patient. It is of note that only 60% of these patients were screened for α_1-antitrypsin deficiency, but 29% of those tested were protease inhibitor type Z. Overall, therefore, it is not clear how many of the cases in this series were truly sporadic or idiopathic and how many were associated with primary diseases.

NONSYNDROMIC PAUCITY WITH PRIMARY DISEASE

Detailed discussions of the various primary diseases are presented elsewhere in this text, so the discussion here will be limited to the pathogenesis of paucity in those few primary conditions in which this pathogenesis is either partially understood or can be plausibly hypothesized.

In terms of paucity associated with well-defined primary diseases, it should be noted that (1) in virtually all of these, paucity is reported in only a small percentage of patients with these diseases, and (2) many of the diseases (eg, trihydroxycoprostanic acid excess, Ivemark syndrome) are themselves quite rare. From these facts, it is evident that a causal association between duct paucity and a number of these disorders is not well established.

Bile Duct Paucity in GVHD

Bile duct injury, sometimes eventuating in duct paucity, is one of the most distinctive hepatic lesions in GVHD. This injury is presumably the basis for the disappearance of ducts and potential paucity that occurs in some patients. It is unusual to find hepatic GVHD lesions in the absence of cutaneous manifestations of GVHD. The duct manifests injury by epithelial atypia, vacuolization, variable staining of nuclei and cytoplasm, and regeneration. Frank necrosis of epithelium can be seen on occasion. Accompanying the epithelial injury, there is often a lymphocytic infiltrate, sometimes with macrophages intermixed. On occasion, there is close proximity of lymphocytes and ducts and even invasion of the ducts by lymphocytes. In any single biopsy, however, it is not uncommon for the injury to be out of proportion to the inflammatory infiltrate, and the presence of endotheliilitis may be useful in indicating that the epithelial lesions reflect GVHD.[223] Centrilobular cholestasis is frequently present and is particularly intense when duct paucity has developed. The duct injury and paucity may be focal. Detailed reconstruction studies have suggested that the injury begins in relatively small ducts (± 30 μm in diameter).[224] When duct paucity is present in a patient with bone marrow transplant or when there is prominent active duct destruction in such a patient, the diagnosis is quite straightforward, particularly in the absence of CMV infection. Reports of duct ultrastructure, which are uncommon, have described a number of rather nonspecific changes involving duct epithelium and basement membrane, as well as close contacts between epithelial cells and lymphocytes.[225,226] Immunohistochemical studies reveal increased numbers of HNK1+ (killer) cells, Leu 3+ cells, and expression of human leukocyte antigen (HLA)-DR (major histocompatibility complex class II) positivity by the epithelial cells.[224,227,228] The latter is not found in normal liver but is found in a variety of conditions affecting the bile ducts, many of which have been speculated to have an immune-related pathogenesis. The precise role and importance of these duct alterations in GVHD and the genesis of the duct lesions remain to be determined, but the effects may be mediated through the action of cytotoxic lymphocytes, as appears to be the situation in mucocutaneous GVHD.[229]

It is interesting to note that despite the rather common occurrence of bile duct injury in GVHD, including a number of cases with paucity of ducts, it is uncommon to find reports of cirrhosis, biliary or otherwise, in GVHD.[230,231] At least superficially, this seems analogous to the similarly infrequent development of progressive liver disease in syndromic bile duct paucity.

Bile Duct Paucity in Liver Allograft Rejection

Bile duct injury is a significant element of the rejection of hepatic allografts,[223,232–235] and evidence of extensive damage (ie, involving greater than 50% of ducts) in a biopsy from a transplanted liver is regarded as strong evidence of acute rejection.[232] This damage is manifest by a variety of histologic features, including vacuolization of epithelial lining cells, variations in nuclei in these cells, and infiltration of the ducts by inflammatory cells. The latter are most commonly lymphocytes, but polys or eosinophils are not uncommon and may occasionally predominate. Active duct injury is accompanied by a lymphocytic or mixed portal infiltrate beyond the ducts. In a full-blown or classic case of cellular (acute) rejection, so-called endotheliilitis (together with duct injury and portal inflammatory infiltrate) forms the third element of a triad diagnostic for rejection.[232] If sufficiently severe, the injury may result in duct loss to the point of paucity, one of the histologic hallmarks of chronic rejection (Figure 50.1-13). The clinical presentation of chronic rejection may be either early or late, with the early-onset form typically occurring within 6 weeks of transplant. These patients often require urgent retransplant owing to the relentless progression of the liver disease. More commonly, patients with chronic rejection present between 6 weeks and 6 months following transplant with progressive jaundice and pruritus, following one or several episodes of acute rejection, or more insidiously, without apparent prior episodes of rejection. Histologically, chronic rejection is characterized by obliterative arteriopathy and bile duct injury, leading to bile duct loss. Degenerative changes in bile duct epithelium may be seen before significant bile duct loss.[236] Focal or transient paucity is not clinically or

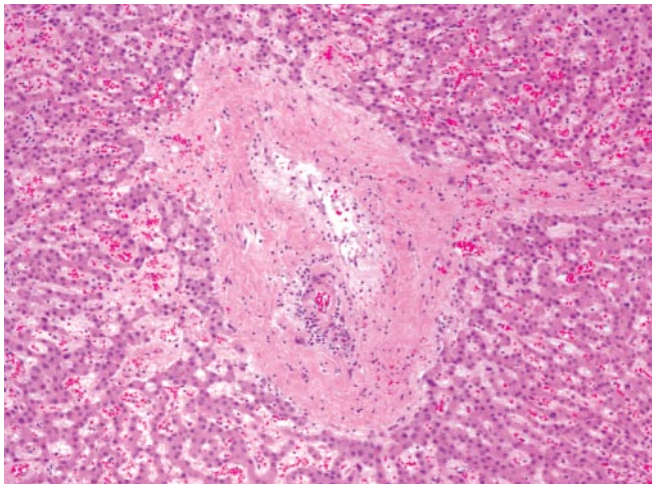

FIGURE 50.1-13 Bile duct paucity resulting from chronic rejection. Chronic rejection of a liver allograft 2 years following transplant. There is loss of bile ducts, with lymphocytic inflammation of the portal tracts and endotheliitis (hematoxylin and eosin; ×100 original magnification).

prognostically significant, but widespread persistent paucity is an ominous prognostic finding.[233] In hepatic allograft rejection, it is characteristic for portal tracts that have lost their ducts to show minimal or no inflammatory infiltrate. This probably speaks to the role of the infiltrating cells in the pathogenesis of the duct injury and loss.

Bile Duct Paucity in Viral Infections

Cholestatic liver disease with hepatocellular giant cell transformation and extramedullary hematopoiesis are frequent in congenital infection with CMV, among which are several well-documented cases of bile duct paucity, postulated to have resulted from an obliterative cholangitis.[237,238] Documentation of CMV-associated paucity in the preterm infant is more problematic because of the reasons stated earlier in the chapter.[239] Obliterative changes with focal loss of bile ducts have also been observed in congenital rubella[240] and in congenital syphilis.[241]

Drug-Associated Bile Duct Paucity

Many different drugs have been reported to cause chronic cholestatic liver disease, defined as the persistence of jaundice for more than 6 months after withdrawal of the causative drug in a patient without previous hepatobiliary disease.[242] More recently, duct injury and loss have been documented, most frequently following the use of antibiotics such as penicillin derivatives, quinolones, tetracyclines, and sulfa drugs, among others.[243–247]

Early biopsies typically reveal an active nonsuppurative inflammatory destruction of bile ducts with evidence of epithelial damage such as vacuolization and nuclear pyknosis. The portal inflammatory infiltrate is usually lymphoid, occasionally with eosinophils, histiocytes, or small granulomas.[247–249] There typically is a lobular hepatic component with canalicular cholestasis. Persistent ductopenia with progression to fibrosis may evolve over the ensuing months even after the cessation of the medication. Progressive loss of intrahepatic bile ducts is noted in untreated cases, as early as 5 to 6 months, and occurs in most patients despite treatment, even when adequate biliary drainage is established.[250–253] Injury by bile stasis, peribiliary ischemia, and continuation of the original insult may all be contributing factors. Heterogeneity and unevenness in the distribution of bile duct loss and occasional nodules of better preserved parenchyma may reflect local differences in biliary obstruction or fibrosis.[250,254]

Bile Duct Paucity in Extrahepatic Atresia

The development of intrahepatic bile duct paucity in relatively long-surviving patients with biliary atresia was recognized prior to development of portoenterostomy and is also seen in patients following portoenterostomy, even when adequate biliary drainage is established.[250,251,253] Injury by bile stasis, peribiliary ischemia, and continuation of the original insult may all be contributing factors. Heterogeneity and unevenness in the distribution of bile duct loss and occasional nodules of better preserved parenchyma may reflect local differences in biliary obstruction or fibrosis.[250,254]

Bile Duct Paucity in Primary Sclerosing Cholangitis

Primary sclerosing cholangitis is a chronic disorder of unknown etiology that is increasingly recognized in children. It is characterized by a generalized beading and stenosis of the biliary tree in the absence of choledocholithiasis, accompanied by histologic abnormalities of the bile ducts (Figure 50.1-14). It may occur in patients who are otherwise well but is often associated with inflammatory bowel disease. Secondary sclerosing cholangitis describes similar bile duct changes when a clearly predisposing factor such as choledocholithiasis or biliary surgery has been identified. There is progressive obliteration of the intra- and extrahepatic bile ducts, which may result in bile duct paucity, biliary cirrhosis, and liver failure.

2. *Biliary Atresia*

Kathleen M. Campbell, MD
Jorge A. Bezerra, MD

Biliary atresia is a progressive fibroinflammatory cholangiopathy of infancy that results in complete obliteration of the entire or portions of the extrahepatic biliary tree within weeks of birth. This obstruction results in impaired bile flow, reactive proliferation of intrahepatic bile ducts, chronic cholestasis, and ongoing hepatocellular injury. In general, infants appear well but display the classic features of jaundice, acholic stools, and hepatomegaly, features shared with other causes of neonatal cholestasis. Therefore, the initial task is to differentiate biliary atresia from other forms of neonatal cholestasis; timely diagnosis is vital because early surgical relief of biliary obstruction may improve long-term outcome. In the absence of surgical intervention, ongoing injury leads to biliary cirrhosis, portal hypertension, and end-stage liver disease. At this stage, liver transplant is the only therapeutic option for long-term survival.

Biliary atresia is the most common cause of prolonged conjugated hyperbilirubinemia in neonates and is the most frequent indication for liver transplant in the pediatric population, accounting for 40 to 50% of all pediatric liver transplants.[1] The health care costs associated with biliary atresia are significant, reaching $65 million/year in the United States alone.[1] Despite the obvious adverse impact to children's health, advances in understanding of the etiology and pathogenesis of biliary atresia have not kept pace with progress in other cholestatic disorders of childhood.[2] The lack of progress reflects the multifactorial nature of the disease, which has challenged physicians since it was recognized early in the nineteenth century (Table 50.2-1).[3] The development of surgical approaches to re-establish biliary drainage and the acceptance of liver transplant as a treatment for end-stage liver disease owing to biliary atresia have markedly improved clinical outcome. Yet multiple challenges remain, such as early recognition of pathologic jaundice by health care providers, accurate diagnosis of biliary atresia, identification of predictors of outcome and optimal timing of transplant, and design of novel and effective medical therapies. The recent development of research agendas to sponsor multicenter studies in Europe and the United States promises to bring biliary atresia to the forefront of patient- and laboratory-based research priorities. Although the biologic basis of biliary atresia is not yet known, important data exist on epidemiology, clinical course, pathology, treatment, and outcome. A review of these data is the focus of this chapter.

EPIDEMIOLOGY

Biliary atresia respects no geographic boundaries; it occurs worldwide and affects 1 in 8,000 to 1 in 15,000 live births. Within regions, there appears to be a higher incidence of the disease in nonwhite populations (African American, French Polynesian, Chinese). Some studies have suggested time-space clustering of cases and seasonal variation, with the majority of cases occurring in the fall and winter months (December to March).[4,5] Two large population-based studies from France and Sweden, however, failed to identify a significant seasonal variation or time-space clustering.[4–7] After controlling for geographic and racial factors, associations have been observed with advanced maternal age and increased parity, and with a tendency for early fetal losses in mothers of infants with biliary atresia.[4,7] In this context, the disease is rarely seen in stillborns or premature infants, although some patients have a low birth weight for gestational age.[4,8] A slight female predominance (1.25:1) may be present among affected infants, particularly in the "embryonic" form of the disease.[9,10] Although the overwhelming majority of cases of biliary atresia are sporadic, there are reports of apparent recurrences within families.[11–13] This may reflect a shared genetic predisposition, but studies of twins have demonstrated that most sets are discordant for the disease.[14,15]

TABLE 50.2-1 HISTORICAL LANDMARKS FOR BILIARY ATRESIA

YEAR	LANDMARK
1817	Burns's description of an infant with features suggestive of biliary atresia
1892	Review of 50 cases by Thomson

NIH = National Institutes of Health.

Taken together, these epidemiologic data suggest that environmental factors and genetic predisposition may be important determinants of disease. They also highlight the widespread occurrence of biliary atresia and underscore the need for physicians to be knowledgeable of the clinical features of the disease so that a diagnosis can be reached in a timely fashion.

CLINICAL PRESENTATION

Common Features

Despite variability in age at onset of symptoms, extent of hepatobiliary involvement, and presence of nonhepatic abnormalities, infants with biliary atresia share the cardinal features of jaundice (owing to conjugated hyperbilirubinemia), acholic stools, and hepatomegaly. This triad presents in infants who otherwise appear well. Although weight gain is initially adequate, it becomes suboptimal with progression of disease. In addition to these common features, variability in clinical presentation results from complications of liver disease or nonhepatic abnormalities. For example, (1) splenomegaly is common at the time of diagnosis and reflects the degree of hepatic fibrosis and portal hypertension, (2) lethargy is uncommon and when present should trigger evaluation of clotting function and of the central nervous system integrity because coagulopathy owing to vitamin K deficiency may result in intracranial hemorrhage, and (3) poor feeding and recurrent emesis may signal the coexistence of intestinal malrotation or hemodynamic instability secondary to a severe cardiac defect (Table 50.2-2).

Other signs and symptoms may develop with progression of liver disease. Ascites is rarely present at the time of diagnosis but may develop in infants with advanced fibrosis, bacterial peritonitis, or obstruction of portal blood flow (owing to portal vein thrombosis). Sometimes the presence of ascites is suggested by the appearance of inguinal or umbilical hernia, which is treated more appropriately by management of ascites rather than herniorrhaphy. When infants have impaired biliary drainage despite portoenterostomy, progression of liver disease is manifest by variable signs of malnutrition, with decreased subcutaneous mass and muscle weakness. In this setting, infants may also have dilated vascular collaterals ascending from the anterior abdominal wall toward the chest in a distended abdomen (caput medusae) because of intra- and/or extrahepatic portal venous hypertension. Careful evaluation and monitoring of these common clinical features are important for appropriate diagnosis and provide critical clues about the state of evolution of the liver disease. The rate of disease progression may also depend on specific clinical forms that have been identified by the systematic cataloguing of clinical features at the time of diagnosis.

TABLE 50.2-2 MAIN (TYPICAL AND ATYPICAL) CLINICAL FEATURES OF BILIARY ATRESIA

Typical Features for Infants at the Time of Diagnosis
Jaundice (secondary to direct or conjugated hyperbilirubinemia)
Acholic stools
Hepatomegaly—with variable degrees of splenomegaly
Clinical Signs Suggestive of Nonhepatic Complications
Easy bruising, central nervous system hemorrhage—coagulopathy owing to vitamin K deficiency
Poor feeding, vomiting—cardiac insufficiency owing to structural defects
Recurrent (bilious) emesis—intestinal malrotation and midgut volvulus
Features of Advanced Disease
Moderate to severe splenomegaly owing to progressive hepatic fibrosis
Growth failure—poor caloric intake, decreased absorption, or increased metabolic needs
Ascites—secondary to portal hypertension
Caput medusae—secondary to portal hypertension
Umbilical and/or inguinal hernia—complication of ascites
Coagulopathy not responsive to vitamin K—hepatocellular failure

Clinical Forms

There are two well-recognized clinical forms of biliary atresia: embryonic and perinatal.[10,16,17] These forms share the cardinal features of jaundice, acholic stools, and hepatomegaly but differ in the presence of associated anomalies, the timing of onset of jaundice, and perhaps clinical outcome. The embryonic form of biliary atresia (also referred to as "congenital" or "fetal") accounts for 10 to 20% of cases and is defined by the presence of congenital nonhepatic anomalies and earlier onset of disease. Infants present with pathologic jaundice at birth or shortly thereafter, frequently overlapping with physiologic jaundice, such that there is no jaundice-free interval. In addition, affected infants are more likely to have birth weights below the 50th percentile for age, even in the presence of maternal diabetes.[10] Notably, these infants may have complete absence of extrahepatic bile ducts, even a fibrous cord, suggesting a true defect in embryogenesis of the biliary system in a subset of patients.

Although the genetic basis for this form is unknown, hepatic and nonhepatic malformations may result from defects in molecules regulating embryonic development of the hepatobiliary system and the asymmetric organization of single organs, a process named laterality. Analysis of a large cohort identified nonhepatic malformations in 20% of the patients with biliary atresia.[18] Among these patients, defects in laterality were present in 29%, whereas isolated gastrointestinal or cardiovascular anomalies occurred in 59% and intestinal malrotation (with or without preduodenal portal vein; Figure 50.2-1A) was present in 12%. Splenic abnormalities (asplenia, double spleen, and polysplenia) may be present in up to 7.5% of patients with biliary atresia (Figure 50.2-1B), occurring in isolation or in combination with one or more additional defects in a variant known as biliary atresia splenic malformation (BASM) syndrome.[10] This syndrome includes polysplenia/asplenia, preduodenal portal vein, intestinal malrotation, abdominal situs inversus, midline liver, hepatic artery abnormalities, absent inferior vena cava, abnormal lung lobation, annular pancreas, and congenital heart disease. Although infants with the embryonic form of biliary atresia, with or without the BASM syndrome, had no obvious clinical or biochemical differences at the time of diagnosis, 15% were born to mothers with diabetes.[10] There is some evidence that patients with the embryonic form of biliary atresia have

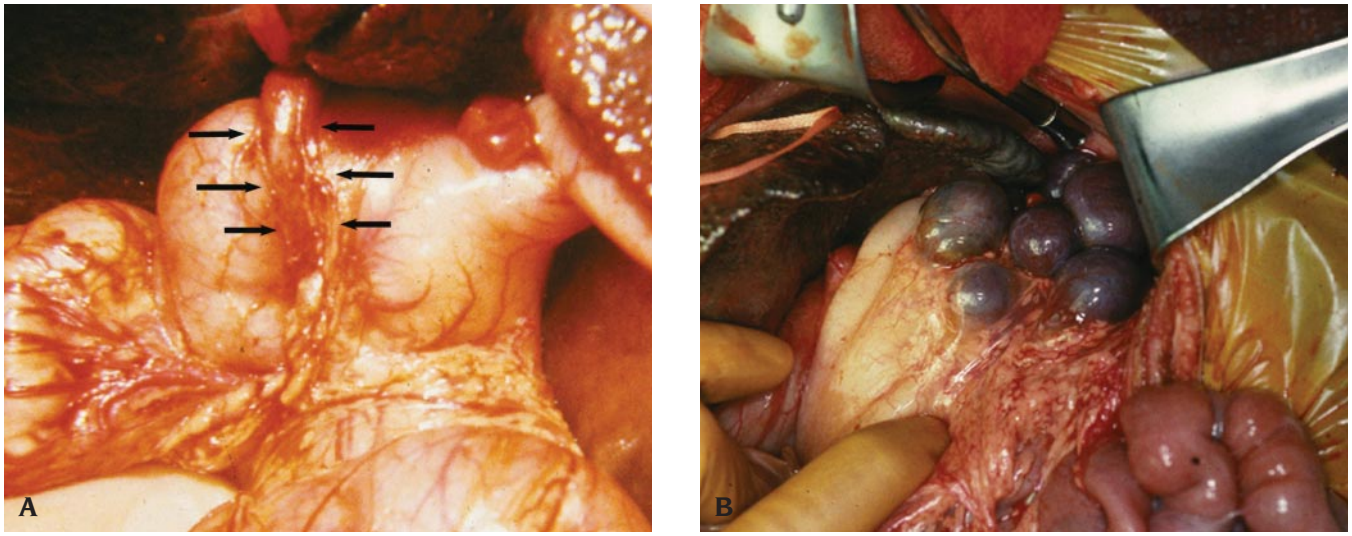

FIGURE 50.2-1 *A*, Operative findings of a preduodenal portal vein (*arrows*) in an infant with the embryonic form of biliary atresia at the time of portoenterostomy. *B*, Polysplenia in an infant with the embryonic form of biliary atresia at the time of portoenterostomy. Courtesy of Dr. Frederick Ryckman, Cincinnati Children's Hospital Medical Center, Cincinnati, OH.

worse outcome following portoenterostomy, with a decrease in actuarial survival (defined as death or transplant) within the first 2 years after surgery.[10] In addition to the challenges that extrahepatic malformations add to the care of infants with biliary atresia, more rapid progression of the hepatobiliary disease in this clinical form may account for a worse outcome.[19]

The perinatal form of biliary atresia (also referred to as "acquired" or "postnatal") accounts for the majority of the cases (80–90%) and occurs in the absence of other congenital anomalies. Most of the infants are born at term with an appropriate weight for gestational age. They have a variable jaundice-free interval after birth but develop jaundice, acholic stools, and dark-colored urine within the first few weeks of life. In contrast to the clinical setting observed in infants with the embryonic form, the combination of jaundice in an otherwise healthy infant and a history of a jaundice-free period is more consistent with a biliary injury that results from a perinatal or early postnatal insult. Efforts to determine the biologic relationship of potential pathogenic mechanisms are particularly important to understand the molecular basis of the clinical forms and to develop new diagnostic/therapeutic modalities for infants with biliary atresia.

PATHOGENIC MECHANISMS OF DISEASE

Any proposed pathogenic mechanism of disease must take into account important clinical features that are exclusive to biliary atresia: (1) onset of disease restricted to the neonatal period, (2) target of injury limited to the biliary system, and (3) lack of recurrence of hepatobiliary lesions typical of biliary atresia following liver transplant. Although inflammation of intra- and extrahepatic biliary tree is universal in biliary atresia, conflicting evidence exists with regard to triggering events, pre- and postnatal timing of onset, and the factors that promote ongoing hepatobiliary inflammation. However, careful observations based largely on epidemiologic and clinical features reported predisposing genetic factors, and the pace of disease progression provided valuable insight into the pathogenesis of disease. Based on these observations, five mechanisms have been proposed: (1) a defect in morphogenesis of the biliary tract, (2) a defect in fetal/prenatal circulation, (3) environmental toxin exposure, (4) viral infection, and (5) immunologic/inflammatory dysregulation (Table 50.2-3).[20]

Evidence for Defective Morphogenesis

Biliary atresia may belong to a spectrum of diseases involving inappropriate persistence or lack of remodeling of the embryonic ductal plate. This concept of ductal plate malformation as a contributing or causative factor for biliary atresia is supported by the persistence of the embryonic shape of interlobular bile ducts in some infants at the time of diagnosis.[17] Also, comparative analyses of the normal embryonic development of the ductal plate and the extrahepatic biliary tree between 11 and 13 weeks of gestation with biliary structures from 205 infants with biliary atresia revealed morphologic similarities in periductular mesenchyme and fibrosis.[21] During this phase of embryogenesis, the ductal plate undergoes remodeling to form large tubular structures surrounded by thick mesenchyme, with shared morphologic similarities to abnormal ductules within the porta hepatis of livers from infants with biliary atresia. Together, these data suggest that abnormal mesenchymal support and improper remodeling of hilar ducts may be important pathogenic factors in early stages of disease development. In agreement with a prenatal onset in some cases, a recent report described segmental cystic dilatation of the biliary system in three fetuses during routine prenatal ultrasonography; postnatally, only duct remnants were detected proximally and distally to the cysts in a fashion similar to the histologic features of biliary atresia.[22]

There is a growing body of evidence pointing to possible roles of specific genes in the control of hepatobiliary

TABLE 50.2-3 POTENTIAL MECHANISMS INVOLVED IN THE PATHOGENESIS OF BILIARY ATRESIA

MECHANISM	SUPPORTING DATA
Defect in morphogenesis	Development of jaundice soon after birth; coexistence of other embryologic abnormalities; polymorphisms in the *Jag1* gene; abnormal remodeling of the "ductal plate"; *inv* mouse: model of biliary obstruction and situs inversus
Defect in prenatal circulation	Intrauterine devascularization results in abnormal extrahepatic bile ducts
Toxin exposure	Time-space clustering of cases
Viral infection	CMV, HPV, reovirus, rotavirus, HHV6 detected in infants with biliary atresia; models of virus-induced injury to biliary tract in suckling mice
Immunologic dysregulation	Increased expression of intercellular adhesion molecules; infiltration of biliary structures by CD4+ and CD8+ lymphocytes; increased frequency of the HLA-B12 allele; expression of proinflammatory cytokines

Adapted from Balistreri WF et al.[20]
CMV = cytomegalovirus; HHV6 = human herpesvirus 6; HLA = human leukocyte antigen; HPV = human papillomavirus.

morphogenesis. From clinical observations, the earlier onset of disease and the presence of nonhepatic malformations in the embryonic form of biliary atresia suggest a prenatal onset and a pathogenesis that differs, at least in part, from that of infants with the perinatal form. The main associated malformations, poly- or asplenia, cardiovascular defects, abdominal situs inversus, intestinal malrotation, and anomalies of the portal vein and hepatic artery, point to potential defects in embryogenesis and asymmetric left-right determination of visceral organs.[18] In support of this concept, abnormalities in organ symmetry and biliary drainage have been identified in the *inv* mouse. In this transgenic mouse line, a recessive insertional mutation of the inversin gene results in complete abdominal situs inversus, severe jaundice, poor weight gain, and death within the first week of life in 100% of homozygous mice.[23] Polysplenia is also occasionally present. In a detailed morphologic analysis of the hepatobiliary system in the *inv* mouse, a defect in patency of the extrahepatic ductular system was identified by trypan blue cholangiography and absent excretion of technetium 99m–labeled tracer.[24] In addition, intrahepatic ductular proliferation was described similar to that seen in biliary atresia. However, the complete absence of inflammation or necrosis within the hepatic parenchyma and the absence of inflammation and fibrosis of the extrahepatic biliary tree are in stark contrast to the histologic features of infants with biliary atresia.[24,25] Furthermore, mutational analyses in children with laterality defects and biliary atresia failed to identify mutations in the inversin gene.[26]

More recently, genetic inactivation of the transcription factors hepatocyte nuclear factor (HNF)-6 and HNF-1β in mice resulted in neonatal cholestasis and growth retardation.[27,28] Morphologic analysis of the HNF-6–deficient mice showed an abnormal development of intrahepatic bile ducts, with a transient formation of cystic structures followed by a new phase of ductular development, with loss of cysts and persistence of a discontinuous ductal plate through the first week of life.[28] In addition, these mice lacked the gallbladder, the extrahepatic bile ducts were replaced by an enlarged structure that connected the liver to the duodenum, and jaundice was present in the first few days of life. Jaundice also developed in HNF-1β–deficient mice but at a later stage of postnatal development. Interestingly, the biliary system of HNF-1β–deficient mice appeared patent, but the gallbladder had a disorganized epithelium, there were variable cystic changes in the extrahepatic bile ducts, and there was a paucity of small intrahepatic ducts.[27] Based on the time-specific onset of biliary abnormalities during fetal development in both mouse lines and on additional gene expression studies in HNF-6–deficient mice, it appears that the development of the biliary system is controlled by a HNF-6 βHNF-1β cascade.[28]

In a different set of experiments, double heterozygozity for the *Jag1* and *Notch2* genes resulted in paucity of intrahepatic ducts in mice, which exhibited some of the cardinal phenotypic features observed in patients with Alagille syndrome.[29–31] Jag1-Notch signaling pathways define a fundamental mechanism controlling cell fate during embryogenesis by modifying the ability of a broad spectrum of precursor cells to progress to a more differentiated state. Although the developmental abnormalities reported for heterozygous *Jag1/Notch2* mice are not similar to those of infants with biliary atresia, the *Jag1* gene may be a modifier of liver disease, as demonstrated by the identification of a high frequency of single-nucleotide polymorphisms of the *Jag1* gene in infants with biliary atresia with poor outcome.[32] Taken together, these data suggest that genetic factors governing morphogenesis of the biliary system may play an important role in development and/or progression of liver disease in biliary atresia.

Evidence for Defective Fetal/Prenatal Circulation

Early interruption to flow in the hepatic artery, which supplies the intra- and extrahepatic biliary system, has been proposed to be an initiating factor in the fibroinflammatory injury of biliary atresia. This is an attractive concept based on the presence of hepatic artery and portal vein abnormalities associated with biliary atresia and the arterial hyperplasia and hypertrophy described in liver specimens of affected infants.[33] Additional data from humans or the development of experimental models to study the impact of blood flow on biliary development are necessary to further validate a potential role of impaired circulation in the pathogenesis of biliary atresia.

Evidence for Environmental Toxin Exposure

To date, the only supportive patient-based data for a role of a toxic insult as a causative factor of biliary atresia are the time-space clustering of cases. In animals, unusual outbreaks of hepatobiliary injury in lambs and calves in New South Wales, Australia, occurred in 1964 and 1988, with pathologic specimens displaying features akin to the pathology seen in humans with biliary atresia. Despite the localized geographic distribution of the outbreaks, an extensive investigation for causative phytotoxins or mycotoxins was unrevealing.[34]

Evidence for Viral Infection

Another environmental factor that may play an important initiating role in biliary atresia is viral infection. The possible role of viral infection as an initiating event in the pathogenesis of biliary atresia was initially suggested by Landing, who viewed biliary atresia as existing along a continuum with choledochal cyst and neonatal intrahepatic cholestasis, which could be linked by a shared infectious insult.[35] Consistent with this concept, different viruses have been detected in the liver of infants with biliary atresia sporadically. For example, hepatitis B virus antigens were detected in the liver of infants with biliary atresia in Japan, but these findings were not reproduced in the United States.[36,37] Likewise, there is little evidence to support the role of hepatitis A or C virus in spite of histologic findings suggesting the presence of non-A, non-B viruses in the liver.[37–39] Subsequent reports using a variety of techniques and substrates for viral detection have implicated cytomegalovirus, retrovirus, human papillomavirus, human herpesvirus 6, reovirus, and rotavirus in specific groups of patients not only with biliary atresia but also with neonatal intrahepatic cholestasis and choledochal cyst.[40–50] The etiologic role for a single agent, however, has not been supported owing to the inability to reproduce the association in other patient populations.[50–54] Nevertheless, among these viruses, reovirus type 3 and rotavirus type C continue to emerge as potential triggering agents for biliary atresia.

Prevalence of antibodies against reovirus type 3 and the detection of the virus in hepatobiliary specimens of patients with biliary atresia have varied according to patient population and laboratory techniques. This is demonstrated by a high prevalence of immunoglobulins G and M to reovirus in infants with biliary atresia,[47–49,55] but at least two studies could not find such an association.[52,56] More recently, the use of virus-specific amplification by reverse transcription–polymerase chain reaction identified reovirus in hepatobiliary samples of 55% of patients with biliary atresia and 78% with choledochal cyst, whereas the virus was present in tissues of only 8 to 21% of appropriately matched controls.[44] The putative association between reovirus and biliary atresia was initially suspected based on studies in young mice, which showed that reovirus infection in the weanling period resulted in the "oily fur syndrome," which is marked by growth failure, jaundice, and oily fur. Histologically, reovirus induced hepatitis and intra- and extrahepatic biliary epithelial necrosis with surrounding edema and inflammation.[57–59] With repeated intraperitoneal injections, weanling mice develop fibrosis of the extrahepatic biliary tree but do not progress to irreversible luminal obstruction.[57]

Administration of rhesus rotavirus type A to newborn mice orally or intraperitoneally produces a notable phenotype resembling biliary atresia, with progressive jaundice, acholic stools, bilirubinuria, and growth failure, eventually culminating in death in many infected animals.[60–62] The histologic appearance of the liver and biliary tree is remarkably similar to that seen in biliary atresia, with inflammation and edema of the intra- and extrahepatic bile ducts 7 days after infection, progressing to sloughing of the biliary epithelium, concentric fibrosis of the extrahepatic bile ducts, and segmental or continuous obstruction of the extrahepatic ductal lumen by cellular debris and inflammatory cells. The precise mechanisms of virus-induced injury have not yet been established, but studies on the potential tropism of the virus to cholangiocytes, the role of inflammatory cells in biliary injury, and the identification of host factors that restrict disease susceptibility of biliary injury by rhesus rotavirus type A to only the immediate postnatal period may provide unique insight into the pathogenic mechanisms of biliary atresia in humans.[60–63]

Evidence for Inflammatory/Immunologic Dysregulation

Several patient-based studies suggest that the inflammation observed in the biliary system is not simply a biologic response to an as yet unidentified insult but rather that it may play a primary role in the targeted destruction of extrahepatic and intrahepatic bile ducts. For example, cholangiocyte pyknosis and necrosis have been associated with infiltration of mononuclear cells into the walls of interlobular bile ducts, as well as lymphocytic infiltration into portal tracts, the duct walls at the porta hepatis, and common hepatic duct remnants of infants with biliary atresia.[64–66] Phenotypic characterization of these inflammatory cells has identified CD8+ T cells infiltrating proliferated bile ducts, although the cells did not express perforin or granzyme B, markers of activated cytotoxic T lymphocytes.[67] In general, however, the lymphocytes infiltrating portal tracts in biliary atresia are CD4+ rather than CD8+ T cells. These cells express markers of T helper (Th) lymphocyte activation and proliferation, such as the interleukin (IL)-2 receptor CD25 and the transferrin receptor CD71.[68–70]

Th lymphocytes are broadly divided into two subtypes: Th1 cells, which regulate cell-mediated immunity, and Th2 cells, which regulate humoral immunity. To initiate a Th-mediated immune response, CD4+ T cells must encounter exogenous antigens complexed with a major histocompatibility complex (MHC) class II molecule on the surface of an antigen-presenting cell. In the context of biliary atresia, cholangiocytes, which normally express MHC class I but not class II antigens, are induced to aberrantly express human leukocyte antigen (HLA)-DR (a major MHC class II molecule) and act as antigen-presenting cells.[68,71,72] Furthermore, intercellular adhesion molecule 1 is expressed on the bile duct cells of patients with biliary atresia, whereas one of its ligands, leukocyte functional antigen 1, is expressed on infiltrating mononuclear cells.[70,73] Interaction between these two molecules is one of the mechanisms necessary for inflammatory cell recruitment and perpetuation of the immune response.

A potential role for Kupffer cells (resident hepatic macrophages) in promoting inflammation and fibrosis has been inferred from their increased number and size in the livers of infants with biliary atresia, as well as from their expression of the MHC class II antigen HLA-DR.[70,74,75] A potential pathway that would explain the interaction of Kupffer cells and lymphocytes in the pathogenesis of biliary atresia involves infiltration of portal tracts by CD14+ Kupf-

fer cells, which are induced to express IL-18, a proinflammatory cytokine that promotes interferon-γ production and Th1-differentiation of lymphocytes.[74,75] Further evidence to support a Th1 proinflammatory immunity in the pathogenesis of biliary atresia has been provided by large-scale gene expression analyses of liver tissue from infants with biliary atresia and neonatal intrahepatic cholestasis. This approach identified a genetic footprint in which genes involved in lymphocyte differentiation (including the regulators of Th1 response osteopontin and interferon-γ) are activated in the early stages of biliary atresia, with simultaneous but transient suppression of markers of humoral immunity.[76] Although circumstantial, these findings point to a potential functional synergism of inflammatory effectors in the development of biliary injury in infants with biliary atresia.

Proposed Model of Disease Pathogenesis

The five proposed mechanisms of disease reviewed above can be grouped into environmental factors (toxins and infections) and processes directly dependent on the host (defective morphogenesis, abnormal fetal/prenatal circulation, and immunologic dysregulation). Collectively, they can be unified in a "working model" in which a toxic or infectious insult to the hepatobiliary system triggers a normal reactive inflammatory response. This response effectively clears the insulting agent and, in the normal infant, stops the injury, repairs the tissue, and restores physiologic homeostasis. In the genetically susceptible infant, however, the injury is perpetuated by a preexisting developmental abnormality or by the predisposition to a proinflammatory differentiation of T lymphocytes, which targets the extrahepatic biliary tract (Figure 50.2-2). Injury to the biliary cells may secondarily result in accumulation of bile acids and activation of apoptosis, which may further exacerbate the tissue injury. As a consequence, the ductular epithelium is destroyed, fibrous material obliterates the lumen, and biliary drainage ceases. The fact that these processes occur in the first few weeks after birth suggests that developmental forces play a key role in disease onset and/or progression.

It remains possible that in a very small number of patients, the biliary injury does not completely destroy the biliary epithelium and allows for the development of different phenotypes: choledochal cyst and chronic hepatitis. This setting is consistent with the model of "infantile obstructive cholangiopathy" proposed by Landing in 1974.[35] Landing's theory was based on several premises. First, biliary atresia is not predominantly a congenital malformation but is probably an acquired obliterative process. Second, biliary atresia displays histopathologic features often found in livers of infants with intrahepatic cholestasis (idiopathic neonatal hepatitis), such as giant cell transformation of hepatocytes and variable degrees of lobular hepatitis. Third, the basic process leading to biliary atresia is inflammatory/immunologic in nature, which is common not only to intrahepatic cholestasis but also to choledochal cyst. Fourth, the inflammation present in choledochal cyst may act in a different manner than in biliary atresia, weakening the duct wall and allowing for aneurysmal dilatation of the affected portion of the duct rather than obliteration of the ductal lumen. Although highly speculative, this theory remains attractive, at least in part, and might be corroborated by recent data from the rotavirus-induced model of biliary injury in neonatal mice. Anatomic analysis of the extrahepatic biliary system in these mice clearly demonstrates a spectrum of hepatobiliary abnormalities, including intrahepatic changes of reactive necrosis and proliferation of small bile ducts, obstruction of the extrahepatic biliary system, and cystic dilatation resembling choledochal cyst.[77]

We have been able to independently reproduce the findings of rotavirus-induced injury in our laboratory. In one set of experiments, intraperitoneal administration of rotavirus type A on the first day of life resulted in biliary injury affecting predominantly the extrahepatic bile ducts, with segmental stenosis, focal dilatation, or complete atresia in 24 of 27 of the mice (Campbell and Bezerra, unpublished data, July 2003). One of the other three mice had a large cystic dilatation of the common bile duct resembling a choledochal cyst and the other two had resolution of acholic stools but continued with jaundice and bilirubinuria. Notably, histopathologic examination of the liver of these two mice with partial improvement of symptoms showed lymphocytic infiltrate in the portal tracts and extensive fibrosis. These data support the concept that one single agent (in this case, rotavirus) induces

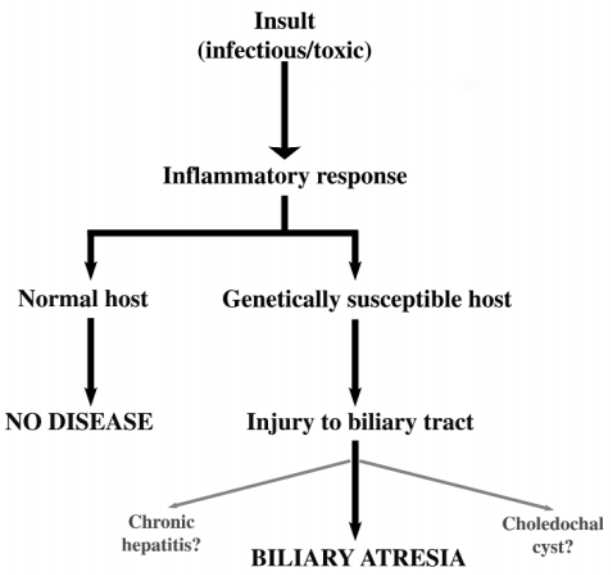

FIGURE 50.2-2 Proposed pathogenic model for biliary atresia. In this model, an infectious or toxic insult to the hepatobiliary system triggers a normal inflammatory response, which results in the clearance of the insulting agent, tissue repair, and restoration of biliary drainage in normal infants. Although the insulting agent may also be cleared in the genetically susceptible infant, a developmental abnormality of the bile ducts and/or a predisposition to a proinflammatory response lead to an ongoing injury that results in the obstruction of the extrahepatic bile ducts by fibrosis (biliary atresia). This model also depicts the potential development of chronic hepatitis or choledochal cyst, rather than biliary atresia, in a very small number of susceptible infants, in whom the injury/inflammation leads to an ongoing injury of intrahepatic bile ducts (chronic hepatitis) or the aneurysmal dilatation of a weak extrahepatic bile duct (choledochal cyst).

a primary phenotype (fibroinflammatory obstruction of the biliary tree) and two secondary phenotypes (choledochal cyst and chronic hepatitis) (see Figure 50.2-2). The use of this animal model and of other in vivo and in vitro models may provide unique insight into the interplay of different factors triggering the biliary injury, modulating the proinflammatory response, and perpetuating disease progression.

DIAGNOSTIC APPROACH

Proper and prompt identification of biliary atresia in the neonate with cholestasis is a high priority because the success of portoenterostomy to restore biliary flow rapidly declines with age.[78–80] Yet the lack of disease-specific clinical signs and laboratory tests makes it difficult to reliably distinguish between biliary atresia, other causes of extrahepatic obstruction, and intrahepatic cholestasis (Table 50.2-4). Therefore, the clinician is challenged to develop a diagnostic algorithm that incorporates ancillary tests with high predictive value for biliary atresia; the approach should be tailored to make full use of center-specific expertise. Our approach to any neonate with cholestasis obeys three diagnostic priorities. First, we establish whether jaundice is due to impaired excretion of conjugated or direct bilirubin. In practice, it is difficult to precisely define the onset of jaundice in the neonate because physiologic and breast milk jaundice may overlap with early phases of pathologic jaundice, defined as serum conjugated or direct bilirubin > 20% of total bilirubin and > 2 mg/dL. Thus, if the neonate is jaundiced beyond 2 weeks, fractionation of serum bilirubin is warranted. Identification of unconjugated hyperbilirubinemia most often points to benign processes, whereas high levels of serum conjugated bilirubin reveal the first clue to an underlying hepatobiliary pathology.

Second, we search for any evidence of systemic or metabolic diseases that may present with neonatal cholestasis and that require immediate treatment. For example, septicemia, galactosemia, and panhypopituitarism are disorders that may present with jaundice and require targeted therapeutics (antibiotics, avoidance of lactose-containing formulas, and thyroid hormone replacement, respectively) to improve survival and optimize long-term outcome. Third, we focus on those diagnostic tools that enable us to differentiate biliary atresia from other causes of neonatal jaundice in a timely fashion. In this context, it must be kept in mind that the most accurate diagnosis derives from careful histopathology combined with intraoperative examination of the extrahepatic ductular system.

HISTORY AND PHYSICAL EXAMINATION

Infants with biliary atresia typically present with jaundice between 3 and 8 weeks of age. They often appear well and develop acholic stools, but in the early stages of disease, the stools may have some bile pigment. Family history of cholestasis is almost always negative in biliary atresia, whereas the history may be positive in 15 to 20% of the cases of intrahepatic cholestasis.[4,81,82] Variable levels of lethargy, emesis, and abdominal distention and a history of bleeding or seizures often reflect coagulopathy secondary to vitamin K deficiency or potentially devastating nonhepatic conditions, such as intestinal volvulus owing to malrotation. On physical examination, hepatosplenomegaly is frequently present; nodular liver surface, prominent splenomegaly, digital clubbing, and arterial desaturation may be seen with advanced disease. Notably, the findings of a liver that is mostly palpable at midline (below the xyphoid process), pathologic murmurs, and dextrocardia in the setting of neonatal cholestasis are highly indicative of biliary atresia, specifically the embryonic form.

Biochemical Analysis

Routine indicators of liver function and injury are helpful but not diagnostic. Although some infants may have prolonged prothrombin time, normalization of coagulopathy following administration of vitamin K and serum levels of albumin above 3 g/dL indicate normal synthetic function. The usual markers of hepatocellular injury, serum alanine and aspartate aminotransferases, are mildly to moderately elevated, whereas the serum levels of alkaline phosphatase and γ-glutamyl transpeptidase (γ-GTP) progressively

TABLE 50.2-4 INTRA- AND EXTRAHEPATIC DISEASES THAT MAY PRESENT IN THE NEONATAL PERIOD AND LEAD TO CHRONIC CHOLESTASIS

INTRAHEPATIC CHOLESTASIS*	EXTRAHEPATIC CHOLESTASIS
α_1-Antitrypsin deficiency	Biliary atresia
Alagille syndrome	Choledochal cyst
Transport defects	Type I: cystic dilatation of the common bile duct
Chronic cholestasis owing to *FIC* mutations	Type II: diverticulum of common duct and/or gallbladder
Chronic cholestasis owing to *BSEP* mutations	Type III: choledochocele
MDR3 deficiency	Type IV: multiple cysts
Cystic fibrosis	Type V: fusiform intrahepatic dilatations (variant of Caroli disease?)
Defects in bile acid synthesis	Spontaneous perforation of the common bile duct
Hypopituitarism/hypothyroidism	Neonatal sclerosing cholangitis
	Biliary sludge and cholelithiasis
	Acalculous gallbladder disease†

BSEP = bile salt export pump gene; *FIC* = familial intrahepatic cholestasis type 1 gene; MDR3 = multidrug resistance protein type 3.
*Detailed differential diagnosis for intrahepatic cholestasis is discussed elsewhere in this book.
†Uncommon in the neonatal period.

increase, indicating more profound biliary injury. γ-GTP levels may have some discriminatory value, with low γ-GTP rarely seen in infants with biliary atresia.[83–85] If infants are evaluated before 4 months of age, conjugated or direct hyperbilirubinemia is present but rarely above 7 mg/dL, despite the existence of an obliterative fibrosis and severe impairment to biliary drainage.

Radiologic Studies and Procedures

A sonographic examination of the upper abdomen is particularly useful in the search for potential causes of anatomic obstruction or cystic abnormalities of the biliary system, such as choledochal cyst, and to survey for congenital malformations, such as midline liver, polysplenia, and vascular malformations. Absence of the gallbladder suggests biliary atresia, but its presence does not rule it out. Examining the hilar structures, the ultrasonographic appearance of a "triangular cord" is suggestive of biliary atresia, with a negative predictive value of over 95% for intrahepatic cholestasis ("neonatal hepatitis").[86,87] This finding corresponds to the fibrous cone of tissue at the bifurcation of the portal vein and is often not present in infants with intrahepatic cholestasis.[86] An evolving technology with a great potential to identify the ductular structures is magnetic resonance cholangiography, but its value is largely unproven to date.[88,89] Despite remarkable improvements in sonographic and magnetic resonance cholangiographic techniques, the main limitation resides in the inability to directly visualize discontinuity of extrahepatic bile ducts with available imaging tools. This can potentially be established using hepatobiliary scintigraphy, a nuclear medicine scan that measures hepatic uptake and excretion of analogs of iminodiacetic acid into the intestine. In infants with intrahepatic cholestasis, uptake is delayed secondary to impaired hepatic function but excretion is not impaired, whereas prompt uptake is not followed by excretion into the duodenum in neonates with biliary atresia. To increase the discriminatory value of the test, phenobarbital may be given at a dose of 5 mg/kg/d for 5 days prior to the study to enhance hepatic uptake and excretion through the biliary system.[90] Despite the potential value of hepatic scintigraphy in establishing patency of the biliary system, the time required for the test may significantly delay the diagnosis.

Aspiration of duodenal fluid is another indirect measure of extrahepatic bile duct patency. If bile-stained fluid is present in a 24-hour collection of duodenal contents, biliary atresia is unlikely.[91,92] A more direct examination can be obtained by endoscopic retrograde cholangiography, which is very useful in adults to determine the patency of extrahepatic ducts but requires an experienced endoscopist for careful examination of the neonate.[93–96]

The combination of specific clinical features and ancillary tests/procedures discussed above may offer a high likelihood of an accurate diagnosis. This was documented in a retrospective review of 288 infants presenting with jaundice before 3 months of age that reported lower birth weight, later onset of jaundice, later onset of acholic stools, and the appearance of pigmented stools within 10 days after admission occurring more frequently in infants with intrahepatic cholestasis rather than in those with biliary atresia.[97] Because of the limited predictive value of scoring systems, however, caution must be exercised and more definitive diagnostic modalities must be pursued because in approximately 10% of infants, intrahepatic disease cannot be reliably distinguished from biliary atresia.[98]

Histopathology

Microscopic examination of a liver biopsy sample is a critical component of the diagnostic approach to the neonate with cholestasis. The initial biopsy is obtained percutaneously and typically shows preservation of basic lobular organization in infants with biliary atresia, with prominent abnormalities in the portal tracts and, to a lesser extent, in the lobule. Portal tracts are expanded by variable levels of edema, proliferation of bile ducts, and fibrosis (Figure 50.2-3). When present, bile plugs within proliferated ducts are highly suggestive of biliary atresia but occur in only about half of the biopsies. Inflammation in the portal space and giant cell transformation of hepatocytes may be seen but are not the dominant features and are more commonly seen in other causes of intrahepatic cholestasis.[99] Canalicular cholestasis, lobular disarray, and extramedullary hematopoiesis do not have discriminatory value between biliary atresia and other causes of neonatal cholestasis. In very young infants, the initial liver biopsy may be inconclusive, in which case, a repeat liver biopsy in 1 to 3 weeks may be necessary before the diagnosis is fully established. Whether these cases represent the sampling error inherent in percutaneous biopsies or the true progression of disease remains to be determined.

Exploratory Laparotomy with Cholangiography

When histopathologic features are suggestive of biliary atresia or the diagnostic workup is inconclusive, exploratory laparotomy must be performed in a timely manner. During laparotomy, direct inspection of the gallbladder and ductular system is the best approach to (1) determine if the ductular system is obstructed, (2) define the site of obstruction, and (3) create a conduit to re-establish biliary drainage. In most cases of biliary atresia, the gallbladder is small and fibrotic, along with diffuse fibrosis of the extrahepatic system extending to or above the level of the porta hepatis. If the gallbladder has a lumen, it may be filled with mucoid clear secretions.

For the cholangiogram, a needle or catheter is inserted into the gallbladder so that diluted contrast material can be injected to document the extent of obstruction and the anatomic variants of extrahepatic disease. These anatomic variants have been proposed by the Japanese Society of Pediatric Surgeons[100] and consist of three main types: type 1, atresia involving primarily the common bile duct; type 2, atresia extending up to the common hepatic duct; and type 3, atresia involving the whole extrahepatic ductular system (Figure 50.2-4). Sometimes a cholangiogram may not be possible owing to extensive fibrosis of the gallbladder or because of an absence of the biliary tree, a condition that has been termed "biliary agenesis." If the contrast delineates the cystic and

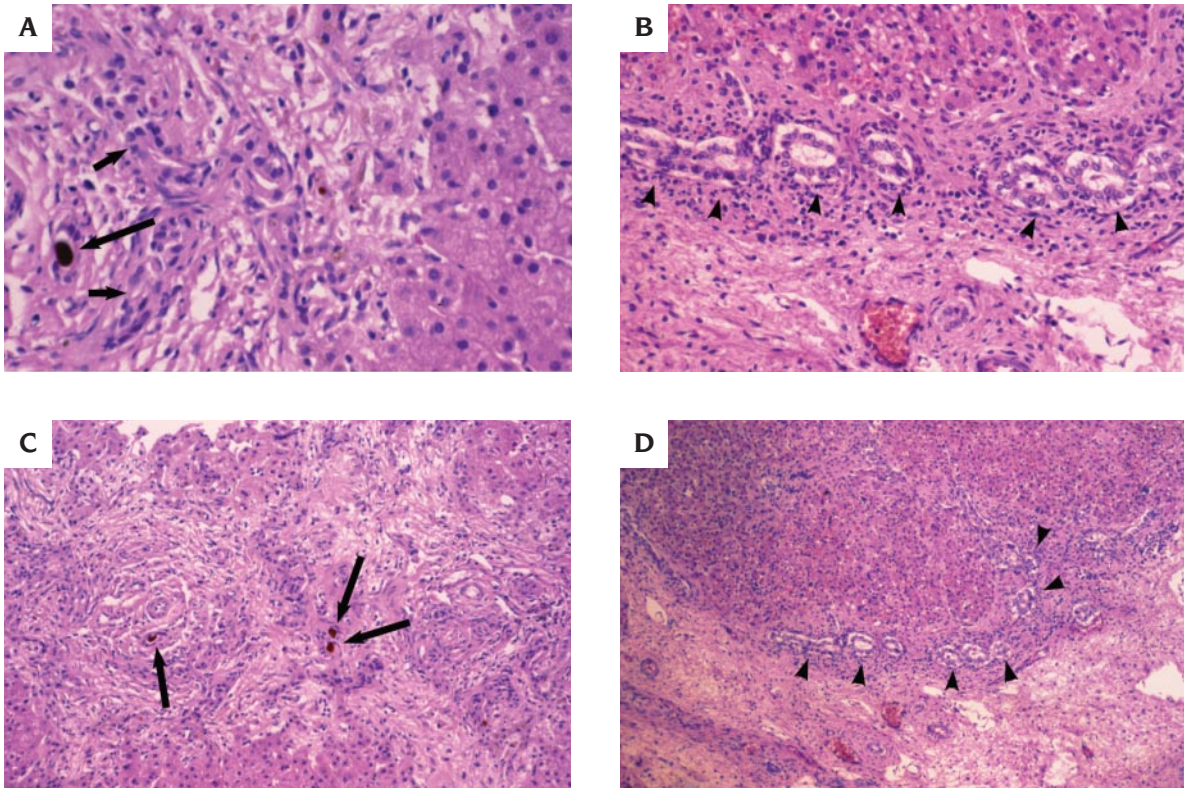

FIGURE 50.2-3 Hematoxylin and eosin staining of liver sections from infants with biliary atresia. *A* and *C* show edema, fibrosis, bile duct proliferation (*short arrows*, *A*) and a bile plug (*long arrow*, *A*) in the liver of an infant with the perinatal form of biliary atresia. In addition to edema and fibrosis, *B* and *D* also show ductal plate malformation (*arrowheads*) in an infant with the embryonic form of biliary atresia. *A* and *B* = ×200 original magnification; *C* and *D* = ×100 original magnification. Courtesy of Dr. Kevin Bove, Cincinnati Children's Hospital Medical Center, Cincinnati, OH.

common bile ducts but fails to show the patency of the hepatic and intrahepatic ducts, gentle and transient clamping of the common duct may be necessary to direct the contract upward, which may enable better filling and visualization of the proximal ductular system by the contrast. Poor filling of intrahepatic bile ducts should be interpreted with caution to avoid the creation of portoenterostomy in patients without biliary atresia. In at least one series, four patients underwent portoenterostomy after inadequate filling of intrahepatic bile ducts at intraoperative cholangiography and were later found to have the phenotypic features of Alagille syndrome.[101] In these patients, portoenterostomy may lead to biliary cirrhosis and a worse prognosis.

Histologically, the extrahepatic biliary remnants show the most typical finding of complete fibrous obliteration of the bile duct at one or more levels (Figure 50.2-5). In some patients, small single-lumen ducts that are present in biliary remnants close to the hilum may show active cholangitis. In other patients, the main duct may be reduced to smaller channels surrounded by moderate chronic inflammatory infiltrate. Although the histologic examination of the biliary structures is essential for a definitive diagnosis, the decision to proceed with portoenterostomy is not delayed until the histologic examination is completed; instead, it is made at the time of laparotomy and is based on data obtained prior to surgery, visual inspection of the biliary tree, and the results of the cholangiogram.

TREATMENT

No medical therapy has been developed to date that effectively halts or reverses cholestasis and hepatic injury in children with biliary atresia. The only therapeutic choice to increase biliary flow and improve jaundice is the portoenterostomy. Prior to the development of this surgical procedure, the mortality from biliary atresia was virtually 100%. Early attempts to relieve obstruction were limited to infants with the "correctable" forms, in which only the common bile duct was obstructed, with patent ducts proximally (type 1 of Figure 50.2-4). In the 1950s, Kasai and Suzuki noted that minute, patent bile duct remnants were present in the fibrous tissue at the porta hepatis. They reasoned that dissection into the liver parenchyma would allow drainage of bile through these ducts, whereas failure to re-establish biliary flow would lead to progressive intrahepatic ductal obliteration. This led to the development of the Kasai portoenterostomy, in which the fibrotic extrahepatic bile ducts are completely excised and an intestinal conduit is anastomosed to the transected surface of the porta hepatis in a Roux-en-Y fashion.[102]

PORTOENTEROSTOMY

Although there have been numerous modifications to the original procedure of portoenterostomy described by Kasai, the concept remains the same: to bypass the fibrotic extra-

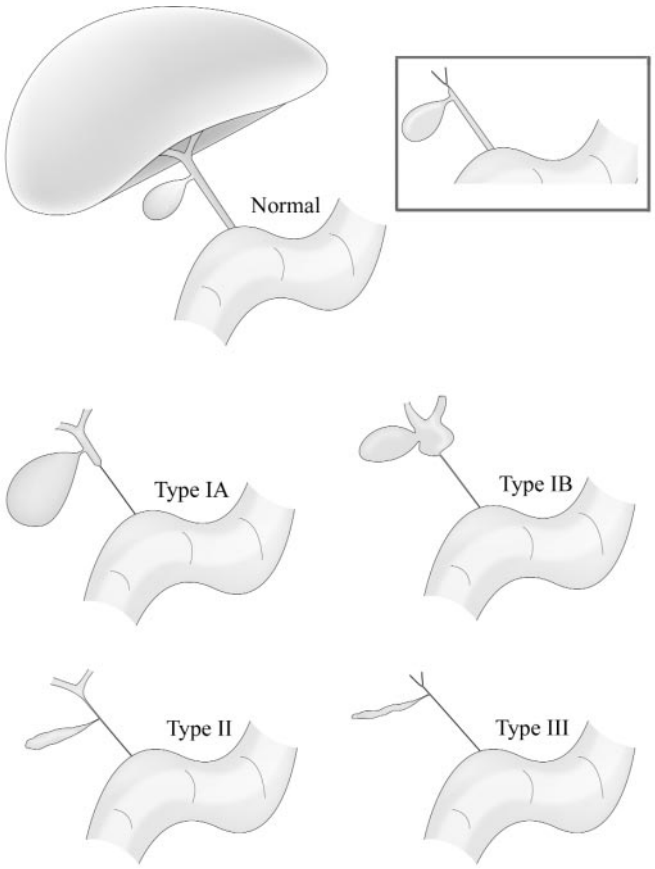

FIGURE 50.2-4 Anatomic variants of the extrahepatic biliary system in infants with biliary atresia. In type 1, the main site of obliteration is the common bile duct, which extends to the hepatic duct in type 2. Type 3, the most common variant, has complete obliteration of the entire biliary system. In the *inset*, a patent common bile duct and gallbladder may be used in lieu of an intestinal conduit to improve biliary drainage by anastomosis of the gallbladder to the hilum ("gallbladder Kasai").

hepatic biliary tree and re-establish bile drainage through intrahepatic ducts that remain patent. On entry into the abdominal cavity, the liver is firm to the touch and appears brown-green, with varying degrees of subcapsular telangiectasia. The liver and intestine are mobilized to expose the ductular and vascular structures, and the gallbladder and extrahepatic ducts are examined. Hilar structures may be edematous in the early phases of disease but are likely fibrotic and more difficult to identify in older infants.

If careful inspection of ductular structures and cholangiography are diagnostic of biliary atresia, the (fibrotic) common bile duct is transected just above the duodenal margin. Next, the gallbladder is mobilized from its hepatic bed, and the bile duct is dissected away from the anterior portal vein wall. Careful dissection toward the hilum is guided by the principle that fibrotic ducts follow the normal biliary position within the portal triad. Therefore, the dissection of the fibrous triangular mass proceeds toward the level of the liver capsule, where the fibrous remnants are transected at the level of the portal vein bifurcation on the right and the umbilical point of the portal vein on the left. Dissection deeper into the hepatic parenchyma has not been shown to significantly increase biliary drainage. At this time, Roux-en-Y anastomosis is achieved with a 35 to 40 cm isoperistaltic retrocolic jejunal limb, which extends from the hilum to the most proximal portion of the jejunum. The Roux-hilar anastomosis is constructed just outside the margin of the hilum where the tissue has been dissected, using absorbable monofilament suture material to avoid the formation of a nidus for future infection. Distally, the intestinal conduit is anastomosed to the proximal jejunum so that biliary drainage optimizes nutrient digestion and absorption. For a small number of infants with anatomic variants of atresia in which there is a patent gallbladder and distal ducts, a "gallbladder Kasai" may be performed (see Figure 50.2-4). In this procedure, the gallbladder is mobilized from its fossa (maintaining intact the cystic artery), the fundus of the gallbladder is transected, and the opening is sutured to the biliary hilum (rather than the use of an intestinal segment). Although logical, this approach may not allow for efficient long-term biliary drainage owing to a potential dysfunction or subsequent obliteration of the common duct.

Medical Treatment following Portoenterostomy

The goals of postoperative management of infants with biliary atresia are threefold: (1) prevention of cholangitis, (2) stimulation of choleresis, and (3) nutritional support. Infants typically receive parenteral broad-spectrum antibiotics for 3 to 5 days postoperatively, followed by oral prophylaxis with trimethoprim-sulfamethoxazole (TMP-SMX; 5 mg TMP/kg/d) or another antibiotic initiated after the patient resumes oral feedings and continued for a variable period of time (3–12 months).[100] Studies do not conclusively demonstrate the efficacy of this approach, but at least one open-label study reported lower recurrence rates of cholangitis when infants received prophylaxis with either TMP-SMX or neomycin.[103]

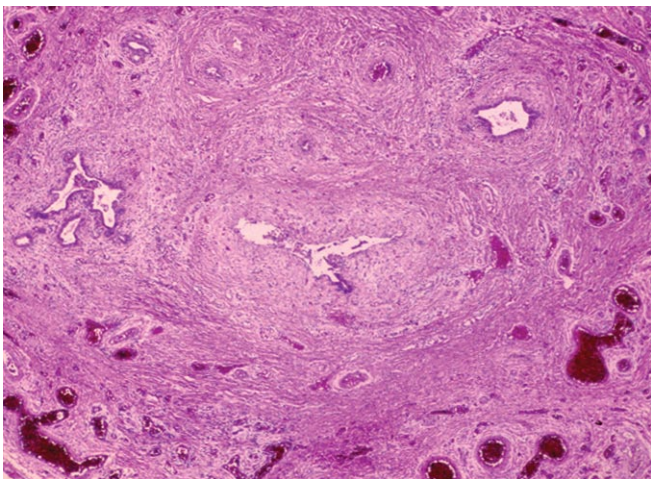

FIGURE 50.2-5 Photomicrograph of a remnant of the extrahepatic bile duct showing marked fibrosis, minute ductules, and vascular channels in a surgical specimen from an infant with biliary atresia. Courtesy of Dr. Kevin Bove, Cincinnati Children's Hospital Medical Center, Cincinnati, OH.

Choleretic and Immunomodulatory Agents. Ursodeoxycholic acid (UDCA; 10–20 mg/kg/d) has been used by many centers to improve choleresis; however, very few studies have documented the efficacy of this approach. In two of these studies, use of UDCA was associated with improved weight gain and decreased levels of serum bilirubin and bile acids in more than half of the patients.[104,105] A similar trend toward improved weight gain, a decrease in the levels of serum aminotransferases and bilirubin, and a reduction in the degree of pruritus has also been reported in infants receiving UDCA, but there were no obvious differences in long-term survival or the need for transplant between treated and nontreated patients.[106]

Corticosteroids are another class of drugs used postoperatively in many centers. At pharmacologic doses, corticosteroids stimulate bile salt–independent bile flow by inducing expression of hepatic Na-K adenosine triphosphatase, a sinusoidal transporter that helps maintain the osmotic and electrical forces necessary for bile formation.[107] In addition, corticosteroids have well-described anti-inflammatory and immunomodulatory properties, including inhibition of leukocyte infiltration and down-regulation of inflammatory mediators, which may lead to decreased hilar edema and scar formation. Dosing regimens and duration of treatment with corticosteroids vary remarkably among published reports. In two early reports, administration of methylprednisolone or prednisolone either the week after portoenterostomy or later in the postoperative course when the infant developed jaundice (3 months to 4 years after surgery) induced a decrease in the levels of serum bilirubin in at least 50% of the patients.[108,109] More recently, two studies in which corticosteroid therapy was initiated soon after portoenterostomy reported improved clinical outcome, as defined by clearance of jaundice and increased survival with native liver, in over 70% of patients.[110,111] Unfortunately, these studies are limited by the use of varying dosing regimens, different indications and timing of treatment, lack of appropriate randomization, and small cohorts of patients. Despite these limitations, the results are promising and provide the basis for future multicenter randomized controlled clinical trials to objectively determine the role of corticosteroids in the treatment of infants following portoenterostomy.

Nutritional Support. Plans for adequate nutritional management should begin at the time of diagnosis and should follow the same general principles for patients with chronic cholestasis: caloric intake to meet energy needs and promote growth and supplementation with fat-soluble vitamins. Serial weight- and height-for-age and weight-for-height measurements are helpful but should be interpreted carefully if the infant develops significant hepatosplenomegaly or ascites. In this setting, high percentiles may derive from organomegaly or fluid retention rather than adequate nutrition. Anthropometrics with triceps and subscapular skin fold thickness may offer more reliable indices. Infants should receive approximately 125% of the Recommended Dietary Allowance based on weight for height at the 50th percentile, with additional calories often needed if biliary drainage is marginal (Table 50.2-5). Breastfeeding should be continued if it fosters adequate weight gain; if weight gain is inadequate or the infant is formula-fed, the use of formulas enriched with medium-chain triglycerides, which are relatively water soluble and directly absorbed into the portal circulation, will increase the pool of available energy and minimize steatorrhea. Intestinal absorption of fat-soluble vitamins A, D, E, and K is strongly dependent on adequate intraluminal concentration of bile acids. Therefore, if cholestasis is present, infants require supplementation and close monitoring to prevent the consequences of vitamin deficiencies. Unfortunately, malnutrition and progressive coagulopathy frequently develop if cholestasis is severe, and liver disease progresses despite adequate nutritional support.

COMPLICATIONS AND SEQUELAE

Most infants with biliary atresia have successful bile drainage after portoenterostomy, but adequate bile flow may be transient. If bile drainage is not achieved, progressive cholestasis and rapid progression to end-stage liver disease are the rule, at which time, orthotopic liver transplant offers the only chance for long-term survival. In the remaining majority of the patients, the clinical course is variable and is often marked by episodes of cholangitis and progressive accumulation of components of the extracellular matrix, which leads to sinusoidal obstruction and portal hypertension.

Ascending Cholangitis

Cholangitis is the rule rather than the exception in infants with successful biliary drainage after portoenterostomy, with an incidence ranging from 40 to 60%.[100,112] Although the pathogenesis is not well defined, clinical observations point to an interplay between the patency of biliary chan-

TABLE 50.2-5 NUTRITIONAL MANAGEMENT OF INFANTS WITH BILIARY ATRESIA

NUTRIENT	TREATMENT OPTIONS	CONSEQUENCES OF DEFICIT
Energy	125% of RDA based on 50th percentile weight for height; protein: 2–3 g/kg/d; lipid: MCT enriched (~ 50% of fat calories)	Malnutrition*
Vitamin A	5,000–25,000 IU/d of water-miscible preparation of vitamin A	Punctate keratopathy[155]
Vitamin D	3–10× RDA for age; 3–5 μg/kg/d as 25-hydroxyvitamin D if rickets is present	Rickets, osteomalacia
Vitamin E	15–25 IU/kg/d TPGS	Neurologic dysfunction
Vitamin K	2.5 mg/twice a week to 5.0 mg/d	Coagulopathy

MCT = medium-chain triglyceride; RDA = Recommended Dietary Allowance; TPGS = *d*-α-tocopheryl polyethylene glycol-1000 succinate.
*Malnutrition may develop in patients with chronic cholestasis and progressive liver disease despite high caloric intake.

nels and enteric pathogens in the development of cholangitis. Pathogens have been proposed to ascend through the intestinal biliary conduit at the porta hepatis, translocate from other intestinal segments, or result from overgrowth favored by bile stasis that may exist in the intestinal conduit regardless of the type of surgical approach.[113–116] One strategy of unproven efficacy, but in widespread use, is the prophylactic administration of TMP-SMX for variable lengths of time during the first year of life to prevent cholangitis. Surgical modifications of the Roux-en-Y, such as partially diverted stoma for decompression of biliary conduit or valve formation in the conduit, have also been employed but have not consistently decreased the incidence of cholangitis.[100] It remains undefined whether the potential immunologic dysfunction that may play a role in disease pathogenesis also makes infants more susceptible to infectious cholangitis.

Typically, infants with cholangitis present with the triad of fever, acholic stools, and increased levels of serum bilirubin. These symptoms can also occur in isolation; therefore, the clinician must keep a high degree of suspicion so that prompt diagnosis is made and antibiotic therapy is initiated. In this context, ascending cholangitis should be suspected following portoenterostomy in any infant with irritability and poor feeding or who suddenly develops fever without an obvious source of infection; acholic stools and jaundice may lag behind by 24 hours. Sudden onset of acholic stools and jaundice in an infant with initial drainage following portoenterostomy should also be considered highly suspicious for cholangitis, even in the absence of fever or additional symptoms. Biochemically, conjugated bilirubin rises and levels of serum aminotransferases, γ-GTP, and alkaline phosphatase may increase above baseline values; leukocytosis with or without immature cells (left shift) may also be present.

Once the presumptive diagnosis of cholangitis is made, blood cultures are obtained, and patients are treated with broad-spectrum intravenous antibiotics. If an organism is identified, dosage and choice of antibiotics should be adjusted based on antimicrobial sensitivity. Intravenous antibiotics are continued for 2 to 3 days after fever resolves. In the event that stools remain acholic and conjugated hyperbilirubinemia persists, a short course of high-dose corticosteroids may be helpful.[108] Surgical revision of the portoenterostomy should be considered when evidence of cholestasis persists despite medical treatment. The surgical approach is made through the anterior wall of the portoenterostomy, followed by débridement of the scarred areas at the porta hepatis. This approach is successful in more than half of patients when they have a history of initial bile flow after primary portoenterostomy, a favorable hepatic histology, and biliary ductal remnants at initial operation or when there is a suspicion of mechanical obstruction in the intestinal conduit.[79,117,118] If revision does not result in improved biliary flow, repeated attempts are discouraged. Repeated revisions and recurrent episodes of bacterial peritonitis may produce perihepatic and intraperitoneal adhesions, which significantly complicate the surgical approach during liver transplant.

Portal Hypertension

In addition to the fibro-obliterative changes in the extrahepatic ducts, variable degrees of intrahepatic fibrosis and portal hypertension are also present at the time of diagnosis of biliary atresia.[119] This fibrosis progresses even in the infants with improved biliary flow[120]; portal pressure gradually increases, and significant portal hypertension develops in 34 to 76% of infants with biliary atresia.[119,121] The clinical consequences of portal hypertension are variable, often resulting in the development of esophageal varices. Interestingly, portal hypertension may resolve spontaneously in older patients. Therefore, the initial approach to portal hypertension in infants with biliary atresia is directed at preventing and treating complications, such as gastrointestinal hemorrhage. A study of a single center's experience in Japan reported esophageal varices in 25% and hypersplenism in 14% of 106 children with biliary atresia without jaundice.[100] Notably, esophageal bleeding occurs in approximately 19% of all long-term survivors[122] and at a higher rate (20–60%) when studies include only those children with esophageal varices.[123]

Primary therapy for children with biliary atresia and hemorrhage from esophageal varices is endoscopic injection sclerotherapy or variceal band ligation.[124–127] Before endoscopy, the patient should be monitored closely, be evaluated for coagulopathy, and receive an infusion of packed red blood cells to restore normal blood pressure. Packed red blood cells should be transfused slowly to avoid sudden expansion of intravascular volume and a new onset of variceal hemorrhage. Continuous infusion of somastomatin analogs to decrease the severity of the bleeding may be particularly valuable to stabilize the patient in preparation for endoscopy. In the setting of active bleeding or in small infants, sclerotherapy is the treatment of choice.

β-Blockers represent another therapeutic option for primary prophylaxis or after an episode of variceal hemorrhage (secondary prophylaxis). Although their use is well accepted in adults, there are few data regarding the efficacy of β-blockers in children. In the one published study to date, 6 of 17 children subjected to primary prophylaxis with propanolol had variceal hemorrhage, whereas 1 of 4 patients receiving secondary prophylaxis bled.[128] In the absence of a control group, it is unclear whether this represents a decrease in the incidence of variceal hemorrhage. Likewise, questions regarding optimum dosage and dosing schedule in children also need to be addressed prospectively. For those patients with recurrent or severe hemorrhage, the utility of the traditional portal shunt (with or without esophageal transection) and transjugular intrahepatic portosystemic shunt should be considered. Decisions regarding these therapies should be made on an individual basis and take into account the available expertise in the medical center. The best therapeutic choice for these patients is timely liver transplant if a suitable organ is available. This is particularly relevant based on recent data suggesting that the outcome of children following the first episode of variceal hemorrhage is related to the coexisting degree of hyperbilirubinemia, with a 12-fold increase in the risk of death or need for transplant if the

serum total bilirubin is > 10 mg/dL versus a 0.6-fold risk when the serum bilirubin was ≤ 4 mg/dL, when compared with children with biliary atresia and no history of variceal hemorrhage.[129]

Other Complications

Hypersplenism is another complication in long-term survivors and is especially problematic in those infants with significant thrombocytopenia and a history of bleeding from esophageal varices. If hypersplenism significantly worsens coagulopathy, splenic embolization has been shown to result in improved blood cell count and hemorrhagic tendency in 60 to 70% of patients, but high fever and abdominal pain are universal complications.[100] Another potential complication in long-term survivors is the development of the hepatopulmonary syndrome, which results from intrapulmonary vascular dilatation with shunting. These patients typically have exercise intolerance, digital clubbing, and cutaneous spider telangiectasia. Currently, no medical therapy alleviates hepatopulmonary syndrome; a definitive cure can be achieved by liver transplant, although children with the syndrome may be more susceptible to complications.[130,131] Lastly, children with biliary atresia may rarely develop cystic dilatation of intrahepatic bile ducts or hepatocellular carcinoma.[132–134]

LONG-TERM OUTCOME

Most patients with biliary atresia have improved biliary drainage following portoenterostomy. Long-term outcome, however, may be better predicted by the serum level of bilirubin 3 months after surgery. In those infants with serum bilirubin levels below 1 mg/dL 3 months after portoenterostomy, 53% had normal growth, no esophageal varix, or hyperplenism at 12 or more years after portoenterostomy.[135] Although the precise mechanisms regulating progression of liver disease are not well defined, ongoing cholestasis, intrahepatic cholangiopathy, persistent inflammatory processes, and progressive fibrosis appear to be important factors.[118,136–139] Specific markers for disease progression and predictors of long-term outcome may emerge from studies of the pathogenesis of biliary atresia. For example, serial levels of serum hyaluronic acid and procollagen propeptides may be unique markers of hepatic fibrogenesis and disease progression.[140]

Actuarial survival with native liver has been estimated at 32 to 61% at 5 years and 27 to 54% at 10 years of life.[100,141,142] Among the several factors that may influence long-term outcome, age and the size of the ductules in biliary remnants at the time of portoenterostomy have been systematically examined. Collectively, studies point to better outcome when portoenterostomy is performed in infants ≤ 60 days of age and when the size of ductules within the biliary remnant measures ≥ 150 μm (Table 50.2-6). The patient's age at operation alone, however, may not be a reliable predictor of outcome, as suggested by a study of infants who underwent portoenterostomy before 30 days of age. In this group, 78% of the patients required liver transplant at a mean age of 6.8 ± 2.3 months.[19] This outcome may reflect a more severe form of disease that leads to early jaundice and early diagnosis of biliary atresia. Other factors that contribute to long-term outcome include episodes of cholangitis after surgery, the decade when surgery was performed, and the experience of the surgical team.[141,143] For example, at Tohoku University Hospital (Japan), actuarial survival of 307 patients treated with the Kasai portoenterostomy improved from ~ 20% before 1971 to ~ 70% between 1971 and 1998.[100] An effect of the "center experience" in achieving high success rates has been emphasized by an improved survival rate to 78% in centers in which a large number of portoenterostomies are performed by the surgical team.[6,144] As long-term survival increases, the quality of life in children with biliary atresia has become a focus of studies designed to improve outcome. In this context, 44 to 47 of 108 patients reported development of pruritus, reduced physical fitness, and the inability to attend school regularly.[143] These results clearly identify areas requiring additional support and therapeutic targets for long-term survivors.

LIVER TRANSPLANT

Liver transplant is a well-accepted treatment option for children with biliary atresia and end-stage liver disease. Access to transplant by a greater number of children has been driven by remarkable improvements in surgical techniques, which have led to the development of reduced-size and living-related donor transplant and to improved immunosuppression.[145–147] As a consequence, biliary atresia has become the most frequent indication for liver transplant in children.[118,148–151] For example, biliary atresia has been the primary indication for liver transplant at the Cincinnati Children's Hospital Medical Center (July 1985 to May 2003), accounting for 44% of 255 transplanted children. Although effective, the timely use of the technique in children with end-stage liver disease is significantly limited by an ever-increasing number of pediatric patients on transplant waiting lists and the scarcity of suitable organs. This is particularly important because the outcome in our center appears to be related to the severity of the patient's illness at the time of transplant.[148,152]

With limited organ availability, the clinician is challenged to identify those patients who may best benefit from liver transplant. In this context, the primary goal should be

TABLE 50.2-6 FACTORS INFLUENCING LONG-TERM OUTCOME OF INFANTS WITH BILIARY ATRESIA

FACTOR	% WITH BILE FLOW	REFERENCE
Age at the time of portoenterostomy		78, 100, 112
< 60 d	67–82	
60–90 d	45–62	
> 90 d	10–44	
Morphology of duct remnants		156
≥ 150 μm lumen size	92	
50–150 μm lumen size	81	
No identified epithelium-lined ducts	18	

to optimize the clinical status and quality of life of all children with their native liver and stay vigilant for the primary indications for transplant evaluation: (1) persistent cholestasis associated with severe malnutrition, growth failure, and hepatocellular dysfunction and (2) decompensated cirrhosis, as evidenced by intractable ascites and hemorrhage. For all children, the overall goals of transplant include restoration of hepatic function, improved nutritional status, adequate growth and development, and improved quality of life with full social reintegration.[149,153]

One additional indication for transplant that generates a significant debate is the use of transplant as the primary treatment modality for infants with biliary atresia who are diagnosed beyond 90 to 120 days of age and have established cirrhosis. Although portoenterostomy in this group has been associated with low incidence of improved biliary flow and poor long-term outcome, data analysis from a large cohort of patients showed a 5-year survival with native liver of ~ 31% when surgery was performed beyond 45 days of age in comparison with ~ 41% when portoenterostomy was performed before 45 days.[144] Therefore, portoenterostomy should remain the first line of therapy in infants with biliary atresia.[154] With appropriate management after portoenterostomy, improved surgical techniques, effective post-transplant immunosuppression, and aggressive management of infectious complications, the overall survival and quality of life of children with biliary atresia will continue to increase.

SUMMARY

Biliary atresia is the most common cause of pathologic jaundice in young infants and results from obliteration of the extrahepatic bile ducts by an inflammatory and fibro-obliterative process. Although the pathogenesis is not fully elucidated, patient- and animal-based studies point to a possible pathogenic model in which a genetically susceptible subject abnormally destroys the extrahepatic biliary system in response to environmental factors. Clinically, the disease is manifest by the triad of jaundice, acholic stools, and hepatosplenomegaly. In approximately one-fifth of the cases, infants also have nonhepatic malformations, such as laterality defects. Because many of the initial features are shared by other causes of neonatal cholestasis, the clinician is challenged to develop a diagnostic algorithm that facilitates the diagnosis so that portoenterostomy is performed in a timely fashion. Postoperatively, infants often require a high-calorie diet, supplementation with fat-soluble vitamins, and medications to induce choleresis and prevent cholangitis. Despite medical and surgical treatments, the disease commonly progresses, with hepatic fibrosis, portal hypertension, and end-stage liver disease occurring in at least half of the patients by 2 years of age. At this stage, liver transplant is an effective treatment modality, but the surgical success presents the infants with new morbidities and carries a high monetary cost to society. Therefore, we are challenged to systematically search for pathogenic mechanisms so that prevention can be attempted and new therapeutic strategies can be developed to stop disease progression and improve long-term outcome.

3. Other Disorders

Philip Rosenthal, MD

CHOLEDOCHAL CYST

Although uncommon, choledochal cysts are classified as congenital anomalies of the biliary tract with varying degrees of cystic dilatation occurring at varying segments of the biliary tree (extrahepatic or intrahepatic). In general, the term "choledochal cyst" refers to all cystic dilatations of the biliary tree; others, however, restrict the term to only cystic abnormalities of the common bile duct.

Epidemiology

Choledochal cysts occur four times more frequently in girls than in boys regardless of racial differences. It is more frequently diagnosed in Asians, with an estimated incidence of 1 in 1,000 live births in Japan.[1] In the United States, the incidence is estimated at 1 in 13,000 live births.[2] About half of the cases are diagnosed in children before the age of 10 years, and another 25% of cases are diagnosed by 20 years of age. Thus, choledochal cysts are predominantly a disorder of children and young adults.[3,4]

Classification

Choledochal cysts have been categorized into several different types.[3] Anatomic classification is of practical importance in the planning of surgical intervention and treatment (Figure 50.3-1).

Type I, which is the most common type encountered, consists of a cystic dilatation of the common bile duct. Observed may be (1) a large saccular cystic dilatation, (2) small segmental cystic dilatation, or (3) diffuse or cylindrical fusiform dilatation. Type I cysts account for 75 to 85% of biliary cysts.

Type II cysts are diverticuli in the extrahepatic ducts. They may be seen in the common bile duct and/or the gallbladder. They represent only 2 to 3% of reported cases.

Type III cysts are choledochoceles. They are also rare, occurring in only about 3.5% of reported cases. A further anatomic classification of type III cysts has been proposed by Sarris and Tsang.[5] In type A, the ampulla opens into the choledochocele, which communicates with the duodenum via another small opening. Type A choledochoceles can be subclassified into A_1, in which the pancreatic and common bile duct share a common opening into the cyst; A_2, in which the openings are distinct; and A_3, in which the choledochocele is small and entirely intramural. In type B, the ampulla opens directly into the duodenum, with the choledochocele communicating only with the distal common duct.

Type IV cysts are multiple cysts. In type IV A, the multiple cysts are in the intra- and extrahepatic bile ducts and account for about 20% of reported cases. Type IV B cysts are rare and include multiple cysts found only in the extrahepatic system.

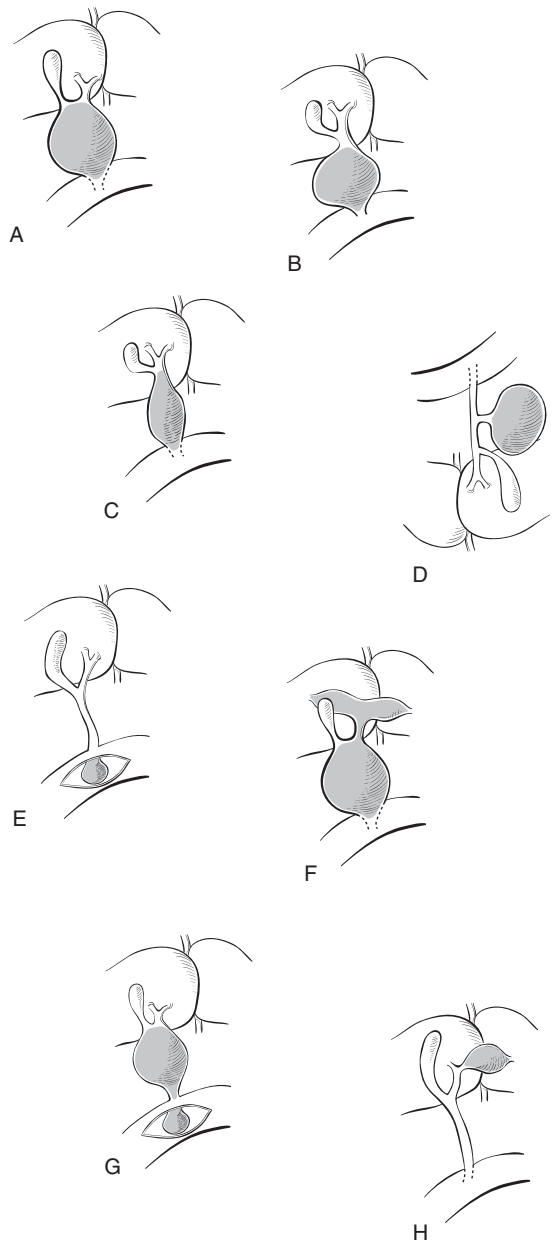

FIGURE 50.3-1 Diagrams demonstrating typing of ductal cysts. Reproduced from Todani T et al[3] with permission from Excerpta Medica.

Type V cysts are either single or multiple intrahepatic bile duct cysts. These are also rare. Type V cysts are identical to the original description of Caroli disease.

Clinical Presentation

Choledochal cysts present clinically with two distinct constellations determined primarily by patient age.[6,7] In infants, jaundice, the result of a conjugated hyperbilirubinemia with or without acholic stools, is observed. The presentation may be indistinguishable from biliary atresia, which is sometimes associated with a choledochal cyst. Abdominal pain may or may not be present. Hepatomegaly may be commonly found, and about half of the children have a palpable abdominal mass if carefully examined. The mass is typically in the right hypochondrium, soft, elastic, round, and mobile and may move with respiration. The classic triad of pain, jaundice, and a palpable abdominal mass occurs in anywhere from 13 to 63% of reported series. Biliary cirrhosis and portal hypertension may also be seen.

In older children and adults, many asymptomatic patients have been reported. Chronic or intermittent abdominal pain is the most common presenting symptom. Also, a history of intermittent jaundice or recurrent cholangitis is obtained. Palpation of an abdominal mass and the presence of cirrhosis or portal hypertension are infrequent in these older individuals compared with infants. However, recurrent pancreatitis is reported only in older children and adults. Frequently, abnormalities of the pancreatic duct system are found. Carcinoma associated with choledochal cysts has been reported only in patients over 10 years of age.

Spontaneous perforation of a choledochal cyst in infancy can occur. In one series, 7% (13/187) of infants with choledochal cysts were encountered with spontaneous perforation of the cyst.[8] Eight patients had biliary peritonitis, and five had sealed perforation. The postulated cause of perforation was biliary epithelial irritation from refluxed pancreatic juice, the result of malformed biliary and pancreatic ducts.

Pathogenesis

The etiology of choledochal cysts is unknown. Theories suggest either a congenital cause or an acquired cause.[9–11] The congenital theory postulates an unequal epithelial cell proliferation during embryogenesis while the embryonic bile ducts are still solid. In support of the congenital theory is the fact that biliary cysts have been reported in utero as early as 15 weeks gestation.[11] Further, after decompression surgery, many cysts fail to shrink, supporting inherently abnormal ductal wall development. The acquired injury theory proposes that choledochal cysts develop owing to an anomalous arrangement of the distal pancreaticobiliary tree. The anomalous merger of the common bile duct and the pancreatic duct proximal to the sphincter of Oddi permits reflux of pancreatic enzymes into the common bile duct, resulting in inflammation, edema, fibrosis, obstruction to bile flow, localized weakness, and dilatation. It is apparent that several factors may be important in the pathogenesis of biliary cysts. No single explanation supports each type of biliary cyst observed.

Diagnosis

Choledochal cysts in the majority of patients are recognized during infancy.[6,7] The diagnosis is suggested if noninvasive imaging studies are sought for vague right upper quadrant symptoms. Ultrasonography is a valued and preferred method to screen for a choledochal cyst (Figure 50.3-2A). Differentiation of a cystic structure that is not the gallbladder is an important consideration (Figure 50.3-2B). Although upper gastrointestinal tract radiographs may outline a mass that displaces the first or second portion of the duodenum, they are unnecessary. If there is doubt following ultrasound examination, the use of nuclear hepatobiliary scans, computed tomography, or magnetic resonance imaging (magnetic resonance cholangiography) may provide important discriminatory information.[12–14]

Percutaneous transhepatic cholangiography (PTC) and endoscopic retrograde cholangiopancreatography (ERCP) can provide excellent detailed information.[15] PTC may be especially helpful in defining complex intrahepatic cysts, whereas ERCP may provide the best visualization of the distal biliary tree. Obviously, PTC and ERCP are more invasive. Ultimate diagnosis can be confirmed by an intraoperative cholangiogram at surgery.

Pathology

The wall of a choledochal cyst is often thickened because of productive fibrosis and inflammation. Histologic examination reveals dense connective tissue, fibrocollagen, and, occasionally, smooth muscle and elastic elements.[16] Often there is no epithelial lining, but islets of preserved cylindrical or columnar epithelium may be found. Externally, duodenal mucosa covers choledochoceles, and, internally, there may be duodenal mucosa, bile duct mucosa, or unclassified glandular epithelium.

Hepatic changes owing to choledochal cyst frequently occur. Biliary cirrhosis, portal fibrosis, or evidence of bile duct obstruction with bile duct proliferation, cholestasis, parenchymal damage, and inflammatory cell infiltration may be seen.[17] Obviously, these changes may simulate biliary atresia.

Treatment

Therapy for choledochal cysts is complete surgical excision.[18,19] It is important that the entire cyst mucosa be removed. Historically, cyst aspiration, external drainage, internal decompression, and drainage into the duodenum or direct anastomosis of the cyst to a jejunal Roux-en-Y loop were used. Each of these techniques retained the cyst abnormal mucosal wall. Poor drainage resulted in stricture formation, biliary lithiasis, and an increased risk of malignant potential in the retained mucosal wall. It is imperative that the extent of any intrahepatic cystic disease be defined at the time of choledochal cyst excision. An intraoperative cholangiogram is well suited for this task. Segmental multifocal cystic disease isolated to a single hepatic lobe can be treated with lobectomy. If the intrahepatic disease is dif-

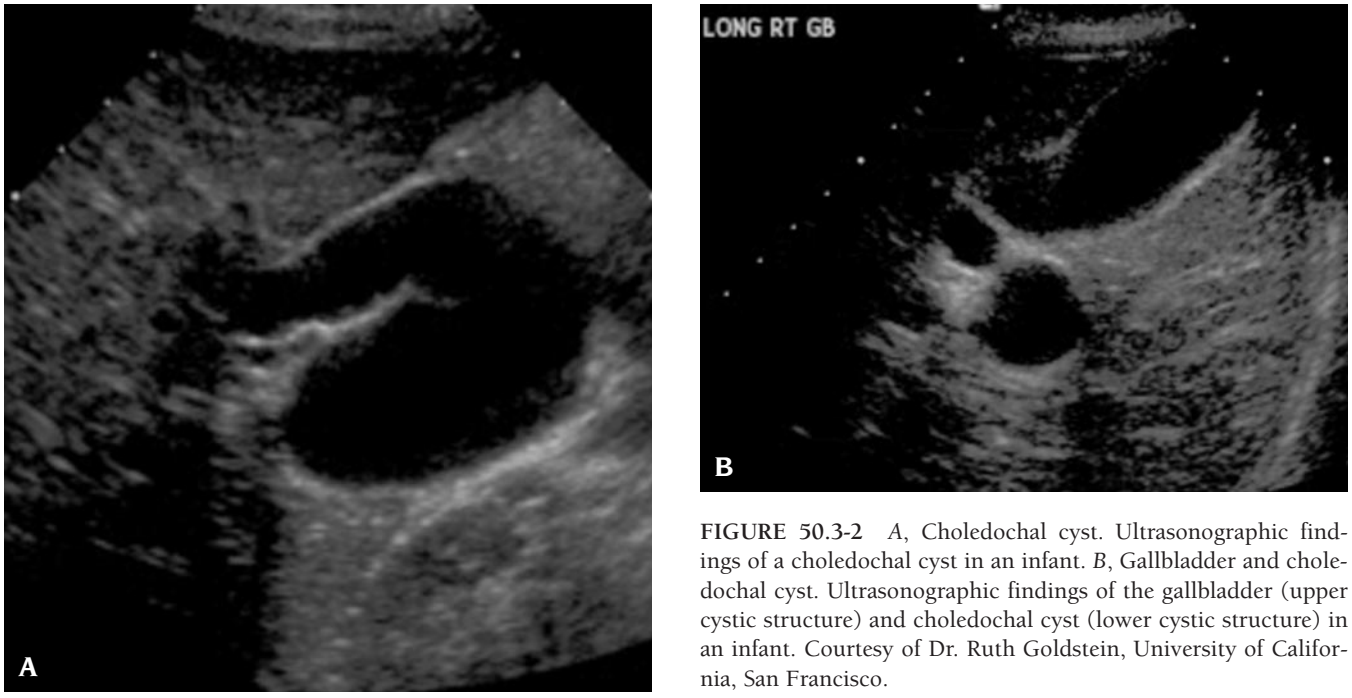

FIGURE 50.3-2 *A*, Choledochal cyst. Ultrasonographic findings of a choledochal cyst in an infant. *B*, Gallbladder and choledochal cyst. Ultrasonographic findings of the gallbladder (upper cystic structure) and choledochal cyst (lower cystic structure) in an infant. Courtesy of Dr. Ruth Goldstein, University of California, San Francisco.

fuse, involving all hepatic lobes, then liver transplant may be required. Following surgery, complications include cholangitis, stricture formation, and pancreatitis. These can be significantly decreased by total cyst excision and careful surgical dissection. Recently, a report of the complete laparoscopic management of choledochal cysts was published.[20] The authors concluded that although feasible, this technique is technically difficult and should currently be restricted to specialized centers dealing with advanced laparoscopic surgery.

Malignancy

The most alarming complication of choledochal cyst is malignancy. Carcinoma has been reported in remaining cystic tissue in up to 26% of patients.[21–24] Although the overall incidence of biliary carcinoma in association with biliary cysts is about 2.5%, the overall incidence of biliary carcinoma in the general population is only about 0.012 to 0.5%. The typical malignancy is adenocarcinoma of the bile duct or gallbladder. Squamous cell carcinoma and cholangiocarcinoma have also been observed. The risk of developing malignancy increases with age. Malignant change can also occur in areas of the biliary tree remote from the cyst. The prognosis if such malignancies develop is grim. Thus, complete cyst removal, even in asymptomatic patients, including those with prior cyst surgery, is warranted.

SPONTANEOUS PERFORATION OF THE COMMON BILE DUCT

Spontaneous perforation of the bile ducts is a rare but well-documented condition in neonates.[25–27] Typically, these infants present with cholestatic jaundice following a postnatal symptom-free interval. There is associated mild jaundice, ascites, acholic stools, poor weight gain, vomiting, and evolving abdominal distention. The combination of a mildly elevated conjugated hyperbilirubinemia with minimally elevated serum transaminases and acholic stools in a neonate should suggest the possibility of the diagnosis. Ultrasonography may reveal ascites or a loculated fluid collection. Nuclear hepatobiliary scintigraphy may demonstrate activity of the isotope outside the biliary tree in the abdomen.[28] Abdominal paracentesis may aid in the diagnosis, revealing clear, bile-stained ascites. Treatment requires surgical intervention to either attempt to repair the perforation or to re-establish bile flow from the liver to the intestine while decompressing the biliary tract. Operative cholangiography may demonstrate the site of the perforation. Often there is stenosis of the distal end of the common bile duct, segmental atresia, or inspissated bile. There is a predilection for the perforation to occur at the confluence of the cystic duct and the common bile duct, suggesting a particular susceptibility to weakness or injury at this site.[29]

NEONATAL SCLEROSING CHOLANGITIS

Sclerosing cholangitis refers to a disorder with irregular narrowing of either the intrahepatic or extrahepatic bile ducts, the result of inflammation and subsequent fibrosis. Obliteration of the bile ducts eventually results in biliary cirrhosis. Cholangiography demonstrates the typical "beading" pattern with alternating areas of strictures and dilatations in the intrahepatic and extrahepatic bile ducts. A neonatal form of sclerosing cholangitis has been reported in infants.[30–35] Jaundice, cholestasis, and acholic stools were observed within the first weeks of life. Cholecystography disclosed abnormal intrahepatic and extrahepatic bile ducts with rarefaction of segmental branches, stenosis, and focal dilation. The early clinical symptoms following birth suggest the possibility of a congenital onset. A history of consanguinity in many of the affected

infants suggests an inherited or genetic basis for this disorder. A case of neonatal sclerosing cholangitis associated with a positive anti–smooth muscle antibody titer (1:320) and elevated immunoglobulin has been reported.[34] Although the cause of neonatal sclerosing cholangitis is unknown, genetic or immunologic factors may be important in its etiology. In all cases of neonatal sclerosing cholangitis reported, jaundice resolved within the first year of life. However, the disease progressed to cirrhosis. Liver transplant has been used to treat some cases of neonatal sclerosing cholangitis.[33] To date, there has been no report of recurrence of disease following transplant. The role of medical therapy, such as ursodeoxycholic acid (UDCA) administration, to alter the progression of neonatal sclerosing cholangitis is unknown.

SCLEROSING CHOLANGITIS

Although more frequently diagnosed in adults, sclerosing cholangitis may also be seen in childhood. Sclerosing cholangitis is defined as a chronic hepatobiliary disorder with inflammation of the intrahepatic and extrahepatic bile ducts. The subsequent periductular fibrosis results in narrowing and dilatation of the bile ducts. Progression of the disorder results in cirrhosis and portal hypertension. Diagnosis can be made by cholangiography and/or histology of the liver parenchyma.

The nomenclature for sclerosing cholangitis is a bit confusing. Primary sclerosing cholangitis (PSC) is the most frequent liver disorder associated with inflammatory bowel disease (IBD). However, PSC may occur in the absence of IBD. Cholangitis related to chronic ascending bacterial infection, stones, bile duct surgery, congenital anomalies of the bile ducts, ischemic injury, neoplasms, or infectious cholangiopathy owing to acquired immune deficiency syndrome (AIDS) is referred to as primary cholangitis. This designation assumes that prior to the onset of PSC, the bile duct anatomy was normal. Secondary sclerosing cholangitis is associated with bile duct injury, the result of choledocholithiasis, postoperative stricture formation, or specific duct involvement from systemic disease. Rather than categorizing sclerosing cholangitis as primary or secondary, Debray and colleagues divide sclerosing cholangitis into three groups: neonatal, postneonatal associated with a disease, and postneonatal not associated with a disease.[36]

The distinction between sclerosing cholangitis and the obstructive cholangiopathies of infancy (ie, biliary atresia, syndromic and nonsyndromic paucity of intrahepatic ducts) is vague. There are histologic and radiographic similarities, suggesting common etiologies. In biliary atresia, there is an inflammatory, progressive, and obliterative destruction of the extrahepatic and intrahepatic bile ducts. Infants with the neonatal form of sclerosing cholangitis may have pathologic and radiographic features that are very similar to biliary atresia early in the course of the disease that do not become characteristic of sclerosing cholangitis until the disease evolves.[31,32] Further, a report of siblings, one with biliary atresia and the other with PSC, has been published.[37]

Sclerosing Cholangitis and Associated Conditions

Reports of PSC associated with both ulcerative colitis and Crohn disease in children are becoming more frequent, potentially as a result of improved cholangiographic techniques being used.[38–50] In adults, PSC is often associated with other disorders with an autoimmune basis, including diabetes mellitus, pancreatitis, and thyroid diseases. These disorders may precede or follow the diagnosis of PSC. In children, besides an association with IBD, PSC may be associated with a wide variety of disorders.[51–58]

Clinical Presentation

Although PSC can occur in infancy, the majority of cases in childhood occur in young adults. As in older adults, there may be a gradual onset of fatigue, malaise, anorexia, and weight loss. Pruritus and intermittent jaundice may then occur. Cholangitis recognized by right upper quadrant pain, fever, and conjugated hyperbilirubinemia is often encountered. In children, growth failure and delayed puberty may also be presenting symptoms. Many children with PSC are clinically asymptomatic, and the disease is detected only as a result of screening serum biochemical abnormalities, which prompts further investigation. There are no pathognomonic laboratory findings in PSC. Commonly in adults, there is an elevated serum alkaline phosphatase. Although this may be variable in children, elevated alkaline phosphatase levels may be difficult to interpret because of growth. An elevated serum γ-glutamyltransferase level appears to be a sensitive indicator for PSC in children. Other variably abnormal biochemical tests include high immunoglobulin G concentrations, positive antinuclear antibodies, anti–smooth muscle antibodies, and antineutrophil cytoplasmic antibodies, suggesting an autoimmune connection. Although the physical examination may be completely normal, often hepatomegaly, splenomegaly, or jaundice is noted.[36,50]

Diagnosis

Cholangiography is considered essential in the diagnosis of PSC (Figure 50.3-3). This may be accomplished by ERCP, PTC, intraoperative cholangiography, or, more recently, magnetic resonance cholangiopancreatography.[38] Characteristic findings are irregular narrowing and stricturing of the hepatic and common bile ducts owing to inflammation and fibrosis. There may be concomitant involvement of the intrahepatic ducts. The strictures may be localized, diffuse, or multifocal. Strictures may be short, with intervening normal duct segments producing the characteristic beaded appearance. The intrahepatic bile ducts may show decreased peripheral arborization, which is referred to as the pruned tree appearance.

Pathology

The characteristic histologic findings in PSC may not be present in many cases in children, limiting the usefulness of this modality for diagnosis.[36,50] Classically, there are focal concentric edema and fibrosis around interlobular bile ducts. This is referred to as an onion skin appearance. Typically, there is portal to portal variability in the biopsy, and a review

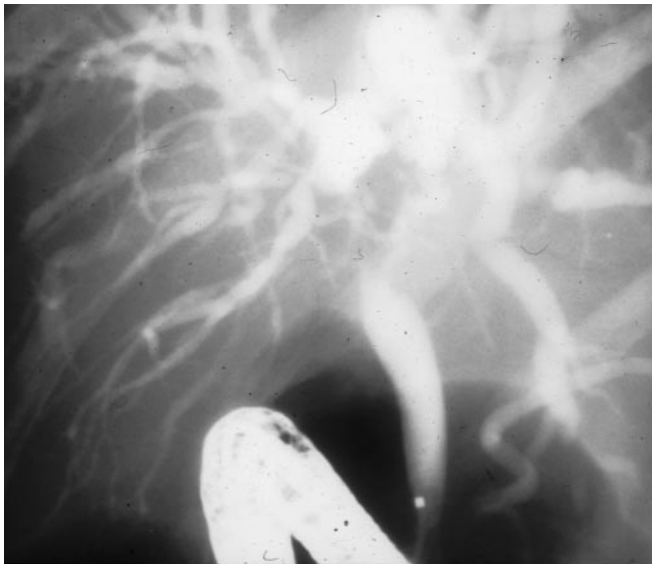

FIGURE 50.3-3 Primary sclerosing cholangitis. Cholangiogram demonstrating irregular narrowing and stricturing of the hepatic and common bile ducts owing to inflammation and fibrosis. Courtesy of Dr. Roy Gordon, University of California, San Francisco.

of serial sections may be required. Serial biopsies demonstrating progressive ductal changes may also be necessary to establish the diagnosis. A fibro-obliterative cholangitis may progress over time to solid cords of connective tissue and loss of interlobular bile ducts, giving the appearance of a paucity of bile ducts per portal zone (Figure 50.3-4). This may continue to progress to frank biliary cirrhosis.

Pathogenesis

The etiology of PSC is unknown. The association of PSC with IBD may suggest potential etiologic mechanisms, but PSC may occur in the absence of IBD.

To incorporate the various proposed theories into a unifying hypothesis, perhaps an immune-mediated destruction of the biliary tree initiated by an infectious agent in a susceptible host with or without intestinal involvement best describes the process. To this end, there is exciting new evidence implicating a retrovirus in the pathogenesis of primary biliary cirrhosis, another obliterative ductal disease.[59] Further, pilot studies using antiviral therapy with lamivudine and zidovudine in adult patients demonstrated significant biochemical and histologic improvement with reversal of ductopenia and normalization of liver function tests.[60] Whether antiviral therapy has a role in PSC remains speculative.

Alterations in the immune system are also proposed to be important in the initiation or perpetuation of PSC (see Chapter 52, "Autoimmune Disease").

Treatment

Unfortunately, there have been no large randomized controlled trials of any potential therapeutic agents for the treatment of PSC in children. UDCA therapy has been used in children with PSC.[40] There were no side effects reported in its use in nine children. There were significant reductions in serum alkaline phosphatase, alanine aminotransferase, aspartate aminotransferase, and γ-glutamyltransferase levels with up to 20 months of treatment. The long-term effect of UDCA therapy for children with PSC awaits further trials.

Immunosuppressive therapy has long been used for PSC therapy in children.[61,62] Certainly, there is a rationale for this in children with PSC with IBD. Those children with autoimmune features of disease might also be expected to respond to this therapy. Oral vancomycin was reported to normalize serum transaminase levels in three children with PSC.[45] Although provocative and supporting a role for intraluminal bacteria, further confirmation is awaited before oral vancomycin therapy can be recommended for routine use in children with PSC.

Surgical options have been used predominantly to relieve biliary obstruction, reduce the occurrence of cholangitis, and combat the consequences of cirrhosis and portal hypertension. Procedures performed either surgically, by interventional radiology, or endoscopically range from drainage procedures, stent placement, balloon dilatation of strictures, resection, and transplant.[33,63–67] Certainly, surgical intervention should be avoided if at all possible and reserved for refractory patients after attempts at dilatation and stent placement have been exhausted. Transplant is appropriate for children with PSC who have progressed to cirrhosis and who have developed portal hypertension in the absence of refractory complications. Unfortunately, recurrence of PSC in the transplanted liver has been reported.[68,69] Recently, a report of a 15-year-old boy who underwent liver transplant for PSC was published.[70] What was novel about this case and another five adult cases in this report was the sequential occurrence of autoimmune hepatitis that evolved to PSC over several years.

Prognosis

The true rate of progression of PSC in children is unknown. Presumably, the rate of progression is slow because PSC is

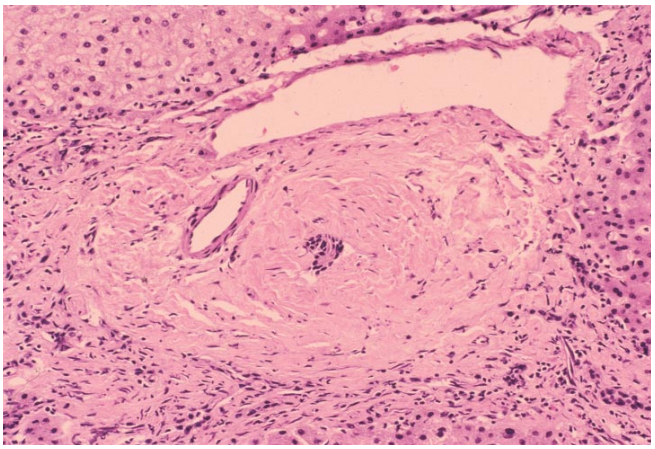

FIGURE 50.3-4 Primary sclerosing cholangitis: portal zone shows prominent periductal fibrosis (onion skin–like fibrosis) around the interlobular bile duct. not one of the leading indications for pediatric liver transplant. The prognosis may be better for children than for adults, based on the study by Floreani and colleagues.[41] In the larger pediatric series, about a third of children died, the result of cirrhosis and portal hypertension, and another third either were listed for transplant or went on to transplant.[36,50]

CHAPTER 51

POSTNATAL INFECTIONS

1A. *Viral Hepatitis* B

Mei-Hwei Chang, MD

Hepatitis viruses can infect individuals of any age. Although most of the complications manifest mainly in adulthood, primary infection may occur in infancy or childhood. Among the hepatotrophic viral infections (A through E), hepatitis A and E run an acute self-limited or fulminant course, whereas hepatitis B, C, and D may follow either an acute or a chronic course. Chronic hepatitis D is very rare in children all over the world, except in a few endemic areas, whereas chronic infection of hepatitis B virus (HBV) is more prevalent and can occur in children of any age, even in the perinatal period. Chronic infection of HBV during childhood may cause chronic hepatitis, cirrhosis, and liver cancer during childhood or later in adulthood. HBV-related carcinogenesis requires time; hepatocellular carcinoma may occur much earlier in those infected in childhood than in those infected in adulthood.

HBV infection is a worldwide health problem. Approximately 2 billion people in the world have been infected by HBV, and 350 million of them are chronic hepatitis B antigen carriers. In hyperendemic areas, where most of the complications of chronic HBV infection develop in adulthood, primary HBV infection occurs mainly during infancy or early childhood.[1] Understanding the long-term natural course of chronic HBV infection in children is very important to evaluate the efficacy and determine the strategy of antiviral therapy for chronic HBV infection in children.

Hepatitis B immunization has effectively reduced the infection and carrier rate of HBV. Immunization is the most important method to achieve the eradication of hepatitis B–related diseases.

HEPATITIS B VIRUS

Hepatitis B virus is a 3.2 kb, circular, partially double-stranded deoxyribonucleic acid (DNA) virus. During active replication in the early phase of infection, viral particles appear in large quantity in the serum in two forms: one is the complete virion of 42 nm diameter, which consists of an envelope, a capsid with capsid protein, a circular DNA molecule, and a DNA polymerase,[2,3] and the other is a 22 nm empty viral envelope, which contains only the hepatitis B surface antigen (HBsAg). In addition, a soluble antigen, hepatitis B e antigen (HBeAg), which is closely related to the nonsecretory capsid antigen (hepatitis B core antigen [HBcAg]), also appears in the serum during the highly replicative phase of HBV infection (Table 51.1A-1).

HBV contains four open reading frames, which encode major structural and nonstructural proteins for HBV. These are the polymerase gene region for polymerase, surface gene region for three surface proteins, precore and core gene regions for HBcAg and HBeAg, and X gene region for

TABLE 51.1A-1 CLINICAL SIGNIFICANCE OF HEPATITIS B VIRUS ANTIGENS, ANTIBODIES, AND DNA

ANTIGEN	CLINICAL SIGNIFICANCE	ANTIBODY	CLINICAL SIGNIFICANCE
HBsAg	Acute or chronic infection	Anti-HBs	Protection by vaccination recovery from infection
HBeAg	Active viral replication	Anti-HBe	Inactive viral replication
HBcAg	Not detectable in the serum	Anti-HBc	Present (IgM, IgG) or detectable in the liver Past infection (IgG)
HBV DNA	Presence of HBV		

Anti-HBc = hepatitis B core antibody; Anti-HBe = hepatitis B e antigen; Anti-HBs = hepatitis B surface antibody; DNA = deoxyribonucleic acid; HBcAg = hepatitis B core antigen; HBeAg = hepatitis B e antigen; HBsAg = hepatitis B surface antigen; HBV = hepatitis B virus; Ig = immunoglobulin.

hepatitis B X protein.[4] HBV has a restricted host range. It infects only humans and chimpanzees.

EPIDEMIOLOGY OF HBV INFECTION IN CHILDREN

HBV infection is prevalent in Asia, Africa, Southern Europe, and Latin America, where the HBsAg-seropositive rate ranges from 2 to 20% in most regions. In hyperendemic areas, HBV infections occur mainly during infancy and early childhood. In Taiwan, the HBsAg carrier rate is approximately 10 to 20%. Before the implementation of a universal HBV immunization program, the HBsAg-seropositive rate in this population was 5% in infants and increased to 10% at 2 years of age, remaining at the same rate thereafter. However, the infection rate, measured by hepatitis B core antibody (anti-HB_c) seropositivity, reached 50% by the age of 15 years. This suggests that most chronic HBsAg carriers are infected before 2 years of age in this population.[1]

Perinatal transmission from HBsAg carrier mothers to their infants is a very important route of transmission, leading to chronicity, in Asia. This mode of transmission accounts for 40 to 50% of HBsAg carriers in Taiwan and many other hyperendemic areas. Approximately 90% of the infants of HBeAg-seropositive carrier mothers become HBsAg carriers,[5] irrespective of a high or low HBsAg carrier rate in the population. The age of infection is an important factor in determining the outcome of infection.[6,7]

In areas of low endemicity, horizontal infection is the main route of transmission. Although Africa is an area of high endemicity, horizontal infection in early childhood is the main route of HBV transmission. The two most important routes of horizontal transmission in children are highly infectious family members, such as siblings, and improperly sterilized syringes.[8] Other sources of horizontally transmitted infections include institutionalized children and multiple or large-volume blood transfusions. In the United States and Europe, HBV is highly prevalent among adopted children from endemic areas of the world.

PATHOGENESIS AND NATURAL COURSE OF HBV INFECTION IN CHILDREN

HBV has an incubation period of 2 to 6 months. Following a primary HBV infection, the host may run an acute, fulminant, or chronic course. The interaction between the host and virus determines the outcome of infection.

Acute and Fulminant Hepatitis B

Acute hepatitis runs a self-limited course. Recovery is marked by hepatitis B surface antibody (anti-HB_s) seroconversion. Fulminant hepatitis is signaled by pathologic mental status changes within 2 to 8 weeks after the initial symptoms in an otherwise healthy child. Trey and Davison defined fulminant hepatic failure as the onset of altered metal status within 8 weeks of initial symptoms in an otherwise healthy individual.[9] Later Bernuau and colleagues defined fulminant hepatitis as hepatic encephalopathy developing within 2 weeks after the onset of jaundice and subfulminant hepatitis as hepatic encephalopathy developing between 2 and 12 weeks after the onset of jaundice.[10]

Symptoms of acute or fulminant hepatitis B may develop as early as 2 months of age in infants of HBsAg carrier mothers. In areas hyperendemic for HBV infection, HBV accounts for around 65% of the etiologic agents for fulminant hepatitis in children. Approximately 65% of pediatric patients with fulminant hepatitis B present in infancy. Maternal transmission is the most important route of transmission in infants with acute or fulminant hepatitis,[11] mainly in infants of hepatitis B e antibody (anti-HB_e)-seropositive mothers.[12]

Fulminant hepatitis carries a very high mortality rate of 55 to 70% without transplant and 30 to 50% with transplant.[11,13] Those who survive usually recover without sequelae. In both acute and fulminant hepatitis B, HBV is cleared rapidly from the host.

Precore mutations have been associated with fulminant hepatitis B in adults, but this has not been confirmed by more recent studies.[14,15] Thirty-three percent of the children with fulminant hepatitis B have the hepatitis B precore stop codon mutant, a prevalence rate similar to that (30%) in children with acute hepatitis B.[16] This suggests that precore stop codon mutations alone do not explain the severe clinical course in fulminant hepatitis B.

Chronic HBV Infection

Children with chronic HBV infection are mostly asymptomatic. They are generally active and grow well, with very rare exceptions. Even with acute exacerbation of liver inflammation, jaundice or growth failure is rare. Although liver damage is usually mild during childhood, serious sequelae, including cirrhosis and hepatocellular carcinoma, may develop insidiously at any age.

The coexistence of high rates of viral replication, normal liver function profiles, and minimal hepatic hisopathology for many years in children with chronic HBV infection suggests that HBV may not be directly cytopathic. An immune-mediated process is the main mechanism for cell damage. During acute exacerbations of chronic HBV infections, CD8-positive cytotoxic T lymphocytes are the predominant cells in the liver in the areas of piecemeal necrosis. As hepatocellular necrosis occurs, there is a gradual decrease of HBV replication and HBeAg serocoversion occurs, along with a decrease in hepatic inflammation (Figure 51.1A-1).

Spontaneous Hepatitis B e Seroconversion. HBeAg is an important marker reflecting active viral replication and infectivity. Its clearance is therefore used as a marker for the success of antiviral therapy. Children with chronic HBV infection are HBeAg seropositive at the initial stage of infection. During this stage, the child is tolerant to HBV, the virus is highly replicative, and serum HBV DNA levels are usually high. The child is thus an important source of horizontal infection in the family and community. Aminotransferase levels fluctuate but are usually normal or mildly elevated, with mean levels higher than those in noncarrier healthy children.[17] Peak alanine aminotrans-

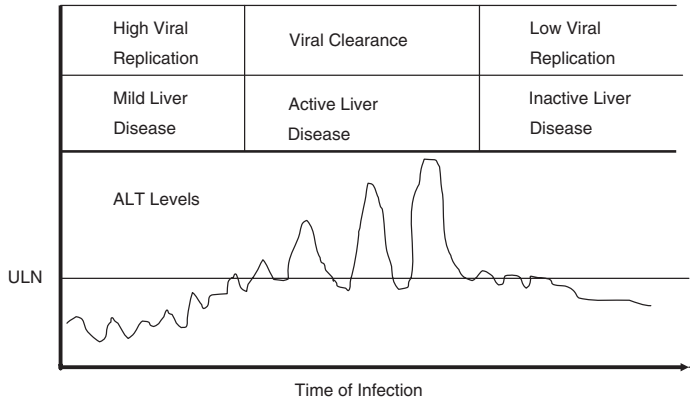

FIGURE 51.1A-1 Natural course of chronic hepatitis B virus infection acquired in childhood. During the early phase of infection, the amount of virus in the liver and blood is usually large, whereas the liver damage is mostly mild. The host immune system gradually recognizes the virus and starts to clear the virus. It results in active inflammation of the liver and elevation of serum aminotransferases. Repeated episodes of elevation of aminotransferases may be followed by hepatitis B e antigen (HBeAg) seroconversion. After HBeAg seroconversion, viral replication declines and the liver inflammation gradually becomes inactive. ULN = upper limit of normal.

ferase (ALT) levels > 100 IU/L are uncommon in this phase. Hepatitis B e antigenemia can persist for years after primary infection.

Spontaneous clearance of serum HBeAg occurs gradually as the child ages. Viral replication is reduced during this process. This process of HBeAg clearance is usually preceded by an elevation of aminotransferases. The peak level of aminotransferase elevation can be mild, transient, and fluctuating. An ALT level > 1,000 IU/mL is unusual. This process of HBeAg seroconversion takes place subclinically in most individuals for a period of 2 to 7 years.[18] After the detection of elevated levels of aminotransferases, around 40% of children will clear HBeAg within 1 year. Children with elevated aminotransferase levels of > 100 IU/mL and HBV DNA levels of < 1,000 pg/mL often seroconvert during the subsequent 1 to 3 years.[17] After HBeAg clearance, aminotransferase levels gradually return to normal limits, and anti-HBe develops spontaneously. In our series, HBV DNA was detectable in only 1% of the anti-HBe–positive sera. However, using polymerase chain reaction (PCR), HBV DNA persists long term in the serum of children with chronic hepatitis B after HBeAg seroconversion. Bortolotti and colleagues. studied 39 children after hepatitis B e seroconversion.[19] They found that 87% of children had detectable HBV DNA by PCR within 5 years of follow-up and in 58% of cases 10 years after seroconversion. ALT levels were persistently normal in 92%, whereas 8% had slightly elevated ALT.

Acute exacerbation of inflammation with reactivation of HBV replication and a rise in aminotransferases is not common in children after hepatitis B e seroconversion.[18,20] Permanent liver damage has occurred, and integration of the genome of HBV has occurred insidiously and gradually, despite clearance of HBeAg. Development of cirrhosis or hepatocellular carcinoma is occasionally observed but is rare during childhood. Most of those who develop these complications of chronic HBV infection are anti-HB_e seropositive.[21]

Factors Affecting Hepatitis B e Seroconversion. Age is an important determinant of the rate of HBeAg seroconversion.[22] Before 3 years of age, the spontaneous HBeAg clearance rate is very low (< 2% per year). The hepatitis B e seroconversion rate gradually increases to around 5% per year after 3 years of age. This might be due to immune tolerance to HBcAg and HBeAg in infected children. Immune tolerance owing to transplacental e antigen has been demonstrated by the absence of a T-cell response to HBcAg in infants and children of HBeAg-positive HBsAg carrier mothers, whereas the T lymphocytes from infants with acute hepatitis of hepatitis B e–negative HBsAg carrier mothers respond very well to HBcAg.[23] The age of hepatitis B e seroconversion varies, ranging from infancy to more than 40 years of age. The most common period is from 15 to 30 years of age. Before 15 years of age, the majority (85% in Taiwan) of HBsAg carrier children are HBeAg seropositive.

Another factor affecting the hepatitis B e seroconversion rate in children is maternal HBsAg.[22] Those with HBsAg carrier mothers have a lower rate of HBeAg clearance than those whose mothers were not HBsAg carriers. Maternal carrier state reflects perinatal transmission or early infection, which will lead to a longer duration of immune tolerance to HBV (Figure 51.1A-2).

HBsAg/Antibody Seroconversion. In our long-term follow-up of HBsAg carrier children, the annual HBsAg clearance rate was very low (only 0.56%),[24] occurring only after clearance of HBeAg. After loss of HBsAg, its antibody (anti-HB_s) remains low or undetectable in the majority (0 to < 100 mIU/mL). The underlying mechanisms of a poor anti-HB_s response in HBsAg carriers who lost HBsAg are multifactorial, including specific failure of antigen presentation or T-cell activation or the lack of a T helper cell–like response to HBsAg.[25] Hepatitis B immunization is not beneficial in these individuals.

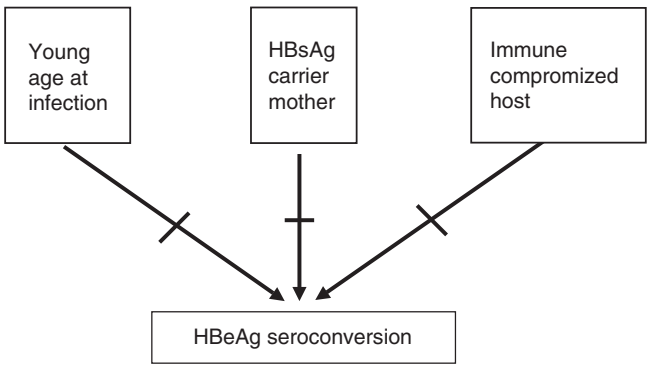

FIGURE 51.1A-2 Factors that may hinder or delay hepatitis B e antigen (HBeAg) seroconversion and viral clearance.

Histopathologic Findings in Children with Chronic HBV Infection. Liver histology in HBeAg-positive HBsAg carrier children generally reveals very mild inflammation and fibrosis.[26] During the process of HBV and HBeAg clearance, the abnormal changes include lobular changes with portal inflammation and fibrosis, with or without piecemeal necrosis. The inflammation is usually milder than that observed in adults. Bridging hepatic necrosis may occur but is uncommon. Within 6 months of hepatitis B e seroconversion, the inflammation is less active and, beyond 6 months, becomes inactive, with mild to minimal inflammation and fibrosis in most children.

The authors have studied the liver histology in 41 asymptomatic HBsAg children at 1 to 9 years of age who were perinatally infected by their HBeAg-positive HBsAg carrier mothers. The histologic findings included chronic active hepatitis (n = 1), chronic persistent hepatitis (n = 8), chronic nonspecific hepatitis (n = 30), and normal histology (n = 2). The histologic abnormalities in the liver begin early in life and may progress to severe liver impairment in later life.

Virologic Factors That May Affect the Clinical Course. During the course of infection, HBV may undergo mutations, which accumulate particularly in some DNA hot spots. Mutations of HBV may affect the outcome of infection or, more commonly, are the result of host immune pressure. HBV precore G to A stop codon mutations at nucleotide 1896 are a common site of mutations detected in patients with fulminant hepatitis, acute hepatitis, chronic hepatitis with acute exacerbation, cirrhosis, or hepatocellular carcinoma in adults.[27,28] We have studied the temporal changes of this mutation in children with chronic HBV infection and found that it emerged before hepatitis B e seroconversion. The proportion of positive precore stop codon mutations increased gradually after HBeAg seroconversion to around 50% of the children.[29]

HBcAg is the target in HBV-infected hepatocytes for cytotoxic T lymphocyte–mediated cell lysis. Mutation of the HBV core gene may change the conformation of core protein and allow the hepatocytes to escape the immune surveillance of the host. Among 31 Taiwanese children with chronic HBV infection, HBV core gene codons 21 (29%), 147 (29%), and 65 (15%) were the frequent sites of mutation.[30]

Genotypes of HBV were reported to correlate with the clinical outcome in patients with chronic hepatitis B. Genotype C was more prevalent in patients with cirrhosis and hepatocellular carcinoma, whereas patients with genotype B experienced earlier hepatitis B e seroconversion and slower progression of liver fibrosis and development of hepatomas.[31,32]

Hepatocellular Carcinoma. Hepatocellular carcinoma is 1 of the 10 most common cancers in the world. In areas prevalent for HBV infection, hepatocellular carcinoma is not rare in children. The rate of seroprevalence of hepatitis B surface antigenemia approaches 100% in children with hepatocellular carcinoma in Taiwan. Maternal transmission or infection in early childhood is an important risk factor.[21,23] Integration of HBV DNA has been detected in the tumor and nonmalignant liver tissue of children with chronic HBV infection and hepatocellular carcinoma.[33]

Core gene mutations were identified much more commonly at some codons (codons 74, 87, and 159) in children with hepatoma than in children with chronic HBV infection but without cancer. Those core gene mutations may induce persistent host immune attacks and lead to severe liver damage, as observed in children with hepatocellular carcinoma.[30]

Hepatitis B Immunoprophylaxis

Prevention of HBV infection can be achieved by passive and active immunization. Passive immunization using hepatitis B immunoglobulin (HBIg) provides temporary immunity. After hepatitis B vaccine became available in 1982, active immunization with three or four doses of HBV vaccine without HBIg has proved to be immunogenic in more than 90% of neonates of noncarrier mothers or HBeAg-negative carrier mothers. In infants of HBeAg-seropositive mothers, it decreased the carrier rate to 24%. Injection of HBIg within 24 hours after birth followed by three doses of HBV vaccine further reduces the carrier rate down to 3% in pilot studies[34] and to 14% in a study of the general population.[35] According to a random sampling study of children in Taiwan 3 years after implementing a universal HBV vaccination program, the protective efficacy was found to be 86% from HBIg plus HBV vaccine and 78% from three doses of HBV vaccine alone.[35]

The first universal hepatitis B vaccination program in the world was launched in Taiwan in July 1984.[36] Pregnant women are screened for both serum HBsAg and HBeAg or titers of HBsAg by a reverse passive hemagglutination test. Infants of mothers with negative serum HBeAg with a reciprocal HBsAg titer lower than 1:2,560 or with negative serum HBsAg receive plasma-derived hepatitis B vaccine at 0, 1, 2, and 12 months for those born before July 1992 or a recombinant hepatitis B vaccine at 0, 1, and 6 months for those born after July 1992. Infants of mothers with positive serum HBeAg or with reciprocal titers of HBsAg by reverse passive hemagglutination ≥ 2,560 receive HBIg within 24 hours after birth in addition to doses of hepatitis B vaccine. The coverage rate of hepatitis B vaccine for neonates is around 94%.

Different immunization strategies are used in different countries, depending on their basic epidemiologic features of HBV infection and available resources. In many hyperendemic countries, HBV vaccination consists of three doses of hepatitis B vaccine and no HBIg for all infants, including infants of an HBsAg carrier mother This has an efficacy of around 75 to 80%. Using this HBV immunization program, the cost of maternal screening and HBIg can be minimized. Other countries, such as the United States, give one dose of HBIg to infants of HBsAg-positive mothers, regardless of their HBeAg status, and three doses of HBV vaccine to all infants.

Impact of Universal Hepatitis B Immunization on Hepatitis B Eradication

The seroprevalence rates of HBsAg and anti-HB_c in Taiwanese children before and 15 years after the initiation of a universal vaccination program were remarkably reduced.[37] The HBsAg carrier rate in Taipei in children < 15 years old decreased significantly from around 10% before to < 1% after the vaccination program (see Table 51.1A-2). The infection rate, measured by the seropositive prevalence of anti-HBc, was decreased in all of the children (anti-HB_c seropositivity declined from 38 to 16% in children below 13 years of age), even in those above 15 years of age who were not vaccinated during infancy. This vaccination program has indeed reduced both the perinatal and the horizontal transmission of HBV.[38] The decrease in horizontal transmission was a result of a decline in the prevalence of sources of infection and the vaccination of the older children.

Although immunoprophylaxis for HBV infection is very successful, around 2.4% of infants of HBeAg-positive mothers still had HBsAg in the serum at birth or shortly after birth.[39] They became HBsAg carriers in spite of complete immunoprophylaxis. Intrauterine HBV infection, although infrequent, is possible. Risk factors for failure of immunoprophylaxis include a high level of maternal HBV DNA, a low level of maternal anti-HB_c, and uterine contraction and placental leakage during the process of delivery.[40,41]

Vaccine Prevention of Hepatocellular Carcinoma

After the implementation of the universal vaccination program for HBV in Taiwan, we have successfully demonstrated a decline in the incidence of hepatocellular carcinoma in children. The average annual incidence of hepatocellular carcinoma in children of 6 to 14 years declined from 0.70 per 100,000 children between 1981 and 1986, to 0.57 between 1986 and 1990, and to 0.36 between 1990 and 1994.[42] In contrast, the incidence of hepatoblastoma in children and the incidence of hepatocellular carcinoma in adults during the same study period were not reduced. Analyzing the incidence of hepatocellular carcinoma according to the birth cohort, the reduction effect is even more impressive. The incidence of hepatocellular carcinoma in children 6 to 9 years of age declined from 0.52 in 100,000 children for those born between 1974 and 1984 to 0.13 in 100,000 children for those born between 1984 and 1986.

Boys may benefit more from HBV vaccination than girls in the prevention of hepatocellular carcinoma.[43] The boy-to-girl incidence of hepatocellular carcinoma decreased steadily from 4.5 in 1981 to 1984 (before the launch of a universal HBV vaccination program) to 1.9 in 1990 to 1996 (6–12 years after the launch of a universal HBV vaccination program) (Table 51.1A-3).

TABLE 51.1A-2 HBSAG-SEROPOSITIVE RATES BEFORE AND AFTER IMPLEMENTATION OF A UNIVERSAL HEPATITIS B VACCINATION PROGRAM IN TAIWAN

	HBSAG-SEROPOSITIVE RATE (%)			
AGE (YR)	1984	1989	1994	1999

Universal hepatitis B vaccination was implemented in Taiwan in July 1984.
Adapted from Ni YH et al.[37]

Long-Term Vaccine Immunogenicity

A large-scale prospective community-based study enrolling 1,200 children with complete HBV immunization in infancy was conducted until the children were 14 years of age. Eleven children had new HBV infections with anti-HB_c seropositivity. None of them became positive for HBsAg or HBV DNA by PCR. The proportion of children with protective anti-HB_s gradually decreased from 71% at age 7 years to 37% at age 12 years in 951 children who did not receive booster doses of HBV vaccine during follow-up. Among the 458 children with anti-HB_s levels lower than the protective level at age 7 years, only 1 of the 200 children in the group that received booster doses and 2 of the 258 children in the group that did not developed a new infection with anti-HB_c positivity during follow-up to age 14 years.[44]

Remaining Barriers to Eradication of HBV

Further investigation into the mechanisms of HBV vaccine failures or nonresponders is critical. Interventions to prevent intrauterine infection, the development of HBV vaccines against surface antigen gene mutants, and better vaccines for immunocompromised individuals will further reduce the incidence of new infections.

Those opposed to the HBV vaccines may be reduced in number by a better understanding of vaccine-related side effects. For instance, although there is little supporting evidence, an association between central nervous system demyelinating diseases and hepatitis B vaccine has been suggested.[45] Clarification of this and other poorly documented side effects of the vaccines may help to reduce anxiety about the risks of the vaccine and enhance an appreciation of HBV vaccine benefits. Finally, it is extremely important to find ways to reduce the cost of HBV vaccines and to increase funding for HBV vaccination of children living in hyperendemic areas under poor economic conditions

TREATMENT

The goal of antiviral therapy for HBV infection is to eradicate HBV and to prevent its related liver damage. However, current antiviral regimens are not completely effective in this regard. Inhibition of viral replication with prevention of liver damage and related consequences is also important and is more achievable with available antiviral agents (Table 51.1A-4).

TABLE 51.1A-3 EFFECT OF UNIVERSAL HEPATITIS B VACCINATION ON THE PREVENTION OF HEPATOCELLULAR CARCINOMA IN CHILDREN IN TAIWAN

YEAR OF DIAGNOSIS	BOYS	GIRLS	TOTAL INCIDENCE OF HCC*	MALE/FEMALE
1981–84†	1.08	0.24	0.67	4.5

Strategies for the Treatment of Chronic Viral Hepatitis

Interferon Therapy. Interferons are antiviral and immunomodulatory proteins.[46] They interact with cells by binding to specific receptors on the cell surface. Interferon-α is produced by leukocyte or lymphoblastoid cells when they are stimulated by virus-infected or tumor cells, bacteria, or viral envelopes. In virus-infected cells, interferons can produce antiviral proteins, inhibit synthesis of viral ribonucleic acid, and enhance the expression of human leukocyte antigen class I antigens, thus allowing recognition of the infected hepatocytes by cytotoxic T lymphocytes. Interferon therapy is employed worldwide and is the most frequently used therapeutic antiviral agent for hepatitis B and C. The disadvantages of this drug are the parenteral route of administration and mostly tolerable but frequent adverse reactions (Table 51.1A-5).

Overall, approximately 30 to 40% of adults with chronic hepatitis B achieve a sustained response to interferon-α at a usual dosage of 5 MU/d or 10 MU three times a week for 3 to 4 months. Evidence for the efficacy of interferon therapy in children with chronic HBV is limited by the small number of children enrolled in most reported studies. As shown in Table 51.1A-6, interferon therapy is not effective for hepatitis B e seroconversion in carrier children with normal liver enzymes. In those with elevated aminotransferases, the results of interferon treatment are similar to those in adults, with a rate of hepatitis B e seroconversion and normalization of aminotransferase levels 20 to 40% higher in the treatment group than in the control group.[47–54] A systematic review of the world literature has shown a significant benefit of interferon therapy for chronic HBV infection in children.[55]

Factors that are predictive for a positive response to interferon include high pretreatment levels of aminotransferase, low pretreatment HBV DNA levels, late acquisition of HBV infection, and hepatocellular inflammation.

The recommended dose of interferon for children is 0.1 MU/kg or 3 to 6 MU/m^2 three times a week for 4 to 6 months. Some studies in a small number of children, using higher doses, 6 to 10 MU/m^2, have shown a higher rate of sustained responses but also a higher rate of adverse effects. If severe reactions to interferon occur, the dose should be modified (50% reduction) or discontinued. Extending the duration of therapy for a total of 12 months may be beneficial for those who have a partial response to initial interferon therapy.

Pegylated interferon is a long-acting interferon successfully used in treating chronic hepatitis C[56] and has also been used in treating hepatitis B in adults.[57] The safety and efficacy have not been reported in children.

Nucleoside Analogs. Lamivudine is a 2′,3′-dideoxynucleoside that is phosphorylated by intracellular enzymes to form lamivudine triphosphate. Lamivudine triphosphate can inhibit DNA synthesis by terminating the nascent proviral DNA chain and interfere with the reverse transcriptase activity of HBV. After oral administration, lamivudine is well absorbed and has a mean absolute bioavailability of > 80% in adults and 68% in infants and children.[58] In clinical trials in adults, lamivudine rapidly reduced HBV DNA to undetectable levels in a daily dose of 100 mg or more.[59,60]

ALT = alanine aminotransferase; IFN = interferon; ULN = upper limit of normal.
*p = .026.

Lamivudine 0.7 to 8 mg/d was well tolerated in 53 European and Canadian children aged 2 to 17 years.[61] Around one-fifth of patients who received 1 month of lamivudine therapy experienced drug-related adverse events. The most common adverse events were ear, nose, and throat problems; gastrointestinal symptoms; general symptoms (malaise and fatigue); and lower respiratory symptoms (see Table 51.1A-5). No serious side effects or need for withdrawal occurred during therapy or follow-up.

Lamivudine was able to eliminate or reduce HBV DNA in pediatric patients after 1 month of therapy in a multicentered study in European and Canadian children.[61] A dramatic fall of HBV DNA of 99.9% and a reduction in HBV DNA of approximately 1,000-fold was noted. However, HBV DNA returned to the pretreatment levels in all patients after cessation of lamivudine. The HBeAg loss rate remained low after 3 months of follow-up. The efficacy of 52 weeks of lamivudine therapy was evaluated in 286 children in a multicentered placebo-controlled study. The complete virologic response (with HBeAg clearance and negative HBV DNA) at the end of treatment was achieved in 23% of the treatment group (191 children) and 13% of the placebo group (95 children). The anti-HB_e seroconversion rate was 22% versus 13% in the treatment group versus the control group. ALT normalization was noted in 55% of the treatment group and 12% of the placebo group. The HBsAg loss rate was minimal (2% in the treatment group and 0% in the placebo group).[62] Higher ALT levels and liver histologic inflammation scores and lower HBV DNA levels before treatment predict a better treatment response.

Lamivudine, at 100 mg/d, is the recommended dose for adults.[60] The recommended dose for children is 3 mg/kg/d up to a maximal dose of 100 mg/day.[61] There is no added benefit to dividing the total daily dose. The optimal duration of treatment requires further investigation. At this time, treatment for 1 year is recommended.

Children aged 2 to 17 years of age who are HBsAg seropositive for more than 6 months with elevated aminotransferase levels and HBV DNA in their serum for more than 3 months may be candidates for lamivudine therapy. This includes HBV carriers who are waiting for a liver transplant, children with repeated acute exacerbations of HBV infections, children with HBV infection < 2 years of age, and children with fibrosing cholestatic HBV hepatitis. Drug compliance should be monitored carefully, particularly in adolescents. Regular physical examinations are mandatory, along with monitoring of serum biochemical markers of inflammation and viral infection, including aminotransferases, coagulation profiles, complete blood cell count, amylase, lipase, urea nitrogen, and creatinine. Liver histology, quantified by the Knodell score, before and 1 year after starting therapy provides valuable information regarding viral clearance, necroinflammatory activity, and fibrosis. Lamivudine should be discontinued if any related adverse reactions develop. HBV DNA, HBeAg, and anti-HB_e should be monitored after discontinuing use of lamivudine because HBV replication frequently resumes.

Mutants of the HBV polymerase gene at the reverse transcriptase region may develop after use of lamivudine for more than 9 months.[63,64] The mutations most frequently found are methionine to valine or methionine to isoleucine mutations at the YMDD (tyrosine-methionine-aspartate-aspartate) motif. The second common site of mutagenesis is leucine to methionine at the polymerase gene nucleotide 528 for gentoype A or nucleotide 526 for genotypes B, C, and F (or reverse transcriptase nucleotide 180).[65] The clinical relevance of these mutations in children infected with HBV is poorly understood at this time. Among the 166 children treated with lamivudine in a muticentered study, 31 developed YMDD mutations at the end of 52 weeks of therapy. Those with YMDD mutants had a

higher (1.5 times) median level of ALT and HBV DNA (19 times) than those without this mutant.[62]

Lamivudine-associated HBV YMDD mutant strains have been reported to be less replicable than the wild-type virus. In fact, the long-term use of lamivudine after the emergence of the YMDD motif mutation may lead to acute exacerbation and subsequent HBV clearance.[66] However, there is a risk of liver failure during these acute exacerbations of infection. Careful monitoring of the quantity of HBV DNA and signs of clinical or biochemical deterioration of liver function is mandatory in children infected with mutant strains.

Adefovir dipivoxil, a nucleoside analog recently approved by the US Food and Drug Administration, is effective in inhibiting the replication of the YMDD motif mutants[67–69] and can be used in patients with acute exacerbation of inflammation during lamivudine therapy. It is an acyclic analog of deoxyadenosine monophosphate that can competitively inhibit deoxyadenosine triphosphate and the first-strand synthesis. It can inhibit > 95% of viral DNA and 30% of pregenomic ribonucleic acid, pre-S (gene of hepatitis B virus middle and large surface protein gene), core proteins, and covalently closed circular hepatitis B virus DNA. Adefovir is nephrotoxic. Other nucleoside analogs, including entecavir and emtricitabine, have good antiviral potential, but their therapeutic benefit in children remains unclear.

Gene Therapy and Immunotherapy

Gene therapy for HBV infection is still under investigation.[70] Antisense oligonucleotides can inhibit hepatitis viral gene expression and may provide a new therapeutic choice for patients with chronic HBV infections.[71] Thymosin α is an immune modifier that has been shown to trigger maturational events in lymphocytes, augment T-cell function, and promote reconstitution of immune defects. It has been reported to be effective in treating chronic HBV infections with clearance of HBeAg and normalization of aminotransferase levels in some[72] but not all studies. DNA vaccines are still in the experimental stage. Injection into mice of a plasmid expressing HBV DNA encoding HBV proteins, under the cytomegalovirus promoter, may induce both cellular and humoral immune responses against this viral antigen.[73,74]

Combination Therapies

Combination therapies are increasingly used for the management of persistent viral infections. The synergistic effect of ribavirin and interferon in treating chronic hepatitis C is one example of successful combination antiviral therapy.

The benefit of different combinations of doses and schedules for interferon plus lamivudine therapy has been controversial in adults.[75] Comparisons between interferon alone versus lamivudine plus interferon have been conducted in children (n = 15 to 47 in each group of treatment) with no statistically significant differences in the outcomes measured. These studies used interferon-α 5 to 10 MU/m^2 three times per week for 6 to 12 months plus lamivudine 4 mg/kg daily (maximun 100 mg daily) for 12 months. A complete virologic response rate of 37 to 47% at 6 months was seen after the end of treatment. It was similar to the 30 to 40% complete virologic response in children treated with interferon alone for 6 to 12 months.[76,77] The use of lamivudine alone for 2 months, then interferon-α 10 MU/m^2 plus lamivudine for 6 months, and then lamivudine alone again for additional 4 months versus interferon plus lamivudine simultaneously for 6 months and then lamivudine alone for another 6 months also showed no differences between the two treatment groups (47% versus 46% complete elimination of HBV).[78] Large-scale studies using other combination schedules or regimens are needed to clarify the efficacy of combination therapy.

FUTURE PROSPECTS

The World Health Organization (WHO) recommended in 1997 that universal hepatitis B immunization should be introduced in all countries. WHO also established the objective to reduce the incidence of new HBV carriers among children by 80% by year 2001 and eventually to eliminate the more than a million deaths that occur annually from HBV-associated cirrhosis and hepatocellular carcinoma.[79,80] Up to now, a total of approximately 140 countries have followed this recommendation. With the integration of the hepatitis B vaccination program into the Expanded Immunization Program in most countries in the world, chronic HBV infection will be further reduced in the twenty-first century. The major issues that remain for hepatitis B prevention include vaccine failure and noncompliance with vaccination programs. Further understanding of the immune defects and pathogenesis of chronic HBV infection will enhance the development of better therapeutic and preventive agents and vaccines focused on the T-cell epitopes of HBV that can be recognized by convalescent patients.

1B. Hepatitis C Virus

Regino P. González-Peralta, MD
Christopher D. Jolley, MD

Although non-A, non-B hepatitis was recognized some 30 years ago,[1,2] its major causative agent was identified only in 1989 and was named hepatitis C virus (HCV).[3,4] Since the discovery of HCV, significant advances have been made in our understanding of the molecular virology and pathobiology of this important viral pathogen. In adults, the epidemiology and natural history of HCV infection are well defined, and approved efficient treatment strategies are available. In contrast, we know much less about the evolution and treatment of HCV infection in children. This part of the chapter summarizes our current understanding of the epidemiology, natural history, and treatment of HCV infection in this young population.

THE VIRUS

HCV is an enveloped, single-stranded, positive-sense ribonucleic acid (RNA) virus that is the major causative agent of non-A, non-B hepatitis. Besides humans, chimpanzees are the only other animals permissive to HCV infection. Based on nucleotide sequence analysis and genetic organization of the viral genome, HCV is classified as an independent genus (*Hepacivirus*) within the Flavivirus family.[5] The HCV genome is approximately 10,000 kb long with one open reading frame that encodes for a polyprotein containing approximately 3,000 amino acids (Figure 51.1B-1).[6,7] The recent detection of a previously unrecognized viral peptide putatively within the core region suggests the presence of a second open reading frame.[8] This new finding, which challenges the prevalent contemporary assertion that the HCV genome consists of only one reading frame, awaits further confirmation. The large viral polyprotein undergoes proteolysis by viral and host-encoded proteases, which results in the formation of the various HCV proteins. The proteolytic processing occurs as the nascent viral polyprotein is newly synthesized (cotranslation) and after it is completely formed (post-translation). The HCV genome is organized so that its 5′ end encodes for the structural proteins. including the core (or capsid) and envelope proteins (E1 and E2), whereas the nonstructural (NS) or functional viral proteins (NS2-NS5) are encoded by the larger subsequent 3′ segment. There are two well-conserved noncoding areas (untranslated regions [UTRs]) flanking the HCV open reading frame that are critically important for the initiation of efficient viral protein synthesis (5′-UTR) and RNA replication (3′-UTR).

The core protein is a highly basic, hydrophobic, and relatively conserved protein that is intimately associated with the viral RNA and forms its "inner shell" or nucleocapsid. In addition to being the integral structural component of HCV, the core protein interacts with several cellular proteins, including apolipoprotein A-2, 60S ribosomal Sub U, hetero-

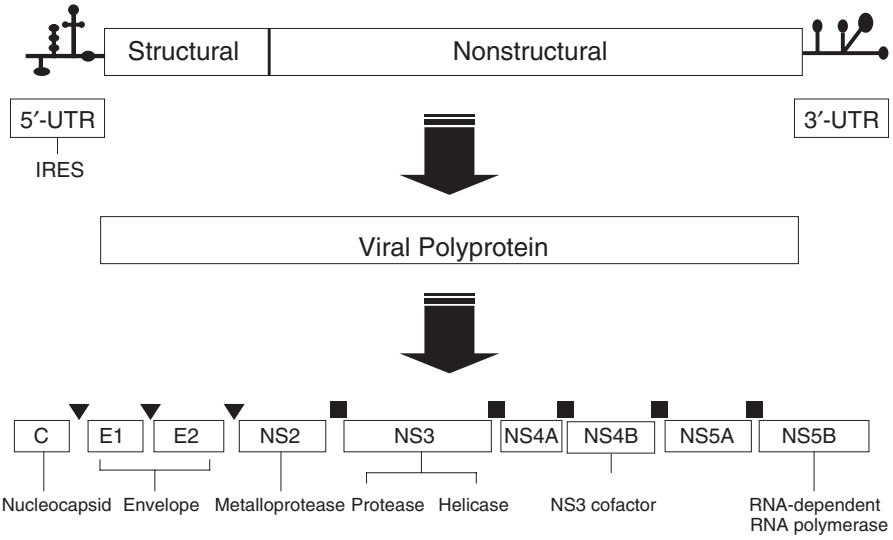

FIGURE 51.1B-1 Processing of hepatitis C virus polypeptide by host (▼) and viral (■) encoded proteases into the various viral proteins. IRES = internal ribosomal entry site; UTR = untranslated region.

geneous nuclear ribonuclear protein, tumor necrosis factor-α receptor, and lymphotoxin-β receptor. Although the precise pathogenetic mechanisms are largely unknown, these virus–host interactions suggest that the HCV core protein may play an important role in directly mediating liver cell damage. Indeed, the HCV core protein has been implicated in the development of hepatic steatosis and liver cancer in a transgenic mouse model.[9] The HCV E1 and E2 proteins are glycoproteins embedded within the viral lipid envelope and are integral constituents of the HCV "outer shell." In contrast to the core protein, the envelope proteins are very heterogeneous and display extensive nucleotide and antigenic variability. This antigenic diversity, greatest within a small area of the 5′ end of the E2 gene (the hypervariable region), is believed to be an important mechanism by which HCV evades host immunologic surveillance, facilitating the establishment of chronic infection. The NS2 segment encodes for a metalloproteinase whose function is limited to specifically cleave the NS2-NS3 site. The 5′ and 3′ ends of the HCV NS3 encode for proteins with serine protease and helicase activities, respectively. The HCV serine protease is the major viral peptidase because it is required for the precise processing of a large segment of the viral polyprotein, including all cleavage sites within the NS3-NS5 segment. The NS3 serine protease interacts with an NS4-derived peptide (NS4 cofactor), which, although not essentially required, augments the proteolytic activity of the viral protease. The HCV helicase encoded by the 3′ end of the NS3 segment is an enzyme that unwinds RNA-RNA duplexes formed during viral replication. Proteolytic hydrolysis of the NS4-encoded protein by viral serine protease yields two peptides, denoted NS4A and NS4B, respectively. In addition to enhancing the activity of the HCV NS3 serine protease activity, as mentioned above, the NS4A product appears to facilitate phosphorylation of the NS5A product. In a similar fashion, NS3-dependent protease cleavage of the NS5 gene results in the elaboration of two viral proteins, NS5A and NS5B. Increased nucleotide heterogeneity within the NS5A product is associated with lower serum HCV RNA levels and more favorable responses to interferon-based therapy,[10,11] suggesting that this protein may be involved in the transcriptional regulation of viral RNA. However, others have not found a link between NS5A mutations and a therapeutic response to antiviral agents[12,13]; the precise function of this gene product remains to be elucidated. The NS5B is an RNA-dependent RNA polymerase, the enzyme responsible for viral replication. The 5′-UTR is an internal ribosomal entry site (IRES) component through which HCV RNA binds to host cellular ribosomes, a necessary step for the initiation of viral protein synthesis. Finally, the 3′-UTR contains a highly conserved region of nucleotide known as the "X region," whose predicted stem-loop structure plays an important role in initiating viral RNA and in enhancing IRES-driven protein synthesis.

Viral Heterogeneity

The NS5B-encoded HCV RNA-dependent RNA polymerase lacks proofreading ability. As a result, like many other RNA viruses, HCV is genetically heterogeneous. Based on phylogenetic analysis of HCV sequences, six major HCV genotypes are currently recognized, and there are multiple subtypes within each viral genotype.[5] Although HCV genotypes 1 and 2 are the most prevalent worldwide, there are unique geographic variations in the global distribution of viral genotypes. Accordingly, HCV genotype 3 is most common in Australia and the Indian subcontinent, and genotypes 4, 5, and 6 are almost exclusively seen in individuals from sub-Saharan Africa, South Africa, and Southeast Asia, respectively. In the United States, HCV genotypes 1, 2, and 3 account for approximately 70%, 15%, and 10% of adult infections, respectively.[14] More recently, some have proposed to divide HCV into six phylogenetically distinct groups called clades. In this new classification scheme, clades 1, 2, 4, and 5 correspond to genotypes 1, 2, 4, and 5; clade 3 comprises genotypes 3 and 10; and clade 6 includes genotypes 6, 7, 8, 9, and 11.[5] The relationship between viral genotypic diversity and clinical disease outcome is a controversial issue because some, but not all, studies correlate HCV genotype 1 infection with more aggressive liver disease and a higher risk for the development of hepatocellular carcinoma.[15] However, HCV genotype 1 is consistently associated with higher serum HCV RNA levels and a significantly poorer response to currently available antiviral regimens than HCV genotype 2 or 3. In fact, based on the results of recent clinical trials in adults, some authorities advocate a shorter duration of therapy for individuals with HCV genotype 2 or 3 than for those infected with HCV genotype 1.[16] Accordingly, determining the HCV genotype has become an essential component of the medical evaluation of infected adults, particularly those who are contemplating initiating antiviral therapy. Much less is known about the geographic distribution of HCV genotypes in children or its impact on the clinical evolution of liver disease in this population. Nevertheless, the viral genotypic distribution in children generally parallels that reported regionally in adults.[17–23] Furthermore, as in adults, HCV genotype 1 correlates with higher serum viral levels and a less favorable response to antiviral treatment.

The degree of genetic heterogeneity is such that even within persons infected with a unique viral genotype, HCV exists as a highly heterogeneous population of different but closely related genomes, which are called quasispecies.[24] HCV quasispecies play an important role in the pathobiology of HCV infection in adults as increased heterogeneity correlates with less favorable response rates to interferon given alone or in combination with ribavirin.[25–27] Assessment of HCV quasispecies by molecular evolutionary analysis has been instrumental in selected situations, such as in verifying the transmission of virus by accidental needle-stick exposures[28,29] or by infected mothers to their offspring (vertical transmission).[30,31] However, little is known about the clinical significance of HCV quasispecies in childhood infection; therefore, its assessment is not currently a component of the routine medical management of patients with HCV infection.

Pathogenesis of Liver Disease

In general, viral infections lead to cellular damage in vivo by either direct cytopathicity or immune-mediated injury, targeted against either viral or autoantigens. HCV may be

directly cytopathic in situations that allow unusually high levels of viral replication and antigen expression, such as in immunosuppressed patients.[32,33] However, a significant amount of accumulating experimental evidence suggests that immune-mediated mechanisms play a more critical role in the controlling and mediating liver cell damage in chronic HCV infection in adults.[34,35] In contrast, our understanding of the pathogenesis of childhood HCV infection is very limited.[36] A Spanish study compared clinical, virologic, and immunohistochemical parameters between 12 children and 24 adults with chronic hepatitis C.[23] Although the HCV genotype distribution and estimated duration of infection were similar between these groups, children had statistically lower serum HCV RNA levels and more benign histologic disease than adults. More importantly, expression of all immunohistochemical markers studied, including CD2+, CD4+ (helper), and activated CD8+ (cytotoxic) lymphocytes; β_2-microglobulin; intercellular adhesion molecule 1; vascular cell adhesion molecule 1; platelet–endothelial cell adhesion molecule 1; and endoglin, were significantly lower in children than in adults. Although limited by the small number of children and adults analyzed, these data suggest that immunologic mechanisms are important in mediating liver cell damage in chronically infected children and that young patients may be more immunologically tolerant to HCV than similarly infected adults.

EPIDEMIOLOGY

The worldwide prevalence of HCV infection is approximately 3%, which represents an estimated 170 million infected persons.[37] Wasley and Alter described several patterns of geographic and temporal variation in the global prevalence of HCV.[37] In the pattern seen in the United States and Australia, individuals younger than 20 years have the lowest prevalence rates, whereas those between the ages of 30 and 49 years have the highest, suggesting that HCV infection is primarily acquired in early adulthood.

Variations in global prevalence rates are observed in children as well and may reflect differences in socioeconomic status. Studies of general pediatric populations have yielded seroprevalence rates as low as 0% (Egypt, Japan, United States) and as high as 14.5% (Cameroon).[38–40] In the United States, the estimated seroprevalence is 0.2% for those children less than 12 years of age and 0.4% among those 12 to 19 years of age.[41] Based on current population statistics, this prevalence rate indicates that there are about 150,000 to 200,000 children who are infected with HCV in the United States.

The prevalence of HCV in the general population of the United States is 1.8% based on serologic analysis from approximately 21,000 subjects in the Third National Health and Nutrition Examination Survey (NHANES III) data, collected between 1988 and 1994.[42] This prevalence rate corresponds to approximately 3.9 million persons nationwide being positive for anti-HCV. It should be noted that children younger than 6 years of age were not represented in this large cohort. The prevalence of viremia as measured by detectable serum HCV RNA among anti-HCV–positive subjects was 73.9%; therefore, an estimated 2.7 million people nationwide are chronically infected with HCV. The factors most strongly associated with HCV infection in persons 17 to 59 years old were illicit drug abuse and practicing high-risk sexual behavior. Age at first sexual encounter was also an important epidemiologic factor because persons who had a first sexual intercourse before the age of 18 years had significantly higher rates of HCV infection than those whose initial sex activity occurred at a later age. Subjects reporting greater use of marijuana had a higher prevalence of HCV infection than those who did not. Because there is no apparent reason to explain the association between increased transmission of HCV and marijuana use, it is presumed that larger amounts of marijuana use serve as a surrogate for other high-risk behaviors such as injection drug abuse or high-risk sexual practices.

Although the seroprevalence among incarcerated adults is as high as 82%,[43] this population was not included in the NHANES III analysis. The prevalence of anti-HCV positivity in incarcerated juveniles in the United States (2%) is significantly higher than that observed in the general adolescent population.[44] High-risk behaviors, which correlated with HCV infection in this confined population, included being sexually active and a history of body piercing. Interestingly, only 6% of the juveniles studied acknowledged injection drug abuse, a well-defined parenteral risk associated with the acquisition of HCV. However, this information was collected by voluntary self-reporting in this study and therefore likely underestimates the prevalence of this illicit practice. Of note, the HCV seroprevalence rate of 2% among incarcerated juveniles in this report is lower than that observed in other studies of homeless or confined young persons, which included a higher proportion of injection drug abusers.[45–47]

Saiman and colleagues retrospectively studied a cohort of 504 internationally adopted children from China, Russia, Southeast Asia, Eastern Europe, and Latin America.[48] Only four children, or 0.8% of the 496 tested, were anti-HCV positive, and none were positive for HCV RNA, compared with 2.8% who tested positive for hepatitis B surface antigen. A study of 169 Romanian orphans found that 36% were positive for hepatitis B surface antigen, whereas only 1 child was anti-HCV positive.[49] Therefore, the seroprevalence of HCV in international adoptees appears to be quite low.

Children who received transfusions of potentially contaminated blood products prior to the institution of routine screening have seroprevalence rates that vary depending on their degree of exposure. Seroprevalence rates of 50 to 95% have been reported in those receiving multiple transfusions or transfusions from pooled plasma, such as factor concentrates.[50–52] Children with fewer but repeated exposures, including those undergoing hemodialysis and cancer survivors, have intermediate seroprevalence rates of 18 to 52%.[53–55]

Since the initiation of routine blood screening in 1992, perinatal transmission has become the predominant source of new HCV infections (see "Natural History"); the seroprevalence of HCV in pregnant women is 1 to 2%.[56,57]

Household nonsexual contacts of infected individuals have a seroprevalence rate of 7%, although this appears to increase with longer duration of exposure to the index patient.[58]

CLINICAL ASPECTS

The mean incubation period of post-transfusion acute HCV infection is 7 to 8 weeks, with a range of 2 to 26 weeks.[59] The majority of acute HCV infections appear within 5 to 12 weeks following transfusion. Acute HCV is usually anicteric or subclinical, and only one-third of patients will develop jaundice or symptoms.[60] Fulminant hepatic failure owing to HCV is exceedingly rare. In adults, 85% of patients exposed to HCV will develop chronic infection, of whom approximately 10 to 20% develop cirrhosis and 1% develops liver cancer. Although the precise mechanisms are unknown, it is now clear that concurrent alcohol ingestion and immunodeficiency accelerate the rate of HCV-related liver disease and thus have a negative impact on its outcome.

In children, the course of HCV infection is generally benign. Most children with acute hepatitis C are asymptomatic and go unnoticed. When symptoms are present, they are often nonspecific (malaise, anorexia) or mild. Jaundice may be evident in only 25% of patients.[41] Children with chronic HCV infection may also remain asymptomatic. Progression to decompensated liver disease (variceal bleeding, ascites) in children can occur, but this is the exception. As in adults, children with immunodeficiency may progress to serious liver disease more rapidly.[61,62]

Biochemical markers such as serum alanine aminotransferase (ALT) typically fluctuate in HCV patients. Normal or only minimally increased ALT levels are usually reported with chronic HCV infection, and serum ALT levels can remain elevated despite anti-HCV seronegativity.[63,64] The histopathologic features of chronic hepatitis C in children are similar to those found in adults.[65–67] Histologic characteristics include portal lymphoid aggregates, bile duct injury, and prominent steatosis. Necroinflammatory activity is commonly mild. Varying degrees of fibrosis and, less commonly, cirrhosis have also been described.

NATURAL HISTORY

The clinical evolution of HCV infection in adults is well defined, but much less is known about the natural history of the disease in children. As in adults, the course of infection in children with parenteral or perinatally acquired HCV may be influenced by host factors such as immunologic status, underlying disease, or the deleterious effects of transfusion-related iron overload on the liver, which further hinders the ability to precisely determine the evolution of this viral infection.

Despite these potential shortcomings, several studies have delineated the clinical impact and evolution of childhood parenteral and perinatal HCV infection (Table 51.1B-1).[68–74] In an early analysis, Chang and colleagues prospectively studied 88 children at risk for HCV infection because of either periodic blood transfusion for hemolytic anemia (33 children), transfusion for cardiac surgery (38 children), or maternal chronic HCV infection (17 infants).[63] Of these, 10 children contracted HCV infection, including 5 with hemolytic anemia, 2 after cardiac surgery, and 3 with HCV-infected mothers. Five children, including the three perinatally infected infants, had detectable HCV RNA and anti-HCV antibodies in serum without symptoms of acute hepatitis. Two of the five patients who developed acute hepatitis exhibited jaundice and malaise. Sixty percent of the 10 children developed chronic infection, and half of these maintained normal ALT during the 3-year follow-up period. As suggested by the authors, these data demonstrate that host factors such as iron overload may play a significant role in the evolution of childhood hepatitis C. This report also shows that HCV seroconversion is a clinically silent process in many exposed children.

In one of the largest natural history reports published to date, Jara and colleagues retrospectively investigated 224 children who were HCV RNA positive.[75] None of the children studied had underlying disease such as malignancy or hemophilia, and the diagnosis of chronic hepatitis was defined by persistently abnormal ALT for more that 6 months or by histologic assessment of liver tissue. Of the 224 children, 45% had an HCV-infected mother and 39% had received transfusion of blood products. At study entry,

‡Complicated by congestive heart disease or hepatitis B virus infection in all cases.

all of the perinatally infected children were asymptomatic, and none of the children exhibited jaundice. Hepatomegaly was a presenting feature in only 15%. The course of infection was studied in 200 of the original 224 children for a period of 1 to 17.5 years (mean 6.2 years). During this time, serum ALT levels normalized and HCV RNA became undetectable in 12 (6%) patients, including 17% of those with perinatal infection. Most children with chronic hepatitis had mild histologic disease, and only one patient, a transfusion recipient, developed cirrhosis and subsequent liver failure in this study. However, older adolescents had greater degrees of hepatic fibrosis than younger children, suggesting that gradual progression of histologic liver disease occurs in young patients.

In general, then, most children exposed to HCV become chronically infected based on persistently detectable serum anti-HCV antibodies and HCV RNA. Acute and chronic hepatitis C in children is usually subclinical, characterized by fluctuating serum ALT and mild histologic abnormalities. However, significant liver disease, including cirrhosis, can occur.

Parenteral Transmission

Liver disease in children with concurrent systemic illness may be related to factors other than HCV infection, and these patients are discussed separately.[76]

Hemophilia. HCV infection is noted in 50 to 98% of children with hemophilia treated with factor concentrates prepared from suboptimally decontaminated pooled plasma.[77–81] The high prevalence rate is particularly important because HCV infection strongly correlates with liver dysfunction in this population.[77,79] In a study from Japan, anti-HCV antibodies were found in 32 of 45 children (80%) with hemophilia who were followed for 1 to 4 years. Twenty-seven of these 32 HCV-seropositive patients were assayed for HCV RNA by polymerase chain reaction. Liver disease was observed in 18 of 22 patients (82%) with detectable HCV RNA but in none of 5 children without this viral marker.[78] In another investigation, HCV infection was demonstrated in nearly 40% of patients with hemophilia with abnormal liver tests, whereas serologic viral markers were found in only 17% of those with normal liver biochemistry.[80] Percutaneous liver biopsies are not usually done in children with hemophilia owing to the potential risk for bleeding. As a result, little is known about the histologic progression of HCV in this group. However, a recent report demonstrated that this procedure can be safely accomplished with appropriate factor replacement therapy.[81] More importantly, mild histologic abnormalities were noted in most of the children with hemophilia analyzed in this report. These data suggest that HCV is associated with liver disease and that clinical and histologic abnormalities are mild in most infected children with hemophilia. In contrast, HCV infection is associated with the development of liver cancer in adults with hemophilia,[82,83] suggesting that earlier viral eradication during childhood may result in reduced HCV-related morbidity later in life.

Thalassemia. Serologic markers of HCV infection are noted in up to 80% of multitransfused children with thalassemia.[84–89] In one prospective 8-year study, 75 of 135 newly diagnosed patients acquired HCV infection, which became chronic in nearly 80% of them, based on persistently elevated transaminase levels. In another prospective study, HCV-infected children were found to have significantly higher levels of transaminases than those without detectable markers of viral infection.[88] The severity of liver disease was not related to HCV genotypes or to HCV RNA levels. Furthermore, hepatic fibrosis was more commonly noted in patients with HCV infection than in uninfected children. To better delineate the rate of liver fibrosis progression, 211 children who had received bone marrow replacement for the treatment of thalassemia underwent serial histologic assessment of the liver by percutaneous biopsy.[90] Of these, 46 (22%) had evidence of fibrosis progression during a median follow-up of 64 months. Using multivariate analysis, hepatic iron overload and HCV infection were noted to be independent risk factors for the progression of liver fibrosis, and their concomitant presence resulted in a striking increase in this risk.

Cancer Survivors. HCV infection has been demonstrated in up to 50% of pediatric cancer survivors and is an important cause of liver disease in this population.[91–94] As a result of an impaired humoral immune response, anti-HCV antibodies are often not detected, despite the presence of HCV RNA in these patients.[91] Thus, the diagnosis of HCV in this population should rely on the detection of HCV RNA by nucleic amplification tests such as polymerase chain reaction or transcription-mediated assays. The clinical impact of HCV infection has been difficult to determine in this group of patients, in whom the pathogenesis of liver disease is likely related to multiple factors. Although elevations of aminotransferase levels are commonly noted during the course of cancer treatment, the biochemical profile and clinical outcomes are similar for children with and without HCV infection.[94,95] These initial retrospective observations, which are limited by the small number of patients included in these reports and relatively brief observation periods, have been verified in large prospective studies. In an Italian study of 114 leukemia survivors, 56 had detectable HCV RNA in serum at the end of chemotherapy, of which 40 had persistent viremia after a mean follow-up of 17 years.[94] At the completion of chemotherapy, a significantly higher proportion of HCV RNA–positive children had elevated serum aminotransferase levels than those without detectable virus. Most patients who underwent liver biopsy at this point had mild histologic abnormalities and the severity of liver disease was similar between HCV RNA–positive and –negative children. During follow-up, all HCV-infected children remained clinically stable, and none developed evidence of decompensated liver disease. Liver tests remained normal in approximately 71% of patients with detectable HCV RNA in serum, whereas 25% and 4% had fluctuating and persistently abnormal levels of serum aminotransferase, respectively. In a preliminary report from a similar ongoing

trial, 77 of 1,175 cancer survivors tested had detectable HCV antibodies.[96] Persistent viral infection, defined by the presence of circulating HCV RNA, was verified in 65 of those with serologic evidence of HCV, most of whom were clinically asymptomatic and had normal liver tests. Although histologic abnormalities were common among the 35 patients who underwent liver biopsy in this report, the degree of disease was mild in most patients at a mean of 6 years after diagnosis of cancer. Of note, three patients had histologic evidence of cirrhosis, and two patients died of complications of HCV-related hepatocellular carcinoma. The two reported cases of hepatocellular carcinoma were leukemia survivors who were transfused prior to routine blood screening.[97] Both patients presented 25 years after their last blood transfusion and were approximately 28 to 30 years old on diagnosis of liver cancer. One of the patients with hepatocellular carcinoma also had chronic HBV infection, another well-known risk factor for this disease. We have also cared for one cancer-surviving adolescent with HCV-related cirrhosis who died of complications of liver cancer, which was discovered while she was being evaluated for liver transplant (R. González-Peralta, personal observation, 1994).

Hemodialysis and Renal Disease. Similar to prevalence rates in adults, anti-HCV antibodies have been detected in 20 to 45% of pediatric patients undergoing hemodialysis but in only 0 to 4% of those on peritoneal dialysis.[98–102] The lower prevalence rate in patients on peritoneal dialysis is likely the result of less exposure to blood products in this group. Most HCV antibody–reactive children develop chronic infection based on persistent detection of viral RNA in serum. More importantly, the majority of children on hemodialysis have persistently normal aminotransferase levels. However, systematic assessment of hepatic histology, a more reliable indicator of liver disease than aminotransferase levels in chronic HCV infection, has not been reported in these children.

Perinatal Transmission

Since the implementation of routine and effective screening strategies, perinatal or vertical transmission has become the primary cause of new HCV infections in children.[103] Perinatal transmission of HCV, suspected even before the virus was discovered,[104,105] has been subsequently confirmed in numerous studies by the detection of HCV RNA in infants born to infected mothers.[106–115] The average rate of vertical transmission is approximately 5 to 6%, which is low compared with those observed for hepatitis B virus and human immunodeficiency virus (HIV). The precise timing and process by which the virus is transmitted from mother to infant are unknown, but high-titer maternal viremia consistently correlates with higher transmission rates and thus appears to facilitate the process. Although the rates of vertical transmission are generally higher in infants born to mothers coinfected with HIV (0–36%; mean 16%),[116–120] other researchers have not documented this correlation.[106,114] Similarly, there are conflicting reports on the influence of mode of delivery on the risk of perinatal transmission of HCV, with increased rates after vaginal delivery noted in some[107,108,115] but not all[112,114] studies. In one report, exposure to contaminated maternal blood and placement of fetal scalp probes during delivery were associated with increased risk for perinatal HCV infection.[121] Interestingly, a recent report noted that human leukocyte antigen DR13–positive infants born to mothers with HCV were less likely to become infected than those who did not express this marker, implying that immunologic mechanisms may play an important role in the transmission of HCV from mother to infant.[122] Of note, there appears to be no increased risk of HCV transmission by breast milk because the rate of viral infection transmission is similar between breast- and formula-fed infants.[110–112,114,115]

Liver Transplant

HCV-related chronic liver disease is a leading indication for liver transplant in adults.[123] However, little is known about the risks, significance, and evolution of HCV infection in children undergoing liver transplant. In a cross-sectional study, the overall prevalence of HCV was found to be 6.5% among 65 children who underwent liver transplant by detection of HCV RNA.[124] All HCV-positive children had undergone liver replacement before the initiation of routine screening for HCV in blood donors. In this cohort, serum transaminase levels were significantly higher in young patients with HCV infection than they were in uninfected children. Recurrent HCV infection is nearly universal after liver transplant, but infection arising de novo is now rare because of improved donor screening.[125] The course of HCV-related liver disease appears to be particularly aggressive in children with de novo infection following liver transplant.[126] In this series, viral infection was verified in 14 of 117 patients who underwent liver replacement before the availability of reliable screening tests for HCV. Nearly all of the children with HCV infection had evidence of histologic progression, varying from nonspecific inflammation to cirrhosis. The overall mortality rate in this group of patients was high (23%), despite intense therapeutic interventions including antiviral treatment and, in a few cases, retransplant.

DIAGNOSIS

The diagnosis of HCV infection is based on detection of antibodies directed against recombinant HCV antigens by enzyme immunoassay (EIA) or recombinant immunoblot assay (RIBA) or by detection of HCV RNA using nucleic acid tests (NATs).

Serologic Tests

Initial, first-generation EIAs were licensed by the US Food and Drug Administration (FDA) in 1990 and detected immunoreactivity against a single viral polypeptide (Figure 51.1B-2).[127] Although the assay provided the first reliable means to easily detect HCV infection, it was limited by occasional false-negative[128] and frequent false-positive results, particularly in patients with elevated globulin levels such as those with autoimmune hepatitis.[129,130] Subsequent

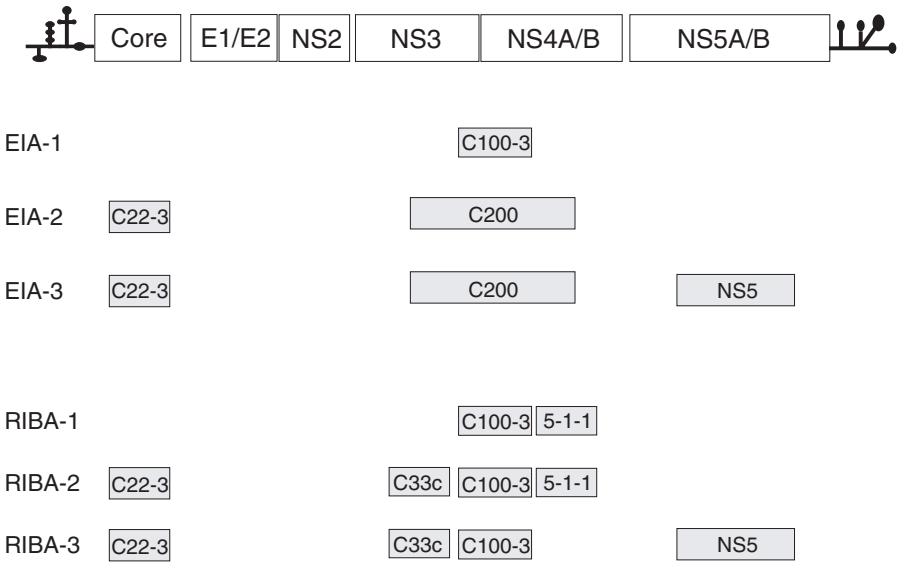

FIGURE 51.1B-2 Hepatitis C virus antigens used in different enzyme immunoassay (EIA) tests. RIBA = recombinant immunoblot assay.

incorporation of additional HCV antigens in second-generation EIAs significantly enhanced the accuracy of the assays (Table 51.1B-2).[131,132] As a result, these more reliable tests were approved by the FDA in 1992 and quickly replaced earlier test versions for the routine detection of anti-HCV antibodies in clinical and laboratory practice. In 1997, the FDA approved a third-generation EIA containing an additional NS5 antigen and reconfigured HCV core and NS3 antigens.[133] However, these modifications did not significantly improve sensitivity and specificity over earlier versions of EIA, and both second- and third-generation assays are currently used. In general, EIAs are easy to perform, yield reproducible results, and are relatively inexpensive, which makes them excellent tools in the initial diagnostic evaluation of and screening for HCV infection. Therefore, the detection of anti-HCV antibodies by these methods in persons with evidence of liver disease and a parenteral risk factor for the virus is probably sufficient to establish the diagnosis of active viral infection. However, the Centers for Disease Control and Prevention advises that anti-HCV EIA–reactive samples be verified by supplemental testing to more precisely identify those harboring HCV.[134]

Like the Western blot test for the detection of HIV antibodies, RIBA detects HCV immunoglobulin (Ig)G antibodies against synthetic HCV recombinant antigens and synthetic peptides immobilized on a solid matrix (nitrocellulose strip) (see Figure 51.1B-2). As in the case of EIAs, more reliable second- and third-generation RIBAs have replaced earlier forms of the test.[135] RIBAs are less sensitive but more specific than EIAs in detecting anti-HCV antibodies. Therefore, RIBAs are not recommended for initial HCV screening and are particularly suited to confirm viral infection.[134]

In addition to IgG anti-HCV antibodies, IgM anti-HCV antibodies are also detected during viral infection. Although the presence of IgM antibodies by EIA correlates well with active viral infection,[136] these are detected in a relatively small proportion of HCV-infected persons. As a result, tests that rely on the detection of IgM anti-HCV antibodies offer little advantage to currently available assays and are not currently used for the diagnosis or clinical management of HCV.

Nucleic Acid Tests

NATs are assays that directly detect circulating virus. There are two NATs currently used for the detection of HCV that rely on different amplification schemes, namely target and signal amplification. In the target amplification process, extracted HCV RNA is transcribed to deoxyribonucleic acid (DNA), which is then directly amplified (polymerase chain reaction) or is converted to RNA during amplifica-

TABLE 51.1B-2 SENSITIVITY AND PREDICTED VALUE OF SEROLOGIC TESTS FOR HCV INFECTION

ASSAY	SENSITIVITY (%)	POSITIVE PREDICTIVE VALUE (%)		TIME TO POSITIVE AFTER INFECTION (WK)
		LOW-PREVALENCE GROUPS	HIGH-PREVALENCE GROUPS	
EIA-1	70–80	30–50	70–85	16
EIA-2	92–95	50–60	88–95	10
EIA-3	97	25	98	7–8

EIA = enzyme immunoassay; HCV = hepatitis C virus.

tion (transcription-mediated assay). Both quantitative and qualitative (generally more sensitive) versions of target amplification tests are available. By contrast, for signal amplification (branched DNA assay, Bayer Diagnostics, Tarrytown, NJ), extracted HCV RNA is captured by specific oligonucleotides fixed on a solid matrix (Microwell). After incubation with amplifying enzyme–labeled probes and specific substrate, viral levels are determined by comparing the chemiluminescence of test samples to those of controls with known HCV RNA concentrations.

Technical advancements in recent years, in particular the development of automated equipment capable of rapidly and accurately analyzing a large number of samples in a standardized format, have led to widespread use of NATs for the routine laboratory evaluation of HCV in clinical practice. Equally important, the results obtained by different commercial NATs are now normalized against a well-characterized HCV RNA standard developed by the World Health Organization.[137,138] Because these assays were initially developed using different HCV standards, conversion factors are necessary to compare the concentration of HCV RNA copies obtained by the various methods (Table 51.1B-3). One of the major advantages of NATs is their ability to provide direct assessment for the presence of circulating virus, which is only indirectly inferred with serologic assays. Therefore, positive HCV NAT results more precisely reflect active viremia than do antibody-based tests. In addition, exceedingly low levels of circulating virus are detected with currently available NATs, with a detection limit in the range of 30 to 50 IU/mL (see Table 51.1B-3).[139] As a result, NATs markedly reduce the time during which HCV infection can be detected.[140] The ability to recognize HCV infection at the earliest possible phase is particularly important in the clinical practice of transfusion medicine, where the use of NATs has led to reductions in the incidence of post-transfusion hepatitis.[141] Like RIBAs, NATs are also used to confirm HCV infection in anti-HCV EIA–reactive individuals in low-prevalence groups. To minimize the possibility of HCV RNA degradation and thereby avert false-negative results, only serum separated within 4 to 8 hours of venesection and those samples that have not undergone repeated cycles of freeze-thaw should be used for NAT.[134,142]

Nuclear amplification tests are particularly useful in certain clinical scenarios. First, because NATs identify the presence of HCV very early in the course of infection, they can be used to diagnose HCV even before the anti-HCV antibodies have appeared.[139] Therefore, NATs are recommended in HCV EIA–negative patients in whom clinical suspicion for HCV exists. Second, NATs are necessary to detect HCV in infants born to infected mothers, in whom HCV antibodies may be of maternal origin and in immunocompromised patients whose ability to produce HCV antibodies may be impaired. Finally, by identifying persons with active viremia, NATs are critically important to select appropriate candidates for, and monitor the response to, antiviral treatment.

MANAGEMENT

Screening for HCV Infection

HCV testing should be considered for children with risk factors for HCV infection, including recipients of blood product transfusions and organ transplants before the implementation of effective routine donor screening strategies (1992) or of clotting factor concentrates before the widespread use of reliable sterilizing techniques (1987), infants born to HCV-infected mothers, and those with a history of injection drug use. Routine screening of internationally adopted children for HCV is generally not recommended unless the biologic mother has a known high-risk factor, such as injection drug use.[143]

General Care Guidelines

Periodic examination of children with chronic HCV infection is recommended, although there is a lack of consensus about which tests to monitor and how often to check them.[143] In our center, infants, children, and adolescents who are newly diagnosed with HCV undergo thorough medical evaluation to determine the risk factor(s) for infection and detect the presence of liver disease or associated sequelae. This is accomplished by a detailed history and physical examination and comprehensive laboratory evaluation, including complete blood count, liver tests, and coagulation studies. In our practice, any abnormal result promptly triggers further serologic evaluation aimed at excluding other potential concomitant causes of liver

disease, including other viral hepatitides, autoimmune hepatitis, α_1-antitrypsin deficiency, Wilson disease, and hemochromatosis, as clinically appropriate. Although an arguable practice, histologic assessment of the liver by percutaneous tissue sampling may be valuable in excluding comorbid diseases and determining the severity of liver damage, particularly in those in whom antiviral treatment is being entertained.

Because patients and their families are frequently ill-informed about HCV at the time of diagnosis, an equally critical component of the management of children with HCV is to provide basic concepts about the virus, including ways to prevent its spread and the implications of infection as they specifically relate to potential clinical outcomes and antiviral treatment. Adolescents, in particular, need to clearly understand the negative impact of alcohol on the course of HCV infection (accelerates progression)[144] and should be counseled to abstain from its consumption. The importance of avoiding high-risk behavior such as sharing of intravenous needles needs to be openly discussed and appropriate psychosocial assistance offered to those actively engaged in such practices. The American Academy of Pediatrics also discourages sharing of personal items such as toothbrushes or razors, which may be contaminated. Exclusion of HCV-infected children from child care centers is not justified.[143] Finally, successful completion of hepatitis B virus vaccination should be objectively ascertained and hepatitis A virus immunization should be offered as necessary.

Antiviral Therapy

In an ideal world, the selection of individuals for antiviral therapy would strictly depend on a well-defined propensity to develop severe, chronic liver disease. In such an ideal approach, patients whose liver disease would be more likely to progress would be treated, whereas those expected to have a benign course would be spared treatment and would thereby avert potential treatment-related adverse effects. Unfortunately, the natural history of hepatitis C is incompletely understood, especially in children in whom precise rates of spontaneous viral remission are not reliably known.[103] Accordingly, determining if and when to treat a child or adolescent for chronic hepatitis C is, at the moment, a challenging and controversial task. Nevertheless, compelling reasons exist to consider treating this unique young population with chronic hepatitis C. First, a significant proportion of children exposed to HCV, particularly infants born to infected mothers, develop chronic infection (see Table 51.1B-1). Second, although chronic hepatitis C is usually a mild disease in children with few, if any, symptoms, significant liver damage, including severe hepatitis, cirrhosis, and liver cancer, can occur, as already noted. Finally, factors associated with a favorable response to antiviral therapy in adults, such as short duration of infection, young age, mild histologic inflammation, and absence of cirrhosis, are commonly noted in children with HCV infection. On a theoretical basis, then, a greater global reduction in HCV-related morbidity and mortality may be attainable by treating children (in whom HCV may be easier to eradicate) than adults.

Interferons are a group of naturally occurring agents with antiviral, antineoplastic, and immunomodulatory properties. Multiple large prospective randomized trials confirm that recombinant interferon therapy results in normalization of aminotransferase levels and reductions in serum HCV RNA below detectable levels in approximately 40 to 50% of adults by the end of treatment. Unfortunately, most of these patients relapse, as manifested by elevations of serum aminotransferases and reappearance of serum HCV RNA within 6 months after discontinuation of therapy. Therefore, sustained virologic responses are achieved in only 8 to 35% of adults given interferons alone.[145] Attempts to improve treatment efficacy by using higher interferon doses and prolonging duration of therapy lead to only marginal improvements in virologic responses at the expense of higher rates of side effects. However, significantly higher sustained virologic responses are attained (30–40%) by combining interferons with ribavirin, a guanosine analog. Longer-acting pegylated interferons have been subsequently developed based on the premise that more sustained drug levels would result in greater antiviral activity. Indeed, several randomized clinical trials in adults verify considerably better virologic responses (50–60%) with the use of pegylated interferons, particularly when given in conjunction with ribavirin.[146,147]

Multiple studies have evaluated the efficacy and safety of interferon alone for the treatment of childhood hepatitis C, as comprehensively reviewed.[148] The use of multiple treatment regimens in mostly small and uncontrolled clinical trials in children makes direct comparisons with adult data difficult. However, in general, sustained virologic response rates in children treated with interferon alone (30–60%) appear to be two- to threefold higher than in similarly treated adults.[148] Importantly, biochemical and virologic responses have been accompanied by significant histologic improvement in all treated patients included in these trials, and interferon has been well tolerated in children.

Based on the observed synergy between interferons and ribavirin in adults with chronic hepatitis C, the efficacy and safety of this combination treatment in children have been assessed in several clinical trials. In an initial dose-finding study, sustained virologic response rates were noted in 33%, 35%, and 45% of children treated with interferon and ribavirin 8, 12, or 15 mg/kg/d, respectively.[149] There were no significant differences in the rate of adverse events between the treatment groups. Because a greater sustained virologic response is achieved with the highest dose while maintaining a safety profile similar to that of the lower ribavirin regimens, ribavirin 15 mg/kg/d has become the standard dose for treating children with chronic hepatitis C. Two subsequent pilot studies of childhood cancer survivors with transfusion-acquired HCV given standard interferon and ribavirin doses further verified these initial results because 50% and 64% of treated children had a sustained response, respectively.[150,151] These preliminary results were further confirmed in two subse-

quent larger studies, which together included a total of 110 chronically infected European and North American children and adolescents.[152,153] In a study from Germany, 25 of 40 children (62%) had a sustained response,[152] whereas this was accomplished in 34 of 70 (49%) of young persons in the other trial.[153] As in adults, several important factors are associated with a favorable therapeutic response to interferon therapy given alone or in combination with ribavirin, including infection with an HCV genotype other than type 1, low pretreatment serum HCV RNA levels, younger age, and absence of cirrhosis.[148–153]

Adverse events such as fever, headache, and influenza-like symptoms, ascribed to interferons, are common during the first two to three treatments and generally improve or resolve afterward.[148–153] These frequent side effects may be minimized by administering interferon in the evenings and prescribing routine acetaminophen or nonsteroidal anti-inflammatory agents during the initial weeks of therapy. Hematologic abnormalities are common with antiviral therapy. Ribavirin-induced anemia occurs in nearly all treated patients within 4 to 8 weeks of initiating treatment and then stabilizes, in association with a reactive reticulocytosis. Concomitantly with a reduction in hemoglobin, mild elevations in serum bilirubin and uric acid levels rarely occur. In a similar fashion, neutropenia is consistently seen with antiviral therapy, but this is not associated with clinically significant infections. Mild thrombocytopenia occurs infrequently. Persistent complications include anorexia, weight loss, and depression. It is important to point out that ribavirin is clearly associated with the development of fetal malformations in many animal species tested. Therefore, it is critical that women of childbearing years avoid pregnancy by effective contraception techniques during ribavirin therapy and for up to 6 months after its discontinuation. Finally, there are reported cases of spastic diplegia and seizures occurring in young infants given interferon for treatment of cutaneous vascular anomalies.[154] Although these infants generally received higher doses of interferon than those proposed for chronic hepatitis C, this medication should probably not be used in the very young patient for the treatment of HCV infection.

Because pegylated interferon–based regimens are better than those that rely on conventional interferon in adults, clinical trials are currently under way to assess the efficacy and safety of pegylated interferon in combination with ribavirin in children with chronic hepatitis C. With the development of novel antiviral agents such as HCV protease, helicase, and polymerase inhibitors and efficient immunomodulatory strategies, the future for the eradication of HCV is promising.

1C. Other Viral Infections

Lee A. Denson, MD

Numerous viruses have been implicated in causing hepatitis. With the exception of hepatitis B and C, which are covered in the preceding parts of this chapter, these are typically acute, self-limited infections. This part reviews the route of transmission, presentation, and diagnosis for the most important agents in immunocompetent individuals (Table 51.1C-1).

Of the known hepatotropic viruses, hepatitis A virus (HAV) causes the majority of cases of community-acquired viral hepatitis in children throughout the world, whereas hepatitis E virus (HEV) plays a significant role in regions where it is endemic.[1] Because a significant number of cases of both post-transfusion and community-acquired hepatitis are not identified as being caused by hepatitis A–E, investigators have sought to identify additional potentially hepatotropic viral agents. In recent years, candidates have included hepatitis G virus (HGV), TT virus (TTV), and SEN virus (SENV). Whether these agents actually do replicate in the liver and cause hepatitis is now in question; however, the current evidence for and against this is briefly summarized. Finally, a number of viral agents can cause what is typically a milder, nonicteric hepatitis as part of an overall viral syndrome in immunocompetent hosts. The presentation and diagnosis of hepatitis owing to cytomegalovirus (CMV) and Epstein-Barr virus (EBV) are reviewed in this regard. Viral hepatitis as part of a congenital or perinatal infection and in the immunocompromised host is reviewed in Chapter 49, "Approach to Neonatal Cholestasis," and Chapter 51.3, "AIDS and Other Immune Disorders," respectively.

HEPATITIS A

HAV is a nonenveloped ribonucleic acid (RNA) virus in the Picornaviridae family.[2] Within this family, which also includes the rhinoviruses, poliovirus, coxsackievirus, echoviruses, and enteroviruses, HAV is classified in the genus *Hepatovirus*.[3] Oral ingestion of infected material leads to absorption from the stomach or intestine, replication in the liver, secretion into bile, and then either excretion in stool or reabsorption.[2] HAV may also replicate in the intestinal epithelial cells.[4] Viral particles may be detected in the bile and blood, and high titers are present in stool for 2 to 3 weeks before symptomatic liver injury as detected by elevated transaminases has occurred.[5] Fecal excretion then persists for an additional 2 weeks. The hepatitis is due to both a direct cytopathic effect of the virus and the resultant immune-mediated injury, although recent studies have favored the importance of the immune-mediated mechanisms.[6,7]

Hepatitis A is the most common cause of acute hepatitis in the United States; however, in recent years, the incidence in the United States has been declining (Figure 51.1C-1). In 2001, 10,616 cases were reported to the Centers for Disease Control and Prevention. From this, it was estimated that there were 45,000 acute clinical cases and 93,000 new infections in the United States that year.[8] This is as compared with 30,021 reported and 128,000 estimated cases in 1997. The reduction in incidence has been particularly striking in children aged 5 to 14 years. Transmission is primarily via the fecal-oral route, with the most common identifiable source being via personal contact. This includes primarily household contacts and day-care centers. In fact, approximately 10% of cases in the United States each year occur in day-care centers in children who are not toilet trained. Because of the risk of transmission to adults, it is recommended that an index case with hepatitis A be excluded from day-care centers and preschools for 1 week.[9] Foodborne epidemics have been associated with contaminated shellfish and have been transmitted in the United States via produce.[10,11] Waterborne transmission is less important in the United States. Although much less common than fecal-oral transmission, parenteral transmission has also been reported.[12]

Immunoglobulin (Ig)M antibodies directed against HAV are usually present in serum when patients present

TABLE 51.1C-1 AGENTS ASSOCIATED WITH NON-B/C VIRAL HEPATITIS

VIRUS	FAMILY	TYPE	ROUTE OF SPREAD	DISEASE
Hepatitis A	Picornavirus	RNA	Oral/fecal	Acute
Hepatitis E	Hepatitis E–like viruses	RNA	Oral/fecal	Acute
Hepatitis G	Flavivirus	RNA	Parenteral	Unlikely
TT	Circovirus	DNA	Parenteral and nonparenteral	Unlikely
SEN	Circovirus	DNA	Parenteral and nonparenteral	Acute/chronic
Cytomegalovirus	Herpesvirus	DNA	Parenteral and nonparenteral	Acute
Epstein-Barr	Herpesvirus	DNA	Nonparenteral	Acute

DNA = deoxyribonucleic acid; RNA = ribonucleic acid.

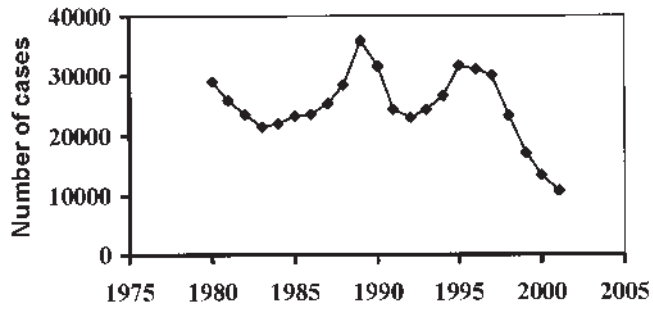

FIGURE 51.1C-1 The annual incidence of reported cases of acute hepatitis A virus (HAV) infection in the United States for the period between 1980 and 2002 is shown. Adapted from the Centers for Disease Control and Prevention.[8]

with clinical symptoms and can first be detected 5 to 10 days after exposure.[13] These are therefore diagnostic of acute infection. An IgG response then occurs that is long-lived and provides resistance against reinfection. The liver injury is likely due primarily to the associated cellular immune response to HAV rather than a direct cytopathic effect of the virus.[6,7] The diagnostic accuracy of the commercially available IgM-specific anti-HAV assay is quite good, with a sensitivity approaching 100%, a specificity of 99%, and a positive predictive value of 88%.[14] Rarely, the test may be negative at the time of presentation but should become positive within 1 to 2 weeks.[15] IgM titers will be detectable for several weeks and then become undetectable. The typical time course of the clinical presentation and viral serology is shown in Figure 51.1C-2.

The clinical presentation of hepatitis A may be classified as sporadic, endemic, or epidemic.[2] Sporadic cases typically occur in older patients and manifest the expected viral prodrome and icteric phase. The endemic form includes a large number of asymptomatic and anicteric cases occurring in younger children.[2] For example, fewer than 10% of children less than 6 years of age will become jaundiced with HAV infection compared with 40% of children between the ages of 6 and 14 years and 70% of children older than 14 years. In endemic areas, 73 to 100% of children have been shown to have been infected in early childhood.[16,17] Epidemics owing to HAV have been reported to have a seasonal pattern, beginning in the fall and peaking in the winter, although the reason for this is not known.[2] The clinical presentation is like that in sporadic cases, with a prodrome featuring anorexia, nausea, vomiting, and malaise leading to the icteric phase. The incubation period averages 30 days, with the prodromal period averaging 7 days. Dark urine is then typically noted before scleral icterus. The duration of jaundice is quite variable but has been reported to range from 7 to 21 days on average.[2] The most prominent finding on physical examination is tender hepatomegaly. The peak bilirubin is typically around 10 mg/dL, and peak alanine transaminase (ALT) is around 3,000 mIU/L (ranging from 20 to 100 times the upper limit of normal). The serum transaminases usually normalize within 2 to 3 weeks, although minor elevations may persist for months, whereas the bilirubin usually normalizes within 4 weeks.

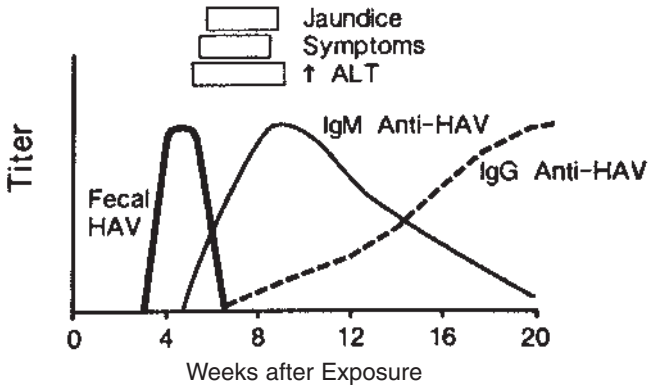

FIGURE 51.1C-2 The sequence and clinical events seen during hepatitis A are shown in this schematic illustration. Fecal hepatitis A virus (HAV) appears during the late phase of the incubation period, peaks near the onset of symptoms, and then declines rapidly; detection of fecal HAV is not used in clinical diagnosis. Diagnosis of acute hepatitis A is usually based on detection of immunoglobulin (Ig)M anti-HAV. Courtesy of the Clinical Teaching Project, American Gastroenterological Association. ALT = alanine transaminase.

Hepatitis A infections may also follow a relapsing, prolonged, or cholestatic course (see Table 51.1C-1). In these individuals, the IgM anti-HAV may persist for 6 to 12 months. Relapses resembling the initial presentation have been documented in 2 to 10% of reported adult series.[18] A prolonged course, with laboratory abnormalities lasting more than 10 weeks, has also been reported in around 9% of cases.[18] Biochemical abnormalities have resolved in these cases by 20 weeks and almost all clinical symptoms by 24 weeks.[2] A cholestatic variant with prominent pruritis, diarrhea, and weight loss has also been described, with eventual complete resolution, although this may take more than 12 weeks.[19] Both the cholestatic and relapsing variants have been associated with an increased frequency of disorders mediated by immune-complex deposition, including cutaneous vasculitis, arthritis, and cryoglobulinemia (see Table 51.1C-1).[20] Finally, there is some evidence that acute HAV infection may trigger an autoim-

mune hepatitis in susceptible individuals.[21] The fatality rate for hepatitis A infection is quite low, reaching a maximum of 1.8% in adults older than age 50 years and less than 0.3% in children under 14 years of age.[8] Older age and underlying liver disease (eg, chronic hepatitis B or C infection) have been associated with more severe disease.

Passive immunoprophylaxis with immune serum globulin is useful for preventing transmission to close contacts of an index case (when given within 2 weeks of exposure) or when traveling to an endemic area. The effectiveness of this strategy has been estimated to be around 90%, although the overall waning of anti-HAV seropositivity in the general population may render this less effective.[22] The US Food and Drug Administration (FDA) has licensed a formalin-inactivated hepatitis A vaccine (Havrix) for administration to children 2 years of age and older. The most recent US recommendations for immunization target children in states with rates of HAV infection twice the national average, or approximately 20 cases per 100,000. Other high-risk populations for which immunization is recommended include travelers to endemic areas (when given within 2–4 weeks of travel), men who have sex with men, users of illegal drugs, persons who are at occupational risk for infection, persons with clotting factor disorders, and persons with chronic liver disease.[23] Individuals with chronic liver diseases should be particularly identified for immunization because coinfection with HAV has been shown to cause more severe liver injury in this setting.[24] However, a recent survey indicated that, in the adult population, HAV immunization in this patient group has not yet been consistently performed.[25] Reported adverse reactions with the vaccine have been minimal, and the seroconversion rate after two doses is 99.8% in healthy individuals.[2] Recent reports have indicated that immunization of the entire population in nonendemic countries would be cost-effective, which may become the policy in the United States in the future.[26,27] Recently, a combination vaccine directed against HAV and hepatitis B virus (HBV) has been approved by the FDA that will be useful in this regard.[28,29]

HEPATITIS E

HEV is a nonenveloped single-stranded RNA virus. It is currently classified within a separate *Hepatitis E–like viruses* genus.[30] Although the general fecal-oral mode of transmission and clinical presentation are quite similar to those in HAV, there are significant differences in its geographic distribution, with endemic areas in subtropical and tropical parts of the world.[31] In contrast to HAV, many outbreaks have been attributable to contaminated water sources, and the highest attack rate is in young adults aged 15 to 40 years.[31] The rate of person to person transmission is relatively lower for HEV relative to HAV, and the prevalence of anti-HEV IgG in endemic areas is much lower, usually not more than 25% for HEV versus 90% for HAV. The case-fatality rate during epidemics is between 0.2% and 4%, with a much higher rate (10–20%) in pregnant women.[31] Endemic areas include parts of India, areas of central and Southeast Asia, northwest China, and parts of Africa (Figure 51.1C-3).

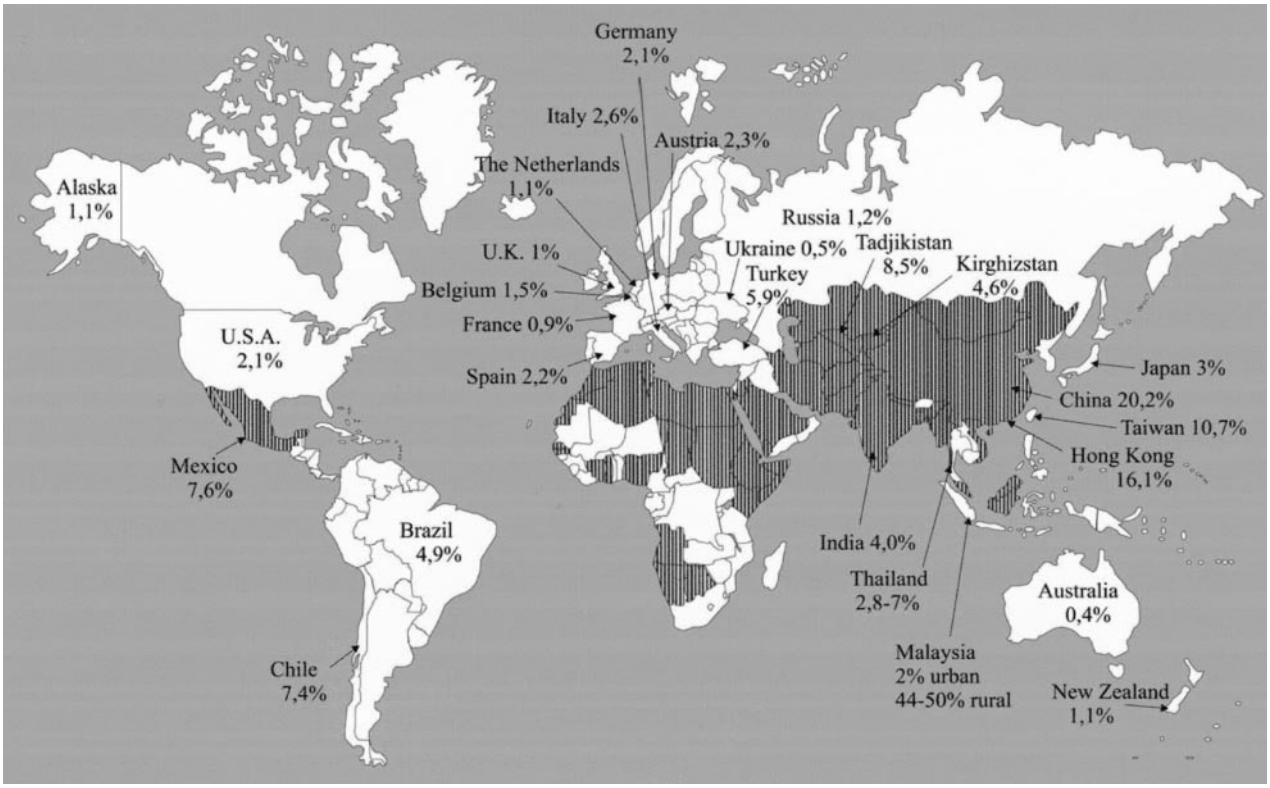

FIGURE 51.1C-3 The prevalence of positive hepatitis E virus serology in various countries is shown. Endemic regions are indicated by the dark vertical bars. Reprinted from Worm HC et al,[30] with permission from Elsevier.

As for HAV, the major mode of transmission for HEV is via the fecal-oral route. Secondary cases in household contacts occur in only 1 to 2% compared with 15% for HAV.[32] Interestingly, cases have not been associated with a foodborne mechanism of transmission. The probability of parenteral transmission is quite low.[33] The prevalence of anti-HEV does not typically exceed 25%, even in endemic areas.[30,31] The reported prevalence in children is much lower (not more than 9%) and increases in adulthood.[34] This is in contrast to other enteric viruses such as HAV, for which the prevalence of anti-HAV may exceed 90% in young children in endemic areas.[35] A low prevalence of anti-HEV ranging from 0.5 to 2% has been consistently detected in the United States and Europe. However, there have been no outbreaks of HEV, and the rare sporadic cases have been primarily limited to travelers to endemic areas. Recent reports have indicated that HEV may also circulate in domestic animals such as swine and in rodents native to industrialized countries; this may represent an increased risk for exposed individuals.[36,37] A recent cross-sectional study identified seropositivity for HEV in 10.9% of North Carolina swine workers compared with 2.4% of nonexposed individuals.[36] This compared with a prevalence of anti-HEV in 34.5% of swine. However, no associated history of past clinical hepatitis or unexplained jaundice was reported in seropositive individuals.

In areas with a low incidence of sporadic HEV, such as the United States and Europe, patients with a recent travel history and acute hepatitis should be evaluated for HEV infection. Otherwise, more common causes should be ruled out first. HEV enters by the oral route and then replicates in the liver.[30] The incubation period ranges from 2 to 9 weeks. The clinical presentation is quite similar to HAV and includes jaundice, malaise, nausea, anorexia, and a variable degree of hepatomegaly. Pruritus may be a prominent feature of the cholestatic form. A flu-like prodrome precedes the acute hepatitic phase. The incubation time is in the range of 15 to 60 days, and the virus is excreted in the stool for an average of 2 weeks after the onset of the illness.[30,32] Abnormalities in transaminases and alkaline phosphatase typically normalize within 1 to 6 weeks.[30] HEV infection may be diagnosed through detection of anti-HEV IgM in serum at the onset of symptoms; this remains positive for 2 to 3 months. Anti-HEV IgG persists long term in about 50% of infected individuals. Although prolonged cases lasting up to 6 months have been reported, there is no evidence that HEV causes chronic hepatitis.[30] As for HAV, HEV superinfection has been reported to worsen liver injury in chronic HBV infection.[38] Although this is typically self-limited, cases of severe liver decompensation have been reported.[39] Thus, patients with chronic liver diseases traveling to or living in endemic areas will be candidates for HEV immunization when a vaccine becomes available.

Strategies to reduce the number of HEV outbreaks and sporadic cases include improved sanitation in endemic areas and the development of an HEV vaccine. This is particularly necessary in endemic areas because of the relatively low prevalence of natural immunity to HEV and the high fatality rate in pregnant women. Because of its high prevalence, HEV is the leading cause of fulminant hepatitis in endemic areas such as India.[40,41] Several efforts are currently under way to develop an effective HEV vaccine, and a candidate vaccine has been evaluated in clinical trials.[42–44]

GB VIRUS C/HEPATITIS G VIRUS

Despite significant advances in the molecular characterization of the primary hepatotropic viruses, A–E, there is still a significant proportion of cases of both post-transfusion and community-acquired hepatitis that are of unknown origin.[45] This includes approximately 10% of cases of transfusion-associated hepatitis and, in some series, up to 20% of cases of community-acquired hepatitis. This and the next two sections briefly summarize the evidence for and against the potential contribution of three recently characterized viruses to these cases: HGV, TTV, and SENV. GB virus C (GBV-C), or HGV, is a recently discovered enveloped RNA virus that belongs to the Flavivirus family.[46] GBV-C and HGV were independently isolated and reported by two different groups; they are 96% homologous, indicating that they are two genotypes of the same virus.[47] Most reported cases have involved parenteral transmission through contaminated blood or blood products; however, cases attributable to intravenous drug use, vertical transmission from mother to child, and sexual transmission have also been reported.[48–50] The risk of vertical transmission is on the order of 50 to 60%, which is much higher than for HCV.[51]

HGV is found throughout the world, with a high prevalence in both healthy populations and in different patient groups.[52–56] This has called into question its actual role in acute or chronic hepatitis.[57–59] Active infection has been detected using a polymerase chain reaction (PCR) assay for HGV RNA in serum, whereas past exposure has been detected using an antibody against the envelope 2 (E2) protein.[50,60] Prevalence rates in healthy populations of 1 to 4% have been reported in Europe and North America and 10 to 33% in South America and Africa.[46] Supporting the parenteral mode of transmission, prevalence rates of 24 to 49% have been reported in intravenous drug use and 18% in polytransfused patients. Rates ranging from 2 to 39% have been reported for acute non-A–E hepatitis and 16 to 43% for fulminant hepatic failure.[46] The majority of adults have a transient infection with clearance of the virus and the appearance of E2 antibodies. However, persistent infections lasting for years in the absence of liver disease have been documented. This has been particularly true in cases of vertical or perinatal transmission.

Although the tissue tropism of HGV is not clearly established, it may replicate in human mononuclear cells rather than in hepatocytes.[61] In this regard, it is interesting to note that coinfection with HGV has been shown to slow the progression of HIV infection, with coinfected patients having higher CD4 counts.[61] Other recent studies have indicated that HGV may also infect and replicate in hepatocytes, albeit without causing any detectable liver injury.[62] Although HGV infection has been implicated in cases of acute, chronic, and

fulminant non-A–E hepatitis, whether it is clearly the cause of these cases has become much less likely with additional negative reports. In most subjects, liver histology has been normal despite evidence of HGV infection in hepatocytes.[62] There is no increase in HGV infection in children with liver disease compared with children without liver disease.[63] Moreover, HGV superinfection has not been shown to worsen liver disease in HCV infection.[64] Overall, most infections are asymptomatic, and whether HGV is truly a cause of non–A-E hepatitis is unlikely.

TT VIRUS

TTV is a nonenveloped single-stranded deoxyribonucleic acid (DNA) virus that was originally identified in an adult with nontypable post-transfusion hepatitis.[65] Although TTV has subsequently been found in patients with non-A–E hepatitis, its overall prevalence has not been different between healthy individuals and patients with liver disease.[66,67] Like HGV, TTV has been detected using PCR from serum samples. A recent study determined the prevalence of TTV in healthy children and children with non-A–E hepatitis and/or a history of transfusion.[68] Depending on the PCR primers used, from 27 to 89% of healthy children had evidence of TTV infection. Children with a history of transfusion had a higher prevalence, ranging from 46 to 100%.[68] However, children with non-A–E hepatitis, whether acute, chronic, or fulminant, did not have a significantly higher prevalence of TTV infection than healthy controls.[68] There was no increase in serum transaminases in children coinfected with TTV and HBV or HCV relative to HBV or HCV alone. Moreover, the treatment response in HCV infection was not affected by coinfection with TTV.[69] Importantly, the data in healthy children also supported a significant nonparenteral route of transmission, beginning in the first year of life and peaking by 4 to 6 years of age. Thus, the data as a whole support both parenteral and nonparenteral routes of transmission for TTV but do not support a significant role for TTV in non-A–E hepatitis in children.[70,71] In fact, more recently, it has been proposed that TTV may represent part of the normal human "viral flora."

SEN VIRUS

The most recent agent to be implicated in non-A–E hepatitis is SENV. SENV is a single-stranded DNA virus from the newly characterized Circovirus family that bears some homology to TTV.[72] Five strains have been characterized, with total SENV detected in 13% of healthy blood donors and up to 70% of transfused patients.[72] The SENV-D and SENV-H strains have been felt to be more promising in terms of potentially causing liver disease, with a prevalence of less than 1% in healthy blood donors and up to 50% in cases of transfusion-associated non-A–E hepatitis.[72] The prevalence of SENV infection was shown to increase with the volume of transfused blood, supporting the parenteral mode of transmission.[72]

In a recent prospective study, 11 of 12 patients who developed nontypable post-transfusion hepatitis were infected with SENV-D and/or SENV-H.[72] However, 55 of 225 patients who did not develop post-transfusion hepatitis were also acutely infected with SENV-D and/or SENV-H. None of the patients were jaundiced; the mean peak ALT level was 396 U/L. In some cases, there was concordance between the level of viremia and ALT. The severity of HCV cases detected in this study was not affected by coincident SENV infection. Most patients cleared SEN-V infection, although 15% were chronic carriers for several years. In two of these patients, chronic viremia was associated with a persistently elevated level of ALT. Overall, this study demonstrated the relatively common occurrence of post-transfusion SENV infection in 30% of patients. Whereas a minority (11/86) of SENV-infected patients did develop acute non-A–E hepatitis temporally related to the appearance of viremia, the majority (75/86) did not. Several recent retrospective studies similarly documented a high prevalence of SENV infection in both healthy individuals and those with acute or chronic liver diseases and also supported a nonparenteral route of transmission.[73–75] Therefore, it is unlikely that SENV infection causes non-A–E hepatitis in most cases. As for TTV, coinfection with SENV has not been shown to affect the severity or response to treatment of HCV; SENV, however, has been shown to be sensitive to interferon therapy.[76] However, further data regarding hepatotrophism and replication will be required to determine whether SENV infection does cause hepatitis in a minority of cases.

CYTOMEGALOVIRUS

It has been estimated that up to 10% of cases of acute viral hepatitis in immunocompetent individuals may be due to non-A–E agents. These may include EBV, herpesviruses, CMV, adenovirus, and parvovirus. The clinical presentation, diagnosis, and management of acute hepatitis associated with CMV and EBV are summarized in the next two sections. A detailed discussion of hepatitis owing to the other viral agents is beyond the scope of this section.

CMV is one of seven members of the herpesvirus family, each of which may infect the liver. Although CMV and other herpes family member infections are a more significant problem in immunocompromised hosts, they may also cause a variety of clinical diseases in immunocompetent patients. This includes what is typically an acute anicteric hepatitis as part of a systemic infection.

By the age of 15 years, approximately 20% of children will have been infected; this reaches a maximum of 50 to 60% by 25 to 30 years of age.[77] The consequences of CMV infection in immunocompromised patients and infants are covered in another chapter. CMV may infect and replicate in both hepatocytes and cholangiocytes.[78] However, whether the resulting liver injury is due to a direct cytopathic effect of the virus or the host immune response is not clear. In fact, this may vary depending on the clinical situation.[78] Whether hepatocytes may harbor CMV in a latent infection is also not well understood and is currently being studied. Finally, it has recently been reported that patients with other forms of chronic viral hepatitis and cir-

rhosis may be more susceptible to developing acute CMV infections that cause additional liver injury.[78]

Although acute primary CMV infection in immunocompetent hosts is usually asymptomatic, it may result in a syndrome similar to EBV mononucleosis.[78] This includes fever, malaise, cervical lymphadenopathy, and splenomegaly. Liver involvement is indicated by a modest elevation in serum transaminases (usually less than threefold) and minimal hepatomegaly.[79] Overt jaundice is rare.[79] The diagnosis of CMV infection may be made by detecting anti-CMV IgM antibodies or CMV antigen in serum or CMV cultured from urine. Typical viral cytomegalic cells or CMV early antigens are rarely detected on liver biopsy, perhaps indicating a vigorous immune response in the normal host leading to destruction of infected hepatocytes. By comparison, cytomegalic cells and both CMV early and late antigens are frequently detected on liver biopsy of transplant patients infected with CMV.[78] Therefore, the liver injury in the normal host may be due primarily to the host immune response, whereas viral cytopathic injury may be more important in the immunocompromised host.[78]

Compared with infection with HAV, patients with hepatitis owing to CMV tend to have fever longer and more prominent cervical lymphadenopathy and splenomegaly.[78] The incubation period ranges from 3 to 12 weeks.[80] Jaundice is much less common, and the maximum elevation in serum transaminases is typically less than 200 U.[80] Transaminases typically peak 2 to 3 weeks after disease onset and normalize by the fifth week.[80] Very rarely, however, acute CMV infection has been reported to cause massive hepatocellular necrosis in a normal host, with attendant fever, jaundice, highly elevated transaminases, and coagulopathy. In severe cases, therapy with ganciclovir or foscarnet may be effective.[81,82]

Ordinarily, CMV infection leads to a lifelong latent phase in the normal host. CMV can then become reactivated in immunocompromised individuals.[78] Patients with chronic liver disease, particularly when it has advanced to cirrhosis, develop a condition of impaired cellular immunity. This may make them more susceptible to CMV reactivation or reinfection. Coincident CMV infection is then associated with an additional impairment in liver function.[78] The specific effect of CMV infection on the progression of chronic liver diseases, including HBV and HCV, is currently the subject of active investigation.[78] A recombinant CMV vaccine has recently completed phase I trials in seronegative toddlers and may prove useful in terms of preventing transmission to woman of childbearing age and other individuals for whom the consequences of primary CMV infection may be severe.[83]

EPSTEIN-BARR VIRUS

As for CMV, EBV may also affect the liver as part of a generalized mononucleosis syndrome in the normal host. This section is limited to a brief review of the hepatitis associated with infectious mononucleosis; the role of EBV in post-transplant lymphoproliferative disease, lymphoma, and acquired immune deficiency syndrome (AIDS) is discussed elsewhere.

Like CMV, EBV is ubiquitous and will have infected over 80% of individuals by the time they are adults.[84] It is a double-stranded DNA virus. Infection of the oropharynx results in ongoing shedding of virus during an active infection. EBV DNA is subsequently incorporated into B cells, resulting in lifelong latent infection. The primary infection in young children is usually asymptomatic.[84] Infection in adolescents leads to the classic infectious mononucleosis syndrome, with fever, cervical lymphadenopathy, sore throat, fatigue, and splenomegaly. Primary infection is confirmed by detection of antiviral capsid antigen IgM in the serum.[84] Liver involvement is similar to CMV, with a mild anicteric hepatitis in most cases. However, from 5 to 10% may develop jaundice.[79,85] Rarely, in about 1 in 3,000 cases of infectious mononucleosis, this may take a more fulminant course, with severe hepatitis, bone marrow failure, and acute respiratory distress syndrome.[84,86] Death may result in these cases from massive hepatocellular necrosis and liver failure. Liver injury owing to EBV is likely secondary to infected cytotoxic T lymphocytes rather than a direct cytopathic effect of the virus on hepatocytes.[87]

FULMINANT HEPATITIS

A more detailed discussion related to evaluation of the child with fulminant hepatic failure is presented in Chapter 58, "Acute Liver Failure." Although each of the viruses previously reviewed may rarely cause fulminant hepatitis in children, a number of cases do not have an identifiable cause. This has led a number of investigators to search for additional causes of severe viral hepatitis.[88] The reported contribution of HAV in developed countries has ranged from < 5% (United States) to 26 to 31% (France and England).[88] Although the reported prevalence of HBV infection in adult fulminant hepatic failure has ranged from 25 to 75%, making it the most common identified viral cause, it remains an uncommon cause in children in nonendemic areas, including the United States.[88] In endemic areas, it plays a significant role, equivalent to the prevalence reported for adults. Also in endemic areas, infection with HEV alone or in combination with HAV has commonly been implicated in pediatric cases of fulminant hepatic failure. This has not been reported in children in the United States or western Europe.[88] As previously reviewed, it is unlikely that HGV or TTV causes fulminant hepatic failure; the potential role of specific strains of SENV remains under investigation. Viruses in the herpes family, including CMV, EBV, herpes simplex virus, and varicella-zoster virus, have each been implicated in causing fulminant hepatic failure, although almost always in an immunocompromised host.

Therefore, a significant proportion of cases of severe hepatitis and, in particular, fulminant hepatic failure in children are presumed to be due to an as yet unidentified virus(es). Survival without liver transplant is lower for this entity than for fulminant hepatitic failure owing to HAV or HBV.[88] The association with aplastic anemia has strengthened the hypothesis that this is a viral infection. In this regard, parvovirus B19 infection has been implicated in

some cases, although its overall contribution is unclear.[89,90] A recent study from Japan identified human herpesvirus 6 in 7 of 11 patients (5 children and 2 adults) with fulminant hepatic failure.[91] With continued improvements in molecular techniques, additional potential viral causes of non-A–E hepatitis will likely be identified in the near future. However, rigorous methods will be required to determine whether these agents are causative or innocent bystanders.

2. Bacterial, Parasitic, and Other Infections

Dinesh S. Pashankar, MD, MRCP
Richard A. Schreiber, MD, FRCPC

The epidemiology of postnatal nonviral infections of the liver varies throughout the world. Whereas in the United States, most nonviral infections of the liver are bacterial, parasites are especially important etiologic agents in developing countries. Although the incidence of hepatic abscesses postappendicitis has decreased substantially owing to the advent of broad-spectrum antibiotics and improvements in surgical care, liver infections in immunocompromised hosts are on the rise. The clinical presentation of hepatic infections may be subtle, and a high index of suspicion is necessary, especially in those patients at high risk. Modern diagnostic techniques and novel therapeutic interventions have afforded significant improvements in mortality rates.[1,2] This chapter discusses the assessment and management of pyogenic liver abscess and some of the other more common nonviral infectious causes of postnatal liver infection.

PYOGENIC ABSCESS

Incidence and Pathogenesis

Pyogenic liver abscess is an uncommon infection in children. The incidence was reported as 0.35% in all pediatric cases coming to autopsy in St. Louis prior to 1967 and as 0.03% of all admissions to Milwaukee Children's Hospital between 1957 and 1977.[3,4] Whereas pyogenic liver abscess in South Africa and India can account for 0.015% and 0.078% of hospital admissions, respectively,[1,5] a hospital rate of 0.025% was noted in a pediatric population from Florida.[6] It is suspected that the incidence of hepatic abscess in children is on the rise, likely owing to improved diagnostic imaging techniques and the changing complexity and survival of pediatric patients at high risk for developing liver abscess, such as those with leukemia or immunodeficiency. Pyogenic liver abscess does occur in neonates, accounting for 0.026% of admissions to a neonatal intensive care unit in one study.[7]

Pyogenic bacteria can reach the liver via the portal vein or hepatic artery from structures adjacent or contiguous to the liver or by direct hepatic trauma. Infections originating within the abdominal cavity (eg, appendicitis, omphalitis, or perforated viscus) can seed to the liver, resulting in abscess formation. Although biliary tract disorders are less common in pediatric patients compared with adults, children who have undergone hepatic portoenterostomy are predisposed to developing ascending cholangitis and liver abscess.[3] In developing countries, malnutrition and helminthic (ascariasis) infestations are the major risk factors associated with liver abscess in children.[1,8] In developed countries, pyogenic liver abscesses occur most frequently in immunocompromised hosts. A review of 92 children with chronic granulomatous disease (CGD) found that 45% of cases were complicated by hepatic or perihepatic abscesses.[9] Children with leukemia on chemotherapy are predisposed to developing bacterial or fungal liver abscesses.[3,10] Patients with congenital neutropenia,[4] hyperimmunoglobulinemia E syndrome,[11] or other congenital or acquired immune deficiency syndromes[12] are also at risk for developing liver abscess. In a review of adult liver transplant recipients, allograft abscess was reported in 1% of cases, with hepatic arterial thrombosis being a significant risk factor.[13] Hepatic "mini-microabscess syndrome" has recently been described in pediatric liver transplant recipients.[14] Liver abscesses have been reported in children with Crohn disease[15] and sickle cell anemia.[16] Ingestion of sharp objects,[17] penetrating injuries to the liver,[18] and the presence of a ventriculoperitoneal shunt[19] can be complicated by the development of liver abscesses. Pyogenic liver abscess also occurs in healthy immunocompetent children, yet no specific etiology is identified in many of these "cryptogenic" cases.[20] The development of liver abscess in neonates is usually associated with umbilical venous catheterization, prematurity, and necrotizing enterocolitis requiring surgical intervention.[7]

Microbiology

A number of pathogenic bacteria can cause pyogenic liver abscess; in some cases, more than one pathogen is recovered (Table 51.2-1). In a review of 96 children with pyogenic liver abscess, *Staphylococcus aureus* was the most common pathogen, seen in 44% of the cases, followed by gram-negative enteric organisms such as *Escherichia coli*, *Pseudomonas*, and *Klebsiella* in 25% of cases and anaerobic organisms in 10% of cases.[21] An increasing role for anaerobes as a source of infection has been appreciated in both adults and children, probably owing to improvement in anaerobic culture techniques.[22] Recently, a severe form of liver abscess owing to *Klebsiella pneumoniae* along with endophthalmitis has been reported in diabetic adults from Taiwan.[23] In neonates with liver abscess, gram-negative enteric organisms are the most common pathogens isolated.[7] Patients with CGD have a high frequency of *S. aureus*, but gram-negative enteric organisms that produce catalase have also been noted.

Knowledge of the source or route of infection can be helpful in predicting a particular pathogen. *S. aureus* is the

most likely organism in children with liver abscess following bacteremia or in those who are immunocompromised. Gram-negative enteric organisms and anaerobes are likely culprits when infection spreads to the portal venous system from the gastrointestinal tract. Fungal liver abscesses may occur in neutropenic children with leukemia who have been on broad-spectrum antibiotics.[10] Patients with acquired immune deficiency syndrome (AIDS) are at increased risk for mycobacterial abscesses owing to *Mycobacterium tuberculosis* and *Mycobacterium avium-intracellulare*.[12]

Clinical Features

In children, the clinical manifestations of pyogenic liver abscesses are nonspecific. A high index of suspicion is necessary to establish the diagnosis, particularly in those patients with predisposing risk factors. The presentation may be acute, with rapid onset of severe symptoms, or chronic, with a more insidious onset over weeks to months. The most common presenting complaints are fever and abdominal pain. Many patients have other associated symptoms, including nausea, vomiting, anorexia, malaise, and weakness. Some children present only with fever of unknown origin. Hepatomegaly is present in 50 to 73% of children with hepatic abscess,[6,20] and right upper quadrant tenderness is noted in 40% of cases.[20] Other findings such as abdominal distention or evidence of pleuropulmonary involvement are uncommon on physical examination. The diagnosis of liver abscess in neonates is especially difficult because the presentation is often similar to neonatal sepsis.[24] Children from developing countries tend to have a more acute presentation, with fever, abdominal pain, tender hepatomegaly, and septic shock.[1,25]

Diagnosis

Routine laboratory tests, like the clinical presentation, are nonspecific and are of little value for establishing the diagnosis of liver abscess. Anemia and leukocytosis are typically seen; however, children with underlying malignancy on chemotherapy may be leukopenic.[3] Hepatic transaminases are usually normal or only mildly elevated. Elevation in serum alkaline phosphatase and bilirubin is present in cases secondary to biliary obstruction. Although the yield of aerobic and anaerobic blood cultures is variable and may be quite low, the documentation of bacteremia with the identification of a specific organism is most helpful for directing treatment. Patients with multiple abscesses are more likely to have positive blood cultures than those with a solitary abscess. In a review of neonates with liver abscesses, half of the patients were bacteremic with the same organism that was eventually cultured from the liver abscess.[7]

Radiologic imaging is the most important tool for establishing the diagnosis of liver abscess. Plain chest radiographs may be abnormal, with the presence of an elevated right hemidiaphragm, right pleural effusion, or air in the abscess cavity. Historically, radioactive-isotope liver-spleen scanning or angiography was used to establish the diagnosis. However, the recent advent of noninvasive imaging techniques, including ultrasonography and computed tomography (CT), has allowed for easy, quick, and accurate diagnosis. Ultrasonography is the imaging study of choice in suspected liver abscess because of its high sensitivity and the relative ease with which it can be performed, even in very young infants. On ultrasonography, abscesses appear as hypoechoic lesions with irregular borders (Figure 51.2-1). In children, a solitary (rather than multiple) abscess located in the right (rather than left) lobe of the liver is the most common finding.[25] The differential diagnosis of a solitary hypoechoic liver lesion includes congenital hepatic cyst, liver tumor, or hydatid cyst. On ultrasonography, pyogenic abscesses are more likely to have a "honeycomb" pattern with irregular margins compared with amebic abscesses.[26] CT (Figure 51.2-2) should be requested in the face of a normal sonogram if the clinical suspicion remains high. Magnetic resonance imaging of a hepatic abscess offers no significant advantage over CT or ultrasonography for detecting or characterizing liver abscess.[27]

Treatment

Antibiotic therapy with drainage of the pus collection is the mainstay of therapy for liver abscess. Supportive management in the form of intravenous hydration and analge-

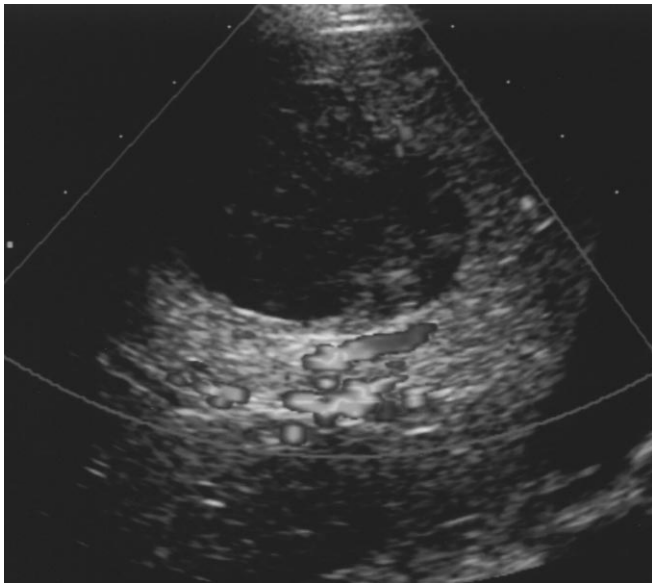

FIGURE 51.2-1 A sonogram of a large solitary abscess in the right lobe of the liver. The abscess appears as a hypoechoic lesion with irregular borders. Courtesy of Dr. D. H. Jamieson, British Columbia's Children's Hospital, Vancouver, BC.

sia may be required. Initial antibiotic therapy should be empiric, broad spectrum, and based on knowledge of the organisms most commonly involved, as discussed earlier. A penicillinase-resistant penicillin should be used, along with an aminoglycoside or third-generation cephalosporin for gram-negative flora, whereas clindamycin, cefoxitin, and metronidazole are appropriate for anaerobes. Empiric parenteral antibiotic therapy should not be delayed, pending the abscess drainage procedure. Once pathogens are identified in blood or abscess cultures, antibiotic therapy can be tailored to susceptibility.

Drainage of the liver abscess can be performed by needle aspiration, percutaneous catheter, or an open surgical approach. In a recent controlled trial, percutaneous continuous catheter drainage was more effective than therapeutic large-needle aspiration.[28] Other reports have documented the safety and efficacy of percutaneous drainage, although left lobe abscesses are more difficult to treat by this route.[6,29] The duration of continuous percutaneous drainage is usually 2 to 3 weeks, whereas parenteral antibiotic therapy should be maintained for at least 2 to 4 weeks, followed by oral antibiotics for a total of 4 to 6 weeks. Longer treatment may be required in immunocompromised children. In a recent report of pyogenic liver abscess in adults, sequential intravenous therapy for 3 weeks followed by oral antibiotics for 3 weeks was safe and equally effective compared with 6-week intravenous antibiotic therapy.[30] Serial ultrasonographic imaging of the abscess cavity and clinical response are helpful in deciding the duration of antibiotic therapy. In a recent series of adults with pyogenic liver abscesses, percutaneous drainage of liver abscesses was associated with a success rate of 90%.[2] Open surgical drainage should be reserved for those cases in which percutaneous drainage is not feasible or fails or cases in which other intra-abdominal pathology is suspected. Drainage procedures may be associated with complications. In a large series of children who were treated with open surgical drainage for pyogenic and amebic liver abscesses, complications such as adhesive intestinal obstruction, incisional hernia, and colonic fistula resulting from erosion of the drain were reported.[25]

Multiple hepatic microabscesses or those abscesses not amenable to continuous drainage have been successfully treated with prolonged antibiotic therapy alone. However, in a large series of South African children with pyogenic or amebic liver abscesses, conservative treatment with antibiotics was successful in only 37% of cases[25]; the remaining cases eventually required surgical drainage owing to worsening of the clinical picture. If a conservative approach is taken, close clinical monitoring with surgical backup is mandatory. The management of children with CGD is difficult. Whereas small abscesses (< 5 cm) may be treated with antibiotics alone, surgical management of larger hepatic abscesses in patients with CGD is crucial for survival.[31] Despite aggressive management, children with CGD may be resistant to the standard therapeutic options of antibiotics and drainage. In this instance, interferon-γ has been employed successfully.[32] Following the successful treatment of a child with liver abscess, appropriate immunologic investigations should be planned because liver abscess may be the presenting manifestation of an immunodeficiency disorder.

Outcome

The complications of pyogenic liver abscess include pleural and pericardial effusions, rupture leading to peritonitis, septicemia, and shock.[25] The mortality associated with pyogenic liver abscess before 1977 was high: up to 27% in children with CGD and 42% in children without CGD.[4] The diagnosis was often missed and was established only at autopsy in many cases. A review of 109 cases of liver abscess in children (excluding neonates) from 1977 to 1988 reported a drop in mortality to 15%.[6] Recently, a mortality figure of 11% was quoted from a series from India of 18 children with pyogenic liver abscesses.[1] Recent

FIGURE 51.2-2 Abdominal computed tomographic scan showing a large multiloculated abscess in the right lobe of the liver.

studies in adults have also reported improvement in mortality rates.[2] In adults, the most important determinant of mortality is the presence of major underlying disease such as malignancy or severe organ dysfunction.[2] Early diagnosis and prompt therapeutic intervention are also important determinants for survival.[2] Thus, the overall outcome for pyogenic liver abscess has been improving in recent years. The principal reasons for this are improvements in imaging techniques (allowing for prompt diagnosis), the introduction of efficacious antibiotic therapy, and novel interventional radiologic techniques.

OTHER BACTERIAL INFECTIONS

Typhoid Fever

Typhoid fever (enteric fever) is an acute systemic illness usually caused by *Salmonella typhi*. It is a major health problem in tropical and developing countries but is uncommon in developed countries. The presenting symptoms, reported in a series of 94 children with typhoid fever from Florida, included fever, diarrhea, vomiting, abdominal pain, and anorexia.[33] Hepatomegaly and splenomegaly were noted in 52% and 23% of children, respectively. A mild elevation of serum hepatic transaminases was noted in the majority of patients in that series, but clinical jaundice was uncommon.[33] In developing countries, clinical and biochemical evidence of hepatic dysfunction is much more obvious, particularly in multidrug-resistant typhoid fever.[34] In one series of adult patients, abnormal liver enzymes were noted in 100% of cases after the first week of typhoid fever, and it was proposed that the liver is always affected to some degree in these patients.[35] Rarely, typhoid fever can mimic an acute viral hepatitis, with fever and moderately abnormal liver enzymes being the sole clinical features.[36] Histologic features on liver biopsy are nonspecific and include focal necrosis with mononuclear infiltrate, inflammation of the portal area, and hyperplasia of Kupffer cells.[35] Other organ complications of typhoid fever in children include encephalopathy, seizures, myocarditis, and circulatory failure. The serodiagnosis of *S. typhi* infection using the Widal agglutination assay is unreliable and not recommended. The diagnosis can be established by positive blood culture or through novel molecular biologic techniques using deoxyribonucleic acid (DNA) probes and polymerase chain reaction (PCR). The abnormal liver function tests seen in typhoid fever completely resolve with appropriate antibiotic treatment.[35] Multidrug-resistant typhoid fever is an increasing problem in tropical countries, and ciprofloxacin and ceftriaxone have been used in such cases.[37] The chronic carrier state for typhoid fever is thought to be due to persistent infection in the liver or gallbladder.

Brucellosis

Brucellosis is primarily a zoonotic infection, caused by *Brucella melitensis*, *Brucella abortus*, or *Brucella suis*.[38] The mode of transmission to humans is direct contact with infected animals, such as cattle and sheep, or consumption of infected unpasteurized milk or milk products. Brucellosis in childhood can present with nonspecific symptoms. In a series of 102 children with brucellosis, the common symptoms were fever, malaise, arthralgia, weight loss, and anorexia.[39] Hepatomegaly was noted in 28% of children in that series, and splenomegaly was present in 35% of cases. Complications of brucellosis include osteomyelitis, pneumonitis, meningitis, and endocarditis. Hepatosplenic abscess has been reported in a 3-year-old child, but this appears to be a rare complication.[40] Common laboratory features include leukocytosis and an elevated erythrocyte sedimentation rate. Elevated hepatic transaminases and alkaline phosphatase were noted in 58% of children.[38] Histopathologic findings in the liver are variable and include inflammation of the portal tract, hepatocellular necrosis, and noncaseating epithelioid granuloma.[41]

The diagnosis of brucellosis should be suspected with a history of exposure, and diagnosis is confirmed by isolation of the organisms in blood or bone marrow cultures. A presumptive diagnosis can be made by high or rising titers of *Brucella* antibodies. Brucellosis responds well to antibiotic therapy, and the prognosis is excellent. In a large multicenter study of children with brucellosis, tetracycline for 3 weeks with initial gentamicin therapy was recommended as the most appropriate therapy for children older than 8 years.[42] For younger children, trimethoprim-sulfamethoxazole can be used in place of tetracycline.

Perihepatitis (Fitz-Hugh–Curtis Syndrome)

Perihepatitis, or Fitz-Hugh–Curtis syndrome, occurs as a complication of pelvic inflammatory disease in young adolescent females. Although the classic cause is *Neisseria gonorrhoeae*, this syndrome has also been described with *Chlamydia trachomatis* infection.[43] The pathophysiology of this syndrome is uncertain, and direct extension of the infection from the genital tract to the hepatic capsule is a possible mechanism.[44] The clinical presentation is one of acute, sharp, right upper quadrant abdominal pain, with or without fever, mimicking the signs of acute cholecystitis.[45,46] Clinical findings may include hepatomegaly, tenderness in the right upper quadrant, and a "friction rub" over the liver. Serum hepatic enzymes and bilirubin are normal.[45]

The history and physical findings of the associated pelvic inflammatory disease are suggestive of the diagnosis, and isolation of the causative organisms from the cervix or urethra confirms the diagnosis. Laparoscopic findings include classic "violin string" adhesions from the liver to the right costal wall.[47] The hepatic parenchyma does not appear to be involved, and liver biopsy findings are normal. Treatment with appropriate antibiotics for the causative organisms is associated with an excellent response.

Cat-Scratch Disease

Cat-scratch disease is an infective illness caused by the gram-negative bacillus *Bartonella* (previously *Rochalimaea*) *hensalae*. Following inoculation of the bacillus, a papule occurs locally, which vesiculates and then encrusts. Within a few days, regional lymphadenopathy (which may suppurate or remain enlarged for a few months) is noted. Although cat-scratch disease occurs in persons of all ages, the highest incidence is among children under 10 years of age.[48] In more than 75% of children, the illness is mild, with generalized

myalgias, malaise, anorexia, fever, and abdominal pain.[49] Unusual clinical manifestations include preauricular lymphadenopathy and conjunctivitis (Parinaud oculoglandular syndrome), pneumonia, erythema nodosum, encephalitis, and granulomatous hepatitis. Cat-scratch disease can also present as a prolonged fever of unknown origin, with or without any obvious adenopathy.[50,51]

Serum hepatic transaminases, alkaline phosphatase, and bilirubin are usually normal, and the erythrocyte sedimentation rate is often elevated. Abdominal imaging (ultrasonography and CT), usually performed as part of the evaluation for fever of unknown origin, may reveal multiple small hypoechogenic lesions in the liver and spleen, with mild enlargement of both organs.[50,52] In a recent retrospective study of 13 children with hypoechogenic liver lesions, 70% were found to have *Bartonella* infection.[51] Liver histology showed epithelioid granuloma with central necrosis and chronic inflammation. Warthin-Starry–stained bacilli may be found in the biopsy specimen. The indirect fluorescence antibody test for *B. henselae* provides a rapid and reliable diagnostic test.[51] The disease is self-limiting in nature, and complete resolution, without any therapy, of radiographically detected hepatic lesions has been reported.[50] However, antibiotics such as ciprofloxacin, azithromycin, and doxycycline have been used in severe cases with good response.[48,53] In a recent report from Texas, 2-week rifampicin therapy resulted in rapid improvement in symptoms and was recommended as an initial antimicrobial treatment of hepatosplenic cat-scratch disease in children.[54]

Spirochetal Infections

Leptospirosis. Leptospirosis is caused by one of several serotypes of *Leptospira interrogans*. Humans acquire infection by exposure to urine or other body fluids of infected animals such as dogs, cattle, hogs, and rats. Leptospirosis is usually a biphasic illness with an initial septicemic or leptospiremic phase lasting 4 to 7 days, characterized by fever, chills, headache, anorexia, abdominal pain, rash, and lymphadenopathy.[55] A second or immune phase, thought to be caused by the host response to the infection, is heralded by a lower-grade fever and complications including hepatitis, jaundice, renal dysfunction, thrombocytopenia, and meningitis. In one series from Brazil, significant jaundice was noted in 70% of infected children, and abnormal liver transaminases were seen in 56%.[56] In another series, 55% of children with leptospirosis had hepatomegaly and acalculus cholecystitis.[57]

Weil syndrome is a rare severe form of leptospirosis associated with hepatic dysfunction, renal failure, hemorrhagic manifestations, and pulmonary involvement, and it portends a high mortality rate.[55] Abnormal laboratory findings in Weil syndrome include direct hyperbilirubinemia, elevated serum transaminases, and prolonged prothrombin time.[55] Histologic changes in the liver include multinucleated cells, proliferation of Kupffer cells, erythrophagocytosis, and cholestasis.[55] Severe hepatic necrosis is unusual, and complete recovery of liver function is seen in those who survive. The diagnosis of leptospirosis requires a high index of suspicion and is confirmed by isolating the organism from blood, cerebrospinal fluid, or urine. A fourfold increase in antibody titers between acute and convalescent sera also establishes the diagnosis.[56] Optimal treatment of leptospirosis is with penicillin or ampicillin, along with supportive management. Antibiotics have been shown to be of significant benefit even in late-presenting or severe cases of leptospirosis.[58] The mortality in children has been reported as 2% in one series, with death owing to respiratory failure secondary to pulmonary hemorrhage.[56]

Lyme Disease. Lyme disease is a multisystem infection caused by *Borrelia burgdorferi*. It is transmitted to humans through the bite of a deer tick. Lyme disease is the most common vectorborne disease among children in the United States.[59] The clinical presentation includes nonspecific symptoms of fever, malaise, and headache associated with a characteristic annular erythematous skin rash (erythema chronicum migrans), which is present in approximately 68% of infected children.[60] The complications of Lyme disease in children include arthritis, facial palsy, aseptic meningitis, and carditis.

Rarely, Lyme disease can present in childhood as acute hepatitis with fever, jaundice, and elevated liver transaminases.[61] In a large prospective series of adults with Lyme disease, 40% of patients had at least one liver test abnormality, whereas 27% had more than one abnormality.[62] These improved significantly or resolved completely after antibiotic therapy. The diagnosis of Lyme disease should be suspected with a history of a tick bite in an endemic area and with finding the classic skin rash on examination. Serologic testing for *B. burgdorferi* is diagnostic. Treatment is with tetracycline except for children under 9 years of age, in whom cefuroxime, amoxicillin, or erythromycin should be used.[63] The prognosis for children adequately treated for Lyme disease is excellent, with no long-term morbidity.[59]

Rickettsial Infections

Rocky Mountain Spotted Fever. Rocky Mountain spotted fever is a clinical syndrome characterized by fever, headache, and a classic maculopapular rash that begins peripherally and spreads to involve the entire body. The disease is caused by *Rickettsia rickettsii*, and ticks serve as vectors for transmission. The clinical presentation is usually with fever, myalgia, rash, headache, abdominal pain, and vomiting.[64] Hepatic involvement may occur in the form of hepatomegaly and jaundice. Variable elevations of serum hepatic transaminases and alkaline phosphatase have been reported.[64] Pathologic changes in one postmortem pediatric study revealed marked inflammation of the portal triad with portal vasculitis and sinusoidal erythrophagocytosis.[65] Rickettsiae have been found in portal blood vessels and in cells of the sinusoidal lining.

A diagnosis of Rocky Mountain spotted fever requires a high index of clinical suspicion. Disease confirmation is established by demonstrating a fourfold rise in antibody titer in the second or third week of illness, using a complement fixation serologic test. About 70 to 80% of

patients will have a positive Weil-Felix reaction, but the test is not specific. Treatment with tetracycline or chloramphenicol is most effective. The treatment should not be delayed pending laboratory diagnosis because untreated infection can lead to severe ilness and fatal outcome.[66]

Q Fever. Q fever is a febrile illness caused by *Coxiella burnetii*. The usual mode of transmission is inhalation, and the animal hosts include cattle, sheep, and goats. The disease presents in acute and chronic forms. Hepatic involvement is common in the acute form, heralded by fever, headache, malaise, vomiting, abdominal pain, and respiratory symptoms. Hepatosplenomegaly may be present on physical examination. In one series, 11 of 13 children with Q fever had elevation of hepatic transaminases.[67] Although quite rare, fulminant hepatic failure and death have been reported in childhood.[68] Liver histology in Q fever shows fatty change with diffuse granulomatous lesions.[69] A classic histopathologic finding is fibrin ring granuloma with a central clear space (Figure 51.2-3). The diagnosis of Q fever is confirmed by serologic testing. The treatment of choice is tetracycline, although most patients recover uneventfully without any specific treatment.

PARASITIC INFECTIONS

AMEBIASIS

Amebiasis is caused by the protozoan *Entamoeba histolytica*. It occurs in all parts of the world and is endemic in southern and western Africa, the Far East, South and Central America, and the Indian subcontinent. In the United States, the prevalence of amebiasis is estimated to be about 4%.[70] The epidemiologic risk factors predisposing to amebiasis are lower socioeconomic status, crowding, poor sanitation, immigration from an area of endemicity, and young age, including infancy.[70] *E. histolytica* is an enteric pathogen that exists in either trophozoite or cyst form. Transmission is by the fecal-oral route, and the infection is acquired by the ingestion of cysts. Cysts dissolve during passage through the small bowel and mature into trophozoites. Trophozoites colonize the colon and may encyst or invade the colonic epithelium, resulting in colitis. Trophozoites reach the liver via the portal venous system and penetrate into the hepatic parenchyma, leading to hepatic abscess. An amebic abscess cavity contains acellular proteinaceous debris surrounded by necrotic hepatic tissue.[71] Fever and right upper quadrant pain are the most common symptoms of hepatic amebic abscess. A history of dysentery may be present; it was reported in up to 16% of childhood cases in one series.[72] On examination, tender hepatomegaly and abdominal distention are usually seen. Clinical jaundice is uncommon. Patients may also present with respiratory symptoms secondary to rupture of the abscess into the pleura or tracheobronchial tree. Rupture of the abscess into the peritoneum may lead to an acute abdomen, and intrapericardial rupture may present as shock.[73]

Routine laboratory tests are of limited value in the diagnosis of hepatic amebic abscess. In one large series, anemia and leukocytosis were seen in more than 90% of children, whereas abnormality of serum transaminases and alkaline phosphatase was observed in only 16% of cases.[72] Examination of stool for cysts or trophozoites is positive in only a minority of cases. Ultrasonography or CT can provide anatomic verification and intrahepatic localization of the abscess cavity. Amebic abscess is usually solitary and is seen in the right hepatic lobe in 75% of cases.[72] Reliable differentiation between amebic and pyogenic abscess is difficult on ultrasonographic appearance alone, but an amebic abscess is likely to have a better defined margin with a peripheral "halo."[26] If a diagnosis of amebic liver abscess cannot be made on the basis of serology and clinical features, needle aspiration of the abscess can exclude the possibility of pyogenic abscess. Aspiration of an amebic abscess yields a reddish brown fluid that has the appearance of anchovy paste.[21] Amebae are usually not recovered from the abscess fluid, and the pus is sterile.

The development of serologic tests for the diagnosis of amebiasis has virtually eliminated the need for needle aspiration. These tests include indirect immunofluorescence, indirect hemagglutination, and enzyme-linked immunosorbent assay.[71] In a recent study, elevated indirect hemagglutination titers (> 1:250) were seen in all children with amebic liver abscess.[72] However, serologic testing may not be as reliable in young infants. In one review, only 62% of infants with amebic abscess had a positive serologic test at presentation.[74] Because each individual test is not always positive, the use of at least two different serologic tests is recommended for diagnostic purposes.

In contrast to pyogenic liver abscess, amebic liver abscess can be successfully treated with antibiotics alone, without aspiration or drainage. Metronidazole (30–50 mg/kg/d in three divided doses for 10 days) is the therapy of choice. A course of intestinal amebicide such as diloxanide furoate (10 mg/kg/d for 10 days) or iodoquinol (30–40 mg/kg/d [maximum 2 g/d] in three doses for 20 days) should be given following metronidazole therapy to eradicate the intraluminal infection.[70] Needle aspiration is recommended when a clinical response is not evident within 48 hours after

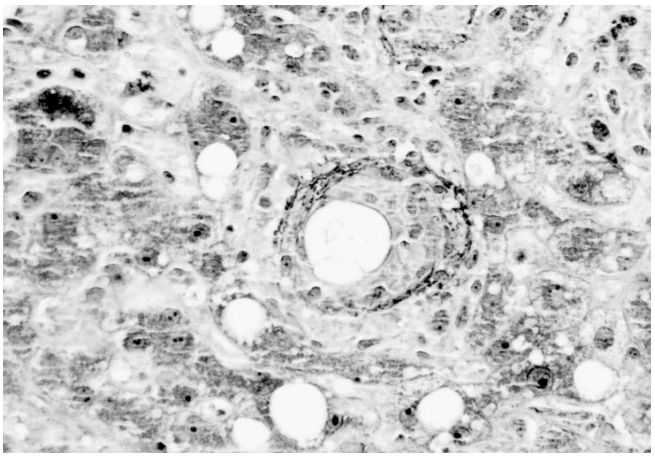

FIGURE 51.2-3 Fibrin ring granuloma with a central clear space in a patient with Q fever (hematoxylin and eosin; ×400 original magnification). Courtesy of Dr. F. A. Mitros, University of Iowa Hospital, Iowa City, IA.

starting medical therapy.[72] Other indications for needle aspiration include an abscess cavity larger than 7 cm and abscesses located in the left lobe (because of the higher risk for pericardial involvement).[72] Surgical intervention is necessary for ruptured amebic abscesses.[73] In one large series, antibiotic therapy along with timely aspiration of the abscess obviated the need for surgical intervention, even in malnourished children who presented late for treatment.[72] The prognosis for uncomplicated amebic abscess is usually good.[71] In infancy, however, the clinical course can be fulminant, with a high mortality rate.[74]

Malaria

Malaria is caused by *Plasmodium vivax*, *Plasmodium falciparum*, *Plasmodium ovale*, and *Plasmodium malariae*. Malaria is an important cause of morbidity and mortality in tropical and subtropical countries, with an estimated incidence of 300 to 500 million cases per year. Malaria is acquired from the bite of infected female anopheline mosquitoes. Sporozoites injected into the bloodstream reach hepatocytes, where further division and maturation take place. Merozoites released from the hepatocytes invade erythrocytes. The symptoms of malaria include fever, abdominal pain, vomiting, and diarrhea.[75] Fever and chills may be periodic (every 48 to 72 hours) or may occur daily. *P. falciparum* infection can result in severe life-threatening disease with complications such as seizures, coma, renal failure, severe anemia, shock, and (rarely) hepatic failure.[76] On examination, tender hepatosplenomegaly is a common finding. Jaundice, usually owing to hemolysis, and mild elevation of liver enzymes may be seen.[75]

Histologic findings in the liver include hyperplasia of Kupffer cells and diffuse periportal infiltration with mononuclear cells.[76] The diagnosis of malaria is established by the detection of parasites in thin and thick peripheral blood smears prepared with Giemsa stains. The drug of choice for all uncomplicated malaria except chloroquine-resistant *P. falciparum* is chloroquine phosphate (10 mg of base per kilogram to a maximum of 600 mg of base [a 1 g tablet] and then half the dose [maximum 500 mg] given once daily beginning 6 hours later, for 2 days). For severe and complicated malaria, quinine is the parenteral drug of choice supplemented with aggressive supportive management.[77] For chloroquine-resistant strains, quinine or mefloquine may be used.

Ascariasis

Ascariasis, caused by *Ascaris lumbricoides* (roundworm), is the most prevalent helminthic infection in the world. Although cases have been reported worldwide, ascariasis mostly occurs in developing tropical and subtropical countries. Ascariasis is most common in childhood and is endemic to areas with poor sanitation. The transmission is via the fecal-oral route. Ingested eggs eventually mature into the adult worm in the small intestine. The clinical manifestations of ascariasis depend on whether the worms reside in the intestinal lumen or whether they invade the pancreatic and biliary ductal system. The usual symptoms are vague abdominal pain and distention.[78] Some heavily infected children may present with an acute abdomen secondary to intestinal obstruction from the mass of worms.[79] Worms invading the ampullary orifice can induce biliary colic or acute pancreatitis.[80] Worm obstruction of the bile duct system can cause acalculous cholecystitis, pyogenic cholangitis, or acute pancreatitis in children.[78] In a report from a children's hospital in Burma, ascariasis was the culprit in acute surgical cases such as biliary obstruction, volvulus, and intestinal obstruction and perforation, accounting for 26.3% of emergency abdominal laparotomies in children.[79] Hepatic abscess has been reported in children and adults owing to worms obstructing the intrahepatic bile ducts.[5,80] In children from developing countries, ascariasis has been considered a predisposing factor for pyogenic liver abscess.[1,5]

The diagnosis of ascariasis is made by the finding of ova in the stools or by a history of passing worms. Elevation of liver enzymes and serum bilirubin may be seen in cases of biliary ascariasis. Ultrasonography of the abdomen is very useful in diagnosing complications, including cholecystitis, biliary tract dilatation, and hepatic abscess.[78] Rarely, an echogenic wormlike structure may be seen within the bile duct on ultrasonography.[81] Worms may also be seen on endoscopic retrograde cholangiopancreatography, and *Ascaris* ova can be found in the bile sample.[80] The treatment of ascariasis is with mebendazole (100 mg twice daily for 3 days) or piperazine salts (50–75 mg/kg/d for 2 days). Surgery may be required for selective obstructive cases, although biliary obstruction and colic symptoms have been treated by the removal of worms with endoscopic retrograde cholangiopancreatography.[80]

Echinococcosis

Echinococcus granulosus infection is found throughout the world and is endemic in sheep- and cattle-raising areas, including the Mediterranean, Australia, New Zealand, and parts of Asia, Europe, and South and North America. Echinococci are small tapeworms that inhabit the intestine of the definitive host, usually dogs, and humans acquire the infection by the ingestion of ova. The parasites may lodge in the liver or lungs of affected patients, leading to the formation of hydatid cysts. The cyst has a thick lamellar layer that supports a thin germinal layer of cells responsible for the budding and production of protoscoleces (Figure 51.2-4). The cyst is surrounded by a fibrous capsule produced by the host. Hydatid cysts may occur in other sites, such as the kidney, spleen, brain, eyes, and pancreas. Although the infection is acquired in childhood, symptoms may not occur for many years owing to the slow growth of hydatid cysts (1 cm in diameter per year).[82]

The clinical presentation of a hydatid cyst of the liver depends on the size of the cyst and on the complications arising owing to the cyst. Common symptoms in children with hepatic hydatid cysts include abdominal pain, abdominal mass, fever, and anorexia.[83] Some children are totally asymptomatic, with the abdominal mass detected incidentally on physical examination. Large hepatic cysts may compress on the venous system or the biliary tract, leading to portal hypertension or obstructive jaundice,

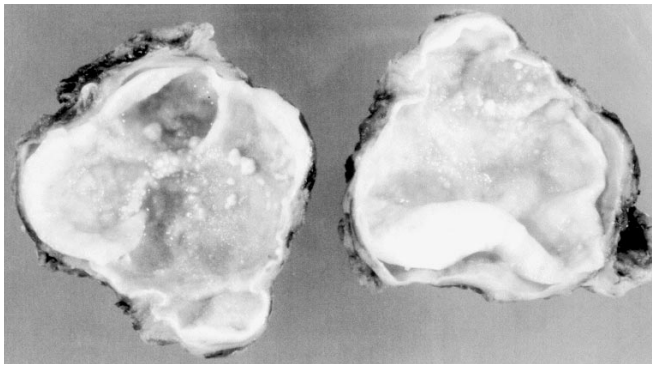

FIGURE 51.2-4 Gross liver resection specimen of a hydatid cyst.

respectively.[84] Cysts may rupture into the biliary tract or the peritoneal or pleural cavities. Anaphylaxis may occur owing to the release of the highly antigenic cystic fluid.[82] Laboratory tests are not specific for the diagnosis of echinococcosis. Eosinophilia, elevated liver enzymes, and hyperbilirubinemia may be present. Plain abdominal radiographs of the abdomen or chest may show a calcified mass. Ultrasonography is useful for diagnosing and localizing the cyst, but imaging does not readily differentiate echinococcal disease from other solitary cysts of the liver unless daughter cysts are present or intracystic septations or calcification of the cyst wall are recognized (see Figure 51.2–4). Definitive diagnosis can be made either by positive serology to *E. granulosus* or by demonstrating the presence of scoleces in the cystic fluid.

Historically, the optimal treatment for hepatic hydatid cyst was surgical, with care taken to avoid spillage of cystic fluid. However, novel reports favor conservative management for uncomplicated cysts. Careful percutaneous drainage combined with albendazole therapy was found to be an effective and safe alternative to surgery in adults.[84] In one long-term follow-up study from Israel, the use of albendazole therapy alone was associated with a cure in 41% of patients with hepatic hydatid cysts and with improvement in another 41% of adult patients.[85] In a recent report from Turkey, 3-month albendazole therapy resulted in successful resolution of hepatic cysts in 27% of children, and medical therapy was recommended as an initial therapy prior to surgery.[86] Medical therapy has also been suggested for children with hydatid cysts under 5 cm in size or for cases in which multiple cysts or multiorgan involvement occurs.[83]

Liver Fluke Infection

Clonorchiasis. Clonorchiasis, caused by *Clonorchis sinensis*, a liver fluke, is endemic throughout the Far East. Infection is acquired by the consumption of raw infected fish, which act as one of the intermediate hosts, along with snails.[87] The parasite migrates from the duodenum into the biliary ductal system and matures in the intrahepatic bile ducts. The injury to bile ducts manifests as adenomatous proliferation and goblet cell metaplasia.[88] Secondary infection occurs frequently, and recurrent pyogenic cholangitis can lead to stricture, periductal fibrosis, and hepatic abscess.[88] Patients with mild disease may be asymptomatic, whereas more severe cases present with recurrent cholangitis, biliary duct obstruction, or portal hypertension.[89] Cholangiocarcinoma has been reported with long-standing disease in adults.[90] Laboratory findings include variable elevation of liver enzymes and bilirubin. Ultrasonography is useful for assessing abnormalities in the biliary ductal system. The diagnosis is made by stool or duodenal aspirate examination for *Clonorchis* eggs. Praziquantel is the drug of choice for treatment.[89]

Fascioliasis. Fascioliasis is caused by *Fasciola hepatica*, the sheep liver fluke, and is found worldwide. Human infection is acquired by ingestion of infected watercress or water. The parasites penetrate the duodenal wall, traverse the peritoneal cavity, and penetrate the hepatic capsule to reach the bile ducts. The disease has two phases: an acute invasive phase, during which the parasite is migrating through the liver, and a chronic phase, during which it resides in the biliary tract.[91] Acute clinical manifestations in childhood include prolonged fever, abdominal pain, and tender hepatomegaly.[92] Significant eosinophilia, raised sedimentation rate, and elevated serum alkaline phosphatase are typically seen. Serum hepatic transaminases are usually normal or only mildly elevated.[91] CT may show abscess-like nodular lesions or multiple hypodense areas in the liver.[93] Liver biopsy findings include eosinophilic abscess (parasitic granuloma) and coagulative necrosis. Chronic fascioliasis can cause biliary colic, jaundice, cholangitis, and pancreatitis owing to obstruction of the bile ducts.[91] The diagnosis is by serologic testing or by finding *F. hepatica* ova in the stool. In a recent report from Egypt, triclabendazole (10 mg/kg single dose) was highly effective and was recommended as the treatment of choice in children.[94]

Schistosomiasis. Schistosomiasis is an important cause of morbidity and mortality in tropical countries. Hepatic schistosomiasis is caused by *Schistosoma mansoni* and *Schistosoma japonicum*. Endemic areas for *S. mansoni* include Africa, the Middle East, and South America, whereas *S. japonicum* infection is endemic in Central and Southeast Asia. Human infection occurs when schistosomes, released from a snail host, penetrate intact human skin. The parasites then migrate to the liver, enter into the portal venous system, and finally reside in the mesenteric veins.[95] Granulomatous hepatic lesions occur as a result of the host's immunologic response to the ova in the portal venous system (Figure 51.2-5). Fibrosis around branches of the portal veins subsequently leads to portal hypertension. Hepatic parenchymal function is usually preserved.

Infection occurs mainly in childhood or adolescence. Acute schistosomiasis (also known as Katayama fever), presumably a consequence of the host's immunologic response to mature worms and eggs, occurs about 4 to 6 weeks after exposure. Clinical features vary and include fever, cough, edema, lymphadenopathy, and eosinophilia.[95] Untreated acute schistosomiasis progresses to chronic disease, resulting in portal hypertension. Children may present with upper gastrointestinal bleeding owing to esophageal varices.

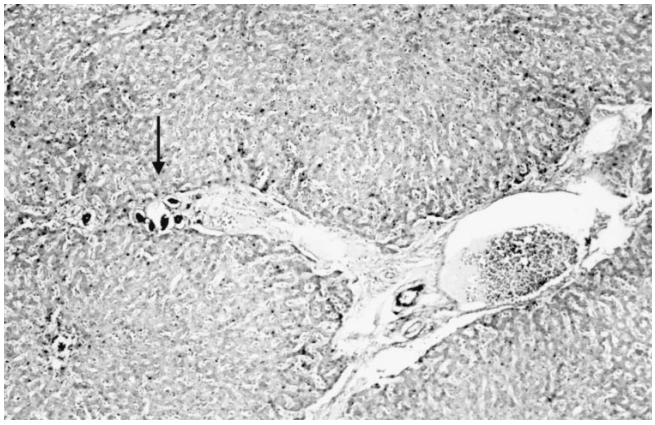

FIGURE 51.2-5 Schistosomiasis with multiple ova (*arrow*) embedded in a fibrotic portal triad (hematoxylin and eosin; ×200 original magnification). Courtesy of Dr. F. A. Mitros, University of Iowa Hospital, Iowa City, IA.

Hepatosplenomegaly can reach massive proportions, and ascites is present in some cases.[95] Other potential complications associated with hepatosplenic schistosomiasis are pulmonary hypertension, myocarditis, and transverse myelitis. Prolonged *Salmonella* infection may be a concurrent feature.

Laboratory features of anemia, leukopenia, and thrombocytopenia may be seen owing to hypersplenism. Eosinophilia and hyperglobulinemia may also occur, but liver function tests are usually normal.[96] Ultrasonography has been used to detect and grade the degree of periportal fibrosis and portal hypertension.[97] Serologic studies using *S. mansoni* egg antigen are helpful for diagnosis. The diagnosis is confirmed by detecting *Schistosoma* eggs in stool or in a rectal biopsy tissue sample. The treatment of choice is a single dose of praziquantel (20–40 mg/kg three times a day for 1 day), resulting in eradication of the parasite in 90% of cases[95] and reversal of periportal fibrosis in some children.[97] The management of portal hypertension and esophageal variceal bleeding may be difficult; however, in most instances, sclerotherapy has been effective. The use of propranolol for the management of portal hypertension in children has not been well studied.[98]

FUNGAL INFECTIONS

Candidiasis

Candida infections are the most frequently encountered systemic fungal infections, with infection of the liver and spleen occurring as a consequence of seeding during fungemia. Candidiasis usually occurs in immunocompromised patients, particularly those on chemotherapy for malignancy. Acute leukemia was the most common malignancy seen in children with hepatosplenic candidiasis.[10] Other risk factors for hepatosplenic candidiasis include neutropenia, recent chemotherapy, and the use of broad-spectrum antibiotics.[10] Clinical symptoms are nonspecific and usually include fever and abdominal pain. On examination, jaundice, hepatomegaly, splenomegaly, and abdominal tenderness may be found. The white blood cell count may be normal, although a history of prolonged neutropenia is usually present. The diagnosis should be suspected in patients with persisting fever and abdominal pain even after resolution of the neutropenia.[99] *Candida* may be isolated from blood, urine, throat, or stool. Serum hepatic transaminases, alkaline phosphatase, and bilirubin are often elevated. Abdominal ultrasonography may show several hypoechoic areas throughout an enlarged liver (Figure 51.2-6). Abdominal CT features include liver enlargement with multiple well-circumscribed low-density areas of 0.5 to 2 cm in diameter, often with accompanying splenic involvement. The appearance of *Candida* abscesses is usually distinct from that of bacterial abscesses, the latter being larger and fewer in number on imaging studies.[100] A percutaneous liver biopsy can confirm the diagnosis in 70% of cases, whereas a laparoscopic or an open liver biopsy provides an even better diagnostic yield.[99] Grossly, the liver surface is studded with yellow to white nodules ranging in size from 1 mm to 2 cm.[99] Histologically, *Candida* abscesses show fungal elements in the necrotic center, surrounded by inflammatory cells and a ring of fibrosis.[101] Granulomatous lesions with occasional giant cells in the liver have also been observed.[10]

The treatment of choice is the use of antifungal agents such as amphotericin B, 5-flurocytosine, or fluconazole. In a recent international consensus conference, fluconazole was favored as first-line therapy for stable patients, whereas amphotericin B was considered the drug of choice for life-threatening infections.[102] The optimal duration of therapy is controversial, and treatment for several months may be required.[103] In the vast majority of cases, drainage of the pus is impractical because of the small size and diffuse nature of the hepatic abscesses. Many of these patients have multisystem disease, and the outcome is poor, with mortality rates in children reported as high as 20%. [10]

Other Fungal Infections

Other fungal organisms such as *Histoplasma capsulatum*, *Aspergillus* species, *Cryptococcus neoformans*, and *Coccidioides immitis* may also infect liver. Similar to candidiasis, these infections usually occur in immunocompromised patients. Children with cancer on chemotherapy are par-

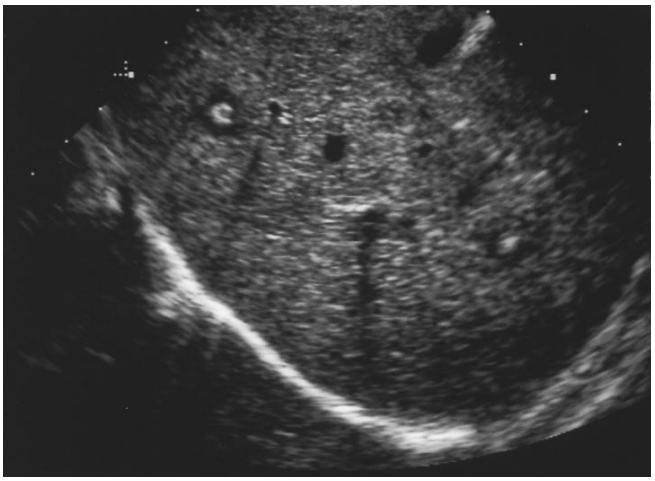

FIGURE 51.2-6 Sonogram of the liver showing multiple foci of *Candida* abscesses in a child with leukemia.

ticularly at risk.[104] Most systemic fungal infections involve organs such as the lungs, skin, central nervous system, and bones, and liver involvement is part of disseminated disease. Hepatic involvement may manifest as hepatomegaly, elevated serum hepatic transaminases, hyperbilirubinemia, and liver abscess formation.[100,105] Histologic findings in the liver include granuloma, inflammatory cells, and fungal organisms.[106] The diagnosis is made by serology or by isolation of the organisms from tissue or body fluids. Optimal treatment is with antifungal agents such as amphotericin B.

3. AIDS *and* Other Immune Disorders

Elizabeth Iofel, MD
Jeremiah J. Levine, MD

Immunodeficiency predisposes the host to the development of recurrent and unusual infections. Liver involvement in these infectious processes is commonly observed. This chapter describes liver infections in three major groups of immunodeficient states: human immunodeficiency virus (HIV) infection, congenital primary immunodeficiencies, and secondary immunodeficiency states associated with bone marrow and solid organ transplant.

As of the end of 2001, the Joint United Nations Programme on HIV-AIDS estimated that more than 40 million adults and children were living with HIV–acquired immune deficiency syndrome (AIDS). In children, there are two important routes of transmission: maternal transfer of virus during pregnancy or in the perinatal period and transmission through blood products. Approximately 90% of pediatric AIDS infections are acquired by the perinatal route.[1] Clinical symptoms in this situation can develop as early as 1 month of age, but the median interval from birth to symptom onset is 8 months. Gastrointestinal problems are typical in patients with HIV, and the liver is commonly involved. Hepatomegaly and abnormal liver function tests are frequently observed in HIV patients.[2–4] Acute hepatitis can be the first manifestation of HIV infection in early infancy.[5] However, significant abnormalities in liver synthetic function, complicated by cirrhosis, hypoalbuminemia, ascites, and portal hypertension, are rare.[2,6]

With newer treatment regimens for HIV, opportunistic infections are decreasing in frequency. On the other hand, mortality from end-stage liver disease among adult patients with HIV is on the rise.[7] Chronic coinfections with hepatitis B and C are the most frequent causes of chronic liver disease in adults with HIV.[3] Because no comparable data are available in the pediatric population, this discussion, for the most part, provides information based on extrapolations from the adult literature. Liver disease in the HIV-infected patient may be caused by a variety of pathogens. The most important ones are listed in Table 51.3-1. Liver damage in HIV-infected patients may also be caused by antiretroviral drugs and medications used for the treatment and prevention of opportunistic infections (Table 51.3-2), as well as tumors. Tumors are exceedingly rare in pediatric patients.

In the earlier stages of HIV infection, liver disease is usually related to drug hepatotoxicity or coinfection with hepatotropic viruses. With disease progression, the systemic opportunistic infections become more problematic. The clinical findings of liver disease in HIV patients are similar, regardless of underlying cause. Fever, malaise, hepatomegaly, right-sided or epigastric abdominal pain, and nausea have all been described. Jaundice is unusual, even in patients with biliary tract disease.

HIV virus has been observed within Kupffer cells and in hepatic endothelial cells,[8] and HIV messenger ribonucleic acid (RNA) has been detected within hepatocytes.[9] Hepatic macrophages and endothelial cells express the CD4 surface molecule and have been shown to support viral replication in vitro.[10] It remains unclear, however, whether HIV can damage the liver directly. There is no correlation between the amount of HIV antigens in the liver and the severity of histologic abnormality, and normal histology can also be seen.[11] There are limited data about hepatic histology in children with HIV disease.[12–14] Steatosis, Kupffer cell hyperplasia, portal inflammation, and focal necrosis are common but nonspecific findings.[15] Certain pathologic features appear somewhat unique to the pediatric age group. The presence of giant cells is common, even in children older than 6 months. The giant cells may be associated with cytomegalovirus (CMV) infection or Kaposi sarcoma but can also be a reaction of the liver to HIV infection.[13,14] Dense lymphoid infiltration of portal spaces with features of chronic active hepatitis has been described in several

Adapted from Weiner FR, Simon D. Liver disease in patients with acquired immunodeficiency syndrome. In: Brandt LJ, editor. Clinical practice of gastroenterology. Vol. 2. Philadelphia: Churchill Livingstone; 1999. p. 975.
HIV = human immunodeficiency virus.

Pitlick and colleagues[18,19] and Guarda and colleagues[20] were the first to report biliary tract involvement in patients with AIDS. The reported infectious agents in these cases include CMV, *Cryptosporidium*,[21] *Microsporida*,[22] and *Isospora*.[23] The spectrum of HIV-related biliary tract disorders includes acalculous cholecystitis, papillary stenosis, and sclerosing cholangitis. Four distinct cholangiographic patterns have been described by Cello.[24] Papillary stenosis occurs in 15 to 20% of patients, sclerosing cholangitis in 20%, and a combination of both in 50% of patients. The pattern of long, 1 to 2 cm extrahepatic bile duct strictures occurs in 15% of cases.

The pathogenesis of the biliary disease in HIV patients is not well understood. It is possible that HIV itself infects and damages the biliary tract. However, to date, HIV has not been isolated from the biliary epithelium.[25] It has been suggested that patients with certain human leukocyte antigen types may develop an immunologic reaction in response to pathogens directed against the biliary epithelium. It is also possible that enteric infection in AIDS patients may lead to portal bacteremia and bile duct injury.[26] Damage to the sphincter of Oddi caused by different pathogens has also been proposed as a possible mechanism.[27,28] The clinical picture of HIV-related cholangitis is similar regardless of the pathogenic organism involved.[24,29] Anicteric cholangitis is a predominant finding. Elevation of serum amylase has also been described, although its significance is unclear.

EVALUATION OF HIV-INFECTED PATIENTS WITH SUSPECTED HEPATOBILIARY DISEASE

Given the wide variety of possible etiologic agents and nonspecific clinical findings of liver disease in patients with HIV infection, an organized approach to the investigation of elevated transaminases, hepatomegaly, and unexplained fever is important. Figure 51.3-1 provides an algorithm for the approach to these patients. The history should focus on prior infections (CMV, hepatitis B or C), recent travel (exposure to tuberculosis, hepatitis A, or parasites), and a history of contact with individuals with highly contagious illnesses (varicella, roseola). Use of potentially toxic medications also has to be evaluated. A complete physical examination can often detect an extrahepatic site of opportunistic infections. Attention should also be paid to the nutritional status of the patient because acute weight loss or precipitous weight gain may cause hepatosteatosis and present as elevated liver function tests.

Although routine liver function tests are of limited value in identifying a specific infection, the magnitude of injury and pattern of injury may be suggested.[4] Two main patterns can be differentiated: hepatocellular dysfunction and cholestasis. With a pattern suggesting predominantly hepatocellular disease, viral hepatitis or drug toxicity should be considered. A cholestatic pattern with right upper quadrant pain, with or without jaundice, should raise suspicion of AIDS cholangiopathy. A markedly elevated serum alkaline phosphatase level in the absence of

bile duct obstruction is suggestive of mycobacterial or fungal infection.[2] Elevation of serum bilirubin and alkaline phosphatase levels without ductal dilatation suggests drug- or virus-induced cholestasis.

The CD4 cell count should be part of the laboratory evaluation because it reflects the degree of immunosuppression. Certain infections, such as *Pneumocystis carinii* and *Mycobacterium avium-intracellulare* complex (MAC), usually occur in severely immunocompromised patients. In contrast, tuberculosis and hepatotropic viruses (hepatitis A, B, or C) can be symptomatic at earlier stages of immunocompromise. Blood cultures, serology, and fungal and viral cultures may help elucidate specific pathogens causing liver dysfunction.

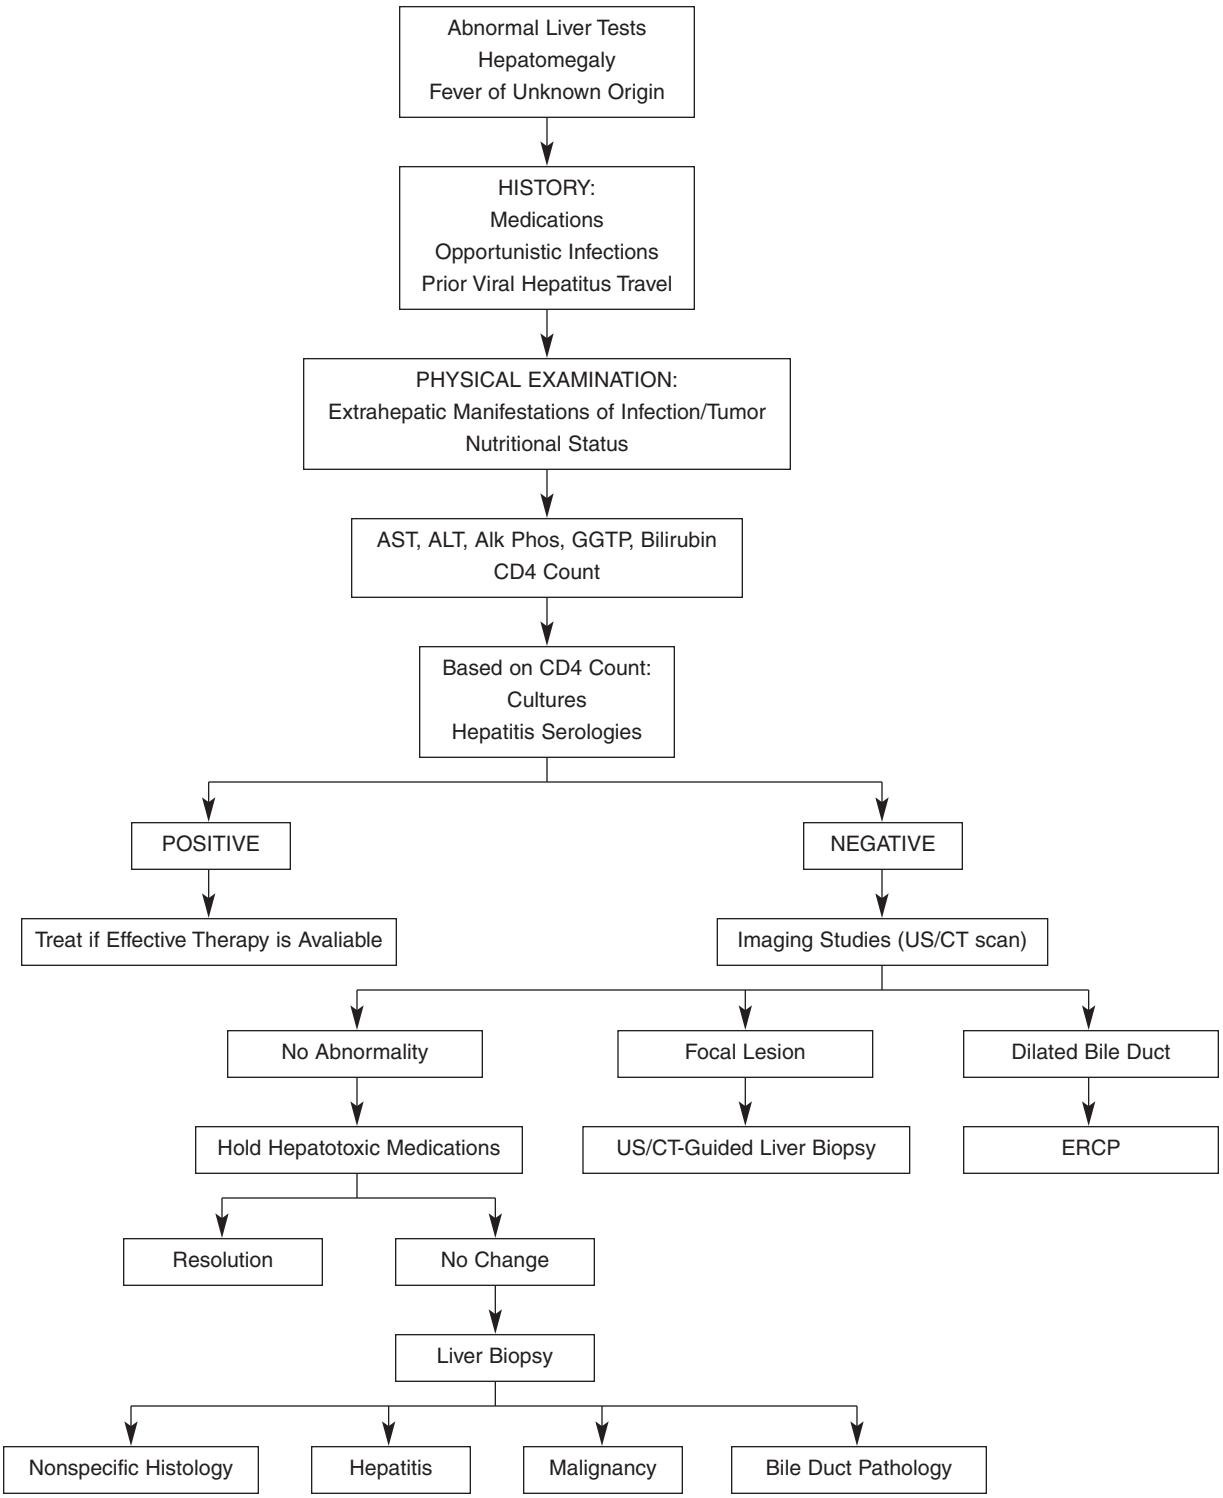

FIGURE 51.3-1 Diagnostic algorithm for the evaluation of human immunodeficiency virus (HIV)–infected patients with hepatobiliary disease. Alk phos = alkaline phosphatase; ALT = alanine transaminase; AST = aspartate transaminase; CD4 count = CD4 count lymphocyte cell count; CT = computed tomography; ERCP = endoscopic retrograde cholangiopancreatography; GGTP = γ-glutamyl transpeptidase; US = ultrasonography.

Ultrasonography is useful in the initial evaluation of suspected biliary tract disease. Although it may miss up to 25% of cases of HIV-related biliary tract disease diagnosed by endoscopic retrograde cholangiopancreatography,[30] it is easily available and inexpensive. Computed tomography (CT) offers a better delineation of focal lesions and intra-abdominal lymph nodes. Both ultrasonography and CT may be useful in performing a liver biopsy. The role of liver biopsy in the evaluation of HIV patients with parenchymal liver disease is controversial. A specific diagnosis may be made by liver biopsy in up to 50% of adult AIDS patients.[31,32] No comparable data are available in the pediatric patient population.

The risk of bleeding after liver biopsy is much increased in AIDS patients, even with normal coagulation. The rate of significant hemorrhage following liver biopsy is described to be as high as 5 to 10%.[15,33,34] Finally, it has not been demonstrated that findings on liver biopsy result in improved quality of life or survival of these patients.[4,35] Despite these issues, a liver biopsy is useful in certain situations. A recent pediatric study has suggested two groups for whom liver biopsy may be very useful when other noninvasive tests are negative: those patients with suspected mycobacterial infections and patients with jaundice.[15] Symptomatic hepatomegaly and persistent fever with a negative noninvasive workup have also been mentioned in the adult literature as indications for biopsy.[4] When a liver biopsy is performed, cultures and special stains should be obtained in addition to routine histology.

In contrast to hepatocellular disease, biliary tract complications of AIDS require an aggressive approach. Patients are frequently symptomatic, and effective palliation is available by endoscopic and surgical means. Endoscopic retrograde cholangiopancreatography remains the gold standard in diagnosing AIDS cholangiopathy.

HIV COINFECTIONS

Hepatitis B

Hepatitis B virus (HBV) and HIV have similar routes of transmission and so frequently coexist. It is unclear whether HIV alters the natural history of chronic HBV infection.[36] Following acute HBV infection, the virus is cleared in 95% of immunocompetent patients. In contrast, 50% of HIV coinfected patients develop chronic infection.[37] Individual case reports suggest that reactivation of HBV infection is associated with progression of the HIV disease.[38–42] Loss of naturally acquired anti–hepatitis B surface antibodies (HBsAB), even in patients who remain hepatitis B surface antigen (HB_sAg) negative, has also been described.[43] Increased prevalence of hepatitis B e antigen (HBeAg) expression and elevated levels of deoxyribonucleic acid (DNA) polymerase in HIV-positive patients has been reported.[37,41,44,45] Therefore, more patients with HIV-HBV coinfection are in a chronic HBV carrier state, with highly infectious serum and body fluids, compared with the HIV-negative population.[45]

Patients with early or well-controlled HIV infection tend to have milder HBV infection, whereas those severely immunosuppressed tend to have severe HBV disease.[46] Spontaneous resolution of chronic HBV infection with an improved immune response in treated HIV patients has also been described.[47] Thus, aggressive treatment of HIV appears to be an important factor in the control of HBV infection. Although HIV-positive patients with HBV may express higher HBV DNA levels and increased HbeAg titers,[36] they often have lower serum transaminases and less histologic damage.[48] Despite these findings, HBV infection in these patients has a greater risk of progression to cirrhosis and development of hepatocellular carcinoma.[49]

The results of interferon treatment in the HIV population are controversial.[50–54] In general, for hepatitis B, response rates to interferon therapy have been less impressive than those seen in the HIV-negative group. Lamivudine significantly lowers HBV DNA and serum transaminases and may result in seroconversion from HBsAg to HB_s antibody.[54,55] Unfortunately, reactivation of hepatitis B may occur following withdrawal of therapy; therefore, long-term treatment appears to be necessary.[38] Mutation of the viral polymerase gene occurs at a rate of approximately 20% per year, similar to that of an immunocompetent host.[56] This mutation leads to antiviral resistance in up to one-third of the patients.[57] The dosage of lamivudine used for HBV treatment in HIV-positive patients is similar to that used for HIV treatment alone (150 mg twice daily) to avoid development of HIV resistance to lamivudine. Minimal published information is available about the role of other nucleoside analogs in the treatment of HBV infection.[47,58–60]

Vaccination against HBV has been recommended for all patients infected with HIV. Unfortunately, HIV infection reduces the efficacy of vaccination in these patients. Several studies demonstrated suboptimal response in both the magnitude and duration of antibody response.[61–64] Loss of anti-HB_s in HIV-infected patients is seen in 43% of persons by 4 years compared with an 8% loss in immunocompetent controls.[65]

Hepatitis C

Hepatitis C virus (HCV) infects an estimated 170 million people worldwide and is five times more widespread than infection with HIV.[66] In the United States alone, approximately 300,000 to 400,000 individuals are HIV-HCV coinfected.[67] For children infected with hepatitis C through vertical transmission, the prevalence of HCV infection is estimated at 8 to 17%.[68,69] With the introduction of highly active antiretroviral therapy (HAART) and improvement in survival, HCV infection has become a major contributor to morbidity and mortality in patients with HIV. End-stage liver disease has become a frequent complication,[67,70,71] and cases of hepatocellular carcinoma (HCC) in HIV-HCV–coinfected adults have been described.[72] HCV also has been implicated as a cause of increased hepatotoxicity of HAART in coinfected patients.[73–75]

In children, HCV is acquired primarily through perinatal transmission. The rate of vertical transmission of HCV alone is 5 to 11%.[76] Maternal coinfection with HIV increases

the rate of perinatal HCV transmission even without simultaneous HIV transmission.[77,78] Likewise, maternal HCV infection has been associated with a higher likelihood of vertical HIV transmission. Perinatal transmission of HIV is approximately two times more frequent in mothers who are infected with both hepatitis C and HIV.[79]

There are no data on the natural history of HCV in HIV-infected children. In adults, HCV infection appears to be more aggressive in HIV-positive patients compared with immunocompetent adults. Hepatic damage from HCV infection is primarily due to direct viral damage. However, an immunologic response is important in the elimination of HCV. Therefore, the rate of HCV replication and levels of HCV viremia are much higher in immunosuppressed individuals.[80] Several studies demonstrated a more rapid progression and more severe course of HCV infection in the HIV population.[81,82]

The US Public Health Service and National Institutes of Health consensus panel has recommended anti-HCV enzyme-linked immunosorbent assay III as a screening test for HCV regardless of the HIV status of the patient.[70] A recent study showed a sensitivity of this test of over 99% in both HIV-infected and HIV-negative patients.[83] The recombinant immunoblot assay produced indeterminate results in 10 to 23% of coinfected subjects.[84] False-negative HCV serology may be associated with CD4 counts less than 200 cells/mm^3. If suspicion of the liver disease is high in those patients, an HCV-RNA test should be performed. The liver biopsy is considered the gold standard for clinical assessment of individuals with chronic HCV infection. Both inflammation and fibrosis tend to be greater in HIV-infected patients, primarily in those with low CD4 counts.[84]

Until recently, treatment of HCV-HIV coinfected patients was with antiretroviral drugs alone. It now has been well documented that HAART does not have any beneficial suppressive effect on HCV.[85] With the improved survival of HIV-positive patients, an aggressive approach to the treatment of HCV infection in this population has been advocated. Monotherapy with interferon-α results in a poor sustained response (0–20%).[79,86] Recent studies with the combination of interferon and ribavirin have demonstrated an end of treatment response rate of 50%, with up to 28% of the patients remaining HCV-RNA negative 3 months after treatment.[86–88] Introduction of pegylated interferon has led to a sustained viral response in 30 to 45%.[89,90] No treatment data are available in the pediatric population.

Hepatitis A, E, and G

The prevalence, morbidity, and mortality of hepatitis A infection are not altered by HIV infection.[91] Vaccination of the HIV-infected patients against hepatitis A is recommended. Vaccination appears to be safe but may be less effective. Prevaccination screening is cost-effective in adults.[91] Hepatitis E virus, a waterborne, fecally-orally transmitted virus, usually causes acute self-limited disease. One study showed an increased incidence of hepatitis E in HIV-infected patients but without clinical significance.[92] Hepatitis G virus (HGV) is present in approximately 20 to 40% of HIV-infected patients.[80] The presence of HGV does not alter the levels of the serum transaminases, CD4 cell count, or plasma HIV-1 levels.[80] Some studies suggest that coinfection of HGV and HIV is a favorable prognostic factor, correlating with a slower progression of HIV disease.[93]

Adenovirus

Adenovirus infections in healthy children usually present as a self-limited upper respiratory tract infection, gastroenteritis, maculopapular rash, and conjunctivitis. In HIV-infected individuals, fulminant multiorgan involvement with bilateral pneumonia, gastroenteritis or colitis, and urinary tract infection is typical.[94–96] Hepatic involvement with rapid progression to liver failure is not uncommon.[95] Ulcerations of the gallbladder wall have also been linked to adenoviral infection.[97] The difference in serotypes affecting healthy and immunocompromised patients may be responsible for the differences in clinical presentation.[98] In adenoviral hepatitis, there is lobular necrosis of the hepatocytes with Cowdry type A basophilic nuclear inclusion bodies. Portal tracts are usually speared. Adenoviral virions can be detected in the hepatocytes by electron microscopy; adenoviral disease is usually more severe. Diagnosis is usually made by viral isolation or histologic examination.

Currently, no effective treatment against adenovirus is available. Use of immunoglobulin (Ig) therapy[99]and intravenous ribavirin[100,101] has been advocated.

Herpes Group Virus Infection

Herpes Simplex Virus (1 and 2). Herpes simplex virus (HSV) dissemination to the liver has been described in patients with HIV.[102] Significant dissemination more commonly occurs with primary infection, although it has also been observed with reactivation. Fulminant liver disease may be the only presenting symptom because mucocutaneous lesions may be absent in up to 50% of the patients.[103] Patients present with significantly elevated transaminases, jaundice, and rapidly progressive liver failure.[80] Liver biopsy demonstrates characteristic intranuclear inclusions (Cowdry type A bodies) in hepatocytes. The intranuclear inclusion bodies produce a typical ground-glass appearance. Although a mild neutrophilic infiltrate is sometimes described, a notable feature of HSV disease is the absence of a significant inflammatory cell response in either the portal areas or parenchyma. Fatty degeneration is frequently observed. Electron microscopy is confirmatory and demonstrates typical intranuclear herpes virions. Viral cultures are usually positive (in more than two-thirds of cases) and should always be obtained.[104] Prompt initiation of acyclovir treatment, as well as discontinuation of all potentially hepatotoxic medications, is recommended.

Human Herpesvirus 3 (Varicella-Zoster Virus). Dissemination of varicella-zoster virus (VZV) infection may occur with primary infection or with reactivation. Certain clinical features distinguish severe VZV and HSV infections. In contrast to HSV, VZV disease is typically accompanied by classic skin and mucous membrane lesions. These lesions are usually obvious on presentation but may be delayed by

3 to 4 days. The main target organ of VZV is the lung. Although the liver is commonly involved in disseminated VZV disease, fulminant hepatitis without significant pulmonary disease is rare.[103] Abdominal pain, nausea, and vomiting are common. Elevated transaminases, with or without bilirubin elevation, and leukocytosis are common with VZV disease, in contrast to the leukopenia associated with HSV dissemination. Coagulopathy, renal failure, and multiorgan system failure are typical of severe VZV.

Immediate administration of varicella-zoster Ig to individuals with no history of chickenpox or without vaccination is recommended within 96 hours of exposure.[103] Prophylactic acyclovir should be prescribed. Intravenous acyclovir is reserved for patients with clinical signs of VZV, and the recommended doses are higher than those for HSV disease.[103]

Among HIV-positive patients, only asymptomatic, nonimmunosuppressed patients should be vaccinated against VZV. Vaccination is contraindicated in all other HIV-positive children.

Human Herpesvirus 4 (Epstein-Barr Virus). Epstein-Barr virus (EBV) infection may present as an acute mononucleosis syndrome, but it has also been implicated in the pathogenesis of non-Hodgkin lymphoma, leiomyomas, and leiomyosarcomas of the liver in children with AIDS.[104,105] If acute mononucleosis syndrome occurs, low-grade fever, abdominal discomfort, nausea, mild hepatomegaly, and lymphadenopathy are common. Hepatitis is frequently present but usually resolves completely. Minimal swelling and vacuolization of hepatocytes associated with lymphocytic and monocytic infiltration of the portal areas are noted in the liver biopsy. Extensive liver necrosis has also been described in HIV patients.

Non-Hodgkin lymphoma is a common feature of AIDS and has been associated with EBV infection. The EBV viral genome has been found within tumor cells by DNA hybridization.[105] It may occur at any stage of AIDS but usually occurs late in the disease. The prevalence of non-Hodgkin lymphoma in HIV is increasing, leading some to suggest that it is the most common AIDS-related neoplasm.[4] Isolated liver involvement without extrahepatic disease has been reported in up to 14% of AIDS patients.[2] Elevation of serum alkaline phosphatase is a very sensitive marker of hepatic involvement; elevation of transaminases and bilirubin is usually observed in the advanced disease. The typical symptoms seen in immunocompetent patients, such as weight loss, night sweats, and fever, are often absent.[105] An abdominal CT scan may help with the diagnosis of non-Hodgkin lymphoma.[4]

Leiomyomas and leiomyosarcomas are extremely rare tumors in children. The incidence of these lesions is increased in pediatric HIV patients. Quantitative polymerase chain reaction (PCR) analysis demonstrated very high levels of EBV in tumor tissue from these patients. No EBV was detected in normal tissues of the same patients or in the tumor tissue of subjects not affected by HIV.[104] The lesions in HIV patients tend to involve the gastrointestinal tract, liver, and lungs.

Human Herpesvirus 6B. Human herpesvirus 6B (HHV-6B) has been implicated in causing roseola (exanthem subitum) in immunocompetent patients. In immunocompromised patients, severe disseminated HHV-6B infection occurs with primary infection and may cause fulminant hepatitis.[106,107] Transaminase elevation, cholestasis, thrombocytopenia, and leukopenia have been reported. There is focal hepatocyte necrosis with mild lymphocytic infiltration of the portal tracts and sinusoids. HHV-6 is detectable in the lymphocytes. The clinical manifestations of HHV-6/-7 reactivation have not been described. Indications for therapy are not clearly defined, but in vitro susceptibility to ganciclovir has been described.[108]

Human Herpesvirus 8. Human herpesvirus 8 viral infection is associated with Kaposi sarcoma, a neoplasm involving skin, mucous membranes, and internal organs. Liver involvement usually occurs as part of a disseminated process, although primary liver disease has also been described.[3,109] Patients are rarely symptomatic from liver disease, although an elevated serum alkaline phosphatase level may be present. Owing to significant sampling error, the diagnosis may be missed if an unguided liver biopsy is performed. Histologically, the lesions appear as dark red to purple nodules in the portal regions, filled with spindle-shaped endothelial cells.

OPPORTUNISTIC INFECTIONS

CYTOMEGALOVIRUS

CMV is one of the most common hepatic infections in HIV-positive adults. CMV is seen in 33 to 44% of all patients and in close to 100% of those who are severely immunosuppressed (CD4 count < 100 cells/mm^3).[80] The incidence of CMV infection associated with symptomatic disease has not been well documented in the pediatric HIV population, with a range of 30 to 60% cited in the literature.[110] The presentation of CMV hepatitis is usually mild, with fever, malaise, hepatomegaly, and transaminitis. CMV typically infects hepatocytes and Kupffer cells, as well as endothelial cells. Inflammation in the portal and periportal areas is usually observed. Intranuclear and intracytoplasmic inclusion bodies are often surrounded by a clear halo ("owl-eye" appearance), and giant cells may be seen in the biopsies.[3,4,13] Less frequently, CMV may affect the biliary epithelium, leading to acalculous cholecystitis, papillary stenosis, and sclerosing cholangitis.[3,4,111]

The diagnosis of CMV may be difficult. The significance of a positive urine culture is unclear because viruria may represent asymptomatic shedding and may persist for months to years.[110] CMV viremia is a much better predictor of active disease.[112] In one study, CMV disease was evident in 57% of children with blood cultures positive for CMV compared with 17% of children with positive urine cultures.[110] There are no controlled trials addressing the use of foscarnet or ganciclovir in the setting of CMV hepatitis. The experience treating nonhepatic infections may suggest their use in hepatitis patients.

Protozoa

Pneumocystis carinii. *Pneumocystis carinii* pneumonia (PCP) is the most common protozoal pathogen among patients with AIDS. The incidence of PCP infection has decreased dramatically, first with the institution of routine PCP prophylaxis and later with the introduction of the HAART regimen. Pulmonary symptoms are the hallmark of *P. carinii* infection. Disseminated infection is not common. Only a few cases of isolated hepatic involvement have been described.[113] It has been suggested that widespread use of aerosolized pentamidine for PCP prophylaxis has contributed to the appearance of *P. carinii* infections of other organs.[114,115] Clinical findings are limited to mild abdominal pain with variable elevation of transaminases. Isolated cases of an obstructive process with increased γ-glutamyl transpeptidase have been reported.[116] Abdominal CT may reveal diffuse punctate calcifications of the liver.[80] Pathology from liver biopsy specimens demonstrates foamy eosinophilic exudate, with the organism demonstrable on silver stain. Acellular nodules in a random or periportal distribution in the lobule, with or without infiltration of the hepatic sinusoids, have also been described.[116,117]

Cryptosporidium. *Cryptosporidium* is the most commonly identified cause of AIDS-related cholangitis. It has been identified in the bile ducts or stools from 20 to 62% of patients with AIDS-related cholangitis.[24] It has been estimated that 10 to 16% of patients with intestinal cryptosporidiosis may develop biliary tract symptoms.[118] Infiltration of portal spaces with eosinophils, plasma cells, and lymphocytes is observed in liver biopsies. Ulceration of the duct epithelium with basophilic Giemsa stain–positive organisms, attached to the luminal surface of the epithelial cells, may be noted.[119]

Microsporida. *Microsporida* is a less common cause of AIDS cholangitis, occurring in less than 10% in most series.[120] The incidence of this infection may be underestimated because techniques for the detection of *Microsporida* are not well developed.[25] The two microsporidia most commonly associated with the disease are *Enterocytozoon bieneusi* and *Enterocytozoon intestinalis*. Clinical symptoms are not different from the cholangitis caused by other organisms and include right upper quadrant pain, nausea, vomiting, and fever. Many patients have associated diarrhea and weight loss. Jaundice is present in only 10% of patients.[121] The diagnosis is based on the detection of *Microsporida* in the stool or bile aspirates. Tissue obtained from the duodenum, ampulla, bile duct, or liver may also be used. Pathogens identified in stools or bile may provide circumstantial evidence that the organism is the etiology of cholangitis. A biopsy specimen from the bile duct revealing the pathogen and inflammation suggests that this pathogen is actually causing cholangitis. Pathogens may be identified in up to 75% of cases.[121]

Fungi

Fungal infections involve the liver only in disseminated disease. These infections share a nonspecific clinical presentation, including fever, hepatomegaly, elevated alkaline phosphatase, and bilirubin.[3] Hepatic involvement may accompany cryptococcal meningitis in the setting of hematogenous dissemination. Opportunistic infections with *Histoplasma*, *Coccidioides*, *Candida*, and *Sporothrix* occur less commonly.[80] Imaging studies may demonstrate diffuse irregularity of the liver parenchyma or, rarely, a formed fungal abscess. Liver biopsy demonstrates nonspecific poorly formed granulomata with minimal inflammatory response.[122] The response to prolonged antifungal therapy is variable, with death resulting from disseminated infection rather than from hepatic involvement itself.

Mycobacteria

MAC includes two closely related species: *M. avium* and *M. intracellulare*. These organisms are small, gram-positive, acid-fast bacilli. Bacterial proliferation typically occurs in the macrophages and is controlled by cell-mediated immunity. With a decrease of the CD4 count, proliferation of the bacteria becomes poorly controlled, and patients are at risk for disseminated MAC infection. CD4 counts of less than 50 cells/mm^3 have been described in patients with disseminated MAC.[123] It is the most common opportunistic pathogen found in AIDS patients. In one series, MAC was found in 38% of cases when liver biopsy was performed.[3] The clinical presentation of disseminated infection is nonspecific and may be attributable to the advanced HIV. Fever, weight loss, hepatomegaly, and anemia have been described. A unique feature of MAC disease in HIV patients is marked elevation of alkaline phosphatase. The enzyme may reach 20 to 40 times the normal level, with little elevation of transaminases, bilirubin, or other parameters of hepatic function.[3] Fractionation shows it to be hepatic in origin. The histologic picture does not show marked abnormalities. This disparity between measured levels and histology suggests interference with enzyme metabolism rather than hepatic destruction.[124]

Diagnosis of MAC infection is based on cultivation of *M. avium* from the liver tissue.

Histology of the liver reveals diffuse, poorly formed noncaseating granulomata, composed mainly of foamy histiocytes. In MAC infection of patients with AIDS, granulomas usually do not contain multinuclear giant cells. Granuloma may be absent in up to 25% of patients. Acid-fast bacilli are found within and around granulomas.

In contrast, *Mycobacterium tuberculosis* is found in patients who are less immunosuppressed (CD4 > 200 cells/mm^3).[3] Extrapulmonary infection with *M. tuberculosis* is seen in over 50% of adult AIDS patients with lung disease.[80] In one study, 7.5% of patients with extrapulmonary disease had hepatic infection.[125] The clinical presentation in these patients is similar to *M. avium* infection; in addition, cough, night sweats, and sputum production may be noted. Tuberculous abscess and biliary obstruction owing to bile duct tuberculoma have rarely been described in adult HIV patients. Liver biopsy reveals well-formed caseating granuloma with a lesser load of acid-fast bacilli compared with MAC infection. Other mycobacteria implicated in liver disease are *Mycobacterium xenopi*, *Mycobacterium genavese*, and *Mycobacterium kansasii*.

Before the availability of HAART, the median survival time in patients with disseminated MAC infection ranged from 5 to 11 months.[123,126] Clinical manifestations of MAC in children receiving HAART have not been described. Treatment regimens have been evaluated in the adult population,[127] with gastrointestinal tuberculosis usually responding to 9 to 12 months of combination antibiotic therapy. Current recommendations for the initial treatment include clarithromycin and azithromycin in combination with ethambutol and rifabutin.[128]

PRIMARY IMMUNODEFICIENCY

Patients with primary immunodeficiency syndromes may have liver disease. Liver infections in these patients can occur due to an increased predisposition to a variety of infectious processes. Causative organisms may vary, based on the type of immunologic defect (Table 51.3-3).

Chronic Granulomatous Disease

Chronic granulomatous disease (CGD) is characterized by the inability of phagocytic cells to reduce molecular oxygen and create the active oxygen metabolites that are necessary for efficient intracellular microbicidal activity. CGD is inherited in an autosomal recessive or X-linked manner. CGD represents a group of four related disorders. The types of infections most frequently encountered include pneumonia, osteomyelitis, skin and soft tissue abscesses, and liver abscess. The increased susceptibility to infection among patients who have CGD is limited to bacteria and fungi that are catalase positive and do not themselves have any production of reduced oxygen metabolites, such as hydrogen peroxide. Catalase-positive organisms are not killed efficiently by the phagocytic cells in patients who have CGD. In contrast, microorganisms that are catalase negative and can produce hydrogen peroxide supply the necessary reactive oxygen metabolites when they are ingested, thereby contributing to their own demise. *Staphylococcus aureus* and *Pseudomonas aeruginosa* are the two most common isolates from a liver abscess in patients with CGD.[129] Needle aspiration of the abscess is needed for the etiologic diagnosis. The use of drainage procedures is limited by poor healing.

Antibiotic therapy should always include penicillinase-resistant penicillin such as nafcillin or oxacillin. These medications may be combined with gentamicin for synergism. Reports of utility of interferon-γ[130] and granulocyte transfusion[131] combined with surgical drainage[132] are present in the literature. Antibiotic prophylaxis with trimethoprim-sulfamethoxazole[133] and use of interferon-γ[130] appear to decrease the incidence of serious infections, including liver abscess, in patients with CGD.

Shwachman Syndrome

Shwachman syndrome primarily affects the exocrine pancreas, bone marrow, and skeleton. The most prominent features seen in this disorder include neutropenia, pancreatic insufficiency, and short stature. Hepatic involvement has frequently been reported with this syndrome and usually manifests as hepatomegaly and elevated transaminases. Biopsy specimens demonstrate steatosis and mild fibrosis. Progression of the liver disease is uncommon.[134,135]

X-Linked Agammaglobulinemia

X-linked agammaglobulinemia presents with recurrent infections in male infants after 9 months of age owing to a failure to synthesize all classes of Igs. Recurrent otitis, sinusitis, pneumonias, and diarrhea are typical. An association with sclerosing cholangitis has occasionally been described. It is not clear whether sclerosing cholangitis is associated with increased autoimmunity in these patients[136] or is caused by opportunistic infections such as cryptosporidiosis.[137]

An unusual syndrome of severe enteroviral infection, most commonly caused by echovirus type 11, has been described in these patients.[138] Patients usually present with meningoencephalitis that has a progressive, usually fatal course. Typical manifestations include fever, dermatomyositis, and significant hepatitis. These symptoms may precede the development of neurologic symptoms. The neurologic disease usually determines survival in these patients.

Common Variable Immunodeficiency

Common variable immunodeficiency is an uncommon disorder with more than 95% of the patients presenting with recurrent sinopulmonary infections. The liver is usually affected by a granulomatous process. This process is thought to be caused by a cytokine disturbance, especially increased production of tumor necrosis factor-α.[139] Approximately 20% of patients have elevated alkaline phosphatase levels that are thought to represent presinusoidal granuloma formation. Most of the patients with liver involvement will develop portal hypertension, esophageal varices, and cirrhosis.

Severe Combined Immunodeficiency

Severe combined immunodeficiency (SCID) is a group of genetic disorders characterized by a block in T-lymphocyte differentiation and may be associated with abnormalities in other lymphocyte lines. At least eight separate diseases comprise this category. Findings indicating combined immunodeficiency include lymphocytopenia; absence of lymph nodes, tonsil tissue, and a thymic shadow on radiographs; low levels of serum Igs; and absent in vitro B- and T-lymphocyte responses to antigens and mitogens. Owing to profound immunosuppression, frequent and severe infections caused by pathogens and opportunistic organisms are commonly observed and may include the liver. In addition, sclerosing cholangitis, possibly caused by biliary tract infection with *Cryptosporidium*, has been reported. Two disorders in this group deserve separate mention with regard to liver disease.

Adenosine deaminase (ADA) deficiency is a systemic metabolic disorder. The enzymatic defect is expressed in all cells, and deoxyadenosine triphosphate, a by-product produced in this disorder, is built up in all cells. Deoxyadenosine triphosphate is extremely toxic to lymphocytes, so 85 to 90% of patients who are ADA deficient present with a picture consistent with severe combined immunodeficiency. These patients are lymphopenic at birth and are pre-

TABLE 51.3-3 COMMON PATHOGENS IN CONGENITAL IMMUNOLOGIC DEFECTS

ABNORMALITY	EXAMPLE	LIVER DISEASE	PATHOGENS			
			BACTERIA	FUNGI	VIRUSES	PROTOZOA
Phagocyte defects						
Quantitative	Neutropenia	Rare	Staphylococci,	*Candida*,		
Qualitative	CGD	Common	streptococci,	*Aspergillus*		
	Shwachman syndrome	Common	*Nocardia*,			
	Leukocyte adhesion defect	Rare	*Escherichia coli*,			
			Klebsiella			
Immunoglobulin deficiencies	X-linked agammaglobulinemia	Rare	*Klebsiella*,		Enteroviruses,	*Giardia*
	Common variable immunodeficiency	Common	*Haemophilus influenzae*,		echoviruses,	
	Hyper IgE (Job) syndrome	Rare	*Streptococcus pneumoniae*		CMV, HSV	
Complement deficiencies		Rare	*S. pneumoniae*,			
			H. influenzae,			
			Neisseria			
Cellular and combined immunodeficiencies	SCID	Common	Mycobacteria,	*Candida*,	CMV,	*Pneumocystis carinii*,
	DiGeorge syndrome	Rare	*Salmonella* spp,	*Histoplasma*,	VZV,	*Toxoplasma gondii*,
	Wiskott-Aldrich syndrome	Rare	*Listeria* spp,	*Cryptococcus*	HSV,	*Cryptosporidium*,
	X-linked lymphoprolipherative syndrome	Common	*Legionella* spp		EBV	*Microsporida*,
						Isospora spp

CGD = chronic granulomatous disease; CMV = cytomegalovirus; EBV = Epstein-Barr virus; HSV = herpes simplex virus; IgE = immunoglobulin E; SCID = severe combined immunodeficiency; VZV = varicella-zoster virus.

disposed to recurrent illnesses caused by both pathogens and opportunistic organisms. Symptoms often begin within a few weeks of birth. Pneumonia, intractable diarrhea, and extensive candidiasis are common. Profound failure to thrive is also frequently present. A growth abnormality of costochondral junctions causing cupping and flaring of rib ends on radiograph has been associated specifically with ADA deficiency. Elevated serum levels of hepatic transaminases are not uncommon in ADA-deficient patients, but the cause usually is not determined. Severe bridging fibrosis has been described in liver specimens during autopsy.[140] Bollinger and colleagues described a patient with ADA deficiency and persistent neonatal hepatitis, apparently unrelated to infection or graft-versus-host disease (GVHD), that responded to ADA replacement therapy.[141] It is thus possible that the toxic effects of ADA substrates may be responsible for the liver disease in these patients.

Omenn syndrome is another variant of SCID. T-lymphocyte infiltration of the skin and gut is the hallmark of this condition. Patients present with erythroderma, alopecia, protein-losing enteropathy, and failure to thrive. Life-threatening infections are common. Marked hepatosplenomegaly and lymphadenopathy may be present within the first weeks of life. Laboratory evaluation usually demonstrates elevated white blood cell and eosinophil counts, increased IgE, hypogammaglobulinemia, and histiocytosis. Severe liver disease, likely owing to infiltration with T cells and histiocytes, is associated with this condition.[142]

X-Linked Lymphoproliferative Syndrome

In 1975, Purtilo and colleagues described a kindred with 18 boys, of whom 6 died of a lymphoproliferative disorder.[143] This syndrome has since been linked to infection with EBV. The affected boys had a T-cell regulatory defect that made them extremely vulnerable to EBV infection, which often is fatal.[144] The immune defect allows an explosive proliferation of B cells after exposure to EBV. Liver involvement is a prominent feature, with progression to multiorgan system failure, and death is typical. Of the patients who survive the initial infection with EBV, 24% will acquire a malignant lymphoproliferative disorder at a median age of 4.9 years. All neoplasms have a B-cell phenotype. The majority of the non-Hodgkin lymphomas occur in the intestinal region, especially the ileocecal area. The overall risk of having a lymphoma has been estimated to be 200 times higher than that for the general population.[144]

INFECTIONS IN TRANSPLANT RECIPIENTS

Infectious complications following solid organ transplant may be divided into three time periods.[145] The early post-transplant period (first 4 weeks) is characterized by nosocomial bacterial and fungal infections. The only significant viral infection observed during the early period after transplant is caused by recurrent HSV.

The risk of infection is directly related to the surgical procedure itself, invasive monitoring with intravascular catheters, or preexisting infection in the donor or recipient. Typically, the specific sites of transplant and allograft are the most likely sites of infection. For example, liver transplant recipients are at risk for biliary sepsis and liver abscesses.

From 1 to 6 months post-transplant, infections are often related to the use of immunosuppressive agents. CMV is the dominant pathogen causing disease during this period. Other major pathogens are *Cryptococcus*, *Candida*, tuberculosis, HBV and HCV, and EBV. Infectious complications that occur later than 6 months after transplant are usually due to one of two factors: the effect of chronic viral infection acquired earlier or chronic graft dysfunction, which requires repeated courses of immunosuppression and puts patients at risk for infection with opportunistic organisms.

The course of the patients who undergo bone marrow transplant may also be divided into three phases.[146] The early phase corresponds to the first 2 to 4 weeks post-transplant. The predominant risk factor in this period is profound neutropenia and damage to mucosal surfaces. Invasive fungal and bacterial infections predominate during this period.

Between the period of engraftment and weeks 15 to 20 post-transplant, infections with opportunistic pathogens (CMV, *P. carinii*) predominate. The major predisposing factors for these infections are the immunosuppressive effects of acute GVHD and its treatment. Serious infections occurring 4 to 6 months after transplant are seen predominantly in patients with chronic GVHD.[146] Liver infections are rare in this period, with the most common being EBV infection.

The majority of patients undergoing solid organ or bone marrow transplant show evidence of CMV infection (a rise in titers or viral isolation from the urine or blood). However, not all patients develop clinical disease. The major determinant of the progression to disease is whether the infection with CMV is primary or secondary. If the organ from a CMV-positive donor is transplanted into a CMV-negative recipient, this will result in primary infection. Primary infection is more likely to be associated with the disease than is CMV reactivation.[147] The severity of the immunosuppression is another determining factor. In general, bone marrow transplant patients have more severe manifestations of CMV disease compared with solid organ transplant patients. Clinical manifestations of CMV infection in transplant recipients are usually a mononucleosis-type syndrome with fever, leukopenia, and elevated transaminases. Interstitial pneumonitis may be life threatening. Liver disease is rarely severe.[146] CMV infection in liver transplant patients may be associated with a higher risk of acute rejection[148] and possibly with an increased incidence of hepatic artery thrombosis owing to endothelial cell infection.[149] HSV and VZV infections are also common during this time, with a clinical course that is similar to that in HIV-infected patients.

EBV is responsible for a number of disorders, but the major concern in solid organ transplant recipients is post-transplant lymphoproliferative disorder (PTLD). Acute infection with EBV leads to polyclonal activation of B cells with expansion of lymphoid tissues. Because the cellular immune responses provided by natural killer and cytotoxic T cells are critical to clearing the virus, the T cell–targeted immunosuppression used in organ transplant puts allo-

graft recipients at risk for PTLD.[150] It has now been well established that as the level of immunosuppression increases, so does the incidence of PTLD.[151,152]

Primary EBV infection, young age, and receiving an EBV-positive donor organ are interrelated predisposing factors to PTLD and are particularly important in pediatric transplant recipients.[153] Many young children, usually EBV negative, receive grafts from older donors who are much more likely to have had previous EBV infection.

Sites of involvement include the small bowel, the intra-abdominal lymph nodes, the tonsillar bed, and the liver. Patients may present immediately post-transplant or months to years after successful transplant. Fever, weight loss, lymphadenopathy, hepatosplenomegaly, and abdominal pain are typical presenting findings. Hepatitis may resemble rejection episodes in liver transplant patients.[150]

How best to prevent EBV infection in the EBV-naive recipient is debatable.[154] Some protocols use intravenous ganciclovir for variable lengths of time; others rely primarily on CMV hyperimmunoglobulin. Along with a preventive strategy, there should be a method of detecting when EBV infection or reactivation first occurs so that immunosuppression levels can be decreased promptly. This determination is best accomplished by serially monitoring the peripheral blood for EBV by quantitative PCR techniques.[155–157]

Hepatitis B infection tends to be more aggressive in immunosuppressed patients. An accelerated course of the disease was described after kidney transplant.[158]

Reactivation of previously quiescent disease has been described in children undergoing chemotherapy[159] and in patients after bone marrow transplant.[160] Hepatitis B may result in mortality rates as high as 12% in bone marrow transplant patients.[161] Increased mortality from liver disease in recipients of kidney transplants has been found in some studies, but if it occurs, it is seen 10 years or more following renal transplant.[162] Fibrosing cholestatic hepatitis is a rare, early, severe complication of renal transplant in HBV-infected recipients of kidney transplants.[163] It is characterized by cholestasis, with only a mild to moderate increase in aminotransferase levels, and by a rapid deterioration in liver function that can lead to short-term liver failure. The liver histology demonstrates periportal and perisinusoidal cholestasis, scarce mixed infiltrates, hepatocellular ballooning, and histologic cholestasis.

In addition, the acquisition of HBV soon after renal transplant carries a risk of early death from liver failure.[162] Reactivation of HBV after renal transplant in patients with preexisting HBV surface antibodies has been reported.[164] Use of immunosuppressive medications has been demonstrated to increase viral replication in vitro.[165] Viral mutations may also be responsible for the more aggressive course of the disease.[166] Hepatitis B–induced chronic liver disease is one of the main indications for liver transplant in adults. Thus, viral reinfection of the allograft is a major challenge in this population but is a less common issue in pediatrics.

The use of hepatitis B immunoglobulin during and after transplant has been proven to decrease the incidence of the recurrence rate in up to 80% of the patients.[167] The limitations of this treatment are indefinite length of the therapy, need for parenteral administration, and drug cost.[168] Other medications used to prevent HBV include agents used in the treatment of HBV in the nontransplant setting. Interferon-α is poorly tolerated and has limited efficacy in this population. Lamivudine and adefovir have been successfully used to prevent HBV recurrence.[58,169] The combination of lamivudine with hepatitis B immunoglobulin has completely eliminated recurrent HBV disease in some series.[170] Previously vaccinated patients who are HBsAg negative should be tested annually for anti-HBV antibodies and should receive booster vaccinations[171] when the titer decreases to < 10 mIU/mL. Allografts from donors who are positive for HBsAg should not be used. Controversy exists with respect to whether allografts from donors who are HBV core antibody positive should be used.

Hepatitis C infection may be caused either by exposure to contaminated blood products or tissues or via recurrence of preexisting HCV infection following liver transplant. In the pediatric population, the former is the more common route. HCV can also be transmitted with other allografts in addition to the liver. In one study, 42% of patients receiving kidneys from donors seropositive for HCV developed clinical hepatitis.[172] Organs from donors with HCV antibody who are HCV RNA positive are most likely to transmit HCV infection, but organs from donors who are HCV antibody positive and HCV RNA negative cannot be regarded as completely safe.[173]

Virtually all liver transplant recipients who are viremic with HCV at the time of transplant will become reinfected.[174–176] Factors associated with a more rapid progression of the disease after transplant may include the degree of immunosuppression,[177] coinfection with CMV,[178] and HCV genotype 1b.[179] In bone marrow transplant patients, HCV infection is a major cause of post-transplant cirrhosis. Clear association with veno-occlusive disease has also been observed.[180] The evolution of the liver disease is typically slow, with the disease following a similar course in liver, heart,[181] kidney,[182] and bone marrow transplant patients. Short-term survival is not affected in kidney transplant patients, but long-term (10 and 20 years) outcome was significantly worse in HCV antibody–positive patients.[183,184] Fibrosing cholestatic hepatitis is the only early but serious complication of HCV infection observed in transplant patients.[180] The clinical and pathologic features are similar to the one described in hepatitis B. Diagnosis is made by detection of HCV RNA by reverse transcriptase PCR and other assays because serology is a poor marker of HCV infection in transplant recipients.[185,186] Liver biopsy is important to confirm the diagnosis histologically and to delineate the severity of the disease.

Treatment is similar to that in the normal host. Interferon alone or in combination with ribavirin is typically used. The concern with the use of interferon is its association with graft rejection in renal transplant; however, these issues do not appear to be valid in liver transplant recipients. The response rates to treatment are lower than those seen in immunocompetent patients.[187] Preemptive therapy prior to liver transplant tends to reduce the viral load and is associated with milder disease and slower progression.

Invasive candidiasis is a major cause of mortality and morbidity in patients with hematologic malignancies. Hepatosplenic involvement is typical, as was initially described by Bodey and colleagues.[188] Risk factors for invasive disease include the presence of acute leukemia, prolonged neutropenia, intravascular catheters, disruption of mucosal barriers, and the administration of broad-spectrum antibiotics.[189] Invasive candidal infection is extremely rare in nonleukemic patients.

Hepatosplenic candidiasis initially presents as neutropenia and fever without focal signs or symptoms that fails to respond to broad-spectrum antibiotics. Liver function tests, as well as ultrasonography and CT scan of the abdomen, are generally normal at this point. Often the patient's leukemia goes into remission, and the neutrophil count recovers. However, high fever, anorexia, and weight loss persist. Right-sided abdominal pain or pleuritic chest pain may be present. Substantial elevation of alkaline phosphatase is noted and may persist for months. Elevation of other liver function tests is usually present but is less impressive.[189]

CT scan identifies lesions in about 90% of the patient, and ultrasonography visualizes pathology in 70 to 75% of patients.[190] CT scan demonstrates small, round, low-attenuation lesions scattered throughout the liver and spleen. The appearance on CT scan is not pathognomonic and may mimic metastatic disease or bacterial abscesses. Histologically, three patterns have been observed: necrosis with minimal inflammatory reaction, microabscesses with severe inflammation, and granulomas.[191] Granulomatous inflammation is usually seen in the liver. Central areas of necrosis or fibrosis, surrounded by granulation tissue, are seen; macrophages, fibroblasts, and giant cells are typically observed.[189]

The diagnosis of invasive candidiasis requires a high index of suspicion. No single noninvasive study is sufficient to establish a diagnosis, and liver biopsy is frequently performed. Because many infections may cause granulomatous inflammation, and given the small size of the lesions, percutaneous liver biopsy may fail to establish the diagnosis. Open liver biopsy is considered by many to be the most reliable way of diagnosing hepatosplenic candidiasis.[192] The optimal management of this condition is not yet established. The response rate to the liposomal formulation of amphotericin B is much better than the response rate to the regular formulation: 85 to 90% versus 50%.[193–195] Fluconazole has a response rate of about 80% and may be effective even in patients who failed to respond to amphotericin B treatment.[193,194,196] It is believed that fluconazole should be the drug of choice for hepatosplenic candidiasis because it is at least as effective as amphotericin B, is less toxic, may be given orally, and is less expensive than liposomal amphothericin B.[197] Usually, it takes 2 to 3 weeks to see a measurable response.

CHAPTER 52

AUTOIMMUNE DISEASE

Diego Vergani, MD, PhD, FRCP
Giorgina Mieli-Vergani, MD, PhD, FRCPCH

Autoimmune liver disorders are inflammatory liver diseases characterized histologically by a dense mononuclear cell infiltrate in the portal tract and serologically by the presence of nonorgan and liver-specific autoantibodies and increased levels of immunoglobulin G (IgG), all in the absence of a known etiology. These disorders usually respond to immunosuppressive treatment, which should be instituted as soon as a diagnosis is made. The onset of these conditions is often ill-defined, and they frequently mimic acute hepatitis; the previously accepted requirement of 6 months duration of symptoms before a diagnosis of autoimmune disease can be made has been abandoned.[1,2]

There are three liver disorders in which liver damage is likely to arise from an autoimmune attack: autoimmune hepatitis (AIH), autoimmune sclerosing cholangitis (ASC), and de novo autoimmune hepatitis after liver transplant.

According to data collected at our tertiary center, there appears to be an increase in the yearly incidence of AIH and ASC in childhood. Thus, in the 1990s, these conditions represented 2.3% of children older than 4 months referred to our unit during 1 year, whereas in the past 3 years, their incidence has increased to 12%.

AUTOIMMUNE HEPATITIS

Clinical Features

Two types of AIH are recognized according to the presence of smooth muscle antibody (SMA) and/or antinuclear antibody (ANA) or liver/kidney microsomal type 1 antibody (LKM-1). A major target of SMA is the actin of smooth muscle,[3] whereas the molecular target of LKM-1 is cytochrome P-4502D6 (CYP2D6).[4] Pediatric series, including our own, report a similarly severe disease in ANA/SMA-positive and LKM-1–positive patients.[5,6] We reviewed the clinical, biochemical, and histologic features and outcomes of ANA/SMA-positive or LKM-1–positive AIH in 52 children referred between 1973 and 1993 (Table 52-1).[6] Thirty-two patients were ANA and/or SMA positive, and 20 were LKM-1 positive. All other known causes of liver disease were excluded. Only one child with the LKM-1 antibody presented with acute liver failure and had received plasma transfusions abroad before referral, as well as had evidence of exposure to hepatitis C virus (HCV) infection, being positive for anti-HCV antibody by second-generation assay. There was a predominance of girls (75%) in both groups. Although LKM-1–positive patients presented at a younger age (median 7.4 versus 10.5 years), the duration of symptoms before diagnosis and the frequency of hepatosplenomegaly were similar in the two groups. There was also no significant difference in the frequency of associated autoimmune disorders and a family history of autoimmune disease between the two groups. Associated autoimmune disorders included nephrotic syndrome, thyroiditis, Behçet's disease, ulcerative colitis, insulin-dependent diabetes, and urticaria pigmentosa in ANA/SMA patients and thyroiditis, vitiligo, hypoparathyroidism, and Addison disease in LKM-1 patients.

We observed three clinical patterns of disease: (1) In 50% of ANA/SMA-positive and 65% of LKM-1–positive patients, the presentation was indistinguishable from that of acute viral hepatitis (nonspecific symptoms of malaise, nausea/vomiting, anorexia, and abdominal pain, followed by jaundice, dark urine, and pale stools); six children (five LKM-1 positive) developed acute hepatic failure with grade II to IV hepatic encephalopathy from 2 weeks to 2 months (median 1 month) after onset of symptoms. In the remaining children, the duration of disease before diagnosis ranged from 10 days to 5 months (median 1.8 months). (2) Twenty-five percent of LKM-1–positive and 38% of ANA/SMA-positive patients had an insidious onset, with an illness characterized by progressive fatigue, relapsing jaundice, headache, anorexia, and weight loss, lasting from 6 months to 2 years (median 9 months) before diagnosis. (3) In six patients (two LKM-1 positive), there was no history of jaundice, and the diagnosis followed presentation with complications of portal hypertension, such as hematemesis from esophageal varices, bleeding diathesis, chronic diarrhea, weight loss, and vomiting.

The mode of presentation of AIH in childhood is therefore variable, and the disease should be suspected and excluded in all children presenting with symptoms and signs of prolonged or severe liver disease.

Laboratory features at presentation are summarized in Table 52-2. Overall, LKM-1–positive patients had higher median levels of bilirubin and aspartate aminotransferase than those who were ANA/SMA positive, but if the six patients presenting with acute hepatic failure are excluded, the differences for these two parameters are not significant. A severely impaired hepatic synthetic function, as assessed by the presence of both prolonged prothrombin time and

TABLE 52-1 CLINICAL FEATURES AT PRESENTATION IN 52 PATIENTS WITH AUTOIMMUNE HEPATITIS DIVIDED ACCORDING TO ASSOCIATED AUTOANTIBODIES

FEATURE	ANA/SMA POSITIVE AIH (*n* = 32)	LKM-1 POSITIVE AIH (*n* = 20)	*p* VALUE

AIH = autoimmune hepatitis; ANA/SMA = nuclear and/or smooth muscle antibody; APS-1 = autoimmune polyendocrine syndrome type 1; GGT = γ-glutamyl transpeptidase; LKM-1 = liver kidney microsomal type 1 antibody.
*Some subjects have more than one disorder.

hypoalbuminemia, tended to be more common in ANA/SMA-positive patients (53%) than in LKM-1–positive patients (30%). The majority (80%) of the patients had increased levels of IgG, but 10 (5 LKM-1 positive) had a normal serum IgG level for age, including 3 patients who presented with acute hepatic failure, indicating that normal IgG values do not exclude the diagnosis of AIH. As previously reported, we found that partial IgA deficiency is significantly more common in LKM-1–positive patients than in ANA/SMA-positive patients (45% versus 9%).[7]

When compared with those of controls, the frequencies of the human leukocyte antigen (HLA)-DR3 were significantly higher in patients with ANA/SMA-positive AIH but not in those with LKM-1–positive AIH. Recent data suggest that possession of DR7 predisposes the patient to type 2 AIH.[8] Although these results should be confirmed in a

AIH = autoimmune hepatitis; ANA/SMA = nuclear and/or smooth muscle antibody; ASGPR = asialoglycoprotein receptor; LKM-1: liver kidney microsomal type 1 antibody; LSP = liver-specific lipoprotein; NA = not applicable; nv = normal value.

larger number of patients and in different centers, they suggest that the immunopathogenic mechanisms involved in the development of the two forms of AIH may be different. Patients with AIH, whether LKM-1 or ANA/SMA positive, have isolated partial deficiency of the HLA class III complement component C4, which is genetically determined, being associated with the possession of the silent gene *C4AQ0* at the C4A locus.[9,10] C4AQ0, either in linkage with DR3 or on its own, has been reported in association with other autoimmune disorders.[11]

The severity of portal tract inflammation, lobular activity, and periportal necrosis, features characteristic of interface hepatitis, at diagnosis was similar in both groups. Cirrhosis on initial biopsy was more frequent in ANA/SMA-positive patients (69%) than in LKM-1–positive patients (38%). Of note is that 57% of patients already cirrhotic at diagnosis presented with a clinical picture reminiscent of that of prolonged acute virus-like hepatitis. Multiacinar or panacinar collapse, which suggests an acute liver injury, was present in eight patients (five LKM-1 positive), six of whom had acute liver failure. In these patients, it was not possible to ascertain the degree of fibrosis or the presence or absence of cirrhosis. The question as to whether the acute presentation in these patients represented a sudden deterioration of an underlying unrecognized chronic process or a genuinely acute liver damage remains open. Progression to cirrhosis was noted in four of seven ANA/SMA-positive patients and in two of five LKM-1–positive patients on follow-up biopsies done between 17 and 56 months from the initial biopsy. Overall, 74% of ANA/SMA-positive and 44% of LKM-1–positive patients showed evidence of cirrhosis on initial or follow-up histologic assessment, indicating that, apart from the higher tendency to present as acute liver failure, the severity of LKM-1–positive disease is not worse than that of ANA/SMA-positive disease. Recently, we have demonstrated that a more severe disease and a higher tendency to relapse are associated with the possession of antibodies to soluble liver antigen, which are present in about half of the patients with AIH type 1 or 2 at diagnosis.[12]

Pathophysiology

The typical histologic picture of AIH, which is characterized by a dense mononuclear cell infiltrate eroding the limiting plate and invading the parenchyma (interface hepatitis), first suggested that autoaggressive cellular immunity might be involved in its causation.[13,14] Immunocytochemical studies have identified the phenotype of the infiltrating cells. T lymphocytes mounting the alpha/beta T-cell receptor predominate. Among the T cells, a majority are positive for the CD4 helper/inducer phenotype, and a sizable minority are positive for the CD8 cytotoxic phenotype. Lymphocytes of non–T-cell lineage are fewer and include (in decreasing order of frequency) natural killer cells (CD16/CD56 positive), macrophages, and B lymphocytes.[15] The recently described natural killer T cells, which express simultaneously markers of both natural killer (CD56) and T cells (CD3), are involved in liver damage in an animal model of autoimmune hepatitis.[16]

A powerful stimulus must be promoting the formation of the massive inflammatory cell infiltrate present at diagnosis. Whatever the initial trigger, it is most probable that such a high number of activated inflammatory cells cause liver damage. There are different possible pathways that an immune attack can follow to inflict damage on the hepatocyte (Figure 52-1). Liver damage is believed to be orchestrated by CD4-positive T lymphocytes recognizing a self-antigenic peptide. To trigger an autoimmune response, the peptide must be embraced by an HLA class II molecule and presented to uncommitted T helper (Th)0 cells by professional antigen-presenting cells (APCs), with the costimulation of ligand–ligand (CD28 on Th0, CD80 on APC) interaction between the two cells. The Th0 cells become activated, differentiate into functional phenotypes according to the cytokines prevailing in the microenvironment and the nature of the antigen, and initiate a cascade of immune reactions determined by the cytokines they produce. Arising in the presence of the macrophage-produced interleukin-12, Th1 cells secrete mainly interleukin-2 and interferon-γ, which activate macrophages, enhance expression of HLA class I (increasing the vulnerability of liver cells to cytotoxic attack), and induce expression of HLA class II molecules on hepatocytes, which then become able to present the autoantigenic peptide to Th cells, thus perpetuating the immune recognition cycle. Th2 cells, which differentiate from Th0 if the microenvironment is rich in interleukin-4, produce mainly interleukin-4, -5, and -10, which induce autoantibody production by B lymphocytes. Physiologically, Th1 and Th2 cells antagonize each other. The process of autoantigen recognition is strictly controlled by regulatory mechanisms. If these regulatory mechanisms fail, the autoimmune attack is perpetuated. Over the past two decades, different aspects of the above pathogenic scenario have been investigated.

An impairment of immunomodulatory mechanisms, which would enable the autoimmune response to develop, has been described in several reports. Children and young adults with AIH have low levels of T lymphocytes expressing the CD8 marker.[17] The notion of defective immunoregulation is supported by the finding that suppressor cell function is also impaired in AIH.[18] Nouri-Aria and colleagues[19,20] have shown that (1) the impairment of immunoregulation segregates with the possession of the HLA haplotype B8/DR3,[19] the haplotype that predisposes to AIH,[21] and (2) this immunoregulatory defect is correctable by therapeutic doses of corticosteroids.[20] In addition, it has been shown that patients with AIH have a specific defect in a subpopulation of T cells controlling the immune response to liver-specific membrane antigens.[22]

Lobo-Yeo and colleagues have shown that hepatocytes from patients with AIH, in contrast to normal hepatocytes, express HLA class II molecules.[23] These hepatocytes, although lacking the antigen-processing machinery typical of APCs, may present peptides through a bystander mechanism.[24] Given the impaired regulatory function and the inappropriate expression of HLA class II antigens on the hepatocytes, the question arises as to whether an autoantigenic peptide is presented to the helper/inducer

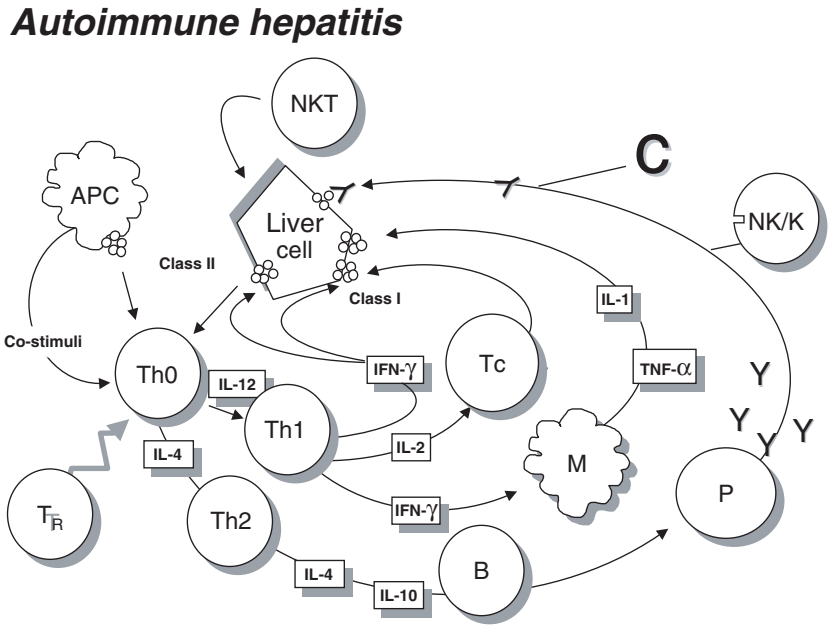

FIGURE 52-1 Autoimmune attack on the liver. A specific autoantigenic peptide is presented to an uncommitted T helper (Th0) lymphocyte within the human leukocyte antigen (HLA) class II molecule of an antigen-presenting cell (APC). Th0 cells become activated and, according to the presence in the microenvironment of interleukin (IL)-12 or IL-4 and nature of antigen, differentiate into Th1 or Th2 and initiate a series of immune reactions determined by the cytokines they produce: Th2 secrete mainly IL-4 and IL-10 and direct autoantibody production by B lymphocytes; Th1 secrete IL-2 and interferon-γ (IFN-γ), which stimulate T cytotoxic (Tc) lymphocytes, enhance expression of class I and induce expression of class II HLA molecules on hepatocytes and activate macrophages; activated macrophages release IL-1 and tumour necrosis factor-α (TNF-α). If T "regulatory" (T_R) lymphocytes do not oppose, a variety of effector mechanisms are triggered: liver cell destruction could derive from the action of Tc lymphocytes; cytokines released by Th1 and recruited macrophages; complement (C) activation or engagement of killer (NK/K) lymphocytes by the autoantibody (Y) bound to the hepatocyte surface. Natural killer T cells (NKT), cells with markers of both natural killer and T cells, are involved in liver damage in an animal model of autoimmune hepatitis. Adapted from Vergani D, Chodhuri K, Bogdanos DP, Mieli-Vergani G. Pathogenesis of autoimmune hepatitis. Clin Liver Dis 2002;6:439–49.

cells, leading to their activation. Although there is no direct evidence as yet that an autoantigenic peptide is presented and recognized, activation of helper cells has been documented in AIH.[15,25] These activated cells possess the CD4 phenotype, and their numbers are highest when the disease is most active.

What triggers the immune system to react to an autoantigen is unknown. A lesson may be learned by the study of humoral autoimmune responses during viral infections. Thus, recent studies aimed at determining the specificity of the LKM-1 antibody, present in both the juvenile form of AIH and in some patients with chronic HCV infection, have shown a high amino acid sequence homology between the HCV polyprotein and CYP2D6, the molecular target of LKM-1, thus implicating a mechanism of molecular mimicry as a trigger for the production of LKM-1 in HCV infection.[4,26,27] It is therefore conceivable that an as yet unknown virus infection may be at the origin of the autoimmune attack in AIH.

Titers of antibodies to liver-specific lipoprotein, a macromolecular complex present on the hepatocyte membrane, and to its well-characterized component asialoglycoprotein receptor, correlate with the biochemical and histologic severity of AIH.[28,29] Antibodies to alcohol dehydrogenase, a second well-defined component of liver-specific lipoprotein, have been described in patients with AIH.[30] Immunofluorescence studies on monodispersed suspensions of liver cells obtained from patients with AIH showed that these cells are coated with antibodies in vivo.[31] A pathogenic role for these autoantibodies has been indicated by cytotoxicity assays showing that autoantibody-coated hepatocytes from patients with AIH are killed when incubated with autologous or allogeneic[32] lymphocytes. The effector cell was identified as an Fc receptor–positive mononuclear cell.[32] More recently, T-cell clones obtained from liver biopsies of children with AIH and expressing the gamma/delta T-cell receptor have been shown to be cytotoxic to a variety of targets but to preferentially kill liver-derived cells as opposed to cell lines derived from other organs.[33–35]

Data from our laboratory show an elevation of the circulating levels of cytokines produced by both Th1 and Th2 cells at diagnosis of AIH, whereas Th1 cytokine levels significantly decrease and Th2 cytokines remain elevated during remission (D. Vergani and colleagues, unpublished data, 2001). This observation, implicating Th1 cytokines in the causation of liver damage, finds support in immunohistochemical studies showing a significantly higher number of cells that produce interferon-γ and interleukin-2 in

the liver tissue of patients with active disease, whereas the number of cells producing interleukin-4 and interleukin-10 is similar in active and inactive biopsies (D. Vergani and colleagues, unpublished data, 2001).

The establishment of cell lines and clones has enabled Wen and colleagues[33,34] and Löhr and colleagues[36,37] to show that the majority of T-cell clones obtained from the peripheral blood and a proportion of those from the liver of patients with AIH are CD4 positive and use the conventional alpha/beta T-cell receptor. Some of these CD4-positive clones were further characterized and were found to react with partially purified antigens, such as crude preparations of liver cell membrane or liver-specific lipoprotein,[34] and with purified asialoglycoprotein receptor[34,37] or recombinant CYP2D6[36] and to be restricted by HLA class II molecules in their response. Because CD4 is the phenotype of Th cells, both Wen and colleagues[34] and Löhr and colleagues[37] investigated whether these clones were able to help autologous B lymphocytes in the production of immunoglobulin in vitro and found that their coculture with B lymphocytes resulted in a dramatic increase in autoantibody production. All of the above experimental evidence suggests that cellular immune responses are involved in the liver damage of AIH even though the evidence that the trigger is an autoantigen is still incomplete.

Treatment

Unless it presents with acute liver failure (which usually requires urgent transplant), AIH responds satisfactorily to immunosuppression. Treatment should be started with prednisolone 2 mg/g/d (maximum 60 mg/d), which is gradually decreased over a period of 4 to 8 weeks if there is progressive normalization of the transaminases, and then the patient is maintained on the minimal dose able to sustain normal transaminase levels, usually 5 mg/d. During the first 6 to 8 weeks of treatment, liver function tests are checked weekly to allow a constant and frequent fine-tuning of the treatment, avoiding severe steroid side effects. If progressive normalization of the liver function tests is not obtained over this period of time or if too high a dose of prednisolone is required to maintain normal transaminases, azathioprine is added at a starting dose of 0.5 mg/g/d, which, in the absence of signs of toxicity, is increased up to a maximum of 2 mg/g/d until biochemical control is achieved. Azathioprine is not recommended as first-line treatment because of its hepatotoxicity, particularly in severely jaundiced patients. A preliminary report in a cohort of 30 children with AIH suggests that the measurements of the azathioprine metabolites 6-thioguanine and 6-methylmercaptopurine are useful in identifying drug toxicity and nonadherence and in achieving a level of 6-thioguanine considered therapeutic for inflammatory bowel disease.[38]

In our experience, although an 80% decrease of initial transaminase levels is obtained within 6 weeks from starting treatment in most patients, complete normalization of liver function may take several months. In our own series, normalization of transaminase levels occurred at medians of 0.5 years (range 0.2–7 years) in ANA/SMA-positive children and 0.8 years (range 0.02–3.2 years) in LKM-1–positive children.[6] Relapse while on treatment is common, affecting about 40% of the patients and requiring a temporary increase of the steroid dose. The risk of relapse is higher if steroids are administered on an alternate-day schedule, often instituted in the unsubstantiated belief that it has a less negative effect on the child's growth. Small daily doses should be used because they are more effective in maintaining disease control and minimize the need for high-dose steroid pulses during relapses (with attendant more severe side effects). If a liver biopsy shows minimal or no inflammatory changes after 1 year of normal liver function tests, cessation of treatment should be considered but not during or immediately before puberty, when relapses are more common. In 13 children (4 LKM-1 positive), the only ones fulfilling these criteria in our series, discontinuation of treatment was attempted. This was successful in six children, all ANA/SMA positive, after a median duration of 3.2 (range 1–11) years of treatment. All six have remained in remission for a period of 9 to 13 years. The remaining children (three ANA/SMA positive and four LKM-1 positive) relapsed between 1 and 15 months (median 2 months) after immunosuppression was discontinued. They all responded to the reintroduction of treatment. These data indicate that most children with AIH, particularly those who are LKM-1 positive, are likely to require lifelong immunosuppressive treatment. An important role in monitoring the response to treatment is the measurement of autoantibody titers and IgG levels, the fluctuation of which is correlated with disease activity.[39] Despite the efficacy of current treatment, severe hepatic decompensation may develop even after many years of apparently good biochemical control. Thus, four of our patients who responded satisfactorily to immunosuppression ultimately required transplant 8 to 14 years after diagnosis. Overall, in our series, 46 of the 47 patients treated with immunosuppression were alive between 0.3 and 19 years (median 5 years) after diagnosis, including 5 patients after liver transplant.

Sustained remission of AIH has been reported in adult patients maintained on azathioprine alone.[40] Following this observation, we have attempted to stop prednisolone, maintaining azathioprine, in five children, two who were ANA/SMA positive and three who were LKM-1 positive. Although the attempt was successful in the ANA/SMA-positive cases, all LKM-1–positive children relapsed and required reinstitution of steroid treatment.

Remission was achieved in 25 of 32 children with AIH treated with cyclosporin A alone for 6 months followed by combined low-dose prednisone and azathioprine for 1 month, after which cyclosporin A was stopped and the other two drugs were continued.[41] The side effects of cyclosporin A were mild, and high-dose steroid side effects were avoided. A disadvantage of this schedule was that all patients were eventually treated with the prednisone-azathioprine combination, whereas by using the conventional treatment schedule, about a third of the children can maintain remission with very-low-dose steroids alone. In addition, longer follow-up of the patients is necessary to establish possible long-term toxicity of cyclosporin A.

Mycophenolate mofetil has been successfully used in adult patients with type 1 AIH who have been either intolerant of or not responsive to azathioprine.[42] Mycophenolate mofetil is an inhibitor of purine nucleotide synthesis and has a mechanism of action similar to that of azathioprine. It is not hepatotoxic or nephrotoxic, and its main side effects are diarrhea, vomiting, and bone marrow suppression. In our experience, the drug was able to resolve laboratory abnormalities in 5 of 12 children who did not tolerate or respond to azathioprine. In four others, it reduced serum aminotransferase levels to a degree that allowed a decrease in the dose of prednisolone. Only three patients did not respond to mycophenolate mofetil, and the side effects were minor, apart from severe nausea and dizziness in one of these three children.

Children who present with acute hepatic failure pose a particularly difficult therapeutic problem. Although it has been reported that they may benefit from conventional immunosuppressive therapy,[43,44] only one of the six children with acute liver failure in our own series responded to immunosuppression and survived without transplant. Of the four LKM-1–positive patients, one died before a donor organ could be found and two died soon after transplant. Encouraging results have been reported using cyclosporin A in LKM-1–positive patients presenting with fulminant hepatitis.[44,45] These results should be evaluated on a larger number of patients because our own experience has not confirmed the value of this therapeutic approach.

AUTOIMMUNE SCLEROSING CHOLANGITIS

Clinical Features

Sclerosing cholangitis is an uncommon disorder, characterized by chronic inflammation and fibrosis of the intrahepatic and/or extrahepatic bile ducts. In childhood, sclerosing cholangitis may occur as an individual disease or may develop in association with a wide variety of disorders, including Langerhans cell histiocytosis, immunodeficiency, psoriasis, cystic fibrosis, and chronic inflammatory bowel disease. An overlapping syndrome between AIH and sclerosing cholangitis has been reported both in adults[46–48] and children.[49–52] In a retrospective study, we have shown that 40% of patients with sclerosing cholangitis have clinical, biochemical, immunologic, and histologic features that are indistinguishable from those of AIH.[49] In both AIH and sclerosing cholangitis, the serum IgG level is similarly increased, and non–organ-specific ANA and/or SMA are frequently present. Both diseases also commonly have portal tract inflammation and interface hepatitis. Most of the reported cases of overlap were originally diagnosed as AIH.[46–48,51] Typically, the overlap with sclerosing cholangitis was not recognized until years later, when biliary features on follow-up liver biopsy examination justified the performance of cholangiography. The sequence of diagnoses was then interpreted as an evolution from AIH to sclerosing cholangitis, when, in fact, the concurrence of these diseases had not been excluded by cholangiographic studies performed at presentation.

In a prospective study over a period of 16 years, we found that 27 of 55 children who presented with clinical and/or laboratory features characteristic of AIH had evidence of sclerosing cholangitis when assessed by cholangiography at presentation.[53] Bile duct abnormalities on cholangiography were both intra- and extrahepatic in two-thirds of patients and intrahepatic in one-third. Because of the cholangiographic changes, a diagnosis of ASC was made in these patients (Figure 52-2).

Of the 27 patients with ASC, 26 were seropositive for ANA and/or SMA and 1 for LKM-1.[53] Fifty-five percent were girls, and the mode of presentation was similar to that of 28 patients with typical AIH. Symptoms were those of acute hepatitis or chronic liver dysfunction. In some instances, symptoms were absent, and the diagnosis was revealed after the incidental discovery of abnormal liver tests. Inflammatory bowel disease was present in 44% of children with cholangiopathy compared with 18% of those with typical AIH, and more than 75% of children with ASC had greatly increased serum IgG levels. Perinuclear antineutrophil cytoplasmic antibodies were present in 74% of patients with ASC compared with 36% of patients with typical AIH.

There was only a partial concordance between the histologic and radiologic findings, and six patients with an abnormal cholangiogram had histologic features more compatible with AIH than sclerosing cholangitis.[53] Interestingly, all patients fulfilled the criteria for the diagnosis of "definite" or "probable" AIH established by the International Autoimmune Hepatitis Group.[1] Indeed, the diagnosis of sclerosing cholangitis was possible only because of the cholangiographic studies. The similarities and differences between type 1 AIH, type 2 AIH, and ASC are summarized in Table 52-3.

Treatment

Children with ASC respond to the same immunosuppressive treatment described above for typical AIH.[53] The liver test abnormalities resolved in almost 90% of our patients within a median of 2 months after starting treatment. This good response is in contrast to the outcome in adults with primary sclerosing cholangitis (PSC) who have no beneficial effects from corticosteroid treatment.[54,55] The PSC of adults, however, is usually diagnosed at an advanced stage and may be the result of various etiologies. Disappointing results with immunosuppressive agents have been reported in a small number of children with sclerosing cholangitis associated with autoimmune features, but these children may have had more advanced disease than those recruited into our prospective study.[51]

Ursodeoxycholic acid (UDCA) was added to our treatment schedule in 1992 following preliminary reports of its value in the treatment of adult PSC.[56,57] The small number of patients and the relatively short follow-up period do not allow us to determine whether treatment with UDCA from onset is successful in arresting the progression of ASC. In adults with well-established PSC, UDCA treatment has been disappointing, possibly because of the advanced stage of the disease at the time of diagnosis.[58]

Measurement of autoantibody titers and IgG levels is useful in monitoring disease activity and response to treatment, not only in AIH but also in ASC.[39]

Follow-up liver biopsies in our series have shown no progression to cirrhosis, although one patient did develop vanishing bile duct syndrome. Follow-up endoscopic retrograde cholangiograms have shown static bile duct disease in half of our patients with ASC and progression of the bile duct abnormalities in the other half. Interestingly, one of the children with AIH who was followed prospectively developed sclerosing cholangitis 8 years after presentation despite treatment with corticosteroids and no biliary changes on several follow-up liver biopsies. This observation suggests that AIH and ASC are part of the same pathogenic process and that prednisolone and azathioprine may be more effective in controlling the liver parenchyma inflammatory changes than the bile duct disease.

The medium-term prognosis of ASC is good.[53] All patients in our series were alive after a median follow-up of 7 years. Four patients with ASC, however, required liver transplant after 2 to 11 years of observation (median interval of follow-up 7 years). In contrast, liver transplant has not been required by any of the 28 children with typical AIH who have been followed for this same time.

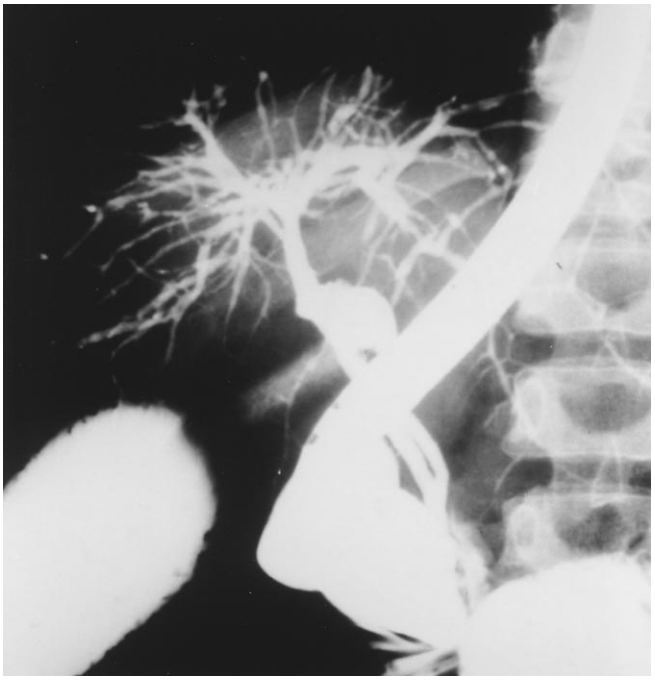

FIGURE 52-2 Endoscopic cholangiography demonstrating widespread intrahepatic changes predominantly affecting the second- and third-order bile ducts.

Pathophysiology

It is unclear if the juvenile autoimmune form of sclerosing cholangitis and AIH are two distinct entities or different aspects of the same condition. Akin to AIH, liver-specific autoantibodies, including antibodies to liver-specific lipoprotein, asialoglycoprotein receptor, alcohol dehydrogenase, and soluble liver antigen, are found in ASC.[12,30,59] HLA-DR3, -DR13, and -DR15 occur as commonly in patients with ASC as in healthy control subjects, but HLA-DR4 occurs less commonly. This HLA profile has also been associated with susceptibility to sclerosing cholangitis in adults.[60]

DE NOVO "AUTOIMMUNE" HEPATITIS AFTER LIVER TRANSPLANT

Clinical Features

Late graft dysfunction not attributable to recognized causes such as rejection, infection, or vascular and/or biliary complications may occur after liver transplant. We have observed and reported a particular type of graft dysfunction associated with autoimmune features in 7 (4%) of 180 children transplanted at our center between 1991 and 1996.[61] They developed an unexplained but characteristic form of graft dysfunction at a median postsurgery period of 24 months (range 6–45 months). Of the seven children, five were boys, and the median age at presentation was 10.3 years (range 2–19.4 years). None of the children had been transplanted for autoimmune liver disease. Indications for transplant were extrahepatic biliary atresia in four children, Alagille syndrome in one child, drug-induced acute liver failure in one child, and α_1-antitrypsin deficiency in one child. At the time of graft dysfunction, four were on triple immunosuppression with cyclosporin A, azathioprine, and prednisolone, whereas three were on tacrolimus. Common causes of graft dysfunction, such as infectious and surgical complications, were excluded. Liver biopsy showed the histologic changes of chronic hepatitis, including portal and periportal hepatitis with lymphocytes and plasma cells, bridging collapse, and perivenular cell necrosis, without changes typical of acute or chronic rejection. All patients had increased levels of IgG and positive autoantibodies, ANAs, SMAs, or atypical liver/kidney microsomal antibodies (LKMs, which, on immunofluorescence, stain the proximal renal tubules similarly to LKM-1, in the absence of liver staining).

Following this report,[61] autoimmune phenomena and liver disease mimicking AIH after liver transplant have been described in adults and children.[62–66] The graft dysfunction has been responsive to therapy with corticosteroids and azathioprine but not to increased doses of cyclosporin A or tacrolimus. [62–66]

Treatment

In our study, all patients but one responded to the conventional treatment regimen for AIH based on prednisolone (2 mg/kg/d) and azathioprine (1.5 mg/kg/d).[61] Antirejection therapy with cyclosporin A or tacrolimus was not changed. Serum aminotransferase abnormalities resolved within a median treatment period of 32 days (range 7–316 days). The one child who did not respond had a history of poor compliance with therapy. One responder relapsed owing to poor compliance, but remission was again obtained after retreatment. All six responders remained in remission on a reduced dose of prednisolone (5–10 mg/d) and azathioprine (1.5 mg/kg/d) during a median follow-up interval of 283 days (range 108–730 d). Similar satisfactory results

TABLE 52-3 COMPARISON BETWEEN AUTOIMMUNE HEPATITIS AND AUTOIMMUNE SCLEROSING CHOLANGITIS

CLINICAL FEATURES AT PRESENTATION	TYPE 1 AIH	TYPE 2 AIH	ASC
Median age (yr)	11	7	12
Females (%)	75	75	55
Mode of presentation (%)			
Acute hepatitis	47	40	37
Acute liver failure	3	25	0
Insidious onset	38	25	37
Complication of chronic liver disease	12	10	26
Associated immune diseases (%)	22	20	48
Inflammatory bowel disease (%)	20	12	44

AIH = autoimmune hepatitis; ANA = antinuclear antibodies; ANCA = antineutrophil cytoplasmic antibody; ASC = autoimmune sclerosing cholangitis; C4 = C4 component of complement; HLA = human leukocyte antigen; IgA = immunoglobulin A; IgG = immunoglobulin G; LKM-1 = anti–liver/kidney microsomal type 1 antibody; SMA = anti–smooth muscle antibody.

have been reported by other authors using prednisolone and azathioprine,[62–66] whereas the condition has worsened in the absence of such treatment.[66] These findings underscore the importance of prompt recognition of the condition and institution of appropriate treatment.

Pathophysiology

Whether the liver damage observed in these patients is a form of rejection or the consequence of an "autoimmune" injury, possibly triggered by drugs or viral infection, remains to be established. Further characterization of the target specificity of intrahepatic lymphocytes may provide information regarding its pathogenesis. The administration of cyclosporin A or tacrolimus to rodents after bone marrow transplant can result in a "paradoxical" autoimmune syndrome in which the immunosuppressive drugs interfere with maturation of T lymphocytes and favor the emergence of autoaggressive T-cell clones.[67–69] This experience in animals may explain, in part, the development of this disorder in immunosuppressed children after liver transplant.

The manifestations of the autoimmune condition in rodents vary in different strains and depend on genetic factors possibly encoded by the major histocompatibility complex.[67] Analysis of the HLA phenotypes of the recipients and donors in our study did not show an association between the development of autoimmune features, the possession of either HLA-DR3 or -DR4, or the degree of donor-recipient HLA mismatch.[61] Five of the seven patients, however, had received livers from donors with HLA markers known to be associated with susceptibility to AIH, including two with DR4, one with DR3, and two with DR3 and DR4.[21]

RECURRENCE OF AUTOIMMUNE LIVER DISEASE AFTER LIVER TRANSPLANT

Recurrence of AIH after transplant has been repeatedly reported in some 30% of patients.[70–75] The recurrence rate may be as high as 68% 5 years after transplant.[76] The diagnosis is based on the reappearance of clinical symptoms and signs, histologic features of periportal hepatitis, raised transaminases, circulating autoantibodies, and elevated IgG, associated with a response to prednisolone and azathioprine. Possession of the HLA-DR3 allele appears to confer predisposition to disease recurrence, as it does to the original AIH,[71] but this has not been universally confirmed.[75] Recurrence has been noted both in adult and pediatric series, and although the rate of this complication increases with the post-transplant interval, it may appear as early as 35 days postsurgery.[77] The reported recurrence rates are likely to be influenced by differences in study design, immunosuppressive regimens, and lengths of follow-up. Most transplant recipients with recurrent AIH respond to an increase in the dose of corticosteroids and azathioprine, but AIH recurrence can lead to graft failure and to the need for retransplant. Caution should be taken in weaning immunosuppression in patients who undergo transplant for AIH because discontinuation of corticosteroid therapy may increase the risk for recurrent disease.

Recurrence of sclerosing cholangitis after transplant has also been reported in 6 to 20% of patients transplanted for this condition, but it is particularly difficult to prove.[78–81] The diagnosis of sclerosing cholangitis is based on the radiographic documentation of biliary tree lesions, which can also arise as a consequence of the transplant surgery or post-transplant complications. Most patients transplanted for sclerosing cholangitis have a Roux-en-Y loop rather than a duct-to-duct anastomosis, with an increased risk of biliary obstruction and radiographic appearances of sclerosing cholangitis in the graft, making it difficult to distinguish secondary from recurrent disease. Moreover, radiologic and histologic features indistinguishable from sclerosing cholangitis may result from ischemic biliary complications.[82] Whether patients with the autoimmune form of sclerosing cholangitis are more likely to experience recurrence than those without is unclear at the present time. Similarly to AIH, immunosuppression may modify or delay the disease expression within the graft. Patient and graft survival, however, do not appear to be affected by recurrence of sclerosing cholangitis in the intermediate term.

CHAPTER 53

DRUG-INDUCED HEPATOTOXICITY

Eve A. Roberts, MD, FRCPC

The liver plays a central role in drug action. It chemically transforms many drugs to their active form and acts on most drugs to expedite their excretion from the body. These functions put the liver at risk for toxicity from these chemicals and their metabolites. Because of its anatomic and physiologic complexity, drug-induced liver disease represents a broad spectrum of biochemical, histologic, and clinical abnormalities. This can make it difficult to diagnose drug-induced liver disease or determine its pathogenesis. The problem of drug-induced liver disease in children is further complicated by a widely held notion that drug hepatotoxicity does not happen very often in children. Children may indeed be protected in some way from drug hepatotoxicity. Whether or not this is true, because the child's liver is in the process of metabolic maturation, the manifestations of drug-induced liver disease may differ in children from those in adults. Because drug hepatotoxicity often imitates other more common diseases, arriving at a diagnosis of drug hepatotoxicity in a child can be especially difficult.

The purpose of this chapter is to address special features of drug hepatotoxicity in children. Mechanistic information gained from studying such processes in children is important for understanding the pathogenesis of drug hepatotoxicity. However, much more is known about the diversity of hepatic drug reactions in adults than that in children. For encyclopedic reviews of which hepatotoxicities a given drug has caused in patients of any age, the reader should consult broader references[1–3] or computerized adverse drug reaction indices (such as <www.fda.gov/medwatch> and <www.pharmacovigilance.org>).

ROLE OF THE LIVER IN DRUG METABOLISM

Hepatic drug metabolism, or biotransformation, contributes to drug hepatotoxicity and to some hepatic neoplasia. Biotransformation in the liver is divided into two broad aspects: activation (phase I) and detoxification (phase II) (Figure 53-1). For hepatotoxicity, the balance between these two processes is critical. Factors that influence this balance include age or stage of development, fasting or undernutrition, coadministered drugs, and immunomodulators resulting from viral infection. Inducing chemicals may affect phase I and phase II processes differently. The pharmacokinetics of the toxic drug also affects hepatic biotransformation. Whether the drug is taken as a single dose or many doses chronically may change its hepatic metabolism. Finally, polymorphisms of cytochromes P-450 and various phase II enzymes also influence this balance.

The cytochromes P-450 are hemoproteins that are found in numerous body tissues but are particularly important in the liver. They carry out most phase I reactions. These reactions are diverse and include various types of hydroxylation, dealkylation, and dehalogenation. The common feature in all reactions is that one atom of molecular oxygen is inserted into the substrate, whereas the other combines with protons to form water. Hence these enzyme activities are monooxygenases. Cytochromes P-450 themselves are diverse and have overlapping substrate specificity. An important characteristic of many cytochromes P-450 is inducibility. Another is functional polymorphism.

The cytochromes P-450 were initially classified on the basis of the predominant inducing chemical: basically either phenobarbital or the polycyclic aromatic hydrocarbon 3-methylcholanthrene.[4] Thirty-six subfamilies of cytochromes P-450 have been distinguished on the basis of similarities in primary amino acid sequence. The cytochrome P-450 1A (CYP1A) subfamily includes those cytochromes induced by polycyclic aromatic hydrocarbons. Two major forms within the CYP1A subfamily have been identified in the rat, mouse, and rabbit and in humans. Apart from various carcinogens, other chemicals, such as caffeine and theophylline, are metabolized by these cytochromes to a varying extent. Induction of the cytochromes in the CYP1A subfamily is regulated through a cytoplasmic receptor protein, the Ah receptor, which has been characterized in humans. The cytochrome P-450 2B (CYP2B) subfamily includes cytochromes induced by phenobarbital. Cytochrome P-450 2E1 (CYP2E1) represents ethanol-inducible cytochrome P-450. The cytochrome P-450 3A (CYP3A) subfamily includes cytochromes induced by pregnenolone and by glucocorticoids. CYP3A4 is the most abundant cytochrome P-450 in human liver. Induction of cytochromes P-450 by phenobarbital involves

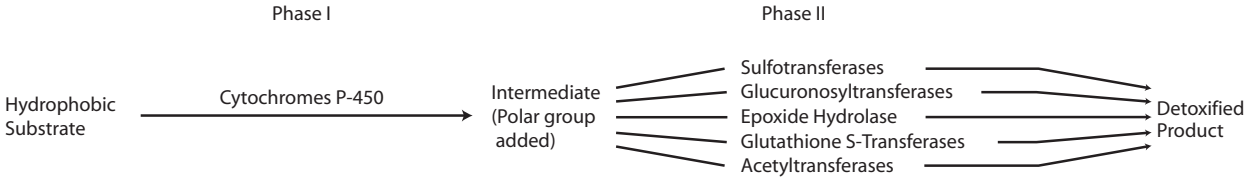

FIGURE 53-1 Phase I and phase II metabolism. Although the main objective is to convert a hydrophobic substance to a detoxified, water-soluble product so that it can be excreted from the body, phase I metabolism is also capable of converting some drugs to their active form or transforming other chemicals to toxic intermediates.

the constitutive active receptor (CAR) for CYP2B cytochromes and the pregnane X receptor (PXR) for CYP3A cytochromes through response elements, but not all details of these regulatory mechanisms are yet known.[5] Drugs that cause proliferation of peroxisomes appear to induce yet another cytochrome P-450 subfamily, P-450 4A (CYP4A). As the hepatic metabolism of common drugs is studied more extensively, these subfamilies, as well as CYP2C cytochromes and CYP2D6, are found to be involved. This has important implications for hepatotoxicity.

Polymorphisms for certain cytochromes P-450 have also been identified in human populations and in laboratory animals. In general, these polymorphisms relate to differences in the rate of enzyme action. An important polymorphism is that for debrisoquine 4-hydroxylation, for which individuals may be "extensive metabolizers" or "poor metabolizers." Other drugs whose metabolism shows the same pattern include sparteine, metoprolol, and dextromethorphan. The poor metabolizer phenotype is associated with absence of cytochrome CYP2D6 protein; several different mutations in the structural gene for CYP2D6 have been described, which account for this phenotype.[6] Poor metabolizers appear to be at greater risk for adverse drug reaction from drugs that are metabolized by this route, although clear relationships to any specific hepatotoxicity have been difficult to prove.[7]

For many drugs, the effect of phase I biotransformation reactions is to create a more polar chemical with a substituent poised for conjugation via a phase II reaction. Phase II detoxifying reactions are performed by a variety of different types of enzymes, including glutathione *S*-transferases, glucuronosyl transferases, epoxide hydrolase, sulfotransferases, and *N*-acetyltransferases. In general, these reactions complete the transformation of a hydrophobic chemical to a hydrophilic one that can be excreted easily in urine or bile. Certain phase II enzymes, such as some glucuronosyl transferases, are subject to induction. Some are polymorphic, notably *N*-acetyltransferase (either rapid or slow acetylators). In some metabolic diseases, the activity of phase II enzymes may be abnormal; for example, in 5-oxoprolinuria, conjugation to glutathione is reduced because of deficiency of glutathione owing to decreased levels of glutathione synthetase.[8] In hereditary tyrosinemia, glutathione *S*-transferase activity is depressed because intermediates in the abnormal tyrosine pathway consume glutathione.

Hepatic drug metabolism shows developmental changes. Caffeine, which is metabolized in part by cytochromes P-450 in the 1A subfamily, exemplifies these changes. The elimination half-life is very long in the newborn period[9] and drops to approximately 3 to 4 hours around 6 months of age.[10] For the balance of childhood, that is, until puberty, caffeine metabolism remains somewhat more rapid than in adults.[11] Clearance of many drugs is more rapid in children than in adults. Prominent examples include theophylline, phenobarbital, and phenytoin. Among phase II processes, a well-known example of late maturation of a detoxifying enzyme is the glucuronosyl transferase for bilirubin conjugation, which is frequently deficient for a short time after birth. Hepatic bile acid metabolism also shows maturational changes in the first months of life. These variations may influence the occurrence and character of hepatotoxicity in children.

The product of a phase I reaction may be an unstable or reactive metabolite. Phase II reactions may inactivate such chemicals before they do much harm. However, it is possible, as in the case of benzo[*a*]pyrene, for the product of phase I to recycle through the same cytochrome a second time and then be metabolized to a proximate carcinogen. Apart from the adequacy of the detoxification systems, whether reactive metabolites actually damage the cell will also depend on how much reactive metabolite actually binds to cellular components, whether these components are critical to cellular function, and whether they can be repaired. If the reactive metabolite binds to intracellular proteins or membranes that are vital to cellular integrity, the hepatocyte may die. If it binds to a genetic apparatus, mutagenesis, carcinogenesis, or teratogenesis may ensue (Figure 53-2).

Toxic metabolites are electrochemically unstable, and thus highly reactive, species derived from drugs, xenobiotics, or endogenous chemicals. Electrophilic intermediates (or electrophiles) are formed when electrons are lost from the original chemical; they carry a net positive charge. Examples include hydroxylamines, quinoneimines, and arene oxides. Tissue nucleophiles, such as glutathione, preferentially combine with these species. Not all nucleophiles are necessarily protective. For example, reactions that involve activation of oxygen produce negatively charged species, which are nucleophiles. They tend to bind to intracellular lipids, leading to lipid peroxidation. Examples include halocarbon and nitroso radicals. Besides lipid peroxidation, membranes can be altered by alkylation (addition of an aliphatic radical such as methyl or ethyl groups), arylation (addition of an aromatic group such as a phenyl group), or acylation (adding a radical derived from a carboxy acid). Glutathione, which is found in most mammalian cells in high concentrations, can react with electrophiles via conjugation reactions catalyzed by glutathione *S*-trans-

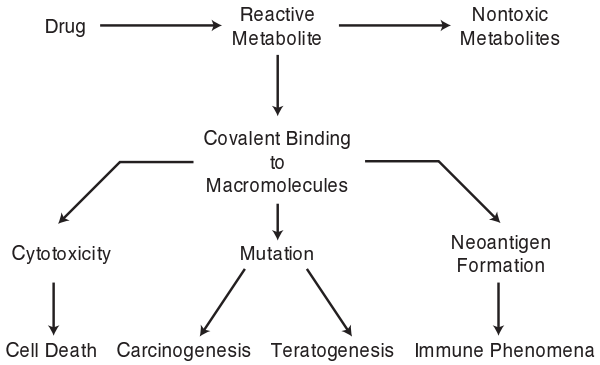

FIGURE 53-2 The potential fates of a toxic intermediate.

ferases. It can also interact with hydrogen peroxide and activated oxygen species via a different enzyme, glutathione peroxidase. In general, when toxic metabolites are the important cause of cell damage, high tissue concentrations of the parent drug are not found. Metabolite(s) covalently bound to cellular constituents may be detected.

The cellular specialization of hepatocytes accounts in part for the diversity of patterns of hepatotoxicity. Binding to certain subcellular elements may interfere with specific metabolic functions such as protein or lipid synthesis or energy production. The parent compound or its reactive metabolites may interfere with biliary excretion or damage proteins within the biliary excretion apparatus, thus leading to cholestasis.[12] In particular, the bile salt excretory pump (BSEP; abnormal in progressive familial intrahepatic cholestasis type 2) appears to be an important target in forms of drug hepatotoxicity with prominent cholestatic features. Additionally, polymorphisms in the genes for these bile canalicular transporters may influence their susceptibility to damage by toxic intermediates. Binding to nuclear deoxyribonucleic acid (DNA) may lead to carcinogenesis. Binding to mitochondrial DNA or otherwise interfering with production of normal mitochondrial DNA may have important consequences for hepatocellular metabolism because, unlike nuclear DNA, mitochondrial DNA has limited resources for DNA repair. Drug-induced injury may occur to other cells in the liver besides hepatocytes. Cytotoxic damage to biliary epithelial cells, hepatic stellate cells, or endothelial cells accounts for some of the clinical diversity of drug-induced liver disease. For example, damage to sinusoidal endothelial cells by reactive metabolites leads to veno-occlusive disease.

CLASSIFICATION OF DRUG HEPATOTOXICITY

The clinical spectrum of drug hepatotoxicity in adults is wide. The clinical patterns of drug hepatotoxicity presented in Table 53-1 form the basis for considering hepatotoxicity in children. It encompasses a combination of clinical presentations, histologic findings, and other factors. Nonspecific elevation of serum aminotransferases is omitted. This form of hepatotoxicity is probably the most common of all, but its causes are extremely heterogeneous and the least understood.

Most drug-induced liver disease is cytotoxic. Clinically, serum aminotransferases are elevated, and hepatic insufficiency may develop. Hepatocellular damage is classically defined in adults as having an alanine aminotransferase (ALT) level greater than two times the upper limit of normal or the ALT-to-alkaline phosphatase (ALP) ratio is ≥ 5.[13] The exact mechanism of cell death is not known and is probably different for different drugs and toxins. Hepatocyte damage may be zonal, reflecting metabolic specialization in various parts of the hepatic lobule. Specifically, hepatocytes in zone 3 of the Rappaport acinus have the highest concentration of drug-metabolizing enzymes and thus the greatest potential for producing toxic intermediates. Zonal hepatocellular necrosis suggests that metabolic activation of toxic metabolites has an important role in the pathogenesis of the toxicity, but spotty necrosis scattered throughout the lobule does not necessarily exclude a mechanism involving toxic metabolites. The same drugs that can cause this spotty hepatocyte damage can, on occasion, cause damage affecting most hepatocytes, leading to massive hepatocellular necrosis. Whenever hepatocellular damage is sufficiently severe, some degree of cholestasis will develop.

Some drug-induced liver disease, however, is predominantly cholestatic. For adults, this is classically defined as serum ALP greater than two times the upper limit of normal or the ALT-to-ALP ratio is ≤ 2.[13] Clinically, this type of reaction is characterized by jaundice, pruritus, prominent elevation of ALP, and mild elevations of serum aminotransferases. Traditionally, these cholestatic injuries have been classified on the basis of histologic inflammation. In hepatocanalicular jaundice, with agents such as chlorpromazine or erythromycin, liver cell injury and inflammation

TABLE 53-1 SPECTRUM OF DRUG-INDUCED LIVER DISEASE

TYPE	EXAMPLES
Acute hepatitis	Methyldopa, isoniazid, halothane, phenytoin
Hepatitis-cholestasis	Erythromycin, chlorpromazine, azathioprine, nitrofurantoin, cimetidine
Zonal liver cell necrosis	Acetaminophen
Bland cholestasis	Estrogens, cyclosporines
Steatonecrosis (like alcoholic hepatitis)	Perhexiline, amiodarone
Phospholipidosis	Amiodarone
Microvesicular steatosis	Valproic acid, tetracycline
Granulomatosis	Sulfonamides, phenylbutazone, carbamazepine
Biliary cirrhosis	Practolol, chlorpropamide
Sclerosing cholangitis	Floxuridine via hepatic artery
Hepatic vascular changes	
Peliosis	Estrogens, androgens
Hepatic vein thrombosis	Estrogens (oral contraceptives)
Veno-occlusive disease	Thioguanine, busulfan, pyrrolizidine (*Senecio*) alkaloids
Noncirrhotic portal hypertension	Vinyl chloride, arsenic
Liver cell adenoma	Estrogens (oral contraceptives), anabolic steroids
Malignant tumors	Estrogens, anabolic steroids, vinyl chloride
Porphyria	2,3,7,8-Tetrachlorodibenzo-*p*-dioxin, chloroquine

are relatively prominent. This mixed picture is characterized biochemically in adults because the ALT-to-ALP ratio is 2–5, and the ALT and ALP are each at least twice the upper limit of normal. In bland cholestasis, with agents such as contraceptive steroids, inflammation is minimal.

It is sometimes useful to think about drug hepatotoxicity in terms of the duration of the hepatotoxic process. Acute hepatotoxic injuries develop over a relatively short time and cause a lesion without any features of chronicity. Subacute hepatotoxicity refers to lesions that have developed over weeks to months as indicated by areas of fibrosis and possibly regeneration. Chronic hepatotoxic lesions include those with fibrosis or cirrhosis, vascular changes, and neoplasia. Some drugs can cause clinical liver disease indistinguishable from autoimmune hepatitis (the so-called "chronic active hepatitis" picture): these include oxyphenisatin, methyldopa, isoniazid, nitrofurantoin, and minocycline.

Our knowledge of the mechanisms of hepatotoxicity is evolving. For many years, hepatotoxicity has been categorized on the basis of predictability. Intrinsic hepatotoxins are differentiated from idiosyncratic heptatotoxins. The intrinsic hepatotoxin causes predictable hepatic damage in almost any individual. The toxicity is dose related: higher doses cause worse damage. Animal models can be developed that exhibit the same type of hepatotoxicity. However, most instances of hepatotoxicity, mainly those associated with medications, are unpredictable, infrequent, and apparently sporadic. If such a reaction is accompanied by systemic features such as fever, rash, eosinophilia, atypical lymphocytosis, and possibly other major organ involvement, then, classically, it has been regarded as an idiosyncratic hypersensitivity reaction, where hypersensitivity, with its connotation of allergy, is left undefined.

An alternate explanation is that idiosyncratic hepatotoxicity has a biochemical basis and is due to metabolic idiosyncrasy. It occurs in individuals who have specific abnormalities in drug metabolism. If this abnormal metabolism is expressed in liver cells, then these rare individuals will develop hepatotoxicity if exposed to the appropriate drug. In most instances, a metabolite, not the drug itself, is responsible for hepatotoxicity (see Figure 53-2). Frequently, the problem seems to be a defect in detoxification of the reactive metabolite because the detoxification system is itself focally defective and cannot meet the normal demands of metabolite production. Sometimes these individuals show systemic features interpreted as hypersensitivity: it is likely that interaction of the reactive metabolite with cellular components, such as the cell membrane, elicits an immune response. In such cases, hypersensitivity is itself the consequence of metabolic idiosyncrasy, not a separate mechanism of drug hepatotoxicity. There may be strictly allergic drug hepatotoxicity, but investigations of the mechanism of drug-induced hepatotoxicity suggest that metabolic idiosyncrasy is much more common than formerly supposed. It seems likely to account for hepatotoxicity with drugs that show two main patterns of toxicity: mild reversible toxicity in a comparatively large segment of patients and severe hepatotoxicity in a few individuals. Toxic metabolites are probably involved in both patterns of toxicity. Severe reactions occur in rare persons with abnormal generation of toxic metabolites or detoxification, irrespective of the appearance of drug allergy. Transient reaction may reflect spontaneous adjustments in hepatic biotransformation for the particular drug.

The major implication of the metabolic idiosyncrasy thesis is that most drug hepatotoxicity is predictable if one understands the pathways of hepatic biotransformation and detoxification for each drug. Given the plethora of drugs and hepatic biotransformation pathways, it is no wonder that most clinically important drug hepatotoxicity appears sporadic and fortuitous. However, enough experimental data are available now to warrant rethinking the standard classification of drug hepatotoxicity that regards all drug-associated hepatotoxicity as either intrinsic, owing to the drug being a poison, or else idiosyncratic-allergic. The definable metabolic defects in hepatic drug metabolism are particularly common in the types of drug hepatotoxicity that occur in children.

Recent research has focused on the role of the immune system in drug hepatotoxicity.[14] It seems likely that for many, if not most, individuals, drug hepatotoxicity depends on immune reactivity as well as personal peculiarities of drug biotransformation. With some drugs, the connection between immune-mediated mechanisms and hepatic damage may be very direct: autoantibodies are elaborated against specific components of the hepatic biotransformation machinery. The target cytochrome P-450 varies with different drugs: CYP2C9 for tienilic acid, CYP1A2 for dihydralazine, and CYP2E1 for halothane. In addition, the herb germander is associated with antibodies directed against the phase II enzyme epoxide hydrolase.[15] Reactive metabolites may alter other components of hepatocytes to form neoantigens. Hepatocyte damage mediated through immune mechanisms involves apoptosis or necrosis. Bile acid–associated hepatocyte injury involves Fas (CD95) activation leading to apoptosis. When toxic metabolites or reactive oxygen species or cytokines stimulate Kupffer cells, specific mechanisms of cell damage are set into motion involving tumor necrosis factor-α or nitric oxide produced by Kupffer cells. Nitric oxide elaborated by Kupffer cells and hepatocytes appears to play a role in acetaminophen hepatotoxicity. Other cytokines, including interleukin-8[16] and other CXC chemokines regulating leukocyte action, may modulate these effects. Moreover, Kupffer cells also elaborate a number of factors that are cytoprotective to hepatocytes.[17] The vigor of the immune response in general, an individual polygenic trait, may also determine the importance of immune mechanisms in drug hepatotoxicity. Thus, the individual's "immunogenetic" makeup and "pharmacogenetic" makeup are important.

In summary, as our knowledge of the complex and numerous individual mechanisms of drug hepatotoxicity continues to evolve, it remains useful to categorize drugs as follows: intrinsic hepatotoxins, contingent hepatotoxins, and drugs eliciting an immunoallergic response. The intrinsic toxin is a true poison and causes predictable damage in all persons in a dose-dependent fashion. The contingent hepatotoxin causes drug hepatotoxicity in individuals who

are susceptible under circumstances that favor imbalance of production of a toxic intermediate and its detoxification. These circumstances may be inborn (such as genetic defects in a phase II detoxification enzyme or genetic polymorphism in a cytochrome P-450) or acquired (such as induction of CYP2E1 by chronic ethanol abuse or depletion of hepatic glutathione by fasting and malnutrition). Genetic variations in expression of cytokines that effect hepatic cytoprotection (such as interleukin-10 promoter region polymorphisms, which regulate its expression) also contribute to the mechanism of contingency. Drugs eliciting an immune response can produce a variety of clinical phenomena: the drug hypersensitivity syndrome (fever, rash, atypical lymphocytosis, eosinophilia, lymphadenopathy, multisystem involvement including hepatitis, renal dysfunction, myocarditis, thyroiditis), hepatic granulomatosis, autoantibodies, and "chronic active hepatitis" fully resembling idiopathic autoimmune hepatitis. Individual immunogenetic makeup probably determines the pattern and extent of this response. These categories are not mutually exclusive. Acetaminophen is an intrinsic toxin at very high doses and a contingent toxin at therapeutic doses. Phenytoin is a contingent hepatotoxin and the archetypal drug for eliciting an immunoallergic response.

INCIDENCE OF DRUG-INDUCED LIVER DISEASE IN CHILDREN

Drug-induced liver disease is generally regarded as rare in children. In a survey of 10,297 pediatric hospital admissions to teaching and community hospitals in Boston, Mitchell and colleagues found that only 2% of hospital admissions were due to any sort of adverse drug reaction.[18] In a subset of 725 patients with cancer, however, 22% of admissions were related to adverse drug reactions. Adverse drug reactions in the whole population were somewhat more common in the 0- to 5-year-old age group than in older children. The most commonly implicated drugs included phenobarbital, aspirin, phenytoin, ampicillin or amoxicillin, and sulfa. Only phenytoin-associated hepatitis was specifically mentioned in this large survey as drug hepatotoxicity. An outpatient study of 1,590 children in Britain also failed to detect drug hepatotoxicity as a problem in children.[19] A recent review of the Yellow Card Scheme for reporting adverse drug reactions in the United Kingdom revealed that between 1964 and December 2000, there were 331 deaths in children possibly owing to drug toxicity, and 50 of these involved hepatic failure.[20] The median age was 5 years old, and the types of drugs most often associated with fatal adverse events were anticonvulsants and antineoplastic drugs. Despite the limitations of this tracking system, these data help to objectify this problem in the pediatric age bracket.

Why childhood drug hepatotoxicity seems uncommon is not certain. Underdiagnosis and underreporting remain a possibility. Another simple reason is that most children take relatively few medications. They do not use ethanol chronically or smoke cigarettes; most are not obese. Thus, they are free of many predisposing factors to drug hepatotoxicity. Interestingly, where drug therapy plays a key role—epilepsy and childhood neoplasia—drug hepatotoxicity is somewhat frequent. Advanced age is a risk factor for severe hepatotoxic reactions. The aging liver metabolizes some drugs more slowly. In view of the increased risk attached to some drug hepatotoxicities in women, one can speculate that changes in drug metabolism possibly associated with puberty may influence the differing incidence of drug hepatotoxicity in childhood and adulthood.

SPECIFIC DRUG HEPATOTOXICITIES IN CHILDREN

Drug hepatotoxicity does occur in children. Hepatotoxicity attributable to most of the following drugs has been diagnosed in children at the Hospital for Sick Children in Toronto in the past 15 to 20 years. Other drugs are included because they are commonly used in pediatric practice and are known to be hepatotoxic in children.

ACETAMINOPHEN

Acetaminophen is commonly used in children as an effective antipyretic and analgesic because its metabolism is rapid enough in most children that it does not accumulate and is not influenced by dehydration. A single large dose is extremely hepatotoxic. The mechanism for this toxicity involves the formation of a toxic metabolite.[21–24] The important role of drug metabolism in this hepatotoxicity is reflected in the predominance of hepatocellular injury in zone 3 (Figure 53-3). Acetaminophen is usually metabolized via sulfation and glucuronidation (Figure 53-4). If a sufficiently large amount is taken, these pathways are saturated, and an otherwise relatively minor pathway through

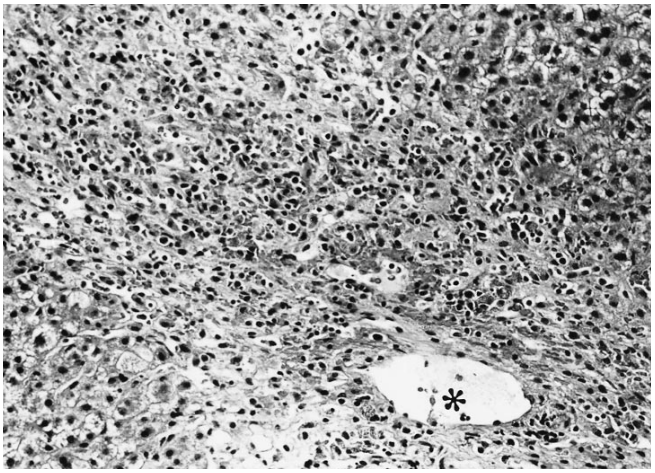

FIGURE 53-3 Liver biopsy in acetaminophen hepatotoxicity. There is a wide zone of necrosis occupying zone 3 of the liver, to which there is only a modest inflammatory cell response. The transition between the necrotic cells and the surrounding hepatocytes, which are swollen, vacuolated, and contain fat, is abrupt. In zone I (not shown), the liver parenchyma is normal. This zonal distribution of necrosis surrounded by swollen fatty hepatocytes is characteristic of acetaminophen hepatotoxicity. Terminal hepatic venule (*asterisk*) (hematoxylin and eosin, ×250 original magnification). Courtesy of Dr. M. J. Phillips.

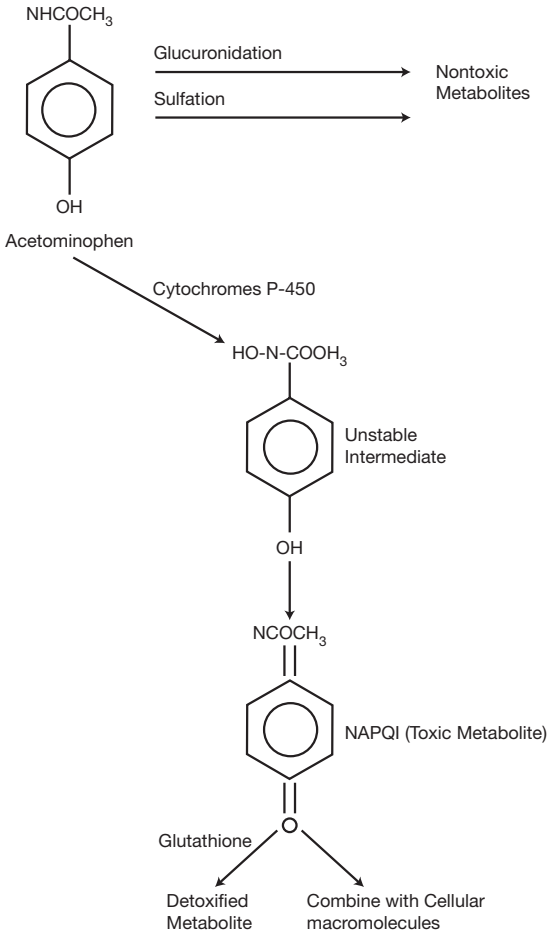

FIGURE 53-4 Metabolism of acetaminophen.

cytochromes P-450 (CYP3A4, CYP2E1, and CYP1A2) becomes quantitatively important. The product of this pathway is a highly reactive species *N*-acetyl-*p*-benzoquinoneimine (NAPQI),[25] a potent electrophile. It is conjugated by glutathione as long as sufficient glutathione is available; otherwise, NAPQI reacts with cellular proteins, causing cell damage and cell death. *N*-Acetylcysteine acts by providing substrate for making more glutathione[26] and thus can minimize hepatotoxicity if given early enough. It does not reverse the toxic effects of the toxic intermediate once they have occurred. Other factors may influence the metabolism of acetaminophen. Cimetidine, which inhibits cytochromes P-450, interferes with acetaminophen toxicity in laboratory animals if given early, but the comparable dose for humans is probably toxic in itself. Concomitant drug treatment may induce cytochromes P-450 involved in the production of NAPQI. Fasting decreases the amount of glutathione in cells and thus increases acetaminophen toxicity. Additionally, recent reports indicate that nitric oxide may play a role in the mechanism of acetaminophen hepatotoxicity[27,28] and that interleukin-10 acts as an immunologic cytoprotective mediator by interfering with nitric oxide production and possibly with the action of other proinflammatory cytokines.[29]

The clinical course of single high-dose acetaminophen hepatotoxicity is distinctive. Immediately after taking a large single dose of the drug, there is nausea and vomiting. These symptoms clear, and then there is an interval before hepatic toxicity becomes clinically apparent. At that point, jaundice, abnormal serum aminotransferases, and coagulopathy develop. Serum aminotransferases may be extremely high in this condition, and the degree of abnormality is not necessarily predictive of outcome. Finally, hepatic failure may supervene with progressive coma. In adults, clinical findings predicting poor outcome (ie, extremely severe hepatic failure) are the concurrent findings of serum creatinine > 300 µmol/L *and* prothrombin time > 100 seconds (international normalized ratio > 7) *and* grade 3 or 4 hepatic encephalopathy in patients with a normal pH or the single finding of arterial pH < 7.3 in a patient who is not hypovolemic.[30]

Whether to use *N*-acetylcysteine can be decided on the basis of plotting on a semilogarithmic graph the patient's plasma acetaminophen concentration against time[31]; if it falls in the zone for probable hepatic toxicity, *N*-acetylcysteine should be given. *N*-Acetylcysteine is most effective if given within 10 hours of acetaminophen ingestion and may be of less benefit if given more than 24 hours after ingestion of the acetaminophen. However, even if there is doubt as to its usefulness, it should be given anyway. Indeed, there is a strong case for treating all patients with *N*-acetylcysteine because some patients who appear to be at low risk by the nomogram develop severe hepatotoxicity.[32] In adults, late administration of *N*-acetylcysteine has been associated with greater survival after acute acetaminophen intoxication; no adverse side effects of the *N*-acetylcysteine were observed.[33,34] A 72-hour regimen of oral *N*-acetylcysteine appears to be as effective as the 20-hour intravenous regimen; the oral regimen may be more effective if treatment is delayed.[35] This regimen consists of a loading dose of 140 mg of oral *N*-acetylcysteine per kilogram of body weight, followed 4 hours later by 70 mg per kilogram given every 4 hours for an additional 17 doses, and it can be given by a nasogastric tube. A recent retrospective study of children 1 to 17 years old who presented with acetaminophen poisoning showed that the best predictor for low risk of acetaminophen hepatotoxicity in this setting was normal prothrombin time *and* aspartate aminotransferase *and* ALT at 48 hours after ingestion, and these authors concluded that treatment with *N*-acetylcysteine should be used for at least 48 hours in children—longer if the clinical situation warranted it.[36] Activated charcoal may be effective but only if administered early (less than 1 hour after the ingestion); interaction with *N*-acetylcysteine reduces the effectiveness of charcoal.[37] Inducing vomiting may not provide any benefit. Hemodialysis, if it is to be effective at all, must be used early when acetaminophen plasma concentrations are high.

Extensive reviews of acetaminophen poisoning in children suggest that younger children tend to be resistant to this hepatotoxicity.[38,39] The incidence of hepatotoxicity was 5.5% in a study of 417 children 5 years old or less compared with 29% in adolescents and adults at comparable toxic blood levels.[38] Various studies of acetaminophen pharmacokinetics, metabolism, and toxicity in children

suggest a biochemical basis for this observation. The elimination half-life is essentially the same in children and adults, although, with interindividual variation, it ranges as much as 1 to 3.5 hours.[40] The elimination half-life is somewhat longer (2.2–5.0 hours) in neonates. The profile of metabolites differs greatly in early childhood from adolescence and adulthood: sulfation predominates over glucuronidation.[41] The switch to the adult pattern seems to occur around 12 years of age. However, even in newborns, urinary metabolites reflecting cytochrome P-450–generated intermediates can be found; thus, the capacity for producing toxic metabolites seems to be present from an early age.[42,43] In vitro studies with fetal human hepatocytes have shown that the cytochrome P-450–generated intermediates can be formed and conjugated to glutathione as early as at 18 weeks of gestation, but the rate of formation is approximately 10% of that in adult human hepatocytes; sulfation, but not glucuronidation, of acetaminophen also can be detected in human fetal liver cells.[44] Studies in young rats showed less susceptibility to hepatotoxicity in the 11-day-old rat compared with the adult rat.[45] In other studies, hepatocytes from young rats were shown to have a higher capacity for synthesizing glutathione than those from older rats and to be able to also increase synthesis when glutathione is depleted.[46] Perhaps human infants also have a greater capacity for synthesis of glutathione than adults and thus can detoxify acetaminophen toxic metabolites more effectively.

Despite their relative resistance to acetaminophen hepatotoxicity, young children definitely can develop severe hepatotoxicity from acetaminophen. The threshold dose for severe toxicity in children has not been determined but is probably in the range of a single dose of 120 to 150 mg/kg.[47] In contrast to single high-dose ingestion, therapeutic misadventure is an important pattern of hepatotoxicity in young children. This term denotes hepatotoxicity that develops after taking repeated doses of relatively small amounts of acetaminophen (three to four times the recommended dose) for a short time, usually a few days.[48–52] Typically, the improper use of acetaminophen occurs because the dosage schedule was not understood, a different preparation of acetaminophen was substituted for the age-appropriate version (eg, tablet substituted for elixir), or the wrong measuring device was used. Incorrect use of sustained-release preparations or inadvertent overdosing because it was not appreciated that many over-the-counter cold remedies contain acetaminophen may also lead to hepatotoxicity. The threshold dose for hepatotoxicity under these circumstances has been estimated at 90 mg/kg/d.[53] The liver disease presents as acute liver failure, which is often attributed to another etiology, usually viral hepatitis. The typical clinical course of the single large-dose ingestion is either not present or not noticed. Serum concentrations of acetaminophen are frequently not in a toxic range. Diagnosis requires an extremely meticulous drug history to find out exactly what preparation of acetaminophen was used and how often. The nomogram for treatment with *N*-acetylcysteine does not apply; however, finding a detectable concentration of acetaminophen at 24 hours or more after the last dose suggests this etiology. An estimated elimination half-life > 4 hours also suggests acetaminophen hepatotoxicity. Detection of serum acetaminophen-cysteine conjugates by high-performance liquid chromatography is a sensitive diagnostic test.[54] These children should be treated with *N*-acetylcysteine as soon as possible. The intercurrent illness for which the acetaminophen was used may have caused enough anorexia to deplete normal glutathione stores. Hepatotoxicity with extreme prolongation of the elimination half-life of acetaminophen has been reported in infants born after maternal self-poisoning with acetaminophen.[43,44]

Rectal administration of acetaminophen may also cause hepatotoxicity. Absorption from the suppository is often highly variable. In general, it takes longer to attain peak blood levels, but bioavailability can vary within the length of a single suppository and between different types of suppository depending on carrier composition. Overall, this appears to be a highly unsatisfactory way to give the drug because it is difficult to predict efficacy, determine dosing interval, and calculate cumulative dose. Hepatic failure associated with rectal acetaminophen has been reported, probably owing to high-dose acetaminophen, although the child also received diclofenac and underwent appendectomy.[55]

Initial studies on the mechanism of acetaminophen toxicity showed that toxicity was worse when animals were pretreated with the polycyclic aromatic hydrocarbon 3-methylcholanthrene, a potent inducer of CYP1A1. It has become evident that chronic alcoholics are more sensitive to acetaminophen than nonalcoholics in that they can develop subacute acetaminophen hepatotoxicity after taking ordinary therapeutic doses over time because of induction of CYP2E1.[56] Some adolescents may be at risk for this type of acetaminophen hepatotoxicity. Whether exposure to environmental toxins such as polychlorinated biphenyls or aromatic hydrocarbons, cigarette smoking, or chronic use of proton pump inhibitors that induce CYP1A2 increases susceptibility to acetaminophen hepatotoxicity remains unproved. Whether obesity (often associated with CYP2E1 induction) enhances the risk of acetaminophen hepatotoxicity has not been established. Available data relevant to children do show that concomitant treatment with medications that induce cytochromes P-450 lowers the threshold for acetaminophen hepatotoxicity. These drugs include phenobarbital, carbamazepine, phenytoin, rifampin, and isoniazid (INH). Mercury poisoning through exposure to elemental mercury apparently enhanced acetaminophen hepatotoxicity in one child.[57]

Phenytoin

Although the commonly used anticonvulsant diphenylhydantoin has been associated with a broad range of adverse effects, phenytoin-induced hepatitis is important because severe hepatic necrosis and liver failure often develop. The perception that it is rare in children is misleading. Phenytoin-associated hepatitis was the only hepatitis mentioned specifically among adverse drug reactions in a large prospective study of adverse drug reactions in children.[18] There are at least 30 cases in the literature[58,59] and an addi-

tional 18 cases of hepatic dysfunction in patients (9 of whom were children) whose adverse reaction to phenytoin was dominated by other organ system involvement.[60]

Phenytoin hepatotoxicity typically presents as part of a systemic disease with fever, rash (including morbilliform rash, Stevens-Johnson syndrome, and toxic epidermal necrolysis), lymphadenopathy, leukocytosis, eosinophilia, and atypical lymphocytosis. Serum aminotransferases are elevated, and the patient may be moderately jaundiced. In severe cases, clinical features of hepatic failure (coagulopathy, ascites, altered level of consciousness) are also present. Histopathologic examination of the liver shows spotty necrosis of hepatocytes, along with features reminiscent of mononucleosis in some cases or of viral hepatitis in others; cholestasis may complicate more severe hepatocellular injury; granulomas are sometimes found.[61] Although treatment of severe phenytoin hepatitis with high-dose intravenous corticosteroids has not been tested in a controlled trial and anecdotal reports do not uniformly show clear benefit, intravenous methylprednisolone 2 mg/kg/d has been effective in some patients. In patients with severe Stevens-Johnson syndrome, use of intravenous gammaglobulin has also been advocated.[62]

The typical clinical presentation of phenytoin hepatotoxicity is termed a "drug hypersensitivity reaction." There is reason to believe that this clinical syndrome develops as a result of abnormal handling of a toxic metabolite of phenytoin. Phenytoin is metabolized via an arene oxide intermediate that is ordinarily metabolized and thus detoxified by epoxide hydrolase.[63] When lymphocytes, which are readily isolated cells complete with most phase II biotransformation pathways, are incubated in vitro with phenytoin and a murine microsomal system that can generate the intermediate metabolites of phenytoin, lymphocytes from persons who have developed the drug hypersensitivity syndrome to phenytoin are killed in excess of control lymphocytes.[63] If lymphocytes from normal individuals are pretreated with chemicals that inhibit cellular epoxide hydrolase, these lymphocytes behave like those from affected individuals.[64] Studies of parents indicate an intermediate sensitivity to the toxic metabolite(s), consistent with an inherited defect in drug detoxification. Instead of causing cell death, binding of the toxic metabolite may create haptens for initiating an immune response. This may account for the appearance of hypersensitivity clinically and for positive immune challenges noted by others.[65] More recent studies have failed to confirm the thesis that deficient epoxide hydrolase activity is responsible for phenytoin hepatotoxicity.[66] Others have shown elaboration of reactive intermediates, including quinone derivatives.[67,68]

Three of four children reported with fatal diphenylhydantoin hepatotoxicity were taking phenobarbital at the same time. Because in vitro studies indicate that some patients who cannot detoxify toxic intermediates of phenytoin are similarly sensitive to phenobarbital, this combined treatment may have made the liver damage worse. Another patient was switched from phenytoin to phenobarbital and then relapsed; he improved when high-dose corticosteroids were given along with phenobarbital.[58]

Carbamazepine

Carbamazepine is a dibenzazepine derivative, similar structurally to imipramine in that it has fundamentally a tricyclic chemical structure. Hepatotoxicity is relatively uncommon. In adults, the predominant hepatotoxicity has been granulomatous hepatitis presenting with fever and right upper quadrant pain, suggestive of cholangitis.[69,70] In children, the clinical picture has been more of a hepatitis, sometimes dominating a drug hypersensitivity syndrome like that of phenytoin. One child died of progressive liver failure when carbamazepine was not stopped in time.[71] Four children with fatal acute liver failure were taking carbamazepine, phenytoin, and primidone.[72] More recently, severe hepatitis was reported in three children taking only carbamazepine: one recovered with corticosteroid treatment, but the others died or required liver transplant.[73] Another child developed acute severe hepatitis 5 months after beginning treatment with carbamazepine; she survived with prednisone treatment.[74] Two other children presented with a mononucleosis-like illness with rash, lymphadenopathy, hepatosplenomegaly, hepatosplenomegaly, and, eventually, neutropenia.[75,76] This is similar to a child treated at the Hospital for Sick Children in Toronto (Figure 53-5), who presented with fever, rash, incipient liver failure, lymphopenia, and eosinophilia. In vitro rechallenge of her lymphocytes with metabolites of carbamazepine provided evidence of defective detoxification mechanisms. An infant boy also presented here with only hepatotoxicity and three other children with drug hypersensitivity to carbamazepine, with hepatitis not the dominant feature, have been described.[60] Carbamazepine may also be metabolized via arene oxides, although not all data support this thesis.[77]

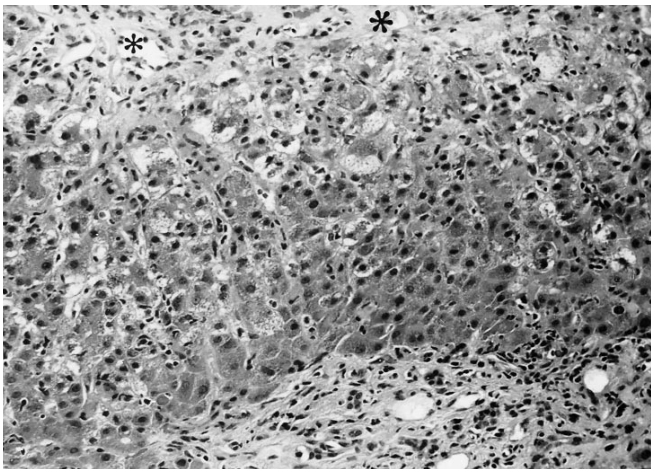

FIGURE 53-5 Liver biopsy in carbamazepine hepatotoxicity. The portal area shows widening with fibrosis, ductular proliferation, and mild chronic inflammatory changes. The lobular parenchyma shows variability in the size of the hepatocytes, with many swollen ballooned hepatocytes in zones 2 and 3 and occasional inflammatory cells. In zone 3, there is central bridging necrosis (*asterisks*). The pathologic diagnosis is drug-induced acute hepatitis with bridging necrosis; these findings are fully representative of the hepatic lesion with carbamazepine (hematoxylin and eosin, ×250 original magnification). Courtesy of Dr. M. J. Phillips.

Recent work indicates that carbamazepine is metabolized to a reactive iminoquinone species that can react with glutathione.[78] Persons with the metabolic idiosyncrasy that renders them susceptible to carbamazepine hepatotoxicity may also be susceptible to phenytoin and phenobarbital hepatotoxicity.

Phenobarbital

Hepatitis is a rare complication of phenobarbital use. When it occurs, it, too, is usually part of a multisystemic drug hypersensitivity reaction, but it may dominate the clinical picture. Seven of 13 patients reported in the world literature were children.[79] Two additional children, a girl aged 3 years and a boy aged 18 months, have been treated at the Hospital for Sick Children in Toronto; both had severe hepatic dysfunction with coagulopathy or ascites but ultimately survived. Two further cases in children have been treated at the Hospital for Sick Children in Toronto, but hepatitis was not the dominant clinical feature.[60] In most cases of major hepatotoxicity, jaundice began 1 to 8 weeks after starting phenobarbital, along with generalized rash and fever. Usually, the liver disease was moderately severe but self-limited; however, a few patients developed severe hepatitis with coagulopathy and ascites, and one died fulminantly. One child developed chronic liver disease. Severe phenobarbital hepatitis may be treated with intravenous methylprednisolone.[79]

The mechanism of this hepatotoxicity remains unclear. Results from in vitro rechallenge indicate an inherited defect in detoxification of active metabolite. Phenobarbital may also be metabolized via arene oxide intermediates, which are typically detoxified via epoxide hydrolase. In in vitro rechallenge, if lymphocyte epoxide hydrolase is inhibited, the extent of cytotoxicity of metabolites generated from phenobarbital, as from phenytoin, increases.[64]

Persons who develop hepatotoxicity from phenobarbital also cannot detoxify other barbiturates and may get worse if so treated. Sedation for a diagnostic procedure in a child is an important opportunity for such a drug exposure. It is also important to bear in mind that persons who cannot detoxify the toxic metabolite(s) of phenobarbital often cannot detoxify those of carbamazepine or phenytoin either.[60] Thus, substituting either may worsen the hepatitis.

Lamotrigine

Lamotrigine may cause hepatotoxicity with a typical anticonvulsant hypersensitivity syndrome clinically.[80–82] Hepatic involvement varies from elevated serum aminotransferases to severe acute hepatitis. Lamotrigine can generate an arene oxide intermediate, which is a candidate for mediating this hepatotoxicity.[83] Whether cross-reactivity between lamotrigine and the phenytoin-carbamazepine-phenobarbital anticonvulsant group exists has not been conclusively proven.

Valproic Acid

Valproic acid (VPA) is chemically very different from the other anticonvulsants above: it is an eight-carbon, branched fatty acid. Hepatotoxicity is mild or severe. In a certain proportion of patients, estimated at 11% overall,[84] serum aminotransferase levels become abnormal, typically within a short time of starting treatment. This biochemical abnormality returns to normal when the dose of VPA is decreased. Much more rarely, patients develop progressive liver failure that, in some cases, looks similar clinically to Reye syndrome. This severe hepatotoxicity does not always regress when the drug is withdrawn. Its occurrence cannot be predicted by regular monitoring of serum aminotransferases and other liver function tests.[85] The time from initiating treatment with VPA and onset of liver disease is usually less than 4 months, but hepatotoxicity may develop later in treatment. A distinctive feature of severe VPA hepatotoxicity is that it is more common in children than in adults.[86] Special identifiable risk factors include age less than 2 years, multiple anticonvulsant treatment along with VPA, and coexistent medical problems such as mental retardation, developmental delay, or congenital abnormalities.[87] In children with these predisposing factors, the risk of fatal hepatotoxicity is 1 in 600.[88] Hyperammonemia, not associated with liver failure, is another metabolic adverse effect of VPA.[89,90]

Severe hepatotoxicity was described with rising use of VPA,[91,92] and the total experience has been reviewed in detail.[84,93,94] The severe hepatotoxicity typically presents with a hepatitis-like prodrome, mainly malaise, anorexia, nausea, and vomiting. Seizure control is often found to deteriorate over the same time period. An intercurrent illness with fever may precede the onset of liver failure. Coagulopathy is often present early; jaundice and other signs of progressive hepatic insufficiency, such as ascites and hypoglycemia, develop later. Death owing to liver failure, complicated by renal failure or infection, is the frequently reported outcome; liver transplant may be performed. Liver histology reviewed in one large series shows evidence of hepatocellular necrosis, which may be zonal, with extensive loss of hepatocytes and severe damage to those remaining.[93] Acidophilic bodies, ballooned hepatocytes, and cholangiolar proliferation may be present. Microvesicular steatosis is the most common finding overall and is often present in addition to the features of cell necrosis. Hepatocellular mitochondria may be prominent on light microscopy so that the hepatocytes have a granular, very eosinophilic appearance (Figure 53-6). In cases presenting clinically like Reye syndrome, fever, coagulopathy, progressive loss of consciousness, severe acidosis, and variably abnormal serum aminotransferases are present, but the patient is not jaundiced.[92] Hepatocellular necrosis, as well as microvesicular fat, is found on histologic examination of the liver, unlike the histologic findings of Reye syndrome. Electron microscopically, the mitochondrial changes associated with VPA toxicity differ from those of Reye syndrome.

The mechanism of this severe hepatotoxicity is thought to involve generation of toxic metabolite(s) plus some type of metabolic idiosyncrasy. Metabolic idiosyncrasy is probable not only because severe hepatotoxicity is rare but because toxic ingestions do not necessarily lead to liver necrosis.[95] VPA is related structurally to two known hepatotoxins: hypoglycin, which causes Jamaican vomiting sickness, characterized by microvesicular steatosis, and 4-pentenoic acid,

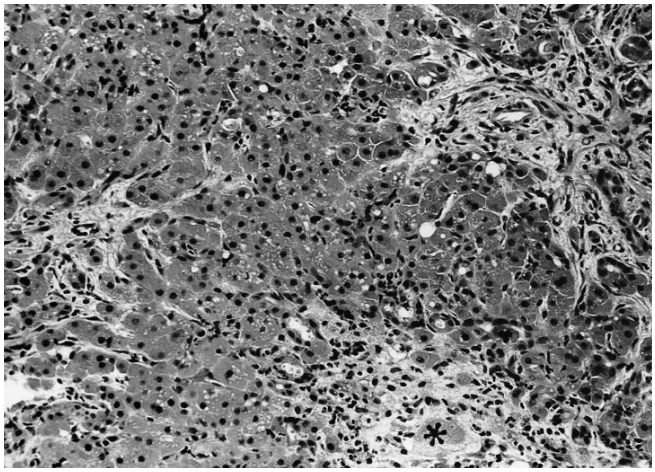

FIGURE 53-6 Liver biopsy in valproic acid hepatotoxicity. The liver lobule shows great reduction in the number of hepatocytes. There is portal tract widening with increased numbers of bile ducts. Hepatocytes are swollen, and most contain multiple microvesicular fat droplets. In zone 3, there is an area of necrosis (*asterisk*) with tubular transformation of hepatocytes surrounding the necrotic zone (hematoxylin and eosin, ×250 original magnification). Courtesy of Dr. M. J. Phillips.

which causes microvesicular steatosis in rat liver and inhibits β-oxidation. The partly unsaturated metabolite 4-ene-valproic acid (4-ene-VPA), produced by Ω-oxidation, which is a minor pathway of VPA metabolism, is chemically very similar to these toxins. Formation of 4-ene-VPA has been demonstrated in a primate model[96] and in patients with liver failure developing on VPA treatment.[97] Administration of 4-ene-VPA to rats caused accumulation of microvesicular fat in hepatocytes along with changes in hepatocyte organelles, including mitochondrial abnormalities and elaboration of myeloid bodies,[98] as well as inhibition of β-oxidation.[99] Both VPA and 4-ene-VPA inhibit β-oxidative metabolism of decanoic acid, a fatty acid of medium length; in contrast, 4-pentenoic acid is only a weak inhibitor in this system.[100] Thus, VPA and its metabolite(s) are capable of causing adverse changes in liver cell metabolism, which may lead to the observed features of this hepatotoxicity. The similarities and differences in these metabolic toxicities compared with those of hypoglycin and 4-pentenoic acid merely reflect the complexity of this metabolic system. The β-oxidation metabolite of 4-ene-VPA, (*E*)-2,4-diene-VPA, may also mediate VPA hepatotoxicity as a toxic intermediate. Urinary levels of thiol conjugates of 4-ene-VPA and (*E*)-2,4-diene-VPA were found to be elevated in children less than 7.5 years old receiving VPA monotherapy and were also elevated in older children if they were receiving treatment with an antiepileptic drug capable of inducing cytochromes P-450 along with the VPA.[101] Concentrations of the thiol conjugates of (*E*)-2,4-diene-VPA were higher than those of 4-ene-VPA.

VPA is capable of inhibiting β-oxidation in humans. Investigations of VPA metabolism in patients with severe hepatotoxicity indicate that β-oxidation is inhibited in these patients,[102] although the step in β-oxidation at which the apparent block occurred varied individually.[103] Increased amounts of 4-ene-VPA were detected in some cases.[97,104,105] Biochemical abnormalities indicating inhibition of β-oxidation have also been found in children on VPA treatment at low risk for hepatotoxicity.[106] These observations suggest a complex pattern of inhibited β-oxidation and increased utilization of alternative pathways, including those associated with cytochromes P-450 and δ-dehydrogenation to produce, among other metabolites, 4-ene-VPA.

In VPA hepatotoxicity, the target organelle appears to be the mitochondrion. An individual who develops severe VPA hepatotoxicity may not be able to detoxify these metabolites or subsequent toxic intermediates before significant mitochondrial damage occurs. The defective detoxification pathway is not yet known. Studies of VPA toxicity in vitro in human liver slices indicate important interindividual variation in susceptibility to toxicity.[107] The metabolic idiosyncrasy might be a functional defect in the mitochondrion itself. An intercurrent environmental problem, such as a viral illness, might additionally inhibit β-oxidation. Experimental data in the ornithine transcarbamylase–deficient mouse support the hypothesis of an intrinsic metabolic defect in the mitochondrion. The ornithine transcarbamylase–deficient mouse develops hepatocellular necrosis and microvesicular steatosis at doses of VPA that do not affect the normal control adversely.[108] Individuals who develop severe VPA hepatotoxicity may have mitochondria biochemically predisposed to this injury. Ornithine transcarbamylase deficiency may be one such definable abnormality and has been suspected in one instance.[109,110] Other mitochondrial abnormalities may have predisposed some patients to VPA hepatotoxicity.[111]

Serum carnitine has been found to be abnormally low in persons with Reye syndrome. Decreased serum carnitine has also been found in VPA hepatotoxicity.[102,112] Serum carnitine is also low in patients treated chronically, without evidence clinically of hepatotoxicity.[112–114] Conjugation to carnitine is a unique metabolic pathway for VPA.[115] Whether this pathway is important for the development of hepatotoxicity is not known. Equally, the value of carnitine repletion as treatment for severe hepatotoxicity remains unproven, and most evidence to date suggests that it is ineffective.[106,116] However, a recent retrospective study indicated efficacy if carnitine was started very early in the course of severe hepatotoxicity.[117]

Sulfonamides

Hepatotoxicity may occur with any sulfonamide antibiotic. In children, this problem arises most commonly in connection with treatment for otitis media and upper respiratory infections or for inflammatory bowel disease. Sulfanilamide, trimethoprim-sulfamethoxazole, and pyrimethamine-sulfadoxine have all been associated with major hepatic injury.[118,119] Sulfasalazine has been associated with severe liver disease in adolescents and young adults.[120–123] Although the liver abnormality may be manifested only by elevated serum aminotransferases or may be a granulomatous hepatitis, the hepatic dysfunction may be severe enough to cause acute hepatic failure, which is fatal in some

cases. In general, hepatotoxicity is part of a clinical drug hypersensitivity reaction. Fever, significant rash, periorbital edema, atypical lymphocytosis, lymphadenopathy, and renal dysfunction with proteinuria have all been described.

Sulfonamide hepatotoxicity is due to elaboration of an electrophilic toxic metabolite in the liver. The intermediate appears to be the hydroxylamine derived from the particular sulfonamide or, more likely, the nitroso species derived from the hydroxylamine.[124–126] Patients who develop severe adverse reactions, including significant hepatotoxicity, have been shown to be slow acetylators (in the rapid/slow polymorphism for *N*-acetyltransferase) and are also unable to detoxify this reactive metabolite. On in vitro rechallenge of their lymphocytes with sulfonamide and a metabolite-generating system, the patient's lymphocytes show significantly more cytotoxicity than controls.[119] Glutathione *S*-transferases may be important for detoxifying the toxic intermediate.[127,128] How this reactive intermediate causes hepatocellular damage is not yet known. The multisystemic hypersensitivity features of this adverse drug reaction appear to be subsequent to metabolic events in that the reactive metabolite probably acts as a hapten to initiate the immune response. Thus, sulfa hepatotoxicity fundamentally represents metabolic idiosyncrasy, not simply allergy.

Erythromycin

Erythromycin estolate and other salts are used frequently in children. Although the estolate was originally associated with a cholestatic hepatic lesion, it is now clear that the ethylsuccinate and other salts are also potentially hepatotoxic.[129–132] Indeed, all forms of erythromycin are potentially hepatotoxic. The clinical presentation includes anorexia, nausea, predominantly right upper quadrant abdominal pain, and jaundice. Pruritus owing to cholestasis has been reported in some adults. Hepatomegaly, sometimes accompanied by splenomegaly, appears to be frequent in children. Erythromycin ethylsuccinate hepatotoxicity in a child was a relatively mild, self-limited disease.[130]

Histologic findings include prominent cholestasis, which is particularly severe in zone 3, focal necrosis of hepatocytes also tending to predominate in zone 3, and eosinophils in the portal infiltrates and in the sinusoids.[129] These histologic findings are different from those of extrahepatic biliary tract obstruction, although the clinical presentation may suggest biliary tract obstruction.

The mechanism of this hepatotoxicity remains obscure. Erythromycin itself, not a specific erythromycin salt, may be the cause of the hepatotoxicity. However, in the perfused rat liver model, erythromycin estolate led to decreased bile secretion, altered canalicular permeability, and decreased activities of Na/K–adenosine triphosphatase and Mg^{++}–adenosine triphosphatase, unlike erythromycin base.[133] Earlier studies in Chang liver cells suggested that erythromycin derivatives cause intrinsic hepatocellular damage. In various types of primary rat hepatocyte culture systems, erythromycin estolate leads to cytotoxicity.[134,135] Erythromycin and other macrolide antibiotics are metabolized in the liver by the CYP3A subfamily. Hepatocellular damage may be due to a toxic metabolite, but this is by no means proven. Cholestasis may also reflect damage to the cellular biliary apparatus. The association of eosinophilia with erythromycin hepatotoxicity in some patients probably represents a forme fruste of a drug hypersensitivity syndrome.

Propylthiouracil

Hepatitis is a rare complication of propylthiouracil treatment for hyperthyroidism. It tends to occur in girls, but this may reflect the greater frequency of thyroid disease in girls.[136–140] The clinical picture typically was a nonspecific hepatitic presentation with anorexia, nausea, vomiting, and jaundice. Serum aminotransferases were moderately elevated. Symptoms began typically within 2 to 3 months of starting treatment, but in one child, liver disease began at least 9 months after starting treatment and in another after 15 months. A more cholestatic picture has been reported in some adults. Liver histology shows mild to severe hepatocellular necrosis, which was characterized as submassive in three cases.

A single case of propylthiouracil hepatotoxicity associated with chronic active hepatitis has been reported in a child.[141] Hepatomegaly with elevated serum aminotransferases developed after more than 1 year of treatment. Both anti–smooth muscle antibodies and anti–liver/kidney microsomal (anti-LKM1) antibodies were negative. Liver biopsy showed portal inflammation with moderate piecemeal necrosis.

Aspirin

Hepatotoxicity has been associated with high-dose aspirin treatment. Approximately 60% of the 300 reported cases have been in patients with juvenile rheumatoid arthritis (JRA) (not necessarily all children), and a further 10% have occurred in children with acute rheumatic fever.[142] Hepatotoxicity may be more frequent in girls. The hepatotoxicity appears to be dose dependent, and patients without rheumatoid disease can develop hepatotoxicity. The preponderance of cases in patients with rheumatologic diseases, however, raises the possibility that these patients have a predisposition to this toxicity. One theory is that chronic inflammation favors generation of oxygen radicals.[143]

In most cases, salicylate hepatotoxicity presents with anorexia, nausea, vomiting, and abdominal pain, along with elevated serum aminotransferases.[144–148] Hepatomegaly is usually present, and the liver may be tender. Progressive signs of liver damage, such as jaundice and coagulopathy, are rare, occurring in approximately 4% of all reported cases.[142] However, even in uncomplicated cases, serum aminotransferase levels may be quite high, greater than 1,000 IU.[146] In some cases, encephalopathy (not related to Reye syndrome) was present.[149,150] Clinical and laboratory abnormalities resolve when aspirin is stopped. Rechallenge with aspirin may lead to recurrent hepatotoxicity. Liver histology frequently shows a rather nonspecific picture with acute, focal hepatocellular necrosis.[144]

A different clinical syndrome with hepatotoxicity has been reported in seven children with JRA, of whom all but one received aspirin.[151] Clinical features included high

fever, drowsiness, vomiting, hepatosplenomegaly, and bleeding owing to disseminated intravascular coagulation and suboptimal clotting factor synthesis. Liver histology showed steatosis (predominantly large droplet) and prominence of reticuloendothelial cells in the liver. Rechallenge with aspirin did not reproduce this syndrome, and it may have been related to other drug treatment or to intercurrent infection. Two children died of coma, but there was neither cerebral edema nor severe hyperammonemia noted, and other features were not typical of Reye syndrome. However, Reye syndrome can occur in children with rheumatologic diseases who receive aspirin chronically,[152] and its clinical presentation may be atypical.

Methotrexate

Methotrexate hepatotoxicity in children appears to be similar to that in adults. Chronic low-dose treatment used for treatment of psoriasis or connective tissue disease can cause hepatic fibrosis with steatosis.[153,154] Histologically, it may resemble alcoholic hepatitis with fibrosis. Cirrhosis can develop, and liver transplant has been performed in some adults treated for psoriasis.[155] In adults, obesity, diabetes, chronic alcohol abuse, older age, and large cumulative dose appear to be factors associated with increased risk of methotrexate hepatotoxicity. Serum aminotransferase levels may not indicate reliably the extent of ongoing liver damage, and liver biopsy prior to treatment and at regular intervals during prolonged treatment has been advised. Recent guidelines for monitoring methotrexate hepatotoxicity in adults with rheumatoid arthritis advocate a more formal approach to monitoring aspartate aminotransferase, ALT, ALP, albumin, and bilirubin (γ-glutamyltransferase to corroborate hepatic origin of ALP should be added to this list) every 4 to 8 weeks; liver biopsy is performed only when sustained abnormalities are found.[156] Liver biopsy prior to starting treatment is reserved for patients with known liver disease or specific risk (chronic hepatitis B or C infection). Meta-analysis indicates that there is a tangible risk in adults for significant hepatotoxicity owing to long-term, low-dose methotrexate.[157]

It is difficult to transpose these data from adults with various diseases directly to children. The risk factors identified in adults have limited applicability to children except for obesity. Regular monitoring of liver function tests in children receiving chronic methotrexate treatment is advisable. Children with JRA on methotrexate should have serum aminotransferases checked frequently (monthly or bimonthly). Those with elevated aspartate aminotransferase or ALT on ≥ 40% of tests in 1 year should be considered for liver biopsy. Generally, the surveillance regimen should be individualized for each child, depending on many variables, such as existence of previous liver disease (including chronic viral infection), concomitant drug therapy, cumulative methotrexate dose, chronic hypoalbuminemia, obesity, and diabetes mellitus. Liver biopsy is indicated to determine the extent of liver damage. Performing a liver biopsy after a large cumulative dose of methotrexate has been taken may be appropriate in some cases, especially if continued treatment is anticipated. A pretreatment liver biopsy is also sometimes appropriate since several studies indicate that hepatic abnormalities may be present prior to treatment, which would otherwise be wrongly attributed to methotrexate hepatotoxicity.

Several recent studies have examined the occurrence of hepatotoxicity in children with JRA treated with methotrexate over the long term. The risk of methotrexate hepatotoxicity in JRA appears to be comparatively low. No child in a cross-sectional study of 14 children with JRA who had received a methotrexate cumulative dose > 3,000 mg or > 4,000 mg/1.73 m^2 body surface area had significant fibrosis; one had moderate to severe fatty or inflammatory changes or hepatocellular necrosis on liver biopsy.[158] In a study of 37 liver biopsies from 25 patients with JRA, most were normal or near normal; 4 had moderate to severe fatty or inflammatory changes, and 2 had mild portal fibrosis. Weak yet statistically significant correlations were found between abnormal histology and percent frequency of serum aminotransferase elevations and body mass index.[159] In similar previous studies, normal or near-normal liver histology was found.[160,161] Two patients with JRA treated with methotrexate have been reported as developing some degree of liver fibrosis.[162]

High-dose methotrexate treatment used in some oncology regimens may cause acute hepatitis.[163,164] After more protracted treatment, hepatic damage may be relatively slight, apart from ultrastructural changes including steatosis, fibrosis, and damage to some hepatocellular organelles.[165] Others have also found steatosis, portal inflammation, or portal fibrosis on light microscopic examination of liver biopsies from children with acute lymphoblastic leukemia, treated with various drugs, including methotrexate.[166] Serum aminotransferase abnormalities did not predict histologic findings, which were, in general, mild after 2 years of treatment.[166,167]

The mechanism of this hepatotoxicity is not known. The dosage schedule may be important. Chronic intermittent administration of methotrexate may lead to recurrent hepatocellular damage superimposed on partial repair and regeneration, not unlike experimental models of carbon tetrachloride–induced hepatic fibrosis.

Antineoplastic Drugs

Besides methotrexate, many drugs used to treat neoplasia in childhood can cause hepatotoxicity.[168,169] A common and perplexing problem is elevation in serum aminotransferases without other evidence of severe liver toxicity. Antineoplastic drugs that commonly produce this reaction include nitrosoureas, 6-mercaptopurine, cytosine arabinoside, cisplatinum, and dacarbazine. Doxorubicin, cyclophosphamide, dactinomycin (actinomycin D), and vinca alkaloids are infrequently associated with hepatotoxicity, although drug interactions may increase their hepatotoxicity. Indeed, the difficulty in assessing the hepatotoxic potential of all of these drugs is that they are rarely used separately, and patients receiving them are usually at risk for multiple types of liver injury.

In children and adults, L-asparaginase has been associated with more severe damage characterized by severe steatosis, hepatocellular necrosis, and fibrosis. This is usu-

ally reversible after the L-asparaginase is stopped.[170] The most likely mechanism for this hepatotoxicity is a profound interference with hepatocellular protein metabolism. Dactinomycin (actinomycin D) is exceptionally associated with severe liver damage. Several patients treated with dactinomycin at the Hospital for Sick Children in Toronto developed acute severe hepatitis, with extremely elevated serum aminotransferases and coagulopathy, all of which resolved spontaneously off the drug. The mechanism is not known. Mithramycin has been associated with acute hepatic necrosis. Thrombocytopenia and acute liver failure have been reported in an 18-year-old patient receiving carboplatin.[171]

Thioguanine and other antineoplastic agents, including cyclophosphamide, cytosine arabinoside, busulfan, dacarbazine, and carmustine, have been associated with veno-occlusive disease (VOD) at conventional or high doses.[172] It most frequently develops after allogeneic bone marrow transplant. It presents acutely with an enlarged tender liver, ascites or unexplained weight gain, and jaundice; serum aminotransferases may be elevated; it may progress to cirrhosis. Although irradiation can, in itself, lead to this type of hepatic vascular damage,[173] the combination of irradiation and chemotherapy in conditioning regimens may lead to earlier development of VOD than after single-agent (irradiation or chemical) injury.[174] Clinical predictors of likelihood for development of VOD in children have not yet been identified, but patients with chronic hepatitis, for example, owing to chronic hepatitis C or possibly nonalcoholic steatohepatitis, preceding bone marrow transplant are at increased risk.

The pathogenesis of VOD involves direct toxicity to the sinusoidal endothelial cells in the liver. When it is due to dacarbazine, the damage to endothelial cells occurs through production of toxic metabolite(s) in the endothelial cells; glutathione appears to protect against toxicity.[175] With cyclophosphamide, the toxic intermediate may be produced in hepatocytes.[176] Treatment with *N*-acetylcysteine may reverse the process.[177] Unchecked, the damage progresses from congestion and hemorrhage into the space of Disse in zone 3 of the Rappaport acinus to damage to terminal hepatic venules, which has been described as sinusoidal obstruction syndrome, and, subsequently, to fibrosis.[178] The term sinusoidal obstruction syndrome emphasizes that damage to sinusoidal endothelial cells is the initiating event in this kind of hepatotoxicity and that terminal hepatic venules may be patent as the lesions evolve; however, in many patients, only the resulting lesion with obliterative damage to terminal hepatic venules (namely, VOD) is identified.

Cyclosporine

Cyclosporine is a calcineurin inhibitor with potent immunosuppressive effects. It is extremely lipophilic and has a novel cyclic structure composed of 11 amino acids. It is metabolized in humans by CYP3A4. Although, at high dosage, jaundice with abnormal serum aminotransferases may develop, the more common hepatic abnormality is mainly cholestasis: direct hyperbilirubinemia without other evidence of hepatocellular damage.[179] Cholestasis without biochemical or histologic evidence of hepatotoxicity after cyclosporine administration has been demonstrated in a rat model.[180] Cyclosporine inhibits the bile salt excretory pump (BSEP) directly,[181] down-regulates expression of the multidrug resistance–associated protein (Mrp2), which is located on the apical membrane, and interferes with enzymes responsible for synthesizing glutathione.[182] It may also affect membrane fluidity and thus impair canalicular transporter function indirectly.[183] Increased incidence of gallstones has been reported in children receiving cyclosporine after organ transplant.[184]

Pemoline

Pemoline, a second-line drug for treatment of attention-deficit disorders, has been associated with significant hepatotoxicity: asymptomatic elevation of serum aminotransferases, hepatitis with jaundice, and acute liver failure.[185–190] The largest series documented hepatitis of variable severity, including one patient who died with fulminant hepatic failure[191]; male patients predominated. Two other deaths associated with hepatic dysfunction while on pemoline have been reported. Both patients were boys: one may have had previous chronic liver disease, and the other may have taken an overdose of pemoline.[192] Other cases of severe hepatotoxicity leading to liver transplant have been reported. Pemoline has been withdrawn in some countries. If it is used, serum aminotransferases and other liver function tests must be monitored frequently throughout the entire term of treatment. When pemoline is associated with elevated serum aminotransferases, it must be discontinued. The mechanism of this hepatotoxicity is not known but is probably related to the hepatic metabolism of the drug, not to immune response. Pemoline should not be combined with other hepatotoxic drugs and should not be used in patients with a history of liver disease.

Risperidone

Risperidone is a new drug for various psychiatric problems, including autistic disorders. A few cases of possible hepatotoxicity in children have been reported in adults,[193,194] although they are difficult to interpret because of prior liver disease or concomitant drug treatment. A report of risperidone hepatotoxicity in two children may actually have been concurrence of nonalcoholic steatohepatitis and possible drug toxicity,[195] and a subsequent case series review did not corroborate these findings.[196] Nevertheless, serum aminotransferase elevations after starting risperidone have been observed in children. Risperidone typically leads to weight gain. Body mass index should be assessed before and during treatment. Children taking risperidone should have serum aminotransferases and bilirubin monitored regularly until the risk of hepatotoxicity is determined.

Isoniazid

In adults, INH is capable of causing a wide spectrum of toxic liver disease.[197,198] Clinically, the common finding is

an asymptomatic patient with elevated serum aminotransferases. The development of a hepatitis-like illness with fatigue, anorexia, nausea, and vomiting is ominous. On histologic examination, INH hepatotoxicity frequently looks like acute viral hepatitis. Submassive hepatic necrosis can occur, and, occasionally, the hepatocellular damage is zonal.

There have been scattered reports of INH hepatotoxicity, including fatal hepatic necrosis, occurring both in children being treated for tuberculosis and in those receiving prophylaxis.[199–205] The overall incidence of symptomatic INH hepatitis in children is 0.1 to 7.1%.[206] Large studies of INH hepatotoxicity as evidenced by abnormal serum aminotransferases in children receiving INH alone as prophylaxis showed a 7% incidence in a series of 369 children[207] and a 17.1% incidence in 239 patients aged 9 to 14 years.[208] The discrepancy in these two studies is partly methodologic. However, these findings are nearly the same as in adults, where the incidence of transiently elevated serum aminotransferases is estimated at 10 to 20%.[198] Several studies of children being treated with INH and rifampicin for tuberculosis also show a high incidence of hepatic dysfunction. Thirty-six of 44 patients receiving INH and rifampicin had some elevation of serum aminotransferases and 15 patients (42%) had elevated AST and were jaundiced.[209] These children received comparatively high doses of INH and rifampicin, and many had severe infection. In another study, 37% had hepatotoxicity, including four of seven under 17 months old.[210] These children received conventional, lower doses of INH and rifampicin and brief sequential courses of streptomycin and ethambutal. Inducers of cytochromes P-450 may contribute to INH hepatotoxicity. Severe INH hepatotoxicity occurred in a 10-year-old boy concurrently treated with carbamazepine.[211] As in adults, hepatotoxicity typically developed in children in the first 8 to 10 weeks of treatment. In most children, it resolved with either no change in dose or else a modest dose reduction. Children with more severe tuberculosis, such as tuberculous meningitis, seemed to be at greater risk for hepatotoxicity.

INH hepatotoxicity appears to be due to a toxic metabolite, although the mechanism remains obscure. Acetylisoniazid or its derivatives have been thought to be the toxic intermediate. Susceptibility to hepatotoxicity has been linked to the polymorphism for *N*-acetylation—rapid acetylators being at greater risk.[198] Clinical studies in children have not shown a universal trend implicating rapid acetylators as more susceptible.[210,212] Metabolism by cytochromes P-450 may also be implicated because pretreatment with phenobarbital appears to increase toxicity in laboratory animal models. Rifampicin may enhance INH toxicity by inducing certain cytochromes P-450.[204]

It is probably inaccurate to regard INH hepatotoxicity as uncommon in children. Some of the hepatotoxicity appears to be dose related, and recent downward revisions of dosage recommendations may eliminate some instances of hepatotoxicity. Children who have more severe tuberculosis or who receive simultaneous treatment with rifampicin, phenytoin, or phenobarbital may be at increased risk. The genetic predisposing factors remain unclear. Monitoring with frequent measurement of serum aminotransferases and direct inquiry for symptoms of hepatitis is important in the first 10 to 12 weeks of treatment. INH should be discontinued if anorexia, nausea, or vomiting develops.

Halothane

Halothane hepatotoxicity shows two major clinical patterns. One is hepatitis indicated by abnormal serum aminotransferases in the first or second week after the anesthetic exposure. The other pattern is severe hepatitis with extensive hepatocyte necrosis and liver failure.[213] It is remarkably infrequent in children. Large retrospective studies in children estimate that the incidence is approximately 1 in 80,000 to 1 in 200,000,[214,215] in contrast to an incidence of 1 in 7,000 to 1 in 30,000 in adults.[216] The infrequency of this hepatotoxicity is not due to lack of exposure to the drug because halothane is a mainstay of pediatric anesthetic practice. However, despite its rarity, it is evident that halothane hepatitis can occur in children. Eight cases have been documented in detail in children aged 11 months to 15 years, all of whom had multiple exposures to halothane; one died of fulminant liver failure, but all others recovered.[217,218] In addition, three cases of halothane hepatitis were found retrospectively,[214,215] as well as three further children who succumbed to fulminant hepatic failure after halothane.[219–221] Perhaps an additional eight cases may be found among other reports of hepatitis or hepatic failure in children after halothane anesthesia where inadequate data or the presence of complicated, and thus confounding, systemic disease make evaluation difficult. Clearly, this problem cannot be discounted in children. There has been some speculation that children with α_1-antitrypsin deficiency may tolerate halothane poorly.

Halothane is metabolized by various cytochromes P-450, and toxic metabolites are generated.[222–224] Depending on the prevailing tissue oxygen tension, oxidative or reductive metabolic pathways predominate (Figure 53-7). The reductive pathway generates a toxic intermediate identified as a chlorotrifluoroethyl radical, which leads to lipid peroxidation,[222] and the oxidative pathway generates a trifluoroacetyl intermediate, which can acetylate cellular membranes. The contribution of these metabolic systems to halothane hepatotoxicity in humans is complex. The oxidative pathway is probably predominant in humans. CYP2A6 and CYP3A4 are associated with the reductive metabolism,[225] and CYP2A6 and CYP2E1 (mainly the latter) are associated with the oxidative pathway.[226]

Recent studies of the mechanism of halothane hepatotoxicity are beginning to show the connection between cytotoxic damage from reactive intermediates and immunologic phenomena often associated with this hepatotoxicity. Patients surviving halothane hepatotoxicity have been found to have an antibody to altered hepatocyte membrane constituents.[227] In rabbits, only oxidative metabolism of halothane has been associated with production of this altered hepatocyte membrane antigen, and the effect is greater after pretreatment with the polycyclic aromatic hydrocarbon β-naphthaflavone.[228] Other investigators have shown that tri-

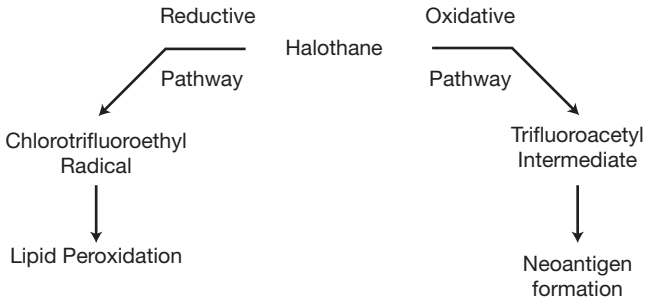

FIGURE 53–7 Metabolic fates of halothane. Whether the reductive or oxidative pathway predominates depends on the prevailing tissue oxygen tension.

fluoroacetyl adducts can be identified with fluorescent-tagged antibodies, mainly in zone 3 hepatocytes in the rat after phenobarbital pretreatment and also on the hepatocyte plasma membrane.[229] Antibodies to these neoantigens have been identified in sera from patients with halothane hepatitis.[230] Further studies have shown that neoantigens, analogous to these neoantigens derived from halothane-treated animals, are expressed in human liver in individuals exposed to halothane.[231] One of these neoantigens has been purified and identified as a microsomal carboxylesterase.[232] Kupffer cells may participate in the process by which the trifluoroacetyl adducts initiate an immune response.[233] Other studies in rats suggest that factors such as gender and previous exposure to specific inducers of cytochromes P-450 may influence the expression of halothane-associated neoantigens.[234] Thus, the oxidative pathway appears to be associated with hepatocellular membrane damage and immune phenomena typical of the clinical hepatotoxic syndrome.

In summary, severe halothane hepatotoxicity involves several factors whose interdependence can be partly defined. Formation of toxic metabolites depends on tissue oxygenation and possibly on which cytochromes P-450 are involved. Idiosyncratic susceptibility with inadequate detoxification of an electrophilic intermediate may play a role.[216] The extent of immune phenomena may further depend on the immunogenicity of adducts formed and the innate immune responsiveness of the host.[229] Halothane hepatotoxicity provides the best example currently available for demonstrating a link between drug metabolism and an immune reaction in hepatotoxicity.

Penicillins

Semisynthetic derivatives of penicillin may cause liver damage. Amoxicillin-clavulinic acid has also been associated with cholestasis[235] or a mixed hepatic-cholestatic reaction.[236,237] The cholestatic effect of flucloxacillin may be mediated by an intermediate produced by hepatocellular cytochromes P-450 that may be toxic to bile duct epithelial cells.[238] With prolonged cholestasis owing to semisynthetic penicillins, the development of small portal ("interlobular") bile duct paucity, known as ductopenia, has been observed in adults.[239] Although small bile duct paucity has been associated with amoxicillin alone,[240] the combination drug containing clavulinic acid appears to be more toxic.[241] Hepatotoxicity has been reported in children with intravenous oxacillin.[242] Ductopenia has been reported with amoxicillin-clavulinic acid in one child, who eventually required liver transplant.[243]

Minocycline

The tetracycline derivative minocycline is often used to treat acne in adolescents. It appears to have a greater potential for causing liver damage than is generally appreciated. Several cases of hepatotoxicity in teenagers have been reported: symptoms of hepatitis, jaundice, elevated serum aminotransferases, and positive antinuclear antibodies were common.[244–248] One typical presentation was polyarthritis with biochemical hepatitis; jaundice was present when hepatitis was severe. Some cases had features of autoimmune hepatitis. In many patients, liver damage resolved when the drug was discontinued. Two cases of acute liver failure in adolescents have been reported[249,250]: one died before transplant and the other underwent liver transplant. Careful monitoring of liver function is indicated when minocycline is used chronically.

Herbals

Complementary medicines are frequently used, usually without a physician's knowledge or review. Problems relating to the purity and strength of the specific preparation and to potential drug interactions complicate the issue of inherent risk for hepatotoxicity.[251] Children may be given herbal medications as tonics, and adolescents may choose to take them on their own. Herbal drugs known to be hepatotoxic include bush teas containing pyrrolizidine alkaloids, comfrey,[252] germander,[253,254] chaparral leaf,[255] kava-kava,[256,257] jin bu huan,[258–260] and ma huang (Ephedra). Comfrey also contains pyrrolizidine alkaloids, which can cause sinusoidal obstruction syndrome.[261] Germander undergoes biotransformation by CYP3A4, leading to diterpenoid toxic metabolites.[262,263] Some of these herbal medications are taken to promote weight loss, and the role of obesity in predisposing patients to hepatotoxicity deserves consideration.

"Ecstasy" (3,4-Methylenedioxymethamphetamine)

This drug is frequently used by adolescents as a recreational drug. It can have severe multisystemic adverse effects, including cardiac arrhythmias, hyperthermia, and rhabdomyolysis. The severity of hepatotoxicity can be extremely variable, including mild to moderate elevations of serum aminotransferases with acute or chronic hepatitis, fibrosis, and, occasionally, a picture resembling autoimmune hepatitis.[264] Acute liver failure occurs, sometimes at the first use, and is either fatal or requires liver transplant.[265,266] This has become an important problem for young adults and, to a lesser extent, adolescents. The mechanism of hepatotoxicity remains unclear. Hepatic biotransformation pathways are complex and involve CYP2D6 as the high-affinity component for the major pathway and also CYP1A2, CYP3A4, and CYP2B6.[267] Whether slow metabolizers in the CYP2D6 polymorphism are at greater risk for Ecstasy-associated hepatotoxicity is disputed.[268,269] Production of Ecstasy is clandestine; thus,

drug potency and purity are always uncertain, factors that may also contribute to hepatotoxicity.

PRINCIPLES OF TREATMENT

Most drug-induced liver disease resolves spontaneously when the hepatotoxic drug is withdrawn. Severe chronic changes should not be expected to regress. However, the histologic finding of bridging necrosis on liver biopsy does not tend to presage aggressive chronic liver damage in drug-induced liver disease. Certain hepatotoxins require timely treatment with specific antidotes, such as *N*-acetylcysteine for acetaminophen hepatotoxicity. Intravenous steroid treatment has been beneficial when severe acute hepatitis dominates a multisystemic hypersensitivity reaction, as with phenytoin, carbamazepine, or phenobarbital. In general, the use of steroids in drug-induced liver disease remains controversial. The treatment of fulminant hepatic failure owing to drug hepatotoxicity is otherwise essentially the same as in viral hepatitis. Liver transplant may be lifesaving in these circumstances.

When the major intervention is to stop a drug treatment, arriving at the diagnosis of drug-induced liver disease becomes all important. A high index of clinical suspicion is critical to making the diagnosis. A meticulous history of the illness with detailed attention to all drugs taken, including over-the-counter preparations, and to the potential for exposure to environmental or industrial toxins is of utmost importance. In children, it is important to ensure that the appropriate dosage was actually given. Liver biopsy, with electron microscopic examination if possible, is often very informative and sometimes definitive. Algorithms for determining the likelihood of an adverse drug reaction,[270] especially those specifically developed for drug hepatotoxicity,[271–273] may be helpful diagnostically. A recent study[274] showed that the Council for International Organizations of Medical Sciences scoring system[271] is superior to that of Maria and Victorino[273]; however, neither is specifically geared for children. In vitro rechallenge of the patient's lymphocytes with generated toxic metabolites usually provides important corroborative evidence,[275] but this remains a research investigation. Rechallenge assays using immunologic end points are often difficult to interpret.

SUMMARY

Drug-induced hepatotoxicity is more common in children than is generally thought. As in adults, the spectrum of disease is wide. Although cytotoxic processes, presenting as hepatitis, predominate, virtually every major type of hepatic pathology can occur. Hepatic drug metabolism has an important role in most of the drugs that most frequently cause hepatotoxicity in children: an imbalance between generation of toxic metabolite and detoxification processes can be identified. Focal defects in detoxification, often responsible for this imbalance, may be inherited. Developmental changes in drug disposition and metabolism further complicate the clinical spectrum of drug hepatotoxicity in children. Developmental and genetically determined aspects of immune function may also play a role. The possibility of drug hepatotoxicity should be considered in every instance of childhood liver disease.

CHAPTER 54

LIVER TUMORS

Milton J. Finegold, MD
Joel E. Haas, MD

Understanding and treating liver tumors in children continues to be a formidable task. The very rarity of such tumors contributes to the difficulty because few individuals or centers compile sufficient experience to provide definitive direction. Additionally, the remarkable diversity of conditions that fall under the term "tumor" makes it difficult to design a unifying formula to approach the subject or individual patient. Another problem is the extraordinary functional capacity of the liver to compensate for the intruding mass, so clues to the presence of a tumor are often few and so late as to make simple removal impossible. Finally, the liver's anatomy encourages internal dissemination of neoplasms and taxes the skills of the most experienced surgeon. Nevertheless, recent advances in knowledge of the molecular biology of gene expression and cellular differentiation, experimental carcinogenesis, monoclonal antibodies for diagnosis and perhaps even treatment, imaging techniques and anesthesia, and transplant immunology make this a time for optimism. But of all of the scientific advances, the single most important advance has already been achieved and is being implemented: vaccination against hepatitis B virus (HBV). In regions where hepatitis B is endemic, such as Taiwan, hepatocellular carcinoma (HCC) has accounted for 13% of all cancers in patients less than 15 years of age. By interrupting the cycle of mother to newborn transmission, vaccination has already begun to eliminate the most important single cause of hepatic malignancy.[1] Prevention of hepatitis C virus (HCV) transmission in blood products will further reduce the incidence of cirrhosis and HCC in adults. Thus far, no children with HCV and liver cancer have been reported. However, two 20-year childhood leukemia survivors developing HCC exhibited antibodies to hepatitis C at the time of diagnosis.[2]

Estimates of the incidence of primary hepatic tumors suggest that they account for about 0.04 to 0.16% of 1,000 US hospital admissions and 0.5 to 2.0% of all pediatric cancers. About three-quarters of the collected tumors in large series worldwide (Table 54-1) are malignant, and 85% of those are of hepatocellular origin.[3] Hepatoblastomas comprise about 43% of all primary hepatic tumors. They occur in about one child per million under the age of 15 years (about 100 cases per year) in the United States.[4]

There is a strong possibility that all series and reports are biased toward malignancy, unusual cases, and unusual circumstances. The relative contribution of referral centers to surgical surveys and national statistics is uncertain, and the use of death certificates without autopsy verification is unreliable. The incidence of hepatoblastoma appears to be increasing,[4] possibly because of the survival of extremely premature infants (< 1,000 g).[5] It was found that 58% of all hepatoblastomas in the Japanese Children's Cancer Registry occurred in children who weighed less than 1,500 g at birth.[6] The relative risk for hepatoblastoma in premature versus term infants was 15.6 for those weighing less than 1,000 g, 2.5 for birth weights of 1,000 to 1,499 g, and 1.2 for birth weights in the 2,000 to 2,499 g range. The Children's Cancer Group (CCG) of the United States found that 13.9% of 72 patients who had gestational histories recorded in their series were premature.[7] Ten of the 18 patients weighed less than 1,000 g at birth—a 16- to 23-fold excess versus term infants. Four percent of the hepatoblastoma patients in the German Registry (3 of 77) were premature infants who required parenteral nutrition,[8] suggesting a potential source of mutagens. Three premature infants treated with long-term parenteral nutrition have developed hepatocarcinoma,[9] but the German Registry reports the first hepatoblastoma–parenteral nutrition association.

ETIOLOGY

Worldwide, HBV has been responsible for more malignancy than any other environmental agent. Among adults, there is a definite relationship to chronic hepatitis and macronodular cirrhosis, and at least 20 years of infection

TABLE 54-1 PRIMARY LIVER TUMORS IN CHILDREN (18 SERIES WORLDWIDE)

TUMOR	NUMBER (%)
Hepatoblastoma	539 (43)
Hepatocarcinoma	287 (23)
Adenoma	23 (2)
Hemangioma, hemangioendothelioma	171 (13)
Mesenchymal hamartoma	76 (6)
Sarcoma	80 (6)
Focal nodular hyperplasia	22 (2)
Other	58 (5)
Total	1,256 (100)

Adapted from Weinberg AG and Finegold MJ.[3]

seem to be required for neoplastic transformation. The occurrence of HCC in children as young as 3 years of age following perinatal exposure to carrier mothers is surely an important clue to the carcinogenic process. Only 2 of 173 black South Africans with HCC under age 30 lacked serologic evidence of HBV infection. One hundred percent of Taiwanese children with HCC are HBV carriers.[10] The younger the child, the less often there is evidence of active hepatitis and cirrhosis. HBV functions like a retrovirus, with reverse transcriptase activity providing the means toward deoxyribonucleic acid (DNA) replication. As with other carcinogenic retroviruses, the DNA may become integrated into the host genome, and there may be associated deletions of portions of the cellular genome, but the integration site is variable, and mutations in the virus may be important.[11] Increasing reports of cell-cycle gene disruptions[12,13] may lead us to anticipate additional specific mutations as molecular methods are applied to HBV-associated HCC. The reason why children exposed to HBV as infants develop HCC so quickly may be that the integration of viral DNA is facilitated by the rapid rate of cell division in the developing liver. Perhaps the effects of early viral DNA integration on hepatocyte differentiation would explain why three of the five HCCs in children with HBV infection described by Ohaki and colleagues[14] contained primitive hepatoblastic foci. We have examined seven tumors containing both HCC and hepatoblastoma in children having a mean age of 8.5 years. All were HBV positive.

At least three-quarters of the mothers of children with HBV infection and HCC in Africa, China, and Japan display hepatitis B surface (HB_s) antigenemia. Curiously, only a minority of the fathers have antigenemia.[10] Even more perplexing is the observation that 27 of 28 fathers of children with HCC in Senegal lacked antibody to the HB_s antigen compared with 48% of age-controlled males in the same population.[15] Eighteen percent of those fathers had HB_s antigenemia, in contrast to 71% of the mothers. The role of gender in the development of liver tumors is indeed noteworthy. Among adults, the male-to-female HCC ratio is said to be 8:1 to 10:1. Most of the difference is attributed to chronic HBV hepatitis with cirrhosis, industrial or occupational exposure, and alcoholism. Only 1 of 15 HB_s antigen–positive mothers of Taiwanese children with HCC had HCC herself, and no malignancy developed in any of their 9 HB_s antigen–positive sisters. However, 5 of 13 HBV-carrying brothers had HCC.[10] Even with underlying genetic diseases and metabolic errors having an autosomal recessive (sex neutral) basis, such as familial adenomatous polyposis,[16] familial cholestatic cirrhosis,[17] and type I glycogen storage disease, the incidence of hepatocellular malignancy in boys is at least double that of girls. Coire and colleagues described liver adenomas in 24 males and 12 females with von Gierke disease.[18] All four patients who later developed carcinomas were males (Figure 54-1).

It is stimulating to consider these clinical observations in light of studies on steroid hormone receptors in normal and neoplastic liver tissue. Iqbal and colleagues found androgen receptors in fetal liver and HCC but not in normal adult liver, whereas estrogen receptors were detected in both tumor and adjacent liver.[19] Nagasue and colleagues were able to detect androgen receptors in normal male liver, and 18 of 23 carcinomas had a significantly higher concentration.[20] The cirrhotic liver of one woman also had androgen receptors. But one of two HCCs in that same liver lacked androgen receptors. Both Nagasue and colleagues[20] and Ohnishi and colleagues[21] found a loss of estrogen receptor activity in HCC versus the surrounding liver tissue. When aplastic or Fanconi anemia patients of either sex are treated with C17–alkylated anabolic steroids, tumors develop with significant frequency, and tumors have also been observed when testosterone was given to correct sexual immaturity in boys.[3] Boys accounted for 25 of the 34 androgen-associated liver tumors in patients less than 20 years of age reviewed by Chandra and colleagues.[22] Although half were discovered at autopsy, just two were judged to be carcinomas. Some of the benign tumors regressed on withdrawal of steroids.

Estrogens in oral contraceptives are definitely associated with hepatic adenoma development. After 8 years of oral contraceptive use, the incidence of hepatic carcinoma in women is 4 to 20 times that of age-matched controls when alcoholism, hepatitis, and cirrhosis are excluded.[23] Focal nodular hyperplasia is a non-neoplastic process that has to be distinguished from adenomas and carcinomas.[24] For a short time, it appeared that this lesion was more common in women. It now seems that the lesion is more often symptomatic in women because oral contraceptives make it more vascular and more likely to bleed. Case reports associate angiosarcoma and cholangiocarcinoma with oral contraceptives. Additionally a 19-year-old girl was found to have a hepatoblastoma after 15 months of "pill" use.[25] Prenatal exposure to synthetic estrogens or gonadotropins has been reported in two infants with hepatoblastoma[3] and one with angiosarcoma.[26] The Children's Cancer Study Group (CCSG) looked for risk factors in

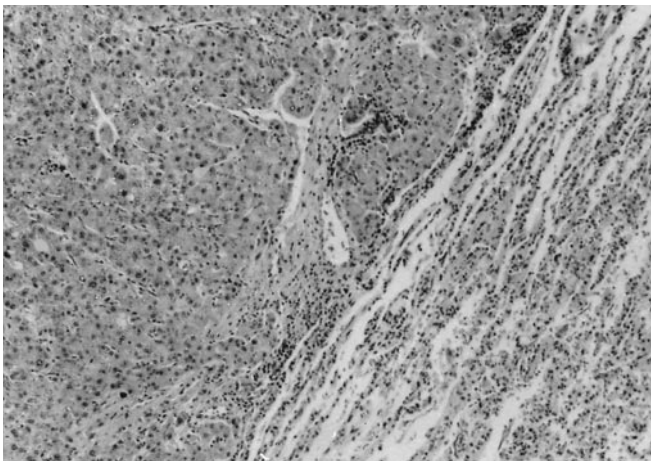

FIGURE 54-1 Hepatocarcinoma metastatic to the lung. A well-differentiated malignancy from a 17-year-old boy who had glucose-6-phosphatase deficiency, managed successfully by frequent and nocturnal feedings. Adenomas were recognized in this liver 3 years earlier. If the illustrated tumor were in the liver, it would be impossible to predict its behavior from histology alone (hematoxylin and eosin; ×63 original magnification).

75 cases of hepatoblastoma versus age-matched controls and found a significantly higher frequency of maternal exposure to metals and petroleum products. Paternal exposure to metals was also excessive.[27]

The importance of oncogene expression in the genesis of hepatic malignancy has been augmented by recent studies of tumor suppressor genes, cell-cycle genes, and growth factors. Baffett and colleagues found expression of N-ras messenger ribonucleic acid (RNA) in 11 of 11 hepatocarcinomas.[28] In 7 of 11 tumors, c-Ki-ras and c-Ha-ras were detected, whereas c-myc and fos were expressed in 2 of 11 tumors. The finding that *c-met* is overexpressed in a significant (8 of 18) proportion of HCCs is intriguing because the protein is a receptor for hepatocyte growth factor, a potent stimulant of hepatocyte mitosis.[29] Overexpression of c-met conferred a worse prognosis (33% 5-year survival versus 80% in low expressors).[30] Likewise, the role of transforming growth factor-α (TGF-α) in hepatocellular malignancy appears to be important. It is produced by fetal hepatoblastoma cells with low proliferative activity[31] and by 65% of hepatocarcinomas.[32] It is a strong stimulus of hepatocyte replication,[33] and, interestingly, only male mice overexpressing TGF-α develop hepatocarcinomas.[34] Telomerase activity in nontumoral regenerative nodules of patients with cirrhosis and hepatocarcinoma was equal to that in the neoplasm and predictive of early recurrence or second primaries.[35] In hepatoblastomas, the most significant genetic abnormalities involve the chromosome 11p15 region, in which the Beckwith-Wiedemann locus is found (see below). Genes for insulin and insulin-like growth factor 2 (IGF-2), both stimulants of fetal cell growth, are located in the same region. Loss of imprinting and loss of heterozygosity for IGF-2 and IGF-2 receptor have both been observed in hepatoblastoma.[36,37] Overexpression of IGF-2 has also been demonstrated in hepatoblastomas by microarray expression technology.[38] That report also revealed surprising breast cancer (BRCA2) expression in hepatoblastomas and binding of antibody to BRCA2 protein by six of six hepatoblastomas but not normal fetal liver.[38]

The exact role of *p53* in the pathogenesis of hepatic neoplasia remains uncertain. No liver tumors were found when the *p53* gene was inactivated by homologous recombination in mice (in whom several other cell types developed neoplasms).[39] When small early HCCs in humans were examined, *p53* expression was normal, whereas 8 of 22 cancers at an advanced stage had mutations.[40] Interestingly, six of those eight cases that were informative also had deletions of the retinoblastoma gene product. The activation of HIC-1, hypermethylated in cancer, a candidate tumor suppressor, by *p53* may be meaningful because messenger RNA for HIC-1 is markedly reduced in precancerous nodules of cirrhosis and even more so in poorly differentiated carcinomas.[41] In Japan, serum antibodies to *p53* were associated with decreased survival.[42]

Many metabolic defects and congenital malformations are associated with and possibly contribute to hepatocellular malignancy.[3] They are listed in Table 54-2. The highest frequency of HCC in a metabolic disease of childhood was found with tyrosinemia type 1, owing to inactivity of fumarylacetoacetate hydrolase.[43] The 18 to 37% incidence of HCC reported in survivors of the infantile period has been reduced by the recent discovery that an inhibitor of an upstream enzyme (4-hydroxyphenylpyruvate dioxygenase) reversed the clinical and chemical abnormalities in four of five children with fumarylacetoacetate hydrolase deficiency.[44] By 2000, over 200 children with tyrosinemia were treated with the inhibitor 2-(2-nitro-4-trifluoromethyl benzoyl)-1,3 cyclohexane dione prior to the age of 2 years. Just two have developed hepatocarcinoma, one of whom (whose treatment began at 5 months of age) was 15 months old when the malignancy was discovered.[45]

Kingston and colleagues found that hepatoblastoma occurred in five families with intestinal polyposis.[46] With an incidence of familial adenomatous polyposis of 1 per 8,300 and an incidence of hepatoblastoma of one per million children under the age of 15 years, this cannot be coincidental. One of 20 hepatoblastomas occurs in a polyposis kindred. Hughes and Michels have pointed out that despite the 500 to 1,000 excess of hepatoblastoma in families with familial adenomatous polyposis, less than 1% of the families are at risk.[47] Garber and colleagues expanded the number of affected families to 25; there were 18 boys and 7 girls.[48] Eleven of the 25 patients have survived, including all but one of the girls but only five of the boys. Six of the seven survivors examined developed colonic polyps as early as 7 years of age. Bodmer and colleagues localized the adenomatous polyposis coli gene (*APC*) for familial polyposis to chromosome 5q21,[49] and it is now possible to screen young children in families with polyposis (Gardner syndrome) for the presence of the gene by a variety of molecular tools. Mutations of *APC* were found in 8 of 13 sporadic hepatoblastomas,[50] but no cytogenetic

abnormalities at chromosome 5q21 have been described (Table 54-3). The mechanism of carcinogenesis by germline *APC* mutations appears to be mediated via a cell adhesion protein that accumulates in cells with the mutation.[51] Activating mutations in β-catenin have been observed in 48% of sporadic hepatoblastomas[52] and 20 to 26% of hepatocarcinomas.[53,54]

Several other cytogenetic abnormalities have been seen in children with hepatic neoplasms (see Table 54-3). Trisomy 2 was complete or partial in 26 of 40 hepatoblastomas, and trisomy 20 was found in 29 of 40 cases.[55,56] A unique t(10;22) was reported in one small cell hepatoblastoma.[57] The relatively small number of reported cytogenetic aberrations in hepatoblastoma may relate to the lack of suitable dividing cell samples. When conventional cytogenetic analyses are limited by the lack of suitable metaphase cells, fluorescent in situ hybridization techniques applied to frozen or paraffin-embedded tissues may reveal abnormalities in chromosome number and structure.[58] Among HCCs, the frequent allelic deletions at 17p (38 to 54%) correlate with deficient p53 function.[59] Among the many other deletions observed in HCC, those at chromosomes 16q and 4q have not been observed in other cancers, so they may be the most meaningful. Molecular genetic analysis of hepatocellular neoplasms has begun to provide important insights into dysregulation of growth. Those occurring with significant frequency are shown in Table 54-4.

Also noteworthy are reports of HCC in relation to chronic biliary tract disease, including extrahepatic biliary atresia, Byler disease, and bile salt export protein deficiency.[60,61] A 6-month-old boy received parenteral alimentation all his life and was found at autopsy to have a microscopic focus of carcinoma.[62] Two more cases have been described.[8] Arteriohepatic dysplasia (Alagille syndrome) was previously not regarded as a preneoplastic condition because 85 to 90% of affected individuals survive without serious hepatic complications of their childhood-onset cholestasis and bile duct paucity. But several patients with the syndrome have been described with HCC, even in the absence of biliary cirrhosis; the youngest was a $3^1/_2$-year-old girl,[63] and there were three affected siblings in one family.[64]

CLINICAL MANIFESTATIONS

Regardless of cell type, the great majority of hepatic tumors are first detected as a mass or abdominal swelling. Upper abdominal pain is the next most frequent presenting complaint, followed by anorexia and weight loss, vomiting, and diarrhea. Infants with vascular hamartomas (hemangiomas) may display signs of congestive heart failure, as have rare patients with mesenchymal hamartomas. Pruritus and frank jaundice are observed when tumors obstruct bile flow. In children, obstruction suggests rhabdomyosarcoma at any level of the biliary tract. Minor blunt trauma or apparently spontaneous hemorrhage of a liver tumor can be the earliest sign of its presence, especially among adolescent girls and young women taking estrogens for oral contraception, when tumors are especially vascular.

Several metabolic effects or paraneoplastic syndromes occur with a variety of hepatic tumors. Hypercalcemia with marked osteopenia can be very severe in children with hepatoblastoma, carcinoma, or sarcoma. As in other malignancy-related hypercalcemias, the mechanism is not fully understood, but ectopic parathormone production is not the reason.[65] Hyperlipidemia has been associated with epithelial malignancies; when caused by hepatoblastoma in infants, it has been associated with early fatality.[66] Both hyperlipidemia and hypoglycemia are thought to be secondary to injury to the remaining liver or dysfunction of the neoplastic epithelial cells rather than a sign of underlying enzymatic error, such as glucose-6-phosphatase deficiency. The rare carcinomas in von Gierke disease do not appear until the midteens or early adulthood.[18] A few case reports of HCC in children and adults with debrancher and

TABLE 54-3 CYTOGENETIC ABNORMALITIES IN LIVER NEOPLASMS

NEOPLASM	ABNORMALITY	INCIDENCE (%)
Hepatoblastoma	Trisomy 20	72 (40 cases)*
	Trisomy 2	65 (40 cases)*
	Trisomy 8	32.5 (40 cases)
	Chromosome 1 translocation	8 cases
	Trisomy 18	3 cases
Hepatocarcinoma	1q excess by CGH	58–72
	4q losses by CGH or LOH	43–77
	8q excess by CGH or LOH	48-77
	16q LOH	52–70
	17p loss or LOH	49–51
Mesenchymal hamartoma	Translocations of 19q13.4	3 cases
	Aneuploidy	2 of 8 cases
Undifferentiated (embryonal)	Monosomy 20	2 cases
	Sarcoma aneuploidy dicentric telomeric association (4;22)(p16;q13)	1 case
Inflammatory myofibroblastoma (pseudotumor)	Hyperdiploidy	4 of 9 cases
	2p23 rearrangements (*ALK* abnormalities)	Unknown for liver

CGH = comparative genomic hybridization; LOH = loss of heterozygosity.
*Two cases each in which trisomy 20 or 2 was the only karyotypic abnormality.[55,56]

HB = hepatoblastoma; HCC = hepatocellular carcinoma; IGF = insulin-like growth factor; LOH = loss of heterozygosity; LOI = loss of imprinting; TGF = transforming growth factor.

branching enzyme deficiencies (glycogen storage disease III and IV) have appeared recently. Thrombocytosis and polycythemia have been observed in some HCC patients, and some 60% of children with hepatoblastoma have thrombocytosis at presentation. Precocious puberty in males has been observed with hepatoblastomas and carcinomas. In most cases, ectopic gonadotropin production is responsible, but a few instances of tumor testosterone synthesis have been reported.[67]

IMAGING TECHNIQUES

Real-time ultrasonography is the hepatologist's "stethoscope." In Japan, where the incidence of hepatic malignancy is high and screening resources are readily available, Okuda compared the various imaging modalities in adults.[68] They found none to be sufficiently sensitive to detect HCCs smaller than 2 cm or to discriminate between regenerating nodules or adenomas and HCCs. Repeat ultrasonography has shown the doubling time for carcinomas to be variable, with growth from 1 to 2 cm taking an average of 3 months. The most proliferative tumors grew from 1 to 3 cm in 4.6 months. Ultrasonography, combined with serum α-fetoprotein measurements, can detect early lesions susceptible to resection in the presence of cirrhosis. Intraoperative ultrasonography has proven a useful aid to partial hepatectomy in children.[69]

Arterial injections of enhancing compounds during computed tomography (CT) or magnetic resonance imaging (MRI) provide more expensive and complex means of detecting small intrahepatic lesions with questionably greater sensitivity than ultrasonography. The application of MRI is especially useful for distinguishing small and common hemangiomas from solid tumors.[70] MRI also shows spread of tumor into large abdominal veins very clearly. By including iodized oil (Lipiodol) in the arterial infusate and taking delayed CT images, cancers as small as 3 mm have been observed because the oily material is retained only by the tumor. CT is useful for scanning the chest and abdomen for other sites of involvement when a liver mass is present. Enhanced CT and MRI have superseded angiography in delineating the extent of disease prior to partial hepatectomy (Figure 54-2).[70] Scintigraphy with radiolabeled sulfur colloids has been used to distinguish lesions containing Kupffer cells (focal nodular hyperplasia) from those without Kupffer cells (adenomas and carcinomas).[71] However, some hepatoblastomas have produced scintigraphic images indistinguishable from those of benign masses. Imaging with radiolabeled monoclonal antibody to α-fetoprotein proved helpful in managing a child whose hepatoblastoma could not be fully resected.[72]

LABORATORY TESTS

Serum α-fetoprotein measurement is the most useful marker of malignant liver tumors. Eighty to 90% of hepatoblastoma patients and 60 to 90% of HCC patients have elevated levels at diagnosis. Small cell undifferentiated hepatoblastomas and rhabdoid tumors in infancy do not produce α-fetoprotein.[73,74] Except for a very few infant mesenchymal hamartomas and germ cell and yolk sac tumors, there are no false indications of hepatocellular malignancy when serum α-fetoprotein levels exceed

FIGURE 54-2 Computed tomography of the hepatoblastoma shown in Figure 58-4. The larger inner zones of calcification are visualized as stellate radiopaque zones, whereas the epithelial portions of the mass are difficult to distinguish from host liver.

500 ng/mL after 3 months of age. Serum α-fetoprotein is elevated, although not to such high levels, in the absence of demonstrable carcinomas in both hereditary tyrosinemia and ataxia-telangiectasia.[3] Both conditions are associated with a high frequency of hepatic malignancy, and the secretion of the fetal protein is indicative of defective regulation of gene expression in the hepatocyte. Regrettably, α-fetoprotein levels may not be elevated in time for effective therapy. For example, elevations may not occur until ordinary HCCs exceed 4 to 5 cm in diameter, which can take several years.[68] Intrahepatic portal vein dissemination has been observed in both hepatoblastomas and primary carcinomas less than 3 cm in diameter. Measuring serum α-fetoprotein to follow recurrences of resected liver tumors can be helpful. However, a return to normal levels has been observed in some patients even though their tumors continued to grow.

Pseudouridine, a catabolic product of transfer RNA, was detectable in the urine of 9 of 13 patients with HCC whose serum α-fetoprotein concentration was normal.[75] Plasma transcobalamin I (vitamin B_{12}–binding protein) and neurotensin have been elevated in patients with fibrolamellar carcinoma (FLC), which is potentially very useful because only 10% of those tumors have increased α-fetoprotein.[71,76,77] An abnormal form of prothrombin, desgamma-carboxyprothrombin, was present in the serum of 74% of 70 adult HCC patients and in blood and tumor cells of three children with hepatoblastoma.[78] Coagulation tests were unaffected. There was no correlation with serum α-fetoprotein levels, and the test was insensitive for carcinomas less than 3 cm in diameter.

Because of the low incidence of childhood hepatocellular malignancy in the United States, screening of children in the United States or elsewhere would be unrewarding. But application of some of these sensitive tools to the small groups of patients with precursor or associated conditions, such as extreme prematurity, tyrosinemia, hepatic glycogenoses, and chronic cholestatic conditions, could be lifesaving.

PATHOLOGY

HEPATOBLASTOMA

This is an embryonal tumor in the classic sense of incomplete differentiation. Ninety percent of the cases are manifest by the fourth birthday, and several have been present at birth. The usual composition reflects the complex origin of the organ, with endodermal derivatives from the original midgut outgrowth and mesodermally derived offspring of the septum transversum. Thus, parenchymal elements include hepatocytes of varying maturity, resembling the early embryonal or later fetal liver, in association with hematopoietic cells (Figure 54-3). Primitive ducts are characteristic of the embryonal pattern, but well-differentiated ductal elements are unusual except in relation to diffusely infiltrating mesenchymal or blastemal cells. In that situation, they represent residual and sometimes proliferating cholangioles of the host liver because they are not found in metastases. However, when ductal epithelium and tumor cells in the middle of a mass are in continuity on ultrastructural examination, it is difficult to regard them as normal remnants.[79] It is not unusual to find portions of the epithelial hepatoblastoma to be indistinguishable from HCC, even in the youngest patients.[3] Undifferentiated mesodermal and/or mature stromal derivatives are present in 20 to 30% of cases. The differentiated stroma usually includes osteoid-like material but less often skeletal muscle or cartilage (see Figure 54-3). The osteoid is clearly related to epithelial rather than mesenchymal cells. Not infrequently, keratinizing squamous nests are found among the embryonal cells. Rarely, ducts resembling primitive intestine, neural rosettes, and melanocytes suggest the possibility of a true teratoma.[80]

Depending on the proportions and degree of maturation of the various elements, the gross appearance ranges from yellow-brown (well-differentiated epithelium) to pink-gray (undifferentiated mesenchyme). Focal necrosis and hemorrhage are found in rapidly growing tumors, and firm, even gritty, areas are present when osteoid is abundant. Generally large multinodular expansile masses, hepatoblastomas appear to be well demarcated from the normal host liver but are not encapsulated (Figure 54-4). They may invade hepatic veins and disseminate to the lungs by the time of discovery or penetrate the capsule to reach contiguous tissues and the peritoneum. Hilar lymph nodes are early targets. Staging of hepatoblastomas is done at diagnosis. Stage I indicates complete resection; II, microscopic residual tumor (IIA, inside the liver; IIB, outside the liver); III, gross residual tumor (IIIA, spillage during surgery or gross nodal involvement; IIIB, incomplete resection with or without spillage or node involvement); and IV, metastatic disease (IVA, primary completely resected; IVB, primary not completely resected). Our review of 316 hepatoblastomas from US Pediatric Oncology Group (POG) contributors from 1986 to 2002 had 79 (25%) stage I, 24 (7.5%) stage II, 153 (48%) stage III, and 60 (19%) stage IV cases. The hepatoblastoma histology classifications by Ishak and

Glunz[81] and Kasai and Watanabe[82] provide the foundation for current microscopic assessment of hepatoblastoma. Incorporating minor modifications from Gonzalez-Crussi and colleagues[83] and Manivel and colleagues,[80] we evaluated tumors in the POG-CCG intergroup study according to the scheme shown in Table 54-5. In the current US intergroup study, the stage I (well-differentiated fetal hepatoblastoma with less than 2 mitoses per 10 high-power fields) has been singled out for surgical treatment without adjuvant therapy. Only 9 of the 316 cases (2.8%) in the POG series qualified, but the decision to spare children with such completely resected tumors the morbidity of adjuvant therapy seems soundly based. Early observations of 100% survival rate in a small group of such tumors treated with surgery alone[3] were augmented by similar cures when surgery was combined with minimal doses of doxorubicin[84,85] or standard chemotherapy.[86]

Quantification of DNA by image analysis and flow cytometry demonstrated good correlation with prognosis (71% 3-year survival for diploid tumors versus 31% for aneuploid lesions).[87] Six of seven pure fetal tumors were diploid (ie, "favorable"), whereas each of two embryonal epithelial tumors was aneuploid. Ruck and colleagues described another important correlation: p53 expression by immunostaining was lacking in fetal areas of eight tumors and mesenchymal areas of four tumors.[88] However, p53 was expressed in both small cell tumors and in embryonal regions of two of eight tumors examined.

Unresolved questions about the relation of histology to outcome relate to the following:

1. The prognostic import of the degree of differentiation of the fetal epithelial component, which often displays gradual but sometimes abrupt transition from a uniformly well-differentiated pattern with few mitoses to a more crowded but still cord- or plate-like architecture in which nuclei are more pleomorphic and mitoses are more numerous (Figure 54-5). Do such tumors require standard chemotherapy if totally resected?
2. The significance of the proportion of prognostically important histology. Rowland recently provided insightful quantitative analysis pertinent to the limitations of prior published associations between histology and outcome.[89] The relation of completely excised well-differentiated pure fetal histology with low mitotic activity to outcome is unquestionable. However, the lack of uniformity in definition of other histotypes combined with limited sampling of unresectable tumors prior to chemotherapy presents challenges to the desired histology outcome paradigm.

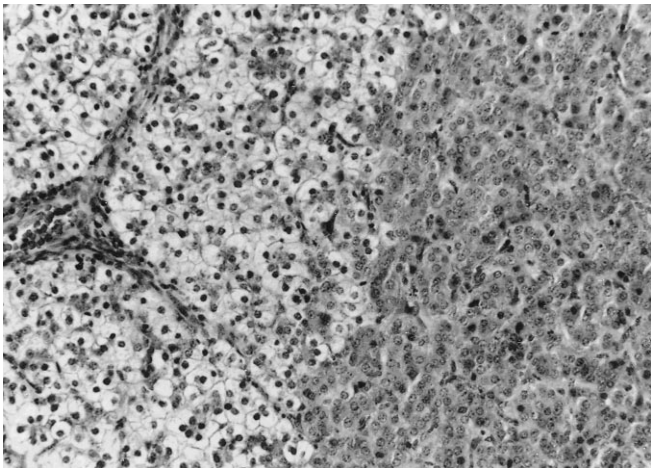

FIGURE 54-5 Hepatoblastoma. The well-differentiated fetal pattern is on the left. Regular cords or plates, one to three cells thick, contain hepatocytes having glycogen-rich clear cytoplasm and regular uniform nuclei and rare mitoses (none in this picture). Immediately adjacent, on the right, the regular cordlike pattern is maintained, but the cells are more numerous and crowded without being macrotrabecular (five to six cells in thickness) or primitive, as in embryonal tumors. The growth rate is increased, as reflected by the presence of two mitoses. A well-differentiated fetal pattern has been associated with an excellent rate of resection and cure. The "crowded" pattern is of uncertain prognostic significance (hematoxylin and eosin; ×160 original magnification).

3. The influence of the differentiated stromal derivatives on prognosis. Muraji and colleagues[66] and Haas and colleagues[84] found that mixed tumors, particularly in stage II–III cases, responded better to chemotherapy than did pure epithelial lesions. However, the impossibility of determining the totality or proportion of all histologic constituents from biopsies of unresectable tumors must be acknowledged.
4. The impact of small undifferentiated cells on prognosis. As the name indicates, these cells fail to demonstrate histologic or ultrastructural features of any known hepatocellular or ductal element, but they contain both cytokeratin filaments typical of epithelial cells and vimentin, a mesenchymal component.[74] Their mitotic activity is variable. Of the 5% of hepatoblastomas that are pure small cell, all but two cases occurred in infants less than 6 months of age, and all such patients have died of disease despite chemotherapy that is highly effective for other histologic subtypes.[85] The role of small cell undifferentiated histology in completely resected hepatoblastoma is becoming more clear.[90] Ten patients with such tumors suffered a relapse in periods ranging from 2 to 21 months. Five whose tumor recurred died. The proportion of small cell histology in four of the fatal cases exceeded 75% of the tissue available for examination, whereas the other fetal case and all of the five survivors had less than 5% small cells. It may be important to note that just three of eight such patients treated with contemporary adjuvant therapy suffered relapse, but none died.[90]
5. The histogenesis of the "rhabdoid" cell type. These monomorphic malignancies of diffusely infiltrating, noncohesive cells with large quantities of intermediate filaments have arisen in several tissues. They tend to occur in young infants, to disseminate widely, and to resist chemotherapy.[73] Immunohistochemical and ultrastructural studies indicate the cells to have both epithelial and mesenchymal characteristics.[91] In the liver, this cell may represent a neoplastic derivative of a stage in the maturation of the undifferentiated mesoderm to the hepatocyte. Except for the presence of epithelial membrane antigen, the immunohistochemical reactions resemble the small undifferentiated or "blastemal" cells of the hepatoblastoma exactly.[92] We have observed transition to "rhabdoid" morphology in otherwise typical hepatoblastomas (Figure 54-6).[3]
6. The significance of postchemotherapy microscopic residual disease. In addition to the greater abundance of osteoid, it is common to find complete necrosis of tumor within hepatic and portal vein branches that are obliterated by scar.[93,94] Nevertheless, nodules of viable tumor are usually found despite marked clinical regression. Most often these have bland fetal histology, but all patterns may be observed, as they are in metastases. The expression of the cell-cycle regulatory protein kinase inhibitory protein (Kip 1 or P27) was markedly reduced in nuclei of residual fetal hepatoblasts after chemotherapy compared with the same cell type before treatment: from a mean of 75% positive tumor cells to 12%.[95] This difference was not associated with increased DNA synthesis, as determined by Mib1 immunostaining. It is not clear which factors govern the susceptibility or resistance of hepatoblasts to current therapeutic regimens, but von Schweinitz and colleagues have emphasized the importance of post-chemotherapy complete resection before development of drug resistance.[96]

HEPATOCARCINOMA

The frequency of cirrhosis in pediatric patients with HCC is much less than in adults (20–25% versus 60–70%), but its presence compounds the therapeutic problem. The appearance of the tumor is similar in children and adults. HCC has a higher frequency of multiple nodules than does hepatoblastoma and exhibits intrahepatic portal vein and lymphatic dissemination more often at the time of diagnosis. A wide range of histologic appearance seems to have little or no influence on resectability or responsiveness to therapy, with one possible exception: the FLC may express different behavior in adults than it does in children.

FLC is rarely associated with cirrhosis, rarely produces α-fetoprotein, and tends to affect young persons. In contrast to the more typical HCCs, just one FLC has been associated with Fanconi anemia.[97] Thirty-nine percent of FLC patients are less than 20 years old, and 90% are less than 25 years of age. Forty-five of 80 tumors occurred in girls, and Malt has called attention to the high incidence of reproductive dysfunction among the group.[71]

The POG-CCG intergroup study has demonstrated that children with FLC do not have a favorable prognosis and do not respond any differently to current therapeutic regi-

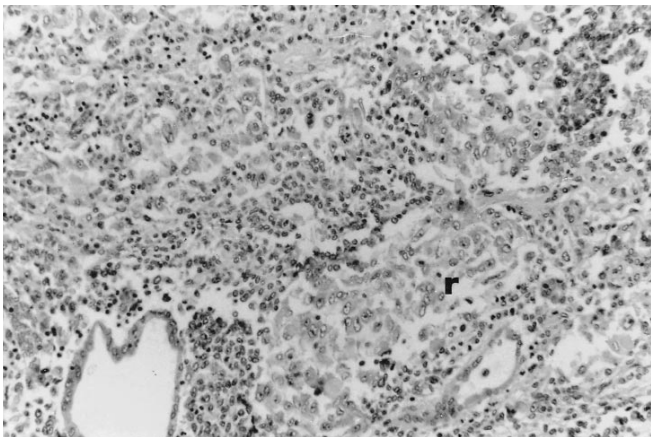

FIGURE 54-6 Hepatoblastoma with focal "rhabdoid" transformation. On the left, fetal-type epithelial components of the neoplasm admixed with hematopoietic cells abut what is probably a residual (non-neoplastic) bile duct. A transition to noncohesive cells of uncertain differentiation is seen in the center right (r). Those cells have larger, vesicular nuclei with prominent nucleoli and perinuclear cytoplasm that is rich in intermediate filaments, producing eosinophilic inclusions in some cells. When tumors are homogeneous for such cells, they are called "rhabdoid." In the liver, they tend to occur in infants younger than 1 year of age, and they behave badly (hematoxylin and eosin; ×160 original magnification).

mens when compared with typical HCC.[98] Although children with initially resectable typical HCC or FLC have a good prognosis (75% 5-year event free survival) irrespective of histologic subtype, outcome is uniformly poor for children with advanced-stage disease.

FLC tends to be a single large bulky light tan to yellow-orange mass with distinct borders. Histologically, large polygonal cells cluster in small groups separated by bands of well-organized collagen (Figure 54-7). Carcinoembryonic antigen and fibrinogen are abundant in the tumor, and the serum concentration of carcinoembryonic antigen has been observed to fall after resection.[99] The tumor cells also tend to be rich in copper and to express the biliary cytokeratin 7 that is not found in ordinary HCC.[100] Intense immunohistochemical staining of TGF-β demonstrable in 9 of 11 FLCs was present in just 3 of 14 typical hepatocarcinomas.[101] The morphologic differences between FLC and ordinary HCC are further reflected in the secretion of neurotensin and by histochemical and ultrastructural evidence of neurosecretory granules.[102] None of these tumors has been associated with clinically evident hormonal effects, and they do not morphologically resemble any of the several cases of primary hepatic carcinoid tumors examined.[3] The exact histogenesis of this epithelial neoplasm is unresolved.

Adenoma and Focal Nodular Hyperplasia

Each condition contributes 2% of the collected series of childhood liver tumors (see Table 54-1). Both adenomas and focal nodular hyperplasia have been observed in patients with glycogen storage disease[18] and in women using oral contraceptives, but only adenoma seems to be causally related to "the pill."[23,24] Both are usually solitary and expansile, but adenoma is more often multiple and is generally encapsulated. Both consist primarily of well-differentiated hepatocytes arranged in cords or plates but without the normal lobular pattern. However, the cells of adenomas may be slightly larger than normal hepatocytes, and their nuclei can be slightly pleomorphic. Adenomas lack bile ducts or portal tracts, and focal nodular hyperplasia has septa radiating from a central region of scarring in which ducts can be numerous. In a needle biopsy, these distinguishing features may be unavailable.

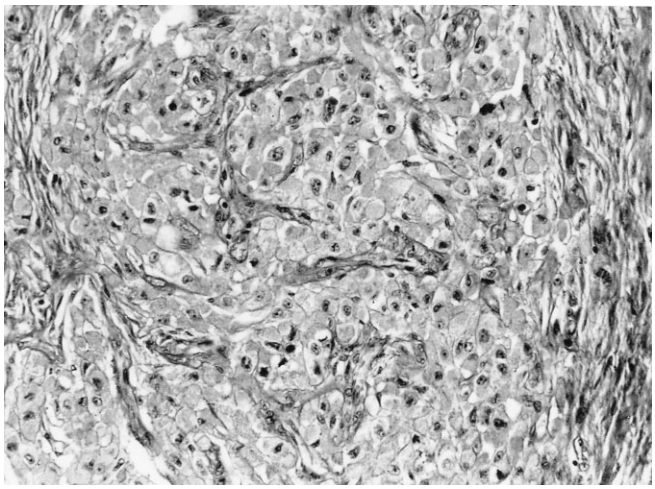

FIGURE 54-7 Fibrolamellar carcinoma. Nests of large polygonal cells with abundant eosinophilic cytoplasm and slightly pleomorphic nuclei are separated by distinct bundles of collagen. Ordinary hepatocarcinomas have little fibrous tissue unless there is a ductal (cholangiolar) component. This was from a 19-year-old girl with normal serum α-fetoprotein. Resection was curative (trichrome; ×160 original magnification).

Vascular Tumors

Hemangioendotheliomas of infancy are the most common benign tumors of the liver and are generally regarded as hamartomas rather than neoplasms. Nevertheless, they may be symptomatic as mass lesions or may produce high-output congestive heart failure owing to arteriovenous shunting. They may rupture and cause intraperitoneal hemorrhage. Occasionally, thrombocytopenia and intravascular coagulation have been observed.[103] Classification depends on the degree of endothelial cell proliferation and the size of the channels. When actively dividing vasoformative cells are plentiful and not quite organized into channels, the lesions are called type II hemangioendotheliomas.[104] The type II lesions have reportedly disseminated occasionally.[104] Type I lesions consist of definite vessels, with few mitoses and no nuclear atypia. Calcification is frequent. Most cases of both types regress spontaneously or respond well to corticosteroid therapy. However, perfectly bland type I lesions have been followed, on at least four occasions, by hepatic angiosarcomas. At that point, atypical rapidly dividing neoplastic cells were widely dispersed through the sinusoids as well as filling vascular lumens and replacing parenchymal tissues.[3] Two additional angiosarcomas in children appeared histologically to have arisen in preexisting hemangioendotheliomas.[26] Sometimes the spleen and other organs have been involved. One infant had documented exposure to arsenicals. The other had been exposed to metals, glue, and oral contraceptives during the first trimester.[26] Two young adults with neurofibromatosis have had hepatic angiosarcomas.[105] A lymphangioendothelioma confined to the liver almost completely replaced the hepatic parenchyma of a newborn.[106] Hepatic angiomyolipomas have been reported in 24% of children with tuberous sclerosis.[107]

Mesenchymal Tumors

The mesenchymal hamartoma of infancy can be present at birth, grow to an enormous size, and cause heart failure because of arteriovenous shunting. Over 90% of cases are manifest in infancy, but individual cases have been observed in adults, the oldest patient being 28 years old.[108] The mass may bulge from the liver and even become pedunculated, but it has no capsule (Figures 54-8 and 54-9). Typically, there are multiple large cystic spaces with a flat endothelial or biliary epithelial lining and serous fluid content (Figure 54-10). The stroma is myxomatous and bland. At the interface with the remaining parenchyma, bile ducts proliferate actively. Seven reports document simultaneous occurrence or subsequent development of undifferentiated or embryonal hepatic sarcoma in mesenchymal hamartoma.[109–115] The frequently observed translocation

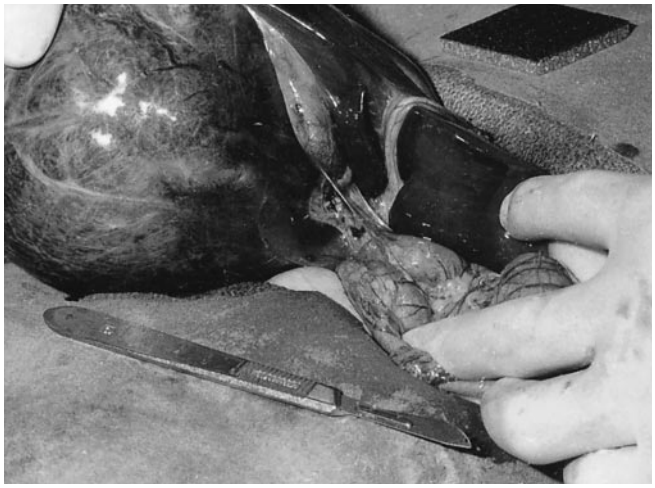

FIGURE 54-8 Mesenchymal hamartoma at surgery. An 11-month-old boy presented with a distended abdomen. Ultrasonography revealed a multilocular cystic mass. It protruded from the right lobe inferiorly and was completely resectable.

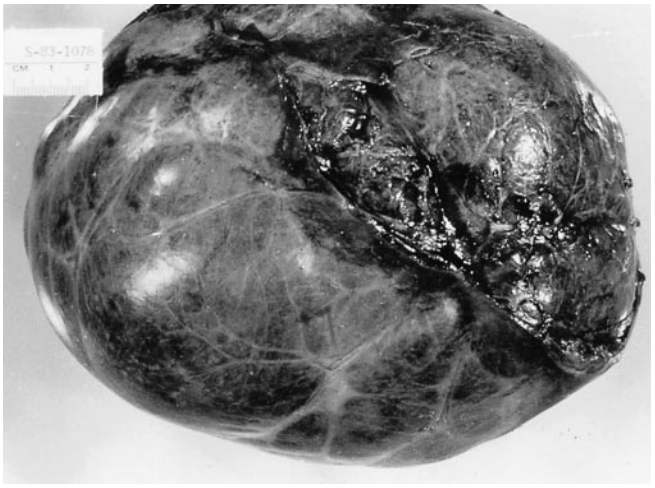

FIGURE 54-9 Mesenchymal hamartoma after resection. The huge bulging mass weighed 1,250 g and consisted mainly of tense cysts. The patient had about 35% of the liver left and recovered uneventfully.

involving chromosome 19q 13.4 in mesenchymal hamartomas has not been described in sarcomas, however. The treatment of unresectable cystic lesions by drainage and marsupialization is undesirable in light of this association.

Malignant mesenchymomas were so named because of the multiple derivatives of stromal cells they contain, including myxoid, chondroid, muscular, bony, and fibrous tissues. Since the report by Stocker and Ishak,[116] most authors have referred to the lesion as an undifferentiated or embryonal sarcoma, even though many of the tumors have indeed had regions of fibrous histiocytoma, liposarcoma, and even benign pericytoma.[117] Half of the cases have presented in children between the ages of 6 and 10 years. Embryonal undifferentiated sarcoma tends to be huge and unresectable at presentation. The liver is found to be replaced by a variegated, hemorrhagic, cystic mass of gray-white soft tissue (Figure 54-11). Microscopically, the undifferentiated aspect is characterized by huge bizarre cells having prominent glycoprotein inclusions associated with small nondescript cells and abundant myxoid stroma (Figure 54-12). One case has occurred in a family with Li-Fraumeni syndrome, in which germline mutations of *p53* have been found.[118] Comparative genomic hybridization of sarcomas has revealed multiple amplifications and deletions, none of which involve the locus affected in mesenchymal hamartoma.[119] The prognosis of these lesions was generally very poor, but reports from Germany,[120] Italy,[121] and the United States[122] indicate that these sarcomas may respond to intensive chemotherapy, with cisplatinum, doxorubicin, and ifosfamide in most regimens.

Rhabdomyosarcomas of the biliary tract tend to form polypoid masses of soft, gelatinous, pink-gray tissue that

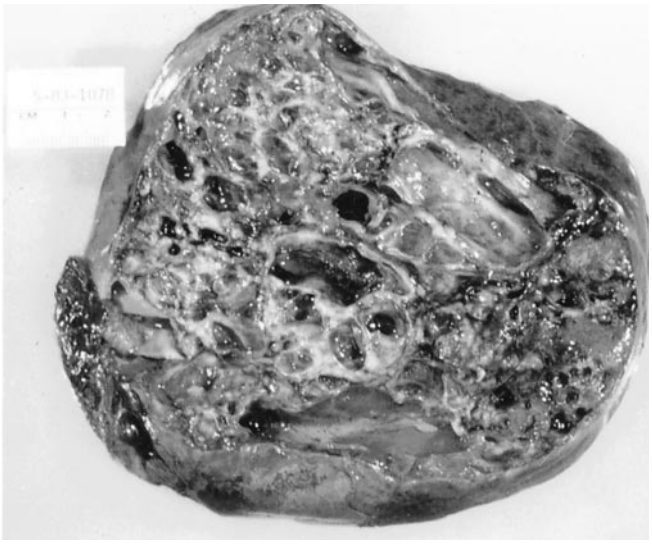

FIGURE 54-10 Mesenchymal hamartoma after sectioning. Multiple cysts filled with serous fluid are separated by myxomatous stroma.

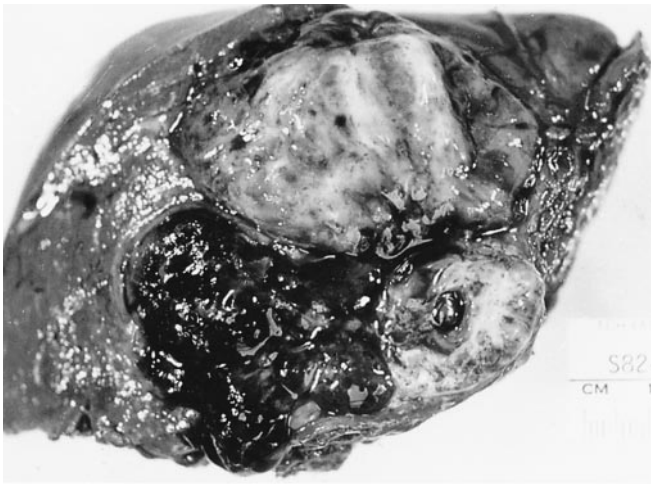

FIGURE 54-11 Undifferentiated sarcoma replaces most of the right lobe in a 6-year-old boy. A multinodular fleshy mass with large areas of hemorrhage and cystic degeneration, it gives the impression of encapsulation but, in fact, insinuates into the surrounding host liver.

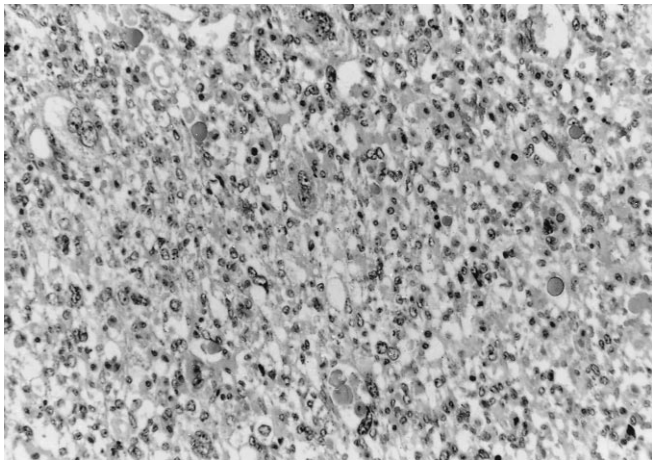

FIGURE 54-12 Undifferentiated sarcoma. Scattered among numerous small and nondescript cells are several giant cells with multilobate vesicular nuclei having prominent nucleoli. Large globular inclusions of glycoprotein are regularly present in the cytoplasm of such cells and sometimes spill out into the adjacent loose ground substance. Portions of such tumors have differentiated into fibroblasts and fibrohistiocytic, lipoblastic, and chondroid cells (hematoxylin and eosin; ×160 original magnification).

tend to obstruct bile flow. The cells are generally primitive embryonal forms with rare, ill-defined muscle filaments. All bile ducts, from ampulla and gallbladder, can be affected. Patients have ranged in age from infancy to the teens. Two of the eight cases reported by Geoffray and colleagues were resectable, but both recurred.[123] In the series of Mihara and colleagues, six of nine patients responded well to vigorous chemotherapy and radiotherapy.[124]

Rhabdoid tumors of the liver were mentioned in the discussion of hepatoblastoma. One such tumor was found in a 14-day-old boy with a primitive neuroectodermal tumor of the cerebrum that contained similar cells,[125] just as has been observed for renal rhabdoid tumors.

A 9-year-old girl with acquired immune deficiency syndrome (AIDS) is the twentieth and youngest child with leiomyosarcoma arising in the liver.[126] No human immunodeficiency virus (HIV) DNA was detected in her tumor. Unlike most such tumors in immunodeficient children,[127] this one was negative for Epstein-Barr virus. Granular cell myoblastomas, which actually arise from Schwann cells, are benign tumors that can arise in the bile ducts. Eighty-seven percent of the cases in the United States have been in the black population. Two have been described in teenagers.[128]

Bile Duct Epithelial Tumors

Biliary cystadenomas with mesenchymal stroma are benign tumors in young women but have malignant potential in middle-aged women. Cholangiocarcinomas have occurred in three adults with congenital hepatic fibrosis, the mild form of infantile polycystic disease.[129] We have observed cholangiocarcinoma in a 1-year-old boy with bile salt excretory protein deficiency. Carcinomas have been observed in the remnants of choledochal cysts, so surgeons have learned to excise the affected region.[130] Two cases of cholangiocarcinoma have been reported in young women with chronic ulcerative colitis and sclerosing cholangitis. One patient was 17 years old.[131]

Teratomas

Primary teratomas are rare and usually affect females; half contain undifferentiated elements. When yolk sac tissue (endodermal sinus tumor) is present or the tumor is wholly yolk sac in type, α-fetoprotein levels can be strikingly increased. It was extremely high (77,000 μg/L) in a 17-month-old child with adjoining benign cystic teratoma and mixed hepatoblastoma and whose preoperative imaging studies identified only the benign tumor.[132] Ninety percent of teratomas are in infants. Treatment is surgical.

Inflammatory Myofibroblastic Tumor, Lymphoma, and Leukemia

Inflammatory myofibroblastic tumor was originally called inflammatory pseudotumor or plasma cell granuloma. Anthony and Telesinghe described 17 patients with liver involvement, 6 of whom were less than 12 years old.[133] They presented with fever, abdominal pain, and/or vomiting. Jaundice was evident in four patients. Weight loss and diarrhea were also noted. There were solitary masses in eight patients and multiple nodules in four. The clinical impression and initial pathologic diagnosis may be confused with malignancy, but the histologic features of dense plasma cell infiltrates associated with active fibroplasia are indications of a chronic inflammatory process. The etiology is unknown, but some tumors have regressed with steroid therapy. On the other hand, the finding of hyperdiploidy in four of nine inflammatory pseudotumors, three of which recurred or metastasized,[134] suggested a neoplastic process. Rearrangements of the *ALK* gene at chromosome 2p23 have been observed in several inflammatory myofibroblastic tumors but not specifically in those involving the liver.[135] Portoenterostomy has been required for biliary obstruction in some cases. Transplant was needed for an 8-year-old girl whose hilar region was so extensively involved as to preclude resection.[136] Primary lymphomas of the liver of children are very rare and have monomorphous infiltrates without fibrosis.[137] Involvement of the liver in various forms of leukemia is common but only rarely of clinical significance. An exception is the megakaryoblastic leukemia of infancy, which can present with hepatomegaly and abnormal liver function tests prior to peripheral blood manifestations.[86] Liver biopsy shows diffuse infiltration of sinusoids by blast cells whose nature may not immediately be apparent. Platelet glycoprotein 2b immunostaining will be diagnostic. Diffuse scarring is prominent and a useful clue to the diagnosis.

Non-neoplastic Hepatic Masses

Non-neoplastic tumors include parasitic cysts, biliary and simple cysts, and nodular regenerative hyperplasia. All but the latter tend to present as masses and rarely because of jaundice. Most are diagnosed readily by a combination of imaging techniques, particularly ultrasonography. Nodular regeneration may present with signs of portal hypertension and is sometimes associated with collagen-vascular dis-

ease. The diagnosis is difficult even on biopsy, but neoplasia can be excluded. Two cases of maldeveloped fetuses with nodular regeneration have been described.[138]

Secondary Neoplasia of the Liver

Neuroblastoma is the most common solid tumor metastasis in children. The primitive cells infiltrating sinusoids may be mistaken for hepatoblastoma in routine microscopic studies of small biopsies. Other malignancies spreading to the liver include Wilms tumor, rhabdomyosarcoma, Ewing sarcoma, intra-abdominal small cell desmoplastic tumor, and ovarian germ cell tumors. Among the 123 cases submitted for review to CCG and POG pathologists in the hepatoblastoma/hepatocarcinoma 1986 to 1989 intergroup study, 13 incorrectly diagnosed cases (10.6%) included examples of each of the above.[86]

TREATMENT

The primary goal in treating liver neoplasms is complete surgical removal. The tendency of tumors to reach very large size before discovery and an anatomy that allows interlobar spread are handicaps. For benign tumors, such as vascular hamartoma, focal nodular hyperplasia, and adenoma, extensive surgery may be unnecessary. Many benign lesions have responded to medical management or arterial embolization, and many are stable indefinitely.[103] Therefore, vigorous efforts are made to reach a diagnosis preoperatively and intraoperatively. When that is not possible or when malignancy is suspected, surgical resection is attempted. Newer imaging modalities have been helpful in delineating the extent of involvement preoperatively[70] and intraoperatively.[69] When initial surgery for a malignancy is deemed to be too risky, preoperative chemotherapy has proven effective in shrinking many hepatoblastomas and some sarcomas to the point of resectability. Beginning in 1981, Gauthier and colleagues have routinely used doxorubicin in combination with vincristine, cyclophosphamide, 5-fluorouracil, or cisplatinum, achieving resectability in over 80% of cases.[139] The POG was able to achieve resectability 29 of 37 (79%) hepatoblastomas with cisplatinum, vincristine, and 5-fluorouracil.[140] Seventy-seven percent of those resected had no evidence of disease at 13 to 54 months, a result identical to that observed among 26 patients who had primary resections. These good results have led some centers to treat all new cases with chemotherapy, sometimes without even a biopsy if the imaging studies and serum α-fetoprotein point to neoplasia.[141,142] This approach is deemed undesirable for three reasons.[143] The first is based on the concept of "favorable" histology discussed (above and) below. Primary resection of a stage I tumor permits a thorough histologic study. If such a tumor has favorable histology, toxic chemotherapy can be minimized or even eliminated. Second, in both the latest CCG[144] and POG[140] trials, the major surgical complications after chemotherapy (hemorrhage or bile duct injury) were significantly greater than those occurring after primary resections (CCG, 25% versus 8%; POG, 23% versus 0%). Finally, small cell undifferentiated histology in otherwise typical, completely resected hepatoblastomas was associated with recurrence and fatality in at least 6 of 10 patients.[86,91] This unfavorable histology requiring alternative adjuvant therapy can easily be missed in a small biopsy.

The same chemotherapeutic regimens used preoperatively for unresectable tumors are then employed postoperatively. Nine patients with hepatoblastoma so treated by Gauthier and colleagues were cured,[139] and there have been case reports of pulmonary metastases being eliminated by such intense regimens. Recently, irinotecan has been added for unresponsive hepatoblastomas by the US Children's Oncology Group. The incidence of severe hematologic toxicity in the CCSG–Southwest Oncology Group study of 57 patients with hepatic malignancies given combination chemotherapy was 50%, and 3 children died of the complication.[145]

When completely resected lesions (stage I), which comprise 15 to 50% of different series, have been reviewed according to histologic subtype, the "pure" or "predominantly" fetal tumors were found in several series to have a good prognosis even without adjuvant therapy.[82,87] An analysis of 168 hepatoblastomas collected by the US Intergroup Study found 28 of 90 fetal cases to be resectable, and 87% of them survived 48 months.[85] In those series, the fetal cases were not further classified into "well-differentiated with low mitotic rate," a requirement that Weinberg and Finegold emphasize is necessary for a "favorable" designation.[3] Only 15% of 333 hepatoblastomas in the Intergroup,[85] Armed Forces Institute of Pathology,[146] and POG studies through 1989[140] were primarily resectable, but 92% (47 of 51) were disease free beyond 2 years. Embryonal tumors behaved less well in the early Intergroup series, with 20 of 50 cases being resectable and 63% of those surviving 48 months. All received combination chemotherapy. Tumors with a macrotrabecular growth pattern were uniformly unresectable, but 9 of 18 survived 48 months, which also is much more favorable than in all other reports to date. Just one of the small cell undifferentiated tumors was resectable, but all 10 children with small cell undifferentiated histology died within 24 months.[86] The POG and CCSG have since treated nine stage I well-differentiated fetal hepatoblastomas with doxorubicin for 4 months, with no recurrences in 5 years.[87] Patients with more advanced disease and unfavorable histologic patterns were treated with cisplatinum, vincristine, and 5-fluorouracil or cisplatinum and doxorubicin by continuous infusion; both groups had excellent results for stage I and II tumors and 64% event-free survival even for stage III. The former regimen had lesser toxicity.[87]

HCCs are resectable only 10 to 20% of the time. Nine of 46 HCCs in the latest intergroup study were resectable. Eighty-eight percent of those patients survived 5 years without disease on the same regimens as above. Neither regimen was beneficial for the higher stages of disease.[147] A better result was reported from Johns Hopkins University School of Medicine, where external beam radiation (2,100 cGy), chemotherapy, and radioiodinated antiferritin antibody were combined.[148] Forty-eight percent of the patients survived 5 years without evidence of tumor. Starzl and colleagues have performed liver transplants in selected

cases with modest success.[149] Many of the failures were in the precyclosporine era, so early death owing to graft rejection or other complications limited evaluation. Starzl and colleagues reported transplant success in three of six patients with unresectable FLCs.[149] On the other hand, they also concluded that aggressive resection was preferable because only one of eight patients with a subtotal hepatectomy suffered a recurrence. A more recent review of the University of Pittsburgh School of Medicine experience with orthotopic liver transplant for liver cancers includes six children with hepatoblastomas, of whom five are alive with no evidence of disease at 1.9 ± 0.5 years, and nine with HCCs, with four being disease free for 1.2 years.[150] One additional patient with HCC who had upper abdominal exenteration is alive 14 months later. Six transplanted patients died of malignancy, five with recurrences and one of lymphoma. More recent transplant data indicate improved transplant expectations for HCC provided that tumors were not multicentric, larger than 5 cm, and did not exhibit vascular invasion, metastasis, or positive margins at initial surgery.[151] There is active discussion among surgeons caring for children with hepatic neoplasms about the potential benefits of primary transplant versus attempted resections in anatomically problematic cases.

CONCLUSION

The likelihood of new metabolic interventions to prevent hepatic malignancies, such as that for tyrosinemia, is currently highly speculative. However, rapidly increasing knowledge about molecular interactions of growth control and gene expression, as in the APC–β-catenin pathway, offers great promise for targeting loci that might be sensitive to manipulation, perhaps by specific inhibitory RNA, for example. Until these measures became clinically applicable, however, the potential benefits of careful periodic screening with the existing tools of ultrasonography and serum α-fetoprotein in susceptible populations such as survivors of extreme prematurity, chronic cholestasis, and the glycogenoses seem worthy of general application.

CHAPTER 55

GENETIC AND METABOLIC DISORDERS

1. *Carbohydrate Metabolism*

Simon Horslen, MB, ChB, FRCPCH

An infant is brought into the office or seen as an inpatient consultation. You ask yourself, "Is this conglomeration of clinical features the result of a defect of hepatic carbohydrate metabolism? If it is, how do I make the diagnosis? How do I manage the infant in the short term? What are the long-term consequences of this disease state? And how do I explain the disease to the family?" The intention of this chapter is to assist in answering these questions.

A brief review of normal hepatic glucose, fructose, and galactose metabolism will allow the individual metabolic defects that have been identified in humans to be placed within a physiologic context. Each enzyme defect is explored in terms of clinical presentation, genetics, pathogenesis and clinical consequences, treatment, and prognosis.

Apart from the classic pathways of carbohydrate metabolism (ie, glycolysis/gluconeogenesis), other pathways involve carbohydrate moieties. Examples include defects of glucuronidation, as in Crigler-Najjar syndrome, in which glucuronide conjugation with bilirubin is interrupted; defective glycosylation of intracellular proteins, as in I-cell disease, in which mannose 6-phosphate fails to be added to proteins intended for lysosomal compartmentalization; and defective glycosylation of glycoproteins, as occurs in the carbohydrate-deficient glycoprotein syndromes. Defects in these pathways may have hepatic implication but lie outside the scope of this chapter.

INITIAL MANAGEMENT OF SUSPECTED CASES OF INBORN ERRORS OF CARBOHYDRATE METABOLISM

The first suspicion that a defect in carbohydrate metabolism may be underlying a child's illness arises from the understanding of the presenting features of this group of conditions. Clinical features that may be associated with disorders of hepatic carbohydrate metabolism are shown in Table 55.1-1. Initial investigations may include those suggested in Table 55.1-2. In many circumstances, an infant may be acutely unwell and in need of care prior to the results of diagnostic tests being available. The following steps should be taken while awaiting the results of diagnostic investigations:

- Measure the blood glucose and correct hypoglycemia with intravenous (IV) glucose solutions aiming at 8 to 9 mg of glucose/kg/min, an infant's normal rate for hepatic glucose synthesis. Avoid protein and lipid input until more diagnostic information is available (there may be an inborn error of metabolism other than one affecting carbohydrate metabolism).
- Collect blood and urine cultures followed by empiric broad-spectrum antibiotics. *Escherichia coli* sepsis is a particular association with galactosemia. Rule out disseminated viral syndromes, particularly herpesviruses.
- Measure prothrombin time and partial thromboplastin time and consider correcting coagulopathy if present.
- Manage any other features of liver failure.
- Provide general supportive measures such as rehydration and management of acidosis.

The approach to investigation and management of infants with potential metabolic defects has been excellently reviewed in a number of publications.[1–3]

TABLE 55.1-1 POSSIBLE PRESENTING FEATURES OF DEFECTS OF CARBOHYDRATE METABOLISM

Neonate	Hypoglycemia, vomiting, diarrhea, lethargy, poor feeding, sepsis syndrome, lactic acidosis, jaundice, hemolysis, hypotonia, seizures, liver failure
Infant	Hypoglycemia or hypoglycemic seizure, failure to thrive, episodic vomiting, hepatomegaly, abnormal liver function tests, chronic liver disease, cataracts
Child	Hepatomegaly, failure to thrive, short stature, anomalous eating behavior/sugar avoidance, developmental delay

TABLE 55.1-2 SUGGESTED INITIAL INVESTIGATIONS

Blood/plasma/serum samples
Electrolytes
Liver function tests
Coagulation studies (prothrombin time/partial thromboplastin time)
Blood gases
Blood glucose
Insulin level
Lactate and pyruvate
Free fatty acid and 3-OH-butyrate
Urate
Triglycerides and cholesterol
Phosphate and magnesium
Red blood cell galactose 1-phosphate uridyl transferase activity
Sugar chromatography
Urine sample
Ketones
Reducing substances

Many of these investigations will be most informative if collected at the time of hypoglycemia. Therefore, when suspecting an inborn error of carbohydrate metabolism in a sick infant, it is important to attempt to collect the samples immediately at presentation because the opportunity for "safe" hypoglycemia may not present itself for some time. In other cases, a controlled fast should be arranged. In many cases, this list will be in addition to specific investigations of infantile liver disease and/or a full metabolic workup depending on specific clinical features.

NORMAL CARBOHYDRATE METABOLISM IN HUMANS

Glucose is the main energy source for most tissues in the human body; therefore, the liver's role in maintaining glucose homeostasis is one of fundamental importance. Glucose derived from dietary intake is intermittent, and it is the responsibility of the liver to maintain the circulating glucose pool within relatively confined limits during fasting and following a feed. To do this, the liver needs to be able to take up and store excess carbohydrate to be released as glucose at times of need. Glucose can be generated either through the pathways of gluconeogenesis or by the degradation of stored glycogen. Although there are gluconeogenic tissues other than liver, such as muscle and kidney, the only cell type capable of exporting free glucose in significant amounts is the hepatocyte. Regulation of glucose uptake and release is under hormonal control. At times of high dietary glucose intake, insulin increases and promotes the uptake of glucose and the laying down of glycogen by the liver cells. As the time from the last feed increases, insulin levels fall, glucagon levels increase, and

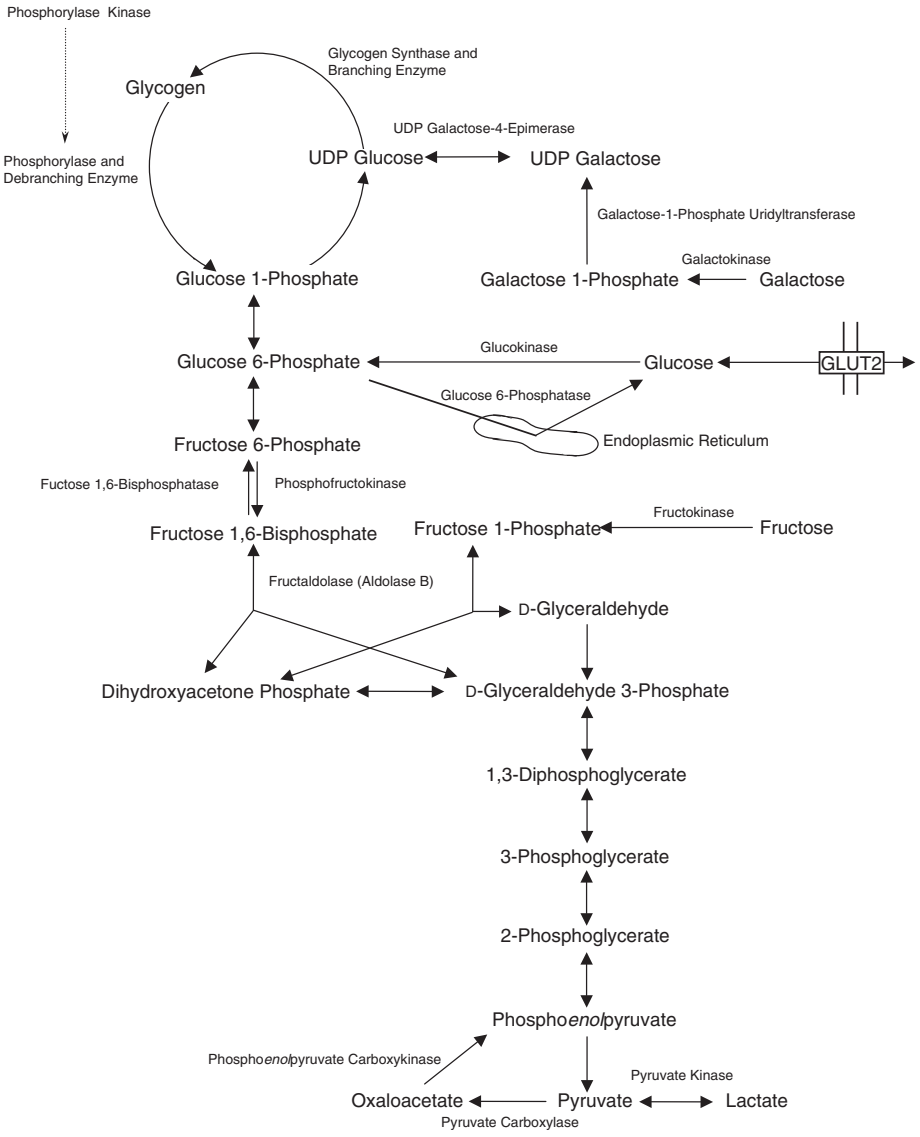

FIGURE 55.1-1 Major pathways of normal hepatic carbohydrate metabolism. Enzymes known to be affected in inborn errors of hepatic carbohydrate metabolism are shown. GLUT = glucose transporter; UDP = uridine diphosphate.

glucose synthesis and release by the liver cells increase. Hepatocytes will also synthesize and release glucose in response to epinephrine as part of the "fight or flight" response. The ability of hepatocytes to generate free glucose is due to the expression of glucose 6-phosphatase, the enzyme required for the dephosphorylation of glucose 6-phosphate. The pathways of normal carbohydrate metabolism are outlined in Figure 55.1-1.

The majority of dietary carbohydrates are absorbed in the form of glucose, galactose, and fructose. Glucose and galactose primarily enter the hepatocytes via the facultative glucose transport (GLUT) protein GLUT2. The GLUT proteins, a family of transmembrane monosaccharide transporters, are present in all human tissues. GLUT isoforms vary by tissue type, with hepatocytes expressing primarily GLUT2. The 12 transmembrane domains are thought to form a hydrophilic tunnel through the hydrophobic lipid cell membrane. Alteration in protein configuration, triggered by the concentration gradient, exposes the specific monosaccharide-binding site either inside or outside the membrane, allowing movement of glucose in both directions. GLUT proteins transport glucose only into most cells because, unlike hepatocytes, they lack net synthesis of glucose. Exceptions to the one-way transport of glucose include, in addition to the hepatocyte, enterocytes and kidney tubular cells. Fructose transport is less clearly understood. All three sugars ultimately enter the common pathway of glycolysis/gluconeogenesis following phosphorylation by specific kinases.

To enable a rapid and consistent generation of free glucose during periods of fasting, a form of storage is essential. This is primarily in the form of glycogen, a branched-chain glucose polymer. Many other tissues in the body have the enzymes required for synthesis and breakdown of glycogen, but most glycogen is found in liver and muscle. In muscle, glycogen is stored as an energy source to be used at times of high energy expenditure by muscle fibers themselves, whereas liver exports glucose to maintain circulating glucose pool and supply the other tissues of the body. Glycogen can be seen on electron microscopy in the form of β particles in muscle and liver and also as larger α particles in liver. The chemical differences to account for the morphologic difference between α and β particles have not been explained. The β particle consists of one molecule of glycogen with the proteins required for glycogen metabolism and some minor constituents, such as glucosamine and inorganic phosphate, the function of which is not clear.

The initiating event in glycogen synthesis is autoglycosylation of the protein glycogenin.[4] This protein not only acts as the substrate to which a glucose residue is covalently bound, it also actively catabolizes the reactions for the polymerization of the growing glucose chain up to a length of 6 to 10 glucose residues. At this stage, further chain lengthening is controlled by glycogen synthase, using uridine diphosphate (UDP) glucose and catalyzing the formation of 1,4-α linkages with the terminal glucose residue of the growing polymer. This produces straight-chain lengthening; the characteristic branching of these chains is catalyzed by another enzyme, amylo-(1,4),(1,6)-transglucosidase ("branching enzyme"). Branching enzyme disrupts 1,4-α bonds, at least six glucose residues from the terminal residue, and reforms a branch point with 1,6-α linkages.

Under hormonal control, glycogen metabolism is able to switch rapidly from net synthesis to net breakdown. Insulin induces glycogen synthesis, but both glucagon and epinephrine can override this mechanism and induce glycogen breakdown to increase glucose production. The hormonal signals have opposing effects on the phosphorylation of key enzymes for both synthesis and breakdown of glycogen. Following a feed, under the influence of elevated insulin levels, glycogen synthase is activated by dephosphorylation, whereas glycogen phosphorylase (responsible for glycogen degradation) is inhibited. In the fasting state, with glucagon predominating, the enzymes are again phosphorylated, which reduces the activity of glycogen synthase, and glycogen phosphorylase is activated.

Glycogen degradation requires two enzymes. Phosphorylase cleaves the 1,4-α link of terminal glycosyl units, releasing glucose 1-phosphate. Phosphorylase is activated by the action of phosphorylase kinase. This cytosolic protein kinase is itself activated by phosphorylation, via cyclic adenosine monophosphate–dependent protein kinase, and by binding ionic calcium. Phosphorylase continues degrading glycogen, one residue at a time, until only four glycosyl residues remain beyond a branch point. At this stage, debranching enzyme is needed for further degradation of the glycogen molecule. Debranching enzyme uniquely possesses two independent catalytic sites on a single polypeptide strand. Initially, the three terminal residues beyond the branch point are moved to the end of another chain using transferase activity. The actual debranching activity (amylo-1,6-glucosidase) then hydrolyzes the 1,6-α branch point, releasing a single molecule of glucose (Figure 55.1-2).

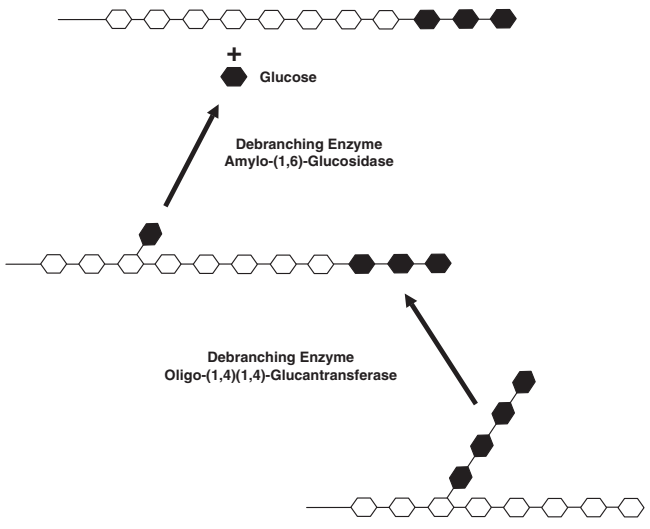

FIGURE 55.1-2 Action of debranching enzyme. Debranching enzyme has two catalytic sites on a single protein strand. When the action of glycogen phosphorylase has reduced a glycogen side chain to just four glycosol residues, the transferase activity of debranching enzyme transfers the three terminal residues to the end of an adjacent branch. The final residue is released as a single molecule of free glucose by glucosidase activity of the debranching enzyme.

Conversion of glucose 1-phosphate to glucose 6-phosphate enables the production of free glucose by the glucose 6-phosphatase system. Unlike other enzymes involved in glycolysis or gluconeogenesis, which are located in cytosol, glucose 6-phosphatase activity is found in the endoplasmic reticulum. This compartmentalization implies the need for a glucose 6-phosphate transporter, as well as the catalytic enzyme itself. These two enzymes, along with a putative phosphate transporter and a glucose transporter, are the proposed components of the "translocase-catalytic unit model" of the glucose 6-phosphatase system (Figure 55.1-3). To date, only the glucose 6-phosphatase and glucose 6-phosphate translocase units have been cloned and characterized. Glucose 6-phosphate can also be catabolized via the glycolysis pathway. This proceeds via triose phosphate to pyruvate and lactate or to acetyl coenzyme A (CoA) and entry into the tricarboxylic acid (TCA) cycle for oxidative phosphorylation and energy production.

In addition to glycogen breakdown, free glucose can also be synthesized via the gluconeogenic pathway. This is essentially the reverse of the glycolytic pathway, using all of the reversible enzyme steps from pyruvate back to glucose 6-phosphate. There are two steps in the glycolytic pathway that are irreversible, and alternate enzymes are used to bypass these steps. The first enzyme of the gluconeogenic pathway is pyruvate carboxylase, which catalyzes the conversion of pyruvate to oxaloacetate. This, in addition to phospho*enol*pyruvate carboxykinase (PEPCK), is essential for bypassing the irreversible action of pyruvate kinase. Pyruvate carboxylase is an intramitochondrial biotin-containing protein and a key regulator of gluconeogenesis. The conversion from oxaloacetate to phospho*enol*pyruvate is catalyzed by PEPCK.

The second irreversible enzymatic reaction in glycolysis involves phosphofructokinase, the conversion of fructose 1-phosphate to fructose 1,6-bisphosphate. Reversal of this, that is, splitting fructose 1,6-bisphosphate to fructose 1-phosphate and ionic phosphate, involves a Mg-dependent enzyme, fructose 1,6-bisphosphatase. The determination of overall flux in the direction of gluconeogenesis or glycolysis involves another isomeric form of fructose diphosphate. Fructose 2,6-bisphosphate inhibits the activity of fructose 1,6-bisphosphatase and activates phosphofructokinase, increasing flux through the glycolytic pathway. Fructose 2,6-bisphosphate synthesized from glucose is present in increased concentrations in the fed state and thus blocks gluconeogenesis.

DEFECTS OF HEPATIC CARBOHYDRATE METABOLISM

Inborn Errors of Glycogen Metabolism

Glycogen Storage Disease Type I: Glucose 6-Phophatase Deficiency (von Gierke Disease). The usual presentation of glycogen storage disease (GSD) I is an infant of a few months with a protuberant abdomen, short stature, and fasting hypoglycemia.[5,6] An overview of hepatic defects of glycogen metabolisms is given in Table 55.1-3. Frequent breast- or bottle-feeding of newborns often protects them during early infancy. A neonatal presentation is recognized with severe metabolic decompensation, hypoglycemia, and lactic acidosis.[7] Such a fulminant presentation may be fatal even with aggressive management.

At the time of presentation, an infant may be noted to have the characteristic "doll's" facies with big cheeks owing to excessive subcutaneous fat deposition. The protuberant abdomen is due to massive hepatomegaly, with-

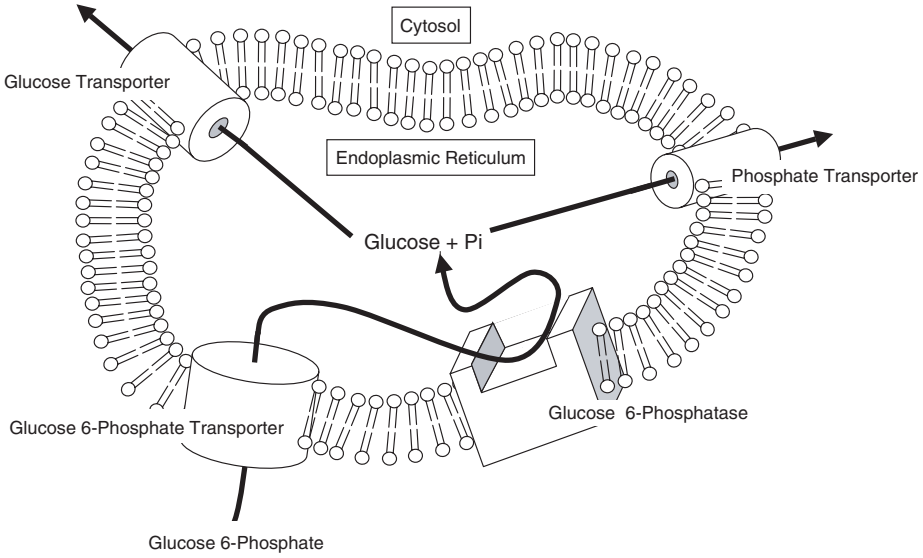

FIGURE 55.1-3 Translocase-catalytic model of the glucose 6-phosphatase system. Glucose 6-phosphatase is transported into the lumen to where the catalytic activity of the enzyme system resides. Free glucose and inorganic phosphate produced by the actions of glucose 6-phosphatase need to be removed from the endoplasmic reticulum because they inhibit the further action of glucose 6-phosphatase. The phosphate transporter remains to be fully characterized and the glucose transporter remains hypothetical at present. Pi = inorganic phosphate.

TABLE 55.1-3 GLYCOGEN STORAGE DISEASES

	EPONYM	ENZYME DEFECT	PRINCIPAL TISSUES AFFECTED
GSD I	von Gierke disease		
	a	Glucose 6-phosphatase	Liver, kidney
	b	Glucose 6-phosphate transporter	Liver, kidney, neutrophils
	c	Phosphate transporter	
	d	Glucose transporter	
GSD II	Pompe disease	Acid α-glucosidase	Heart, muscle
GSD III	Forbes or Cori disease	Debrancher enzyme	
	a		Liver, muscle
	b		Liver
GSD IV	Andersen disease	Brancher enzyme	Liver, heart
GSD V	McArdle disease	Muscle phosphorylase	Muscle

GSD IX (VIII McKusick)		Phosphorylase kinase	Liver
FBS	Fanconi-Bickel syndrome	GLUT 2	Liver, kidney
GSD 0		Glycogen synthase	Liver

GLUT = glucose transporter; GSD = glycogen storage disease.

out splenomegaly. Kidney enlargement is also present but is usually noted only on ultrasonography. The characteristic biochemical features of GSD I are fasting hypoglycemia with elevated plasma lactate, urate, and triglycerides. Cholesterol is also elevated, but not to the same extent as triglycerides. Mucosal bleeding or excessive bruising may be noted owing to platelet dysfunction as a consequence of hyperlipidemia.

Liver histology shows swollen hepatocytes with apparent cell wall thickening owing to peripheral displacement of organelles by the stored glycogen, which produces an appearance likened to plant cells. The excessive cytoplasmic glycogen stains with periodic acid–Schiff (PAS) and is readily digested by diastase. Microvesicular fat is almost invariably seen in the biopsy, but there is little in the way of inflammatory activity or fibrosis. These changes, although characteristic, are not pathognomonic, and differentiating the type of GSD on histologic criteria is not reliable.

A German pathologist, Edgar Otto Conrad von Gierke, first described GSD I in 1929.[8] Later it was demonstrated that the disease was due to the lack of activity of hepatic glucose 6-phosphatase activity.[9] There were, however, many patients who shared the phenotype but who still had glucose 6-phosphatase activity on frozen liver specimens. These patients were said to have GSD Ib. The hypothesis that this subtype was due to a defect in microsomal membrane transport was eventually proven with the identification of glucose 6-phosphate translocase (see Figure 55.1–3).[10–12] A third subtype, GSD Ic, has been shown to be genetically separate from types Ia and Ib and is thought to be a defect in a microsomal phosphate/pyrophosphate transporter.[13] Finally, it has been proposed that a microsomal glucose transporter is also part of the glucose 6-phosphatase system, and although a deficiency of this glucose transporter has been postulated (GSD Id), it has not been convincingly demonstrated.[14,15]

Both GSD Ia and GSD Ib are autosomal recessive conditions. The catalytic unit of glucose 6-phosphatase is located at chromosome 17q21 and encodes an endoplasmic reticulum membrane protein with nine transmembrane domains and a catalytic site on the luminal side of the endoplasmic reticulum membrane.[16] Over 70 separate mutations have been identified, and there is generally no genotype–phenotype correlation.[6] Glucose 6-phosphatase maintains latent activity and is dependent on transport of substrate from the cytosol into the endoplasmic reticulum lumen.[17] If the endoplasmic reticulum membrane is disrupted, either by freezing or detergent action, the catalytic activity is released and becomes apparent on enzymologic testing. The gene encoding glucose 6-phosphate translocase is located at chromosome 11q23. The protein has 10 transmembrane domains and is expressed in many human cell types, unlike glucose 6-phosphatase, which is expressed only in gluconeogenic tissues such as liver and kidney tubular cells.[18] Specifically, the glucose 6-phosphate transporter has been demonstrated in human neutrophils, where it may have a second, unspecified function, the lack of which presumably is the cause for the immune dysfunction seen in GSD Ib.[19,20]

The metabolic consequences of GSD Ia and Ib are similar, with the exception of the neutrophil dysfunction seen in GSD Ib (Figure 55.1-4).[21] Glucose 6-phosphatase is the only enzyme system capable of producing significant amounts of free glucose; therefore, the liver in GSD I is unable to maintain circulating glucose levels when the supply from a feed has been exhausted. The block in the last step of gluconeogenesis leads to excessive hepatic and renal accumulation of glycogen, which is the main cause of hepatomegaly and nephromegaly in this condition.[6] Recurrent hypoglycemia leads to increased glucagon production, which stimulates glycogen breakdown with accumulation of glucose 6-phosphate. As glucose 6-phosphate enters the glycolytic pathways, excess lactate is produced, giving rise to acidosis.

Lactate competes with urate for tubular excretion in the kidney.[5] Increased urate levels are, therefore, in part attributable to decreased urate excretion but may also be due to increased urate production. Glucose 6-phosphate may be shunted into the pentose-phosphate cycle, which stimulates synthesis of PP-ribose-P, degradation of which leads to further urate production. Finally, depletion of intrahepatic phosphate, as a result of production of glucose 6-phosphate

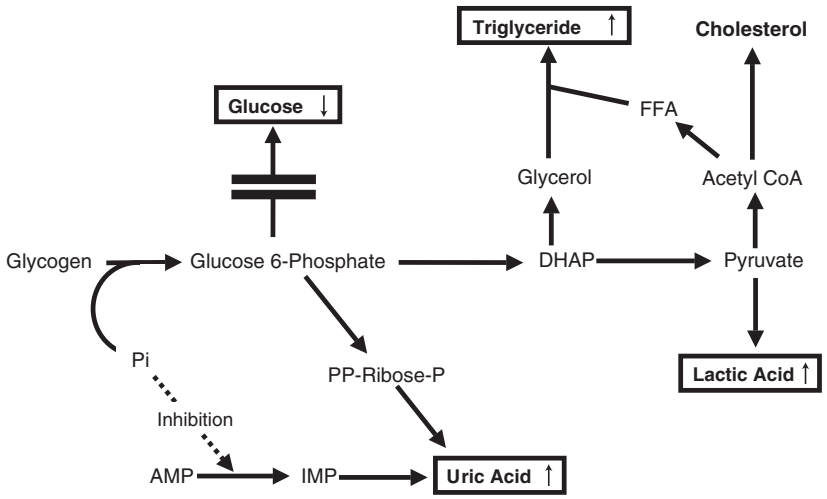

FIGURE 55.1-4 Schematic representation of the biochemical derangements responsible for the metabolic consequences of glycogen storage disease 1, namely hypoglycemia, lactic acidosis, hyperuricemia, and hypertriglyceridemia. AMP = adenosine monophosphate; CoA = coenzyme A; DHAP = dihydroxyacetone phosphate; FFA = free fatty acids; IMP = inosine monophosphate; Pi = inorganic phosphate.

from both dietary glucose and glycogen breakdown, relieves inhibition on adenosine monophosphate (AMP) deaminase, which converts AMP to inosine 5-monophosphate (IMP), which is metabolized to uric acid.[22,23]

Excess glucose 6-phosphate feeding into the glycolysis pathway increases production of glycerol and acetyl CoA and the energy precursors reduced oxidized nicotinamide adenine dinucleotide ($NADH^+$) and reduced oxidized nicotinamide adenine dinucleotide phosphate ($NADPH^+$), which provide substrates and cofactors for hepatic triglyceride production. Decreased peripheral use of fatty acids and increased lipolysis can result from low insulin levels. Bandsma and colleagues conclude that increased free fatty acid flux from adipose tissue to the liver probably makes the major contribution to hyperlipidemia and hepatic steatosis seen in GSD I.[24]

A diagnosis of GSD is usually suspected on the basis of clinical and biochemical features. Liver histology will suggest GSD but is not specific for the type. Glucagon stimulation is rarely carried out now, but in GSD I, there is little or no elevation in the plasma glucose following glucagon infusion, but lactic acid levels increase.[25] Enzyme assays on fresh (intact microsomes) and frozen (disrupted microsomes) liver biopsy specimens will diagnose and differentiate GSD Ia and Ib. Recent recommendations suggest that mutational analysis should precede liver enzymology (Table 55.1-4), with liver biopsy reserved for cases in which mutations in glucose 6-phosphatase or glucose 6-phosphate translocase genes cannot be identified but the diagnosis is still suspected.[6]

The clinical consequences of GSD I largely mirror the metabolic features discussed earlier. Recurrent hypoglycemia necessitates frequent feeding because the liver is unable to maintain glucose levels when the dietary supply of carbohydrates dissipates. Newborn infants often feed every 1 to 2 hours on demand, without significant periods of fasting, so that features of hypoglycemia may not appear. In addition, possibly because the brain can use lactate as an energy source, infants with GSD are often remarkably tolerant of hypoglycemia.[26] Hypoglycemia may first be manifest at several months of age because feeding frequency tends to decrease or at times of an intercurrent illness when dietary intake is impaired. There is an unexplained increase in fasting tolerance with age, and it may be that there is recruitment of other mechanisms for free glucose production. It is known, for example, that small amounts of free glucose can be produced by α-glucosidase, a lysosomal enzyme, deficiency of which produces GSD II, Pompe disease, and that a single molecule of free glucose is produced when debranching enzyme cleaves an 1,6-α branch point on a glycogen chain.

Untreated, massive hepatomegaly is the rule through childhood but tends to be relatively less significant in adults. There is often a modest increase in transaminases, but features of chronic liver disease are absent. Fibrosis is unusual, as is portal hypertension, but hepatic adenomas are very commonly found in untreated adults with GSD I. Adenomas in the liver are prone to bleeding and may undergo malignant transformation to hepatocellular carcinoma.[7,27]

There is slow linear growth in untreated children seen in infancy and childhood.[28] Adults tend to be short. There is frequently pubertal delay, and females have polycystic ovaries. With increasing body stores of uric acid, gout was frequently seen (before modern therapy) occurring initially at or around the time of puberty.[29] Xanthomata and lipemia retinalis may be seen at the time of presentation in infancy.[5] Massive hypertriglyceridemia is the cause proposed for the increased cases of pancreatitis seen in uncontrolled GSD I and also contributes to the platelet dysfunction responsible for the increased bleeding tendency.[30] The risk of atherosclerosis may be increased owing to the hyperlipidemia associated with GSD I.[31]

Renal dysfunction is first manifest with hyperperfusion and hyperfiltration causing an increase in creatinine clearance, but actual renal damage is heralded by microalbuminuria that may progress to frank proteinuria.[32] Chronic

TABLE 55.1-4 DIAGNOSTIC INVESTIGATIONS

DISEASE	TISSUE FOR ENZYME STUDIES	ROUTINE DNA TESTING AVAILABLE	HUMAN GENE LOCUS
GSD Ia	Liver	Yes	17q21
Ib	Liver	Yes	11q23
III	Liver and muscle	Exon 3 mutations only (ie, GSD IIIb)	1q21
IV Liver and other affected tissues	No	3p12	
VI	Liver	No	14q21–22
IX	Liver, erythrocytes, leukocytes, other affected tissues	No	Product of multiple genes
Glycogen synthase deficiency	Liver	No	12p12.2
Fanconi-Bickel syndrome	Liver, kidney	No	3q26.1–26.3
Fructosuria	Liver	No	2p23.3–23.2
Hereditary fructose intolerance	Liver	No	9q22.3
Fructose 1,6-bisphosphatase deficiency	Liver	No	9q22.2–22.3
D-Glyceric acid	Liver?	No	Unknown
Galactokinase deficiency	Erythrocytes	No	17q24
Galactose 6-phosphate uridyl transferase deficiency	Erythrocytes	Yes	9p13
UDP galactose 4-epimerase deficiency	Erythrocytes	No	1p36-35
Pyruvate carboxylase deficiency	Fibroblasts	No	11q13.4–13.5
Phospho*enol*pyruvate carboxykinase deficiency	Liver?	No	20q13.31 (soluble) Unknown (mitochondrial)

GSD = glycogen storage disease; UDP = uridine diphosphate.
Tissues primarily tested for enzyme activity in defects of hepatic carbohydrate metabolism. Few of these conditions can presently be diagnosed routinely by deoxyribonucleic acid (DNA) analysis, although the loci for most genes are known.

renal failure may ensue with hypertension, hypercalciuria, and nephrocalcinosis. Renal calculi may occur. Acidosis and renal Fanconi syndrome can accompany the renal dysfunction. Osteopenia, rickets, and fractures are also commonly seen. Histologic changes on kidney biopsy are those of focal segmental glomerular sclerosis.

In addition to the above features, there is a tendency to recurrent bacterial infections with neutropenia in GSD Ib, which may be cyclical or persistent.[21] Mucosal inflammation is common, and overt inflammatory bowel disease may be present.

It has been demonstrated that avoidance of hypoglycemia and maintenance of normoglycemia improve overall metabolic control.[33] This can be achieved with frequent enteral feeds, total parenteral nutrition, or continuous nasogastric tube feedings. The standard approach at diagnosis is now continuous overnight nasogastric feeding with glucose polymer solution or a specialized infant formula aiming to supply glucose at rates equivalent to normal hepatic synthesis, which for infants is 8 to 9 mg/kg/min and for older children is in the range of 5 to 7 mg/kg/min. During the day, frequent feeds are given. The patient should avoid galactose and fructose because these are converted to glucose 6-phosphate without contributing free glucose. In older children, the diet should be rich in complex carbohydrates. Uncooked cornstarch given every 4 hours to young children at a dose of 1 to 2 g/kg can act as a slow-release form of glucose.[34] It is slowly hydrolyzed in the gut and improves the duration of normoglycemia.[35] The period between cornstarch feeds can be extended as the child gets older, and some adults can tolerate a full 8 hours sleep on a single intake of cornstarch. Care needs to be taken when patients with GSD I are unwell. IV fluids should always contain appropriate amounts of glucose. Lactated Ringer solution should not be used. Metabolic control should be achieved and strictly maintained prior to surgery to limit bleeding problems. Successful pregnancies have been documented in women with GSD I, but strict dietary control is recommended prior to and during pregnancy.[36–38]

The use of diazoxide has been suggested to increase fasting tolerance, and Nuoffer and colleagues showed an impressive response in terms of normoglycemic control and linear growth in two patients treated with this drug.[39] Allopurinol is useful in the management of hyperuricemia, and evidence is accumulating that angiotensin-converting enzyme inhibitors may be helpful in treating the proteinuria, an early indicator of renal dysfunction.[29,40,41] With regard to the management of neutropenia and recurrent infections in patients with GSD Ib, granulocyte colony-stimulating factor has been demonstrated to increase the neutrophil counts and reduce the frequency and severity of bacterial infections.[42,43]

Orthotopic liver transplant has been carried out in patients with GSD I, usually for multiple adenomas and fear of malignant change.[44] Hypoglycemia and metabolic control are improved with successful liver transplant.[45] Hyperuricemia, lactic acidosis, and hypertriglyceridemia clear; however, it is unclear whether liver transplant influences the progression of renal disease. In those patients with end-stage renal disease, kidney transplant has been performed, but this does not improve the systemic manifestations of deranged hepatic metabolism.[46] There is one report of isolated hepatocyte transplant for this condition in an adult with poor compliance to dietary management.[47] The authors documented improved glycemic control but did not demonstrate that infused hepatocytes had, in fact, engrafted or that enzyme activity on liver biopsy had increased. Gene therapy is presently confined to laboratory studies on animal models of GSD Ia.[48,49]

Prior to modern treatment, patients frequently died soon after presentation. If they survived, they were likely to live through to adulthood with short stature and multiple complications, as discussed previously. Modern therapy, with the maintenance of normoglycemia and metabolic stability, has changed this dramatically. Although some infants succumb to acute metabolic collapse and lactic acidosis in the neonatal period, with urgent attention to glucose replacement and appropriate intensive management, these children should survive. With aggressive dietary management, overnight tube feedings, and cornstarch feeds, metabolic control can be maintained, avoiding hyperuricemia, lactic acidosis, hypertriglyceridemia, and recurrent hypoglycemia and allowing the children to achieve normal growth velocities.

Obesity can be a problem with the high carbohydrate intake, and hyperlipidemia may not be fully ameliorated.[31] Long-term sequelae such as adenomas appear to be less frequent, and adenomas already present may regress when appropriate treatment is started in teenagers and adults.[50] In spite of adequate therapy, there are suggestions that renal dysfunction may not be completely prevented; specifically, hyperfiltration does not appear to be affected even by excellent glycemic control.[5]

GSD III: Debranching Enzyme Deficiency (Cori Disease, Forbes Disease, Limit Dextrinosis). GSD III, like GSD I, commonly presents in infancy with signs and symptoms of hypoglycemia and a protuberant abdomen owing to hepatomegaly. Growth retardation is common, as is hyperlipidemia. Hypoglycemia and hyperlipidemia are frequently less severe than in GSD I and occasionally are absent completely. In addition, children may present later in childhood with isolated hepatomegaly or abnormal liver enzymes, which, in some cases, may be very high.[51] Some patients present first in adulthood with a distal myopathy.[52,53] Liver biopsy in early childhood tends to show a typical glycogenosis but is more likely to show diffuse fibrosis and less steatosis than is seen typically in GSD I. Based on clinical phenotypes, GSD III has been divided into subtypes a and b. GSD IIIa has typical liver involvement with later muscle involvement. GSD IIIb accounts for about 15% of cases, with only the liver affected by this deficiency.[5]

Snappes and Van Creveld described the first cases of this condition in 1928, and because most patients with GSD III survive into adulthood, the authors were able to demonstrate a deficiency of the debranching enzyme in the original cases 35 years later.[54] This was after Illingworth and colleagues had identified that the deficiency of this enzyme was the cause of GSD III.[55] GSD III has been identified in all races, but there is a higher incidence in Faroe Islanders (incidence 1:3,600) and North African Jews (incidence 1:5,400).[56,57] Differential translation of a single gene, located on chromosome 1p21, is responsible for the liver and muscle isoforms of this enzyme.[58,59] This gene encodes a single polypeptide that possesses two separate catalytic sites that can function independently (see Figure 55.1-2), and occasional case reports have suggested selective absence of either the glucosidase activity or the transferase activity. These cases have been termed GSD IIIc and GSD IIId, respectively.[60–62]

Glucagon stimulation gives differing results in GSD III depending on whether it is carried out in the fed or fasting state.[63] After a feed, glucagon stimulation leads to a rise in plasma glucose because hepatic phosphorylase is able to release glucose from the end-chains of glycogen. However, if the glucagon challenge takes place after an 8-hour fast, no rise in glucose is seen because the side chains have already been shortened as far as the branch points, and no further degradation can be effected in the absence of debranching enzyme. Fasting hypoglycemia results from incomplete glycogen degradation, lactic acidosis is not seen because there is no block in gluconeogenesis, and ketosis is more apparent during hypoglycemia than in GSD I.

Although hypoglycemia and hepatomegaly tend to recede with age, hepatic fibrosis and even micronodular cirrhosis can be seen in this condition.[64–66] Adenomas have been reported, but in GSD III, hepatocellular carcinoma appears to be associated only with cirrhosis.[67,68] Progressive myopathy and occasionally cardiomyopathy can occur in GSD IIIa patients, being an infrequent finding in childhood but often becoming a significant functional impairment by the third or fourth decade.[52] It is usually manifest by slowly progressive weakness and muscle atrophy. Ventricular hypertrophy is commonly seen, but frank cardiac dysfunction is the exception.[69] Polycystic ovaries have been noted in affected females; however, fertility appears to be unaffected.[70,71]

The diagnosis of GSD III is suspected on clinical and biochemical grounds, and the diagnosis is confirmed by liver enzymology, although the enzyme is expressed in other tissues such as fibroblasts. Differentiation of GSD IIIa from GSD IIIb requires a muscle biopsy. Deoxyribonucleic acid (DNA) techniques are now available for mutational analysis (see Table 55.1-4), and there appears to be a special association between exon 3 mutations and GSD IIIb.[62] More studies are needed before the type of GSD III can be ensured purely by mutational analysis.

Treatment of GSD III is similar to GSD I in that hypoglycemia needs to be effectively managed with frequent feeds, nighttime nasogastric tube feeding, and the introduction of cornstarch as the patients get older. It has been suggested that a high-protein diet can be helpful because amino acids can act as a gluconeogenic precursor and that a high-protein diet may be useful in the slowing of the progression of the myopathy even though long-term outcome studies are not available.[72] Similarly, there may be no need to restrict galactose and fructose intake because there is no impairment to their conversion to free glucose, as there is in GSD I.

Most patients with this condition survive into adulthood, usually with minimal hepatic symptoms and with an ability to tolerate a normal diet. The myopathy is slowly progressive but may become debilitating in later adulthood.

GSD IV: Branching Enzyme Deficiency (Andersen Disease, Amylopectinosis). In 1956, Andersen described a

child with progressive hepatomegaly and a hepatic storage substance similar to amylopectin, the insoluble component of plant starch.[73] In 1966, the defect in the branching enzyme was reported.[5] Although this remains the characteristic form of GSD IV, this condition has an extremely variable phenotype.[74] In addition to Andersen disease, there have been cases described with nonprogressive hepatic disease, patients with associated cardiomyopathy, or multiple system involvement including neuromuscular involvement in the form of peripheral myopathy and neuropathy with or without cardiomyopathy. A severe neonatal form with hypotonia, muscle atrophy, cardiomyopathy, arthrogryposis, pulmonary hypoplasia, and hydrops fetalis has also been attributed to mutations within the gene responsible for GSD IV. Finally, an adult-onset disease called polyglucosan body disease, a severe progressive neurologic condition with peripheral neuropathy, seizures, and dementia, has been identified to be due to a defect of branching enzyme.

GSD IV is the least common of the hepatic GSDs, and the variants are still more rare. In the classic form of this disease, the affected infant is normal at birth; however, liver disease progresses rapidly through infancy with hepatosplenomegaly, cirrhosis, and portal hypertension. Without liver transplant, death usually occurs between the ages of 2 and 5 years. Fasting hypoglycemia and massive hepatomegaly are generally absent. Liver histology differs from other forms of hepatic GSD as well, with interstitial and portal fibrosis leading to micronodular cirrhosis. Hepatocytes are enlarged and stain PAS positive but are only partially digested by diastase. On electron microscopy, aggregates reminiscent of amylopectin are visible, along with more normal-appearing glycogen particles.

The mechanism by which the abnormal unbranched glycogen leads to hepatocyte damage is not clear. It is presumably related to abnormal and insoluble glycogen inducing a foreign body reaction within hepatocytes, leading to individual hepatocyte death with an inflammatory response and fibrosis thereafter. GSD IV is an autosomal recessive condition. The gene coding for the branching enzyme has been localized to chromosome 3p12.[75] Although the enzyme is usually assayed on liver, it is also expressed in leukocytes, red blood cells, and fibroblasts (see Table 55.1-4). In addition, branching enzyme can be assayed in amniocytes and chorionic villous cells, facilitating prenatal diagnosis.[76]

There is no specific treatment for this condition. General supportive measures are recommended to maintain growth. Liver transplant has been shown to be both feasible and effective.[44] However, there are a few cases in which, after transplant, progressive cardiomyopathy has occurred, leading to death.[77,78] The situation is difficult because there is no predictor as to which patients will proceed to a progressive cardiomyopathy. Starzl and colleagues have reported patients who had evidence of cardiac involvement that regressed after liver transplant.[79] It is possible that, with further molecular studies, genotype–phenotype correlations may help to understand and predict the outcome in these patients after liver transplants.

GSD VI: Phosphorylase Deficiency (Hers Disease). Diminished phosphorylase activity in patients with excessive hepatic glycogen storage was first ascribed the term GSD VI in 1960.[5] Many of these patients have since been shown to have a defect in activation of glycogen phosphorylase rather than a defect in the gene coding for glycogen phosphorylase itself, localized to chromosome 14q21-22.[80] The number of cases with proven mutations in the phosphorylase gene is small.[81,82] Usually, GSD VI is a benign condition and affects only liver because other tissues express glycogen phosphorylases that are the products of completely separate genes. If present at all, hypoglycemia is mild and present only in infancy and early childhood. Similarly, ketosis and hyperlipidemia are minimal. Lactate and urate levels are normal. Hepatomegaly and poor growth in early childhood are the most notable features, and both tend to improve with age. In most cases, treatment is not required. If hypoglycemia is present, it can be managed with frequent feeds and nighttime tube feeding. Prognosis is excellent, and normal growth velocities can be expected beyond the first few years of life.

GSD IX: Phosphorylase Kinase Deficiency (GSD VIII according to McKusick's Online Mendelian Inheritance in Man). Of the group of mild GSDs with decreased phosphorylase activity, family studies showed that a significant proportion of these were X-linked. Defective activation of hepatic phosphorylase was demonstrated, as well as deficiency of phosphorylase kinase activity within the blood cells of these patients.[83,84] A smaller number of patients, also with measurable deficiencies of phosphorylase kinase, have an autosomal recessive mode of inheritance.[85,86] The classification of this condition (strictly a group of conditions) is a little confused; most authorities refer to phosphorylase kinase deficiency as GSD IX, but McKusick's Online Mendelian Inheritance in Man[87] categorizes it as GSD VIII.

The common presentation for this condition is that of a young child, usually not an infant, with a protuberant abdomen and moderate growth retardation. Laboratory testing may show elevated transaminases, modestly elevated cholesterol and triglycerides, and fasting ketosis. Hypoglycemia is uncommon. Like GSD VI, growth retardation is confined to early childhood. Hepatomegaly is the most dramatic finding, but this resolves with age. Curiously, the liver biopsy may show mild inflammatory changes with some fibrosis in addition to glycogen-distended hepatocytes (Figure 55.1-5). Steatosis is not usually apparent.

In the majority of cases, GSD IX is a benign condition; there are, however, a few descriptions of more significant disease with symptomatic hyperglycemia requiring dietary management as described for other GSDs.[88,89] Other patients have had more aggressive liver disease, with progression to cirrhosis, and still others have had muscle involvement.[86,90–92] The variable phenotype is largely explained by the complex nature of the phosphorylase kinase protein, which consists of multiple copies of four separate gene products: the α, β, γ, and δ subunits.[5] The α and β subunits are regulatory subunits, regulated by phos-

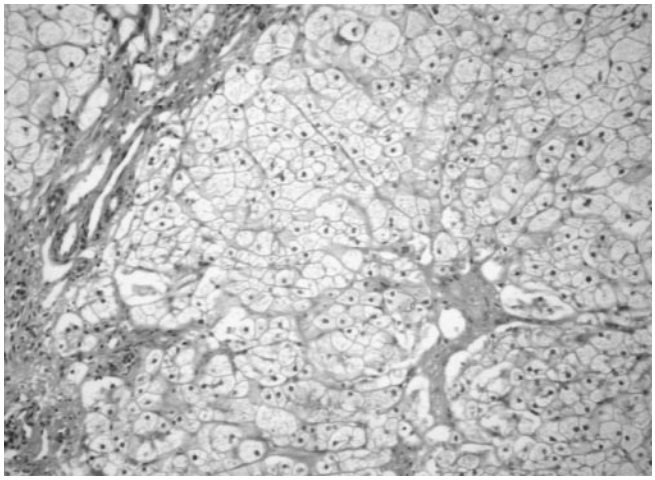

FIGURE 55.1-5 Liver histology from a 2-year-old patient with X-linked phosphorylase kinase deficiency. Note distended hepatocytes and mild periportal, pericentral, and intralobular fibrosis (hematoxylin and eosin stain; ×20 original magnification).

phorylation and dephosphorylation. There are two genes, both on the X chromosome for the α subunit, one predominantly a muscle subunit (pHka1) and the other mainly expressed in liver phosphorylase kinase (pHka2, locus Xp22.2-22.1). The β subunit is coded at chromosome 16q12-13. The γ subunit is the catalytic subunit, and, again, there are two genes on separate chromosomes for this subunit: pHkg1 (muscle) on chromosome 7 and pHkg2 (testis and liver subunit) at chromosome 16p12.1-12.2. The δ subunit is the calcium binding protein calmodulin.

Over 75% of described cases of phosphorylase kinase deficiency have defects in the α liver subunit and produce the benign hepatic form of GSD IX. Patients with β subunit defects are more likely to have evidence of muscle involvement, and cirrhosis is characteristic of the defect in the liver/testis subunit gene *PHKG2*.[85,86] Diagnosis depends on enzyme assay, which can be carried out either in red cells or liver (see Table 55.1-4). Management is generally symptomatic, but the majority of patients require no intervention. The prognosis for the X-linked glycogenosis is excellent, with hepatomegaly receding certainly by teenage years, and final adult height within the normal range. Prognosis for the variant forms is presently unclear.

Fanconi-Bickel Syndrome (Hepatorenal Glycogenosis with Renal Fanconi Syndrome). In 1949, Fanconi and Bickel described a 3-year-old boy, born to consanguineous parents from a small alpine village, with renal Fanconi syndrome and hepatomegaly.[93] He had increased liver glycogen, fasting hypoglycemia, hyperlipidemia, and renal tubular defects. Santer and colleagues reviewed this patient, with over 50 years of follow-up.[94] The same group reported knowledge of 112 patients, the vast majority being white.[95] Presentation is usually in the first year, with failure to thrive, vomiting and diarrhea, rickets and polyuria, and a protuberant abdomen. Findings include glycosuria, generalized aminoaciduria, phosphaturia, and calciuria with renal tubular acidosis. There is increased plasma alkaline phosphatase, mild to moderate fasting hypoglycemia, and hyperlipidemia; however, plasma lactate and uric acid levels are usually normal. Of particular note are postprandial hyperglycemia and hypergalactosemia. Later clinical features include a moon-shaped face, truncal obesity, retarded growth and puberty, bone problems associated with hypophosphatemic rickets, and dental caries. Cataracts from hypergalactosemia have only rarely been described, and the renal lesion is usually not progressive in nature.

The facultative glucose transporter GLUT2 was localized to chromosome 3q26.1–26.3 in 1988 and is expressed on hepatocytes, renal tubular cells, enterocytes, and pancreatic β islet cells.[95,96] It was not, however, until 1997 that a defect in GLUT2 was proposed as the possible metabolic basis for Fanconi-Bickel syndrome (FBS).[97] Mutations in the gene for GLUT2 have been demonstrated in FBS subjects, including the original patient described by Fanconi and Bickel.[98]

The features of FBS can be explained by the loss of GLUT2 function. GLUT proteins are membrane-bound monosaccharide transporters that transport sugars in an energy-independent manner. GLUT2 is responsible for transport of glucose (and galactose) into hepatocytes after feeding and export of free glucose out of hepatocytes during fasting. The hyperglycemia and hypergalactosemia seen postprandially are due to reduced uptake of these monosaccharides by the liver and may be enhanced by the poor insulin response to elevated blood glucose levels demonstrated in patients with FBS.[95] Glucose is transported inefficiently into pancreatic β cells because of the defect in GLUT2, thus failing to provoke an appropriate insulin response. Fasting hypoglycemia results from defective export of free glucose from hepatocytes when peripheral glucose supplies have been exhausted. Elevated intracellular levels of glucose stimulate increased glycogen production. Glycosuria is the result of failure to export glucose across the basolateral membranes of renal tubular cells. This again leads to an increased intracellular glucose and stimulates glycogen production. The excessive intracellular glycogen may be responsible for the other features of renal Fanconi syndrome. Finally, defective transport of glucose and galactose across enterocytes may be responsible for the diarrhea and malabsorption seen.

The treatment of patients with FBS is based on the management of renal Fanconi syndrome with maintenance of water and electrolyte balance; supplementation of vitamin D, calcium, phosphorus, and bicarbonate; and the management of the deranged glucose homeostasis. The ideal diet has not yet been decided on, but suggestions have included frequent small meals, the ketogenic diet, or uncooked cornstarch, as is used in GSD I.[95,99] On these diets, the hepatomegaly has been seen to diminish. It has also been noted that fructose metabolism does not appear to be affected by the defect in GLUT2; therefore, the use of fructose may be useful in the dietary management of patients with FBS.[100]

The prognosis for this condition appears to be generally good in terms of survival, but adults are universally short in stature. Many also have ongoing bony problems

related to rickets and osteomalacia. Hepatomegaly tends to recede after puberty.[95]

GLYCOGEN SYNTHASE DEFICIENCY

Although referred to as GSD 0, there is no excessive storage of glycogen, and, in fact, there is a demonstrable reduction in hepatic glycogen in this condition. Like many enzymes for glycogen metabolism, separate gene products account for glycogen synthase activity in muscle and liver, GYS1 and GYS2, respectively.[87]

The deficiency state of GYS2 is very rare in humans.[101,102] Although Aynsley-Green and colleagues have reported apparent asymptomatic patients with this condition, on the whole, patients have presented in infancy with features of fasting hypoglycemia.[103] The characteristic biochemical features are fasting ketotic hypoglycemia with low alanine and lactate levels and postprandial hyperglycemia with increased circulating lactate levels. There is no hepatomegaly in this condition because there is no glycogen storage, and hyperlipidemia does not occur. Liver biopsy is required for enzymologic diagnosis (see Table 55.1-4). The gene locus is chromosome 12p12.2, and mutational analysis has been conducted on affected subjects.[104] With avoidance of symptomatic hypoglycemia, the prognosis is good.

INBORN ERRORS OF FRUCTOSE METABOLISM

Fructosuria

Essential fructosuria is due to deficiency of fructokinase, which converts free fructose to fructose 1-phosphate.[105] It was first revealed in a patient checked for glycosuria while being investigated for possible diabetes.[106] Fructose, although containing no aldehyde group, becomes a reducing sugar in basic solution and will give a positive test when urine is checked for reducing substances but gives a negative reaction on glucose oxidase stick testing. Fructokinase deficiency is an autosomal recessive condition, but it is likely that many cases go undetected because of its entirely benign nature.

Hereditary Fructose Intolerance

In contrast to the previous condition, hereditary fructose intolerance (HFI) is a potentially life-threatening condition. The defect is due to absence of aldolase B (fructose 1,6-bisphosphate aldolase) from the liver, kidney, and small intestine. Other tissues in the body express aldolase A or C. This enzyme catalyzes the conversion of fructose 1,6-phosphate and fructose 1-phosphate to triose phosphates.[106]

Patients with this condition remain entirely healthy provided that they do not ingest significant amounts of fructose or sucrose. The infant is protected from harm by breastfeeding, and modern infant formulas no longer contain fructose or sucrose as a sweetener. Problems may occur on weaning to solid foods, particularly with the introduction of fruit and baby food sweetened with sucrose. Symptoms include poor feeding, vomiting, failure to thrive, and abdominal pain. If intake of fructose persists, acute hypoglycemia, bleeding, hepatomegaly, and trembling or jerking can occur. This may proceed to metabolic collapse with liver and kidney failure and, ultimately, death. With acute illness, laboratory findings are consistent with liver failure, lactic acidosis, hyperuricemia, and proximal renal tubular dysfunction. The histology of the liver at this stage shows isolated hepatocyte necrosis with intralobular and periportal fibrosis and diffuse fatty change.

If the diagnosis is not made, but the patient survives, the course may be intermittent and chronic.[106] As these children grow, they develop a dramatic aversion to sweet foods, and sometimes their odd eating habits are the reason for medical attention. Dentists have noted complete absence of caries in adult patients, and this has, on occasion, prompted the diagnosis.[107] Others have been diagnosed in adulthood after metabolic collapse, or even death, when intravenous fluids containing fructose or sorbitol have been given for routine surgeries.[108,109]

With intermittent exposure to fructose in HFI, many nonspecific symptoms may occur, such as poor feeding, intermittent vomiting, failure to thrive, irritability or apathy, and diarrhea. Chronic liver disease can also occur with hepatomegaly and cirrhosis. Symptoms are related to the fundamental toxicity of fructose. It has been demonstrated in animals and humans that large infusions of fructose are, in themselves, toxic and produce many of the features seen in patients with hereditary fructose intolerance, particularly increased circulating lactic acid and hyperuricemia.[110] The mechanism for this commences with the rapid and irreversible conversion of free fructose to fructose 1-phosphate by fructokinase.[111] Further metabolism of fructose 1-phosphate to D-glyceraldehyde and dihydroxyacetone phosphate is prevented. Production of large amounts of fructose 1-phosphate effectively sequestrates inorganic phosphate, causing a drastic reduction in cytoplasmic phosphate concentrations. This leads to a depletion of adenosine triphosphate (ATP) because of irreversible deamination of AMP to IMP. Further mitochondrial regeneration of ATP is prevented by the lack of inorganic phosphate. Elevation in Mg^{2+} seen in acute episodes is related to the fact that a large quantity of Mg is bound to ATP, and with the loss of ATP, Mg^{2+} is released.[106] The overall effect of this is a loss of cellular energy supply, and studies using ^{31}P magnetic resonance spectroscopy are providing direct proof of this mechanism.[112,113] Hypoglycemia during acute exposure to fructose is due both to deranged gluconeogenesis because of the increased fructose 1-phosphate levels and to failure of glycogenolysis because inorganic phosphate deficiency inhibits glycogen phosphorylase. Hypoglycemia can be reversed by galactose infusion, implying that there is no inhibition of the glucose 6-phosphatase pathway. Glucagon cannot correct hypoglycemia during these episodes because of the deranged gluconeogenic pathways.[114]

Aldolase B gene is located on the long arm of chromosome 9 (9q22.3).[115] The incidence of this condition in Switzerland, from where many cases have been described, is estimated at about 1 in 20,000.[116] However, the incidence in other populations is unknown and is complicated by the fact that many affected individuals may live a long life without the diagnosis being made.

The diagnosis of HFI is dependent on the physician having a high degree of awareness of this condition. A careful nutritional history will solidify the suspicions, and the urine can be checked for non–glucose-reducing substances; however, absence does not rule out the diagnosis. On initial suspicion, all dietary fructose, sucrose, and sorbitol should be excluded from the diet. Infants presenting with severe toxic episodes may need intensive support for an extended period. Once recovered, the child should be maintained on a fructose-free diet for several weeks to ensure recovery and improved growth. A fructose tolerance test can then be carried out.[117] A small dose, standardized at 200 mg/kg, is infused while monitoring laboratory parameters such as glucose, plasma phosphate, uric acid, lactate, and Mg^{2+}. A characteristic response is an increase in plasma urate and magnesium with a corresponding fall in phosphorus and glucose. Aldolase B can be assayed on liver biopsy, and DNA mutational analysis is now also available.[118,119]

Treatment involves removal of all known dietary sources of fructose, sucrose, and sorbitol, which are found naturally in fruits, vegetables, and honey, as well as in processed food. Fructose is so widespread that patients should be very open about their intolerance so as not to be inadvertently exposed. This is especially true in any contact with medical professionals. Medicines may be sweetened with sucrose. IV fluids or parenteral nutritional supplements using fructose or sorbitol have been advocated in the past but should be avoided in all patients. When recovery occurs, it is complete, with reversal of hepatic histologic changes and renal dysfunction. Growth and development become normal.

Fructose 1,6-Bisphosphatase Deficiency

Fewer than 100 cases of fructose 1,6-biphosphatase deficiency have been reported. Affected individuals may present with neonatal jaundice, but, more commonly, episodic bouts of hyperventilation around the time of weaning from frequent milk feeds are seen.[120] The hallmark is ketotic hypoglycemia, lactic acidosis on fasting, and elevated uric acid. Metabolic collapse may be rapidly lethal, and fasting or infections often trigger late episodes.

After stabilization and avoidance of dietary fructose, an IV fructose tolerance test is abnormal, but unlike HFI, there is no aversion to sweet foods and no proximal renal tubular signs. Liver biopsy shows steatosis but no fibrosis. Again, this enzyme can be assayed in liver biopsy. The condition is inherited as autosomal recessive, and the gene has been localized to the almost identical locus to aldolase B on the long arm of chromosome 9. Treatment consists of IV glucose for the acute episode and long-term avoidance of fasting. Fructose should be limited, but complete avoidance is probably unnecessary. When the diagnosis is made and treated appropriately, the course is said to be favorable.[106]

D-Glycericaciduria

This extremely rare condition is due to the absence of D-glycerate kinase, which is required in the pathway of metabolism of D-glyceraldehyde, which, in turn, is derived from the metabolism of fructose 1-phosphate or glycerol. The presence of D-glyceric acid in urine is associated with hyperglycinemia, metabolic acidosis, and neurologic features that include hypotonia, seizures, severe developmental delay, and spastic quadriplegia. However, other cases have been relatively asymptomatic.[121,122] Dietary restriction of fructose has been suggested as management for this condition.

INBORN ERRORS OF GALACTOSE METABOLISM

Galactokinase Deficiency

The first step in the hepatic metabolism of free galactose is the conversion to galactose 1-phosphate catalyzed by galactokinase, the deficiency of which was first described in a child with bilateral cataracts.[123] This has been a consistent feature in all cases described since, and it is notable that the other features of classic galactosemia do not occur. There is no acute metabolic episode associated with this condition. Ovarian failure and growth failure do not occur. Galactokinase deficiency is not thought to pose neurodevelopment problems, although pseudotumor cerebri has been described in a few cases.[124,125] Galactokinase deficiency is probably less common than classic galactosemia, based on neonatal screening data, but its true incidence is undetermined.

The diagnosis is suspected either on the basis of neonatal screening or because of infantile cataracts and is confirmed by demonstrating deficient galactokinase activity with normal galactose 1-phosphate uridyl transferase (GALT) activity in red blood cells (see Table 55.1-4). The cause of the cataracts appears to be galactitol, the product of reduction of galactose by aldose reductase.[126] High concentrations of this enzyme occur within the ocular lens and lead to accumulation of galactitol. Galactitol is poorly mobilized from the lens media and exerts an osmotic effect.[127] Cataracts can be prevented in experimental animal models of galactokinase deficiency by inhibiting aldose reductase.[128] The management of this condition involves dietary galactose exclusion and is highly effective provided that the vision has not been permanently damaged prior to diagnosis.

GALT Deficiency

GALT deficiency is the most common defect of galactose metabolism, and the clinical picture was first described by Goppert in 1917.[129] The frequency of GALT deficiency varies in different populations, with the highest incidence in Irish travelers of 1 in 480 and an estimated prevalence overall of 1 in 62,000.[125,130] In the United States, most infants with galactosemia are now diagnosed on infant screening. Often the patients are asymptomatic at diagnosis. Some infants present acutely within days of birth with vomiting and diarrhea, irritability, or lethargy with hypotonia, and the rapid diagnosis allowed by the early neonatal screening may assist in the care of these sick infants. If galactose ingestion continues, this progresses to hemolysis with jaundice and acidosis. There may be acute metabolic collapse with liver and kidney failure leading to death. Many of the fulminant early infantile cases are related to the high incidence of bacterial septicemia, with the

causative organism most commonly being *E. coli*.[131] *E. coli* sepsis is so characteristic that any neonate so affected should be investigated for underlying galactosemia. Other infants follow a more chronic course with poor feeding and growth and progressive liver disease leading to cirrhosis. In surviving children, mental retardation is almost universal, although this is rarely at a profound level. Cataracts have been observed within days of birth but are more commonly seen later in infancy in those on an unrestricted diet.

GALT catalyzes the reaction that converts galactose 1-phosphate to UDP galactose (Figure 55.1-6). The acute metabolic syndrome is probably due to sequestration of inorganic phosphate as galactose 1-phosphate, with resulting deficiency in cellular energy owing to loss and insufficient restitution of ATP supply, possibly analogous to the demonstrated acute effects of fructose intake in patients with HFI. Galactose 1-phosphate itself inhibits a number of enzymes, in vitro, involved in glucose metabolism. The acute disturbance leads to liver disease, hemolysis, lactic acidosis and renal tubular acidosis, proteinuria, and aminoaciduria.

With the introduction of neonatal screening, individuals were identified with milder disease.[132] The "Duarte" variants identified on neonatal screening have structurally altered GALT that is functionally deficient, at least in young infants. However, after a few months, GALT activity can often be measured in the 50% range. Development in patients with a Duarte variant is normal, and they can tolerate an unrestricted diet. It had also been noted that galactosemia was commonly less severe in black individuals. Despite complete peripheral GALT deficiency, such patients are able to tolerate a normal diet. This so-called "Negro" variant has zero activity of GALT in erythrocytes but up to 10% GALT activity when measured on liver biopsy.

The GALT gene is located at chromosome 9p13. A large number of mutations have been identified (some are specifically associated with variants); the most common mutation in Caucasians causing classic galactosemia is Q188R. The "Negro" variant is associated with the most common mutation in the GALT gene found in black populations, *S135L*.

The diagnosis is frequently made on the basis of a neonatal screen. Positive neonatal screens should always be followed up with assay of red blood cell GALT activity (see Table 55.1-4). Isoelectric focusing of GALT will identify the Duarte variant, which has a faster electrophoretic mobility than normal GALT. In the unscreened population, the clinical presentation with metabolic collapse and/or *E. coli* sepsis is a clue to check for nonglucose urinary reducing substances (remember that this will become negative following the cessation of galactose-containing feeds). With clinical suspicion, milk feeds should be discontinued and IV glucose given until enzyme activity can be proven to be present.

The treatment for galactosemia is dietary galactose restriction, which, for an infant, means removal of breast milk or regular formula feeds and substitution with a galactose-free formula. The elimination of galactose will lead to a fall in red cell galactose and urinary excretion of metabolites such as galactitol and galactinate within a few days. However, red cell galactose 1-phosphate levels remain high and fall only gradually, and red cell galactose 1-phosphate levels never return fully to normal. The introduction of a galactose-exclusion diet allows recovery from the initial acute illness and prevents further acute metabolic episodes. It will reverse liver and renal dysfunction and prevent the formation of cataracts. Unfortunately, the diet as it exists presently appears to do little for the long-term complications of mental retardation or ovarian dysfunction in females.[133] In addition, growth failure, speech delay, and delayed-onset neurologic lesions are also not obviously affected by diet.[134] Waggoner and colleagues have shown that the incidence of these complications in patients who start a galactose-free diet later after a clinical presentation is not significantly different from those children on galactose elimination prior to the onset of symptoms because of neonatal screening or because of a previously affected sibling.[135]

Therefore, if galactose restriction does not alter long-term outcome, what is the pathogenesis of these long-term complications? The answers remain to be elucidated, but the debate revolves around a number of questions. The first is, Does the insult or injury occur before or after birth? Amniotic fluid of fetuses with classic galactosemia has been demonstrated to have increased levels of galactitol,

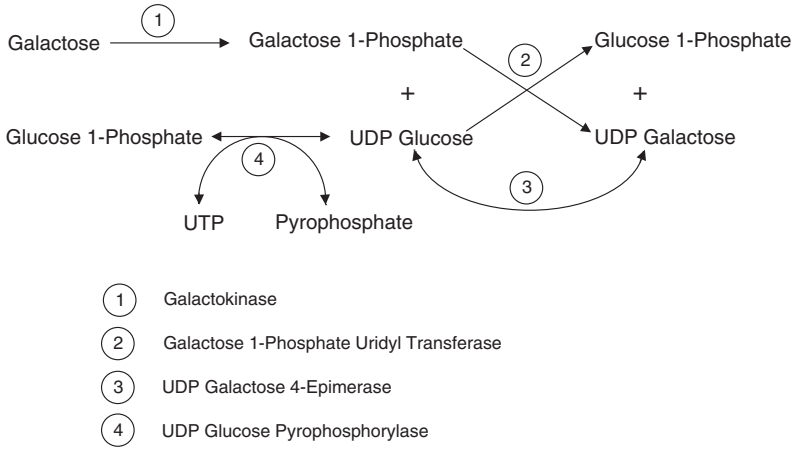

FIGURE 55.1-6 Metabolism of galactose to uridyl diphosphogalactose. UDP glucose = uridyl diphosphoglucose; UTP = uridyl triphosphate.

and cord blood has increased galactose 1-phosphate, even if the mother is on a galactose-restricted diet, suggesting in utero metabolic derangement.[136] To support the idea of postnatal injury, it has been noted in a number of studies that mental retardation measured by DQ/IQ is not a fixed defect but falls progressively with age and may not be affected by the patient's compliance with galactose restriction.[137] Similarly, ovarian failure common in affected females is not always manifest with primary amenorrhea; secondary amenorrhea may even occur after a successful pregnancy. It would seem quite possible that there is a contribution to the long-term complications of galactosemia, both from antenatal and postnatal insults.

The second question is, If the diet is adequately restricted, where does the toxic galactose come from? Are there unrevealed dietary sources of galactose, or is this some form of "autointoxication" with de novo synthesis of galactose or galactose 1-phosphate in the body? In practical terms, a completely galactose-free diet is effectively impossible. Although the vast majority of galactose in the diet comes from milk and dairy products, there are other sources of dietary galactose. Free galactose exists in some fruit and vegetables, and galactose can be derived from animal glycoproteins, galactolipids, and galactosides.[138] It has been suggested that plant oligosaccharides, which contain galactose such as raffinose and stachyose, may contribute to galactose intake. However, humans do not possess the digestive oligosaccharides to free galactose from these sugars. On the other hand, a female volunteer with classic galactosemia had no change in galactose metabolites when taking a diet rich in fruit and vegetables known to contain free galactose compared with when she adhered strictly to a galactose exclusion of less than 8 mg galactose/d.[139] This implied to the authors de novo synthesis of galactose, giving support to the "autointoxication" hypothesis. Galactose 1-phosphate can be synthesized through cleavage of UDP galactose. These metabolites are produced by the reversible actions of UDP galactose 4-epimerase from UDP glucose (see Figure 55.1-6). The flux through this pathway in the absence of GALT activity is not known.

The third question is, Are the long-term complications attributable to the toxic effects of galactose 1-phosphate and other aberrant metabolites or to defective synthesis of glycoproteins and other essential galactose-containing molecules owing to a relative depletion of UDP galactose? This, again, depends on whether the flux through the pyrophosphorylase pathway can make up for the lack of UDP galactose, which, under normal circumstances, appears predominantly to come from metabolism of free galactose. These questions are, as yet, unanswered.

Current recommendations are to maintain galactose restriction as severely as possible, especially in early infancy, while the prognosis in terms of growth and development remains guarded.

UDP Galactose 4-Epimerase Deficiency

This condition was again identified as a result of newborn screening for galactosemia. The initial patients were noted to have normal growth and development. The enzyme deficiency in these patients is restricted to circulating red blood cells and leukocytes, with normal activity of the epimerase enzyme in liver and fibroblasts.[126] This condition is entirely benign.

In contrast, a severe form has been reported in only three families, each with highly consanguineous lineages.[140] The clinical features are those of severe classic galactosemia with early metabolic dysfunction and liver disease. Galactose restriction prevents the acute syndrome but does not influence the growth and mental retardation observed. Walter and colleagues have given small amounts of lactose to these patients in an attempt to maintain essential glycoprotein synthesis because, unlike in GALT deficiency, UDP galactose cannot be generated via the pyrophosphorylase pathway (see Figure 55.1-6).[140]

INBORN ERRORS OF PYRUVATE METABOLISM

Pyruvate Carboxylase Deficiency

Pyruvate carboxylase is key to the initiation and regulation of gluconeogenesis, as well as maintaining cellular concentrations of oxaloacetate. Deficiency of pyruvate carboxylase has been identified in only a small number of patients, but there appear to be three distinct phenotypes.[141] The first group presents in infancy, with lactic acidosis, organic aciduria, elevated plasma levels of pyruvate and alanine, and severe mental retardation. Of particular note is the frequency of this condition among Canadian Natives.[142] The second group is a severe neonatal form, with macrocephaly, intractable lactic acidemia with elevated lactate-to-pyruvate ratios, hyperammonemia, hypercitrullinemia, and hepatomegaly.[143] Death usually occurs by 3 months. Finally, there are two cases described of children with intermittent acidosis but normal development.[144,145] Pyruvate carboxylase activity in fibroblasts is low in all groups of patients, but only in the severe neonatal group are cases found in which no pyruvate carboxylase activity, protein, or messenger RNA can be detected.[146] The variation in phenotype is possibly related to the amount of residual pyruvate carboxylase activity.

Lactic acidosis and elevated alanine levels are related to excess pyruvate accumulation, but the more severe symptoms of hyperammonemia and deranged lactate-to-pyruvate ratios seen in the neonatal form result from an inability to maintain cellular concentrations of oxaloacetate, which is necessary to maintain the TCA cycle and to synthesize aspartate.[141] Aspartate is an essential nitrogen donor for the urea cycle; therefore, citrulline and ammonia accumulate. Aspartate depletion also disrupts transport of reducing equivalents ($NADH^+$ and $NADPH^+$) into the mitochondria, which is reflected in the deranged lactate-to-pyruvate ratio.

Dietary treatment with correction of acidosis and addition of aspartate to supplement the cellular amino acid depletions has been tried.[147] Thiamine, a cofactor for pyruvate dehydrogenase complex, and dichloroacetate, which stimulates pyruvate dehydrogenase activity, may allow

more pyruvate to be metabolized through to acetyl CoA. Biotin, although a cofactor for pyruvate carboxylase, has not been shown to have benefit. There is one report of orthotopic liver transplant in a child with a severe form of pyruvate carboxylase deficiency, and although transplant was unable to reverse preexisting neurologic damage, much of the systemic metabolic disturbance was corrected.[148] There was some optimism that the neurologic progression of this disease may have been slowed.

PEPCK Deficiency

PEPCK, the second enzyme in the gluconeogenic pathway from pyruvate, is dependent on guanosine triphosphate for the conversion of oxaloacetate to phospho*enol*pyruvate. There are two forms of this enzyme: one soluble or cytosolic and the other mitochondrial, which are products of different genes. A number of cases of PEPCK deficiency have been described in children.[149–152] Certain cases have since been demonstrated to be due to generalized mitochondrial defects.[153] The features attributed to the cases that remain are infantile hypoglycemia, fatty infiltration of both liver and kidneys, and liver failure. The extent of the phenotype is not well defined owing to the difficulty of the enzyme assays and the extreme rarity of the cases.

2. *Amino Acid Metabolism*

Karen F. Murray, MD
C. Ronald Scott, MD

Vomiting, irritability, and failure to thrive are frequent symptoms for which consultation with a pediatric gastroenterologist is sought. Especially when the child is an infant, inborn errors of metabolism must be included in the list of potential diagnoses. Discussed in this chapter are those errors of metabolism that occur in the use or breakdown of amino acids—frequent disorders that can result in common symptoms encountered in pediatric gastroenterology practice. Additionally, because the liver is the main site for many of these metabolic processes, other nonspecific findings, such as hepatomegaly or hepatic dysfunction, may precipitate referral erroneously for evaluation of primary liver disease. Understanding the most common conditions, their forms of presentation, and the methods with which they can be quickly distinguished and diagnosed is the main goal of this chapter.

The metabolic conditions can be categorized into (1) disorders of the aromatic amino acids, of which hereditary tyrosinemia is the most common disorder encountered by gastroenterologists; (2) disorders of branched-chain amino acids (BCAAs), including maple syrup urine disease (MSUD), isovalericaciduria (IVA), propionicaciduria (PA), and methylmalonicaciduria (MMA); and (3) the urea cycle defects, including ornithine transcarbamylase (OTC) deficiency, carbamyl phosphate synthetase (CPS) deficiency, citrullinemia, argininosuccinicaciduria, *N*-acetylglutamate synthetase deficiency, and argininemia. It should be noted that other amino acid metabolic disturbances have been identified in rare subjects; consequently, unusual patterns of metabolite profiles could be encountered for which additional consultation for diagnosis should be considered.

For each condition, the molecular basis of the disease is reviewed, the common clinical presentations are discussed, the method of diagnosis and the distinguishing patterns of metabolites detected with each condition are reviewed, and the effective therapies are covered. Additionally, it is important to understand that nonspecific amino acid disturbances occur with liver disease in general, and the bases for these changes are discussed so that they may be properly interpreted when encountered.

DISORDERED AMINO ACID PROFILES SEEN WITH HEPATIC DISEASE

Hepatic dysfunction with or without hyperammonemia, severe hepatitis, and cholestatic liver disease may cause nonspecific abnormalities in serum and urine amino acid profiles. In the setting of hyperammonemia, concentrations of glutamine, alanine, and sometimes aspartic acid are elevated. With cholestatic liver disease, severe hepatitis and hepatic dysfunction elevation of tyrosine and methionine are frequently seen as a consequence of a nonspecific reduction of tyrosine aminotransferase enzyme activity. Tyrosine aminotransferase is the rate-limiting step in tyrosine metabolism, and its activity can be reduced by as much as 50% with liver disease.

DISORDERS OF AROMATIC AMINO ACIDS

Hereditary Tyrosinemia

Disorders of aromatic amino acids are the most common of the inborn errors of amino acid metabolism owing to the high frequency of phenylketonuria in the population and frequency of alkaptonuria and tyrosinemia, types II and III. However, for the gastroenterologist, it is the disorder of tyrosinemia type I that is of major concern.

Tyrosinemia type I is a devastating disease of childhood that causes liver failure, painful neurologic crises, hepatocarcinoma, and usually death prior to the age of 10 years. It is a rare disorder in the general population, with an incidence no greater than 1 in 100,000 newborns.[1] However, because of the inconsistent and confusing nature of its clinical presentation, it is estimated that less than 50% of cases are diagnosed before their demise. Children born with tyrosinemia type I typically develop severe liver disease at less than 6 months of age and, if unrecognized or untreated, die within a few weeks to months. A more chronic form of the disorder exists in which children develop first symptoms older than 6 months and have a better short-term prognosis. These patients typically present with a Fanconi-like renal syndrome, rickets, and growth failure. They may have repetitive bouts of neurologic crises that are similar in nature to those seen in older patients with acute intermittent porphyria (changes in mental status, abdominal pain, peripheral neuropathy, respiratory depression). In all cases, the symptoms are severe, leading either to death in infancy or to chronic early childhood morbidity, with the eventual development of hepatocarcinoma and death in the later years of childhood.

Molecular Defect

Tyrosinemia type I occurs because of a deficiency of fumarylacetoacetate hydrolase (FAH),[2,3] the terminal enzyme in the tyrosine catabolic pathway (Figure 55.2-1). With the deficiency of FAH, the immediate precursor, fumarylacetoacetate (FAA), is prevented from being con-

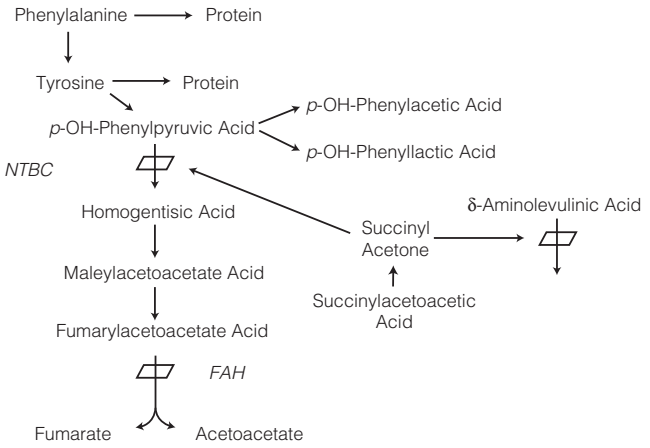

FIGURE 55.2-1 Tyrosine pathway indicating the enzymatic deficiency in tyrosinemia type I and the sites of succinylacetone inhibition. 2-(2-Nitro-4-trifluoromethylbenzoyl)-1,3-cyclohexanedione (NTBC) acts as an inhibitor of *p*-hydroxyphenylpyruvate oxidase. FAH = fumarylacetoacetate hydrolase.

verted to fumerate and acetoacetate, and FAA is instead diverted to succinylacetoacetate and succinylacetone. These two compounds, particularly succinylacetone, are believed to be the toxic metabolites in tyrosinemia. It is known that succinylacetone interferes with two enzymatic reactions, *p*-hydroxyphenylpyruvic acid dioxygenase (*p*-HPPD) and δ-aminolevulinic acid (δ-ALA). The elevation of plasma tyrosine observed in tyrosinemia is secondary to the inhibition to *p*-HHPD by succinylacetone.

Succinylacetone is also a potent inhibitor of δ-ALA hydratase.[4] It is the inhibition of this enzyme that precipitates the acute neurologic episodes. δ-ALA dehydratase activities have been shown to be reduced in liver and circulating red cells, and δ-ALA is excreted in high levels in children with tyrosinemia type I.[5] There are also suggestions that succinylacetone may interfere with immune functions, cell functions, heme synthesis, and renal tubular function.[6–8]

Two regions of the world have a higher than expected frequency of tyrosinemia type I. In Norway and Finland, the incidence at birth is estimated to be approximately 1 in 60,000 live births, and within the Saguenay-Lac Saint-Jean region of Quebec, Canada, there is an incidence of 1 in 1,846 live births that has occurred because of a founder effect.[9] A common mutation exists within the latter population (IVS12+5 G→A). Within the United States, only a few mutations account for the majority of cases, with these mutations introduced from the populations of northern and southern Europe and from Mexico.

Clinical Features

The clinical presentation of patients with tyrosinemia can be divided into two main groups: those presenting at less than 6 months of age with severe liver involvement and those presenting after 6 months of age with either mild liver dysfunction or renal involvement, growth failure, and rickets (Table 55.2-1). Children less than 6 months of age typically have acute liver failure, with a markedly prolonged prothrombin time and partial thromboplastin time that are not corrected by vitamin K supplementation. The analysis of other clotting factors indicates the preservation of factor V and factor VIII levels but a decrease in factors II, VII, IX, XI, and XII. Serum transaminase levels may be modestly elevated, and serum bilirubin may be normal or only slightly elevated. Thus, the loss of clotting factors from synthetic function is the major abnormality in the early phases of the disorder.[11] The other striking biochemical feature is a markedly elevated α-fetoprotein that averages approximately 160,000 ng/mL at the time of diagnosis. For those children presenting in the acute phase of their illness, appropriate intervention strategies are essential to prevent their demise. This early phase can progress to loss of liver function and the appearance of ascites, jaundice, and gastrointestinal bleeding. There may be a characteristic odor of "boiled cabbage" or "rotten mushrooms." The odor and elevation of α-fetoprotein often lead to the recognition and eventual documentation of elevations of plasma methionine and tyrosine and the identification of succinylacetone in urine or plasma.

In the more chronic form of the disorder, renal involvement is the major manifestation. The renal tubular dysfunction involves a generalized aminoaciduria, phosphate loss, and, for many, renal tubular acidosis. The continued renal loss of phosphate is believed to be the mechanism for the development of rickets because abnormal calcium levels have not been systematically documented. Growth failure can be ascribed to the chronic illness from poor nutritional intake, liver involvement, or chronic renal disease.

Repeated episodes of neurologic crises often go unrecognized. Mitchell and colleagues reported that 42% of the patients in the French Canadian population had experienced these episodes.[5] They often are associated with excruciating pain and posturing and can last 1 to 7 days. They are associated with weakness or paralysis that, in some cases, may require mechanical ventilation for survival. Van Spronsen and colleagues reported in the international survey that 10% of deaths occurred during a neurologic crisis, representing a major life-threatening mechanism independent of liver failure.[10]

Diagnosis

The pathognomonic metabolite for the confirmation of the diagnosis is succinylacetone. Succinylacetone can be detected in the urine of all untreated patients with tyrosinemia type I. Organic acid analysis by gas chromatography–mass spectroscopy will identify an organic acid pattern with elevations of parahydroxyphenylacetic acid, parahydroxyphenyllactic acid, and significant elevations of succinylacetone. Succinylacetone may need to be requested specifically on laboratory request forms.

The measurement of FAH in cultured skin fibroblasts can be used as a confirmatory test or, potentially, the identification of an abnormal mutation within the FAH gene. These latter approaches are not readily available as a common clinical assay.

TABLE 55.2-1 COMPARATIVE FEATURES OF THE MOST COMMON DISORDERS OF AMINO ACID METABOLISM

DIAGNOSIS	PHENOTYPE	CLINICAL FEATURES	SERUM GLUCOSE	SERUM AMMONIA	METABOLIC ACIDOSIS	URINE KETONES	SERUM AMINO ACIDS	URINE AMINO ACIDS	URINE ORGANIC ACIDS	DIAGNOSIS
Tyrosinemia type I	Acute chronic	Acute liver failure or renal Fanconi syndrome with rickets	Normal	Normal	Absent or mild	None	Elevated methionine and tyrosine	Elevated methionine and tyrosine	Succinylacetone	Succinylacetone in urine or plasma
Maple syrup urine disease	Classic	Neonatal encephalopathy; "maple syrup" urine odor	Sometimes low	Normal	Prominent	Elevated	Markedly increased alloisoleucine, BCAAs	Elevated BCAAs	Elevated BCKAs	BCKD activity in cultured fibroblasts or lymphocytes < 2%
	Intermediate	Developmental delay, seizures	Normal	Normal	Prominent during symptoms	Elevated	Same as above	Same as above	Same as above	3–30%
	Intermittent	Episodic ataxia and lethargy	Normal	Normal	Prominent during symptoms	Elevated during symptoms	Elevated BCAA during symptoms	Elevated BCAA during symptoms	Elevated BCAA during symptoms	5–20%
Isovalericaciduria, propionicaciduria, methylmalonicaciduria	Same as above	Same as above; dehydration, hepatomegaly; "sweaty feet" odor in IVA	Variable	Elevated	Prominent	Elevated	Nonspecific elevations of glycine	Nonspecific elevations	Specific OA patterns	Cultured fibroblast enzyme activity
Ornithine transcarbamylase deficiency	Classic	Lethargy, poor feeding, coma, seizures, developmental delay	Normal	Elevated	Absent	None		Nonspecific elevation	Orotic acid elevation	Small intestine or liver biopsy enzyme activity
Carbamyl phosphate synthetase deficiency		Same as above	Normal	Elevated	Absent	None	Absent citrulline	Nonspecific elevation	Nonspecific elevation	Same as above
Citrullinemia		Same as above	Normal	Elevated	Absent	None	Elevated citrulline	Elevated citrulline	Nonspecific elevation	Cultured fibroblast or lymphocyte enzyme activity
Argininosuccinicaciduria	Neonatal	Same as above; fragile hair	Normal	Elevated	Absent	None	Elevation of glutamine and argininosuccinic acid	Elevated arginine-succinate	Nonspecific elevation	Cultured fibroblast or erythrocyte enzyme activity

Treatment

Prior to 1995, there was no effective medical treatment for tyrosinemia type I. Dietary interventions using an artificial formula, low in phenylalanine and tyrosine, were modestly helpful in reducing the formation of succinylacetone and were of some benefit in the more chronic forms of the disease. They were not very effective, however, in managing the acute stage of the disease of young children presenting with liver failure or in the long-term prevention of hepatocarcinoma for those children who survived their early presentation. Data supplied by van Spronsen and colleagues in 1994 showed that for those children diagnosed at less than 2 months of age, there was a 75% mortality rate by 2 years; for those diagnosed between 2 and 6 months of age, there was a 70% mortality by 6 years; and for those diagnosed older than 6 months of age, there was a 40% mortality by 10 years.[11] The only effective therapy was liver transplant to remove the genetic burden of FAH deficiency from the host.

In 1992, Lindstedt and colleagues reported preliminary data on the use of an inhibitor called NTBC [2-(2-nitro-4-trifluoromethylbenzoyl)-1,3-cyclohexanedione] (or nitisinone; available as Orfadin from Rare Disease Therapeutics, Nashville, TN) as an effective inhibitor of parahydroxyphenylpyruvic acid oxidase for the treatment of tyrosinemia.[11] This inhibitor blocks the enzyme proximal in the catabolic pathway of tyrosine and prevents substrate from reaching the FAH enzyme. Thus, succinylacetoacetate and succinylacetone are unable to be formed, and this prevents the deleterious consequences of their existence. In studies in Europe and the United States, over 250 children with documented tyrosinemia type I have now received this compound (E. Holme, personal communication, 2001). It has reduced the mortality of children with tyrosinemia type I and has dramatically affected the natural history of the disease. Within the United States, of 63 children placed acutely on the medication, there have been 5 deaths. Each death occurred within the first 2 weeks of drug administration, all in children in acute liver failure who were unable to recover from the acute stage of their disease. For the remainder of the children, there was a dramatic improvement (C. R. Scott, unpublished data, 2004). Liver function begins to recover within a week, prothrombin and thromboplastin times return to normal values within 1 month and 2 months, respectively, high levels of α-fetoprotein return to normal levels between 6 months and 1 year, and detectable succinylacetone in the urine disappears within 1 to 2 days of initiation of oral treatment. Normal growth has been demonstrated in children following treatment for a period of 5 to 7 years (C. R. Scott, unpublished data, 2004).

Dietary intervention remains an important aspect of treatment, even with the use of nitisinone. Because nitisinone blocks *p*-hydroxyphenylpyruvic acid oxidase, tyrosine values in blood can rise to levels that cause tyrosine crystals to be deposited in tissue. Tyrosine has a low degree of solubility and readily crystallizes in tissue at concentrations that exceed its solubility. The major complication from nitisinone therapy is tyrosine crystal deposition in the cornea, which leads to photophobia and an inflammatory response in the eye. To prevent this, it is recommended that tyrosine concentrations be monitored in children on a tyrosine-restricted diet and nitisinone to maintain the tyrosine concentration at less than 500 μM. At this level, no eye complications have been observed. To achieve a satisfactory plasma concentration of tyrosine requires special formulas deficient in phenylalanine and tyrosine, coupled with a low-protein diet, not dissimilar to that given to children with phenylketonuria. For young children under the age of 6 months, this is usually not a problem; however, for older children, it may require significant nutritional skills and counseling to achieve these goals.

Monitoring of the liver for the potential development of hepatocarcinoma is essential. It is recommended that magnetic resonance images or computed tomographic scans of the liver be obtained on an annual basis. Given that the liver texture is frequently nodular, monitoring for interval changes that could suggest emerging or enlarging hepatocarcinoma, in the setting of persistently elevated α-fetoprotein, is imperative. This, coupled with monitoring of α-fetoprotein as an indicator of tumor formation, is necessary. Radiographic monitoring should continue until the α-fetoprotein has persistently returned to normal.

Liver transplant still remains an option for eventual treatment but is not as emergent as in the past. Longer-term studies are necessary at this time to make a value judgment on whether liver transplant will be necessary in a significant percentage of affected children, depending on their age of diagnosis or the eventual formation of hepatic nodules with transformation. Of the 19 patients who underwent liver transplant, only 5 patients were operated on for the possibility of hepatocarcinoma, and 4 of these were confirmed to have carcinomatous changes.

DISORDERS OF BCAAS

Maple Syrup Urine Disease (Branched-Chain Ketoaciduria)

The cases of four siblings with cerebral degeneration within the first weeks of life and death within months, all with urine smelling of maple syrup, were first reported in 1954.[12] Westall and colleagues subsequently studied another child with the same clinical features and found high levels of serum BCAAs, and coined the term "maple syrup urine disease."[13] High levels of the branched-chain α-keto acids (BCKAs) derived from the BCAA were then isolated in the urine of these patients, implicating the decarboxylation step as the blocked step in the metabolism of the α-keto acids—hence the alternate name "branched-chain ketoaciduria."[14]

Hepatic presentations may occur with MSUD and other organicacidurias with a Reye-like syndrome characterized by coma, cerebral edema, hepatomegaly, liver dysfunction, hypoglycemia, and hyperammonemia with liver histology showing macro- or microvesicular fatty infiltration.[15] Additionally, pancreatitis is sometimes observed with MSUD and other organicacidurias.[16]

MSUD is an autosomal recessive panethnic metabolic disorder caused by a deficiency in activity of the mitochondrial branched-chain α-keto acid dehydrogenase (BCKD)

complex. The worldwide frequency is approximately 1 in 185,000 live births. In select genetically isolated populations such as the Old Order Mennonite populations of Pennsylvania, however, MSUD occurs as frequently as 1 in 176 live births.[17]

Molecular Defect

MSUD results from a deficiency in the activity of the BCKD multienzyme complex (Figure 55.2-2). In normal catabolism of BCAAs, the amino acids are transported into the cell by a cytosolic membrane transporter. Inside the cell, they are reversibly transaminated by the cytosolic or mitochondrial isoforms of the BCAA aminotransferase to produce the BCKA. The BCKAs are then translocated by a specific transporter into the mitochondria, where they are oxidatively decarboxylated by the single BCKD complex. These reactions generate the corresponding branched-chain acyl CoAs, which are further metabolized to acetyl CoA and acetoacetic acid (leucine), acetyl CoA and succinyl CoA (isoleucine), and succinyl CoA (valine). These end products are used in fatty acid and cholesterol synthesis and adenosine triphosphate synthesis. In the human, the skeletal muscle is the main site of BCAA transamination and oxidation, but there is also BCKD activity in the liver, kidney, heart, brain, and adipose tissue.

Deficiency of the BCKD complex results in inadequate oxidative decarboxylation of the BCKAs, causing the accumulation of BCAAs (leucine, isoleucine, valine) and the associated BCKAs (α-ketoisocaproic acid, α-keto-α-methylvaleric acid, α-ketoisovaleric acid).

The mitochondrial BCKD is an enzyme complex macromolecule with three catalytic components: a thiamine pyrophosphate–dependent decarboxylase, a transacylase, and a dehydrogenase. Additionally, the complex has two regulatory enzymes, a kinase and a phosphatase, which control the complex's activity through reversible phosphorylation-dephosphorylation. Each component is coded for by a separate characterized gene, leading to wide genetic heterogenicity underlying the MSUD phenotype.

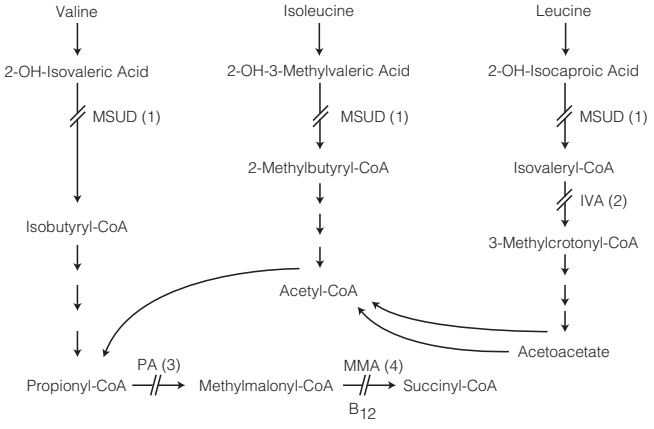

FIGURE 55.2-2 Branched-chain amino acid metabolism. IVA = isovalericaciduria; MMA = methylmalonicaciduria; MSUD = maple syrup urine disease; PA = propionicaciduria. 1 = branched-chain ketoacid decarboxylase; 2 = isovaleryl-CoA dehydrogenase; 3 = propionyl-CoA carboxylase; 4 = methylmalonyl-CoA mutase.

Clinical Features

Multiple clinical phenotypes of MSUD are described based on the biochemical and clinical features (see Table 55.2-1). Distinction based on the patient's responsiveness to thiamine is also made in practice.

Classic. The "classic" form of MSUD is both the most common and most severe form of the disease. It is characterized by the onset of encephalopathy in the neonatal period with high levels of BCAAs, particularly of leucine, in the blood, cerebrospinal fluid, and urine. The presence of alloisoleucine is also characteristic. Symptoms usually develop toward the end of the first week of life, but breastfeeding may delay the onset into the second week. Lethargy and apathy toward feeding are followed by progressive neurologic signs of alternating hyper- and hypotonia, with dystonic extension of the upper extremities and weight loss. It is at this stage that ketosis and the maple syrup or burnt sugar odor to the urine become apparent. Hypoglycemia is not a prominent feature but can be observed. Ultimately, seizures and coma followed by death will occur unless treatment is instituted. Untreated, most patients die in the first months of life from repeated bouts of metabolic crisis and ongoing neurologic deterioration precipitated by infection or other stresses. Surviving individuals may suffer from mental retardation and spasticity. Early treatment has greatly improved the complications faced by these patients, but patients are still at high risk of neurologic sequelae. Even in apparent metabolic control, transient ataxia can occur, and visual hallucinations are frequently experienced in periods of ketonemia.[18] Metabolic crises induced by physical stress can cause encephalopathy and death.[18,19] These patients usually have less than 2% of the normal BCKD activity in cultured fibroblasts or lymphoblasts.

Intermediate. These rare patients are spared the catastrophic neonatal neurologic crises but do have persistently elevated BCAAs. Neurologic impairment with developmental delay and seizures are still a risk. In these subjects, the BCKD activity is roughly 3 to 30% of normal. Few patients have been diagnosed with this form of MSUD, most in the 5-month to 7-year age range during evaluations for their neurologic abnormalities.

Intermittent. Children with this variant usually present between 5 months and 2 years of age. Earlier in life, they have normal growth and development; however, with infectious stresses such as normal childhood illnesses, they develop metabolic decompensation, exhibited most commonly as ataxia and lethargy. More subtle findings of unsteady gait or behavioral changes may progress to seizures, stupor, and coma. Although the plasma BCAAs are normal during well, nonstressed times, the classic findings of maple syrup urine odor and elevated plasma BCAAs and BCKAs occur during symptomatic periods and can be detected in serum amino acid and urine organic acid profiles. The BCKD complex activity typically ranges between 5 and 20% of normal.[17]

Thiamine-Responsive MSUD. Some individuals who have a chronic elevation of BCAAs and gradual advancement of neurologic involvement without crises (intermediate variant) will have enhanced responsiveness with thiamine administration in addition to the usual protein restriction therapy. The patient population is heterogeneous, and none have been able to be treated with thiamine alone.

Diagnosis

Detection of elevated BCKAs by gas chromatography–mass spectroscopy analysis of urine and elevated BCAAs in the blood by amino acid analysis is indicative of the disorder. The presence of alloisoleucine is pathognomonic for MSUD. Definitive diagnosis is established by a low measured activity of BCKD in cultured lymphocytes or fibroblasts.

Newborn Screening and Prenatal Diagnosis

In some states, MSUD may be detected by newborn screening. The fragmentation pattern of the protonated molecular ions of leucine, isoleucine, and alloisoleucine is measurable by tandem mass spectroscopy. Classic and intermediate variants can be detected through newborn screening; however, the intermittent variant may be missed if their levels of BCAAs in the newborn period are normal.

Prenatal diagnosis is possible by measuring the BCKD activity from cultured cells obtained through amniocentesis (amniocytes) or chorionic villus sampling. The BCKD activity from these cultured cells is in the same range as found with cultured fibroblasts and can be performed from amniotic fluid cells obtained at midtrimester (weeks 14 to 18 of gestation).

Treatment

Both removal of the toxic metabolites and minimizing catabolism and promoting anabolism are important in the initial phase of management. In the acute symptomatic situation, treatment must be instituted emergently to prevent or limit the rapid neurologic deterioration that will otherwise occur. Hemodialysis and continuous venovenous hemofiltration are the most efficient methods for BCAA and BCKA clearance from very high levels.

Dietary therapy is the mainstay of acute and chronic management. Initially, the BCAAs are totally omitted from the diet for a few days to allow for correction of their elevated levels. When enteral intake is possible, this can be achieved with BCAD 1 or 2 (Mead Johnson and Company, Evansville, IN) or Ketonex 1 or 2 (Ross Pediatrics, Abbott Laboratories, Columbus, OH), formulas that are leucine, isoleucine, and valine free (Table 55.2-2). The plasma levels of isoleucine, followed by valine, and then leucine 7 to 10 days later, will normalize with proper management. Because leucine is the most neurologically toxic metabolite, its normalization is imperative. Leucine-level normalization can be accelerated by adding isoleucine and valine into the diet to maintain their plasma concentration above normal. When parenteral nutrition is necessary, a BCAA-free L-amino acid mixture in combination with glucose, lipid, electrolytes, and vitamins can provide balanced nutrition. Again, isoleucine and valine supplementation after the first few days of therapy can expedite the return to normal levels of leucine. With either parenteral or enteral nutrition, special attention to the changing protein requirements of the subject must occur to properly adjust their dietary therapy.

During stable metabolism, the daily requirements for the BCAA vary dramatically with age, the severity of the enzyme deficiency, and the child's growth rate. The leucine requirement is highest in the first 6 months of life and then falls to stable requirements around the second and third year of life, remaining relatively stable through the first decade. Although the normal daily leucine requirement is between 300 and 600 mg, the optimal intake of this BCAA in subjects with MSUD must be individualized because their requirements may be a fraction of those for normal children. Plasma levels should be kept as close to normal as possible but less than 300 μM, with special attention to avoiding the situation of high leucine in relation to valine and isoleucine. Frequent monitoring of these levels is advisable during the first year of life.

In some subjects, pharmacologic doses of thiamine (5 mg/kg/d) for 3 weeks may improve BCAA tolerance[20] and biochemical stability. Consequently, a trial of thiamine is usually warranted.

TABLE 55.2-2 ENTERAL FORMULAS FOR METABOLIC DISEASE

METABOLIC DISORDER	DESCRIPTION	FORMULAS	
		MEAD JOHNSON NUTRITIONALS*	ROSS PEDIATRICS*†
Tyrosinemia	Phenyalanine and tyrosine free	TYR 1‡ and Tyros 2, 3200AB§	Tyrex 1 and 2
Maple syrup urine disease	Leucine, isoleucine, and valine free	BCAD 2,‖ MSUD diet‡	Ketonex 1 and 2
Propionicaciduria, Methylmalonicaciduria	Isoleucine, valine, methionine, and threonine free	OS 1 and 2#	Propimex 1 and 2
Isovalericaciduria	Leucine free		I-Valex 1 and 2
Urea cycle defects	Contains only essential and some conditionally essential amino acids	UCD 1,# WND 2§	Cyclinex 1 and 2

*"1" formulas are for infants under 1 year of age and "2" formulas are for children over 1 year of age.
†Ross products contain carbohydrate: hydrolyzed cornstarch; fat: coconut, soy, and palm oil; electrolytes, minerals, vitamins, and trace elements.
‡Contains carbohydrate: sucrose; fat: corn oil; electrolytes, minerals, vitamins, and trace elements. Formula names and formulas are subject to change.
§Contains corn syrup solids, modified tapioca starch, corn oil; electrolytes, minerals, vitamins, and trace elements.
‖Contains corn syrup solids, sugar, modified corn starch, soy oil; electrolytes, minerals, vitamins, and trace elements.
#Contains sucrose, no fat; electrolytes, minerals, vitamins, and trace elements.

In severe cases of the neonatal (classic) form of MSUD, liver transplant has been used successfully to correct the metabolic perturbations and allow an unrestricted diet with neurologic stability.[21]

Isovalericaciduria, Propionicaciduria, and Methylmalonicaciduria

Like MSUD, these organicacidurias result from defects in the catabolism of the BCAAs. They, too, can present clinically with severe neonatal crisis, intermittent and late forms, and chronically progressive forms with developmental delay, hypotonia, failure to thrive, and seizures.

Molecular Defects. *Isovalericaciduria*. The first children described with IVA were siblings with an odor of "sweaty feet" or "cheese."[22,23] IVA is now known to be an autosomal recessive inherited disorder caused by a deficiency in the mitochondrial flavoprotein isovaleryl-CoA dehydrogenase apoprotein, which transfers electrons to the respiratory chain via the electron transfer flavoprotein (see Figure 55.2-2, enzyme 2). This deficiency results in the accumulation of isovaleryl-CoA derivatives, including isovaleric acid, 3-hydroxyvaleric acid, *N*-isovalerylglycine, and isovaleryl-carnitine; the latter two forms are nontoxic, readily excreted derivatives of the toxic isovaleric acid; hence, glycine and carnitine can be used therapeutically to aid in isovaleric acid excretion.

***Propionicaciduria*.** PA is an autosomal recessive disorder with an incidence of less than 1 in 100,000 live births.[16] It is caused by a deficiency in the mitochondrial biotin-dependent enzyme propionyl-CoA carboxylase (see Figure 55.2-2, enzyme 3). This enzyme defect results in elevated levels of free propionate, propionylcarnitine, 3-hydroxypropionate, and methylcitrate in the urine and blood. More rarely combined defects that are partly responsive to biotin have been described.

***Methylmalonicaciduria*.** MMA is an autosomal recessive disorder, with an incidence of 1 in 100,000 live births, caused by a deficiency in vitamin B_{12}–dependent methylmalonyl-CoA mutase apoenzyme (see Figure 55.2-2, enzyme 4). The resultant metabolic block results in elevated levels of methylmalonyl CoA, methylmalonic acid, and, secondarily, the same elevations as seen with PA in plasma and urine. In subjects in whom elevated methylmalonic acid is found, vitamin B_{12} deficiency must be ruled out.

Clinical Features. The clinical presentations of patients with IVA, PA, or MMA follow the same patterns as those in subjects with MSUD. Patients presenting with IVA, PA, or MMA are frequently dehydrated and commonly have moderate hepatomegaly. They have a metabolic acidosis from hyperlactacidemia, elevated anion gap, and ketonuria. Hyperammonemia is uniformly present with IVA, PA, and MMA and, if severe enough, can cause a confounding picture that may lead the clinician to erroneously diagnose a urea cycle defect (Figure 55.2-3). Moderate hypocalcemia and variable glucose levels (hypo-, normal, or hyper-) are common, and cytopenias are frequent with IVA, PA, and MMA. IVA can be distinquished by its "sweaty feet" unpleasant odor.

Diagnosis and Prenatal Diagnosis. Diagnosis in IVA, PA, and MMA is based on the detection of the elevated organic acids in the plasma or urine in the pattern specific for the different disorders.

For those states or countries using tandem mass spectroscopy as a component of newborn screening, each of these organic acid disorders will be detected from submitted blood spots. An abnormal profile of acylcarnitine will detect increased concentrations of propionyl-, methylmalonyl-, or isovalerylcarnitine.

In the case of IVA, PA, and MMA, reliable and fast prenatal diagnosis is possible by the twelfth to fourteenth week of gestation by directly measuring the metabolites in the amniotic fluid. Direct enzyme analysis can also be performed from fresh or cultured chorionic villi or cultured amniocytes.

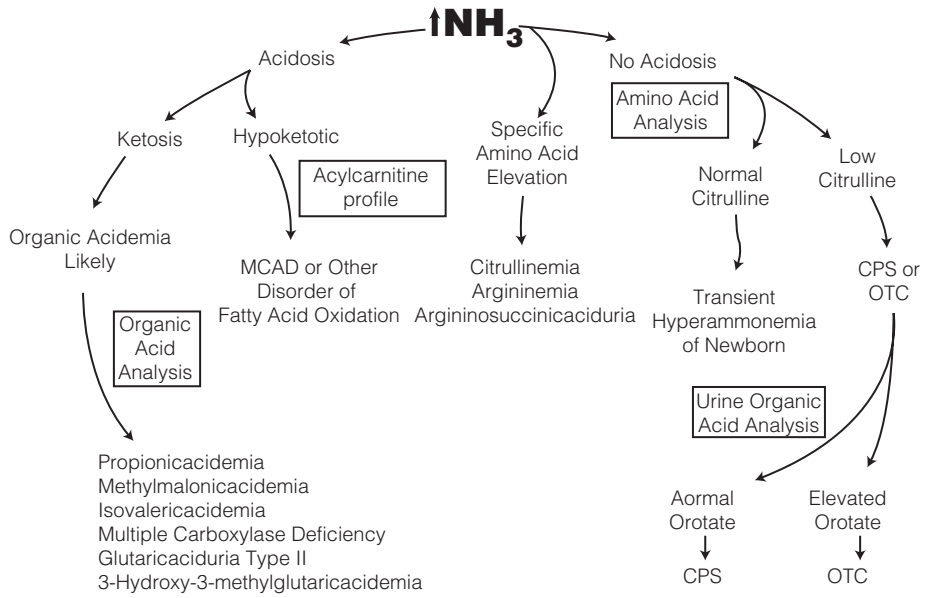

FIGURE 55.2-3 Diagnostic evaluation of the hyperammonemic infant. CPS = carbamyl phosphate synthetase; MCAD = medium-chain acyl-CoA dehydrogenase deficiency; OTC = ornithine transcarbamylase deficiency.

Treatment. The same principles as with the treatment of MSUD apply to the treatment of these disorders. Protein restriction, specifically BCAA restriction, is required. Specialty formulas with supplemental amino acids or protein as indicated are again effective (see Table 55.2-2) with attention to maintaining anabolism even in the face of metabolic crisis. In the case of IVA, leucine restriction is required. For patients with defects of PA, the administration of biotin (5 mg/d orally) may help in clinical and biochemical improvement.

In acute metabolic crisis, hemodialysis or continuous venous-venous hemoperfusion is effective, and for IVA, oral L-glycine (250–600 mg/kg/d) and intravenous L-carnitine (100–400 mg/kg/d) may assist with toxin removal.

DISORDERS OF THE UREA CYCLE

The urea cycle serves to convert the ammonia into nontoxic and readily excreted urea. Ammonia is produced continuously from degradation of the amino groups of amino acids and purines and from the amide groups of glutamine and asparagine. Although some is reused in the synthesis of nonessential amino acids and pyrimidines, the majority of ammonia is excreted as urea. The urea cycle is found in its entirety only in the liver and is composed of both cytosolic and mitochondrial enzymes. Patients with defects at each step in the cycle have been detected, resulting in disorders of the urea cycle. Although there are clinical distinctions between these conditions, they all result in significant hyperammonemia, neurologic compromise, and significant morbidity and mortality. Presentation with these disorders can occur at any time, but they typically become apparent with higher protein intake or metabolic stress from infection; hence, infancy, the toddler years, and puberty are the greatest risk periods. The distinction in infancy between the different disorders of hyperammonemia resulting in coma can be important for therapeutic intervention (see Figure 55.2-3).

The mainstay of therapy involves protein restriction, but pharmacologic interventions are also effective with many of these disorders. Despite therapy and dietary control, however, many of these conditions will result in repeated episodes of hyperammonemia and mental deficiency. Consequently, liver transplant has been offered and has been successful for many of the more aggressive conditions to ameliorate the metabolic deficiency.[24–29]

OTC Deficiency

Molecular Defect. OTC deficiency is an X-linked disorder of the mitochondrial enzyme OTC (Figure 55.2-4, enzyme 2). Enzyme activity is found exclusively in the liver, although some activity is in the small intestine, and a minimal amount is found in the brain. The enzyme catalyzes the formation of citrulline from carbamyl phosphate and ornithine. Its absence results in the accumulation of not only ammonia but also orotic acid and other pyrimidine derivatives, including uracil and uridine, which are derived from the excessive carbamyl phosphate.[30] These accumulated compounds can be detected in blood and urine.

Clinical Features. *Males.* The classic and severe form of OTC deficiency results in an enzyme activity level of less than 2% of normal and the death of 75% of the affected male infants in the first months of life.[30] Within hours or days of birth, poor feeding, lethargy, and tachypnea with labored breathing become apparent. Seizures and coma subsequently develop, and cerebral edema and death follow without treatment. In those patients who survive, severe neurologic impairment with mental retardation is common.

A milder variant occurs in males who present at a later age, usually precipitated by a protein challenge either from a dietary change, infection, or concomitant illness. These individuals generally have a higher level of enzyme activity. Hepatomegaly may be observed in these older patients.

Heterozygous Females. In females, the most common presenting symptoms are those of vomiting, feeding difficulties, headache, or tiredness after a protein-containing meal. Onset is in infancy or during the first decade most commonly. In older subjects, again, hepatomegaly may be observed.

Diagnosis. The condition should be suspected in any male infant with hyperammonemia without acidosis (see Figure 55.2-3). The presence of oroticaciduria and the absence of citrulline in plasma are diagnostic. Enzyme analysis from duodenal or rectal mucosal biopsy or liver tissue will confirm the diagnosis and determine the degree of enzyme deficiency.

Heterozygosity for OTC deficiency in females may be detected by assaying the urine for orotic acid following a protein load of 1 g/kg. The urine is collected in three 4-hour aliquots after the protein ingestion.[30,31] Loading with alanine has alternatively been used; however, false-positive results are more common.[32] The allopurinol test is also a

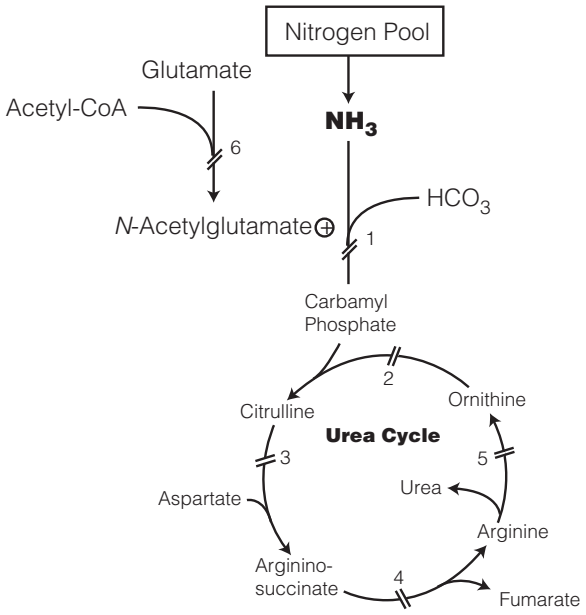

FIGURE 55.2-4 The urea cycle and associated defects. 1 = carbamyl phosphate synthetase; 2 = ornithine transcarbamylase; 3 = argininosuccinate synthetase; 4 = argininosuccinase; 5 = arginase; 6 = *N*-acetylglutamate synthetase.

common way to detect heterozygotes. Allopurinol inhibits the decarboxylation of orotidine monophosphate, a breakdown product of ototic acid. This accumulation of orotidine monophosphate can then be detected in the urine as orotic acid and orotidine.[33] In all cases, an experienced laboratory is required to perform and interpret these tests.

Treatment. The goal of treatment of patients with urea cycle defects is to eliminate the accumulated ammonia and precursors to its formation, decrease ureagenesis by a low-protein diet, and increase arginine levels (except in arginase deficiency) for the conversion of waste nitrogen into urea.

In the acute setting with hyperammonemia causing life-threatening symptoms, rapid and effective ammonia removal can be achieved with hemodialysis or continuous venous-venous hemoperfusion.[34,35] All protein intake should be stopped and an infusion of 10% glucose initiated.

The pharmacologic provision of alternative routes for waste nitrogen excretion is also effective after the acute removal of ammonia (NH_3) (Figure 55.2-5). Glycine and glutamine can be removed from the nitrogen pool by giving benzoate and phenylbutyrate, respectively. Benzoate conjugates to glycine, forming hippurate, and phenybutyrate conjugates to glutamine, forming phenylacetylglutamine. Each mole of glycine conjugated to benzoate removes one mole of NH_3, and each mole of glutamine conjugated to phenylacetate removes two moles of NH_3. Hippurate and phenylacetylglutamine are excreted in the urine without the need for conversion to urea.[30,35,36] Providing arginine as a substrate for ornithine in those without complete deficiency in OTC can help in urea synthesis and hence further enhance nitrogen excretion, but this is far more helpful in those with citrullinemia or argininosuccinicaciduria. Practically, these compounds are delivered by a loading infusion of 200 to 800 mg/kg arginine hydrochloride, 250 mg/kg sodium benzoate, and 250 mg/kg sodium phenylacetate in 20 mL/kg of 10% glucose over 1 to 2 hours intravenously. A continuous infusion of 250 mg/kg/d each of sodium benzoate and sodium phenylacetate and 200 to 800 mg/kg/d of arginine hydrochloride in 10% glucose with maintenance electrolytes is then provided until the ammonia level is normal.[30] The 10% glucose further limits hyperammonemia by minimizing catabolism and hence ammonia production. The additional use of mannitol in the setting of cerebral edema may further aid in nitrogen excretion by promoting diuresis.

The long-term management of the chronically hyperammonemic child usually requires a combination of dietary and pharmacologic manipulations. Phenylbutyrate 250 mg/kg/d (less odoriferous than phenylacetate) can be given alone or in combination with sodium benzoate (250 mg/kg/d) and arginine (200 mg/kg/d). The diet is usually restricted to protein of 700 mg/kg/d, with the essential amino acids added at 700 mg/kg/d total through a combination of regular formula and the specialty formulas (see Table 55.2-2).

CPS Deficiency

Molecular Defect. CPS I (CPS) is a liver mitochondrial enzyme that catalyzes the formation of carbamyl phosphate from ammonia using acetylglutamate as an activator and is the first step in the urea cycle (see Figure 55.2-4, enzyme 1). There also exists cytosolic CPS, designated CPS II, which is involved in pyrimidine biosynthesis and is largely responsible for the formation of orotic acid in the face of carbamyl phosphate excess with OTC deficiency. CPS I deficiency is a rare condition resulting from an autosomal recessive mutation. This mutation gives rise to a wide clinical heterogenicity in the patients affected depending on the degree of enzyme deficiency. Owing to the early block in the urea cycle caused by this deficiency, subjects have high ammonia in the face of low orotic acid, citrulline, and arginine.

Clinical Features. Children affected with CPS deficiency typically present in the first days of life after feeds are initiated. Drowsiness, poor feeding, lethargy, vomiting, and hypo- or hypertonia become apparent, followed by seizures, hypothermia, and coma. Death usually occurs in the first 2 to 18 months without treatment. Untreated survivors are typically mentally retarded, with neurologic complications.

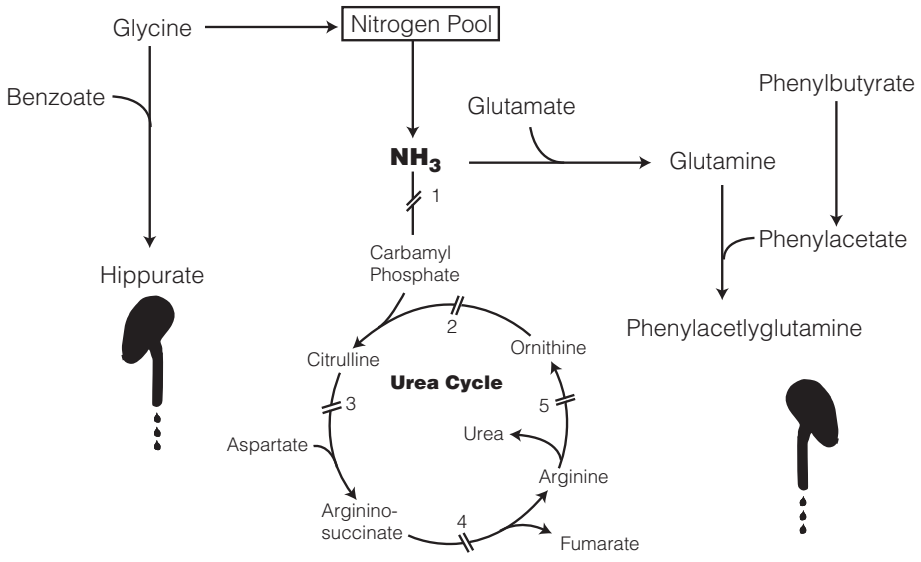

FIGURE 55.2-5 Alternative routes of waste N_2 excretion. 1 = carbamyl phosphate synthetase; 2 = ornithine transcarbamylase; 3 = argininosuccinate synthetase; 4 = argininosuccinase; 5 = arginase; 6 = *N*-acetylglutamate synthetase.

More rarely, a partial deficiency of CPS I results in older individuals having episodic lethargy and vomiting associated with high protein intake or states of catabolism, usually with progressive, severe neurologic consequences.

Diagnosis. CPS deficiency should be suspected in the young infant with hyperammonemia in the absence of a metabolic acidosis, low orotic acid, low citrulline, and low arginine. The diagnosis can be confirmed and enzyme activity measured from biopsy material from the liver, small intestine, or rectal mucosa.

Treatment. The treatment of CPS is the same as that for OTC deficiency.

Citrullinemia

Citrullinemia was first reported in 1963[37] and is now known to be secondary to deficiency of argininosuccinate synthetase, a widely expressed enzyme.

Molecular Defect. Citrullinemia is an autosomal recessive disorder resulting from a mutation in the gene for the cytosolic enzyme argininosuccinate (argininosuccinic acid) synthetase, mapped to chromosome 9 at q34.[38] This enzyme catalyzes the formation of argininosuccinic acid from citrulline and aspartic acid (see Figure 55.2-4, enzyme 3). Argininosuccinate synthetase is widely distributed and has been measured in cultured fibroblasts and in liver.

Clinical Features. The clinical presentation of patients with citrullinemia is heterogeneous. The majority of subjects present in infancy either with the classic neonatal form or later in the first year with a more subacute form. Patients with the neonatal form resemble infants with OTC deficiency. After the first few days, infants develop poor feeding, lethargy, and irritability; seizures are common, followed by coma and death within weeks, if not treated. Hepatomegaly is sometimes observed. In infants with the classic neonatal form, the enzyme activity is usually zero. The subacute form may present later in the first year with developmental delay, failure to thrive, recurrent vomiting, ataxia, or seizures. Presentations in late childhood or early adulthood have been reported in some patients.[39]

Diagnosis and Prenatal Diagnosis. Diagnosis should be suspected in the hyperammonemic infant without metabolic acidosis and with elevation of plasma and urine citrulline. The diagnosis can be confirmed and level of enzyme activity determined from cultured fibroblasts or lymphocytes.

Prenatal diagnosis is possible by analyzing the amniotic fluid for citrulline or by assay of the enzyme from cultured amniocytes or, less reliably, chorionic villi.

Treatment. The general principles of treatment are the same as in the treatment of patients with OTC deficiency. In citrullinemia, however, the administration of arginine can dramatically lower the level of ammonia by providing this compound as the backbone for urea synthesis. Furthermore, as the elevated citrulline is not thought to be the toxic metabolite (ammonia causes the toxicity), and citrulline itself is excreted in the urine, the provision of arginine allows for increased synthesis of citrulline, use of ammonia, and its subsequent excretion. Citrulline adds only one N atom to ornithine and hence is not as efficient as urea in waste nitrogen excretion but is adequate in times of anabolism. Arginine can be provided along with sodium benzoate and phenylacetate in both the loading solution and continuous infusion solution at a dose of at least 660 mg/kg.[39] Sodium bicarbonate and chloride monitoring may be necessary because arginine is supplied as arginine hydrochloride for intravenous use.

Argininosuccinicaciduria

Argininosuccinicaciduria is somewhat unique compared with the previous urea cycle defects discussed in that many patients with this disorder come to attention for chronic, more indolent complaints of alopecia or mild retardation, and most have hepatomegaly. The majority, however, do present in the neonatal period with symptoms typical of the urea cycle disorders.

Molecular Defect. This condition results from a defect in the enzyme argininosuccinate lyase (argininosuccinase), which catalyzes the conversion of argininosuccinic acid (ASA, formed from aspartate and citrulline) to fumarate and arginine (see Figure 55.2-4, enzyme 4). These patients have marked elevations in the levels of ASA in blood, urine, and cerebrospinal fluid and also may have elevations of orotic acid because this is created from the combination of aspartate and carbamyl phosphate.

Deficiency of argininosuccinate activity is inherited in an autosomal recessive manner, and the gene for this enzyme has been localized to chromosome 7.[40] The enzyme deficiency has been demonstrated in the liver, red blood cells, and cultured fibroblasts.[41]

Clinical Features. *Neonatal.* This is a relatively rare condition in which infants present in the first days of life with the classic symptoms of a urea cycle defect and similar to those with OTC deficiency. Differing features have been observed, however, including hepatomegaly and abnormally fragile hair by weeks of age.

Infantile. Patients present at months of life with failure to thrive, feeding difficulties, and, later, seizures and psychomotor retardation.

Late Onset. This is the most common form of presentation. In the second year of life, patients are noted to have developmental delay and frequently develop feeding difficulties, irritability, and seizures. Symptoms more attributable to hyperammonemia, such as episodic ataxia, lethargy, and seizures, are provoked by infection or increased protein in the diet. Many of these subjects have hepatomegaly, and roughly 50% have abnormally fragile hair. The hepatomegaly is usually associated with elevation of transaminases, but the synthetic capacity of the liver is generally preserved.[42,43]

The fragile hair is trichorrhexis nodosa, short dry hair that never needs to be cut because it breaks easily. Microscopically, the hair shafts have nodules.

Diagnosis and Prenatal Diagnosis. The diagnosis is made by demonstrating an excess of ASA in urine or plasma. The diagnosis can then be confirmed by assaying ASA lyase in red blood cells or cultured fibroblasts.[41]

Prenatal diagnosis is possible by assaying for enzyme activity in cultured amniocytes[44] or by the detection of ASA in amniotic fluid.

Treatment. Treatment is similar to that of citrullinemia. Providing arginine enables forward cycling of the urea cycle using ammonia in the formation of ASA. ASA is effectively excreted in the urine and is as effective in N removal as urea. Sodium benzoate and phenylacetate are not generally needed; however, sodium bicarbonate and chloride monitoring may be necessary because arginine is supplied as the hydrochloride for intravenous use.

N-Acetylglutamate Synthetase Deficiency

Few patients have been reported with deficiency of hepatic *N*-acetylglutamate synthetase. This mitochondrial enzyme catalyzes the combination of acetyl CoA and glutamate to form acetylglutamate, which, in turn, is required for activation of CPS I (see Figure 55.2-4, enzyme 6). The clinical phenotype and treatment are similar to those observed with CPS deficiency.

Argininemia

Argininemia is the least common of the urea cycle defects and was initially reported in 1965 and 1969.[45,46]

Molecular Defect. Argininemia is an autosomal recessive disorder caused by a deficiency of arginase, an enzyme coded for on chromosome 6 at band q23.[47] Arginase is responsible for the conversion of arginine to ornithine and urea (see Figure 55.2-4, enzyme 5). Individuals with arginase deficiency have a nearly complete absence of enzyme activity and have predictably elevated levels of arginine. They may also have elevated levels of orotic acid, however, because arginine serves an effector function toward *N*-acetylglutamate synthetase, which, in turn, stimulates CPS to form carbamyl phosphatase. Because ornithine is lacking in the face of arginase deficiency, the carbamyl phosphate flows in the pathway of pyrimidine synthesis and orotic acid is formed.

Clinical Features. Symptomatic onset is usually in infancy, with irritability, poor feeding, vomiting, lethargy, seizures, and coma. Unlike with the other urea cycle defects, however, survivors have spasticity or opisthotonos with developmental delay and may be thought initially to have cerebral palsy. Although ammonia levels elevate intermittently with infection or increased protein in the diet, the degree of ammonia elevation in this condition is not as dramatic as with the other urea cycle defects.

Diagnosis. Elevated plasma arginine levels are diagnostic, and the enzyme activity can be assayed in erythrocytes.

Treatment. The principle of treatment is to restrict arginine from the diet by providing a mixture of amino acids at an equivalent of 2 g/kg of protein, fat and carbohydrates to supply 125 kcal/kg/d, and vitamins and minerals. As the child ages, fruits, low-protein vegetables, and cereals can be introduced and then later the protein types liberalized but to never exceed 5 g/d of high biologic protein (300 mg arginine). Arginine intake must be episodically reduced in the face of infection or illness and blood levels of arginine and ammonia monitored regularly.[43]

3. Inherited Abnormalities in Mitochondrial Fatty Acid Oxidation

Carla D. Cuthbert, PhD
Silvia Tortorelli, MD, PhD
Regina E. Ensenauer, MD
Piero Rinaldo, MD, PhD
Dietrich Matern, MD

Mitochondrial fatty acid β-oxidation (FAO) plays a pivotal role in energy production and homeostasis once glycogen stores are depleted owing to fasting, during febrile illness, and owing to increased muscular activity. Mitochondrial fatty acid β-oxidation provides as much as 80% of energy for heart and liver functions at all times.[1] In the liver, the oxidation of fatty acids fuels the synthesis of ketone bodies, 3-hydroxybutyrate and acetoacetate. Ketones are used as an alternative energy source by extrahepatic organs, particularly the brain, and the oxidation of long-chain fatty acids also provides the energy required for nonshivering thermogenesis by brown adipose tissue.

The first genetic defect of FAO in humans was recognized in 1973 as a disorder of skeletal muscle presenting with exercise-induced rhabdomyolysis and myoglobinuria.[2] Many additional FAO disorders covering a wide spectrum of phenotypes have since been discovered. A growing number of clinical entities such as Reye syndrome, sudden infant death syndrome, cyclic vomiting syndrome, liver failure, and maternal complications of pregnancy have been associated with various FAO disorders.[1]

BIOCHEMISTRY OF MITOCHONDRIAL FATTY ACID METABOLISM

Lipid Mobilization and Transport

Glycogen serves as the primary energy source, but once glycogen stores become depleted, energy must be acquired by alternative means. Decreasing blood glucose concentrations cause a reduction of the insulin-to-glucagon ratio and subsequent lipid mobilization from adipose tissue. Free fatty acids are released into the plasma following the hydrolysis of triglycerides by endothelial-bound lipoprotein lipase and hepatic lipase. The most abundant species are long-chain fatty acids, in particular palmitic ($C_{16:0}$), stearic ($C_{18:0}$), oleic ($C_{18:1}$), and linoleic ($C_{18:2}$) acids.[3,4]

Long-chain fatty acids are weakly soluble in plasma and readily bind to albumin. Two models, involving both saturable (protein mediated) and nonsaturable (nonprotein mediated) components, specific for cellular long-chain fatty acid uptake exist.[5] In a non–protein-mediated model, fatty acids partition into membranes and become protonated, and the neutral molecule is translocated across the membrane into the cytosol.[6] Growing evidence also supports the presence of high-affinity tissue-specific fatty acid transporters on liver and muscle cell membranes (Figure 55.3-1).[7] A family of fatty acid transport proteins (FATPs) has been characterized in different species, and in vitro experiments demonstrated increased fatty acid import when expressed in cultured cells and reduced uptake when the *FATP1* gene was disrupted.[8,9] To date, however, mutations in the *FATP1* gene have not been associated with a disease.

Inside the cytosol, fatty acid binding proteins play a similar role as plasma albumin in the binding and transportation of intracellular fatty acids.[10] Eventually, the intracellular fatty acids are esterified by acyl coenzyme A (CoA) synthetases to fatty acyl CoAs. These can bind to ubiquitously expressed, high-affinity acyl-CoA binding proteins (ACBPs) or to the lower-affinity fatty acid binding proteins (~ 1,000-fold lower affinity than the ACBPs). Bound to ACBPs, acyl-CoA esters are delivered to carnitine palmitoyltransferase (CPT) 1.[11]

Role of Carnitine

Whereas short- and medium-chain fatty acyl-CoA esters are able to passively cross the mitochondrial membranes, long-chain fatty acyl-CoA esters are actively transported. This transport mechanism requires intracellular carnitine as a cofactor and involves three steps mediated by two CPTs (1 and 2) and a carnitine acylcarnitine translocase (CACT) (see Figure 55.3-1).[12]

Carnitine (β-hydroxytrimethylaminobutyrate) is an essential molecule in intermediary metabolism.[13] It is involved in the transfer of cytosolic fatty acids across the mitochondrial membrane for β-oxidation. Products of peroxisomal β-oxidation are also transported by carnitine to the mitochondria for further oxidation. Carnitine influences the acetyl CoA to free CoA ratio by acting as a reservoir for activated acetyl groups. Finally, carnitine influences the toxicity associated with abnormal accumulation of fatty acids and organic acids by forming carnitine esters, which can be removed from the intracellular environment.

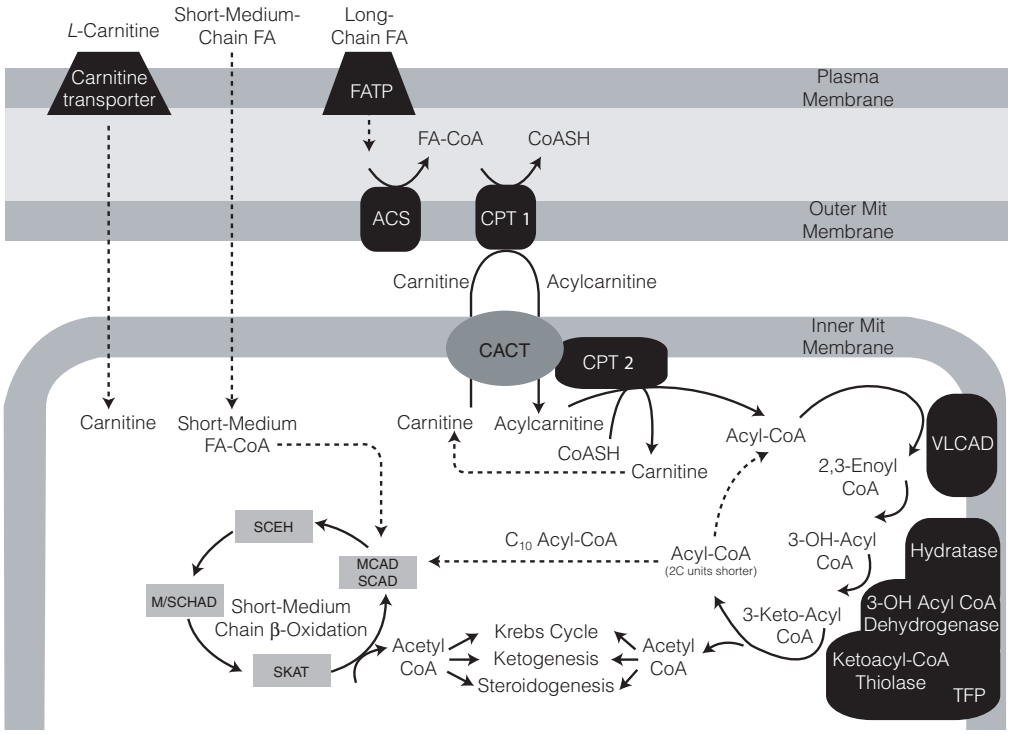

FIGURE 55.3-1 Overview of fatty acid import and metabolism. ACS = acyl-CoA synthetase; CACT = carnitine acylcarnitine translocase; CoA = coenzyme A; CoASH = unacylated coenzyme A; CPT1 = carnitine palmitoyltransferase 1; CPT2 = carnitine palmitoyltransferase 2; FA = fatty acid; FA-CoA = fatty acyl CoA; FATP = fatty acid transport protein; MCAD = medium-chain acyl-CoA dehydrogenase; Mit = mitochondrial; M/SCHAD = medium-/short-chain 3-hydroxyacyl-CoA dehydrogenase; SCAD = short-chain acyl-CoA dehydrogenase; SCEH = short-chain enoyl-CoA hydratase; SKAT = short-chain ketoacyl-CoA thiolase; TFP = trifunctional protein; VLCAD = very-long-chain acyl-CoA dehydrogenase.

Carnitine originates to about 75% from dietary intake of meat, fish, and dairy products. Under normal conditions, endogenous synthesis from lysine and methionine plays a minor role but can be stimulated by a diet low in carnitine. Carnitine is not further metabolized and is excreted in urine as free carnitine or as conjugated carnitine esters. Adequate intracellular levels of carnitine are therefore maintained by mechanisms that modulate dietary intake, endogenous synthesis, reabsorption, and cellular uptake.

Plasma Membrane Uptake of Carnitine

Only the kidney, liver, and brain have the full complement of enzymes necessary to synthesize carnitine. Other tissues depend on carnitine from the circulation. Carnitine uptake is an active process and occurs against a gradient to concentrate intracellular levels as free carnitine or carnitine esters. In humans, concentrations of carnitine in skeletal and cardiac muscle tissue exceed levels in plasma by 50-fold.

Muscle, heart, placenta, and fibroblasts have been shown to possess high-affinity carnitine transport systems with Michaelis constant (*K*m) values ranging between 6 and 60 μM. The best characterized member of this family is the organic cation transporter 2 (OCTN2) (encoded by the *SLC22A5* gene), a low-*K*m (2–6 μM), high-affinity, sodium-dependent active transporter present in muscle, heart, and renal tubule cells.[13] OCTN2 dysfunction, particularly in the kidney, results in excessive carnitine losses to the urine and consequently reduced plasma and tissue carnitine levels, affecting particularly those tissues relying heavily on ketogenesis as an energy source.

Carnitine Cycle

CPT1 is located in the outer mitochondrial membrane and converts long-chain acyl-CoA intermediates into the corresponding acylcarnitine. There are muscle and liver isoforms of this enzyme, the latter also being expressed in fibroblasts and amniocytes. CACT mediates the transfer of acylcarnitine species from the intermembrane space into the mitochondrial matrix in exchange for free carnitine, thereby maintaining the mitochondrial and cytosolic carnitine pools. CPT2 is located on the matrix aspect of the inner mitochondrial membrane and converts the translocated long-chain acylcarnitine back into its corresponding acyl-CoA ester, releasing free carnitine.

Mitochondrial β-Oxidation

Substrates for β-oxidation are fatty acyl-CoA esters, which repeatedly undergo four chain-shortening steps, each cycle resulting in the removal of a 2-carbon acetyl group (Figure 55.3-2). The four steps of each cycle require the action of four enzymatic activities, each with overlapping chain-length specificities for very-long-, long-, medium-, and short-chain acyl-CoA fatty acid substrates. They include (1) acyl-CoA dehydrogenases (ACADs), (2) 2-enoyl-CoA hydratases, (3) 3-hydroxyacyl-CoA dehydrogenases, and (4) 3-ketoacyl-CoA thiolases. The enzymes with specificity for very-long-chain and long-chain fatty acid substrates are membrane associated, whereas the enzymes recognizing the medium- and short-chain fatty acids are soluble mitochondrial matrix enzymes. The genes for most enzymes involved in FAO have been cloned and pathogenic mutations identified.[14]

Acyl-CoA Dehydrogenases. ACADs are flavin adenine dinucleotide (FAD)-requiring oxidoreductases that catalyze the first dehydrogenation step in the β-oxidation of fatty acids, resulting in the formation of a double bond between the 2 and 3 position of the fatty acyl-CoA derivative. Very-long-chain acyl-CoA dehydrogenase (VLCAD) is

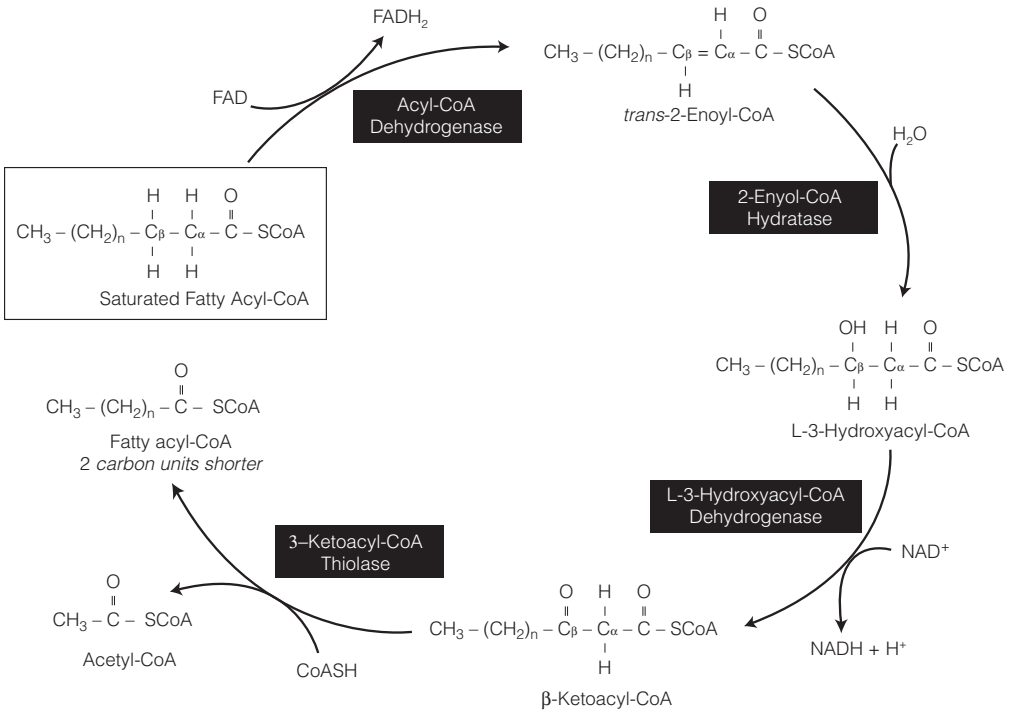

FIGURE 55.3-2 Reactions involved in β-oxidation of saturated fatty acids. CoA = coenzyme A; CoASH = unacylated coenzyme A; FAD = flavin adenine dinucleotide (oxidized form); $FADH_2$ = flavin adenine dinucleotide (reduced form); NAD = nicotinamide adenine dinucleotide (oxidized form); NADH = nicotinamide adenine dinucleotide (reduced form).

a 154 kD heterodimer associated with the matrix surface of the inner mitochondrial membrane.[15] Medium- and short-chain acyl-CoA dehydrogenases (MCAD and SCAD, respectively) are located within the mitochondrial matrix and are homotetramers with subunits ranging from 43 to 45 kD.[16,17] Chain-length specificities for the various ACADs are C_{14} to C_{20} fatty acyl CoA for VLCAD, C_{12} to C_{18} for long-chain acyl CoA dehydrogenase (LCAD), C_6 to C_{10} for MCAD, and C_4 to C_6 for SCAD.

Enoyl-CoA Hydratases. The second step of β-oxidation is catalyzed by 2-enoyl-CoA hydratase and results in the hydration of the double bond of the 2-*trans*-enoyl-CoA ester to form L-3-hydroxyacyl CoA. There are two different hydratases with different substrate specificities. The short-chain enoyl-CoA hydratase, also referred to as crotonase, acts on substrates with short chain lengths with reduced activity as chain length increases. The hydratase with specificity for longer-chain substrates is part of the trifunctional protein (TFP).

Trifunctional Protein. TFP is a hetero-octamer ($\alpha_4\beta_4$) that catalyzes three steps in the mitochondrial β-oxidation of long-chain fatty acids. Long-chain enoyl-CoA hydratase (LCEH) and long-chain 3-hydroxyacyl-CoA dehydrogenase (LCHAD) activities are located at the amino- and carboxy-terminal domains, respectively, of the four α subunits, whereas the four β subunits contain long-chain ketoacyl-CoA thiolase (LCKAT) activity.[18]

L-3-Hydroxyacyl-CoA Dehydrogenases. The conversion of L-3-hydroxyacyl CoA to the corresponding 3-ketoacyl-CoA derivative is mediated by L-3-hydroxyacyl-CoA dehydrogenase and occurs with the concomitant reduction of oxidized nicotinamide adenine dinucleotide (NAD^+) to reduced nicotinamide adenine dinucleotide. Long-chain 3-hydroxyacyl-CoA substrates are metabolized by LCHAD, which is part of the aforementioned TFP. The medium-/short-chain L-3-hydroxyacyl-CoA dehydrogenase (M/SCHAD) has highest activity toward 3-hydroxybutyryl CoA but will also recognize substrates with higher chain lengths with reducing activity as chain length increases.

3-Ketoacyl Thiolase. The last reaction in the β-oxidation spiral is performed in the presence of CoA and involves a thiolytic cleavage between C-2 and C-3 atoms of the 3-ketoacyl-CoA intermediate with the release of acetyl CoA and the generation of an acyl-CoA product shortened by two carbons. There are two mitochondrial thiolases. The ketothiolase that resides in the β subunit of the TFP cleaves long-chain substrates, whereas the remaining keto acyl-CoA derivatives of shorter chain lengths are substrates for medium-chain ketoacyl thiolase (MCKAT).[18]

Oxidation of Unsaturated Fatty Acids

Unsaturated dietary fatty acids such as oleic ($C_{18:1}$), linoleic ($C_{18:2}$), and linolenic ($C_{18:3}$) acids undergo β-oxidation in a manner similar to saturated fatty acids, sequentially releasing acetyl CoA with each round until the formation of intermediates, which are not recognized by the enzymes of β-oxidation (Figure 55.3-3). Unsaturated fatty acids with double bonds located at odd-numbered and even-numbered positions, respectively, generate intermediates with the double bond between the C-3 and C-4 atoms (*cis*-3-enoyl CoA) and between the C-2 and C-3 atoms (*cis*-2-enoyl CoA). Further metabolism requires modification by ancillary enzymes. The *cis*-2-enoyl-CoA esters can be hydrated and either be epimerized to form L-(+)-3-hydroxy intermediates or converted to

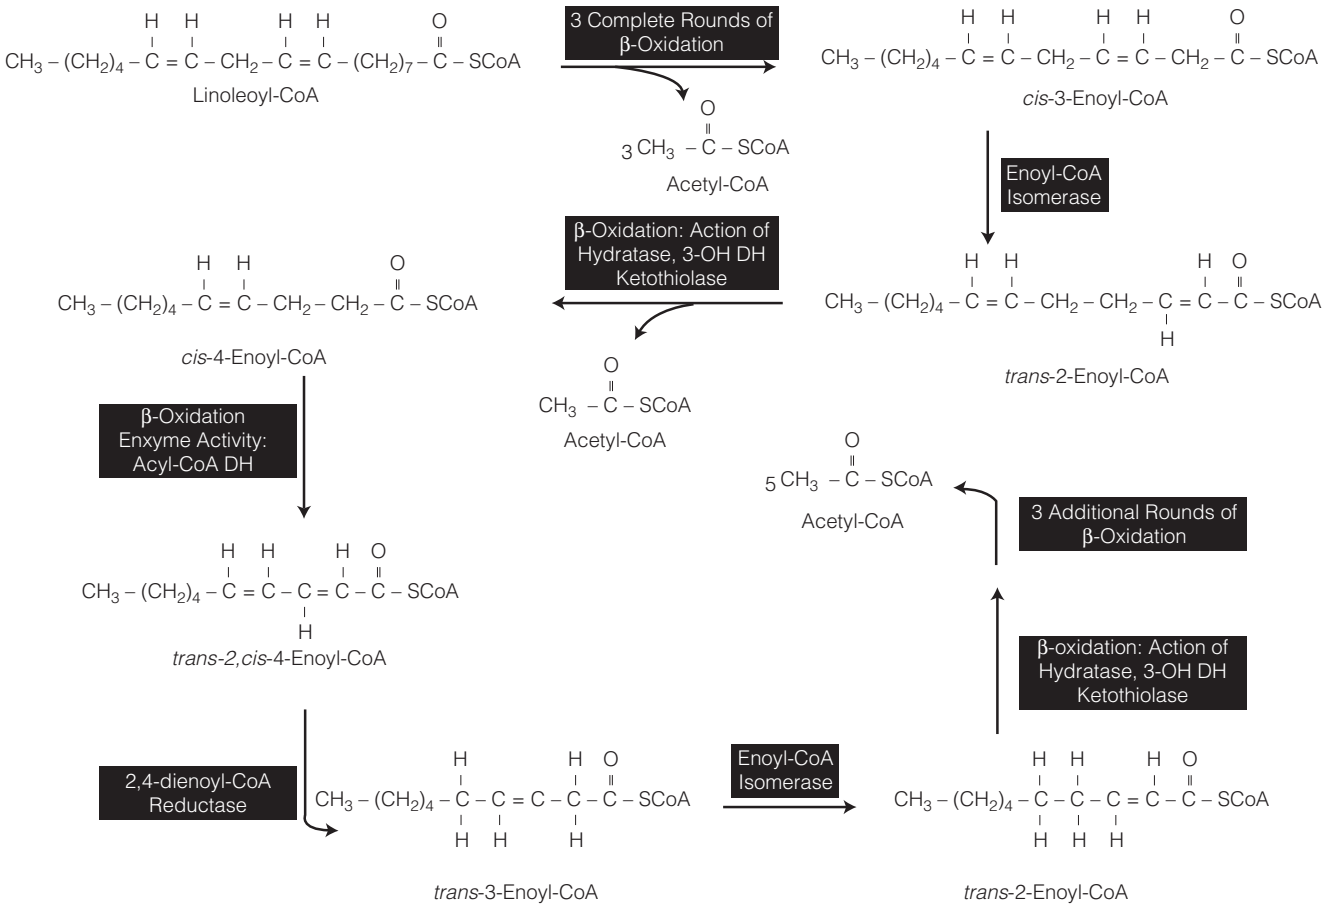

FIGURE 55.3-3 Oxidation of unsaturated fatty acids. CoA = coenzyme A; DH = dehydrogenase.

3-*trans*-enoyl-CoA esters by the action of 2,4-dienoyl-CoA reductase. Re-entry of 3-enoyl-CoA intermediates into the β-oxidation pathway is accomplished by a reaction mediated by 3,2-*trans*-enoyl-CoA isomerase, which results in a shift of the double bond from the C-3 position to the C-2 position. In this step, all 3-enoyl-CoA intermediates, occurring in either the *cis* or *trans* configuration, are converted into their corresponding 2-*trans*-enoyl-CoA intermediates, which can subsequently be metabolized by the enoyl-CoA hydratase of the β-oxidation pathway.

Only one patient has been described with 2,4-dienoyl-CoA reductase deficiency.[19] No defect of enoyl-CoA isomerase has been reported to date.

Oxidation of Odd-Chain Fatty Acids

Fatty acids with an odd number of carbons undergo β-oxidation as described above until the 3-carbon propionyl-CoA molecule is formed. Propionyl CoA is also generated by the metabolism of amino acids and is decarboxylated to methylmalonyl CoA by propionyl-CoA carboxylase. Methylmalonyl CoA is further metabolized by methylmalonyl-CoA mutase to form succinyl CoA, an intermediate of the Krebs cycle.

Ketone Body Metabolism

The three compounds referred to as ketone bodies are acetoacetate (AcAc), 3-hydroxybutyrate (3HB), and acetone. They represent the physiologic products of the metabolism of fatty acids and ketogenic amino acids. The two predominant ketone bodies are AcAc and 3HB, and they share a metabolic relationship in the mitochondria similar to that of pyruvate and lactate in the cytoplasm. 3HB is a stable, nonvolatile metabolite that arises only through the reduction of AcAc. Acetone, formed by the decarboxylation of the chemically unstable AcAc, is responsible for the fruity smell recognized in ketoacidotic individuals.

Acetyl CoA generated by fatty acid β-oxidation is converted to acetoacetyl CoA by the action of β-ketothiolase (Figure 55.3-4). This reaction marks both the first step in ketogenesis and the last step in ketolysis. This enzyme can also catalyze the conversion of the isoleucine intermediate 2-methylacetoacetyl CoA to acetyl-CoA and propionyl CoA. Human β-ketothiolase is a homotetramer composed of 41 kD subunits, and two isoenzymes have been described. The human β-ketothiolase gene is known, and pathogenic mutations have been described in deficient patients.[20]

Acetoacetyl CoA thus formed is transformed into 3-hydroxy-3-methylglutaryl (HMG)-CoA by mitochondrial HMG-CoA synthase. Two HMG-CoA synthase isoenzymes are encoded by distinct genes. One is located inside the mitochondria and is involved in ketogenesis; the other is located in the cytoplasm and plays a role in cholesterol synthesis. Patients with mitochondrial HMG-CoA synthase

deficiency have been described clinically and confirmed at the molecular level.[21]

In the last step of ketogenesis, HMG-CoA is irreversibly converted to AcAc by HMG-CoA lyase. The mitochondrial HMG-CoA lyase is a homodimer, the gene of which has been identified.[22] The HMG-CoA lyase enzyme is also targeted to the peroxisome, where its physiologic role is as yet undefined.[23]

The interconversion between AcAc and 3HB is mediated by 3HB dehydrogenase (3HBD). This protein is located on the inner mitochondrial membrane and has an absolute requirement for phosphatidylcholine as an allosteric activator. Highest activity has been described in the liver, with lower activity present in the heart, adrenal glands, and kidney.

Ketolysis involves the metabolism of AcAc and 3HB and occurs in the mitochondrial compartment of extrahepatic tissue (see Figure 55.3-4). The action of 3HBD converts 3HB to AcAc, which can subsequently be metabolized by succinyl-CoA oxoacid transferase (SCOT) to AcAc-CoA. β-Ketothiolase present in these cells converts AcAc-CoA into Ac-CoA, which subsequently enters the Krebs cycle. SCOT is a monomer that assembles into a homodimer. Although highly expressed in heart muscle, kidney, adrenal glands, and brain, SCOT is not present in liver.[24]

Electron Transfer to the Respiratory Chain Complex

The electron transfer flavoprotein (ETF) and ETF-ubiquinone oxidoreductase (ETF-QO) function together to transfer electrons from at least nine flavoprotein dehydrogenases.[25] Electrons are transferred between the two flavin moieties in the dehydrogenases and ETF. The reduced ETF is subsequently reoxidized by ETF-QO activity, with the concomitant reduction of ubiquinone.[26]

ETF is a mitochondrial matrix heterodimer consisting of α and β subunits, which are encoded by different genes.[27,28] ETF-QO is a monomer associated with the inner mitochondrial membrane. It contains two redox groups, a FAD cofactor and an iron-sulfur prosthetic group, which are thought to act as entry and exit sites, respectively, for electron transfer.[29] The gene for ETF-QO and pathogenic mutations have also been identified.[30]

PATHOPHYSIOLOGY AND CLINICAL PRESENTATION

Typically prompted by increased energy requirements during fever, fasting, or prolonged exercise, an enzyme defect in the FAO pathway leads to energy depletion owing to inadequate production of acetyl CoA, ketone bodies, and, ultimately, adenosine triphosphate in tissues with high energy demands, such as liver, heart, skeletal muscle, and brain.[1,31] Transient to fulminant liver failure, hepatic encephalopathy, dilated or hypertrophic cardiomyopathy, skeletal myopathy, and sudden, unexpected death at any age are the major clinical manifestations. The biochemical hallmark of FAO defects is hypo- or nonketotic hypoglycemia resulting from two different mechanisms: glucose depletion and secondary impairment of gluconeogenesis owing to a lack of reducing equivalents. Nonmetabolized free fatty acids are incorporated into triglycerides and can account for the observed fat storage in liver and muscle.[32]

Intracellular toxicity is triggered by the accumulation of acyl-CoA intermediates upstream of the block and the secondary depletion of carnitine and CoA. The metabolites may have toxic effects either directly (ie, membrane disruption) and/or by the inhibition of other enzymes. For example, cardiac arrhythmias are thought to be caused by long-chain acylcarnitine accumulation in mitochondrial fatty acid transport and β-oxidation defects.[33]

Complications of Pregnancy

A peculiar association between FAO disorders and severe complications during pregnancy has been well documented in women carrying LCHAD-deficient fetuses.[34,35] Preeclampsia, HELLP (hemolysis, elevated liver enzymes,

and low platelets) syndrome, acute fatty liver of pregnancy (AFLP), and placental floor infarction are the observed maternal phenotypes (Table 55.3-1).[36] The mechanism of this association is not clearly understood. A combination of different factors might result in hepatic dysfunction during the third trimester of pregnancy.[1]

It is possible that the placenta, which shares the same genetic makeup as the fetus, is responsible for the production and accumulation of abnormal fatty acid metabolites.[37] These metabolites pass into the maternal circulation and overwhelm the β-oxidation pathway of the heterozygote mother, who has reduced capacity to oxidize long-chain fatty acids. In addition, during the latter trimester of pregnancy, β-oxidation in the mother is already challenged by the shifting of maternal metabolism toward ketogenesis. This metabolic imbalance is also harmful for the fetus, making it difficult to receive enough energy from the placenta.

Intrauterine growth retardation and premature delivery are relatively common observations. Although there is a predominant association with LCHAD deficiency, severe complications during pregnancy have been reported also in other FAO.[36]

Other Clinical Manifestations

Less frequently observed and poorly understood clinical manifestations have also been described. Hyperinsulinism, described in a case of SCHAD deficiency, supports the hypothesis of the existence of a lipid signaling pathway, strictly related to the β-oxidation spiral, which intervenes in the control of insulin secretion.[38] Hypoparathyroidism has been an occasional finding in patients affected with LCHAD or TFP deficiency.[39]

GENERAL APPROACH TO THE DIAGNOSIS

The approach to the diagnosis of patients at risk for FAO disorders should involve a combination of routine, specialized, and in vitro analyses, with careful consideration of the clinical condition at the time of sample acquisition (Table 55.3-2). When the patient is clinically stable and in an anabolic state, the concentration of key metabolites may not be significant. Patient samples collected under these conditions may not be informative because the metabolic intermediates may be absent or undetectable. The most useful specimens for evaluation are typically acquired during periods of metabolic decompensation, before the initiation of treatment. Because metabolic status has such critical consequences on the metabolite profiles, the interpretation of biochemical parameters relies heavily on the clinical and therapeutic context at sample procurement. Accordingly, it must be remembered that although metabolite analyses can be diagnostic, negative or inconclusive results in cases of high clinical suspicion should be followed up by in vitro investigations that are independent of patient status.

Routine Testing

During episodes of metabolic decompensation, plasma and urine specimens should be collected at the earliest possible opportunity. Hypoketotic hypoglycemia is a hallmark of most, but not all, FAO disorders. Routine chemistries include blood gases, electrolytes, glucose, ammonia, uric acid, liver function tests, creatine kinase, ratio of lactic to pyruvic acid, 3-hydroxybutyric and acetoacetic acids, and urinalysis. These more readily available analyses help to assess the extent of organ involvement and often allow for initiation of adequate treatment, while awaiting the results of more specialized metabolite analyses in plasma and urine. Careful consideration of the patient's personal (eg, preceding fever, fasting), pregnancy (eg, maternal liver disease during pregnancy, intrauterine growth retardation, prematurity), and family history (ie, sudden unexpected death in a sibling) may also provide important clues that should trigger inclusion of FAO disorders into the differential diagnosis.[40,41]

Specialized Metabolite Analyses

Defects associated with mitochondrial FAO result in the accumulation of fatty acids and acyl-CoA intermediates proximal to the metabolic block. These intermediates can be converted into dicarboxylic and hydroxydicarboxylic acids through peroxisomal ω- and ω-1-oxidation. Mechanisms to detoxify these accumulating metabolites and to restore the depleted pool of CoA result in the formation of acylglycine conjugates and acylcarnitine species from their respective acyl-CoA esters. Abnormal accumulation of these acyl-

glycine and acylcarnitine metabolites can therefore assist in the evaluation of the metabolic defect in these patients. Of note, the buildup of esterified carnitine fractions can subsequently result in secondary L-carnitine deficiency, a condition frequently observed in patients with FAO disorders.

Urinary Organic Acid Analysis. Organic acids are water-soluble compounds that have at least one carboxyl group. They are best detected in urine by gas chromatography–mass spectrometry (GC-MS).[42] Urine organic acid analysis plays an important role in the diagnosis of FAO disorders. Especially during metabolic stress, the finding of inadequate ketonuria in the presence of particular excretion patterns of medium-chain saturated and unsaturated dicarboxylic acids and acylglycines provides strong evidence for an underlying mitochondrial FAO disorder. Nonspecific and even normal organic acid profiles are typically encountered in defects of fatty acid transport, carnitine uptake, and HMG-CoA synthase.

Urinary Acylglycine Analysis. Stable isotope dilution GC-MS allows for quantitative determination of specific urinary acylglycines at concentrations below the detection limit of routine organic acid analysis. MCAD deficiency can be diagnosed reliably by the findings of elevated excretions of hexanoylglycine, phenylpropionylglycine, and suberylglycine in random specimens of asymptomatic patients.[43] Other FAO disorders with informative acylglycine profiles are SCAD deficiency, MCKAT deficiency, and glutaricaciduria type II (ETF and ETF-QO deficiencies).[44–46]

Acylcarnitine Analysis. Acylcarnitine analysis has become the most widely used tool for the investigation of FAO disorders. However, although it is capable of identifying and distinguishing most of the different FAO defects, limitations of this methodology are frequently overlooked. Because adequate tissue levels of free L-carnitine are necessary to form carnitine esters, patients with FAO disorder and severe secondary carnitine deficiency may not exhibit diagnostic or even abnormal acylcarnitine accumulations.[47] Patients with primary carnitine deficiency are also expected to have overall low concentrations of acylcarnitine species.[48] In addition, acylcarnitine analysis cannot differentiate between isomeric carnitine esters, making the performance of other biochemical investigations a necessity to provide appropriate interpretation.[49,50]

Free and Total Carnitine Analysis. Determination of total and free carnitine as well as the acylcarnitine fraction aids in the diagnosis of primary carnitine deficiency and CPT1 deficiency, which are not readily identified by the above-mentioned analyses. Furthermore, carnitine analysis is useful when deciding whether L-carnitine supplementation is warranted in disorders associated with secondary carnitine deficiency and for monitoring patients on carnitine supplementation.[51]

Fatty Acid Analysis. Quantitative determination of plasma fatty acid profiles, in particular C_8 to C_{18} species and 3-hydroxy fatty acids, also provides useful and complementary information when assessing patients suspected of having an FAO defect.[52] Abnormal profiles may be observed in patients with MCAD, LCHAD/TFP, SCHAD, and VLCAD deficiencies as well as glutaricacidemia type II.[53,54]

Biochemical In Vitro Studies

Cell-based biochemical in vitro assays are used to confirm a preliminary diagnosis suggested by clinical findings and biochemical data. With the ability to establish fibroblast cultures from small skin punch biopsies, assays were developed allowing metabolic in vitro challenges for the diagnosis of most FAO disorders in a single test.[55,56] Only those few FAO disorders not expressed in fibroblasts (ie, the muscle form of CPT1) are not amenable to this approach and require more specific enzyme investigations in other tissues or a molecular genetic approach. Assays for direct enzyme and transporter analyses are available in a few laboratories worldwide.[57]

Molecular Genetic Studies

Genes harboring disease-carrying mutations responsible for FAO disorders have been identified, and a genotype-phenotype correlation is emerging in a few disorders as well. Accordingly, mutation analysis can principally confirm a tentative diagnosis and facilitate counseling. However, such studies are available for only relatively common mutations that have been described in a few defects. In many cases, deoxyribonucleic acid (DNA) sequencing of the complete gene would be required to reach a conclusive diagnosis by identification of private mutations, which hinders the broad application of molecular genetic analysis to the diagnosis of FAO disorders.[14]

PRENATAL DIAGNOSIS

All known FAO disorders have an autosomal recessive mode of inheritance, carrying with it a recurrence risk of 25% in another pregnancy of the same couple. A rare exception was recently described in two unrelated cases with fatal TFP deficiency whose etiology was found to be associated with uniparental disomy for chromosome 2, which has a significantly lower recurrence risk.[58] Parental investigations are therefore a prerequisite for the provision of comprehensive genetic counseling. Because FAO disorders cover a wide spectrum of clinical presentations and treatability, and disease status in the fetus may even have consequences on the mother's well-being, several criteria must be considered before seeking prenatal diagnostic testing.[36]

Treatment of most FAO disorders is simple and results in a normal life when initiated early. However, an ethical issue may arise when families who suffered the tragic loss of an undiagnosed child are reluctant to accept that simple treatment is indeed available. The decision is easier for disorders in which the outcome must be considered dismal based on the absence of significant treatment options. A prerequisite for all prenatal diagnostic considerations is a related index case with a well-established diagnosis and the availability of a diagnostic test that can be performed on amniotic fluid,

amniocytes, or chorionic villi samples using any or a combination of metabolite, protein, and molecular analyses.[59–62]

With the exception of cases in which the prognosis is clearly poor or the mother's health is a significant cause for concern, it is recommended that newborns suspected of having an FAO disorder should undergo a comprehensive evaluation and be managed aggressively immediately after birth until the FAO in question has been excluded.

NEWBORN SCREENING

Newborn screening is a public health program whose mandate is the early identification of diseases in newborns in whom timely intervention could significantly improve the prognosis for their long-term health. Guthrie's innovative application of the bacterial inhibition assay to the detection of levels of phenylalanine in dried blood spots on filter paper led to the establishment of the first newborn screening assay for phenylketonuria.[63] In the following decades, additional tests were added to screening panels using similar or entirely new technology for the detection of key metabolites or enzymatic activity.

The introduction of tandem mass spectrometry (MS/MS) to newborn screening as a sensitive and specific means for the simultaneous detection of key diagnostic metabolites has significantly increased the number of metabolic diseases that could be screened for in a single process using dried blood spot specimens.[64] Currently, over 30 diseases can be screened for, and in addition to several organic acidemias and aminoacidopathies, the ability to quantify acylcarnitine species has also enabled the detection of FAO disorders.[31] However, there is no uniformity in the panel of disorders that each state screens for, with the number of diseases ranging from 4 to over 30.[65]

The prognosis for most patients with FAO disorders who are identified presymptomatically and managed appropriately is generally favorable and suggests benefit from early diagnosis and treatment.

POSTMORTEM SCREENING

The period after birth is a critical time for infants with FAO disorders, and episodes of hypoglycemia can be triggered by inadequate food intake and limited glycogen stores.[66] The severity of these episodes is variable, with symptoms resolving in response to either intravenous glucose or feeding in some patients, whereas, on the other end of the spectrum, the decompensation events may be fatal, resulting in sudden and unexpected death.[67] An estimated 5% of sudden, unexpected deaths in children less than 1 year of age and an even higher percentage of deaths observed in the 1- to 5-year age group are caused by FAO disorders.[68–70]

Postmortem studies involving histochemical and biochemical analyses of liver specimens,[70] organic and fatty acid analysis of urine and plasma specimens,[69] analysis of acylcarnitine profiles in dried blood and bile spots,[71,72] and the determination of FAO rates using cultured skin fibroblasts[73] have all been used to investigate sudden unexpected death in previously healthy patients.

An approach for the investigation of such a patient suspected of having an FAO disorder has been described.[74]

We propose a complete postmortem investigation and genetic counseling of parents who lost a child suddenly and/or unexpectedly. Blood and bile could be conveniently collected on the same filter paper card, one identical to those used for newborn screening, which can be shipped at room temperature. Liver and skin biopsies should also be collected and kept until the blood and bile samples have been analyzed. Both of these specimens should be collected to provide a better chance to detect and independently confirm the largest possible number of disorders. In cases with a higher level of suspicion, an effort should be made to collect a frozen specimen of liver and a skin biopsy. Although fatty infiltration of the liver and/or other organs (heart, kidneys) is a common finding in FAO disorders, caution should be exercised not to use steatosis as the sole criteria to indicate a possible underlying FAO disorder during the postmortem evaluation of a case of sudden death.[70] Additional risk factors include a family history of sudden death, Reye syndrome, or maternal pregnancy complication and evidence of lethargy, vomiting, and/or fasting in the 48 hours prior to death. To ensure that all possible avenues are covered, cases of alleged child abuse should also be fully investigated. The frozen liver and skin biopsy could be discarded at a later time without further testing when a credible cause of death has been established but could otherwise be crucial to reach a proper diagnosis and conclusive confirmation in vitro.

These studies are important in providing the basis for appropriate genetic counseling and even testing of family members because the identification of affected, healthy appearing siblings is not uncommon.[75]

DISORDERS OF PLASMA MEMBRANE FUNCTIONS

Long-Chain Fatty Acid Transport/Binding Defect

Two patients have been described who presented with episodes of acute liver failure and mild acute encephalopathy associated with nonketotic hypoglycemia and hyperammonemia.[76] Both of them received liver transplants, and their further development was normal. The biochemical phenotype of these patients was nonspecific, and steatosis was not observed in either patients' livers. In cultured skin fibroblasts, reduced intracellular concentration of C_{14} to C_{18} fatty acids and reduced cellular oxidation of palmitate and oleate were found. The latter finding was normalized by permeabilization of the plasma membrane with digitonin. No mutations were found by sequencing of several target genes involved in fatty acid transport. The exact defect in these patients remains to be determined.

Carnitine Uptake Defect

Carnitine uptake defect is the only cause of primary carnitine deficiency and is due to a defective plasma membrane carnitine transporter. Renal reabsorption and intestinal uptake are impaired, with subsequent tissue depletion of

carnitine. Intracellular carnitine deficiency impairs the entry of long-chain fatty acids into the mitochondrial matrix and therefore compromises FAO, particularly in tissues that are most reliant on this pathway. Patients present with progressive cardiomyopathy, episodes of hypoketotic hypoglycemia associated with encephalopathy, and hepatomegaly. Skeletal myopathy is also a common clinical manifestation. Some patients had episodes of abdominal pain and diarrhea owing to gastrointestinal dysmotility; others had hypochromic anemia.[77,78] Several cases of sudden and unexpected death at variable ages have also been reported.[67,79] Microvesicular steatosis and lipid infiltration may be seen in liver and muscle biopsies, respectively. Plasma carnitine concentrations are less than 10% of normal and typically associated with increased urinary carnitine excretion. The diagnosis is confirmed either by determination of carnitine uptake in fibroblasts or molecular genetic analysis of the gene (*SLC22A5*) encoding the sodium ion-dependent carnitine transporter OTCN2. A genotype-phenotype correlation is not apparent.[80] Presymptomatic identification through newborn screening using tandem mass spectrometry has been reported.[48] Heterozygotes for OTCN2 mutations show moderately reduced plasma carnitine levels and reduced rates of carnitine uptake,[79] increased urinary carnitine losses,[81] and predisposition to late-onset benign cardiac hypertrophy.[82]

DISORDERS OF THE CARNITINE CYCLE

CPT1 Deficiency

CPT1 exists as two tissue-specific and genetically distinct isoforms, a hepatic (CPT1A) and a muscle type (CPT1B).[83,84] CPT1A is expressed in liver and other tissues except muscle, whereas CPT1B is primarily expressed in skeletal and cardiac muscle. Accordingly, CPT1A deficiency is characterized primarily by nonketotic hypoglycemia and liver dysfunction, which may result in a fatal Reye-like encephalopathy. Several cases were reported with cardiac (cardiomegaly, arrhythmia) and renal involvement (distal renal tubular acidosis).[85,86] AFLP was reported in two subsequent pregnancies, both resulting in CPT1A-deficient offspring.[87]

The biochemical diagnosis is not straightforward. Organic acid analysis of urine collected during clinically significant episodes is not informative. Blood acylcarnitine analysis may reveal an elevation of free and acetylcarnitine in the presence of relatively low concentrations of long-chain acylcarnitines allowing the calculation of a ratio specific for CPT1 deficiency.[88] In contrast to other FAO defects, CPT1A deficiency is associated with an elevated level of plasma carnitine, in particular free carnitine. This is probably caused by the unusually high renal threshold for free carnitine and secondary increase in carnitine transport.[89] Accordingly, high plasma concentrations of total and free carnitine in a patient with a suspicious clinical presentation should lead to the inclusion of CPT1 in the differential diagnosis. CPT1A can be confirmed by enzyme assay in fibroblasts and molecular genetic analysis of the CPT1A gene. However, most mutations are private, with the exception of the G710E mutation, which is common in the Hutterite communities of North America.[90] Treatment is based on strict avoidance of fasting and subsequent hypoglycemia and a low-fat diet supplemented with medium-chain triglycerides (MCTs). Patients with CPT1B deficiency have not been reported to date.

CACT Deficiency

Patients with CACT deficiency typically present in the neonatal period with hypoketotic hypoglycemia, liver failure accompanied by hyperammonemia, and/or hypertrophic cardiomyopathy.[91] Impaired motility of the whole gastrointestinal tract has been reported in one patient.[92] Frequent feedings of a low-fat diet, with most fat consisting of MCTs, which do not require CACT to cross the mitochondrial membranes, are the mainstay of treatment. Nevertheless, despite therapeutic efforts, most patients will die following the development of cardiac arrhythmias, possibly caused by an accumulation of arrhythmogenic long-chain acylcarnitines.[33] Autopsy reveals fatty infiltration in liver, kidney, and muscle and hypertrophic cardiomyopathy.[92,93] Outcome has been more favorable for patients, with in vitro evidence of some residual enzyme activity.[91,94,95] Because CACT deficiency is identifiable through expanded newborn screening using tandem mass spectrometry, it is expected that in the future, more patients will be identified and treated before the onset of symptoms. Whether the prognosis can be improved by presymptomatic initiation of treatment, however, remains to be seen. Acylcarnitine analysis in plasma or dried blood spots reveals markedly elevated long-chain acylcarnitines, with C_{16} and C_{18} species being particularly prominent. However, because CPT2 deficiency (see below) results in virtually the same acylcarnitine profile, further biochemical testing by enzyme assay or molecular genetic analysis of the CACT gene is necessary to arrive at the correct diagnosis. Molecular analysis usually requires gene sequencing owing to significant allelic heterogeneity.[91]

CPT2 Deficiency

CPT2 deficiency can be differentiated into several clinical presentations. A relatively mild, adult-onset form of CPT2 deficiency was the first mitochondrial FAO defect to be described.[96] It is typically limited to the skeletal muscle, with episodes of myopathy and rhabdomyolysis usually triggered by prolonged exercise combined with either fasting or cold exposure. One patient had recurrent pancreatitis with intermittent myoglobinuria; another's myopathic crises appeared to be induced by valproate therapy.[97,98]

A recently proposed classification is based on organ involvement, residual enzyme activity, and genotype.[99] Accordingly, CPT2 type I is the most severe form that presents in the neonatal period and affects the liver, skeletal muscle, and heart and is associated with congenital brain and kidney abnormalities.[100,101] CPT2 type II involves the liver, skeletal muscle, and heart and presents in the first few years of life. Type III is limited to skeletal muscle, presents in early adulthood, and, relative to types I and II, is associated with the highest residual enzyme activity. Because of several patients having experienced malignant

hyperthermia during surgery, it has been suggested to include CPT2 deficiency in the differential diagnosis of this anesthetic complication.[102]

Myoglobinuria and markedly elevated serum creatine phosphokinase levels are hallmarks of CPT2 deficiency. Acylcarnitine profiles are also abnormal but identical to those observed in CACT deficiency. More specific enzyme assays or molecular genetic tests are needed to verify a presumptive diagnosis. The most common mutation in CPT2 type III is S113L, whereas 413delAG appears to be common in the Ashkenazi Jewish population.[103] Symptomatic heterozygotes for particular mutations have also been described.[104]

DISORDERS OF LONG-CHAIN FATTY ACID METABOLISM

VLCAD Deficiency

The first patients with VLCAD deficiency were described as having LCAD deficiency, based on the ETF reduction assay using palmitoyl CoA as a substrate.[105] However, once molecular genetic studies of the LCAD gene were possible and the VLCAD protein was identified, patients previously labeled as LCAD deficient were shown to have no mutations in the LCAD gene, whereas they had no detectable VLCAD protein by immunoblot analysis.[106] A patient with true LCAD deficiency has not yet been described. However, an LCAD knockout mouse model features typical symptoms of an FAO disorder, suggesting that LCAD is indeed a critical enzyme and will likely be demonstrated in humans eventually.[107]

VLCAD catalyzes the first step of the fatty acid β-oxidation spiral. The severity of the phenotype seems to correlate with specific genotypes.[108] The most severe phenotype manifests early in life and is associated with nonsense mutations, resulting in complete loss of enzyme activity. Morbidity and mortality are significant owing to involvement of multiple organ systems, in particular the liver and heart, resulting in recurrent metabolic crises and cardiomyopathy.[109] Patients carrying missense mutations or with single amino acid deletions permitting some residual enzyme activity are at high risk of metabolic decompensation with nonketotic hypoglycemia and a Reye-like syndrome triggered by increased energy demands (eg, prolonged fasting, fever).[110] The phenotype switches from a more hepatic presentation to muscle weakness as patients become older; some are able to sustain metabolic stress during childhood and do not present until adulthood with exercise-induced myopathy and rhabdomyolysis.

Laboratory hallmarks during acute episodes include hypoketotic hypoglycemia and creatine phosphokinase elevations. Urine organic acid analysis is nonspecific, with hypoketotic dicarboxylicaciduria. Acylcarnitine analysis is most informative, revealing a characteristic profile with elevated levels of saturated and unsaturated C_{14} to C_{18} carnitine esters, the predominant species being tetradecenoylcarnitine ($C_{14:1}$).[57] The diagnosis can be confirmed by specific enzyme assay or FAO in vitro probing in fibroblast cultures[111] or by molecular genetic analysis of the VLCAD gene. Because acylcarnitine analysis can be performed in newborn screening blood spots, early identification and treatment of affected patients are generally possible.[112,113]

TFP and LCHAD

The TFP is a hetero-octamer containing four α and four β subunits encoded by two different genes. The α subunit harbors the activities of the second and third steps of fatty acid β-oxidation, LCEH and LCHAD. The β subunit harbors LCKAT, which catalyzes the last step in β-oxidation of long-chain fatty acids. Although mutations in either gene may cause complete TFP deficiency, a few mutations in the α subunit cause isolated LCHAD deficiency. In keeping with the previously mentioned disorders, a genotype-phenotype correlation has also emerged for TFP deficiency, with residual enzyme activity being associated with a milder, later-onset phenotype. Patients with late-onset TFP deficiency present with a progressive peripheral neuropathy and episodic rhabdomyolysis.[114] Recently, two patients with lethal TFP deficiency owing to isodisomy for chromosome 2 were described. This finding is of great importance in particular for genetic counseling of families because the recurrence risk in future pregnancies would be significantly lower than the 25% risk typical for FAO disorders, which are generally autosomal recessive.[58]

Although the phenotype of both disorders includes all of the symptoms expected in a FAO disorder, patients with LCHAD and TFP deficiencies may also develop pigmentary retinitis and a peripheral neuropathy, the pathophysiology of which remains obscure. In addition, many patients are born prematurely and small for gestational age. The initial hypothesis that a secondary deficiency of docosahexaenoic acid may cause the retinal changes and may be treatable by dietary supplementation has not been proven conclusively.[115]

A recent study described the clinical and biochemical abnormalities in 50 patients with isolated LCHAD deficiency.[116] All patients presented by 26 months, and most became symptomatic within the first 6 months of life. Thirty-nine patients had episodes of acute metabolic decompensation, with symptoms of hepatic dysfunction (79%), coma (56%), seizures (38%), and apnea (23%). Fewer patients experienced cardiorespiratory arrest, arrhythmia, and sudden death. Hypoglycemia was a key laboratory finding in all 39 patients, and most of the patients showed decreases in total carnitine and significant elevations in plasma lactate, aspartate aminotransferase, creatine kinase, and ammonia levels. The 11 patients who did not experience an acute metabolic decompensation before diagnosis of LCHAD deficiency were also found to have a range of more chronic symptoms, which included hepatomegaly, cholestasis and hepatic dysfunction, cardiomyopathy, feeding difficulties, failure to thrive, hypotonia and lethargy, psychomotor retardation, peripheral neuropathy, and microcephaly. This spectrum of clinical signs before and at the time of diagnosis was similar for both groups of patients presenting with or without acute metabolic crisis. With more newborn screening laboratories introducing tandem mass spectrometry for acylcarnitine analysis into their programs, patients should come to attention earlier in life, and follow-

up studies will have to determine whether presymptomatic initiation of treatment is beneficial.[50,117]

Patients with isolated LCHAD deficiency have a reduction in LCHAD activity with normal LCEH and LCKAT activities. The most common cause of isolated LCHAD deficiency is the 1528G→C mutation, which changes a glutamate to a glutamine residue (E474Q) in the active site of the α subunit of the LCHAD gene. The replacement of the acidic residue with a neutral amide amino acid is thought to affect the NAD^+-binding site of the enzyme and subsequently results in an isolated reduction of LCHAD activity without affecting the activities of LCEH and LCKAT.

Another feature that was thought to be specific to LCHAD deficiency was the observation that approximately 20% of patients were born following pregnancies complicated with maternal liver disease, in particular AFLP and HELLP syndrome. However, several other FAO disorders have meanwhile been implicated as possible triggers of maternal liver disease during pregnancy.[36] The simplified hypothesis is that pathologic fatty acid metabolites accumulating in the affected fetus eventually overwhelm the obligate heterozygous mother's FAO capacity, which already is reduced in the third trimester of pregnancy.[34]

DISORDERS OF MEDIUM-CHAIN FATTY ACID METABOLISM

MCAD Deficiency

MCAD is responsible for the initial dehydrogenation of acyl CoAs with a chain length between 4- and 12-carbon atoms. MCAD deficiency is probably the best known FAO defect because it has gained prominent attention over the last decade as a disorder fulfilling all classic criteria for inclusion into newborn screening programs.[118,119] Early diagnosis is crucial because MCAD is a potentially lethal disease, documented by the fact that up to at least 20% of undiagnosed patients die during their first metabolic decompensation.[120] A common missense mutation (985A→G; K304E) has been identified in whites of Northern European descent that results in reduced production of an unstable protein. But patients homozygous for this mutation may present at any time during life—typically, when a metabolic stressor is experienced (fever, prolonged fasting) that triggers an acute manifestation. However, identification of patients by newborn screening has led to the discovery of cases with only mild biochemical abnormalities and specific genotypes involving mutations that preserve significant enzyme activity in vitro. Whether patients with such genotypes will remain asymptomatic even during times of increased energy demands remains to be determined either by long-term follow-up or by carefully conducted fasting challenges.

A defect of the MCAD enzyme leads to fasting-induced hypoglycemia and accumulation of medium-chain fatty acids. The latter are further metabolized not only to dicarboxylic and carnitine esters but also to glycine esters, which can be determined in urine by organic acid analysis or more accurately by stable isotope dilution methods and GC-MS.[43] Analysis of plasma acylcarnitines by MS/MS reveals accumulation of C_6 to C_{10} acylcarnitine species, with prominent octanoylcarnitine.[121] Detection of these metabolites is the basis for newborn screening for MCAD deficiency by MS/MS.[64,118] Affected individuals may develop secondary carnitine deficiency; thus, the characteristic metabolites may not be reliably detectable.[47] Urine acylglycine analysis should therefore be pursued in carnitine-deficient and asymptomatic patients, making obsolete previously advocated provocative tests in most cases.[43] The biochemical diagnosis of MCAD deficiency can be confirmed by measurement of the activity of the MCAD enzyme in fibroblasts and other tissues and by molecular genetic testing of the *ACADM* gene; both test methods can be used for prenatal diagnosis. MCAD deficiency has been observed in all populations but Asians.[122]

M/SCHAD Deficiency

Previously, the clinical entity now known as M/SCHAD deficiency was described as a defect of SCHAD, an enzyme of the mitochondrial short-chain fatty acid β-oxidation pathway converting L-3-hydroxybutyryl CoA to acetoacetyl CoA.[123] However, our present understanding of the protein encoded by the SCHAD gene suggests a chain-length specificity toward C_8 to C_{10} acyl CoA.[124] At the clinical and biochemical levels, a deficiency of this enzyme has been described with three different phenotypes. The first one presented with cardiomyopathy and recurrent rhabdomyolysis, culminating in death as a teenager.[125] Enzyme activity was reduced in skeletal muscle but not in skin fibroblasts; other tissues were not studied enzymatically. A second phenotype was described with a presentation similar to that seen in ketotic hypoglycemia, and enzyme deficiency was described in isolated mitochondria from cultured skin fibroblasts.[126] Other tissues were not analyzed in these patients. A third group of patients had hepatic involvement and steatosis; the catalytic activity with the C_4 substrate was deficient in liver but normal in muscle and fibroblasts.[127] Mutation analysis of the SCHAD gene in these patients has been inconclusive, suggesting the existence of another protein with high activity toward acetoacetyl CoA.[128]

Recently, however, five patients in two unrelated families were reported who presented with hypoketotic hypoglycemia associated with hyperinsulinism, reduced M/SCHAD activity in fibroblast mitochondria, and mutations in the SCHAD gene.[38,129,130] Further molecular information and detailed studies of M/SCHAD protein interactions will hopefully improve our understanding of the function, substrate specificity, and tissue expression of this peculiar enzyme.

In addition to hypoglycemia, which may be either ketotic or hypoketotic, elevated transaminases, creatine phosphokinase, and hyperammonemia may be present during acute episodes of metabolic decompensation in affected patients. Specific laboratory findings include various chain-length dicarboxylic and 3-hydroxydicarboxylicaciduria. Plasma acylcarnitine analysis may be normal or show an elevated concentration of 3-hydroxybutyryl carnitine.[38]

MCKAT Deficiency

Only one patient with this disorder has been described to date.[131] This Japanese male newborn presented at 2 days

of life with emesis, dehydration, liver dysfunction, and terminal rhabdomyolysis and died several days later. Laboratory findings included hypoglycemia, hyperammonemia, metabolic acidosis, and elevated creatine phosphokinase levels. Urine organic acid analysis showed ketotic lacticaciduria and significant C_6 to C_{12} dicarboxylicaciduria, with prominent C_{10} and C_{12} species. Whereas palmitate oxidation on skin fibroblasts was normal, octanoate oxidation was reduced to 31% of controls. An isolated deficiency of MCKAT was demonstrated in fibroblasts. This result was supported by the findings of immunoprecipitation studies, which demonstrated a 60% reduction in protein signal. A better understanding of this disorder will require the elucidation of the molecular basis and identification of additional patients.

DISORDERS OF SHORT-CHAIN FATTY ACID METABOLISM

SCAD Deficiency

Initially suggested in 1984,[132] SCAD deficiency has been reported in less than 30 patients.[1,14] The first SCAD-deficient patients reported were two newborns with unusually large urinary excretion of ethylmalonic acid (EMA). One of these patients died during the neonatal period, whereas the other suffered only one metabolic decompensation in the newborn period and remained asymptomatic thereafter.[133]

EMA is an alternative metabolite of butyryl CoA that accumulates when β-oxidation of fatty acids cannot proceed in shortening fatty acyl CoAs with four carbons owing to inactivity of SCAD. Butyryl CoA is then carboxylated by propionyl-CoA carboxylase to EMA, which is readily excreted in urine, where it can be measured by organic acid or acylglycine analysis. Butyryl CoA can also be esterified with carnitine to facilitate egress out of the mitochondria and eventually into the blood, where it is measurable as a C_4-acylcarnitine by MS/MS. An increased concentration of butyrylcarnitine in blood and excretion of EMA into urine are considered biochemical markers of SCAD deficiency, although these findings are not specific for this disorder.

A variety of symptoms have been described, the most common being developmental delay and muscle hypotonia.[134] The laboratory confirmation of SCAD deficiency is difficult and should include both biochemical and molecular genetic studies. Most conveniently, fibroblasts can be used to first assess FAO,[135,136] followed by SCAD gene sequencing. However, although several pathogenic, mostly missense mutations have been identified, molecular genetic testing for SCAD deficiency is complicated by two SCAD gene variants, 511C→T (R147W) and 625G→A (G185S), which occur in the homozygous or compound heterozygous state in 7% of the US population.[137] Among patients overexcreting EMA, these variants are even more frequent.[138,139] In addition, some patients with biochemical evidence of SCAD deficiency do not carry any other SCAD gene mutations.[134,140] In vitro studies revealed that these variants compromise SCAD activity owing to abnormal protein folding and thermolability, respectively.[139,141] All of these findings considered, these variants are believed to confer disease susceptibility in combination with other, as yet unidentified genetic or environmental factors.

DISORDERS OF KETOGENESIS

HMG-CoA Synthase Deficiency

Only six patients with HMG-CoA synthase deficiency have been described to date.[21,142–145] All patients presented with recurrent hypoketotic hypoglycemic episodes leading to coma, usually triggered by prolonged fasting owing to gastroenteritis.

This diagnosis may be underestimated because of the relatively nonspecific biochemical phenotype during an acute episode with hypoketotic hypoglycemia, dicarboxylicaciduria, and normal blood acylcarnitine profile in the presence of elevated free fatty acids.[21]

Enzymatic analysis is difficult because HMG-CoA synthase is expressed in the liver, and its substrates and products are also used or synthesized by other proteins. The human *HMGCS2* gene, however, has been isolated, and the diagnostic potential of a molecular approach has been documented by the detection of disease-causing mutations.[21,146]

HMG-CoA Lyase Deficiency

HMG-CoA lyase is the second mitochondrial enzyme that mediates ketogenesis from fatty acids (see Figure 55.3-4). It also catalyzes the final step of leucine catabolism. Approximately 60 patients described presented with acute, often lethal episodes of hypoketotic hypoglycemia and acidosis.[147] Fifty percent of the cases presented in the first weeks of life acutely, triggered by fasting or intercurrent illness. Exceptionally, the onset is after 2 years of age. The central nervous system appears to be particularly vulnerable during metabolic crises, but abnormal magnetic resonance imaging signal abnormalities in white matter were observed even in asymptomatic patients.[148] In addition to possible neurologic sequelae, pancreatitis, cardiomyopathy, and deafness associated with retinopathy have been described.[149–151]

The urine organic acid profile is characteristic, with abnormal excretion of 3-hydroxy-3-methylglutaric, 3-methylglutaconic, 3-methylglutaric, and 3-hydroxyisovaleric acids. Acylcarnitine analysis in plasma and newborn screening blood spots is remarkable for elevated 3-methylglutarylcarnitine.[152] The diagnosis should be confirmed by measurement of enzymatic activity in fibroblast cultures or molecular genetic testing. The defect appears to be relatively frequent in Saudi Arabia, where it accounts for about 16% of inherited metabolic diseases.[153]

SCOT Deficiency

Succinyl-CoA:3-oxoacid-CoA transferase is the first step of ketone body use in extrahepatic tissues, particularly the heart, kidney, and brain (see Figure 55.3-4). The typical clinical presentation includes recurrent episodes of severe ketoacidosis, with persistent ketonuria and hyperketonemia even during the fed state. In almost all described patients, the onset was in the first year of life.[154] In two cases, cardiomegaly was noted,[155] and behavioral problems have also been reported.[156]

Urine organic acid analysis reveals persistent, although nonspecific, ketonuria. A tentative diagnosis should be confirmed by enzyme assay or molecular genetic analysis.[157]

The disease is potentially fatal. Treatment relies on limitation of protein intake, provision of adequate calories, and alkaline therapy to prevent aggravation of ketosis at the onset of any intercurrent infection.[158]

Mitochondrial β-Ketothiolase Deficiency

β-Ketothiolase is a ketogenic and ketolytic enzyme that also intervenes in isoleucine catabolism (see Figure 55.3-4). Although variable, most patients present with acute ketoacidosis accompanying infections and vomiting. Dilated cardiomyopathy, neutropenia, and thrombocytopenia are also possible.[147] Neurologic complications, such as mental retardation and basal ganglia involvement, have been described in a few patients.[159,160] However, asymptomatic affected individuals have been documented in families with an affected case.[161]

Urine organic acid analysis is diagnostic with the documentation of a large excretion of 2-methyl-3-hydroxybutyric acid and tiglylglycine, reflecting a block in isoleucine catabolism. The enzymatic assay presents some technical difficulties because of the presence of three other thiolases. Significant genetic heterogeneity hinders a rapid molecular genetic approach to the diagnosis.[162]

Key biochemical findings associated with the disorders of ketone body metabolism are presented in Table 55.3-3.

OTHER DISORDERS

Glutaric acidemia Type II

Primary defects of ETF or ETF-QO result in glutaric acidemia type II. This disorder is also known as multiple acyl-CoA dehydrogenase deficiency because the reoxidation of several mitochondrial dehydrogenases is impaired owing to the inability of their cofactor, FAD, to transfer electrons to ETF. The clinical phenotype is variable, with an early-onset, severe form with or without congenital anomalies and a milder, later-onset form of the disease.[162] The milder phenotype has also been described as ethylmalonic-adipicaciduria.

The severe, neonatal-onset form with congenital anomalies is often associated with prematurity. Patients generally present with overwhelming illness within the first 2 days of life and die shortly thereafter. Hypotonia, severe hypoglycemia, metabolic acidosis, large kidneys, and renal dysgenesis have also been described. Congenital anomalies include dysmorphic facial features, rocker-bottom feet, muscular and abdominal wall defects, and genital anomalies.[163–165]

Patients with early neonatal onset without congenital abnormalities also initially present with hypotonia, metabolic acidosis, hypoglycemia, tachypnea, hepatomegaly, and the odor of sweaty feet. These patients may survive for a few months with treatment. Death is often due to severe cardiomyopathy. An even longer survival was noted in patients who initially presented with hypoglycemia in the newborn period followed by episodes of Reye-like illness.[164–168]

There is considerable variability in patients with the milder, late-onset phenotype.[165] The clinical presentation may include episodic vomiting, hypoglycemia, and acidosis. Hepatomegaly, carnitine deficiency, and lipid storage myopathy have also been described. Whereas some patients present clinically within the first few years of life,[169] others may remain symptom free until adulthood.[170]

Mutations in ETF-QO but not ETF are associated with renal cysts. Although several mutations have been described in the genes for the ETF α subunit and ETF-QO, there are no common mutations. Olsen and colleagues examined the genetic basis of nine patients with the three different clinical phenotypes of glutaric acidemia type II and showed a relationship between the genotype and the phenotype.[171] The three patients with neonatal-onset and congenital anomalies were homozygous for null mutations and demonstrated palmitate oxidation levels of less than 5% of control cell lines in metabolic flux studies. The milder clinical phenotypes are associated with mutations that result in residual enzymatic activity, which itself may be modulated by environmental factors, such as fever.

Glutaric acidemia type II has a characteristic biochemical phenotype, primarily associated with the secondarily altered metabolism of its related dehydrogenases.[172] Urinary organic acid profiles demonstrate an accumulation of EMA, glutaric acid, and 2-hydroxyglutaric acid. Isovalerylglycine and hexanoylglycine accumulation is notable, particularly by urinary acylglycine analysis, and elevated levels of butyrylcarnitine, isovalerylcarnitine, glutarylcarnitine, and several other medium- and long-chain acylcarnitine species are observed by acylcarnitine analysis in plasma and newborn screening blood spots.

2,4-Dienoyl-CoA Reductase Deficiency

There has only been one published case of 2,4-dienoyl-CoA reductase deficiency.[19] The patient was a term female who presented at 2 days of age with hypotonia. Notable

TABLE 55.3-3 DISORDERS OF KETONE BODY METABOLISM AND CHARACTERISTIC BIOCHEMICAL ABNORMALITIES

DISORDER	KETOSIS	ACIDOSIS	BLOOD GLUCOSE	BLOOD AMMONIA	PLASMA LACTATE
Ketogenesis					
HMG-CoA synthase deficiency	–	–	↓	N	N
HMG-CoA lyase deficiency	–	+	↓		↑
Ketolysis					
SCOT deficiency	+++	+	N/↓	N	N
β-Ketothiolase deficiency	+++	+	↑/N/↓	N	N

HMG-CoA = 3-hydroxy-3-methylglutaryl coenzyme A; N = normal; SCOT = succinyl-CoA oxoacid transferase; ↓ = reduced; ↑ = elevated.

physical features included microcephaly; a large face; small arms, feet, and fingers; and a small trunk. The biochemical phenotype consisted of hyperlysinemia, carnitine deficiency, and a normal urinary organic acid profile. Acylcarnitine analysis, however, revealed an abnormal accumulation of decadienoylcarnitine ($C_{10:2}$) in blood and urine. The infant was placed on a lysine-restricted diet with MCTs and carnitine supplementation. Although this diet resulted in some weight gain, at 4 months of age, the patient ultimately suffered a fatal episode of respiratory distress. Autopsy findings also demonstrated pulmonary vascular congestion and bilateral hypertrophy. It is surprising that no additional cases have been found after the initial report despite the routine application of acylcarnitine analysis in the laboratory evaluation of metabolic patients.

GENERAL APPROACH TO TREATMENT

The mainstay of treatment is the avoidance of fasting. Frequent feedings are recommended to avoid accumulation of toxic metabolites resulting from peripheral lipolysis and hypoglycemia that may occur in affected patients when hepatic glycogen stores become depleted during prolonged fasting and periods of higher energy demands.[173] Infants should be fed every 3 to 4 hours, and older patients may be given uncooked cornstarch as a source of complex carbohydrates, which are slowly released into the bloodstream, allowing longer feeding intervals and prolonged nighttime rest. The initial dose is 1.0 to 1.5 g/kg, which can be slowly increased to 1.75 to 2 g/kg by 2 years of age.[174] If this is not tolerated well, a bedtime snack rich in complex carbohydrates should be provided. In severe cases with a high risk of recurrent hypoglycemia, continuous overnight administration of carbohydrates by nasogastric or gastrostomy tube may be required.

Restriction of Fat Intake

A dietary regimen of fat restriction and high carbohydrate intake has been generally recommended for the long-term management of FAO disorders. The exact limitations, however, have not been studied systematically and vary, ranging from 10 to 35%, with a median fat restriction of 29%.[173] Depending on the severity of the disorder, a reasonable approach appears to be the reduction to 25 to 30% of total calories from fat. The substitution of MCTs as a lipid substrate has been suggested for patients with long-chain FAO defects because medium-chain fatty acids do not require the carnitine cycle to cross the mitochondrial membranes and enter the β-oxidation pathway downstream of the defective enzyme.[175] Ten to 20% of total calories should come from MCT oil in these disorders.[173,176] However, MCT oil must not be prescribed for patients with deficiencies of medium- and short-chain fatty acid metabolism and ketogenesis. Supplementation of essential fatty acids at 1 to 2% of total energy intake by the use of flaxseed, canola, walnut, or safflower oils has been suggested, particularly when MCT oil is a significant part of the diet and because deficiency of docosahexaenoic acid has been hypothesized as a possible cause for the development of pigmentary retinopathy in patients with LCHAD deficiency.[115,173,177] Fat-soluble vitamins should also be supplemented to meet Recommended Dietary Allowance standards.[173]

Carnitine Supplementation

Primary carnitine deficiency (carnitine uptake defect) is the only disorder for which the supplementation of L-carnitine is proven to be essential and lifesaving.[78] In this condition, oral doses of 100 mg/kg/d and higher are required to maintain plasma carnitine levels in the normal range. The use of carnitine in other disorders of FAO that are associated with secondary carnitine deficiency is controversial. Arguments in support of carnitine are based on its potentially beneficial role in the removal of accumulated toxic acyl-CoA intermediates and repletion of the intramitochondrial carnitine pool. However, neither protective nor deleterious effects of carnitine have been proven conclusively. Treem and colleagues reported a study of one patient with MCAD deficiency who was fasted before and on carnitine supplementation.[178] Treatment did not prolong the period of fasting tolerance or prevent the accumulation of abnormal metabolites. Furthermore, the benefit of L-carnitine supplementation has been questioned for long-chain FAO disorders in particular because the accumulation of long-chain fatty acylcarnitines may cause fatal cardiac arrhythmias.[33,179] On the other hand, L-carnitine has been proposed as an antiarrhythmic medication.[180] Den Boer and colleagues did not find evidence that carnitine supplementation had any effect on the number of metabolic decompensations in LCHAD-deficient patients.[114] In a few patients with LCHAD deficiency, a positive response to carnitine administration was reported with respect to serum carnitine values and clinical status.[181,182] Other patients with FAO disorders died while treated with carnitine,[183–185] whereas the clinical condition improved for others who did not receive carnitine.[186]

Other Treatment Modalities

Although no data regarding efficacy are available, riboflavin is sometimes prescribed (100 mg/d) for SCAD and ETF/ETF dehydrogenase deficiencies. The rationale is that riboflavin, a cofactor of dehydrogenases, may boost any residual enzyme activity. More recently, Roe and colleagues reported the use of an anaplerotic odd-chain triglyceride, triheptanoin, in three patients with VLCAD deficiency.[187] It is postulated that triheptanoin increases the concentration of oxaloacetate (derived from propionic acid) that can serve to favor oxidation of acetyl CoA by the Krebs cycle or enter gluconeogenesis. This anaplerotic effect was found to be effective in the normalization of the acylcarnitine profile and some clinical symptoms in patients with VLCAD deficiency.[187] It is unclear whether odd-chain fatty acids offer any therapeutic advantage over the widely available MCT-rich diet for patients with carnitine or acylcarnitine translocase deficiency. Cardiomyopathy and muscle weakness resolved in these patients, and rhabdomyolysis did not occur at least during the 26 months of treatment with this dietary modification. Side effects were also not observed, but a larger, longer-term study has not been reported, and

studies using many available mouse models for FAO disorders have not yet been conducted.

Future pharmacologic approaches to the treatment of FAO disorders may also include the use of fibrates, which have been shown in vitro to increase enzyme activity at least in patients with some residual enzyme activity. So far, this has only been shown to be of potential benefit in CPT2–deficient fibroblast cultures.[188] The beneficial effect of increased enzyme activity appears to be related to fibrate acting as a ligand of peroxisome proliferator–activated receptor α, which induces expression of β-oxidation enzyme genes.

Management during Intercurrent Illness

The most pressing issue in a patient with an impending or present metabolic decompensation is the reversal of catabolism by provision of energy in the form of glucose. When oral intake of adequate amounts of carbohydrates cannot be achieved, intravenous glucose (8–10 mg/kg/min) should be administered. This should stimulate insulin secretion and hence suppress peripheral lipolysis. Some, particularly newborn, patients do not appear to clinically improve despite the development of even hyperglycemia. However, hyperglycemia may not be a reflection of a glucose overload but can be caused by an inadequate insulin response. In such cases, glucose should not be reduced, but insulin therapy should be carefully initiated to allow the patient's metabolism to use the administered glucose.

Once diagnosed, all patients should be provided with a frequently updated "emergency" letter to be given, if needed, to health care providers who may not be familiar with the patient's disorder. This letter should include a detailed explanation of the management of acute metabolic decompensation, emphasizing the importance of preventive measures (eg, intravenous glucose regardless of "normal" laboratory results, overnight in-hospital observation), and the telephone numbers of the patient's metabolic specialist.

4. Bile Acid Synthesis and Metabolism

Kenneth D. R. Setchell, PhD
Nancy C. O'Connell, MS, CCRC, CCRA

For several decades, bile acids have been implicated in the pathogenesis of liver disease; however, their exact role in initiating or perpetuating liver injury has proven difficult to discern. Nonspecific alterations in serum, urinary, and biliary bile acid composition are found in infants and children with neonatal cholestasis. However, until recently, it was difficult to determine whether such changes were primary or secondary to the cholestatic condition. Largely as a consequence of methodologic advances,[1] specific inborn errors in bile acid biosynthesis have been recently recognized[2–5] that appear to be causal in the pathogenesis of the idiopathic and familial forms of neonatal hepatitis.[6–13] Although the exact genetic basis for these defects is still to be established, the deficiency in activity of specific enzymes involved in bile acid synthesis results in diminished production of the primary bile acids that are essential for promoting bile flow[14] and the concomitant production of atypical bile acids with the potential for causing liver injury.[15] This chapter outlines the pathways for bile acid synthesis, highlights the features of bile acid metabolism in early life, and describes the clinical and biochemical characteristics of inborn errors in bile acid synthesis.

CHEMISTRY

The bile acids are a group of compounds that belong to the steroid class.[16] Structurally, they consist of a four-ringed, cyclopentanoperhydrophenanthrene nucleus (ABCD rings) with a side chain, most commonly of five carbon atoms length, terminating in a carboxylic acid (Figure 55.4-1); they are therefore classified as acidic steroids. A great variety of bile acids can be found in biologic fluids, and significant species differences exist with regard to the synthesis and metabolism of the bile acids.[17] The vast majority of naturally occurring bile acids have the C-5 hydrogen oriented in the 5β-configuration, thereby confirming a *cis*-A/B ring structure. Bile acids with a 5α-H are referred to as *allo*-bile acids,[18] and these are found as minor metabolites in biologic fluids. In humans, the principal bile acids synthesized by the liver[3,19] have hydroxyl groups substituted in the nucleus at the carbon positions C-3, C-7, and C-12. Additional reactions involving other hydroxylations, epimerization, and oxidoreduction also take place, leading to a complex array of structures (see Figure 55.4-1). Although many of the products of these reactions may be of negligible quantitative importance in health, they are found in substantial concentrations in cholestatic syndromes, arising out of the induction of cytochrome P-450 hydroxylations.[1] During early development, alternative pathways for bile acid synthesis and metabolism become quantitatively important, as is evident from the findings of relatively high proportions of bile acids hydroxylated at the C-1, C-2, C-4, and C-6 positions of the nucleus.[20,21]

The two principal bile acids synthesized by the liver and referred to as the "primary" bile acids are cholic acid (3α,7α,12α-trihydroxy-5β-cholanoic acid) and chenodeoxycholic acid (3α,7α-dihydroxy-5β-cholanoic acid; a description of the conventions used for the systematic nomenclature of bile acids is reviewed elsewhere.[22] These bile acids are extensively conjugated to the amino acids glycine and taurine.[23] To a lesser extent, conjugation occurs with glucuronic acid to form glucuronide ethers[24] and esters[25] and with sulfuric acid to form sulfate conjugates.[26] More recently, bile acid conjugates of glucosides,[27,28] *N*-acetylglucosaminides,[29] and drugs[30] have also been recognized (see Figure 55.4-1). The diversity in bile acid structure is further increased by the fact that unsaturation (double bonds) in the steroid nucleus and side chain and substitution of oxo-groups also occurs, whereas bile

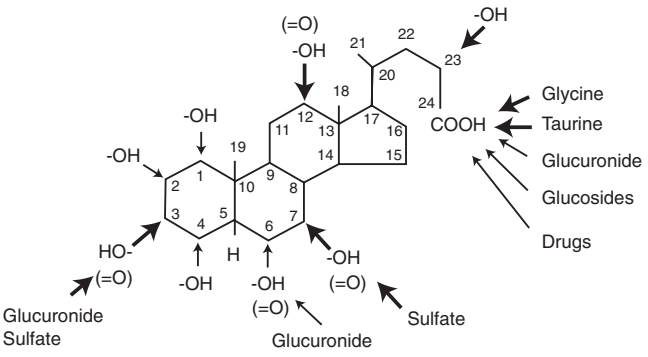

FIGURE 55.4-1 Chemical structure of the bile acid (5β-cholanoic acid) nucleus indicating the numbering system for each carbon atom and the various positions of the substituent groups for the majority of bile acids found in normal and pathophysiologic conditions. The size of the arrows indicates the relative importance of each of the substituent groups. Bile acids can additionally possess unsaturation in a number of positions in the nucleus and the side chain, but for simplicity, this is not indicated.

acids may be found with side chains longer or shorter than the usual 5-carbon side-chain length.[1]

The bile acids perform several important functions. They represent one of the major catabolic pathways for the elimination of cholesterol from the body.[3,19] From the standpoint of hepatobiliary disease, bile acids provide the primary driving force for the promotion and secretion of bile[14] and are essential to the development of the biliary excretory route for the elimination of endogenous and exogenous toxic substances, including bilirubin, xenobiotics, and drug metabolites. Within the intestinal lumen, the detergent action of bile acids facilitates the absorption of fats and fat-soluble vitamins, and the importance of this role becomes apparent in chronic cholestasis, where failure to thrive, fat malabsorption, and fat-soluble vitamin deficiency present significant clinical management problems. Indeed, the measurement of fat-soluble vitamin status is a very sensitive marker of disturbances in bile acid synthesis and secretion, as is evident from the manifestation of inborn errors in bile acid synthesis.[6,7,9–11,13]

Physiologically, the normal bile acid pool size is 2 to 4 g, but the effectiveness of this pool is increased by an efficient enterohepatic recycling (10–12 times/d) stimulated by postprandial gallbladder contraction.[31] Conservation of the bile acid pool occurs by an efficient reabsorption, principally from the small intestine, and an effective hepatic extraction from the portal venous circulation so that each day less than 5% of the pool is lost in the stool.[32] This bile acid loss is compensated for by hepatic synthesis of newly formed bile acids; therefore, in the steady state, determination of fecal bile acid excretion provides a reliable estimate of daily bile acid synthesis rates.[32]

PATHWAYS FOR BILE ACID SYNTHESIS

The biochemical pathways for bile acid synthesis in the adult have been relatively well defined and are reviewed in detail elsewhere.[3,19] Much of our understanding of these pathways results from in vitro and in vivo studies of precursor-product relationships in various animal species, most notably the rat and rabbit, and from studies of pathologic disorders affecting bile acid production. This discussion therefore serves to indicate only the salient features of the pathways. The conversion of cholesterol, a C_{27} sterol, to the two primary bile acids, cholic and chenodeoxycholic acids, requires significant alterations to the steroid nucleus (Figure 55.4-2) and side chain (Figure 55.4-3) of the molecule. These include (1) the introduction of additional hydroxyl groups at positions C-7 (for both chenodeoxycholic and cholic acids) and C-12 (for cholic acid); (2) epimerization of the 3β-hydroxyl group; (3) reduction of the Δ^5 bond; (4) reduction in length of the side chain from C_8 to C_5, with the formation of a terminal carboxylic acid; and (5) conjugation to the amino acids glycine and taurine.

Several pathways are responsible for bile acid synthesis from cholesterol.[33–35] Beginning from cholesterol, two reactions are possible: 7α-hydroxylation, initiating bile acid synthesis via the classic pathway, now referred to as the neutral pathway, or 27-hydroxylation, referred to as the acidic pathway. Although, classically, the 7α-hydroxylation pathway has been considered the major pathway for primary bile acid synthesis and cholesterol 7α-hydroxylase the accepted rate-limiting enzyme, more recently, the quantitative importance of the acidic pathway has been realized.[9,33,35–37] Nevertheless, irrespective of the route by which primary bile acids are synthesized, common reactions occur, and the enzymes catalyzing these reactions have broad specificity.[3] For the sake of simplicity, this review highlights the individual reactions involved in the classic (neutral) pathway, but it should be pointed out that these reactions do not necessarily occur in this orderly fashion. Indeed, permutations of these sequences of reactions give rise to the complex array of bile acids typically found in physiologic and pathophysiologic states, highlighting the promiscuity of these enzymes.

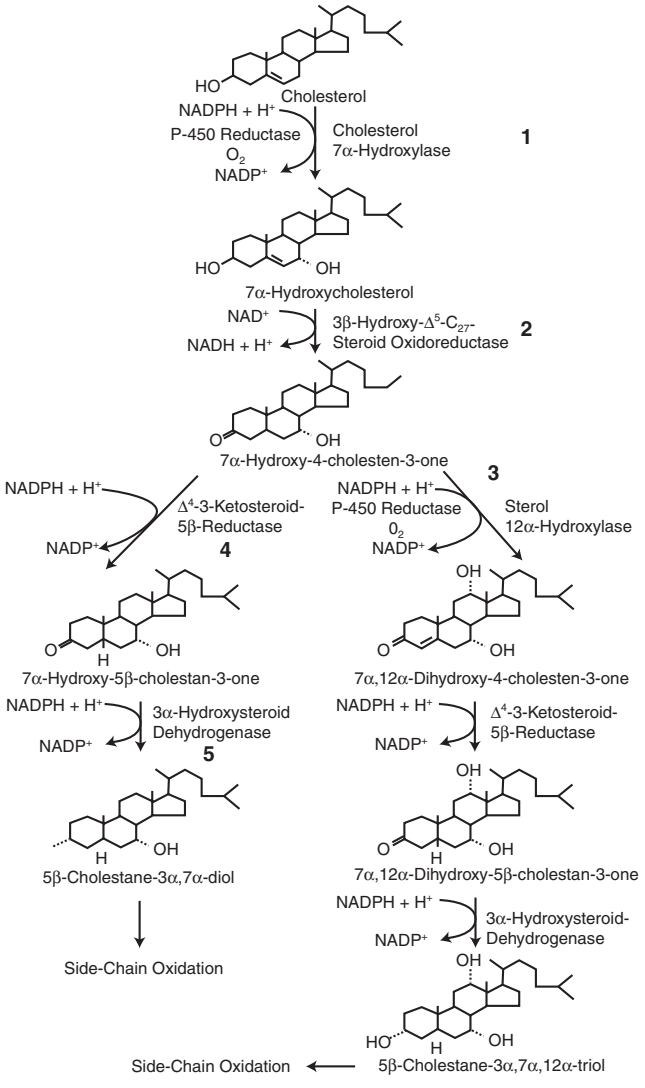

FIGURE 55.4-2 Metabolic pathway for the biosynthesis of the primary bile acids indicating the reactions involved in modifying the steroid nucleus in the conversion of cholesterol to 5β-cholestane-3α,7α,12α-triol. In the classic (neutral) pathway, these reactions were considered to precede side-chain oxidation. NADP = nicotinamide adenine dinucleotide phosphate; NADPH = reduced nicotinamide adenine dinucleotide phosphate.

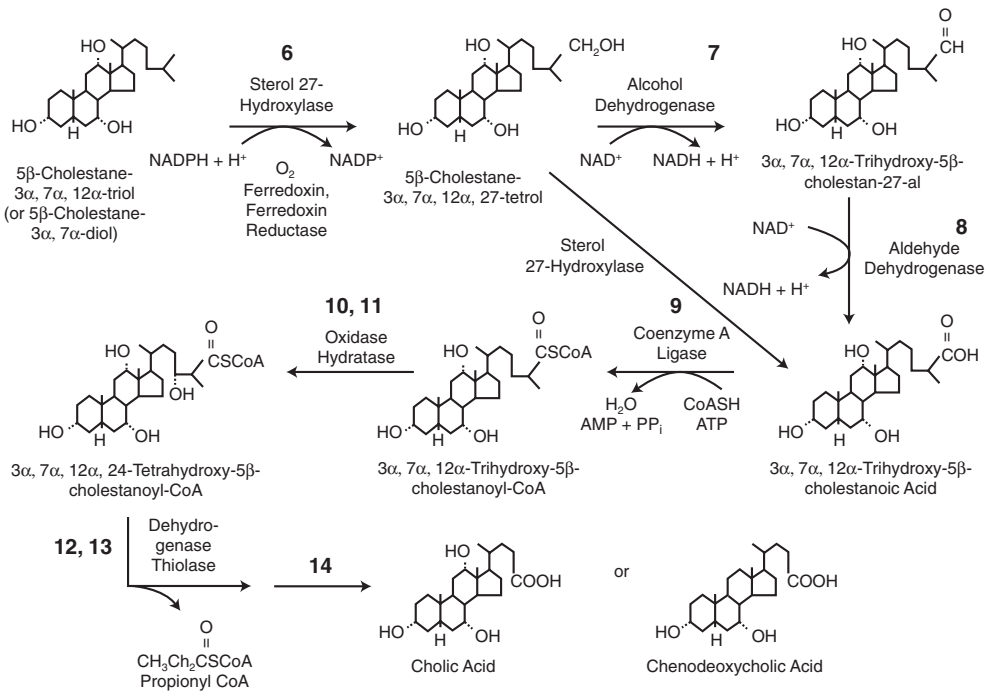

FIGURE 55.4-3 Sequence of reactions involved in the side-chain oxidation of 5β-cholestane-3α,7α,12α-triol to yield cholic or chenodeoxycholic acids, which are then conjugated with glycine and taurine. AMP = adenosine monophosphate; ATP = adenosine triphosphate; CoA = coenzyme A; NAD = nicotinamide adenine dinucleotide; NADH = reduced nicotinamide adenine dinucleotide; NADP = nicotinamide adenine dinucleotide phosphate; NADPH = reduced nicotinamide adenine dinucleotide phosphate.

In the classic pathway for bile acid synthesis from cholesterol, nine principal steps occur. All of the enzymes responsible for catalyzing these reactions are located in various subcellular fractions within the hepatocyte; consequently, there is considerable intracellular trafficking of the products of these reactions. Additionally, several of the enzymes are expressed in extrahepatic organs and tissues, including fibroblasts, macrophages, brain, lung, kidney, and vascular endothelia.[38–45] Why these enzymes are located in these tissues is unclear, but they are considered to play an important role in cholesterol homeostasis independent of their primary function, which is to catalyze reaction rates for primary bile acid synthesis.

Step 1: Cholesterol 7α-Hydroxylase

The first step in bile acid synthesis involves the introduction of a hydroxyl group at the C-7 position of the nucleus.[46] This reaction is catalyzed by a microsomal cholesterol, 7α-hydroxylase,[47] a cytochrome P-450 liver-specific enzyme with a molecular weight of 57 kD. A vast literature exists on the role of cholesterol 7α-hydroxylase in bile acid synthesis and the factors involved in its regulation that cannot be covered within the scope of this review, and the reader is directed to several excellent articles on this topic.[3,19,47,48] This step is potentially the most important because it is rate limiting for bile acid synthesis[49] and is subject to negative feedback regulation by the flux of bile acids returning to the liver. Differences exist, however, in the ability of different bile acids to regulate this enzyme.[50] For example, unlike primary bile acids, bile acids possessing a 7β-hydroxyl group (such as ursodeoxycholic acid [UDCA]) are unable to down-regulate bile acid synthesis,[51] and UDCA may even be mildly stimulatory.[52] Biliary drainage increases cholesterol 7α-hydroxylase activity approximately 10-fold in rats,[53,54] whereas taurochenodeoxycholic acid infusion restores activity to normal.[55] Likewise, cholestyramine administration increases the activity of cholesterol 7α-hydroxylase. Because bile acid synthesis is self-regulated via the activity of cholesterol 7α-hydroxylase, this provides the basis for the feeding of oral primary bile acids for the treatment of metabolic defects involving enzymes in the pathway.[56–60]

Changes in the activity of cholesterol 7α-hydroxylase parallel changes in 3-hydroxy-3-methylglutaryl coenzyme A (HMG-CoA) reductase activity; consequently, these two key enzymes regulate the cholesterol pool size.[61] A diurnal rhythm in cholesterol 7α-hydroxylase activity occurs synchronously with the diurnal rhythm in the activity of the HMG-CoA reductase.[62–64] Bile acid synthesis increases nocturnally[65] and may be regulated by glucocorticoids.[66]

Cholesterol 7α-hydroxylase has been isolated and purified from rat liver,[67] the protein structure has been sequenced, and complementary deoxyribonucleic acids (cDNAs) have been prepared for the rat and human enzymes.[68–70] This enzyme has been shown to be exclusively of hepatic origin. With molecular tools, many studies of the gene, the messenger ribonucleic acid (mRNA), and the protein have been carried out.[71–74] These studies have also heightened awareness of the complexity in the regulation of bile acid synthesis and have led to the realization that the classic neutral pathway is not the sole contributing pathway for bile acid synthesis. When the gene for cholesterol 7α-hydroxylase is knocked out in a mouse,[37,75] most of the animals die within the first few weeks of life from liver failure and the consequences of fat-soluble vitamin malabsorption, highlighting the importance of bile acids for lipid absorption. However, if these animals are fed fat-soluble vitamins and cholic acid, they survive, the symptoms resolve,[76] and primary bile acid synthesis takes place via the developmental expression of an oxysterol 7α-hydroxylase specific to the acidic pathway.[37] Furthermore, in rats, if activity of cholesterol 7α-hydroxylase is completely

repressed by continuous infusion of squalestatin, bile acid synthesis 24 hours later is still 43% of preinfusion levels, indicating that the acidic pathway accounts for almost half of the total bile acid synthesis in the rat.[36] Our recent discovery of a genetic defect in the oxysterol 7α-hydroxylase causing fatal liver disease[9] suggests that the acidic pathway is quantitatively the most important, at least in early infancy. This contention is based on the fact that even though the patient had a normal cholesterol 7α-hydroxylase gene, there was no detectable mRNA or enzyme activity. Also, cholesterol 7α-hydroxylase activity was not detected or was very low in liver samples from infants of less than 1 year of age, confirming earlier reports that have shown cholesterol 7α-hydroxylase enzyme activity to be low or undetectable in human fetal and infant liver.[77,78] What triggers the increased activity in cholesterol 7α-hydroxylase during development is uncertain. Overall, it appears that there are significant species differences with regard to the developmental expression of the neutral and acidic pathways.

It has been shown that bile acids and their oxysterol intermediates interact with a number of nuclear orphan receptors.[79–81] Furthermore, bile acids are present in the nucleus of hepatocytes.[82] At least four such orphan receptors have been identified: liver X receptor, farnesoid X receptor (FXR), pregnane X receptor, and constitutive androstane receptor; there may be others yet to be identified.[79,80,83,84] It appears that these may be important at two levels of regulation: in the liver by transcriptional regulation of cholesterol 7α-hydroxylase[85–87] and at the intestinal level by inducing transcription of the ileal bile acid binding protein that is involved in the ileal uptake and conservation of the bile acid pool.[88] The importance of these orphan receptors in regulating bile acid synthesis and expression of bile acid transporters is illustrated from significant changes observed in studies of gene knockout models of these orphan receptors.[83,89] It is now evident that bile acid synthesis and transport may, in the future, be manipulated by the use of specific ligands for these orphan receptors to treat cholestatic liver diseases and disorders of cholesterol metabolism. Chenodeoxycholic and cholic acids have a high affinity for FXR,[81,88,90,91] and this dihydroxy bile acid is also a potent regulator of cholesterol synthesis.[88] UDCA, on the other hand, has little affinity.

Step 2: 3β-Hydroxy-C_{27}-Steroid Oxidoreductase (3β-Hydroxy-C_{27}-Steroid Dehydrogenase/Isomerase)

The conversion of 7α-hydroxycholesterol to 7α-hydroxy-4-cholesten-3-one is catalyzed by a microsomal 3β-hydroxy-C_{27}-steroid oxidase (previousy referred to as a 3β-hydroxy-C_{27}-steroid dehydrogenase/isomerase enzyme, and considerable effort has gone into understanding the mechanism of this relatively complex two-step reaction[92,93] that involves oxidation of the 3β-hydroxyl group and isomerization of the Δ^5 bond. It is possible that 7α-hydroxy-5-cholesten-3-one is formed as an intermediate, but attempts to isolate this compound have proved unsuccessful. In 1981, Wikvall isolated what appeared to be a single, highly specific enzyme of molecular weight 46 kD responsible for catalyzing this reaction in rabbits.[94] The enzyme was later isolated and purified to homogeneity from pig liver and shown to have a molecular weight of 36 kD.[95] More recently, a single gene (*HSD3B7*) on chromosome 16p11.2-12 encoding the enzyme was identified and sequenced, and a number of mutations associated with progressive familial cholestatic liver disease were described.[96,97] The enzyme only catalyzes the conversion of 7α-hydroxylated sterols or bile acid intermediates with a 3β-hydroxy-Δ^5 structure to the corresponding 3-oxo-Δ^4 metabolites. It shows no activity toward corresponding 7β-hydroxy analogs. Comparable reactions occur in the biosynthetic pathways for steroid hormones, but the enzyme active on the sterol intermediates of bile acid synthesis differs from the isozymes described for C_{19} and C_{21} neutral steroids, for which cDNAs are described.[98–101] The 3β-hydroxy-C_{27}-steroid oxidoreductase enzyme is expressed in fibroblasts,[102] although its function is unknown. Nevertheless, this does enable its activity to be determined in patients in whom there is a evidence of a deficiency in this enzyme; however, sequencing of the DNA is a preferred approach to accurately confirming a biochemical defect in this reaction step.

Step 3: 12α-Hydroxylation

The conversion of 7α-hydroxy-4-cholesten-3-one into 7α,12α-dihydroxy-4-cholesten-3-one is catalyzed by cytochrome P-450–dependent microsomal 12α–hydroxylase, which has a relatively broad substrate specificity. This reaction is responsible for diverting sterol intermediates into the cholic acid pathway. The enzyme was purified from rabbit liver and shows specificity toward 5α-cholestane-3α,7α-diol and 7α-hydroxycholesterol in rabbits.[103] The primary structure of the rabbit, mouse, and human enzymes has been deduced by molecular cloning of the cDNAs, and the enzyme has been expressed in COS cells.[104,105] There is little similarity in its peptide sequence with other cytochrome P-450 enzymes involved in bile acid synthesis, and because it shows a 43% homology with prostacyclin synthase (*CYP8A1*), it has been designated as *CYP8B1*.[105] The human gene has been localized to chromosome 3p21.3-p22 and structurally has been found to be the first cytochrome P-450 enzyme to lack introns. The enzyme is well expressed in rabbit and human liver, two species in which deoxycholic acid is quantitatively important, and to a lesser extent in rats and mice. Studies in rats have shown that the introduction of a C-27 hydroxyl group prevents subsequent 12α-hydroxylation and that thyroid hormone inhibits its activity while stimulating microsomal C-27 hydroxylase activity.[106,107] It is also transcriptionally downregulated by hydrophobic bile acids.[108] Both enzymes may therefore be of importance in regulating the synthesis of cholic acid in rats.[107] This, however, seems not to be the case for humans, in whom the introduction of a C-27 hydroxyl group has no inhibitory effect on the microsomal 12α-hydroxylase activity and thyroid hormone has only a small influence on the cholic-to-chenodeoxycholic acid ratio. These differences highlight species variations[17] that require consideration when using animal models. Other

factors influencing microsomal 12α-hydroxylase include bile acid feeding,[109,110] which has an inhibitory effect, and cholestyramine administration, which increases the ratio of cholic-to-chenodeoxycholic acid[111] owing to an interruption of the normal enterohepatic circulation of bile acids. Similarly, biliary drainage[49] and starvation[103,112] increase its activity, the latter by an increase in mRNA levels. There appears to be no correlation between 12α-hydroxylase activity and the ratio of biliary cholic acid to chenodeoxycholic acid in humans,[113] indicating that other factors, such as the extent of enterohepatic recycling, intestinal metabolism, and absorption, may be important in regulating the relative proportions of intermediates that are diverted to each pathway. Additionally, the existence of alternative pathways for bile acid synthesis, particularly chenodeoxycholic acid,[33–35] which may be under separate regulatory control, could explain this lack of relationship.

Step 4: Δ^4-3-Oxosteroid 5β-Reductase

A soluble reduced nicotinamide adenine dinucleotide phosphate (NADPH)-dependent Δ^4-3-oxosteroid 5β-reductase enzyme is responsible for catalyzing the reaction that leads to the saturation of the Δ^4-bond and the formation of the 5β-(H) configuration at the AB-ring junction[114,115] that is common to the majority of bile acids found in most animal species, including humans. The Δ^4-3-oxosteroid 5β-reductase has been purified,[116] and sequence analysis of both the human[117] and rat[118,119] cDNA encoding this enzyme indicates its molecular weight to be 37 to 38 kD, being made up of 327 amino acids. The rat and human enzymes show similar homology but differ significantly in structure from the analogous 5α-reductase enzyme responsible for the formation of *allo*-bile acids. The activity of this enzyme parallels that of cholesterol 7α-hydroxylase, as indicated from the finding that the plasma concentration of 7α-hydroxy-4-cholesten-3-one correlates with hepatic cholesterol 7α-hydroxylase activity.[120] Although this enzyme does not appear to be of regulatory importance for bile acid synthesis under normal conditions, the finding of significantly elevated levels of Δ^4-3-oxo-bile acids in severe cholestasis[121] would suggest that under pathologic conditions, it may become rate limiting for primary bile acid synthesis.

Step 5: 3α-Hydroxysteroid Dehydrogenase

Conversion of 7α-hydroxy-5β-cholestan-3-one and 7α,12α-dihydroxy-5β-cholestan-3-one by reduction into the respective 3α-hydroxy analogues takes place in the cytosolic fraction under the influence of a NADPH-dependent 3α-hydroxysteroid dehydrogenase enzyme.[114,115] This enzyme, which has broad substrate specificity, has been purified to homogeneity, and a number of cDNAs have been sequenced.[122–125] In addition to its role in metabolism, 3α-hydroxysteroid dehydrogenase was shown to be identical to the 33 kD Y′ bile acid binders involved in the intracellular transport of bile acids.[126] The enzyme is inhibited by indomethacin, and bile acid binding to this protein is a major determinant of the intracellular distribution.[127]

Step 6: Sterol 27-Hydroxylase

The mechanism by which oxidation of the C_{27} sterol side chain occurs has been the subject of extensive study. Under normal conditions, it would appear that the first step involves the introduction of a hydroxyl group at the C-27 position (see Figure 55.4-3). This reaction can take place in both the microsomal and mitochondrial fractions[3,19]; for humans, the mitochondrial C-27 hydroxylase (formerly referred to as a C-26 hydroxylase) is quantitatively more important. The mitochondrial C-27 hydroxylation has been shown to be stereospecific, involving hydroxylation of the 25-pro-*S* methyl group to yield the 27-hydroxylated product with a 25(R) configuration. On the other hand, the microsomal C-27 hydroxylation seems to involve the formation of the 25(S) product. The mitochondrial C-27 sterol hydroxylase exhibits a broad substrate specificity toward many sterols, including cholesterol and vitamin D,[128–130] but is particularly active toward 5β-cholestan-3α,7α-diol, 5β-cholestan-3α,7α,12α-triol, and 7α-hydroxy-4-cholesten-3-one.[131,132] The reaction involves a cytochrome P-450 species,[133] and the enzyme can be induced by phenobarbital treatment and by starvation. In addition to 27-hydroxylation, this enzyme is capable of catalyzing multiple oxidation reactions that give rise to 3α,7α,12α-trihydroxy-5β-cholestanoic acid (THCA).[134]

Although the microsomal C-27 hydroxylase (which is also cytochrome P-450 dependent) is of minor quantitative importance in humans, compared with the mitochondrial enzyme, it has a higher substrate specificity in the rat.[131] The microsomal fraction of rat liver, however, catalyzes the hydroxylation of the C-23, C-24 (α and β), and C-25 carbons, with the latter being as efficient as C-27 hydroxylation.[135]

It would appear that the 27-hydroxylation of cholesterol that drives the acidic pathway is catalyzed by the very same sterol 27-hydroxylase enzyme that is active on cholestane-3α,7α,12α-triol in the neutral pathway. This is in contrast to 7α-hydroxylation, in which there are separate and distinct enzymes in both pathways.[9] The sterol 27-hydroxylase is expressed in many extrahepatic tissues,[35,39,40,43,44,128,136,137] but especially in the adrenals, intestine, and lung, where its activity is highest. Its function appears to be one of facilitating the removal of cellular cholesterol for subsequent oxidation to bile acids. In the lung, where it is highly expressed, the ratio of 27-hydroxycholesterol to cholesterol is high. It appears that this organ accounts for most of the production of 3β-hydroxy-5-cholestenoic acid[38]; interestingly, removal of one lung reduces the level of this cholestenoic acid by half.

cDNAs encoding the rat, rabbit, and human C-27 hydroxylase have been isolated,[128,136,138,139] and whereas the activity and message for the sterol 27-hydroxylase have been determined in many tissues, its role in regulating bile acid synthesis is unclear, and it is evident that there are significant species differences. In the rabbit, the activity of cholesterol 27-hydroxylase is unaffected by bile acids,[140,141] whereas in rat hepatocytes transfected with the sterol 27-hydroxylase gene, bile acids repress transcription.[142] Sterol 27-hydroxylase appears to be much more important for bile acid synthesis in the mouse than in the human. When

the gene was disrupted in the mouse, the formation of bile acids was shown to be markedly reduced.[143] This is not the case in humans, in whom mutations in the cholesterol 27-hydroxylase gene account for the lipid storage disease of cerebrotendinous xanthomatosis (CTX). In CTX, bile acids are produced by a compensatory pathway involving the 25-hydroxylation pathway leading to cholic acid, but chenodeoxycholic acid synthesis is markedly impaired.[144–146]

Step 7: Formation of Cholestanoic Acids

The oxidation of the C-27 hydroxylated sterol intermediates to the respective cholestanoic (C_{27}) acids takes place in two steps[147] with the formation of an aldehyde as the intermediate. After purification of the enzymes responsible for these reactions, it was concluded that they were identical to the hepatic alcohol dehydrogenase and aldehyde dehydrogenase enzymes.[148–152] The relative importance of these enzymes in the oxidation of the side chain compared with that of the C-27 hydroxylase catalyzed reaction is unknown,[152] but the resulting product formed is the enantiomer (25R)3α,7α,12α-trihydroxy-5β-cholestanoic acid ((25R)THCA).

Step 8: Oxidation of the Side Chain

Initiation of side-chain oxidation occurs with the formation of the CoA ester of (25R)THCA, a reaction that takes place in the endoplasmic reticulum and is catalyzed by a THCA-CoA synthetase.[153,154] Racemization of (25R)THCA-CoA to (25S)THCA-CoA takes place, catalyzed by 2-methylacyl-CoA racemase,[155] and this is an obligatory step to enable subsequent peroxisomal β-oxidation to occur because only the (25S)-enantiomers are substrates for the peroxisomal branched-chain acyl-CoA oxidase that leads to primary bile acid formation. 2-Methylacyl-CoA racemase is also responsible for catalyzing the stereoisomerization of the branched-chain fatty acid (2R)pristanoyl-CoA to its corresponding (S)-isomer.[156] The gene encoding this enzyme has been sequenced, and mutations have been reported in three adult patients with sensory neuropathies[155] and in two infants with liver disease and fat-soluble vitamin malabsorption.[13] Once formed, (25S)THCA-CoA undergoes oxidation by a series of reactions analogous to those responsible for the mitochondrial β-oxidation of fatty acids, involving the formation of 24α-hydroxylated and CoA derivatives with subsequent release of propionic acid to yield the cholanoic (C_{24}) acid CoA ester.[157,158] These reactions occur in the peroxisome, although, at one time, they were thought to be of microsomal origin.[152,158] Once within the peroxisome, the rate-limiting enzyme in side-chain oxidation, THCA-CoA oxidase, yields a Δ^{24} intermediate. A cDNA encoding the THCA-CoA oxidase was recently cloned and characterized in the rat, rabbit, and human.[159–162] This enzyme is distinct from the very-long-chain fatty acid (VLCFA) CoA oxidase that performs an analogous reaction[163] but is common to the oxidation of 2-methyl branched-chain fatty acids.[156] The Δ^{24} product of this reaction is then hydrated to form 24-hydroxy-THCA-CoA, which, in turn, is dehydrogenated to yield 24-oxo-THCA-CoA.[19,156,158,163,164] These two reactions are catalyzed by a multifunctional protein,[165–167] of which two forms are known, multifunctional enzyme (MFE)-I and MFE-II, the latter being the one responsible for the degradation of bile acids and branched-chain fatty acids.[168] It is possible that the sterol carrier protein SCP-2/SCPx, which binds and complexes acyl CoAs and acyl-CoA oxidases within the peroxisome, may play a role in side-chain oxidation of bile acids, at least in the mouse, because when the gene was knocked out, an accumulation of 3α,7α,12α-trihydroxy-27-nor-5β-cholestan-24-one occurred.[169] The final step in the sequence of reactions for side-chain oxidation involves thiolytic cleavage of propionic acid, and this yields cholanoyl CoA.[170,171] The mechanisms involved in these reactions are described in more detail in a separate chapter on peroxisomes in this book.

Step 9: Conjugation of Bile Acids

The CoA derivatives of cholic and chenodeoxycholic acids are finally conjugated with the amino acids glycine and taurine. It is not known whether this reaction takes place exclusively within the peroxisome[172,173] or, as was originally thought, the cytosol, or both of these compartments.[174,175] A microsomal bile acid–CoA synthetase has been isolated,[175] which may be involved in the hydrolysis of the CoA ester and subsequent transport of cholic and chenodeoxycholic acids between these compartments.

Bile acid amino acid conjugates are formed in two consecutive enzymic reactions. The unconjugated bile acid is first converted to an acyl-CoA thioester,[174,176–178] a reaction that is catalyzed by a rate-limiting hepatic microsomal[179] bile acid CoA ligase (EC 6.2.1.7). This enzyme has also been identified in a rat kidney.[180] It has been purified and characterized from rat liver and found to have a molecular weight of 65 kD, and, more recently, its cDNA has been cloned and expressed in insect Sf9 cells.[181] It shows activity toward chenodeoxycholic and cholic acids but is inhibited by more hydrophobic bile acids, especially lithocholic and deoxycholic acids. Although the gene for the human hepatic enzyme has yet to be identified and sequenced, a gene encoding a 58 kD protein, recognized as a bile acid CoA ligase, was interestingly identified from *Eubacterium* sp strain VPI 12708.[182]

In the second reaction, the bile acid CoA thioester, catalyzed by a cytosolic bile acid–CoA:amino acid *N*-acyltransferase (EC 2.3.1.65),[183] is coupled to the amino acids glycine and taurine. This enzyme has been purified from human liver,[184] and its substrate specificity has been well characterized.[184–186] A cDNA encoding the human bile acid CoA:amino acid *N*-acyltransferase has been isolated, characterized, and expressed in bacteria,[187] as has a cDNA for the corresponding mouse enzyme, the gene for the latter being localized to chromosome 4.[188] The human cDNA encoded a monomeric protein of 46,296 D, and although there was reported close homology with the mouse enzyme[188] and with *kan-1*, a putative rat liver *N*-acyltransferase,[189] a significant species difference in substrate specificity was demonstrated. The human bile acid–CoA:amino acid *N*-acyltransferase is capable of conjugating cholic acid with both glycine and taurine, whereas

the mouse enzyme showed selectivity toward taurine only. This is consistent with the fact that the mouse is an obligate taurine conjugator of bile acids, as are the rat and the dog.[190] The human bile acid–CoA:amino acid *N*-acyltransferase was recently found to be capable of conjugating fatty acids with glycine,[191] and because it is expressed in many tissues that play no role in bile acid synthesis, it was suggested that its function in extrahepatic tissues may be one of regulating intracellular levels of VLCFA.

Bile acids with a side-chain length of four carbon atoms (nor-bile acids) and six carbon atoms (homo-bile acids) are poor substrates for the enzymes; however, cholestanoic acids (C_{27} bile acids) are conjugated efficiently with taurine, as evidenced from their conjugation patterns in patients with peroxisomal defects.[2,192] The final products of the above-described multiple reactions, glycocholic, taurocholic, and chenodeoxycholic acids, are referred to as primary bile acids and are secreted in bile. In the normal adult, the ratio of glycine to taurine conjugated bile acids is 3:1,[23] but this can be altered by an increased availability of taurine, as occurs during taurine feeding[193] or in early life,[21] when hepatic taurine stores are high[194] because of selective placental transfer.[195] Unusual amidated conjugates are formed in some species, as evidenced by the finding that 3% of the biliary deoxycholic acid of the domestic rabbit is a glycyltaurine conjugate.[196]

Other bile acid conjugates occur naturally, and these include sulfates,[26] glucuronide ethers and esters,[24,25,197–200] glucosides,[27,28,199] *N*-acetylglucosaminides,[29,201] and conjugates of some drugs.[30,202,203] These metabolic pathways serve to increase the polarity of the molecule, thereby facilitating its renal excretion, and to decrease the membrane-damaging potential of the more hydrophobic unconjugated species.[204,205] Under normal conditions, these pathways are of minor quantitative importance but are activated in early life in the diseased state, particularly cholestasis, in the presence of an increased bile acid load such as exogenous bile administration or by drug administration.

A sulfotransferase enzyme catalyzes the formation of bile acid sulfates, most commonly at the C-3 position, but C-7 and C-12 sulfates are also found.[206–208] This enzyme shows sex-dependent differences in rats[208] but not in humans. Its activity has been shown to be low in the fetus compared with the adult,[209] as is evident from the finding of relatively small proportions of bile acid sulfates in fetal bile.[21] Although sulfation of bile acids has traditionally been considered to occur in the liver, it is evident that renal sulfation is important,[210,211] and most probably accounts for the increased concentrations of urinary bile acid sulfates in cholestasis.[212]

Glucuronidation is catalyzed by a number of glucuronyl transferase isozymes[199] that give rise to glucuronide ethers (ring conjugation) and esters (side-chain carboxyl conjugates). The affinity of this conjugation system is relatively specific[213]; short-chain bile acids are preferentially glucuronidated,[214] whereas bile acids possessing a 6α-hydroxyl group form the 6-O-ethers.[200,215]

Several other conjugation pathways for bile acids have been recently recognized. Glucosides[27,28,216] and *N*-acetylglucosaminides[29,201] of nonamidated and glycine- and taurine-conjugated bile acids have been found in normal human urine,[28,217] and quantitative excretion (1 μmol/d) approximates that of bile acid glucuronides.[198,218] A microsomal glucosyltransferase from human liver has been isolated and characterized and found in extrahepatic tissues.[216] This enzyme exhibits substrate specificity toward 7β-hydroxylated bile acids,[29] which explains why *N*-acetylglucosaminide conjugates of UDCA are found in large proportions in the urine of patients undergoing UDCA therapy.[212,219]

The identification of bile acid conjugates of fluorouracil[30,203,216] demonstrates that drug interactions with hepatic conjugation enzymes can take place and may play a role in the development of drug-induced cholestasis.

Alternative Pathways for Bile Acid Synthesis

The simplified view of the pathways for bile acid synthesis described above assumes that the sequence of reactions occurs in an orderly manner, with changes to the steroid nucleus preceding side-chain oxidation. This, of course, is not the case, as is apparent from in vitro studies of enzyme kinetics using radiolabeled intermediates, which demonstrate the existence of alternative pathways for primary bile acid synthesis (Figure 55.4-4).[220–222] This is reinforced by the finding that patients with T tubes converted radiolabeled 27-hydroxycholesterol to chenodeoxycholic acid to a greater extent than 7α-hydroxycholesterol.[223] This pathway was denoted the acidic pathway[33] and is under separate regulatory control to the classic cholesterol 7α-hydroxylase (neutral) pathway. The relative importance of alternative pathways for primary bile acid synthesis, which mainly relate to initiating hydroxylation reactions on the side chain followed by 7α-hydroxylation, has become more recently appreciated.[33,35] These reactions occur in the liver and in many different extrahepatic tissues, including the brain, alveolar macrophages, vascular endothelia, and fibroblasts.[41,45,224] Their extrahepatic function may be related in some way to the regulation of cholesterol homeostasis because of their ability to generate significant amounts of oxysterols that are potent repressors of cholesterol synthesis.[35,44,225,226]

Under normal conditions, the neutral pathway is still considered to be quantitatively the most important one for cholic acid synthesis in adults. Recent studies, however, now indicate that the acidic pathway contributes significantly to overall total bile acid synthesis, especially to chenodeoxycholic acid synthesis.[33,35] It has also become evident that the acidic pathway, although being developmentally induced in the rodent,[37] is possibly the most important one for bile acid synthesis in early human life.[9] This contention is based on the finding that an infant having a mutation in the oxysterol 7α-hydroxylase gene but a normal cholesterol 7α-hydroxylase gene failed to synthesize primary bile acids[9] and instead accumulated massive quantities of 24-hydroxy-, 25-hydroxy-, and 27-hydroxycholesterol. Although the sterol 27-hydroxylase directs intermediates into the acidic pathway, it is the subsequent 7α-hydroxylation that is the most important step in this pathway because

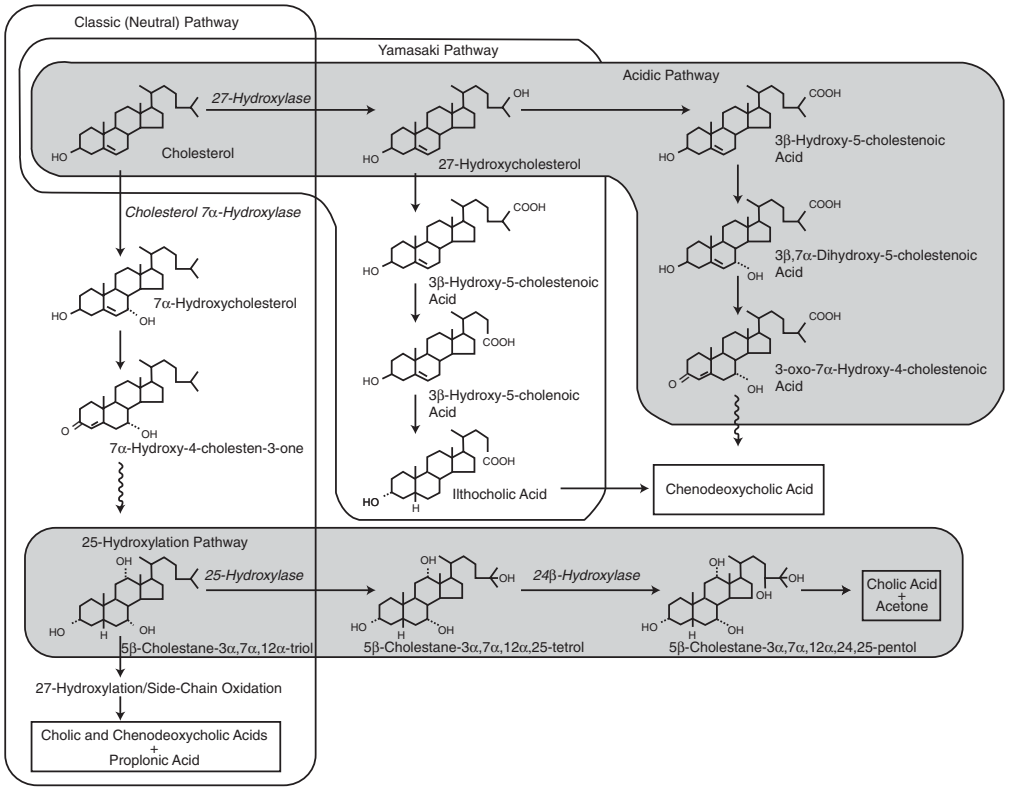

FIGURE 55.4-4 Alternative pathways for bile acid synthesis and their relationship to the classic "neutral" pathway.

it is essential to protect the liver from the toxicity of monohydroxy bile acids,[227–230] which would otherwise be formed if 7α-hydroxylation did not take place.[9]

For some time, it was evident that there were separate 7α-hydroxylases[33,231–233] and that bile acid synthesis via the acidic pathway was regulated differently and independently of the microsomal cholesterol 7α-hydroxylase.[35,50–52] The enzyme, referred to as oxysterol 7α-hydroxylase (*CYP7B1*), has a high activity in human liver,[233] but its regulation is not fully understood.[234,235] At least in the cholesterol 7α-hydroxylase (*CYP7A1*) knockout mouse, it is not affected by changes in the enterohepatic flux of cholesterol or bile acids induced by cholesterol or cholestyramine feeding.[236] It shows broad substrate specificity, being active on both 27- and 25-hydroxycholesterol[42,45,232,233] and 3β-hydroxy-5-cholenoic and 3β-hydroxy-5-cholestenoic acids.[231] The cDNA encoding the rat,[41] mouse,[235] and human[9,234] hepatic oxysterol 7α-hydroxylase (*CYP7B1*) has recently been reported. Translation of the human cDNA revealed the enzyme to have 506 amino acids, and there is a 56% and 66% homology with the rat and mouse enzymes, respectively.[9] The gene is localized to chromosome 8q21.3 and in close proximity to the gene encoding cholesterol 7β-hydroxylase (*CYP7A1*). Evidence for yet a further 7α-hydroxylase became apparent from studies of the *CYP7B1* knockout mouse,[237] which, unlike the human infant with a defect in this enzyme,[9] did not exhibit liver disease or accumulate to the same extent the oxysterols. This suggested that there was a third enzyme capable of 7α-hydroxylation, and, subsequently, *CYP39A1* was isolated[238] and shown to be active on 24-hydroxycholesterol. This enzyme is also present in humans, but its role is unclear.

The quantitative importance of the acidic pathway for bile acid synthesis has been hotly debated. When the cholesterol 7α-hydroxylase gene is knocked out in a mouse model, by 3 weeks of life, almost normal levels of bile acids are synthesized. This occurs following the developmental expression of the oxysterol 7α-hydroxylase.[37] In the rat, when cholesterol 7α-hydroxylase is chemically inhibited by continuous infusion of squalestatin, bile acid synthesis is still 43% of preinfusion levels after 24 hours.[36] These findings suggest that the acidic pathway accounts for about half of the total bile acid synthesis in the rodent. Under normal conditions, both the acidic and neutral pathways lead to the formation of cholic and chenodeoxycholic acids; however, it is suggested that 50% of the chenodeoxycholic acid synthesis is derived via this acidic pathway.[33]

As detailed above, side-chain oxidation proceeds with an initial C-27 hydroxylation and release of propionic acid; however, a pathway involving microsomal C-25 hydroxylation followed by 24-hydroxylation and release of acetone has been described. The cDNAs have been cloned of the cholesterol 25- and 24-hydroxylases,[239] and these enzymes have been found to play a key role in regulating lipid metabolism, particularly in the brain. The relative quantitative importance of this pathway to bile acid synthesis in healthy adults has been controversial.[144–146] Available evidence overwhelmingly supports 27-hydroxylation as the more important reaction initiating side-chain oxidation in normal humans.[240–242] This was confirmed in vivo by measuring the production of [^{14}C]acetone following prior labeling of the cholesterol pool with [26-^{14}C]cholesterol[145]; the 25-hydroxylation pathway accounted for less than 2% and 5% of the total bile acid synthesis in adult rats and humans, respectively.[145,146]

An alternative pathway for chenodeoxycholic acid synthesis[222] that is seemingly important in early life involves side-chain shortening prior to nuclear modifications, reactions that are initiated via a cholesterol C-27 hydroxylase.[34,210] In this pathway (often termed the Yamasaki pathway),[222] 27-hydroxycholesterol is oxidized directly to 3β-hydroxy-5-cholenoic acid, lithocholic acid, and, finally, chenodeoxycholic acid.[223,243–247] Although this pathway could be of minor importance in the adult, it may account for the increased levels of 3β-hydroxy-5-cholenoic and lithocholic acids in early life and in severe cholestatic conditions.

In many lower vertebrates, *allo*(5α-H)-bile acids are the major species of bile acids.[17,18] However, in humans, they are normally present in relatively small proportions and are generally believed to result from bacterial metabolism of 3-oxo-5β-bile acids during the course of their enterohepatic circulation. Studies of rodents have indicated that *allo*-bile acids may also be derived from 5α-cholestanol,[248,249] which can be efficiently 7α-hydroxylated in rat liver[250] and subsequently converted to 7α-hydroxy-5α-cholestan-3-one and then to 5α-cholestane-3α,7α-diol.[251] The 12α-hydroxylase enzyme shows a high specificity toward 5α-sterols,[252–254] and 5α-cholestane-3α,7α,12α-triol is readily formed from 5α-cholestane-3α,7α-diol and converted to *allo*-cholic acid in the bile fistula rat.[251]

A further mechanism for the formation of *allo*-bile acids involves their direct conversion from 7α-hydroxy-4-cholesten-3-one and 7α,12α-dihydroxy-4-cholesten-3-one by the action of an active Δ^4-3-oxosteroid 5α-reductase. The enzyme shows a three- to fourfold higher activity in female rats compared with male rats,[255] but no gender differences have been demonstrated for humans. The quantitative importance of this reaction in humans is uncertain. Large amounts of *allo*-bile acids are found in patients with a deficiency in the bile acid Δ^4-3-oxosteroid 5β-reductase.[7]

Intestinal microflora play an important role in bile acid metabolism[256] and therefore in the maintenance of the integrity of the enterohepatic circulation. Lithocholic (3α-hydroxy-5β-cholanoic) and deoxycholic (3α,12α-dihydroxy-5β-cholanoic) acids, the major bile acids excreted in feces,[32] are referred to as "secondary" bile acids. Both are formed from conjugated chenodeoxycholic and cholic acids by deconjugation and 7α-dehydroxylation, by enzymes found in a variety of organisms, such as *Bacteroides*, clostridia, bifidobacteria, and *Escherichia coli*. The mechanism by which 7α-dehydroxylation occurs has been extensively investigated by Hylemon, who purified a bile acid–CoA hydrolase from a strain of *Eubacterium* sp.[257] The dehydroxylation reaction involves a series of steps and appears to be initiated from the CoA thioester of the unconjugated bile acid but proceeds only following deconjugation.

Lithocholic acid is relatively insoluble and is consequently poorly absorbed from the intestinal lumen. It is found in relatively high proportions in meconium[258] and amniotic fluid[259,260] but is barely detectable in fetal bile.[21] In severe cholestatic conditions, deoxycholic acid levels in the serum become undetectable, and this bile acid is a useful marker of the extent of impairment of the enterohepatic circulation. Conversely, elevations in the serum unconjugated bile acid concentrations,[261] particularly secondary bile acids, reflect bacterial overgrowth of the small bowel.[262,263] Elevations in lithocholic acid sulfate, which occur in severe cholestasis,[264] demonstrate that lithocholic acid is also a primary product of hepatic synthesis and under such circumstances arises via the alternative pathways discussed previously.

BILE ACID SYNTHESIS DURING EARLY DEVELOPMENT

Knowledge of hepatic bile acid synthesis and metabolism during human development is limited and is derived largely from analysis of biologic fluids[21,265–271] and in vitro studies of the enzymes in fetal liver homogenates.[77,272–274] Ontogenic studies have been carried out in several animal species.[209,272,275–281] Detailed analytic studies of human fetal gallbladder bile[21,270] and in vitro studies of hepatic subcellular fractions[273,274] established significant qualitative and quantitative differences in bile acid synthesis and metabolism between the developing and adult liver. Because biliary excretion is the principal route for bile acid secretion, analysis of gallbladder bile permits a direct means of assessing hepatic synthesis and secretion.

The earliest studies of human fetal gallbladder bile used methodology less advanced than is currently available but nevertheless established primary bile acid synthesis to be relatively well developed during early gestation.[266,270] These early studies showed the concentration of chenodeoxycholic acid to be greater than cholic acid at midgestation, and primary bile acids were conjugated mainly with taurine. These findings were later corroborated using improved methodology, which confirmed that for humans, pathways for primary bile acid synthesis are developed as early as the twelfth week of gestation.[21] The activities of enzymes catalyzing 7α-hydroxylation, 12α-hydroxylation, side-chain oxidation, and conjugation of the primary bile acids and bile acid intermediates in homogenates of rat liver from rat embryos and suckling rats were found to increase 30-fold from day 15 after fertilization to day 5 of life.[275] Studies of preterm and older infants have found that the bile acid pool size is only one-sixth that of adults, and a rapid expansion of the pool occurs over the first year of life.[282–285] The chenodeoxycholic acid concentration in human fetal bile is relatively low in early gestation and exceeds the cholic acid concentration. This is in marked contrast to the biliary bile acid composition of the full-term infant and the adult, in whom cholic acid is the predominant bile acid.[265,267] Similar developmental differences in bile acid composition are found in amniotic fluid collected at different times of gestation.[260] There are several possible explanations for these differences: (1) cholic acid synthesis would be reduced in early life if there was an immaturity in hepatic 12α-hydroxylase activity; however, in vitro studies have established the activity of this enzyme to be relatively well developed[77,275]; (2) preferential clearance of cholic acid by metabolism to more polar C-1, C-2, C-4, or C-6 tetrahydroxylated bile acids would lead to a relative increase in the proportion of chenodeoxycholic acid; however, tetrahy-

droxy bile acids constitute less than 2% of the total biliary bile acids of the human fetus[21]; (3) chenodeoxycholic acid synthesis occurs via the C-27 hydroxylase pathway, which is under separate regulatory control and appears to be upregulated when the activity of cholesterol 7α-hydroxylase is low, as would be expected in utero. This latter explanation is most likely and would explain the increased amounts of monohydroxy bile acids found in meconium.[258]

A conspicuous feature of bile acid synthesis and metabolism during development is the relatively large proportion of a complex array of bile acids not typically found in adult bile.[20,21] Interestingly, the profile of biologic fluids of the newborn and fetus[20,21,270,286] resembles that observed for adult patients with severe cholestasis.[287,288] Analysis of human fetal gallbladder bile[21,270] and in vitro incubations of hepatic subcellular fractions with radiolabeled bile acids[273,274] has served to confirm the quantitative importance of several hepatic hydroxylation pathways, including C-6 and C-1 hydroxylation. Hyocholic acid (3α,6α,7α-trihydroxy-5β-cholanoic acid) is a major biliary bile acid of the fetus, and concentrations often exceed cholic acid concentrations,[21] whereas a series of C-1 hydroxylated isomers can also be found.[21,270]

1β-Hydroxylation has been demonstrated in vitro by human fetal microsomes,[273] and several C-1 hydroxylated bile acid isomers have been found in the urine of healthy adults[287] and infants,[286,289] in meconium,[2,20,258,268] and in biologic fluids from patients with liver disease.[288,290] A novel and prominent C-4 hydroxylation pathway was recently discovered and suggested to be unique to early human development.[21,271] 3α,4β,7α-Trihydroxy-5β-cholanoic acid was identified and found to account for 5 to 15% of the total biliary bile acids in early gestation.[271]

Newborn infants in the first few days of life excrete significant amounts of 3-oxo-Δ^4 bile acids, and this is indicative of an immaturity in bile acid synthesis.[286,291] The levels of these unsaturated bile acids typically decline rapidly in the first few months of life, but when high levels persist, a "primary" deficiency in the Δ^4-3-oxosteroid 5β-reductase enzyme should be suspected.[7] High levels of 3-oxo-Δ^4 bile acids are also associated with a severe loss of hepatic synthetic function, and differentiating the primary from the secondary deficiency in the Δ^4-3-oxosteroid 5β-reductase enzyme can be difficult.[8,121]

Secondary bile acids can be found in fetal bile but only in very small proportions. This is consistent with the lack of bacterial flora in the fetal gut and the maternal-fetal placental transport of secondary bile acids that has been demonstrated in vivo[277,278] and in vitro.[292]

The principal bile acid conjugation reaction of the fetal liver is amidation with taurine. In fetal bile, 85% of the total biliary bile acids are taurine conjugates,[21] which contrasts to the pattern for adult bile, for which the glycine-to-taurine ratio is approximately 3:1.20.[23] This reflects the increased accumulation and availability of taurine in the fetal liver[194] resulting from selective placental transport.[195]

Bile acid sulfates, which are generally increased in cholestatic conditions in adults,[264,287,293–295] are virtually absent in early gestation.[21] This probably reflects an immaturity in the bile acid sulfotransferase enzyme or may be a consequence of additional and preferential metabolism of bile acids by hydroxylation. Lithocholic acid sulfate and 3β-hydroxy-5-cholenoic acid sulfate are found in relatively large proportions in the meconium[258] and amniotic fluid[259,260,296] as a result of accumulation and sequestration during gestation.

Meconium also contains a series of short-chain monohydroxylated bile acids.[297–299] These compounds possess a steroid nucleus of 20-, 21-, and 22-carbon atoms and are predominantly found as glucuronide or sulfate conjugates.[214,299] In contrast to the monohydroxy-C_{24} bile acids, which are cholestatic, etianic acid (3α-hydroxy-5β-androstan-17β-carboxylic acid) produces a marked choleresis in the rat,[214] illustrating how relatively small changes to the structure of the steroid nucleus can cause marked differences in physiologic actions. The origin of short-chain bile acids is unknown, but their close similarity in structure to steroid hormones suggests that they may be metabolic end products of steroid hormones formed during pregnancy.

INBORN ERRORS IN BILE ACID SYNTHESIS

Disorders in bile acid synthesis and metabolism can be broadly classified as primary or secondary. Primary enzyme defects involve congenital deficiencies in enzymes responsible for catalyzing key reactions in the synthesis of cholic and chenodeoxycholic acids, and, to date, the following such defects have been described:

- Cholesterol 7α-hydroxylase (*CYP7A1*) deficiency leading to disturbances in lipid metabolism but not manifest as liver disease[300]
- 3β-Hydroxy-C_{27}-steroid dehydrogenase/isomerase (3β-hydroxy-C_{27}-steroid oxidoreductase) deficiency[6] involving the conversion of 7α-hydroxycholesterol into 7α-hydroxy-4-cholesten-3-one caused by mutations in the *HSD3B7* gene encoding this enzyme[97]
- Δ^4-3-Oxosteroid 5β-reductase deficiency[7] involving the cytosolic enzyme that catalyzes the reduction of the Δ^4-bond to give rise to a 5β-H and consequently the *cis*-configuration of the A/B rings of the bile acid nucleus
- Oxysterol 7α-hydroxylase deficiency[9] caused by a mutation in the gene encoding the enzyme catalyzing the 7α-hydroxylation of 27-hydroxycholesterol in the "acidic" pathway for bile acid synthesis
- CTX, a rare lipid storage disease[301] caused by mutations in the sterol 27-hydroxylase gene
- 2-Methylacyl-CoA racemase deficiency causing liver disease and fat-soluble vitamin malabsorption in early life[13] and late-onset sensory motor neuropathy in adults[155]
- Trihydroxycholestanoic acid CoA oxidase deficiency involving an initial step in the side-chain oxidation[10,12,302–305]
- An amidation defect involving a deficiency in the bile acid–CoA ligase, the rate-limiting enzyme for conjugation of cholic and chenodeoxycholic acids with glycine and taurine[11]

- Side-chain oxidation defect in the 25-hydroxylation pathway for bile acid resulting in an overproduction of bile alcohols[306]

Secondary metabolic defects that impact on primary bile acid synthesis include the following:

- The cerebrohepatorenal syndrome of Zellweger[307] and related disorders[308] involving enzymes responsible for β-oxidation of the side chain of cholestanoic acids, which result from abnormal peroxisomal assembly, structure, or function
- Mutations in the genes encoding organic anion transport proteins,[309,310] in particular progressive familial intrahepatic cholestasis (PFIC) type 1 or Byler disease, a familial and fatal progressive intrahepatic cholestatic syndrome
- RSH/Smith-Lemli-Opitz syndrome,[311] a disorder caused by a deficiency of Δ^7-desaturase that results in reduced cholesterol synthesis and therefore has a knock-on effect in the bile acid pathway by limiting the available supply of cholesterol

Hepatic synthesis of the primary bile acids cholic and chenodeoxycholic acids is critical to the development and maintenance of the enterohepatic circulation because of the pivotal role of bile acids in promoting the secretion of bile.[14] Progressive cholestatic liver disease is consequently a striking clinical manifestation of patients presenting with severely impaired primary bile acid synthesis, and this includes patients with both of the steroid nuclear defects and those patients with the more severe peroxisomopathies.[2,4,9,13,312] The recent identification of single-enzyme defects in side-chain oxidation and conjugation presenting as disorders of fat-soluble vitamin malabsorption or rickets[10,13] attests to the importance at the intestinal level of adequate concentrations of primary bile acids for lipid absorption.

The biochemical presentation of these bile acid synthetic defects includes a markedly reduced or complete lack of cholic and chenodeoxycholic acids in the serum, bile, and urine and greatly elevated concentrations of atypical bile acids and sterols that retain the characteristic structure of the substrates for the deficient enzyme. These signature metabolites are generally not detected by the routine or classic methods for bile acid measurement, and mass spectrometric techniques presently provide the most appropriate means of characterizing defects in bile acid synthesis. Screening procedures using liquid secondary ionization mass spectrometry (LSIMS) indicate that inborn errors in bile acid synthesis probably account for 2 to 5% of the cases of liver disease in infants, children, and adolescents, making this an important and specific category of metabolic liver disease.

PRIMARY ENZYME DEFECTS

Cerebrotendinous Xanthomatosis

CTX is a rare inherited lipid storage disease, first described by Van Bogaert and colleagues,[301] with an estimated prevalence of 1 in 70,000.[4] Characteristic features of the disease in adults include progressive neurologic dysfunction, dementia, ataxia, cataracts, and the presence of xanthomatous lesions in the brain and tendons; however, in infants, we have characterized this defect in a number of patients with neonatal cholestasis (K. D. R. Setchell, unpublished data, 2003). Biochemically, the disease can be distinguished from other conditions involving xanthomatous deposits by (1) significantly reduced primary bile acid synthesis; (2) elevations in biliary, urinary, and fecal excretion of bile alcohol glucuronides; (3) low plasma cholesterol concentration, with deposition of cholesterol and cholestanol in the tissues; and (4) marked elevations in cholestanol. Elegant studies by Salen and colleagues demonstrated the metabolic defect to be an impairment in oxidation of the cholesterol side chain,[313,314] and chenodeoxycholic acid synthesis is reduced to a greater extent than cholic acid synthesis.[315–317] Initially, it was thought to be due to a defect in sterol 24-hydroxylase,[313] but later studies indicated the primary defect to be a deficiency in the mitochondrial sterol 27-hydroxylase (Figure 55.4-5).[318] The following evidence supports this contention: (1) the mitochondrial fraction of the liver from a patient with CTX was shown to be completely devoid of sterol 27-hydroxylase activity[318]; (2) in liver homogenates, the amount of 5β-cholestane-3α,7α,12α-triol, the substrate for this enzyme, was 50-fold higher than normal[318]; (3) 27-hydroxycholesterol in the serum of patients with CTX is markedly reduced or undetectable[319]; (4) intravenous administration of radiolabeled precursors showed that only precursors with a C-27 hydroxy group were converted to cholic acid[318]; (5) the increased amounts of bile alcohol glucuronides synthesized in this defect are polyhydroxylated in the side chain and mainly at positions other than the C-27 carbon.

To explain the findings of greatly increased amounts of 5β-cholestane-3α,7α,12α,25-tetrol, Salen initially proposed a deficiency in microsomal 24(S)hydroxylation; this reaction normally yields 5β-cholestane-3α,7α,12α,24,25-pentol.[316] Studies using this radiolabeled cholestane-pentol showed that it was converted to cholic acid, indicating an alternative pathway to the classic C-27 hydroxylation pathway for cholic acid synthesis,[144,313] but the quantitative importance of this pathway in health has since been established to be relatively minor.[145,146] Furthermore, if the primary defect in CTX was a deficiency in 24(S)-hydroxylase, this would not explain the greatly reduced synthesis of chenodeoxycholic acid,[320] which, in humans, is synthesized in significant amounts via the C-27 hydroxylation pathway. A deficiency in sterol 27-hydroxylase, on the other hand, would lead to elevations in 5β-cholestane-3α,7α-diol and 7α-hydroxy-4-cholesten-3-one[321]; thus, these intermediates are available for 12α-hydroxylation and preferential conversion to cholic acid via the C-25 hydroxylation pathway.[322] Interestingly, microsomal 12α-hydroxylase activity has been shown to be threefold higher in patients with CTX.[317] Evidence reinforcing a sterol 27-hydroxylase deficiency as the primary enzyme defect in CTX was established following the cloning of the cDNA for

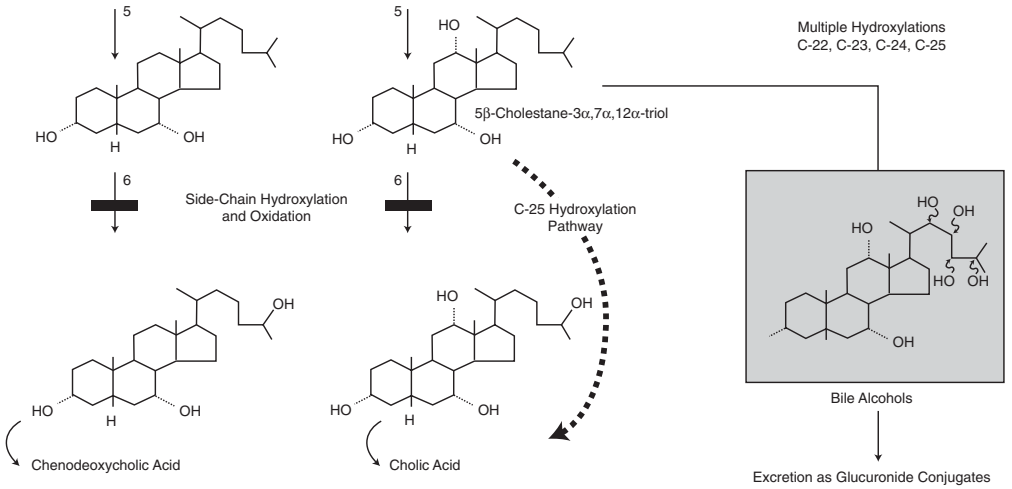

FIGURE 55.4-5 Biochemical defect in the sterol 27-hydroxylase deficiency of cerebrotendinous xanthomatosis.

this enzyme.[128,136,138,139] Using this probe, the mRNA was isolated from fibroblasts of two CTX patients, and the corresponding cDNA was synthesized by reverse transcription. Point mutations in the gene located on the long arm of chromosome 2 were identified and expressed in COS cells, and the resulting sterol 27-hydroxylase enzyme was found to be inactive.[139] These molecular studies clearly establish the primary defect in CTX to be due to a deficiency in the mitochondrial C-27 hydroxylase. In recent years, several types of mutations have been identified in CTX patients from different countries, and these include insertion, deletion, and point mutations.[323–344]

Impaired oxidation of the cholesterol side chain results in accelerated cholesterol synthesis and metabolism that leads to greatly increased production and excretion of bile alcohol glucuronides,[314,345–349] which can be readily detected in urine by fast atom bombardment ionization mass spectrometry (FAB-MS) (Figure 55.4-6).[2,350] These bile alcohols have the common 5β-cholestane-3α,7α,12α-triol nucleus, with additional hydroxyl groups in the side chain, mainly at the C-22, C-23, C-24, and C-25 positions (see Figure 55.4-5). The major bile alcohol excreted in bile and feces is the 5β-cholestane-3α,7α,12α,25-tetrol,[314,347,351,352] whereas the more polar 5β-cholestane-3α,7α,12α,23,25-pentol predominates in urine.[348,351,353] It has been suggested that the difference in these patterns could be due to more efficient renal excretion of the more polar pentol or a result of renal C-23 hydroxylation of 5β-cholestane-3α,7α,12α,25-tetrol.[351,352]

The elevation in 5α-cholestan-3β-ol (cholestanol) in the nervous system of CTX patients first observed by Menkes and colleagues[354] and the high plasma concentrations of this sterol[316] are unique features of the disease. An elevated plasma cholestanol-to-cholesterol ratio has been proposed to be diagnostic[355] but is not specific because elevations in this ratio also occur in liver disease. The origins of the increased cholestanol may be from elevations in the precursor sterol 4-cholesten-3-one; hepatic microsomes prepared from CTX patients have been shown to produce three times more 4-cholesten-3-one than similar preparations from healthy controls.[356] Using pulse-labeling techniques, Salen and colleagues showed that 4-cholesten-3-one would yield labeled cholestanol, whereas the corresponding 7α-hydroxyl intermediate was converted to bile acids.[356] An alternative pathway for the formation of cholestanol, not involving 7α-hydroxyl intermediates, was proposed implicating hepatic, rather than intestinal, 7α-dehydroxylation with the production of cholest-4,6-dien-3-one intermediate.[357,358] Evidence to support this pathway is the finding of increased levels of 7α-hydroxy-4-cholesten-3-one and cholest-4,6-diene-3-one in CTX and the observation that cholestyramine treatment, which stimulates cholesterol 7α-hydroxylase activity, increases cholestanol output, whereas the opposite response occurs during chenodeoxycholic acid feeding. The neurologic dysfunction observed in CTX appears to be a consequence of cholestanol deposition in the tissues, and because the sterol 27-hydroxylase is found in extrahepatic tissues, it is possible that some of the manifestations of the disease may be the result of nonhepatic perturbations in metabolism. Recent studies in a rat model indicate that cholestanol induces apoptosis of cerebellar neurons, and it was suggested that this could induce cerebellar ataxia in CTX patients.[359] Early diagnosis of this disorder, which is readily

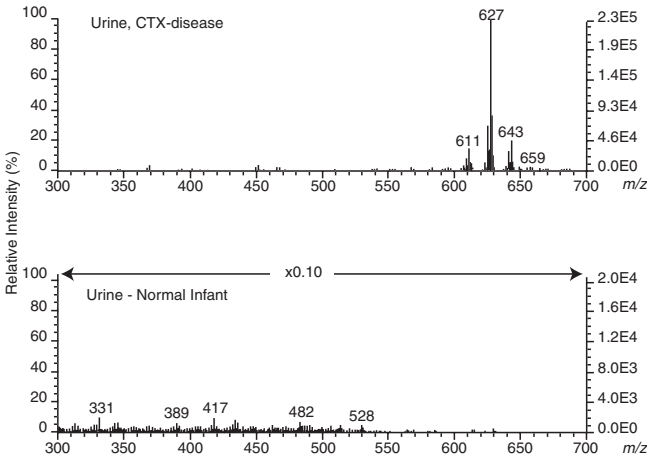

FIGURE 55.4-6 Negative-ion liquid secondary ionization–mass spectrometry mass spectra comparing the urine of a normal infant with that of a patient with cerebrotendinous xanthomatosis (CTX). The presence of increased levels of bile alcohol glucuronides is indicated by the specific ions at *m/z* 611, 627, 643, and 659.

achieved by mass spectrometry analysis of the urine, is crucial to prevent the progressive accumulation of cholestanol and cholesterol in tissues in the long term, but suspicion of a metabolic defect is not always realized because in the early years, the patients may be relatively asymptomatic. More recently, we have found a number of infants that had deficiencies in the sterol 27-hydroxylase owing to mutations in the gene encoding this enzyme but only because of a clinical presentation of elevated liver enzymes and bilirubin, which ultimately resolved by about 6 months of age presumably because the size of the cholic acid pool expanded with compensatory synthesis via the alternative 25-hydroxylation pathway. We suggest that this may be the typical early clinical presentation of CTX even though this has never been previously documented. The earliest age of diagnosis we have made was in a 1-day-old infant, which was made possible by the fact that this infant was born to a family that had a previous child with neonatal cholestasis that we had diagnosed with sterol 27-hydroxylase defect at 8 weeks of age.

3β-Hydroxy-C_{27}-Steroid Oxidoreductase Deficiency

This was the first metabolic defect to be described involving an early step in the bile acid biosynthetic pathway; the conversion of 7α-hydroxycholesterol is to 7α-hydroxy-4-cholesten-3-one, a reaction catalyzed by a 3β-hydroxy-C_{27}-steroid oxidoreductase. In response to a deficiency in this enzyme, 7α-hydroxycholesterol is metabolized by the remaining reactions, and the final products of hepatic synthesis are C_{24} bile acids that retain the 3β-hydroxy-Δ^5 structure characteristic of the enzyme substrates (Figure 55.4-7).[6] The index case was identified in a fifth child born to Saudi Arabian parents who were first cousins and was the third infant to be affected by progressive liver disease from birth; the previous infants had died within the first few years of life following similar clinical histories. Subsequently, a further infant with this defect was born to a first-cousin marriage in the kindred. The 3β-hydroxy-C_{27}-steroid oxidoreductase is the most common of all of the bile acid synthetic defects described thus far.

Although the clinical presentation of this disorder is somewhat heterogeneous, all patients generally present with progressive jaundice, elevated transaminases, and a conjugated hyperbilirubinemia.[6,58,59] Clinical features include hepatomegaly, with or without splenomegaly, fat-soluble vitamin malabsorption, and mild steatorrhea, and in most instances, pruritus is absent. The liver histology shows a generalized hepatitis, the presence of giant cells, and evidence of cholestasis.[6,58,360–362] Although the earliest cases were identified in infants, increasingly, idiopathic late-onset chronic cholestasis has been explained by this disorder.[58,59] In such patients, liver disease is not always evident in the early presentation, and many patients often have fat-soluble vitamin malabsorption and rickets, which are corrected with vitamin supplementation. Serum liver enzymes that are often normal in the early stages of the disease later show progressive increases. Serum bile acid concentrations when measured by conventional routine methods are normal or low and incompatible with the severity of liver dysfunction. However, urinary and serum bile acid concentrations are always elevated when determined by more specific techniques.

Of significance is the finding of a high association of this disease with a normal γ-glutamyl transpeptidase (Figure 55.4-8).[58,59,363] This is also a feature of patients with other conditions of familial progressive intrahepatic cholestasis or Byler disease,[364–367] but differential diagnosis of the two disorders can be readily made on the basis of the serum primary bile acid concentration, which, in the latter, is markedly elevated. Measurement of serum bile acids can be useful in establishing a diagnosis of inborn errors in bile acid synthesis and should be included in the workup of the patient with idiopathic cholestasis.

Definitive diagnosis of the 3β-hydroxy-C_{27}-steroid oxidoreductase deficiency presently requires mass spectrometric analysis of biologic fluids and is readily accomplished by LSIMS, formerly referred to as FAB-MS,[2,4,350] or by electrospray and tandem mass spectrometry.[368–371] LSIMS analysis of the urine permits the detection of the sulfate and glycosulfate conjugates of the 3β-hydroxy-Δ^5 bile acids that are the signature metabolites of this bile acid defect (Figure 55.4-9). Additionally, sulfate conjugates of tetrahydroxy-

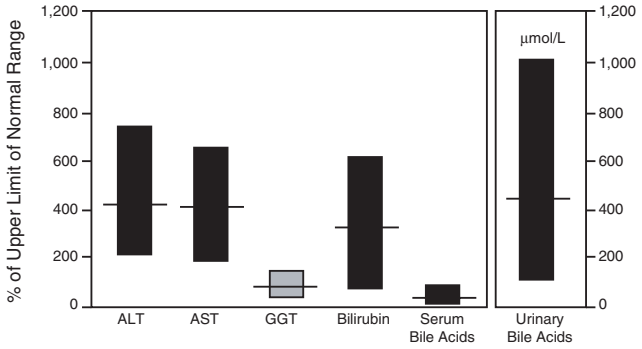

FIGURE 55.4-8 Summary of the mean and range of serum biochemistries in patients (n = 20) with the 3β-hydroxy-C_{27}-steroid oxidoreductase deficiency. ALT = alanine transaminase; AST = aspartate transaminase; GGT = γ-glutamyl transpeptidase.

and pentahydroxy-bile alcohols with a 3β,7α-dihydroxy-Δ^5 and 3β,7α,12α-trihydroxy-Δ^5 nucleus are also found in significant amounts in the serum and urine.[60]

Primary bile acids are not found in the urine but may be present in small amounts in the bile because of the action of a bacterial 3β-hydroxysteroid dehydrogenase/isomerase during the enterohepatic recycling of the atypical bile acids. This may explain the longer survival of these patients compared with patients with other defects in bile acid synthesis. Interestingly, 3β-hydroxysteroid dehydrogenase/isomerase isozymes are also involved in catalyzing analogous reactions in the pathways for steroid hormones, but steroid hormone synthesis and metabolism are unaffected in these patients. This is because the enzyme, which was recently purified, uses only intermediates that have a 3β-hydroxy-Δ^5 structure and is inactive on C_{19} and C_{21} steroids.[95]

Expression of the 3β-hydroxy-C_{27}-steroid oxidoreductase in fibroblasts affords a means of further establishing a deficiency in the activity of this enzyme. In contrast to healthy controls, patients with this defect have undetectable enzyme activity in fibroblasts, whereas the heterozygous genotypes have low or subnormal levels of activity.[102] However, this approach is somewhat redundant because molecular techniques that have led to the cloning of the *HSD3B7* gene encoding 3β-hydroxy-C_{27}-steroid oxidoreductase now permit the accurate genetic basis of the defect.[96] Using this approach to confirming the biochemical diagnosis of this enzyme deficiency in 15 patients from 13 kindreds, 12 different mutations were found to account for the disease.[97] The mechanism of cholestasis and liver injury is speculated to be the result of the failure to synthesize adequate amounts of primary bile acids that are essential to the promotion and secretion of bile and the increased production of unusual bile acids with hepatotoxic potential. The monohydroxy bile acid 3β-hydroxy-5-cholenoic acid has been shown to be markedly cholestatic in the rat and hamster,[229] and although 3β,7α-dihydroxy-5-cholenoic acid did not cause cholestasis in this latter species,[247] this may be explained by its metabolism to chenodeoxycholic acid. Recent studies using rat liver membrane vesicles have demonstrated that the taurine conjugate of 3β,7α-dihydroxy-5-cholenoic acid inhibits adenosine triphosphate–dependent bile acid transport at the canalicular plasma membrane and is not transported across this membrane.[15,372] These findings serve to explain the failure to find significant levels of bile acids in the bile of patients with the 3β-hydroxy-C_{27}-steroid dehydrogenase/isomerase defect and substantiate our initial theory that this is a cause of cholestasis.

Δ^4-3-Oxosteroid 5β-Reductase Deficiency

Application of LSIMS for urine analysis led to the discovery of a defect in the Δ^4-3-oxosteroid 5β-reductase, which catalyzes the conversion of the intermediates 7α-hydroxy-4-cholesten-3-one and 7α,12α-dihydroxy-4-cholesten-3-one to the corresponding 3-oxo-5β(H) intermediates (Figure 55.4-10).[7] The defect was initially identified in monochorionic male twins born with a marked cholestasis; a previous sibling with neonatal hepatitis had died of liver failure at 4 months of age. The clinical presentation of this defect is similar to that of patients with the 3β-hydroxy-C_{27}-steroid dehydrogenase/isomerase deficiency; however, in contrast, the γ-glutamyl transpeptidase is usually elevated, and the average age at diagnosis is lower in the Δ^4-3-oxosteroid 5β-reductase. The Δ^4-3-oxosteroid 5β-reductase has since been found in a number of patients presenting with neonatal hemochromatosis.[8] Liver function tests in these infants showed elevations in serum transaminase levels, marked conjugated hyperbilirubinemia, and coagulopathy. Liver biopsies[362,373] revealed marked lobular disarray as a result of giant cell and pseudoacinar transformation of hepatocytes, hepatocellular and canalicular bile stasis, and extramedullary hematopoiesis. On electron microscopy, bile canaliculi were small and sometimes slit-like in appearance and showed few or absent microvilli containing electron-dense material.[7]

Diagnosis of this defect is possible by LSIMS and gas chromatography–mass spectrometry (GC-MS) analysis of the urine. LSIMS spectra reveal elevated amounts of bile acids with molecular weights consistent with taurine con-

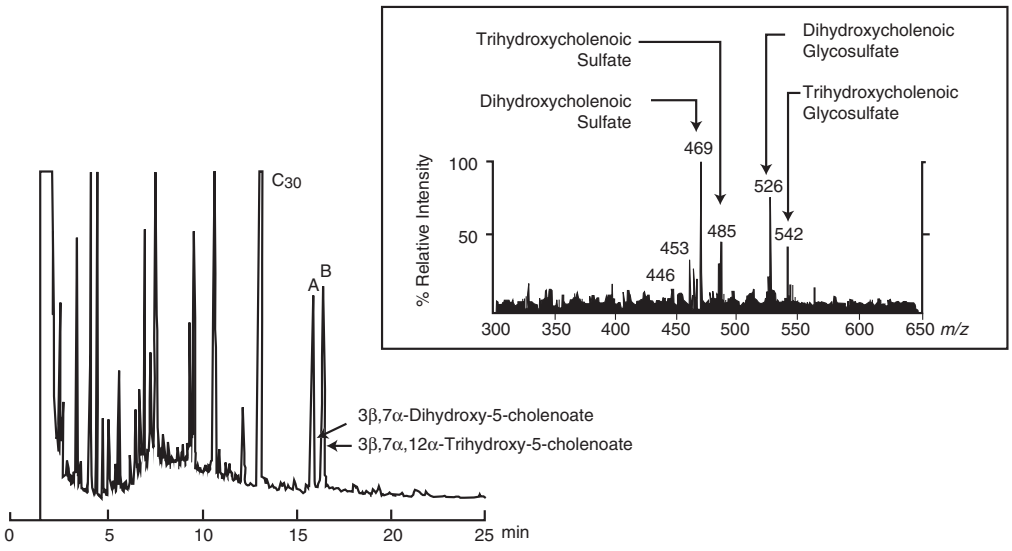

FIGURE 55.4-9 Negative-ion liquid secondary ionization–mass spectrometry mass spectrum and gas chromatography analysis of a typical urine from a patient with a 3β-hydroxy-C_{27}-steroid oxidoreductase deficiency.

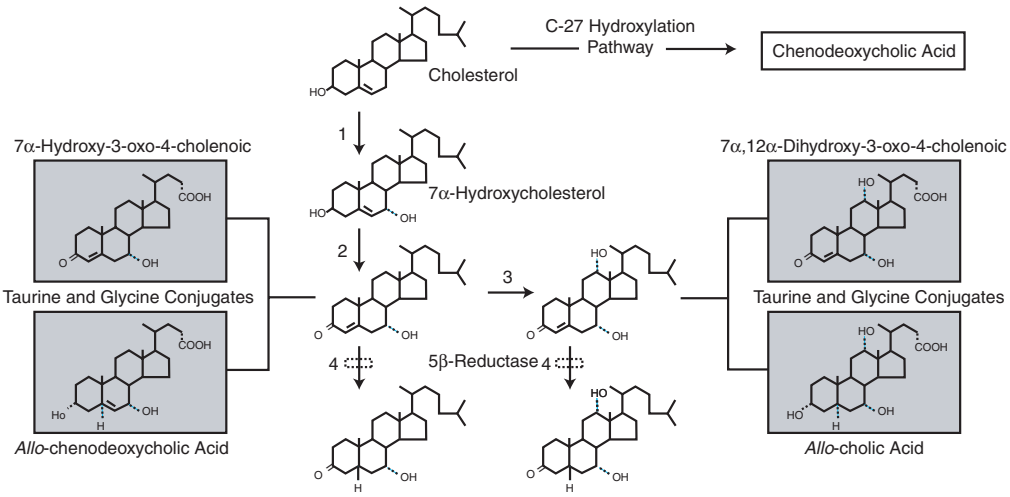

FIGURE 55.4-10 Biochemical defect in the Δ^4-3-oxosteroid 5β-reductase deficiency.

jugates of hydroxyoxocholenoic and dihydroxyoxocholenoic acids. GC-MS analysis following extraction, solvolysis, hydrolysis, and derivatization of bile acids[374] is essential to confirm the predominance of the major metabolites, 3-oxo-7α-hydroxy-4-cholenoic and 3-oxo-7α,12α-dihydroxy-4-cholenoic acids. Urinary bile acid excretion is generally elevated and consistent with a cholestatic condition. Quantitatively, the Δ^4-3-oxo bile acids comprise more than 75% of the total urinary bile acids. Gallbladder bile contains only traces (less than 2 μM) of bile acids, and because urinary excretion becomes the major route for bile acid loss, estimates of bile acid synthesis rates can be made from the daily urinary output and indicate markedly reduced total bile acid synthesis rates (less than 3 mg/d) compared with reported data for newborn infants[282] or adults.[375] In serum, relatively high concentrations of *allo*-chenodeoxycholic and *allo*-cholic acids are found, which lends support for an active hepatic Δ^4-3-oxosteroid 5α-reductase catalyzing the conversion of the Δ^4-3-oxo sterol intermediates to the corresponding 3α-hydroxy-5α(H) structures.

The Δ^4-3-oxosteroid 5β-reductase is exclusively of hepatic origin and, unlike the 3β-hydroxy-C_{27}-steroid dehydrogenase/isomerase, is not expressed in fibroblasts. Monoclonal antibodies raised against the rat cytosolic Δ^4-3-oxosteroid 5β-reductase have been used to demonstrate an absence of the 38 kD protein in a number of these patients and the formation of a truncated protein.[3] In one patient from Japan who met our previous biochemical criteria for a deficiency in this enzyme, sequence analysis of the gene revealed a single silent mutation in the coding region of the gene,[117] but the protein was normally expressed when analyzed by immunoblot of the liver homogenate using a monoclonal antibody.[376] Increased production of Δ^4-3-oxo bile acids occurs in patients with severe liver disease[121] and in infants during the first few weeks of life.[291] It is important to perform a repeat analysis of urine in the case of a suspected Δ^4-3-oxosteroid 5β-reductase deficiency because on rare occasions, a resolution of the liver disease occurs and the atypical bile acids disappear.[377] This is also the case with developmental immaturity. In general, however, it is our experience that markedly elevated levels of 3-oxo-Δ^4 bile acids are indicative of a poor clinical prognosis.

The liver injury in this defect is presumed to be the consequence of the diminished primary bile acid synthesis and the hepatotoxicity of the accumulated Δ^4-3-oxo bile acids. The lack of canalicular secretion can be explained by the relative insolubility of oxo-bile acids, and the cholestatic effects of the taurine conjugate of 7α-dihydroxy-3-oxo-4-cholenoic acid have been demonstrated in rat canalicular plasma membrane vesicles.[15] The unique morphologic findings in these patients[373] may indicate that maturation of the canalicular membrane and the transport system for bile acid secretion may require a threshold concentration of primary bile acids in early development.

Oxysterol 7α-Hydroxylase Deficiency

The recent discovery of a genetic defect in oxysterol 7α-hydroxylase[9] establishes the acidic pathway as a quantitatively important pathway for bile acid synthesis in early life. Unlike the mouse, in which this enzyme appears to be developmentally regulated,[37] or the rat, in which it is induced when there is suppression in cholesterol 7α-hydroxylase activity,[36] it would appear that in the human, the oxysterol 7α-hydroxylase may be more important than cholesterol 7α-hydroxylase for bile acid synthesis in early life. In common with the 3β-hydroxy-Δ^5 steroid-C_{27}-oxidoreductase deficiency[6] and the Δ^4-oxosteroid 5β-reductase deficiency,[7] this genetic defect presents as severe progressive cholestatic liver disease.

To date, this defect has been found in only one infant, a 10-week-old boy of parents who were first cousins, who presented with severe cholestasis, cirrhosis, and liver synthetic failure from early infancy. The patient became progressively jaundiced by 8 weeks of age and had markedly elevated serum transaminases and a normal serum γ-glutamyl transpeptidase. On examination, there was hepatosplenomegaly, and his liver biopsy revealed cholestasis, bridging fibrosis, extensive giant cell transformation, and proliferating bile ductules.[9] Oral UDCA therapy led to deterioration in liver function tests, and oral cholic acid was therapeutically ineffective. The patient subsequently underwent orthotopic liver transplant at $4^1/_2$

months of age, only to succumb to a disseminated Epstein-Barr virus–related lymphoproliferative disease.

Analysis of the urine by LSIMS revealed intense ions in the spectrum at mass-to-charge ratio (*m/z*) 453 and *m/z* 510, corresponding to sulfate and glycosulfate conjugates of 3β-hydroxy-5-cholenoic and 3β-hydroxy-5-cholestenoic acids (Figure 55.4-11). These accounted for 97% and 86% of the total serum and urinary bile acids, respectively, and primary bile acids were virtually undetectable. Monohydroxy bile acids with the 3β-hydroxy-Δ^5 structure have been previously shown to be extremely cholestatic.[229,230] Their hepatotoxicity in this patient is presumed to have been exacerbated by the lack of primary bile acids necessary for the maintenance of bile flow. Because the formation of 3β-hydroxy-5-cholenoic and 3β-hydroxy-5-cholestenoic acids occurs exclusively in the acidic pathway,[378] these findings and the observation that 27-hydroxycholesterol concentrations in serum and urine were more than 4,500 times normal support a defect in the oxysterol 7α-hydroxylase enzyme (Figure 55.4-12). Analysis of the neutral sterol fraction from serum and urine failed to demonstrate any 7α-hydroxysterols.

Molecular studies of the liver tissue established the cholesterol 7α-hydroxylase gene to be normal, but there was no measurable enzyme activity or mRNA; low or undetectable cholesterol 7α-hydroxylase activity has been previously reported for the human infant.[77] It is conceivable that gene expression may have been repressed by accumulation of the vast amounts of oxysterols. Oxysterol 7α-hydroxylase mRNA was also not present in this patient's liver tissue, and analysis of the oxysterol 7α-hydroxylase gene revealed a cytosine to thymidine transition mutation in exon 5 that converts an arginine codon at position 388 to a stop codon. The patient was homozygous for this nonsense mutation, whereas both parents were heterozygous.[9] When human embryonic 293 or Chinese hamster ovary cells were transfected with the cDNA with the R388* mutation, there was no detectable 7α-hydroxylase activity, and immunoblot analysis confirmed that the mutated gene encoded a truncated and inactive protein.

Unlike the other two nuclear defects in bile acid synthesis, the oxysterol 7α-hydroxylase deficiency is particularly severe and untreatable by primary bile acid therapy. It is possible that this cause of idiopathic liver disease may go unrecognized owing to its rapid downhill course in the early months of life. The characteristic metabolites formed in the genetic defect are some of the most cholestatic bile acids known, and, clearly, oxysterol 7α-hydroxylase is crucial for protecting the liver against the toxicity of monohydroxy bile acids produced in the acidic pathway. It is probable that our failure to find additional patients with this inborn error may be because of the devastatingly severe nature of this fatal liver disease, which does not respond to oral bile acid therapy, as in the other bile acid synthetic defects.[9]

2-Methylacyl-CoA Racemase Deficiency

2-Methylacyl-CoA racemase is a crucial enzyme that is uniquely responsible for the racemization of (25R)THCA-CoA to its (25S) enantiomer, while also performing the same reaction on the branched-chain fatty acid (2R)pristanoyl-CoA (Figure 55.4-13). Defects in this enzyme therefore have profound effects on both the bile acid and the fatty acid pathways. Mutations in the gene encoding 2-methylacyl-CoA racemase were first reported in three adults who presented with a sensory motor neuropathy[155] and later in a 10-week-old infant who exhibited severe fat-soluble vitamin deficiencies, hematochezia, and mild cholestatic liver disease in the first months of life.[13] This patient was initially and incorrectly reported in the previous edition of this book and elsewhere as having a possible THCA-CoA oxidase deficiency.[10] The infant had the same missense mutation (S52P) as that described in two of the adult patients yet was seemingly phenotypically quite different.[13] Two of the adult patients had neurologic symptoms but were asymptomatic until the fourth decade of life, whereas the other adult was described as having the typical features of Niemann-Pick type C disease at 18 months of age and presumably had some liver dysfunction. The clinical descriptions of these adult patients,[155] in particular the early history, were too scant to draw conclusions about the

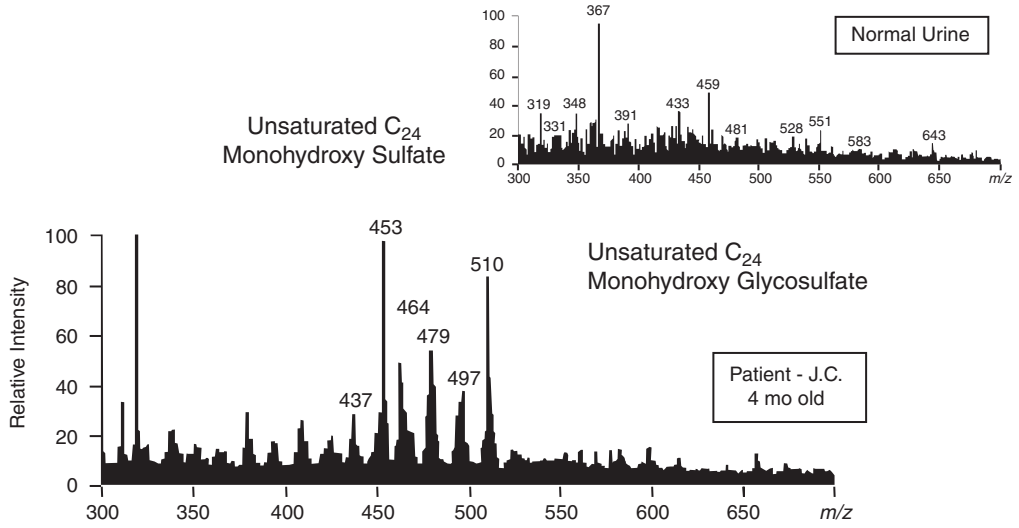

FIGURE 55.4-11 Negative-ion liquid secondary ionization–mass spectrometry mass spectra of the urine from a patient with the oxysterol 7α-hydroxylase deficiency and a normal age-matched infant. Ions characteristic of the signature metabolites of the defect are seen at *m/z* 453 and 510, corresponding to the sulfate and glycosulfate conjugates, respectively, of the monohydroxylated bile acid 3β-hydroxy-5-cholenoic acid.

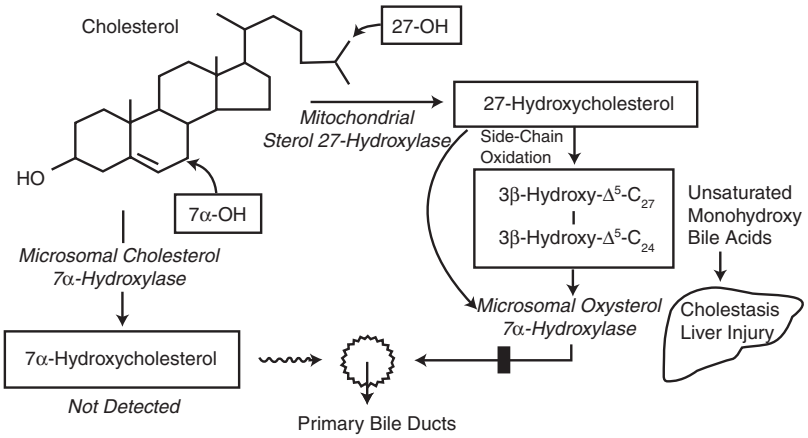

FIGURE 55.4-12 Biochemical basis for a defect in the oxysterol 7α-hydroxylase. Reproduced from Setchell KDR et al.[9]

phenotypic differences between the adult and the early presentation of the 2-methylacyl-CoA racemase. It is therefore possible that these adults could have had undocumented mild liver disease and fat-soluble vitamin absorption early in life and, if undiagnosed in infancy, would probably lead to a neuropathy owing to the tissue accumulation of phytanic and pristanic acids. Remarkable about the case of the first infant described with the 2-methylacyl-CoA racemase deficiency was the finding that the liver from a 5½-month-old sibling, who 2 years previously had died from an intracranial bleed, had been used for transplant in a child with end-stage liver disease.[13] Analysis of the urine from the recipient confirmed the same biosynthetic defect in the donor liver. Diagnosis of the defect in the infant was based on urinary, serum, and biliary bile acid analysis by FAB-MS, GC-MS, and electrospray ionization–tandem mass spectrometry, which revealed subnormal levels of primary bile acids and markedly increased concentrations of cholestanoic (C_{27}) acids, which are characteristically found as major bile acids of the alligator, other reptiles, and amphibians.[379,380] However, these cholestanoic acids were identified exclusively as the (25R)enantiomers.[13,381] The mass spectrum and GC profiles in this defect resemble closely those observed in peroxisomal disorders impacting bile acid synthesis, such as Zellweger syndrome; however, in other peroxisomopathies, both the (25S)THCA and (25R)THCA enantiomers are present, but the (25S)isomer predominates.[381] Differential diagnosis of the 2-methylacyl-CoA racemase deficiency from generalized peroxisomal disorders requires direct analysis of the urine or serum, omitting the use of destructive alkaline hydrolysis methods.[13,381] This is best achieved by high-performance liquid chromatography electrospray ionization–tandem mass spectrometry, which permits the separation and quantification of the two enantiomers of THCA,[382] which are otherwise difficult to measure by conventional techniques of bile acid analysis. Fibroblast studies can be used to further confirm a deficiency in peroxisomal 2-methylacyl-CoA racemase.[383] Incubation of cultured fibroblasts with the stereospecific (25R)THCA and (2R)pristanoic acid, the signature metabolites of this disorder, permits reduced activity of the enzyme to be established, although DNA sequencing would be the preferred approach to confirmation.

Primary bile acid therapy with cholic acid has proven effective in normalizing liver enzymes and preventing the onset of neurologic symptoms in the infant; additionally, dietary restriction of phytanic acid and pristanic acids is likely to be necessary in the long term for such patients to prevent neurologic symptoms owing to the brain accumulation of these fatty acids.

THCA-CoA Oxidase Deficiency

A number of patients have been reported to have side-chain oxidation defects involving the THCA-CoA oxidase.[12,302–305] The clinical presentation differs among these cases, and although all impact on primary bile acid synthesis, neurologic disease was the main clinical feature.[13] Whether these are primary bile acid defects or secondary to single-enzyme defects in peroxisomal β-oxidation is

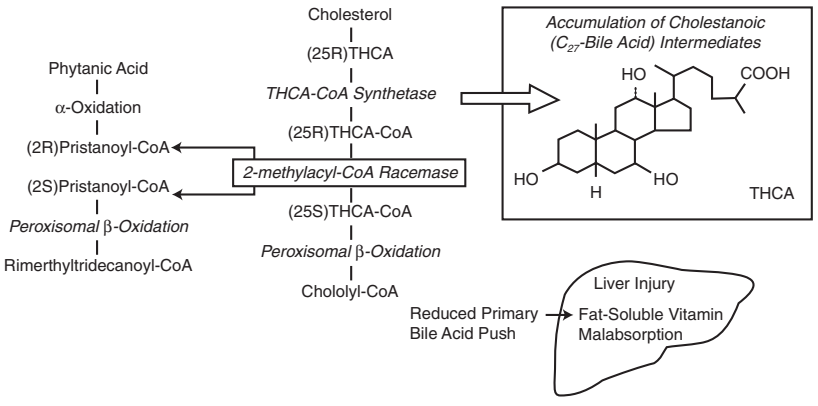

FIGURE 55.4-13 Biochemical defect in bile acid synthesis showing position of the enzyme deficiency in 2-methylacyl-CoA racemase and depicting its impact on the fatty acid and cholestanoic acid oxidation pathways. CoA = coenzyme A; THCA = 3α,7α,12α-trihydroxy-5β-cholestanoic acid.

unclear. Two distinct acyl-CoA oxidases have been identified in humans,[156] whereas the rat has three isozymes.[384] The human acyl-CoA oxidase active on bile acid C_{27} cholestanoic acid intermediates has been found to be the same enzyme that catalyzes the oxidation of 2-methyl branched-chain fatty acids.[156] The cDNA of the gene encoding this human enzyme has been cloned.[161] Of the case reports in the literature of the proposed THCA-CoA oxidase deficiency, interestingly, phytanic and pristanic acids, when measured, were elevated.[12,302–305] All had ataxia as a primary feature of the disease, with its onset occurring at about $3^1/_2$ years of age. None had evidence of liver disease. It is possible, with the exception of the patient described by Clayton and colleagues,[306] that these patients had a 2-methylacyl-CoA racemase deficiency, but the analysis of the cholestanoic acids was not sufficiently detailed to permit the diastereoisomers of THCA and 3α,7α-dihydroxy-5β-cholestanoic acid (DHCA) or pristanic acid to be measured, which would have helped in the differential diagnosis. In the case of the patient reported by Clayton and colleagues, we were able to obtain urine, serum, and bile for analysis by electrospray ionization–tandem mass spectrometry, and the major enantiomer of THCA in this patient was found to be the (25S) isomer, therefore excluding the 2-methylacyl-CoA racemase as an explanation for the clinical presentation.[306] It is evident that the phenotypic presentation of defects involving the peroxisomal apparatus can present with a wide diversity in symptoms that make it difficult to pinpoint the exact defect involved. In all suspected cases, analysis of peroxisomal enzymes, pristanic and phytanic acids, VLCFAs, and plasmalogens should be performed to complement detailed bile acid analysis.

Bile Acid CoA Ligase Deficiency and Defective Amidation

The final step in bile acid synthesis involves conjugation with the amino acids glycine and taurine.[23] Hepatic conjugation is extremely efficient, and negligible amounts of unconjugated bile acids typically appear in bile under normal and cholestatic conditions[385] and also when large doses of an unconjugated bile acid such as UDCA are administered.[386] Two enzymes catalyze the reactions leading to amidation of bile acids. In the first, a CoA thioester is formed by the rate-limiting bile acid–CoA ligase, after which glycine or taurine is coupled in a reaction catalyzed by a cytosolic bile acid–CoA:amino acid *N*-acyltransferase. A defect in bile acid amidation, presumed to involve the bile acid–CoA ligase, was described in three patients presenting with fat and fat-soluble vitamin malabsorption.[11]

The index case was a 14-year-old boy of Laotian descent who, in the first 3 months of life, presented with conjugated hyperbilirubinemia, elevated serum transaminases, and normal γ-glutamyl transpeptidase. This child also had a form of β-thalassemia. Two other patients, a 5-year-old Saudi Arabian boy and his 8-year-old sister, who were products of a consanguineous marriage, have since been diagnosed. In early life, the boy had undergone a Kasai procedure for a mistakenly diagnosed biliary atresia. The girl was asymptomatic at the time of diagnosis, and there was little clinical history available. Liver function tests were either normal or mildly elevated at the time of diagnosis. The primary manifestation of a bile acid conjugation defect is severe fat-soluble vitamin malabsorption with rickets, and in one patient, this had led to a fracture. All had subnormal levels of vitamin E, vitamin K, 25-hydroxyvitamin D, and 1,25-dihydroxyvitamin D.

The diagnosis was based on the LSIMS analysis of the urine and serum and bile, which revealed unique negative-ion spectra featuring a major peak of mass (*m/z* 407) corresponding to unconjugated cholic acid (Figure 55.4-14). In addition, ions characterizing sulfate and glucuronide conjugates of dihydroxy and trihydroxy bile acids were present. There was a complete lack of the usual glycine and taurine conjugated bile acids, and this was confirmed after chromatographic separation and GC-MS. Serum and urinary bile acids were markedly elevated and comprised predominantly cholic and deoxycholic acids. Attempts to identify bile acid–CoA esters yielded negative data, suggesting that the likely point of defective bile acid amidation was rate-limiting bile acid–CoA ligase.[174,177–179] All of these patients have been lost to follow-up, making it impossible to ascertain the molecular genetics of the defect despite the fact that the cDNAs for both conjugating enzymes have been cloned.[181,188]

The clinical presentation and biochemical features of defective amidation in these patients closely parallel the presentation and features hypothesized by Hofmann and Strandvik.[387] Whereas the previously described inborn errors in bile acid synthesis present as well-defined progressive familial cholestatic liver diseases,[6,7,9] in contrast, cholestasis does not occur in this amidation defect because the synthesis of unconjugated cholic acid provides sufficient stimulus for bile flow. The fat-soluble vitamin malab-

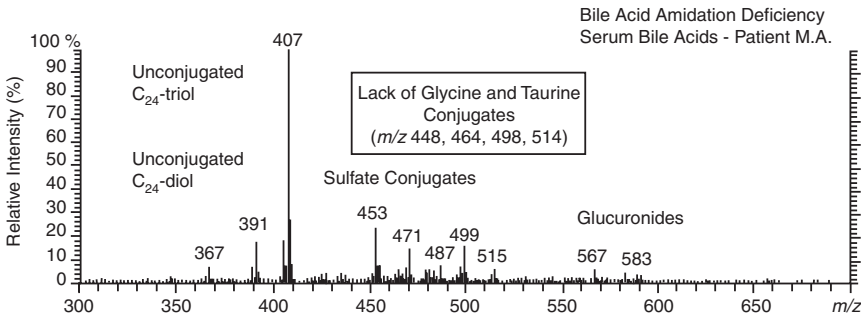

FIGURE 55.4-14 Negative-ion liquid secondary ionization–mass spectrometry mass spectrum of the serum from a patient with a defect in the bile acid-CoA ligase leading to deficient amidation of bile acids. The major ion at *m/z* 407 indicates the presence of unconjugated cholic acid.

sorption in these patients is postulated to be the result of reduced biliary secretion of bile acids and the inability to form mixed micelles because of rapid passive absorption of unconjugated cholic acid in the proximal small intestine.[388] Although these patients did conjugate bile acids with glucuronic and sulfuric acids, these conjugated bile acids are of little help in promoting lipid absorption.[389–391] Administration of primary conjugated bile acids should provide a therapeutic approach to correcting the fat-soluble vitamin malabsorption in this defect, and the recognition that genetic defects in bile acid synthesis are associated with fat-soluble vitamin malabsorption warrants a more concerted effort to explore this type of patient population.

Side-Chain Oxidation Defect in the Alternate 25-Hydroxylation Pathway

A speculative diagnosis of a defect in side-chain oxidation in the 25-hydroxylation pathway[144–146] was proposed by Clayton and colleagues for a 9-week-old infant presenting with familial giant cell hepatitis and severe intrahepatic cholestasis.[306] The rationale for the diagnosis was based on the finding of reduced cholic and chenodeoxycholic acids in the serum, concomitant with high concentrations of bile alcohol glucuronides, specifically 5β-cholestane-3α,7α,12α,24-tetrol, 5β-cholest-24-ene-3α,7α,12α,24-tetrol, and 5β-cholestane-3α,7α,12α,25-tetrol. These bile alcohols are not normally found in the plasma of infants with liver disease. Bile alcohol glucuronides were also identified as major metabolites in the urine.[306] Although the profile resembled that seen in CTX patients, it was concluded on the basis of the liver disease (not previously reported for CTX) that this represented a different side-chain defect and that it was possibly an oxidation defect downstream of the 25-hydroxylation step in this minor pathway for bile acid synthesis. The implications of the findings are that it could indicate that the 25-hydroxylation pathway, considered of negligible importance in adults,[146] may be an important pathway for infants. This is speculation, and further studies to prove the exact site of the defect are required before this is convincing. The patient was, however, treated with chenodeoxycholic acid and cholic acid, and this led to a normalization in serum transaminases and a suppression in the production of bile alcohols.

Cholesterol 7α-Hydroxylase Deficiency

Several patients have recently been identified with a homozygous mutation deletion in the *CYP7A1* gene, and when the cDNA of this mutant was expressed in vitro in cultured HEK 293 cells, cholesterol 7α-hydroxylase was found to be inactive.[300] Bile acid synthesis was reduced, and up-regulation of the alternative sterol 27-hydroxylase pathway presumably compensated for the reduced synthesis of bile acids via absent cholesterol 7α-hydroxylase activity. Three patients carrying this mutation were found to have abnormal lipids, but, in contrast to an infant identified with a mutation in oxysterol 7α-hydroxylase,[9] there was no evidence for abnormal liver function in these patients. Instead, the clinical phenotype was one of markedly elevated total and low-density lipoprotein (LDL) cholesterol and premature gallstones in two patients and premature coronary and peripheral vascular disease in one patient. The elevated serum cholesterol concentration was unresponsive to HMG-CoA reductase inhibitor therapy. Interestingly, individuals who were shown to be heterozygous for this mutation were found to have an above normal level of serum cholesterol. The phenotype of this deficiency in cholesterol 7α-hydroxylase differed significantly from that expressed in the *CYP7A1* knockout mouse model.[37] It is possible that *CYP7A1* deficiency predisposes the patient to cholesterol gallstone disease and seems to account for abnormal lipids but, surprisingly, not to liver disease. The important role of *CYP7A1* in the regulation of lipids is further supported by earlier studies showing that a number of polymorphisms in the *CYP7A1* gene were associated with abnormal LDL cholesterol concentrations in the general population.

SECONDARY BILE ACID DEFECTS

Disorders of Peroxisomal Function

Genetic defects involving peroxisomes include the cerebrohepatorenal syndrome of Zellweger[307] and related diseases. Excellent reviews describe the clinical and biochemical features of these disorders[308,392–395]; consequently, the following text focuses only on the impact of these diseases on bile acid synthesis (see Chapter 55.8, "Zellweger Syndrome and Other Disorders of Peroxisomal Metabolism").

The peroxisomopathies can be broadly subdivided into two main groups. Those syndromes in which there is a generalized impairment in numerous peroxisomal functions as a consequence of a markedly reduced or undetectable number of peroxisomes include Zellweger syndrome,[307,392,396] infantile Refsum disease,[397] neonatal adrenoleukodystrophy,[398] hyperpipecolic acidemia,[399] and rhizomelic chondrodysplasia punctata,[400] and these conditions share many similarities in their clinical presentation and neurologic manifestation. These include severe hypotonia, psychomotor retardation, hepatomegaly, simian crease, craniofacial dysmorphism, and failure to thrive. Genetic diseases involving a single-enzyme defect and a normal number of peroxisomes[401–403] include pseudo-Zellweger syndrome,[403] which shows many clinical and pathologic similarities to Zellweger syndrome.

Only those disorders with a generalized impairment in peroxisomal function have been found to have abnormal bile acid synthesis reflected by an accumulation of bile acid precursors. Although both the mitochondrial and microsomal fractions were originally shown to convert THCA into cholic acid, the peroxisomal fraction was later found to have the highest capacity for this reaction.[164] For this reason, elevated levels of trihydroxycoprostanoic (THCA) and dihydroxycoprostanoic (DHCA) acids are consistently found in the biologic fluids of patients with Zellweger syndrome, neonatal adrenoleukodystrophy, pseudo-Zellweger syndrome, and infantile Refsum disease (Figure 55.4-15). Interestingly, these long-chain C_{27} bile acids are not found in rhizomelic chondrodysplasia punctata,[400] and to our knowledge, there appear to have been no studies of bile acid metabolism in hyperpipecolic acidemia[399] and acatalasemia.[404] The presence of

other bile acid precursors is not uncommon, and it is possible that earlier descriptions of increased proportions of bile acid precursors in children with intrahepatic biliary atresia may have been due to the failure to recognize milder variants of Zellweger syndrome.[405,406] The in vivo and in vitro capacity of the liver to convert bile acid precursors into cholic and chenodeoxycholic acids by patients with Zellweger syndrome was studied by Kase and colleagues.[164,242,407] Tritiated 7α-hydroxy-4-cholesten-3-one was rapidly converted to DHCA and THCA but only slowly converted to cholic and chenodeoxycholic acids, with only 10% conversion after 48 hours, whereas cholic acid and chenodeoxycholic acid pool sizes and synthesis rates were markedly reduced. These data confirmed a defect in side-chain cleavage of the cholestanoic acid precursors and highlighted the important role of the peroxisome in bile acid synthesis.[408] Frequently, levels of DHCA are lower than THCA, which may be accounted for by its rapid transformation by 12α-hydroxylation to THCA.[409] Despite the reportedly low bile acid synthesis rate,[242] many studies have shown normal or increased serum levels of primary bile acids in patients with peroxisomal disorders. This may be a consequence of impaired hepatic uptake of bile acids because of generalized hepatic dysfunction.

In addition to DHCA, THCA, and varanic acid (the C-24 hydroxylated derivative of THCA), other atypical bile acids have been identified in Zellweger syndrome. C_{29} dicarboxylic acid is a major component of the serum (see Figure 55.4-15),[410,411] and although not always present, it can account for up to 40% of the total serum bile acids in Zellweger syndrome and infantile Refsum disease.[192,242,410,412–414] The biosynthetic pathway leading to the production of this unusual bile acid is uncertain. Administration of tritiated 5β-cholestane-3α,7α,12α-triol and THCA to a patient with Zellweger syndrome showed only a slow conversion to the C_{29} bile acid; however, its accumulation in serum may be accounted for by its relatively poor renal clearance and biliary excretion. Monohydroxy C_{27} bile acids also found in the serum of patients with Zellweger syndrome include 3α-hydroxy-5β-cholestanoic and 3β-hydroxy-5-cholestenoic acids.[410,415] In contrast to other cholestatic conditions, only low concentrations of 3β-hydroxy-5-cholenoic acid have been reported in the serum and urine of three patients with Zellweger syndrome.[410]

Perhaps not surprisingly, in view of the predominance of 1β- and 6α-hydroxylation pathways in early life,[21,270] the urine of these patients usually contains large proportions of 1β- and 6α-hydroxylated tetrahydroxycholestanoic acids that are mainly conjugated with taurine.[192] These more polar metabolites arise from the accumulated THCA and DHCA, and this metabolic pathway consequently facilitates the urinary excretion of these metabolites. These specific urinary metabolites are of diagnostic significance for the Zellweger and pseudo-Zellweger syndromes and can be recognized by LSIMS from the intense ion of *m/z* 572 corresponding in mass to the taurine conjugated tetrahydroxycholestanoic acids.[192]

Of the well-defined single-enzyme defects, X-linked adrenoleukodystrophy,[416–418] involving the VLCFA acyl-CoA synthetase, and pseudoneonatal adrenoleukodystrophy,[419] a defect in the VLCFA-CoA oxidase, both show normal bile acid synthesis and highlight the fact that there are separate isozymes for this common reaction sequence. Pseudo-Zellweger syndrome, a defect of the thiolase,[170,412] and a deficiency in the multifunctional protein[420] are conditions that present with abnormal bile acid synthesis.[421] A number of isolated examples of patients in whom there is impaired β-oxidation of bile acids have been reported, but the exact defects were not defined. With improvements in methodologies[422] and the advantage of molecular probes to identify the enzymes and sequence genes, it is expected that further defects will be delineated.

Defects in Canalicular Bile Acid Transport Proteins

In the last decade, tremendous strides have been made in the understanding of the mechanisms behind bile formation and the transport of organic anions across the hepatocyte.[423,424] Full details of these advances are in Chapter 55.6, "Billary Transport," and in an excellent summary by Trauner and colleagues.[425] It is outside the scope of this

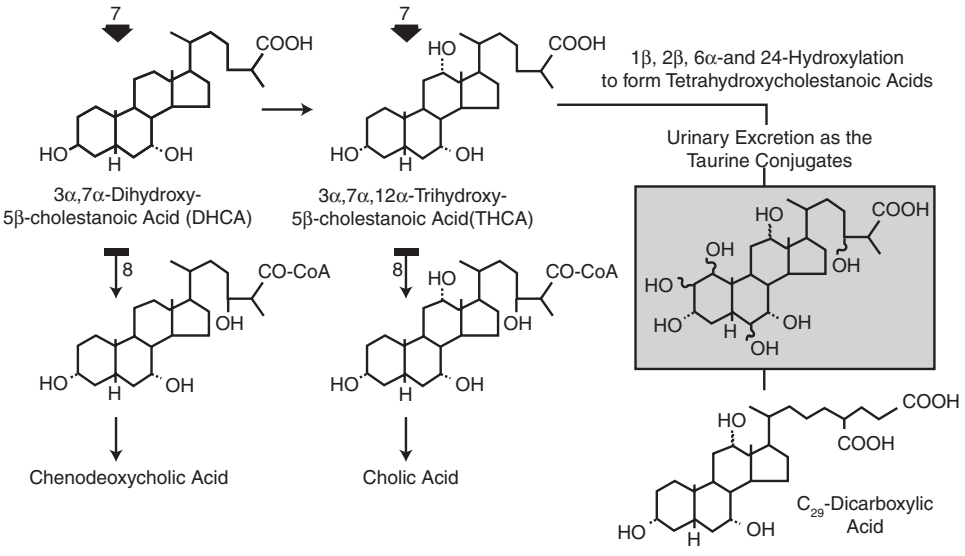

FIGURE 55.4-15 Biochemical defect in the cerebrohepatorenal syndrome of Zellweger.

review to detail the voluminous work on transport proteins and their role in cholestasis, and the reader is directed to an excellent summary by Trauner and colleagues.[425] Bile acids play a critical role in providing the major driving force for the promotion and secretion of bile, and defects in bile acid synthesis will inevitably cause cholestasis. In recent years, familial cholestasis has also been associated with mutations in the genes encoding the transport proteins for organic anions.[310,426,427] In the context of bile acid synthesis, patients with Byler disease (now classified as PFIC type 1) are of interest. This is an autosomal recessive familial progressive intrahepatic cholestasis[364,428] that has been shown to be due to a mutation in the *FIC1* gene encoding a P-type adenosine triphosphatase.[309] Some of the clinical features of PFIC are shared with bile acid synthetic defects, most notably the low γ-glutamyl transpeptidase.[59,367,429] However, they are easily differentiated because, unlike primary bile acid synthetic defects, patients with PFIC type 1 do synthesize primary bile acids, albeit in suboptimal levels. A striking feature of the bile from patients with PFIC type 1 is the negligible amount of chenodeoxycholic acid present, even though cholic acid is secreted, indicating impaired canalicular secretion of this dihydroxy bile acid.[430] In contrast, serum and urinary bile acids are composed of large proportions of chenodeoxycholic acid and its 6α-hydroxylated metabolite hyocholic acid.[367,429,431] 6α-Hydroxylation of bile acids is not, however, specific for PFIC type 1 because hyocholic acid can be found in biologic fluids from patients with other cholestatic diseases and is a characteristic of early development. Activation of this P-450 enzyme is presumed to occur in response to increases in intracellular chenodeoxycholic acid concentrations. Biochemical confirmation of this specific bile acid transport defect is by analysis of duodenal or biliary bile for the ratio and concentration of the primary bile acids.

RSH/Smith-Lemli-Optiz Syndrome

Since publication of the previous edition of this book, there has been an expansive literature on the RSH/Smith-Lemli-Optiz syndrome covering clinical features and variants, biochemical presentation, pre- and postnatal diagnosis, and the molecular genetics of this syndrome. It is beyond the scope of this review to detail all of these studies, and the reader is directed to the articles cited here and references therein. RSH/Smith-Lemli-Optiz syndrome is an autosomal recessive disease with an estimated frequency of 1 in 20,000 to 40,000.[4] The clinical characteristics of this syndrome are highly variable but include dysmorphism, microcephaly; poor growth; limb abnormalities; cardiac, renal, and endocrine abnormalities; cataracts; mental retardation; and early death.[311,432–434] It is considered the second-most common genetic defect in the North American white population. Biochemically, the condition is characterized by markedly reduced plasma cholesterol concentrations and elevated concentrations of 7-dehydrocholesterol and isodehydrocholesterol, and these Δ^7 sterols, which are normally not present, are the major neutral sterols of tissue, plasma, and feces.[435–437] The condition is accounted for by a defect in the 7-dehydrocholesterol Δ^7-reductase (7-DHC), an enzyme that catalyzes the final reaction in the formation of cholesterol.[438] 7-DHC has the highest activity in the adrenal glands and the liver.[439] The defect can be reproduced in an animal model using a drug (BM 15.766), a competitive inhibitor of 7-DHC.[440] The 7-DHC gene has been cloned for the human[439,441,442] and rat[443] enzymes and is localized on chromosomes 11q13 and 7F5, respectively. It encodes a 55 kD protein,[439] and a number of missense, nonsense, and splice-site mutations have been described.[432 ,444] Although this is a primary defect in cholesterol biosynthesis, it impacts on bile acid synthesis because the available supply of cholesterol is reduced, and Δ^7 sterols are poor substrates for 7α-hydroxylation; consequently, bile acid synthesis is markedly reduced.[436]

Diagnosis and Treatment of Inborn Errors in Bile Acid Synthesis

A battery of techniques is available for the measurement of bile acids in biologic fluids, and these have been compiled and extensively reviewed in the book series *The Bile Acids*[1] and elsewhere.[445–447] Technologic advances have meant that techniques such as paper and thin-layer chromatography have largely become superseded by extremely sensitive and specific assays. Immunoassays[448] are commonly used in routine laboratories because of their high sensitivity, precision, and suitability for handling large numbers of samples but presently lack the specificity for detecting specific inborn errors in bile acid metabolism. High-performance liquid chromatography is a useful tool[449,450] but, owing to its limited sensitivity, particularly with ultraviolet detection, is best suited to the analysis of the principal amidated species of biliary bile acids and has limited value in measuring the lower concentrations of bile acids in serum. Improvements in sensitivity have been achieved by pre- or postcolumn reactions,[447,449] coupling with thermospray,[450] or electrospray ionization–mass spectrometry.[451,452]

Accurate identification of inborn errors in metabolism requires techniques that afford detailed metabolic profiles, and, for the moment, GC-MS continues to be the principal confirmatory analytic tool.[446,453,454] Because of the high cost, technical difficulty, and time-consuming nature of bile acid analysis by GC-MS, the technique is outside the scope of most routine clinical laboratories. For this reason, the diagnosis of patients with inborn errors in bile acid synthesis has proven difficult and probably accounts for the low reported incidence of such metabolic defects.

Perhaps the most significant advances in mass spectrometry in recent years have been the introduction of FAB-MS and electrospray mass spectrometry, both of which are referred to by the generic term LSIMS. These techniques greatly simplified and extended the scope of mass spectrometry so that many nonvolatile compounds can be analyzed rapidly and directly in biologic samples or simple crude extracts, thereby circumventing the need for extensive and time-consuming sample pretreatments. Intact bile acid conjugates are ideally suited to LSIMS, and negative ionization mass spectra of steroid and bile acid conjugates can be generated from microliter volumes of urine and blood.[2,192,350,370,446,451–456]

In healthy individuals, urinary bile acid excretion is of negligible quantitative importance; consequently, the mass spectrum obtained is unremarkable, showing only background ions from the matrix and the presence of some steroid hormone metabolites. During cholestasis, urinary bile acid excretion increases and bile acid conjugates can be readily detected by the presence of single intense ions corresponding to the pseudomolecular ($[M\text{-}H]^-$) ions. With cholestasis, and in the absence of an inborn error in bile acid synthesis, the ions corresponding to the glyco- and tauroconjugates of the primary bile acids appear in the mass spectrum, and the intensity of the ions is proportional to the degree of cholestasis.[2] When bile acid synthesis is impaired, a unique mass spectrum is obtained, revealing ions corresponding in mass to the accumulated intermediates and/or metabolites with structural characteristics of the substrates proximal to the enzyme block. Positive identification of these bile acids generally requires GC-MS analysis after prior hydrolysis of the conjugates and preparation of volatile derivatives, and this is a time-consuming technique. Positional or stereoisomers of bile acid conjugates can be differentiated if reaction chemistry is carried out in a tandem mass spectrometer, and useful collision-dissociated spectra can be obtained.[369,457–460] The potential for rapid screening of bile acid defects has been realized with the electrospray ionization–mass spectrometry, and bile acid metabolites can be detected in dried blood spots obtained from newborns for the Guthrie test.[370] This approach allows fast throughput of samples for screening, but definitive diagnosis of suspected inborn errors in bile acid synthesis is still likely to be complemented with GC-MS and, for the moment, will be restricted to specialist laboratories. Now that many of the genes encoding the enzymes involved in bile acid synthesis have been cloned, the application of molecular techniques to sequence DNA from patients identified by mass spectrometry as having bile acid synthetic defects is an important complementary tool and should prove of value in prenatal diagnosis in these familial diseases.

Early diagnosis of inborn errors in bile acid synthesis is important because, untreated, these conditions are inevitably fatal. The reduced or total lack of synthesis of primary bile acids, coupled with the overproduction of large amounts of atypical bile acids and sterols that have intrinsic hepatotoxicity,[15,228,372] results in a clinical course leading to fibrosis, cirrhosis, and liver failure in most patients with the steroid nuclear defects.[6,7,9] The possibility of bile acid synthetic defects in older children, and even some adults with idiopathic forms of liver disease, should also be considered given that many cases of 3β-hydroxy-C_{27}-steroid oxidoreductase have been found in older children and teenagers presenting with late-onset chronic cholestasis.

We now appreciate that the inability to synthesize primary bile acids may clinically manifest as a fat-soluble vitamin malabsorption syndrome that can cause rickets in the absence of symptomatic liver disease. Again, treatment with primary bile acids is important in these conditions because it will facilitate the absorption of vitamins A, D, E, and K while also staving off cholestatic liver disease in the longer term. The rationale for using primary bile acids, rather than UDCA, which is commonly prescribed for cholestatic liver diseases, is threefold. Primary bile acids provide a stimulus for bile flow and will generate a choleresis. Primary bile acids, unlike UDCA, down-regulate cholesterol 7α-hydroxylase, the rate-limiting enzyme for bile acid synthesis, thereby limiting further production and accumulation of hepatotoxic atypical bile acids. Also, primary bile acids will facilitate the absorption of fats and fat-soluble vitamins by providing adequate intraluminal bile acid concentrations.

The earliest experience with feeding a primary bile acid was for the treatment of CTX,[56,57] even though this is not a condition that is manifest as liver disease. Long-term treatment with chenodeoxycholic acid (750 mg/d) normalized plasma cholestanol concentrations,[56,461] markedly reduced the urinary excretion of bile alcohols,[2,57,348] and improved the clinical condition.[461–463] Similar suppression of endogenous synthesis of cholestanol and bile alcohols occurs with cholic acid and deoxycholic acid administration.[57] UDCA, which is unable to down-regulate cholesterol 7α-hydroxylase, is ineffective in CTX.[57,461] The improvement in the biochemical and clinical status of CTX patients treated with chenodeoxycholic acid is the result of marked suppression in endogenous bile acid synthesis mediated by the negative feedback on hepatic cholesterol 7α-hydroxylase and HMG-CoA reductase, the latter enzyme being rate controlling for cholesterol synthesis. Treatment of these patients may be more effective if bile acid is combined with an HMG-CoA reductase inhibitor because this combination has a greater effect in lowering plasma cholestanol.[464,465]

Oral bile acid therapy was found to be an effective means of treating patients with the 3β-hydroxy-C_{27}-steroid oxidoreductase (Figure 55.4-16) and the Δ^4-3-oxosteroid 5β-reductase deficiencies.[58,60,466] The first patient diagnosed with the 3β-hydroxy-C_{27}-steroid oxidoreductase deficiency was treated with chenodeoxycholic acid (125–250 mg/d), with remarkable results.[60] Serum liver enzymes and bilirubin normalized, and there was an improvement in clinical symptoms. However, one concern with chenodeoxycholic acid therapy, particularly for patients with liver disease, is that it can cause increases in serum transaminases and symptoms of diarrhea, as was documented when it was used for gallstone dissolution. For patients with preexisting liver disease, chenodeoyxcholic acid alone is a less desirable option. We subsequently chose to treat patients with cholic and ursodeoxycholic acids in combination or with cholic acid alone. The therapeutic dose of bile acid is somewhat empiric and has been based on the ability to significantly suppress the continued production of the atypical bile acids that are monitored by LSIMS. In general, the dose administered is in the range of 10 to 15 mg/kg body weight/d. UDCA has proven helpful for some patients with the 3β-hydroxy-C_{27}-steroid oxidase deficiency, lowering serum transaminases and improving liver histology.[59] However, it does not suppress the synthesis of atypical 3β-hydroxy-Δ^5 bile acids, which, over the long term, is important given that these bile acids are cholestatic and interfere with canalicular bile acid transport.[15,372] When UDCA was

used in combination with cholic acid, it was our experience that the effectiveness of cholic acid in down-regulating endogenous bile acid synthesis was reduced, and this we believe is because UDCA during its enterohepatic recycling competitively inhibits the ileal uptake of cholic acid. Based on our experiences to date, we recommended that these patients be treated with cholic acid alone.

We have learned that it is almost impossible to completely shut down hepatic bile acid synthesis by feeding orally primary bile acids. Nevertheless, significant down-regulation occurs, sufficient to markedly reduce the signature atypical metabolites of the inborn error. Concomitant with this effect is an improvement in liver function tests, clinical symptoms, and liver histology.[373] In several patients, significant morphologic changes in the fine ultrastructure were noted. Electron micrographs of the canaliculi of patients with the Δ^4-3-oxosteroid 5β-reductase indicate significant abnormalities, including a loss of the usual microvillus structure and electron-dense material within and around the canaliculi. After bile acid therapy, electron microscopy showed a normalization in morphology with a disappearance of the electron-dense material,[373] suggesting that a threshold level of primary bile acids may be essential for normal morphologic development of canalicular structure.

The success of this therapeutic approach for patients with these two defects[58–60,466] is evident from the few treatment failures, and several patients have avoided the need for orthotopic liver transplant even though they were waitlisted for a donor liver. One notable failure was the treatment of the only patient found to have a mutation in the oxysterol 7α-hydroxylase gene.[9] Cholic acid therapy was unable to down-regulate the synthesis of the oxysterols and hepatotoxic 3β-hydroxy-Δ^5-monohydroxy bile acids, and this patient eventually underwent transplant.[9] Although cholic acid treatment should be considered potentially beneficial for patients with an oxysterol 7α-hydroxylase deficiency because it will provide a pool of primary bile acid, it is crucial to concomitantly inhibit the sterol 27-hydroxylase to protect the liver from the toxicity of the monohydroxy bile acids that are synthesized.

Oral bile acid therapy has been used to treat the liver disease associated with some of the peroxisomal disorders affecting side-chain oxidation of bile acids. Its success, however, has been hampered by the multiorgan involvement of these conditions, but it can be helpful in managing some of the symptoms of the disease. Peroxisomal proliferating drugs such as clofibrate[467,468] have proved to be of no therapeutic value. The progressive liver disease in peroxisomopathies is probably the result of the increased synthesis and accumulation of C_{27} bile acids combined with reduced primary bile acid synthesis. Infusion of tauro-THCA in rats, for example, has been shown to induce red cell hemolysis and to produce hepatic lesions showing mitochondrial disruptions similar to those found in patients with Zellweger syndrome.[469] Down-regulation in endogenous synthesis of C_{27} bile acids, as occurs with primary bile acid administration, was found to improve serum liver enzymes and bilirubin in one patient with Zellweger syndrome, even though the patient eventually succumbed with pulmonary failure.[470] Liver histology showed a reduction in the extent of bile duct proliferation and inflammation, and a significant improvement in neurologic symptoms occurred after initiating bile acid therapy with cholic acid.[470] It is probable that cholic acid may be of greater benefit to patients with single-enzyme defects involving bile acid synthesis by preventing liver disease in the longer term. One patient with the 2-methylacyl-CoA racemase deficiency has now been on therapy for 7 years, and this has served to correct the abnormally low serum fat-soluble vitamin levels.

Finally, what can be offered to patients with a bile acid conjugation (amidation) defect?[11] In these cases, they are able to make unconjugated bile acids, mostly cholic acid, yet they fail to absorb fat-soluble vitamins. Restoring the conjugated bile acid pool seems logical, and this is possible by administration of a conjugated bile acid such as taurocholate or glycocholate. Alternatively, cholylsarcosine may also be helpful because this has been shown to improve fat absorption in a patient with short-bowel syndrome.[471] The limited availability of these primary bile acids and their conjugated forms remains a major problem that needs to be addressed for the clinic.

SUMMARY

Inborn errors in bile acid synthesis represent a specific category of metabolic liver disease. These disorders have a significant effect on gastrointestinal physiology and function because of the key role that bile acids play in maintaining the enterohepatic circulation and in facilitating the absorption of fats and fat-soluble vitamins. At the Cincinnati Children's Hospital Medical Center, almost 4,000 cases of idiopathic liver disease have been screened in the last 15 years for bile acid synthetic defects, and more than 100 patients have been identified with defects, accounting for 2 to 3% of the cases of unexplained liver disease in infants and children. Early diagnosis is important because the liver disease and fat-soluble vitamin malabsorption associated with these inborn errors can be successfully treated medically, thereby avoiding the only alternative of orthotopic liver transplant in what are otherwise progressive and fatal conditions when undiagnosed or untreated.

5. Bilirubin Metabolism

Glenn R. Gourley, MD

Many diseases are associated with elevations of the serum bilirubin level. This chapter focuses on conditions in which hyperbilirubinemia results from a primary abnormality in the metabolism of bilirubin, whereas other liver disease is absent (Tables 55.5-1 and 55.5-2). These conditions must be distinguished from many other conditions in which hyperbilirubinemia is a secondary phenomenon caused by such things as primary liver disease, hematologic abnormalities, or infection. To understand and remember these primary defects in the metabolism of bilirubin, it is helpful to approach them from the viewpoint of the normal route by which bilirubin is metabolized and cleared from the circulation. Thus, this chapter begins by presenting the three hepatic steps necessary for clearance of bilirubin: (1) hepatocyte uptake of bilirubin from the sinusoid, (2) enzymatic conjugation of bilirubin within the endoplasmic reticulum of the hepatocyte, and (3) secretion of bilirubin conjugates out of the hepatocyte via the canalicular membrane. Defects in these metabolic steps result in the disorders described in this chapter. Recent reviews exist.[1–3]

BILIRUBIN MEASUREMENT

Serum bilirubin measurements are very common, being made in 61% of term newborns.[4] The two components of total serum bilirubin routinely measured in the clinical laboratory are conjugated bilirubin ("direct" reacting in van den Bergh test in which color develops directly without adding methanol) and unconjugated bilirubin ("indirect"). Together these components comprise the total bilirubin. Although the terms direct and conjugated bilirubin are often used as synonyms, this is not always quantitatively correct because the direct fraction includes both conjugated bilirubin and delta bilirubin.[5] Delta bilirubin results spontaneously when the conjugated bilirubin is elevated and a covalent bond is formed with albumin. Delta bilirubin is metabolized with albumin (half-life approximately 22 days), thus potentially prolonging jaundice when other liver function tests are improving. Serum bilirubin measurement has long been known to have significant interlaboratory variability,[6,7] and a variety of methods exist.[5,8,9] The Jendrassik-Grof procedure is very popular, although it is not without problems.[10] Two newer methods use high-performance liquid chromatography (HPLC)[11] and multilayered slides.[12] Analysis with HPLC is the acknowledged "gold standard" but too costly for a routine clinical laboratory.[5] Analysis with automated multilayered slide technology (Kodak Ektachem/Vitros, Johnson & Johnson Clinical Diagnostics, Rochester, NY) is currently used in some clinical laboratories and allows measurement of specific conjugated and unconjugated bilirubin fractions

TABLE 55.5-1 COMPARISON OF DISORDERS OF UNCONJUGATED HYPERBILIRUBINEMIA

	GILBERT SYNDROME	CRIGLER-NAJJAR TYPE 1	CRIGLER-NAJJAR TYPE 2
Prevalence	3%	Rare	Rare
Inheritance	Autosomal dominant or recessive	Autosomal recessive	Autosomal recessive, rarely dominant
Genetic defect	*UGT1A1* gene	*UGT1A1* gene	*UGT1A1* gene
Hepatocyte defect site	Microsomes ± plasma membrane	Microsomes	Microsomes
Deficient hepatocyte function	Glucuronidation ± uptake	Glucuronidation	Glucuronidation
BUGT activity	5–53% of controls	Severely decreased	2–23% of controls
Hepatocyte uptake	Decreased in 20–30%	Normal	Normal
Serum total bilirubin level (mg/dL)	0.8–4.3	15–45	8–25
Serum bilirubin decrease with phenobarbital (%)	70	0	77
HPLC serum bilirubin composition:			
Fraction (Normal %)			
Unconjugated (92.6)	98.8	~ 100	99.1
Diglucuronide (6.2)	1.1	0	0.6
Monoglucuronide (0.5)	0	0	0
Bile bilirubin conjugates:			
Fraction (Normal %)			
Diglucuronide (~ 80)	60	0 to trace	5–10
Monoglucuronide (~ 15)	30	Predominant if measurable	90–95
Other routine liver function tests	Normal	Normal	Normal
Prognosis	Benign	Kernicterus common	Occasional kernicterus

BUGT = bilirubin uridine diphosphate glucuronosyltransferase; HPLC = high-performance liquid chromatography.

TABLE 55.5-2 COMPARISON OF DISORDERS OF CONJUGATED HYPERBILIRUBINEMIA

	ROTOR SYNDROME	DUBIN-JOHNSON SYNDROME
Prevalence	Rare	Rare
Inheritance	Autosomal recessive	Autosomal recessive
Genetic defect	Unknown	MRP2 (cMOAT) gene
ABCC2		
Hepatocyte defect site	GST	Apical canalicular membrane
Deficient hepatocyte function	Intracellular binding of bilirubin and conjugates	Canalicular secretion of bilirubin conjugates
Brown-black liver	No	Yes
Serum total bilirubin level (mg/dL)	2–7	1.5–6.0
Serum conjugated bilirubin (%)	> 50	> 50
Other routine liver function tests	Normal	Normal
Oral cholecystogram	Usually visualizes	Usually does not visualize
^{99m}Tc- HIDA cholescintigraphy		
Liver	Poor to no visualization	Intense, prolonged visualization
Gallbladder	Poor to no visualization	Delayed or nonvisualization
Sulfobromophthalein clearance test	Serum sulfobromophthalein levels elevated (delayed clearance)	Serum sulfobromophthalein levels normal at 45 min but elevated at 90–120 min
Indocyanine green clearance test	Delayed clearance	Normal
Response to estrogens or pregnancy	No change	Increased jaundice
Total urinary coproporphyrin excretion (isomers I + III)	2.5–5 times increased	Normal
Urinary coproporphyrin isomer I composition (%) (normal = 25%)	Usually < 80% of total	> 80% of total
Prognosis	Benign (asymptomatic)	Benign (occasional abdominal complaints; probably incidental)

ABCC2 = ATP-binding cassette, subfamily C (CFTR/MRP), member 2 (cMOAT); cMOAT = canalicular multispecific organic anion transporter; GST = glutathione *S*-transferase; MRP2 = multidrug resistance–associated protein 2; ^{99m} Tc-HIDA = technetium 99m hepatobiliary iminodiacetic acid.

without inclusion of delta bilirubin. Noninvasive point of care methods for transcutaneous bilirubin measurement continue to develop. At present, two such methods are available in the United States: BiliCheck (Respironics, Pittsburgh, PA)[13] and Jaundice Meter (Minolta/Air Shields, Air-Shields Vickers, Hatboro, PA).[14]

BILIRUBIN CLEARANCE

Hepatocyte Uptake

The architecture of the liver is important for hepatic uptake of bilirubin. Cords of hepatocytes are arranged radially so that adjacent sinusoids border all hepatocytes and allow uptake of bilirubin by individual hepatocytes. Portal venous pressure rather than arterial pressure generates slow sinusoidal flow of blood. Albumin-bound bilirubin from the plasma passes into the tissue fluid space (space of Disse) between the endothelium and the hepatocyte. This is facilitated by the lack of basal laminae, which are found in other organ capillary systems.[15,16] The pores of the endothelium allow direct contact with the plasma membrane of the hepatocyte.

A schematic illustration of hepatic bilirubin metabolism is shown in Figure 55.5-1. Bilirubin dissociates from albumin[17] and can enter the hepatocyte via a membrane receptor-carrier. Carrier-facilitated transport into the hepatocyte has been demonstrated for organic anions such as bilirubin, sulfobromophthalein (Bromsulfphthalein), and indocyanine green.[18] Recently, bilirubin has also been shown to be able to pass through membranes by simple passive diffusion.[19] Bilirubin, sulfobromophthalein, and indocyanine green are believed to share the same hepatocyte receptor-carrier because they exhibit competitive inhibition when injected simultaneously. Subsequent intrahepatic metabolism of these anions is quite different and therefore cannot explain their competitive inhibition: bilirubin undergoes microsomal glucuronidation, sulfobromophthalein undergoes cytosolic conjugation with glutathione, and indocyanine green is excreted directly without biotransformation. Rat hepatocyte data suggest that the receptor-carrier is a dimeric protein with a subunit molecular weight of 55,000.[20–22] Additional supportive data regarding this receptor-carrier include antibody studies showing the expected plasma membrane location[21] and demonstrating blockage of uptake.[22]

Differences in protein binding inside and outside the hepatocyte necessitate carrier-mediated transport of bilirubin. Outside the hepatocyte, bilirubin is bound to albumin (affinity constant ~ 10^8; concentration 0.6 mM).[23] Inside the hepatocyte, bilirubin is bound to glutathione *S*-transferase B (GST; also known as ligandin or the Y protein; affinity constant ~ 10^6; concentration 0.04 mM).[24,25] GST consists of a family of proteins that can function both as enzymes and as intracellular binding proteins for nonsubstrate ligands such as bilirubin.[26] GST binds both bilirubin and bilirubin conjugates and decreases reflux from the hepatocyte back into plasma.[27]

Conjugation

Inside the hepatocyte, bilirubin enters the endoplasmic reticulum (microsomes), where it is conjugated with glucuronic acid.[28] Uridine diphosphate glucuronic acid (UDPGA) is the glucuronic acid donor. Conjugation disrupts the intracellular hydrogen bonding (Figure 55.5-2A) by forming an ester linkage with one or both of the propionic acid side chains on the

B and C pyrrole rings of bilirubin (Figure 55.5-2B). Bilirubin uridine diphosphate glucuronosyltransferase (BUGT; Online Mendelian Inheritance in Man [OMIM] *191740; < http://www.ncbi.nlm.nih.gov/Omim/>) is the enzyme responsible for this esterification. Other glucuronosyltransferase isoforms catalyze the conjugation of thyroxine, steroids, bile acids, and xenobiotics.[29–33] The lipid environment of BUGT is important in determining enzyme activity. In vitro assays of BUGT can use different methods to perturb this lipid environment and thus greatly affect measured BUGT activity. A permease has been hypothesized to facilitate the transport of UDPGA from the cytosol across the lipid layers to the interior of the endoplasmic reticulum, where BUGT is located. The existence of a permease has been proposed because UDPGA is the preferred donor for bilirubin conjugation, despite the observation that uridine diphosphate glucose (UDPG) is present in the cytosol at higher concentrations.[34] Uridine diphosphate *N*-acetylglucosamine can increase in vitro BUGT activity threefold and is therefore considered to be a physiologic regulator of BUGT.[35] It is speculated that the mechanism for this involves facilitation of the permease UDPGA transporter.[36] Following conjugation, UDP can be converted to uridine and inorganic pyrophosphate by a nucleoside diphosphatase in the interior of the endoplasmic reticulum,[37] thus preventing the reverse reaction.

The specific isoform responsible for bilirubin conjugation is UGT1A1 (trivial name HUG-Br1, EC 2.4.1.17).[38] This is part of the UDP glycosyltransferase superfamily of enzymes encoded by the *UGT1* gene complex on chromosome 2 (Figure 55.5-3).[39] The *UGT1* gene encodes several isoforms and has a complex structure consisting of four common exons (2–5) and 13 variable exons encoding different isoforms.[40] During transcription, messenger ribonucleic acid from each variable exon 1 is spliced to exon 2 and the intervening ribonucleic acid is excised. The variable exons impart substrate specificity, whereas the common exons determine the UDPGA binding site and the membrane spanning region of the enzyme. More than 30 different *UGT1* mutant alleles have been described that cause Gilbert syndrome (GS) and Crigler-Najjar syndrome types I and II.[41] UGT1A1 catalyzes the formation of both bilirubin mono- and diglucuronides.[42–46] In normal human adults, bilirubin conjugates are excreted in the bile mainly as bilirubin diglucuronides (~ 80%) (Figure 55.5-4) with lesser amounts of bilirubin monoglucuronides (~ 15%) and very small amounts of unconjugated bilirubin and other bilirubin conjugates (eg, glucose, xylose, and mixed diesters).[47–52]

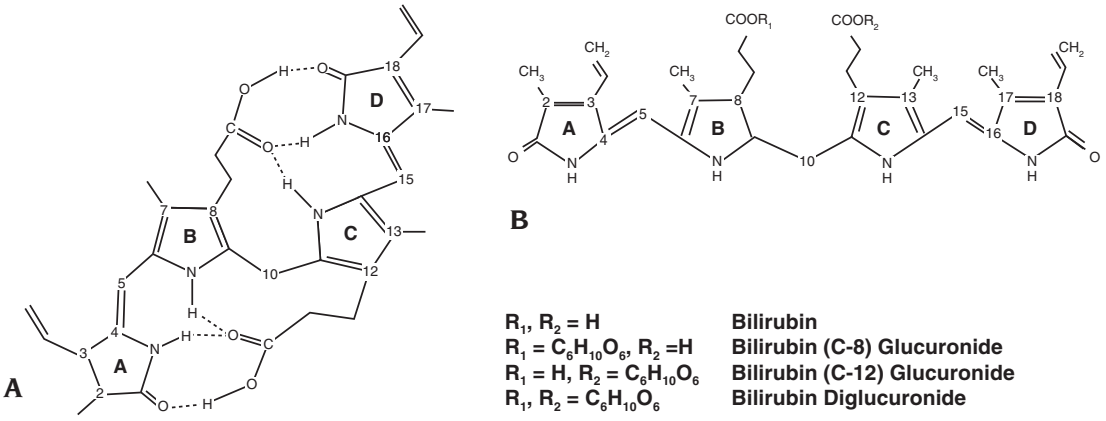

FIGURE 55.5-2 4Z,15Z-bilirubin IX-α depicted with standard carbon atom numbering demonstrating (*A*) normal internal hydrogen bonding and (*B*) conjugation sites. Substitutions (R_1 and R_2) indicate mono- and diglucuronides, which interrupt the internal hydrogen bonding, thus increasing the solubility of the bilirubin conjugates.

Secretion of Bilirubin Conjugates

Following conjugation, bilirubin conjugates are excreted against a concentration gradient from the hepatocyte through the canalicular membrane into the bile. Data from purified rat liver canalicular membrane vesicles indicate that bilirubin diglucuronide transport through the canalicular membrane is carrier mediated, electrogenic, and stimulated by bicarbonate.[53] Similar data suggest that bilirubin glucuronides are transported across the canalicular membrane by both adenosine triphosphate (ATP)-dependent and membrane potential–dependent transport systems, and in the normal rat, these systems are additive.[54] The ATP-dependent transporter responsible for bilirubin glucuronide passage from the hepatocyte through the canalicular membrane is canalicular multispecific organic anion transporter (cMOAT). cMOAT is a member of the ATP-binding cassette (ABC) transporter superfamily and is homologous to the multidrug resistance–associated protein 2 (MRP2).[55,56] cMOAT/MRP2 is involved with ATP-dependent transport across the apical canalicular membrane of a variety of endogenous compounds and xenobiotics,[57] including both bilirubin mono- and diglucuronide.[58] cMOAT/MRP2 has previously been described as the non–bile acid organic anion transporter, the glutathione *S*-conjugate export pump, or the leukotriene export pump.[59] Genetic mutations that alter these ABC transporters cause diseases, which include cystic fibrosis, hyperinsulinemia, adrenoleukodystrophy, multidrug resistance,[60] and, as is discussed later in this chapter, Dubin-Johnson syndrome (DJS). This mechanism can be saturated with increasing amounts of bilirubin or bilirubin conjugates.[61–63] Many other organic anions (eg, sulfobromophthalein, indocyanine green) are believed to share this same canalicular membrane excretion mechanism.[64] Simultaneous infusions of sulfobromophthalein and indocyanine green will decrease the maximal canalicular excretion of bilirubin and vice versa.[65,66] Bile salts do not use the same canalicular excretion mechanisms. In DJS, biliary excretion of conjugated bilirubin and sulfobromophthalein is decreased, although bile salt excretion is not impaired.[67] However, infusion of bile salts does increase the maximal excretion of bilirubin conjugates so that bile salt and bilirubin conjugate excretion by the canalicular membrane are not completely independent.[68] A similar effect is also seen with phenobarbital.[69] Conversely, the maximal excretion of bilirubin conjugates can be decreased by cholestatic agents such as estrogens and anabolic steroids.[70,71]

GILBERT SYNDROME

Clinical Presentation

GS (OMIM #143500) was first described in 1901 by Gilbert and Lereboullet.[72] GS is a hereditary, chronic or

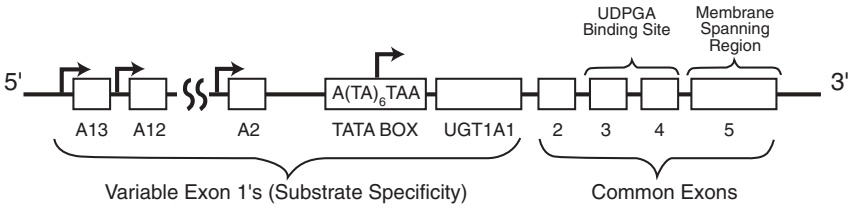

FIGURE 55.5-3 The human uridine diphosphate glucuronosyltransferase-1 (*UGT1*) gene. During transcription messenger ribonucleic acid from each variable, exon 1 (A1–A13) is spliced to exon 2, and the intervening ribonucleic acid is excised, resulting in a variety of isoforms. The variable exons impart substrate specificity, whereas the common exons determine the uridine diphosphate glucuronic acid (UDPGA) binding site and the membrane spanning region of the enzyme. The *UGT1A1* gene that results from this splicing encodes bilirubin glucuronosyltransferase.

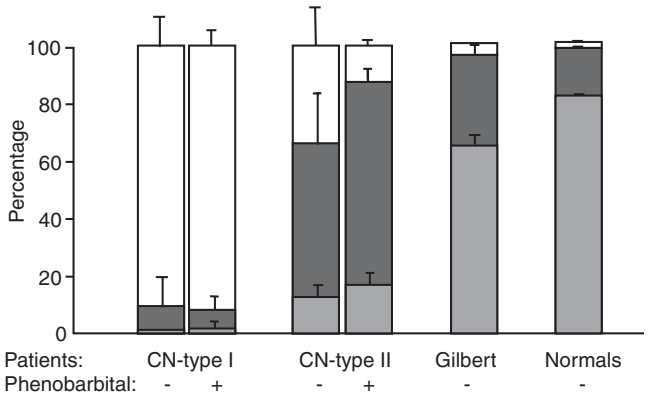

FIGURE 55.5-4 Bile pigment composition in bile from normal (n = 8), Crigler-Najjar (CN) syndrome type I (n = 3), CN type II (n = 3), and Gilbert syndrome (n = 16) patients, receiving (+) or not receiving (–) phenobarbital. Relative bile pigment composition is indicated in the vertical columns as a percentage of the total ± SD. recurrent, mild unconjugated hyperbilirubinemia with otherwise normal liver function tests.[2,73,74] The serum unconjugated bilirubin level usually ranges from 1 to 4 mg/dL (17 µmol/L = 1 mg/dL). Often patients are first identified by an elevated serum bilirubin on routine blood chemistry or mild jaundice (perhaps only scleral icterus) during a period of fasting associated with viral illness or religious activities[75] or anorexia nervosa.[76] Icteric plasma from a blood donor may suggest GS.[77] Alternatively, hyperbilirubinemia post-transplant of an apparently healthy donor liver may be a sign that the donor had GS.[78–81] GS is generally associated with no negative implications for health or longevity, despite the large variety of symptoms reported by GS patients.[82,83] These symptoms include vertigo, headache, fatigue, abdominal pain, nausea, diarrhea, constipation, and loss of appetite. The possible relationship of these symptoms to GS has been evaluated in a group of 2,395 Swedish subjects.[84] The only symptom that was more common in the GS group was diarrhea in male subjects aged 57 to 67 years. The authors suggested that this was most likely type 1 error because of the large number of comparisons made and concluded that there was no higher prevalence of symptoms associated with GS. There are limited reports suggesting that GS is a risk factor for chronic fatigue syndrome.[85,86]

Large surveys of normal individuals found approximately 3% of the population with serum bilirubin levels greater than 1.0 mg/dL.[87,88] Although one survey noted a bimodal distribution of serum bilirubin concentrations with antimodes of 1.4 mg/dL in male patients and 0.7 mg/dL in female patients,[87] other studies have not observed this. If these levels were used to define the upper limit of normal for serum bilirubin concentration, the incidence of GS would be approximately 6% of the population, and the sex distribution would be close to 1:1. If 1.4 mg/dL is used as the upper limit of serum bilirubin concentration for both sexes, then there is a strong male predominance (approximately 4:1). This finding might be related to the observation that female subjects clear bilirubin better than male subjects.[89] GS may be inherited in either an autosomal dominant[90–93] or recessive[94] fashion.

GS is rarely diagnosed before puberty, although it is a congenital disorder. Hormonal changes of puberty have been suggested as one explanation. Steroid hormones can suppress hepatic bilirubin clearance.[71] Increased estrogen levels of pregnancy are associated with impaired clearance of exogenous bilirubin.[95] Gonadectomy has been shown to alter BUGT activity.[96] Odell speculated that some infants with nonhemolytic neonatal jaundice are manifesting GS.[97] Use of genetic markers (see below) has allowed investigation of the role that GS plays in neonatal jaundice. Individuals carrying such markers have been shown to have a more rapid rise in their jaundice levels during the first 2 days of life,[98] a predisposition to prolonged or severe neonatal hyperbilirubinemia,[99–101] and variably increased jaundice when the GS polymorphism is coinherited with hematologic abnormalities such as glucose-6-phosphatase dehydrogenase (G6PD) deficiency,[102,103] β-thalassemia,[102,104,105] hereditary spherocytosis,[106] ABO incompatibility,[107] and sickle cell disease.[108] Kaplan and colleagues have shown that infants with G6PD deficiency do not have an increased incidence of hyperbilirubinemia (compared with G6PD normals) unless they also carry the UGT1A1 promoter polymorphism[103]; homozygotes for this polymorphism have a significantly higher incidence of hyperbilirubinemia than do heterozygotes (Figure 55.5-5). Thus, numerous studies indicate that GS, as detected by *UGT1A1* analysis, is one of the many factors related to neonatal jaundice. GS may also be a factor related to the jaundice associated with pyloric stenosis.[109] GS is associated with an increased incidence and/or earlier diagnosis of gallstones when coinherited with hematologic abnormalities such as congenital dyserythropoietic anemia,[110] thalassemia,[111] or hereditary spherocytosis.[112]

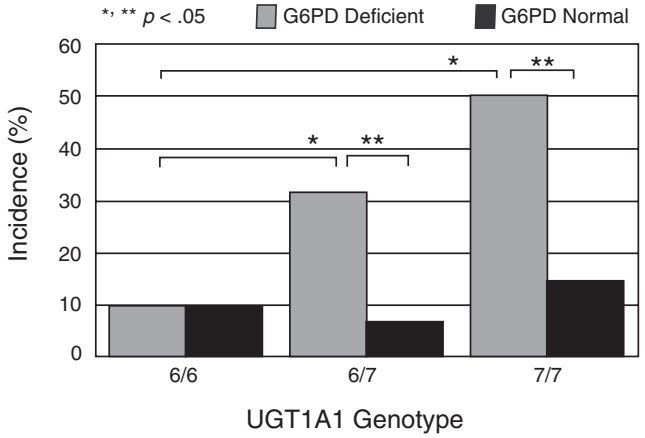

FIGURE 55.5-5 Incidence (percentage) of hyperbilirubinemia (serum total bilirubin ≥ 257 µmol/L) in glucose-6-phosphatase dehydrogenase (G6PD)-deficient neonates and normal controls, stratified for the three genotypes of the bilirubin uridine diphosphate glucuronosyltransferase 1A1 (UGT1A1) promoter. Reproduced with permission from Kaplan M et al.[103]

Pathophysiology

GS is a heterogeneous group of disorders sharing a significant (≥ 50%) decrease in hepatic BUGT activity.[113–116] There are at least four subtypes of GS based on the plasma clearance of sulfobromophthalein and indocyanine green, which share the same hepatocyte uptake receptor-carrier.[117,118] In GS type I, clearance of sulfobromophthalein and indocyanine green is normal. In GS type II, sulfobromophthalein clearance is delayed, but indocyanine green clearance is normal. Because sulfobromophthalein uptake is normal in type II, delayed clearance must be related to subsequent intrahepatic metabolism or canalicular excretion.[119] In GS type III, clearance of both sulfobromophthalein and indocyanine green is delayed. The delay in the initial rate of disappearance from the plasma suggests a defect in uptake at the hepatocyte plasma membrane.[119] In GS type IV, indocyanine green uptake is delayed, but sulfobromophthalein uptake is normal. Thus, GS may include delayed uptake of bilirubin into the hepatocyte, delayed biotransformation, or both abnormalities.[52,120–122] Immunohistochemical staining for BUGT shows a clear reduction throughout the hepatic lobule in specimens from individuals with GS when compared with normals.[123]

The elucidation of the structure of the *UGT1* gene that encodes human bilirubin, phenol, and other UDP-glucuronosyltransferase isozymes[39] led to the discovery of *UGT1A1* mutations or polymorphisms associated with GS.[124] In white populations, the homozygous finding of an additional TA repeat in the promoter region or so-called TATA box (ie, $[TA]_7TAA$, rather than $[TA]_6TAA$) of the *UGT1A1* gene has been shown to be a necessary, although not sufficient, condition for GS.[125–127] This homozygous polymorphism occurs in 10 to 13% of whites.[125,128] Approximately 42% are heterozygous for the $(TA)_7$, and these individuals have significantly higher serum bilirubin levels than individuals with the wild-type six repeats ($[TA]_6$).[125] Hepatic UDP glucuronosyltransferase activity appears to be inversely related to the number of TA repeats in whites.[129] In Asian populations, the $(TA)_7TAA$ mutation is relatively rare,[130] but several different *UGT1A1* mutations have been associated with GS.[93,131,132] These Asian mutations involve exons of the *UGT1A1* gene rather than the previously described promoter region. One of the most common mutations in Asians, a Gly71Arg mutation in exon 1, has also linked GS and severe or prolonged neonatal hyperbilirubinemia.[100,101,133] It has recently been reported that although within whites, the promoter TA repeat number and bilirubin level are strongly positively correlated, in other ethnic groups (eg, Africans, where two other variants $[TA]_5$ and $[TA]_8$ have been identified), there is a negative correlation.[134] Thus, the ethnic implications of these genetic polymorphisms of the *UGT1A1* gene require further analysis.

Despite the universal BUGT decrease in GS, the correlation is poor between measured hepatic enzyme activity and serum bilirubin concentration.[135] This may be due to the increased bilirubin production associated with the decreased red cell half-life seen in up to 40% of patients with GS.[92,122] Although some conditions with increased bilirubin production (eg, sickle cell disease) result in BUGT induction, this is not the case in GS.[136] Even phenobarbital produces little BUGT induction in GS.[114] Hepatic BUGT activity in GS significantly overlaps with that seen in Crigler-Najjar type II (CNII),[116] although activity in GS is usually higher. If an individual has one allele producing nonfunctional UGT1A1 (Crigler-Najjar) and the other structurally normal allele possesses the GS promoter polymorphism, the resulting hyperbilirubinemia would be expected to be more severe than that found in GS but less severe than that found in Crigler-Najjar I (CNI).[137]

Consistent with the decreased hepatic BUGT activity, bile from GS individuals contains decreased bilirubin diglucuronides and increased bilirubin monoglucuronides compared with normals (see Figure 55.5-4).[49,52,116,138] This finding is similar to biliary bile pigment profiles seen in infants.[139] Phenobarbital normalizes the bile pigment profile in duodenal fluid,[52] lowers plasma bilirubin levels, and increases hepatic clearance of bilirubin.[140,141] Clofibrate and glutethimide also normalize serum bilirubin levels but do not normalize the distribution of bilirubin conjugates in duodenal bile.[142] In animals, clofibrate is an inducer of BUGT but does not affect sulfobromophthalein uptake or GST.[143]

A characteristic but poorly understood finding in GS is the exaggerated rise in serum bilirubin associated with fasting.[144–147] Normal individuals can double their serum bilirubin level when fasting, but in GS, a more pronounced increase occurs. Because indocyanine green clearance is not affected, this is not related to decreased hepatic blood flow.[145] Fasting reduces BUGT activity[147] and increases heme oxygenase (the enzyme responsible for bilirubin production) activity,[148] but these effects are not believed to explain the fasting hyperbilirubinemia of GS.[140,149] Intraluminal noncalorie food bulk can blunt the bilirubin rise.[150]

Diagnosis and Treatment

Generally, a diagnosis of GS can be made when there is a mild fluctuating unconjugated hyperbilirubinemia; otherwise, liver function tests are normal, and there is no hemolysis. Hemolysis can add confusion because it can result in similar findings, and it is not unusual in GS. Hence, other diagnostic tests are sometimes helpful.

One diagnostic test used with GS involves measuring the rise in serum bilirubin following intravenous administration of nicotinic acid.[151] Nicotinic acid is usually administered to adults in a dose of 50 mg over 30 seconds,[152–154] although similar results were seen with 300 mg injections.[155] Nonconjugated serum bilirubin is then measured every 30 to 60 minutes for the next 4 to 5 hours. Nicotinic acid produces a rise in serum unconjugated bilirubin in both normals and those with GS. However, in GS, the bilirubin rise is higher, and clearance is delayed longer.[151,155–158] Nicotinic acid causes increased osmotic fragility and hemolysis of red blood cells with splenic sequestration. Induced splenic heme oxygenase rapidly converts heme to bilirubin.[157] Nicotinic acid–induced hemolysis produces a rise in serum iron that is similar in healthy controls and those with GS.[158] Hence, the prolonged serum bilirubin levels are related to delayed hepatic

clearance of bilirubin. Nicotinic acid infusion can be a better diagnostic method for GS than a 400 kcal fast because delayed bilirubin clearance can be seen after nicotinic acid in GS subjects who otherwise had normal serum bilirubin levels.[152] The nicotinic acid test cannot differentiate GS from chronic liver disease.[159]

Rifampin, given to fasting or nonfasting adults in one oral dose of 900 mg, increases total serum bilirubin levels in normal subjects and subjects with GS, although there is an exaggerated rise in those with GS (fasting: > 1.9 mg/dL rise in bilirubin concentration 2 to 6 hours after rifampin; nonfasting: > 1.5 mg/dL rise 4 to 6 hours after rifampin).[160] This exaggerated rise in serum bilirubin enabled differentiation of 10 normal subjects and 15 GS patients with high sensitivity and specificity. This finding could not be explained by hemolysis, although haptoglobin levels were significantly lower in GS patients, compatible with baseline hemolysis.

Alkaline methanolysis and thin-layer chromatography have been used to diagnose GS by accurately separating and measuring total serum bilirubin as conjugated and unconjugated fractions.[161,162] In GS, only approximately 6% of the total serum bilirubin was conjugated compared with approximately 17% in normal subjects or those with chronic hemolysis and 28% in those with chronic persistent hepatitis. Fasting increased the serum total bilirubin level but did not change the percentage of conjugates in GS. An overlap of only three individuals was seen among the 77 subjects with GS and 60 normal subjects.[162] Other studies support these findings.[163] HPLC of serum showed similar findings with significantly decreased bilirubin monoglucuronides (1.1% vs 6.2% in normals) and increased unconjugated bilirubin (98.8 vs 92.6 in normals).[164]

Monaghan and colleagues have suggested GS genetic screening for the *UGT1A1* TA repeat as a simple, useful additional test in the investigation of very prolonged neonatal jaundice in North American, African, and European populations and for the Gly71Arg mutation in Asians.[99] Although genetic testing may be helpful in individual patients, the screening value of such a genetic test cannot be fully determined until accurate data regarding the prevalence and penetrance of the GS genotype are known.[165] Thus, genetic testing for GS cannot be routinely recommended.[165]

GS is generally believed to have no significant negative health implications. Drug metabolism studies have revealed no major dangers,[163,166] although there appears to be an increased incidence of slow acetylators,[167,168] lorazepam clearance is 20 to 40% decreased,[169] and drug-mediated toxicity is a concern.[170] Concurrent genetic deficiencies in other xenobiotic pathways may put individuals with GS at increased risk of drug toxicity to such compounds as acetaminophen[171,172] or CPT-11 irinotecan, a cancer chemotherapeutic agent metabolized by UGT1A1.[173] No specific treatment is necessary for GS, although phenobarbital has been shown to lower serum bilirubin levels.[174] If the well-documented antioxidant effect of bilirubin[175] provides a biologic advantage,[176] then the mild hyperbilirubinemia of GS might actually be a significant benefit against such things as ischemic heart disease,[177–179] in which free radicals are involved in pathogenesis. Schizophrenic patients with GS have significant enlargement of many components of their cerebrospinal fluid spaces compared with schizophrenic patients without GS and normal controls, although the significance of this remains unknown.[180]

CRIGLER-NAJJAR SYNDROME

Clinical Presentation

Crigler and Najjar, in 1952, reported seven infants with congenital familial nonhemolytic jaundice who developed severe unconjugated hyperbilirubinemia shortly after birth and died from kernicterus within months.[181] These infants were from three related families. Serum bilirubin levels reached 25 to 35 mg/dL despite a lack of hemolytic disease and otherwise normal liver function tests. Liver histology showed only deposition of bile pigments. Many subsequent reports have documented kernicterus as the main risk for patients with the Crigler-Najjar syndrome.[182] An excellent review of the neurologic perspectives of Crigler-Najjar syndrome has recently been published.[183] Although some patients survive into the second decade with normal development,[184] the possibility of developing late kernicterus is always a concern, even in adulthood.[185–188] Serum bilirubin levels vary from approximately 15 to 45 mg/dL. A Web site addressing many aspects of Crigler-Najjar syndrome has been developed (<www.crigler-najjar.com>).

Arias and colleagues, in 1969, reported a second, more frequent type of severe nonhemolytic hyperbilirubinemia.[189] The previous syndrome was termed CNI (OMIM #218800), whereas the new findings were termed CNII or Arias syndrome (OMIM #606785).[189] In CNII, hyperbilirubinemia is less severe, varying from approximately 8 to 25 mg/dL. Hence, kernicterus, although reported,[190,191] is less common in CNII.

Pathophysiology

Both CNI and CNII are generally inherited in an autosomal recessive manner, although one case of autosomal dominant inheritance of CNII has been reported.[192] CNI and CNII result from mutations to the *UGT* gene complex,[40] of which more than 50 different mutations have been described.[193] Patients with one normal allele demonstrate normal metabolism of bilirubin.[194] The genetic details determine the severity of clinical disease. In CNI, there is a complete absence of functional UGT1A1, whereas in CNII, UGT1A1 activity is markedly reduced.[195] In CNI, 18 of 23 described mutations of the *UGT1* gene are found in the common exons 2 to 5 and thus affect many UGT1 enzymes.[40,196] Intronic mutations causing CNI have also been reported.[197] However, in CNII, four of nine known mutations are found in exon 1A1. There is some overlap in classification of mild CNII and GS (eg, Gly71Arg), which relates to differences in definitions based on serum bilirubin levels.[40] The TATA box TA_7 repeat mutation seen in GS can be seen along with other mutations resulting in either CNI or CNII.[198] Thus, various homozygous, heterozygous, or compound heterozygous mutations of the *UGT1A1* gene can lead to varying degrees of reduction in hepatic bilirubin UGT activity and thus to varying degrees of clinical

hyperbilirubinemia, including severe CNI, intermediate CNII, and milder GS.[199]

In both CNI and CNII, assays of liver tissue from affected patients demonstrate negligible or very low BUGT activity.[49,50,116,186,189,200,201] Thus, liver biopsy is not helpful in differentiating these two disorders. This inability to conjugate bilirubin results in a profound block in bilirubin excretion. Study of the resected livers from four patients with CNI undergoing liver transplant showed that there was heterogeneity of the ability to glucuronidate various substrates other than bilirubin.[202] There is considerable overlap of hepatic BUGT activity between CNII and GS (see Table 55.5-1).[116] Consistent with the presumed autosomal inheritance of CNI, family studies have shown partial deficiencies in the glucuronidation of salicylate and menthol among siblings, parents, and grandparents.[203,204]

CNI and CNII are differentiated by the response to drugs that stimulate hyperplasia of the endoplasmic reticulum. In CNII, phenobarbital or diphenylhydantoin caused a significant decline in the serum bilirubin level, increased hepatic clearance of radiolabeled bilirubin,[141,189,190,205–208] and increased biliary levels of bilirubin diglucuronides (see Figure 55.5-4).[49,191] In a study of five CNII patients, phenobarbital caused a decrease in serum bilirubin ranging from 2.1 to 12.1 mg/dL (27–72%) with pre- and postphenobarbital serum bilirubin levels ranging from 7.8 to 16.9 and 4.7 to 10.1 mg/dL, respectively.[49] Summarizing data from seven earlier studies[141,189,190,205–208] regarding the response of CNII patients to oral phenobarbital treatment revealed that 11 female patients and 13 male patients had a total serum bilirubin of 15.7 ± 13.8 (mean ± SD) prior to phenobarbital. After phenobarbital (90–390 mg/d or alternatively 4 mg/kg/d), the serum bilirubin decreased 12.0 ± 4.0 mg/dL (77 ± 13%). The lowest total serum bilirubin following phenobarbital therapy was 5.9 mg/dL. Drugs have no significant effect on serum bilirubin or biliary bilirubin conjugates in CNI (see Figure 55.5-4).[49,185] Thus, response to phenobarbital is the accepted criterion by which CNI and CNII are differentiated.[209] Bile analysis has also been suggested as another method to differentiate CNI and CNII.[49] In CNI, bile contains insignificant bilirubin conjugates (< 10%), and unconjugated bilirubin predominates. In CNII, bile contains predominantly bilirubin monoglucuronides (> 60%).[116]

Two cousins with Crigler-Najjar syndrome have been described, which raises the possibility of a new variant of this syndrome (CNIII).[210] This new variant resembled CNI with no biliary excretion of bilirubin mono- or diglucuronide, but there was excretion of mono- and diglucoside conjugates of bilirubin. It has been speculated that type III patients lack the long proposed permease,[36] which has been hypothesized to transport UDP-glucuronic acid to the luminal side of the endoplasmic reticulum, where BUGT is located. This absence is suggested to result in UDP-glucose being used for bilirubin conjugation.

Diagnosis and Treatment

Evaluation for Crigler-Najjar syndrome invariably begins during the first few days of life, when serum bilirubin levels exceed 20 mg/dL. The conjugated fraction will not be elevated except possibly for the factitious elevation, which is sometimes seen when the total serum bilirubin is very high.[211] Evaluation of such infants should eliminate the more common causes of jaundice, including hemolysis, hypothyroidism, and infection. Formula feedings will help identify those infants with jaundice related to human milk. During these early days of life, Crigler-Najjar patients will require prompt and intense phototherapy and possibly exchange transfusion to avoid kernicterus and bilirubin encephalopathy.[212] Jaundice will be persistent and problematic. At present, there is no widely available simple clinical test to confirm a diagnosis of Crigler-Najjar syndrome. Crigler-Najjar syndrome can be excluded by finding significant amounts of bilirubin conjugates in neonatal stools. This HPLC analysis must be done on stools collected prior to establishment of sufficient intestinal bacterial flora to convert all bilirubin conjugates to urobilinoids.[182] HPLC analysis of duodenal bile will show that in CNI, there are negligible bilirubin di- or monoglucuronides, whereas in CNII, these conjugates are present but in low concentration.[40,49] However, this bile analysis led to misdiagnosis in six of nine infants examined during the first 3 months of life.[213] Bile can easily be collected with a pediatric Enterotest capsule (HDC Corporation, San Jose, CA).[138] This approach can potentially avoid a liver biopsy for confirmation of negligible BUGT activity using an in vitro assay. The ratio of serum bilirubin conjugates (as determined by alkaline methanolysis with thin-layer chromatography or HPLC) to total bilirubin, although abnormally low, does not allow differentiation of Crigler-Najjar patients from those with GS.[162] Deoxyribonucleic acid (DNA) analysis can be very helpful in establishing the correct diagnosis, although this is not routinely available.[214]

A world registry of patients with CNI aimed at developing management guidelines has been published.[215] Phenobarbital (4 mg/kd/d in infants) should be used when there is concern about CN. Within 48 hours, CNII patients can demonstrate a significant decrease in the serum bilirubin levels (as detailed above) and an increased biliary excretion of bilirubin di- and monoglucuronide,[50,191] whereas CNI patients will show no significant response. Occasionally, CNII patients do not respond to the first trial of phenobarbital therapy, but subsequent trials months later will demonstrate the significant decrease in serum bilirubin level.[209] Doses of phenobarbital as low as 0.6 mg/kg/d have been reported to completely normalize serum bilirubin in one patient. However, despite the decrease in serum bilirubin in response to phenobarbital, CNII patients will usually continue to manifest a significant hyperbilirubinemia (approximately 5–15 mg/dL). Phototherapy for 6 to 12 hours daily has been the primary modality to keep serum bilirubin levels below 20 mg/dL during the first several months of life[216] because CNI patients can excrete all bilirubin photoisomers.[217] CNI patients will require lifelong treatment with phototherapy until more definitive therapy such as liver transplant. Phototherapy has been found to be least intrusive when given at night, and improvements have been made in effectiveness and comfort.[218] Although phototherapy is very helpful

in infancy, in adolescence, social inconvenience and compliance problems can bring increased risk of kernicterus.[215]

Oral administration of agents that bind bilirubin can be helpful. Options include agar, cholestyramine, and calcium phosphate.[219–222] These agents block the enterohepatic circulation by binding to bilirubin, which has reached the intestinal lumen owing to phototherapy or through direct intestinal permeation.[223] Agar varies significantly in bilirubin binding affinity among various preparations and batches.[186,219,224] Cholestyramine prompts concerns about cost, taste, and bile salt depletion and fat malabsorption. Plasmapheresis can be very helpful after the first year of life as it has been shown to rapidly decrease serum bilirubin levels.[186,225] Peritoneal dialysis and exchange transfusion have not been helpful in this setting.[185] Repeated intramuscular injections of tin-protoporphyrin, a heme oxygenase inhibitor that blocks bilirubin formation, have been used in a CNI patient, with data suggesting a decreased need for phototherapy.[226] Two patients with CNI were treated with tin-mesoporphyrin to block bilirubin formation, daily phototherapy, and intermittent plasmapheresis over a 400-day period.[227] They developed an iron deficiency anemia believed to be due to the porphyrin therapy,[228] but tin-mesoporphyrin (2–4 μmol/kg)[229] is suggested to offer a promising, although still experimental, additional therapy for controlling episodes of acute, severe jaundice. Drugs that bind to albumin and can potentially displace bilirubin should be avoided at all times.[230]

Auxiliary liver transplant would be feasible for CNI patients because their liver function is normal, except for bilirubin glucuronidation. This option has only recently become clinically available.[231–233] Thus, more commonly, orthotopic liver transplant,[234–241] including living-related liver transplant,[242] represents the only true cure for the hyperbilirubinemia of CNI. The timing of transplant should precede irreversible neurologic injury. When infants are small, sleeping under a phototherapy unit plus the medical measures noted above can be effective in managing hyperbilirubinemia and avoiding kernicterus. However, there is always the risk of intercurrent illness, which can precipitate worrisome hyperbilirubinemia. As children grow, phototherapy and other medical therapies may decrease in effectiveness. Thus, the risk of kernicterus must be balanced against the risks associated with liver transplant, including lifelong immunosuppression. This can be a very difficult decision. The effectiveness and ease of medical management of hyperbilirubinemia are important considerations, as are the long-term success and complication rate of the specific transplant center involved. Bilirubin levels must be followed and extreme hyperbilirubinemia avoided at any age because the development of kernicterus is not restricted to the neonatal period. Transplant of other BUGT-containing tissues (eg, segments of small intestine,[243,244] kidneys[245]) remains experimental. Successful cloning of the gene responsible for bilirubin glucuronosyltransferase activity offers the hope of future gene therapy to correct this deficiency.[246–250] Gene therapy,[251–254] encapsulated hepatocytes,[255] and gene repair have shown success in lowering serum bilirubin levels in Gunn rats,[256] the congenitally jaundiced model for CNI.[257] In a 10-year-old girl with CNI, isolated hepatocytes equivalent to approximately 5% of the normal host hepatocyte mass were infused through the portal vein, survived for more than 11 months, and lowered serum bilirubin levels from approximately 25 mg/dL to 10 to 15 mg/dL while still receiving 6 to 8 hours of phototherapy per day.[258] More recent isolated hepatocyte transplant for the correction of another inborn error of metabolism (ornithine transcarbamylase deficiency) resulted in temporary improvement, which was lost after 11 days presumably because of rejection of the transplanted cells because of insufficient immunosuppression.[259] Isolated hepatocyte transplant remains experimental.[257]

ROTOR SYNDROME

Clinical Presentation

Rotor syndrome (RS; OMIM *237450) is a familial disorder, first described in 1948, that involves chronic elevation of both the conjugated and unconjugated serum bilirubin fractions.[260,261] Fractionation of the serum total bilirubin shows that half or more is conjugated, and total bilirubin levels range from 2 to 7 mg/dL but occasionally may reach 20 mg/dL.[262] Liver functions tests are otherwise normal, and there is no evidence of hemolysis. Both light and electron microscopy reveal normal liver histology. Oral cholecystograms reveal normal gallbladder opacification. This disorder can present in early childhood[263] or in infancy if associated with other hematologic diseases[264] and manifests no gender predisposition. Family studies suggest an autosomal recessive mode of inheritance.[260,261,265]

Pathophysiology

The primary abnormality in RS is a deficiency in the intracellular storage capacity of the liver for binding anions.[266,267] This can be demonstrated by constant infusions of sulfobromophthalein and indocyanine green.[268] Patients with RS demonstrate a delayed plasma clearance of both sulfobromophthalein and indocyanine green, and heterozygotes show delayed sulfobromophthalein clearance with values intermediate between normal subjects and those with homozygous RS.[266] GST serves as an intracellular carrier protein of certain organic molecules, acting as an intracellular equivalent to albumin in blood plasma.[269] Patients with RS have been shown to have a deficiency of hepatic GST,[270,271] resulting in impaired uptake of bilirubin within the cytosol. This appears to be due to mutations in the *hGSTA1-1* gene.[271] In addition, because bilirubin conjugates are bound to GST while awaiting excretion from the hepatocyte via the canalicular membrane,[272] deficient intracellular storage would result in leakage of bilirubin conjugates back into the circulation, with subsequent serum elevations of both conjugated and unconjugated bilirubin.

Urinary excretion of coproporphyrin is important in RS. In normal healthy individuals, only the I and III isomers of coproporphyrin are excreted in the urine. In RS, total urinary coproporphyrin excretion (isomers I + III) is markedly increased, and, usually, isomer I comprises less than 80% of the total. Heterozygotes demonstrate urinary

coproporphyrin values, which are intermediate between normal subjects and homozygotes.[273] Urinary excretion of coproporphyrin is believed to be increased because biliary excretion of coproporphyrin is impaired, similar to findings in other liver diseases.[274]

Diagnosis and Treatment

In all individuals with elevation of both conjugated and unconjugated serum bilirubin fractions along with otherwise normal liver function tests, a diagnosis of RS should be considered. The diagnosis can be confirmed by measuring urinary coproporphyrin levels, which are 2.5 to 5 times higher than normal levels.[273] Of the total urinary coproporphyrin isomers (I + III), isomer I constitutes less than 80% of the total in RS.[275] Technetium 99m hepatobiliary iminodiacetic acid cholescintigraphy has also been shown to be useful to diagnose RS and demonstrates poor to no visualization of the liver.[276,277]

Patients with RS require no specific therapy and are asymptomatic. Although jaundice is a lifelong finding, it is not associated with morbidity or mortality.

DUBIN-JOHNSON SYNDROME

Clinical Presentation

DJS (OMIM #237500) was first described in 1954[278] and involves elevation of both the conjugated and unconjugated serum bilirubin fractions.[279] Fractionation of the serum total bilirubin shows that half or more is conjugated, and total bilirubin levels usually range from 1.5 to 6 mg/dL, although they have been reported to be as high as 25 mg/dL during intercurrent illness.[280] Patients with DJS report vague abdominal complaints, although this is not believed to reflect serious pathology. Hepatomegaly is sometimes seen, but liver function tests are otherwise normal, including bile acids,[281] and there is no evidence of hemolysis.[278,279,282] Although this syndrome occurs in both sexes, males predominate and present at an earlier age. It occurs in all races; however, Iranian Jews have an increased incidence.[283,284] It is usually diagnosed after puberty, although cases have also been reported in neonates,[285–288] at which time, cholestasis can be significant.[287,289–292] DJS is inherited as an autosomal recessive trait, with heterozygotes manifesting normal serum bilirubin levels.[283,293,294] This syndrome is far more common than RS, and jaundice can be worsened by pregnancy and oral contraceptives.[295] Often patients with DJS do not visualize the gallbladder with an oral cholecystogram.[279]

Brown to black discoloration of the liver is a striking characteristic of this syndrome. This pigment is located in the lysosomes.[296] The exact identity of this pigment is still uncertain. Once thought to be lipofuscin, more recent data provide conflicting evidence for a relationship to melanin[297–299] or polymerized epinephrine or other metabolites,[300,301] which accumulate in the lysosomes. It is hypothesized that these pigments accumulate in the liver because of impaired secretion of various metabolites from the hepatocyte into the bile.[301] This pigment has been shown to disappear from the liver during acute viral hepatitis, with subsequent reappearance.[302] Other than this striking pigmentation, the liver histology is normal.

Pathophysiology

The primary defect in DJS is deficient hepatic excretion of non–bile salt organic anions at the apical canalicular membrane by the ABC transporter originally known as cMOAT (OMIM 601107)[303,304] but now also called MRP2.[305,306] The gene encoding this protein is designated *ABCC2*. cMOAT/MRP2 is encoded by a single-copy gene located on chromosome 10q24.[307] Mutations of this gene have been shown to produce a highly defective cMOAT/MRP2, which is nonfunctional or absent from the apical membrane and associated with DJS.[60,303,304,308–311] Similar findings made in the homologous cMOAT/MRP2 gene of two rat models of hyperbilirubinemia (GY/TR$^-$ and Eisai) have been very helpful in understanding DJS in humans.[60,312]

Although hepatic sulfobromophthalein clearance tests are no longer performed, they clearly demonstrate the effect of deficient transport via the canalicular membrane, which is characteristic of DJS.[313] Initially, the clearance rate of intravenously administered sulfobromophthalein from the circulation is rapid and results in sulfobromophthalein retention that is often normal at 45 minutes. However, a subsequent rise in serum sulfobromophthalein concentration occurs at 90 and 120 minutes because the conjugated sulfobromophthalein cannot be excreted and thus refluxes out of the hepatocyte back into the circulation.[313–316] Data suggest that sulfobromophthalein hepatic storage is normal, but there is a 90% decrease in the sulfobromophthalein excretory transport maximum.[295,315] Other substances (eg, indocyanine green, rose bengal, and dibromosulfophthalein) have also been shown to have a decreased excretory transport maximum, although these substances do not require hepatic biotransformation and do not show the late rise in plasma levels during clearance tests.[317] Hence, in DJS, deficient excretion of bilirubin glucuronides at the canalicular membrane, in the presence of otherwise normal intrahepatic metabolism, results in reflux of conjugated bilirubin back into the circulation.

Urinary excretion of coproporphyrins is important in patients with DJS.[318,319] DJS patients have an increase in the urinary excretion of coproporphyrin I with a concomitant decrease in the excretion of coproporphyrin III. This results in a total coproporphyrin excretion (I + III) that is normal or only slightly increased but that consists of greater than 80% coproporphyrin I (normal 25%).[319–322] In heterozygotes, the coproporphyrin I-to-III ratios are intermediate between normal subjects and homozygotes,[319,321,322] although there is some overlap between them. The explanation for these findings regarding urinary coproporphyrin excretion is unclear, and several pathogenic mechanisms have been suggested.[319] Fecal coproporphyrin levels are normal.[319] Healthy neonates have been shown to have impressive elevations of urinary coproporphyrin levels, with more than 80% isomer I on the first 2 days of life[323]; however, by day 10, levels fell to overlap normal adult values.

Diagnosis and Treatment

A diagnosis of DJS should be considered in all individuals with an elevation of conjugated bilirubin in the serum along with otherwise normal liver function tests. Measurement of urinary coproporphyrin isomers I and III can confirm the diagnosis. The total coproporphyrin level will be approximately normal, but more than 80% will be isomer I. This finding is pathognomonic for DJS when congenital erythropoietic porphyria[324] or arsenic poisoning[325] has been excluded. Although an oral cholecystogram may fail to visualize the gallbladder, ultrasound examination will show a normal biliary tree. Cholescintigraphy demonstrates prolonged intense visualization of the liver with delayed appearance of the gallbladder and only faint or nonvisualization of the biliary ducts.[277,326,327] Computed tomography of the liver has shown increased attenuation in one report.[328] Because cMOAT/MRP2 transport of leukotrienes into bile is defection in DJS, there is increased excretion of leukotriene metabolites into urine, and this has been suggested to be a new approach to the noninvasive diagnosis of this disease.[329]

No specific therapy is needed for patients with DJS. Although jaundice is a lifelong finding, it is not associated with morbidity or mortality. Avoidance of oral contraceptives has been recommended[330] because this can increase jaundice. Anticipatory guidance regarding pregnancy[295] is appropriate. Increased fetal wastage has been reported in one study.[331] In one case report of neonatal DJS with severe cholestasis, phenobarbital significantly decreased serum levels of bilirubin and bile acids,[289] although chronic phenobarbital therapy is not recommended.[1]

6. Biliary Transport

Benjamin L. Shneider, MD

Cholestasis, which is a major manifestation of a wide range of pediatric liver diseases, is ultimately the result of specific or nonspecific abnormalities in biliary transport. These abnormalities can be the result of genetic defects in specific hepatic-based transporters or can be part of a series of molecular responses to a pathophysiologic process. Examples of the former include genetically determined defects in the expression of the canalicular bile acid transporter or the canalicular phospholipid flippase. An example of the latter is the cascade of responses that follow gram-negative sepsis. This chapter describes the current knowledge of disorders of biliary transport and how pathologic changes in these systems lead to pediatric liver disease. Current understandings of the natural history of, diagnostic approaches to, and treatment of these newly described diseases are reviewed.

BILIARY TRANSPORT

Bile flow is dependent on a series of vectorial transport proteins that are arrayed on the basolateral and canalicular membranes of hepatocytes (Figure 55.6-1). In addition, bile flow also requires an ordered hepatocellular processing of bile components. Transport processes in the intestine, kidney, pancreas bile duct, and gallbladder have significant effects on bile formation. This highly complex process is subject to a number of levels of regulation and consists of a diversity of genetically distinct elements. Bile itself consists of multiple individual components, including bile salts, bilirubin, phospholipids, cholesterol, and a large variety of endogenous and xenobiotic organic compounds. Vectorial flow of each of these components may be under separate genetic and regulatory controls. As such, it is not surprising that a wide variety of cholestatic liver diseases may exist, each with a separate genetic basis and each with distinct clinical characteristics and therapeutic approaches. A brief review of hepatocyte transport of bilirubin, bile acids, and organic anions is presented here (see Chapter 5.1, "Bile Formation and Cholestasis," for a comprehensive review of bile formation), especially as it pertains to the biliary transport disorders listed below. The interested reader is also directed to recent comprehensive reviews of biliary transport and analyses of modifications of bile by bile ductular epithelium.[1–5] Given the interrelation of disease and physiology in this rapidly developing field, details of the discovery of the various transporters are described in the following sections related to specific biliary transport diseases.

Highly efficient mechanisms for the basolateral extraction of bile components from serum into hepatocytes have developed partly in an effort to minimize the concentrations of these potentially toxic compounds in the systemic circulation. At least three different transporters have been shown to be potentially involved in basolateral transport of bile acids. The first and potentially most physiologically significant of these is the Na^+-dependent taurocholate cotransporting polypeptide (NTCP). This 48 kD protein is a hepatocyte-specific integral membrane protein.[6,7] It was the first of the bile acid–specific transport proteins to be cloned. Its discovery revolutionized the current approach to studying the physiology and pathophysiology of bile formation. In addition to NTCP, two other proteins have been shown to transport bile salts: the organic anion transport protein (OATP[8]) and microsomal epoxide hydrolase.[9] The physiologic significance of these latter two proteins in hepatic extraction of bile salts is currently not clear. OATP may be more important in hepatic extraction of organic anions such as bilirubin.[10]

The mechanisms involved in the transcellular movement of bile components from the basolateral to the canalicular membrane are not well understood. It is not certain whether this process involves specific binding proteins or specialized vesicles. Intracellular binding proteins for bile components have been described, although their physiologic necessity is not known. Bile acids have been shown to bind to dihydrodiol dehydrogenase, whereas bilirubin binds to ligandin.[11] Several lines of investigation have suggested that bile components are associated with or found within intracellular vesicles. As such, it is possible that molecular motor systems using

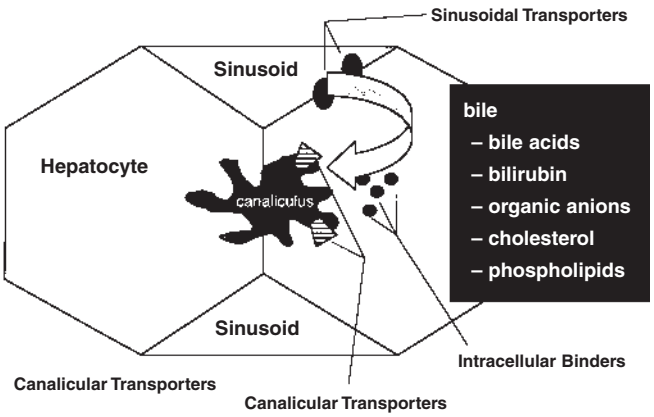

FIGURE 55.6-1 Diagram of mechanisms of bile flow. Cartoon depiction of hepatocyte couplet with vectorial flow of bile from sinusoidal blood to bile canaliculus via basolateral and canalicular transporters.

microfilaments and/or microtubules may play a role in promoting transcellular bile flow. These processes have been very difficult to assess using currently available experimental methods. Like the biliary transport proteins, it is very likely that studies of naturally occurring defects in these proteins will clarify this field. Bile acid conjugation is an additional intracellular event that influences bile flow. Conjugated bile acids are more water soluble and thus are more easily excreted.

Canalicular transport of bile components is generally recognized to be rate limiting for bile flow, and, as such, these transporters have been under active investigation by a number of laboratories. In addition, impairment of the function of any of these transport proteins has the potential to lead to the hepatocellular accumulation of toxic compounds and therefore directly lead to liver disease. A variety of studies indicated that many of these transport processes were adenosine triphosphate (ATP) dependent; thus, the ATP-binding cassette (ABC) proteins became likely candidates as transporters. A combination of basic laboratory investigations, animal models, and genetic analysis of cholestatic liver diseases (see individual sections below) ultimately identified three important ABC proteins as canalicular biliary transport proteins (Table 55.6-1). Specific and genetically distinct proteins have been identified that mediate ATP-dependent transport of bile acids (bile salt export pump [BSEP]/sister of P-glycoprotein [SPGP]), organic anions (multidrug resistance–associated protein 2 [MRP2]/canalicular multispecific organic anion transporter [cMOAT]), and phospholipids (multidrug resistance protein 3 [MDR3]) from the hepatocyte into the bile canaliculus. ATP hydrolysis is critical for each of these transport functions because the transport process takes place against a very steep concentration gradient (ie, concentrations in bile are much greater than within the hepatocyte).

NOMENCLATURE

The nomenclature that currently exists in the field of biliary transport disorders is complex, confusing, and likely to undergo significant change. In this chapter, older terminology, in particular that uses progressive familial intrahepatic cholestasis (PFIC), is generally replaced by specific reference to the defective gene or protein. This has only recently become possible because the molecular identification of the defects involved in the various forms of PFIC have been elucidated.[1–3] The future utility of these historical designations may no longer be apparent. Many of the patients who have these diseases do not have other family members who are affected by the disease; thus, the familial portion of the designation becomes limiting. As the full range of the clinical phenotype of these various disorders becomes known, a more specific and helpful system of nomenclature may be devised.

DEFECTS IN CANALICULAR BILE ACID TRANSPORT

The pivotal role of canalicular transport of bile acids in the formation of bile has made this transport process a focus of active investigation in the pathophysiology of pediatric cholestatic liver disease. In spite of the fact that it has been expected that a defect in canalicular transport of bile acids would lead to severe cholestatic liver disease, discovery of this abnormality had been very difficult. Technical problems in the analysis of canalicular transport processes have been in large part responsible for delays in these discover-

TABLE 55.6-1 SUMMARY OF BILIARY TRANSPORT DISEASES

DISEASE	*SPGP/BSEP* DEFICIENCY	*MDR3* DEFICIENCY	DUBIN-JOHNSON SYNDROME	BYLER DISEASE
PFIC designation	PFIC2	PFIC3	None	PFIC1
Common name	BSEP	MDR3	MRP/cMOAT	FIC1
Defective transport gene	*ABCB11*	*ABCB4*	*ABCC2*	*ATP8B1*
Chromosomal localization	2q24	7q21	10q24	18q21-q22
mRNA size (kb)	5.5	4.1	6.5–9.5	7.0
Protein size (kD)	170	170	200	145
Tissue distribution	Liver	Liver	Liver >> intestine	Intestine > liver
Transporter substrate	Bile acids	Phospholipids	Organic anions	Aminophospholipids?
Animal model	Mouse knockout[27]	Mouse *mdr2* knockout[31]	Rat TR$^-$ or Eisai[58]	Mouse Byler equivalent[83]
Alanine aminotransferase level	++	++	nl	+
Bilirubin level	+ -> +++	+ -> +++	++	++ -> nl -> +++
Cholesterol and γ-GTP levels	nl	++	nl	nl
Serum bile acid level	+++	++	nl	+++
Histologic findings	Giant cell transformation	Ductular prolifer Portal fibrosis/cirrhosis	Melanin-like pigment in hepatocytes	Bland intracanalicular cholestasis; diminished canalicular γ-GTP
Special diagnostic tests	Biliary bile acids	Lipoprotein X; biliary phospholipids	Urine coproporphyrin I	Electron microscopy
Treatment	Liver transplant; biliary diversion?	Liver transplant	None	Partial biliary diversion; ileal bypass
Key references	17, 20	42	54, 61	66, 70, 78

BSEP = bile salt export pump; cMOAT = canalicular multispecific organic anion transporter; GTP = glutamyl transpeptidase; MDR = multidrug resistance; mRNA = messenger ribonucleic acid; MRP = multidrug resistance–associated protein; PFIC = progressive familial intrahepatic cholestasis; SPGP = sister of P-glycoprotein.

ies. Efflux transport processes, by their very nature, are much more complex to study than uptake mechanisms.[12] Accurate analysis of efflux is critically dependent on uniform loading of either cells or vesicles, which can be nearly impossible to perform. The alternative of examining reverse transport into cells or vesicles is subject to a number of artifacts. Isolation of relatively purified inside-out canalicular membrane vesicles permitted more exact analysis of canalicular transport via uptake.[13] It was not until recently that it was determined that the primary driving force for canalicular transport of bile acids was related to the hydrolysis of ATP.[14–16] This finding suggested that the canalicular bile acid transporter might belong to a superfamily of proteins referred to as ABC transporters. These transport proteins include a number of critically important proteins that, when defective, lead to a range of diseases, including cystic fibrosis, Wilson disease, adrenoleukodystrophy, Tangier disease, and Dubin-Johnson syndrome. The ABC transporters are integral membrane proteins, which typically have two cytoplasmic consensus sequences for ATP binding. Degenerate oligonucleotide primers were designed for these binding domains, and reverse transcriptase–polymerase chain reactions were used to clone the rat canalicular bile acid transporter.[17] The cloned gene was very similar to a previously cloned pig gene referred to as the *SPGP*.[18] Expression of the protein product of the *SPGP* complementary deoxyribonucleic acid (DNA) in two separate systems, *Xenopus laevis* oocytes and *Sf9* insect cells, resulted in augmentation and acquisition, respectively, of ATP-dependent taurocholic acid transport activity. Northern blotting and immunoelectron microscopy indicate that the expression of this gene is hepatocyte specific and is localized to the canalicular membrane. Overall, these studies therefore indicated that the *SPGP* was a canalicular BSEP.

The clinical relevance of the discovery of BSEP became apparent as a result of genetic studies that were conducted nearly simultaneously. Homozygosity linkage studies mapped the genetic defect in a subset of Saudi Arabian patients with progressive familial cholestasis to chromosome 2q24.[19] Further refinement of the PFIC2 locus was performed using a larger group of patients with progressive familial cholestasis and ultimately led to the identification of the human correlate of *BSEP* as the defective gene in *PFIC2*.[20] Ten different mutations in *BSEP* were initially described (Figure 55.6-2). Four were nonsense mutations leading to a truncated protein, whereas the remaining six were missense mutations involving amino acid residues in key portions of the predicted bile acid transporter structure.

The clinical presentations of defects in *BSEP* are being defined, although the full range of presentations is not yet well understood.[20–24] Cholestasis often is manifest by pruritus and jaundice early in life, typically before 1 year of age. The inability of infants to scratch may translate into irritability as a first feature of this disorder. Biochemical findings are consistent with progressive intrahepatic cholestasis and include markedly elevated serum bile salts. There are typically variable elevations in serum bilirubin and aminotransferase levels with normal γ-glutamyl transpeptidase and normal cholesterol levels (see Table 55.6-1). Liver biopsies performed in the first 2 years of life are notable for giant cell hepatitis and cholestasis. The electron microscopic appearance of bile is reported to be distinct from that seen in familial intrahepatic cholestasis type 1 (FIC1) disease (see below). Immunohistochemical analysis of hepatic γ-glutamyl transpeptidase has been preliminarily reported to reveal strong staining at the bile canaliculus in contrast to the diminished staining observed in FIC1 disease (see below).[25] Some defects in BSEP lead to absent expression of its protein, which potentially can be demonstrated by immunohistochemistry.[26] Prospective and/or blinded analysis of these findings will be needed to confirm them as potential diagnostic criteria. Given the key role of BSEP in bile formation, it is not surprising that the clinical progression of liver disease in these patients is relatively rapid. Interestingly, a *BSEP* knockout mouse is

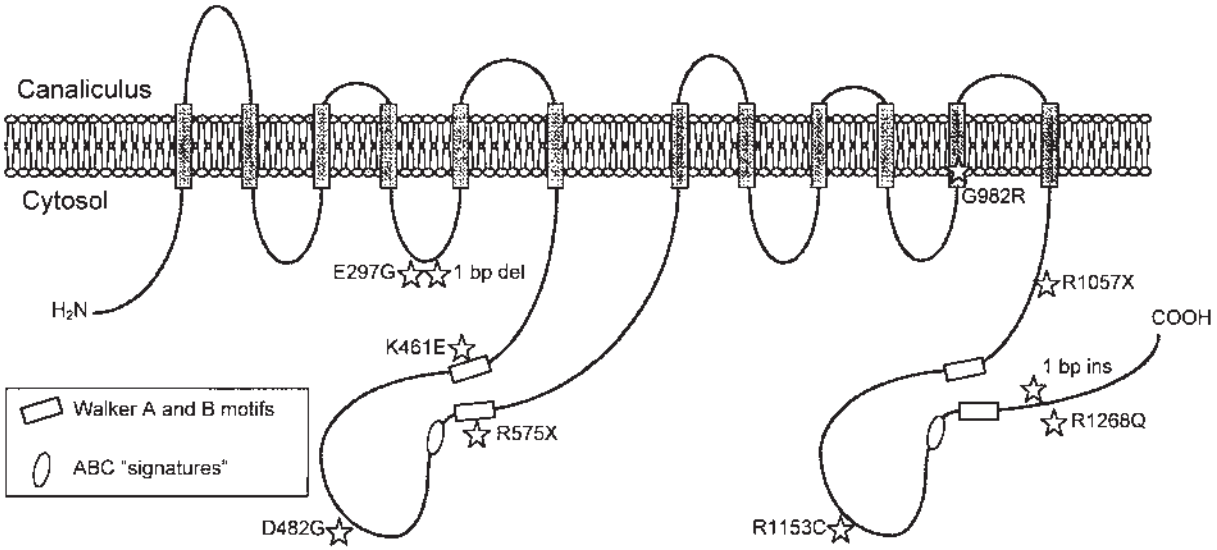

FIGURE 55.6-2 Diagram of defects in the bile salt excretory protein. Model of canalicular bile salt transporter protein embedded within the cell membrane. Specific mutations are indicated by the stars. Reproduced with permission from Thompson R.[20]

not characterized by progressive liver disease, suggesting that alterative transport mechanisms exist.[27] Because BSEP is liver specific, it is also not surprising that liver transplant appears to be curative.[17,20] A subset of patients may have mutations in BSEP that lead to a partially active protein.[23,28] These patients may have a more moderate disease course and could potentially be amenable to nontransplant surgical interventions such as partial biliary diversion or ileal bypass (see below).[29]

The diagnosis of a defect in *BSEP* should be suspected in any infant or young child with cholestasis who has normal γ-glutamyl transpeptidase and cholesterol levels. Biliary bile salt levels have been reported to be very low; unfortunately, biliary bile is often not available for routine clinical analysis. Differentiation of this disease from FIC1 disease may be problematic. It has been assumed that defects in *BSEP* have significantly more rapid progression to decompensated liver disease than seen in FIC1 disease. Careful genotype and phenotype studies are under way, and preliminary reports indicate that this assumption may not have been entirely accurate.[29] The ultrastructural appearance of canalicular bile in patients who are not receiving ursodeoxycholic acid may also be diagnostically useful.[30] Ultimately, some form of molecular diagnostic study, either analysis of hepatic protein or messenger ribonucleic acid (mRNA) expression or genomic sequencing of the *BSEP* gene, may be required to confirm a suspected diagnosis. Accuracy in assigning an appropriate diagnosis may be imperative because defects in *BSEP* appear to respond well to liver transplant, whereas FIC1 disease may not and may require a more specialized surgical approach (see below).

DEFECTS IN CANALICULAR PHOSPHOLIPID TRANSPORT

Phospholipid excretion into bile was presumed to be a passive process until the recent discovery of a P-glycoprotein, which mediates ATP-dependent phospholipid transport into bile.[31] This transport protein was somewhat serendipitously discovered in an effort to further understand the multidrug resistance proteins. One member of this class, *MDR3* (*mdr2* in mice), had been cloned and was found to be expressed in human liver, although its function was unknown.[32] Preliminary attempts to express this gene product in cell lines were uninformative with regard to its function[33]; therefore, the gene was "knocked out" of mice by homozygous targeted disruption. The resulting homozygous *mdr2*$^{-/-}$ mice have provided great insights into the physiology of bile formation and formed the basis for the understanding of a new class of cholestatic liver diseases.[31] Elevated bilirubin, alkaline phosphatase, and alanine aminotransferase were detected in the serum of these mice. Bile duct proliferation with a mixed portal infiltrate associated with loss of bile canalicular microvilli was observed in the homozygote knockout mice. Biliary bile flow and bile acid output by these mice were normal. Phospholipid, cholesterol, and glutathione secretion were all markedly reduced in bile with a graded reduction in phospholipid only in heterozygote mice. The *mdr2* gene product was therefore presumed to be involved in canalicular excretion of phospholipid.

Further analysis of the *mdr2* knockout mice provided additional insights into the function and importance of this P-glycoprotein. Long-term histopathologic studies of the *mdr2*$^{-/-}$ mice demonstrated a novel progression from a nonsuppurative inflammatory cholangitis to metastatic hepatocarcinogenesis.[34] *MDR3*, the human homologue of the mouse *mdr2* gene, was introduced as a transgene into *mdr2*$^{-/-}$ mice.[35] Fibroblasts from the transgenic mice and not the knockout mice were able to transfer phospholipid from the inner hemileaflet to extracellular acceptor liposomes. This apparent phospholipid flippase activity was found to be an ATP-dependent phenomenon that could be observed using hepatic canalicular membrane.[36] Ultrarapid cryofixation of the liver from *mdr2*$^{-/-}$ mice with subsequent analysis by electron microscopy elegantly confirmed the suspected function of the mdr2 protein to be a phospholipid flippase (Figure 55.6-3).[37] In normal bile canaliculi, phospholipid accumulation on the outer hemileaflet of the canaliculus leads to the formation of vesicles that ultimately bud off into the canalicular lumen. These vesicles primarily contain cholesterol and phospholipid. These vesicles are targeted to plasma as opposed to bile in cholestasis and result in the formation of the characteristic lipoprotein X that is seen in obstructive liver disease, especially when it is secondary to bile duct obstruction.[38] *Mdr2*$^{-/-}$ mice do not accumulate lipoprotein X in the face of extrahepatic bile duct obstruction. Absence of phospholipid flippase function results in bile characterized by significant concentrations of unmicellized bile salts. This bile therefore has high detergent capacity and is toxic to the canalicular membrane and therefore the liver. Interestingly, *mdr2*$^{-/-}$ mice can be functionally rescued by either hepatic-specific transgenic expression of the human homologue *MDR3* or by hepatocyte transplant.[39,40]

The comprehensive characterization of the *mdr2*$^{-/-}$ mouse and the elucidation of the function of the *mdr2* gene product laid the groundwork for identification of human disease related to abnormal expression of the human homologue *MDR3*. The first preliminary description of a defect in this gene product included two children who initially presented with pruritus and hepatosplenomegaly. The *MDR3* mRNA could not be detected by Northern blotting in one of these patients, and phospholipid levels in bile were markedly reduced in the second.[41] Neither of these suggestive findings could definitively demonstrate a genetic abnormality in *MDR3*.

A subsequent report definitively established defects in *MDR3* as a cause of cholestatic liver disease in two children.[42] As in the previous report, both children presented with jaundice and hepatosplenomegaly. Like the *mdr2*$^{-/-}$ mice, both children had elevated alanine aminotransferase and γ-glutamyl transpeptidase levels. Serum bile acid levels were markedly elevated in both children. Portal inflammation with bile duct proliferation and fibrosis was present despite a patent and normal extrahepatic biliary tree. Neither child was responsive to ursodeoxycholic acid therapy,

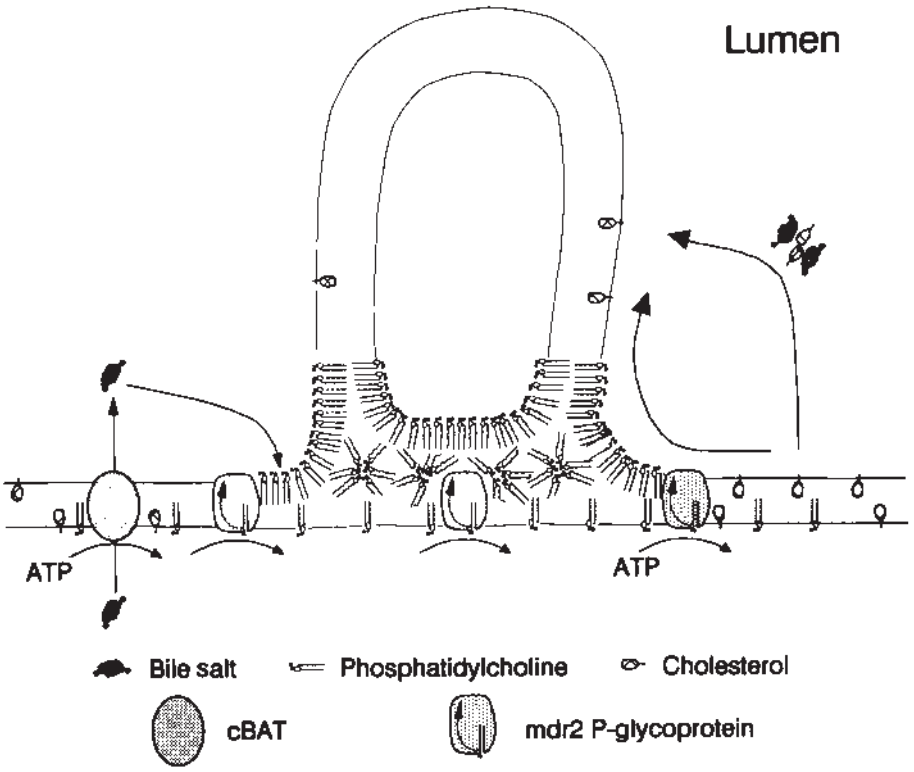

FIGURE 55.6-3 Diagram of function of the multidrug resistance 2 (mdr2) protein. In this model, the mdr2 (equivalent to human MDR3) protein is shown to function as a phospholipid flippase. Adenosine triphosphate (ATP) hydrolysis leads to the "flipping" of phospholipid from the inner to the outer hemileaflet of the lipid bilayer. Accumulation of phospholipid on the outer hemileaflet leads to the formation of vesicles, which contain cholesterol and phospholipid. cBAT = canalicular bite acid transporter (also known as BSEP). Reproduced with permission of Crawford AR et al.[37]

and complications of end-stage liver disease led to liver transplant at the ages of 3.5 and 9.0 years. Immunohistochemical analysis of the explanted liver from both children revealed an absence of staining for the MDR3 protein using a specific polyclonal antibody.[43] Reverse transcriptase–polymerase chain reaction analysis of the *MDR3* mRNA sequence in both patients identified homozygous defects that lead to premature stop codons and presumably truncated, unstable, and nonfunctional phospholipid flippase proteins. In one patient, the specific defect permitted genomic analysis of the proband and his family. The patient was found to be homozygous for the mutation at the genomic level, whereas his parents were both heterozygotes. His unaffected sister was homozygous for the wild-type gene.

The full range of the phenotypic expression of defects in the *MDR3* gene is not known and is under investigation at this time. Cholestasis of pregnancy was prevalent in one of the families of the children reported to have an *MDR3* nonsense mutation. There appears to be an association between heterozygosity for this defect and the propensity for the development of cholestasis of pregnancy.[44–46] A similar phenomenon has been observed with fatty liver of pregnancy and heterozygosity for fatty acid oxidation defects.[47] MDR3 defects have been reported in children with neonatal cholestasis, in children and adults with intrahepatic cholelithiasis, and in adults with chronic hepatitis and biliary cirrhosis.[48–52] Therefore, defects in *MDR3* should be considered in any child or adult with high γ-glutamyl transpeptidase levels and cholestasis or biliary cirrhosis of unknown etiology. Supporting clinical, biochemical, and histologic features would include onset in early childhood, significant pruritus, absent serum lipoprotein X, a normal extrahepatic biliary tree, and histologic findings, including bile duct proliferation, portal inflammation, and biliary fibrosis and cirrhosis (see Table 55.6-1). When available, analysis of phospholipid in bile can also support this diagnosis. Immunohistochemical analysis of a percutaneous liver biopsy might someday be a useful screening assay. Ultimately, analysis of genomic DNA and/or liver mRNA will be required to establish a specific genetic defect.

There are important clinical implications of a diagnosis of an MDR3 defect. At present, in its severe form, this appears to be a progressive and unremitting disease, which leads to end-stage liver disease within the first two decades of life, typically in the first decade. Neither ursodeoxycholic acid nor partial biliary diversion or ileal bypass appears to be effective in amelioriating either the pruritus or progression of this disease. Animal models of this disease indicate a potential risk for the development of liver cancer, although this has yet to be described in humans. The tissue distribution of the MDR3 protein appears to be liver specific, and, as such, liver transplant should be and has been curative.[43] Interestingly, animal studies have shown that the functional defect and presumably the disease can be ameliorated by both transgenic expression of a normal *MDR3* gene or by hepatocyte transplant.[42,53] There appears to be a subset of patients with presumably partial defects in MDR3 that are responsive to high-dose ursodeoxycholic acid.[51] Therefore, a trial of ursodeoxycholic acid is warranted in children with cryptogenic and nonobstructive liver disease characterized by high serum γ-glutamyl transpeptidase levels.

DEFECTS IN CANALICULAR ORGANIC ANION TRANSPORT

Dubin-Johnson syndrome was described in the 1950s and has been presumed to be the result of a defect in canalicular bilirubin transport.[54] Transport studies had indicated that a variety of organic anions, including conjugated bilirubin, were transported into the bile canaliculus by an ATP-dependent mechanism.[55] The identification of the specific protein involved in this transport process was aided by a naturally occurring rat species with chronic conjugated hyperbilirubinemia, the TR$^-$ rat.[56,57] Presuming that the canalicular organic anion transporter was homologous to a previously cloned human MRP1, Paulusma and colleagues screened a rat liver complementary DNA library for related gene products.[58] One of the novel isolated genes was highly expressed in liver and ultimately found to be mutated in the TR$^-$ rat. Immunoblot analysis revealed that this new protein, MRP2 (which is also referred to as cMOAT), was absent from canalicular membrane vesicles prepared from the TR$^-$ rat. Subsequent studies demonstrated a different defect in the same gene product in the Eisai hyperbilirubinemic rat.[59] The role of defects of the *MRP2* gene in Dubin-Johnson syndrome was initially complicated by the finding of absent immunostaining for MRP2 at the bile canaliculus but unexpected strong staining at the lateral or basolateral membrane of the hepatocyte.[60]

Dubin-Johnson syndrome is characterized by benign direct hyperbilirubinemia. Diagnosis is made on the finding of mild direct hyperbilirubinemia, with an absence of evidence of hepatocellular or canalicular injury. Urine typically contains an elevated percentage of coproporphyrin isomer I. Liver biopsy reveals no significant changes in hepatic architecture and characteristic melanin-like pigment in hepatocytes. When performed, the sulfobromphthalein test reveals normal hepatic uptake, delayed canalicular excretion, and a secondary peak owing to presumed reflux of dye into plasma. A number of mutations have now been described in the *MRP2/cMOAT* gene in patients with well-characterized Dubin-Johnson syndrome.[61–64] The initial confusion about the persistent basolateral staining for the transporter in these patients has been clarified with the current identification of six *MRP* genes. MRP2-specific antibodies reveal no immunologically recognizable protein in the liver from Dubin-Johnson syndrome patients.[65] The originally described basolateral staining was, in fact, cross-recognition with MRP3.

FIC1 DISEASE (BYLER DISEASE)

Byler disease has been viewed by many as the prototype for a genetic form of biliary transport disorder, yet unlike the other transport defects, its exact molecular pathophysiology remains elusive. Byler disease was first described in the 1960s as a cholestatic disease that affected members of the Amish community who were direct descendants of Jacob Byler and Nancy Kaufmann.[66,67] The disease appears to consist of two phases; the first cholestatic jaundice phase occurs in infancy. The jaundice associated with the first phase typically resolves, although the hallmark pruritus persists. The second phase of the disease includes end-stage liver disease with associated recurrent jaundice and typically becomes manifest at the end of the first decade or some time into the second decade of life. Early investigations into the pathophysiology of this disease included in vivo analysis of bile acid clearance in a patient with Byler disease.[68] Kinetic analysis of these studies pointed to a defect in hepatic excretion of bile salts, and, as such, Byler disease has always been presumed to be the result of defective biliary transport. Subsequent examination of the composition of bile in a separate set of patients supported the concept of a defect in canalicular excretion of bile salts.[69]

The clinical syndrome of Byler disease is characteristic and ultimately permitted genetic studies of a relatively homogeneous patient population. All patients have severe and, if untreated, relatively unremitting pruritus. This is in contrast to benign recurrent intrahepatic cholestasis, where the pruritus is episodic.[70] The pruritus in Byler disease is associated with markedly elevated serum bile salt levels. The biochemical pattern of the cholestasis in Byler disease is quite characteristic and includes relatively normal transaminase levels, variable bilirubin levels depending on the phase of the disease, and normal cholesterol and γ-glutamyl transpeptidase levels. In many ways, the biochemical markers are quite similar to those seen in defects in *BSEP* disease. Severe and sometimes disabling diarrhea and malabsorption may also be present. This appears to be the result of more than simple cholestasis because it may persist after successful liver transplant.[71] Wheezing and elevated sweat chloride levels have been described in some patients with Byler disease.[72,73]

The histologic findings in Byler disease have been carefully documented.[30,74] Prospective correlation of histology with genotyping is needed. Therefore, at present, it is difficult to assess whether the histologic findings that are described are relevant for PFIC in a general sense or to genetically proven Byler disease. It appears that Byler disease leads to a histologically bland form of intracanalicular cholestasis.[30] Histologic findings are clearly dependent on the age of the patient at the time of the biopsy. Early on, minimal giant cell hepatitis with mild portal inflammation is present. Bile duct paucity is not a characteristic finding, although the bile ducts themselves may be small. Over time, fibrosis in the biopsy may progress, and bile duct proliferation may be noted. A characteristic appearance of the bile on electron microscopic analysis (Figure 55.6-4) includes a coarsely particulate and amorphous granular biliary material.[30,75] Immunohistochemical analysis of liver from children with FIC1 deficiency has revealed diminished expression of γ-glutamyl transpeptidase at the bile canaliculus.[25] The specificity of these histologic and ultrastructural findings will need to be reassessed and correlated with genetic abnormalities in the *FIC1* gene (see below).

The approach to the identification of the cause of Byler disease used a genome screening technique referred to as searching for share segment.[76,77] This approach is based on the assumption that there is a common founder mutation in a population and that this mutation is the basis of a well-

characterized disease in a relatively closed community. Byler disease, as described in the Amish community, a priori appeared to fit these criteria quite well. Initially, analysis revealed that the Byler locus was found at chromosome 18q21-q22. Interestingly, this is the same locus that was identified for benign recurrent intrahepatic cholestasis. At the time of this discovery, interesting speculation took place as to the relationship between Byler disease and benign recurrent intrahepatic cholestasis. Possibilities included linked genes, a common regulatory gene, or different mutations with different functional consequences. Ultimately, more refining linkage analysis and complementary DNA library screening led to the identification of a defect in a gene labeled *FIC1* as the cause of both Byler disease and benign recurrent intrahepatic cholestasis.[78] Subsequent clinical studies have revealed that there is a clinical spectrum of disease between benign recurrent intrahepatic cholestasis and Byler disease and the designation of all of these disorders because FIC1 disease is more accurate.[79]

The current challenge is to determine the function of FIC1 and how different mutations lead to the diseases recognized as either benign recurrent intrahepatic cholestasis or Byler disease. Cloning of FIC1 led to the discovery that this gene product has a wide tissue distribution, including mRNA expression in the pancreas, small intestine, stomach, bladder, heart, placenta, lung, liver, and kidney.[78] Surprisingly, expression appears to be greatest in the pancreas and intestine. Immunohistochemistry reveals that it is expressed on the apical surface of many of these cells.[80,81] The range of tissues that express FIC1 might explain many of the systemic manifestations, including wheezing, elevated sweat chloride, and diarrhea. Recent investigations have revealed expression in bile duct epithelium, and this may be as relevant for the hepatic manifestations of the disease.[81] Computer-assisted homology analysis indicates that *FIC1* may be related to a previously cloned bovine adenosine triphosphatase II gene, which appears to have aminophospholipid transporting activity.[82] This type of transport function is critical for perpetuation of the physiologically important assymmetry of phosphatidylserine distribution within the lipid bilayer of a variety of cells. The exact interaction between FIC1 and bile acid transporters is yet to be determined. A mouse model of Byler disease is characterized by abnormal regulation of ileal bile acid transport.[83] Analysis of human ileum indicated that the ileal bile acid transporter (apical sodium dependent bile acid transporter = *SLC10A2*) is relatively overexpressed in children with absent FIC1 expression.[84] This suggests that FIC1 disease may, in part, be the result of a gain of function defect in the ileal bile acid transporter. In rats, indirect immunofluorescence and Western blotting indicate that the FIC1 protein is expressed on the canalicular surface of hepatocytes and the brush border membrane of enterocytes.[80,81] Expression in the intestine appears to be along the entire length of the small intestine. Presumably, abnormalities in FIC1 function alter the assymmetric distribution of phospholipids in the hepatic canalicular and intestinal brush border membrane and secondarily affect the normal function of critical solute transporters. The common link in these abnormalities may be a defect in the activity of the farnesoid X receptor (FXR). The FXR plays a key role in the regulation of genes involved in bile acid biosynthesis and transport.[85,86] Absence of FIC1 in the ileum of patients and in cell lines treated with FIC1 antisense oligonucleotides is associated with a reduction in FXR expression.[84] In cell lines FXR does not translocate into the nucleus when FIC1 is not expressed.[84] These studies suggest that FIC1 activity alters signal transduction pathways involved in FXR nuclear translocation.

Mutational analysis of FIC1 disease patients has revealed specific and distinct homozygous defects in patients of Amish and European origin.[78,87,88] Severe mutations have the potential to disrupt key ATP-binding sites in the FIC1 molecule. In contrast, the defects that have been identified in patients with benign recurrent intrahepatic cholestasis appear to involve less critical residues. As such, the defect in benign recurrent intrahepatic cholestasis may only partially affect FIC1 function and thus might lead to a milder phenotype. A wide variety of distinct mutations have been described in patients with either Byler disease or benign recurrent intrahepatic cholestasis (BRIC), including 13 missense mutations, 1 nonsense mutation, 3 small deletions, 1 large genomic deletion, and 5 splice-site defects.[87] A number of compound heterozygote states have been detected, most of which lead to a phenotype most consistent with BRIC. Homozygosity for one of these defective alleles (G308V) is associated with classic Byler disease, whereas compound heterozygosity of the same allele leads to BRIC. This defect has been introduced into a mouse model of this disease, which is currently under study.[89] Careful analysis of the clinical course of these patients appears to indicate that a spectrum of disease

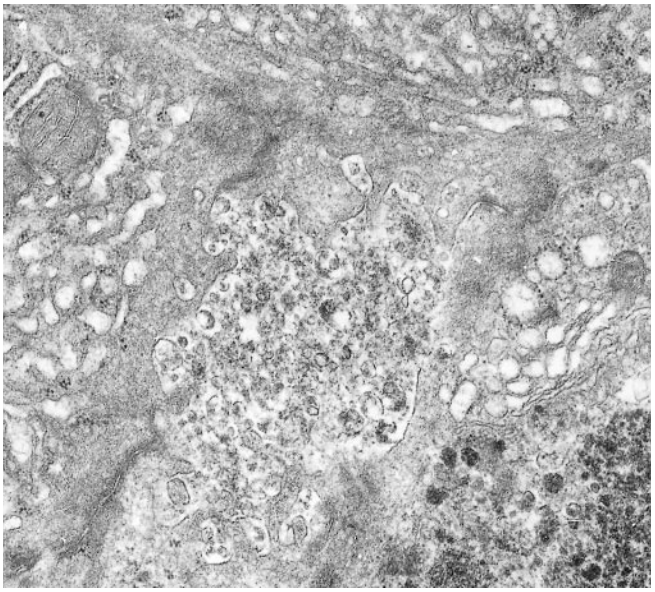

FIGURE 55.6-4 Electron microscopic appearance of Byler disease bile. Coarsely granular bile is seen in a patient with Byler disease (osmium tetroxide/uranyl acetate/lead citrate; ×31,625 original magnification). Courtesy of A. S. Knisely, Institute of Liver Studies, London, UK.

exists between BRIC and Byler disease. Clinical variability has been observed between patients with the same FIC1 genotype, suggesting that environmental influences and/or variable penetrance may exist for this disease.

Correct diagnosis of FIC1 disease has potentially very important clinical and therapeutic consequences. This diagnosis should certainly been considered in the setting of a patient with cholestasis characterized by severe pruritus who has markedly elevated serum bile salts with relatively normal cholesterol and γ-glutamyl transpeptidase. Being a member of the Amish community is highly suggestive but not diagnostic of this disorder.[90] Alternative defective genes have recently been described in Amish children. These children have compound defects involving tight junction proteins and bile acid conjugation enzymes. The slower clinical progression of FIC1 disease may help distinguish it from defects in *BSEP*. The characteristic electron microscopic appearance of bile (with the patient off ursodeoxycholic acid therapy) is highly suggestive of this diagnosis.[30] Immunohistochemical analysis of γ-glutamyl transpeptidase in liver may also be suggestive of a defect in FIC1.[25] Molecular analysis is now available on a research basis and should be sought out to help confirm a defect in *PFIC1*. Absence of intestinal FIC1 expression at the level of either protein or mRNA may be a shortcut to this diagnosis in patients with defects that lead to an unstable or absent mRNA or protein.[84]

The clinical consequences of a correct diagnosis are related to the appropriate choice of therapy. It has become apparent from clinical experience and basic investigations that *FIC1* has a wide distribution of tissue expression, and FIC1 disease, as such, is a systemic disease. Liver transplant is therefore not necessarily curative, unlike the clinical experience in cases of *BSEP* and *MDR3* deficiencies. Persistent diarrhea, graft steatosis, growth failure, and pancreatitis have all been observed after liver transplant in children with FIC1 disease.[71] Instead, surgical approaches that use depletion of the bile salt pool seem to be effective and involve significantly less risk than liver transplant. These methods include partial biliary diversion and partial ileal bypass.[91–98] Both techniques lead to wasting of bile salts and presumed depletion of toxic bile salts, although this explanation is not completely clear. Interruption of the enterohepatic circulation may ameliorate some of the problems associated with the gain of function in the ileal bile acid transporter. Both treatments have been shown to markedly improve pruritus and to stabilize or even improve both the biochemical and histologic manifestations of the disease. Clearly, at this time, these surgical approaches are the treatment of choice for compensated FIC1 disease. Better understanding of the pathophysiology of FIC1 disease might lead to alternative medical approaches, potentially including specific and highly potent bile acid–binding resins or bile acid transport inhibitors.

DISORDERS OF BILIARY TRANSPORT IN SYSTEMIC DISEASE

Jaundice and cholestasis are well-recognized features of conditions that nonspecifically affect the liver. Examples include gram-negative sepsis, administration of parenteral hyperalimentation, drug toxicity, and liver regeneration. The specific effects of these various conditions on transporters involved in bile formation can explain the development of cholestasis and might lead to specific interventions to prevent liver injury. The best understood example is the effect of gram-negative sepsis. The association between jaundice and cholestasis[99] and gram-negative sepsis has been recognized for a long time.[100,101] The molecular basis of this is now beginning to be understood. Gram-negative sepsis is associated with circulation of endotoxin, which leads to the formation of tumor necrosis factor-α and a range of inflammatory cytokines (eg, interleukins 1 and 6). Via specific interactions with *cis* elements in the promoter of the basolateral bile acid transporter, *NTCP* is down-regulated.[99,102–104] Canalicular transport of bile acids and organic anions also appears to be impaired by sepsis and is mediated by down-regulation in *MRP2/cMOAT* and *BSEP*.[105–107] The molecular effects of the administration of parenteral hyperalimentation, drug toxicities, and hepatic regeneration are currently under investigation.

CLINICAL APPROACH TO COMPLEX FORMS OF CHOLESTASIS

In the current era, the clinician is faced with an evolving and complex series of potential diagnostic and therapeutic approaches for children and adults with nontypical forms of cholestasis. An algorithmic approach to the evaluation of these nonstandard forms of cholestatic liver disease is suggested in Figure 55.6-5. The presence of pruritus and/or significantly elevated serum bile acid levels in combination with measurement of serum γ-glutamyl transpeptidase may be useful in the initial categorization of the potential molecular process underlying the particular cholestatic condition. Supplemental assays including electron microscopy, biliary bile acid and biliary phospholipid analysis, serum lipoprotein X measurement, and urine coproporphyrin analysis may support a potential molecular diagnosis. In the current era, molecular diagnostics should be strongly considered part of the comprehensive evaluation of the patient with complex cholestasis. Given the divergent potential treatments for these distinct disorders, this degree of sophisticated diagnostic testing appears warranted.

FUTURE DIRECTIONS

Our current understanding of biliary transport defects is clearly in its infancy. A variety of areas of investigation will need to be explored. New molecular mechanisms of cholestasis and genetic defects leading to biliary transport disorders are yet to be discovered. The full range of the clinical phenotypes of the currently described disorders needs to be discerned. The role of partially functioning transporters or heterozygote states in commonly occurring but poorly understood cholestatic conditions, like that seen during parenteral hyperalimentation, will need to be investigated.

Bile excretion by the liver is a critical function, and, as such, its underlying molecular mechanisms are complex.

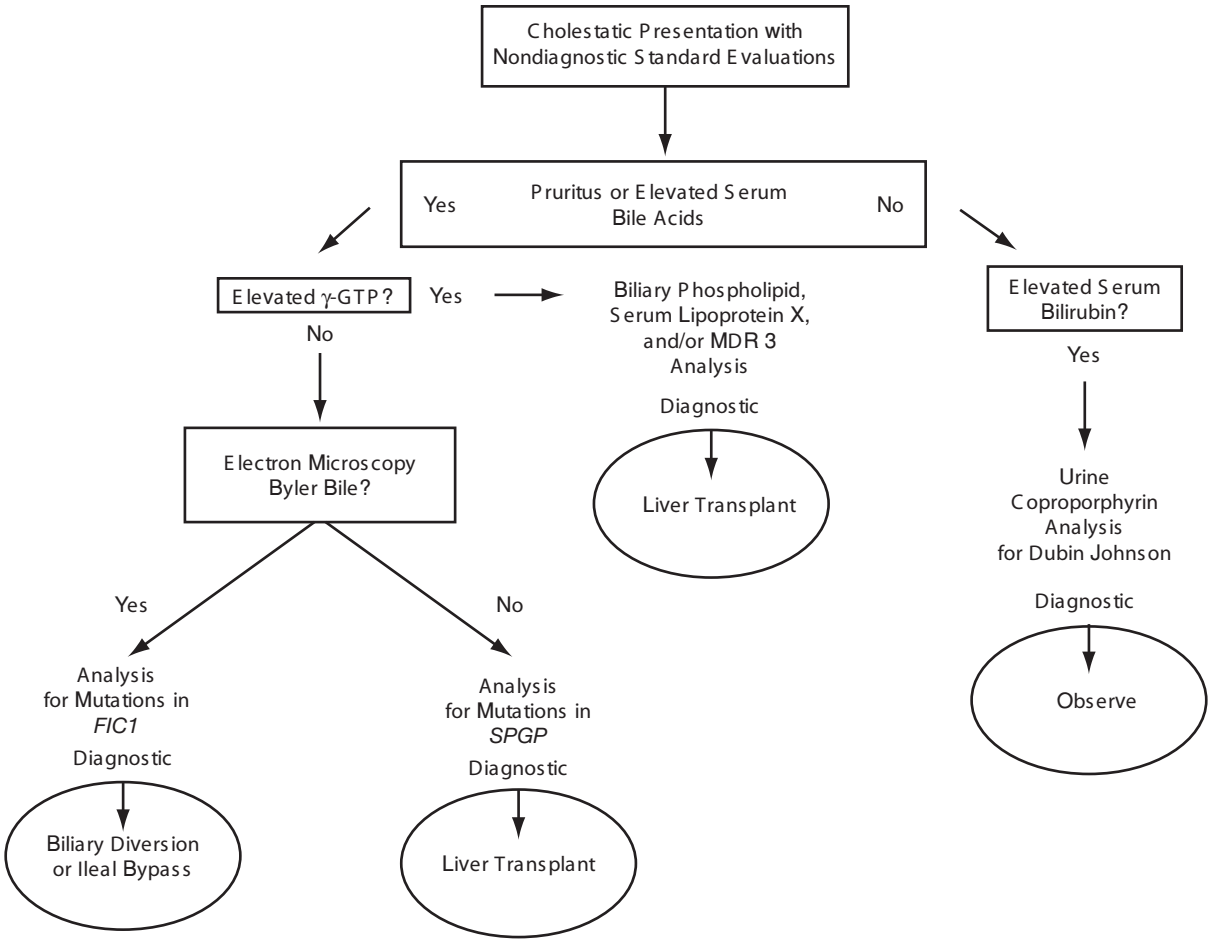

FIGURE 55.6-5 Diagnostic and therapeutic algorithm for complex cholestasis. GTP = γ-glutamyl transpeptidase; MDR = multidrug resistance; *SPGP* = sister of P-glycoprotein.

Significant achievements have been made in understanding the process of bile excretion, but a great deal remains undiscovered. Examples of areas of ongoing research include the exact pathways involved in the intracellular translocation of components of bile from the basolateral membrane to the bile canaliculus, the role of the cytoskeleton in canalicular function, the mechanisms of regulation of canalicular transport proteins, and the functional consequences of bile duct transport processes on the formation of bile. It is expected that molecular defects in each of these important pathways and mechanisms of regulation of bile formation may lead to cholestatic liver disease.

A number of cholestatic phenotypes exist for which a molecular mechanism remains elusive. A third locus for low γ-glutamyl transpeptidase cholestasis appears to exist.[108] Aagenaes syndrome is another form of inherited cholestasis that consists of periods of severe pruritus but has the additional finding of lower extremity lymphedema.[109] A syndrome of arthrogryposis, renal tubular acidosis, and cholestasis with normal γ-glutamyl transpeptidase levels has been reported in 11 kindreds, and the molecular defect has recently been described.[110,111] Rotor syndrome, like Dubin-Johnson syndrome, is characterized by persistent direct hyperbilirubinemia with no significant intrahepatic liver injury.[112] Distinguishing features include the absence of hepatic pigmentation and the urinary pattern of coproporphyrins. Neonatal sclerosing cholangitis is a relatively rare form of neonatal cholestasis and has been linked to a new and unique genetic locus (R. Thompson, personal communication, 1999).[113] Genetic, molecular, and physiologic studies of these syndromes are likely to expand our knowledge of disorders of biliary transport.

The current clinical presentations of the various disorders of biliary transport that have been described in this chapter probably do not represent the full spectrum of the clinical phenotypes that may exist. As the molecular etiology of a disease is discovered, the clinical spectrum of the disease in question changes significantly, and, in some ways, the definition of the original disease comes into question. Two recent noteworthy examples are cystic fibrosis and Alagille syndrome.[114–116] Abnormalities in the *CFTR* gene have recently been described in patients with absent vas deferens or chronic pancreatitis who do not have the usual clinical features that are characteristic of cystic fibrosis.[117–119] Similarly, isolated cardiac anomalies have been described in patients with mutations in the *JAGGED1* gene, yet these patients do not meet the standard defining criteria for a diagnosis of Alagille syndrome.[120,121] It will therefore be very important to examine the level of expression and genotype of the various newly described

transport genes in a spectrum of pediatric liver diseases in which the etiology is currently unknown.

In a related area of investigation, it will be important to carry out similar investigations of the level of expression and genotype of transporter genes in what are currently felt to be relatively well-understood disorders. Many cholestatic liver diseases have well-described phenotypes and are labeled with well-entrenched names, but have basic etiologies that are not well understood. Primary sclerosing cholangitis, total parenteral hyperalimentation, and drug-related cholestasis are potential examples. Many of the features of primary sclerosing cholangitis, especially the intrahepatic form, are akin to defects in *MDR3*. Predisposition to the development of cholestasis during total parenteral hyperalimentation may, in some cases, be related to heterozygote status for defects in one of the biliary transport genes. Alternatively, patients might be homozygotes or compound heterozygotes for mutations that lead to partial inactivation of the transporter. Similarly, drug-related cholestasis might be the result of partially dysfunctional genotypes, especially those that involve the *MRP2/cMOAT* gene. The recent description of cholestasis of pregnancy being related to heterozygote status for a defect in the *MDR3* gene is a good example of the potential implications of this process.[44]

SUMMARY

A new era in the understanding of cholestatic liver disease in children has been ushered in by the discovery of a variety of gene products that play a key role in the formation of bile. Defects in the canalicular transporters for bile acids, organic anions, and phospholipids all lead to distinct forms of cholestatic liver disease, whose onset is during early childhood. Liver transplant at present remains the best long-term approach to the treatment of defects in bile acid or phospholipid excretion. Byler disease is distinct from these disorders and involves a defect in a gene whose exact function in bile formation remains a subject of intense investigation. Clinical and laboratory studies indicate that Byler disease is a systemic disease, and, as such, liver transplant may not be curative. Partial biliary diversion or ileal bypass may be more appropriate means of treatment of this disease. Our understanding of biliary transport disorders is in its infancy, and the future holds great promise for further understanding of the mechanisms of and optimal treatment for cholestatic liver disease in children.

7. α_1-Antitrypsin Deficiency

David H. Perlmutter, MD

The classic form of α_1-antitrypsin (α_1-AT) deficiency, homozygous for the mutant α_1-*ATZ* allele, is associated with premature development of pulmonary emphysema and, in some cases, chronic liver disease. This deficiency is the most common metabolic cause of emphysema in adults and liver disease in children and is the most common metabolic disease for which children undergo liver transplant (United Network for Organ Sharing Data Request Service, personal communication, 2000). In the most extensively studied population (the Swedish population), the incidence of the deficiency is approximately 1 in 1,639 live births.[1] Data from eight separate studies suggest that the prevalence of α_1-AT deficiency in the United States is 1 in approximately 2,000 individuals.[2] It especially affects whites of northern European ancestry.[3,4]

α_1-AT is an approximately 55 kD secretory glycoprotein that inhibits destructive neutrophil proteases, including elastase, cathepsin G, and proteinase 3. Plasma α_1-AT is predominantly derived from the liver and increases three- to fivefold during the host response to tissue injury or inflammation. It is the archetype of a family of structurally related circulating serine protease inhibitors termed serpins.

In the deficient state, there is ~ 85 to 90% reduction in serum concentrations of α_1-AT. A single amino acid substitution results in an abnormally folded protein that is unable to traverse the secretory pathway. This α_1-ATZ protein is retained in the endoplasmic reticulum (ER) rather than secreted into the blood and body fluids.

Although it does not occur until adulthood, many α_1-AT–deficient individuals develop destructive lung disease and emphysema. Most of the data in the literature indicate that emphysema results from a decreased number of α_1-AT molecules within the lower respiratory tract, allowing unregulated elastolytic attack on the connective tissue matrix of the lung.[5,6] Oxidative inactivation of residual α_1-AT as a result of cigarette smoking accelerates lung injury.[7] Moreover, the elastase-antielastase theory for the pathogenesis of emphysema is based on the concept that oxidative inactivation of α_1-AT as a result of cigarette smoking plays a key role in the emphysema of α_1-AT–sufficient individuals, the vast majority of emphysema patients.[5,8]

It has been more difficult to explain the pathogenesis of liver injury in this deficiency. The results of transgenic animal experiments have provided strong evidence that liver disease does not result from a deficiency in antielastase activity.[9,10] Most of the data in the literature corroborate the concept that liver injury in α_1-AT deficiency results from the hepatotoxic effects of retention of the aggregated mutant α_1-ATZ molecule in the ER of liver cells. Nationwide prospective screening studies done by Sveger in Sweden have shown that only 10 to 15% of the deficient population develop clinically significant liver disease over the first 20 years of life.[1,11] These data indicate that other genetic traits and/or environmental factors predispose a subgroup of deficient individuals to liver injury.

The diagnosis of α_1-AT deficiency is based on the altered migration of the abnormal α_1-ATZ molecule in serum specimens subjected to isoelectric-focusing gel analysis. Treatment of liver disease associated with α_1-AT deficiency is mostly supportive. Liver replacement therapy has been used successfully for severe liver injury. Although clinical efficacy has not been demonstrated, many patients with emphysema owing to α_1-AT deficiency are currently being treated by intravenous or intratracheal aerosol administration of purified plasma α_1-AT. An increasing number of patients with severe emphysema have undergone lung transplant. Several new pharmacologic and genetic strategies for prophylaxis of both liver and lung disease are currently under development for clinical application.

STRUCTURE OF α_1-ANTITRYPSIN

α_1-AT is encoded by a single approximately 12.2 kb gene on human chromosome 14q31-32.3.[12–15] There is a sequence-related gene 12 kb downstream from this gene.[14,16–18] Because there is no evidence that the sequence-related gene is expressed, it is considered a pseudogene. The genes for three other members of the serpin family, α_1-antichymotrypsin, protein C inhibitor, and corticosteroid-binding globulin, are also closely linked on chromosome 14.[15,19]

The α_1-AT gene (Figure 55.7-1) is organized in seven exons and six introns.[12,20] The first three exons and a short 5′ segment of the fourth exon code for 5′ untranslated regions of the α_1-AT messenger ribonucleic acid (mRNA). The first two exons and a short 5′ segment of the third exon are included in the primary transcript in macrophages but not in hepatocytes, accounting for a slightly longer mRNA. There are, in fact, two mRNA species in macrophages, depending on alternative post-transcriptional splicing pathways involving one of the first two most 5′ exons.[20,21] Most of the fourth exon and the remaining three exons encode the protein sequence of α_1-AT. There is a 72-base sequence that constitutes the 24–amino acid amino-terminal signal sequence. There are three sites for asparagine-linked carbohydrate attachment: residues 46, 83, and 247. All three are used for post-translational glycosylation. The active

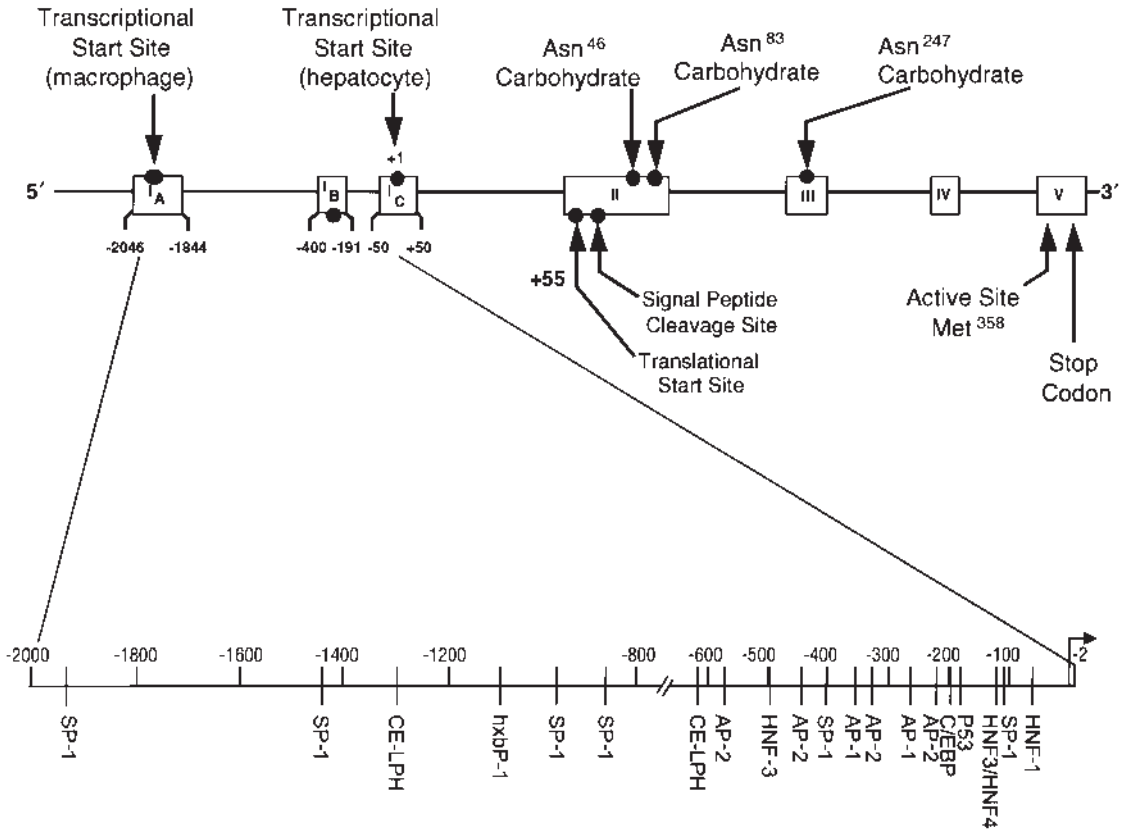

FIGURE 55.7-1 Schematic representation of the structure of the α_1-antitrypsin gene (not to scale) and map of potential regulatory elements based on its sequence.

site, so-called P_1 residue, Met 358, is encoded within the seventh exon (exon V).

The α_1-AT protein is a single-chain, approximately 52 to 55 kD polypeptide with 394 amino acids and three asparagine-linked complex carbohydrate side chains.[22] There are two major isoforms in serum, depending on the presence of a biantennary or triantennary configuration for the carbohydrate side chains.[23] X-ray crystallography studies have shown that α_1-AT has a globular shape and a highly ordered internal domain composed of two central β sheets surrounded by a small β sheet and nine α helices.[24,25] The dominant structure is the five-stranded β-pleated sheet termed the A sheet (Figure 55.7-2).

α_1-AT is the archetype of a family of structurally related proteins called serpins that includes antithrombin III, α_1-antichymotrypsin, C1 inhibitor, α_2-antiplasmin, protein C inhibitor, heparin cofactor II, plasminogen activator inhibitors I and II, protease nexin I, ovalbumin, angiotensinogen, corticosteroid-binding globulin, and thyroid-binding globulin.[25,26] These proteins share about 25 to 40% primary structural homology with higher degrees of regional homology in functional domains. Most serpins function as suicide inhibitors by forming equimolar complexes with a specific target protease. Other serpins are not inhibitory. For instance, corticosteroid and thyroid hormone–binding globulins, which are thought to represent carriers for corticosteroid and thyroid hormone, respectively, form complexes with, but do not inactivate, their hormone ligands.

A comparison of α_1-AT with other members of the serpin supergene family has generated several important concepts about the structure and function of α_1-AT. For instance, the reactive site P1 residue of α_1-AT is localized to a canonical loop that rises above the gap in the center of the A sheet (see Figure 55.7-2).[27,28] This loop may provide a certain degree of flexibility to the functional activity of the inhibitor. The reactive loop conformation of serpins is also thought to make them susceptible to proteolytic cleavage by thiolenzymes and metalloenzymes. The P1 residue itself is the most important determinant of functional specificity for each serpin molecule. This concept was dramatically confirmed by the discovery of α_1-AT Pittsburgh, a variant in which the P1 residue of α_1-AT, Met 358, is replaced by Arg 358. In this variant, α_1-AT functions as a thrombin inhibitor, and severe bleeding diathesis results.[29]

The carboxyl-terminal fragment of α_1-AT and the other serpins also bears important structural and functional characteristics. There is a much higher degree of sequence homology among serpins in the carboxyl terminus. A small fragment at this terminus is cleaved during formation of the inhibitory complex with serine protease. This carboxyl-terminal fragment possesses chemotactic activity.[30,31] Moreover, this fragment bears the receptor-binding domain for cell surface binding, internalization of α_1-AT elastase and other serpin-enzyme complexes, and activating a signal transduction pathway for up-regulation of α_1-AT gene expression.[32,33]

Protease Inhibitor System for Classification of Structural Variants of α_1-Antitrypsin

Variants of α_1-AT in humans are classified according to the protease inhibitor phenotype system as defined by agarose electrophoresis at acid pH or isoelectric focusing of plasma in polyacrylamide.[34] The protease inhibitor classification assigns a letter to variants according to the migration of the major isoform, in alphabetic order from anode to cathode or from low to high isoelectric point. For example, the most common normal variant migrates to an intermediate isoelectric point, designated M. Individuals with the most common severe deficiency have an α_1-AT allelic variant that migrates to a high isoelectric point, designated Z. Using restriction fragment length and direct deoxyribonucleic acid (DNA) sequence analysis together with isoelectric focusing, more than 100 allelic variants of α_1-AT have been reported.[35]

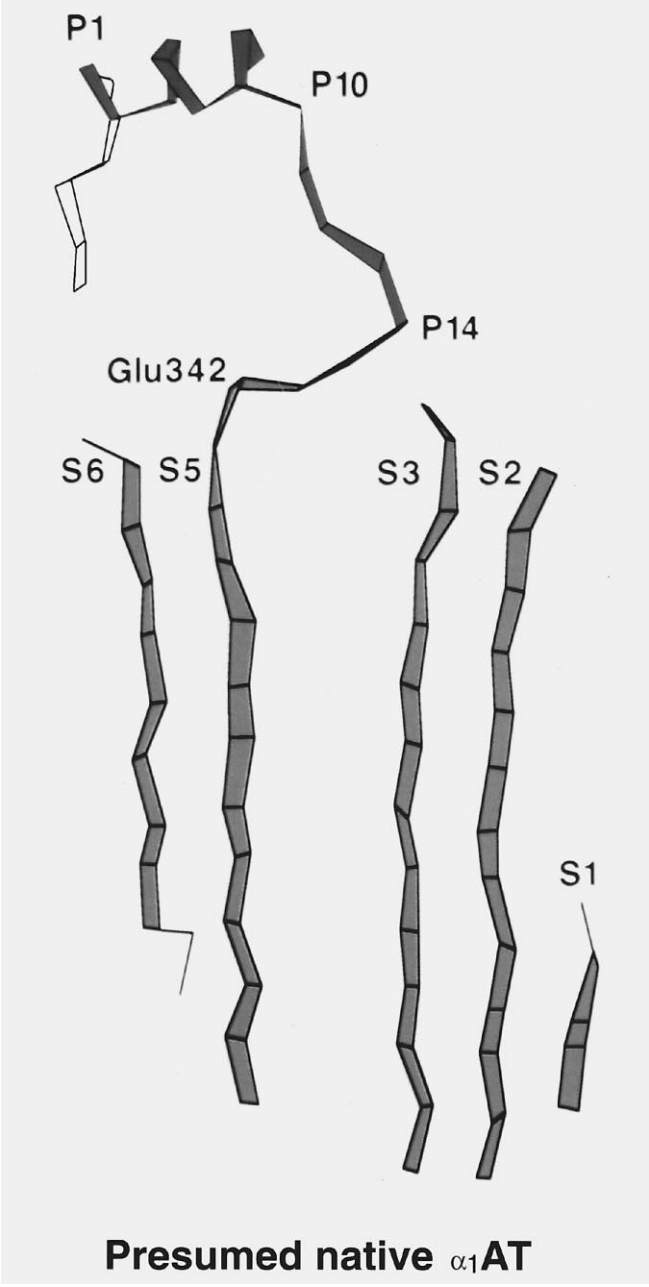

FIGURE 55.7-2 Ribbon diagram of the A sheet and reactive center loop of native α_1-antitrypsin (AT). Because native α_1-AT has not been crystallized, this ribbon diagram is generated by computer models, based on the crystal structures of cleaved α_1-AT and native ovalbumin. The reactive center loop is shown in dark gray (magenta). Residues P10 and P14 are numbered from the reactive-site methionine P1. The carboxyl-terminal fragment is shown as a white ribbon. Beta-helices of the A sheet are shown as light gray (blue) ribbons and referred to as S1, S2, S3, S5, and S6 (for color figure, see CD-ROM). The Glu 342 residue that is replaced by Lys in α_1-ATZ is designated. Adapted from Carrell RW, Evans DL, Stein DE. Mobile reactive centre of serpins and the control of thrombosis. Nature 1991;353:576.

Normal Allelic Variants. The most common normal variant of α_1-AT is termed M_1 and is found in 65 to 70% of whites in the United States.[35] A restriction fragment length polymorphism may further subdivide individuals with the classic M_1 allele.[36] The normal M_3 allele, which differs from M_1 by a single-base change,[35] is found in approximately 10% of the same population. The M_2 allele, characterized by an additional base change from the M_3 sequence, occurs in 15 to 20% of the white population.[37,38] There are many rare normal allelic variants with allelic frequencies of less than 0.1%.[38–42] In each case, these variants are associated with serum concentrations of and functional activity for α_1-AT within the normal range.[1]

Null Allelic Variants. Variants in which α_1-AT is not detectable in serum are called null allelic variants (Table 55.7-1) and, when inherited with another null variant or deficiency variant, are associated with premature development of emphysema.[43] Several types of defects, including insertions and deletions, appear to be responsible for these variants. In two cases, α_1-AT $Null_{Isola\ di\ procida}$ and α_1-AT $Null_{Reidenburg}$, there is deletion of all α_1-AT coding regions.[44,45] In two other cases, α_1-AT $Null_{Bellingham}$ and α_1-AT $Null_{Granite\ Falls}$, α_1-AT mRNA is undetectable.[46–49] Three other null alleles result in truncated proteins that are degraded in the ER—$Null_{Mattawa}$, $Null_{Hong\ Kong}$, and $Null\text{-}_{Clayton}$.[50–53] A single-base substitution has been discovered in the $Null_{Ludwigshafen}$ allele.[54] A recent study suggests that this mutant α_1-AT molecule is synthesized and secreted in transfected heterologous cells, but there is a slight decrease in its rate of secretion, and it completely lacks functional activity.[55] It is not yet known whether instability or accelerated catabolism in vivo is the explanation for the inability to detect this mutant α_1-AT molecule in serum specimens.

Dysfunctional Variants. Dysfunctional variants of α_1-AT include $\alpha_1\text{-}AT_{Pittsburgh}$.[29] There also is a decrease in serum concentration and functional activity for α_1-AT $M_{Mineral\ Springs}$.[56] For several variants that have been identified in compound heterozygotes, such as α_1-AT F,[57] α_1-AT $Null_{Newport}$, and α_1-AT $Z_{Wrexham}$,[58] it is not clear whether the variants result in normal, null, deficient, or dysfunctional changes.

Deficiency Variants. Several variants of α_1-AT associated with a reduction in serum concentrations of α_1-AT have been described and are called deficiency variants

(Table 55.7-2). Some of these variants, such as the S variant, are not associated with clinical disease.[12,59,60] Other deficiency variants are associated with emphysema, such as $M_{Heerlen}$,[61,62] $M_{Procida}$,[63] M_{Malton},[64,65] M_{Duarte},[66] $M_{Mineral\ Springs}$,[56] P_{Lowell},[42] and $W_{Bethesda}$.[67] In two persons with M_{Malton} and one with M_{Duarte}, hepatocyte α_1-AT inclusions and liver disease have been reported.[64,66,68] In one person with the deficiency variant S_{Iiyama}, emphysema and hepatocyte inclusions were reported, but this person did not have liver disease.[69]

FUNCTION

α_1-AT is an inhibitor of serine proteases in general, but its most important targets are neutrophil elastase, cathepsin G, and proteinase 3, proteases released by activated neutrophils. Several lines of evidence suggest that inhibition of neutrophil elastase is the major physiologic function of α_1-AT. First, individuals with α_1-AT deficiency are susceptible to premature development of emphysema, a lesion that can be induced in experimental animals by instillation of excess amounts of neutrophil elastase in the airways.[70] In fact, these observations have led to the concept that destructive lung disease may result from perturbations of the net balance of elastase and α_1-AT within the local environment of the lung.[5] Second, the kinetics of association of α_1-AT and neutrophil elastase are more favorable by several orders of magnitude than those for α_1-AT and any other serine protease.[71] Third, α_1-AT constitutes more than 90%

of the neutrophil elastase inhibitory activity in the one body fluid that has been examined, pulmonary alveolar lavage fluid.

α_1-AT acts competitively by allowing its target enzymes to bind directly to a substratelike region within the carboxyl-terminal region of the inhibitor molecule. This reaction between enzyme and inhibitor is essentially second order, and the resulting complex contains one molecule of each of the reactants. A peptide bond in the inhibitor is hydrolyzed during formation of the enzyme-inhibitor complex. However, hydrolysis of this reactive site peptide bond does not proceed to completion. An equilibrium near unity is established between complexes in which the reactive site peptide bond of α_1-AT is intact (native inhibitor) and complexes in which this peptide bond is cleaved (modified inhibitor). The complex of α_1-AT and serine protease is a covalently stabilized structure that is resistant to dissociation by denaturing compounds, including sodium dodecyl sulfate and urea. The interaction between α_1-AT and serine protease is suicidal in that the modified inhibitor is no longer able to bind and/or inactivate enzyme. Studies have now shown that the irreversible trapping of target enzyme is mediated by a profound conformational change in α_1-AT such that the cleaved reactive loop, with bound enzyme, inserts into the gap in A sheet (see Figure 55.7-2).[72] Carrell and Lomas have likened the inhibitory mechanism to a "mousetrap, with the active inhibitor circulating in a metastable, stressed-form and then springing into the stable relaxed form to lock the complex with its target protease."[72] The protease is crushed and inactivated during this structural transition.[73]

The net functional activity of α_1-AT in complex biologic fluids may be modified by several factors. First, the reactive site methionine of α_1-AT may be oxidized and thereby rendered inactive as an elastase inhibitor.[74] In vitro, α_1-AT is oxidatively inactivated by oxidants released by activated neutrophils and alveolar macrophages of cigarette smokers.[75,76] Second, the functional activity of α_1-AT may be modified by proteolytic inactivation. Several members of the metalloprotease family (including collagenase and *Pseudomonas* elastase) and the thiol protease family can cleave and inactivate α_1-AT.[77] DNA released by dying cells at sites of tissue injury or inflammation has the capacity to interfere with the protease inhibitory activity of α_1-AT. [78]

Although α_1-AT from the plasma[79] or liver[80] of individuals with α_1-AT deficiency is functionally active, there may be a decrease in its specific elastase inhibitory capacity. Ogushi and colleagues have shown that the kinetics of association with neutrophil elastase and the stability of complexes with neutrophil elastase were significantly decreased for α_1-AT from deficient plasma.[81] There was no decrease in functional activity of α_1-AT from individuals homozygous for the α_1-ATS allelic variant.

Several studies have indicated that α_1-AT protects experimental animals from the lethal effects of tumor necrosis factor.[82,83] Most of the evidence from these studies indicates that this protective effect is due to inhibition of the synthesis and release of platelet-activating factor from neutrophils,[83,84] presumably through the inhibition of neutrophil-derived proteases. A recent report has suggested that α_1-AT inhibits infectivity of human immunodeficiency virus (HIV) type 1 and its production by infected cells.[85]

α_1-Antitrypsin also appears to have functional activities that do not involve the inhibition of neutrophil proteases. The carboxyl-terminal fragment of α_1-AT, which can be generated during the formation of a complex with serine protease or during proteolytic inactivation by thiol- or metalloproteases, is a potent neutrophil chemoattractant.[30,31,86] This fragment also appears to activate mononuclear phagocytes with respect to production of cytokines, active oxygen intermediates, scavenger activity, and lipid metabolism.[87]

There are several reports of α_1-AT altering immune function through effects on lymphocytes.[88,89] However, there are inherent conflicts in some of the reports, and the data have not been duplicated. There is no evidence that the immune response is systemically altered in α_1-AT–deficient individuals.

BIOSYNTHESIS AND REGULATION OF α_1-ANTITRYPSIN

The predominant site of synthesis of plasma α_1-AT is the liver. This is most clearly shown by conversion of plasma α_1-AT to donor phenotype after orthotopic liver transplant.[90,91] It is synthesized in human hepatoma cells as a 52 kD precursor, undergoes post-translational, dolichol phosphate–linked glycosylation at three asparagine residues, and undergoes tyrosine sulfation.[92–94] It is secreted as a 55 kD native single-chain glycoprotein with a half-time for secretion of 35 to 50 minutes.

Tissue-specific expression of α_1-AT in human hepatoma cells is directed by structural elements within a 750-nucleotide region upstream of the hepatocyte transcriptional start site in exon Ic (see Figure 55.7-1). Within this region, there are structural elements that are recognized by nuclear transcription factors, including hepatocyte nuclear factor (HNF)-1α and HNF-1β (–70 to –57), C-EBP (–86 to –75), HNF-4 (–134 to –100), and HNF-3 (–195 to –185).[95]

Of these factors, HNF-1α and HNF-4 appear to be particularly important for expression of the human α_1-AT gene. Two distinct regions within the proximal element bind these two transcription factors. In fact, substitution of five nucleotides at positions –77 to –72 disrupts binding of HNF-1α and dramatically reduces expression of the human α_1-AT gene in the liver of transgenic mice.[96] Substitution of four nucleotides at positions –118 to –115 disrupts the binding of HNF-4 but does not alter expression of the human α_1-AT gene in the liver of adult transgenic mice. The latter mutation does result in a reduction in the expression of human α_1-AT in the liver during embryonic development. HNF-1α and HNF-4 have a synergistic upregulating effect on expression of the α_1-AT gene in hepatocytes and enterocytes.[97]

Several elements in the upstream flanking region have enhancer activity. There is a strong enhancer element located approximately 200 nucleotides upstream of the

transcriptional start site, but the element is not specific for hepatocyte transcription.[98] This element is identical to the binding site for transcription factor AP-1. Similar AP-1 binding sequences have been identified in the 5′ flanking region of metallothioneins I and IIa, sv40, retinol-binding protein, collagenase, and stromelysin. Transcription factor AP-1 is also thought to be one of the transcription factors that mediate the effects of phorbol esters and thus of the activation of protein kinase C.[99] It represents a complex of several different proteins, including proteins encoded by the proto-oncogenes c-*jun* and c-*fos*.[100] There is a region with weak enhancer activity at residues –488 to –356,[98] but it is not clear whether this is due to transcription factor AP-1, AP-2, SP-1, HNF-3, or another transcription factor with a consensus element in this region. There are also several regions with similarity to the recognition element for transcription factor IL-6DBP (also called H-APF-2, NF-IL-6, LAP/LIP) at –195 to –189 and –169 to –164 from the hepatocyte α_1-AT cap site and –178 to –169 from the macrophage α_1-AT cap site, which may explain the effect of interleukin (IL)-6 on α_1-AT gene expression.[21]

Plasma concentrations of α_1-AT increase three- to five-fold during the host response to inflammation and/or tissue injury.[101] The source of this additional α_1-AT has always been considered the liver; thus, α_1-AT is known as a positive hepatic acute-phase reactant. Synthesis of α_1-AT in human hepatoma cells (HepG2, Hep3B) is up-regulated by IL-6 but not by IL-1 or tumor necrosis factor.[102] Plasma concentrations of α_1-AT also increase during oral contraceptive therapy and pregnancy.[103]

α_1-AT is also synthesized and secreted in primary cultures of human blood monocytes as well as bronchoalveolar and breast milk macrophages.[104] The cellular defect in homozygous α_1-AT deficiency, the selective defect in secretion of α_1-AT, is expressed in monocytes and macrophages from deficient individuals.[105] Transcription of the α_1-AT gene in macrophages starts about 2 kb upstream from the start site used in hepatocytes.[21,22,106] Although the same polypeptide is synthesized in the two cell types, slightly longer mRNA transcripts are present in macrophages (see Figure 55.7-1), depending on alternative post-transcriptional splicing of two upstream short open reading frames.[21,22]

Expression of α_1-AT in monocytes and macrophages is profoundly influenced by products generated during inflammation, such as bacterial lipopolysaccharide[107,108] and IL-6[102] (Figure 55.7-3). Bacterial lipopolysaccharide mediates a 5- to 10-fold increase in synthesis of α_1-AT in mononuclear phagocytes, predominantly increasing the translation efficiency of α_1-AT mRNA. The translational regulation of α_1-AT by lipopolysaccharide therefore involves a mechanism analogous to that of the yeast gene *GCN4* during amino acid starvation and that of the human ferritin gene in response to iron. The analogy to yeast *GCN4* is interesting in that both macrophage α_1-AT mRNA and *GCN4* mRNA have multiple short open reading frames with initiation codons in the upstream untranslated regions.[21,22,106] These sequences have been shown to control the translation of the yeast *GCN4* gene product, both under basal conditions and in response to amino acid starvation.[109]

Synthesis of α_1-AT in liver cells and mononuclear phagocytes is also regulated by a feed-forward mechanism (Figure 55.7-4). In this regulatory loop, α_1-AT–elastase complexes mediate an increase in synthesis of α_1-AT through the interaction of a pentapeptide domain in the carboxyl-terminal tail of α_1-AT with a novel cell

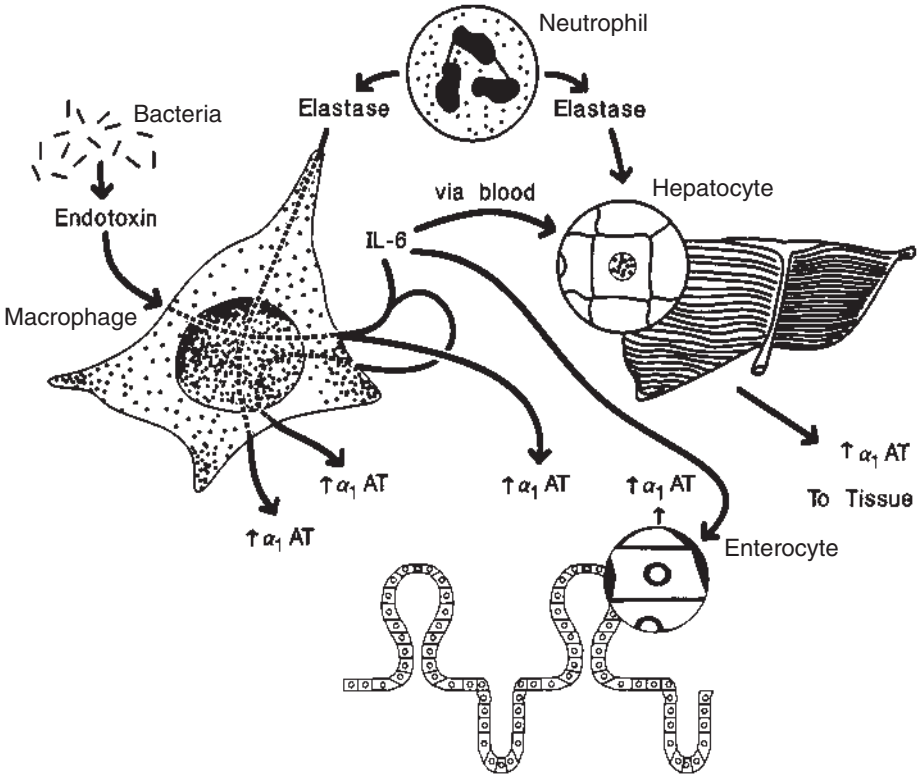

FIGURE 55.7-3 Schematic representation of the regulatory factors that affect α_1-antitrypsin (AT) expression in hepatocytes, enterocytes, and macrophages. IL-6 = interleukin-6.

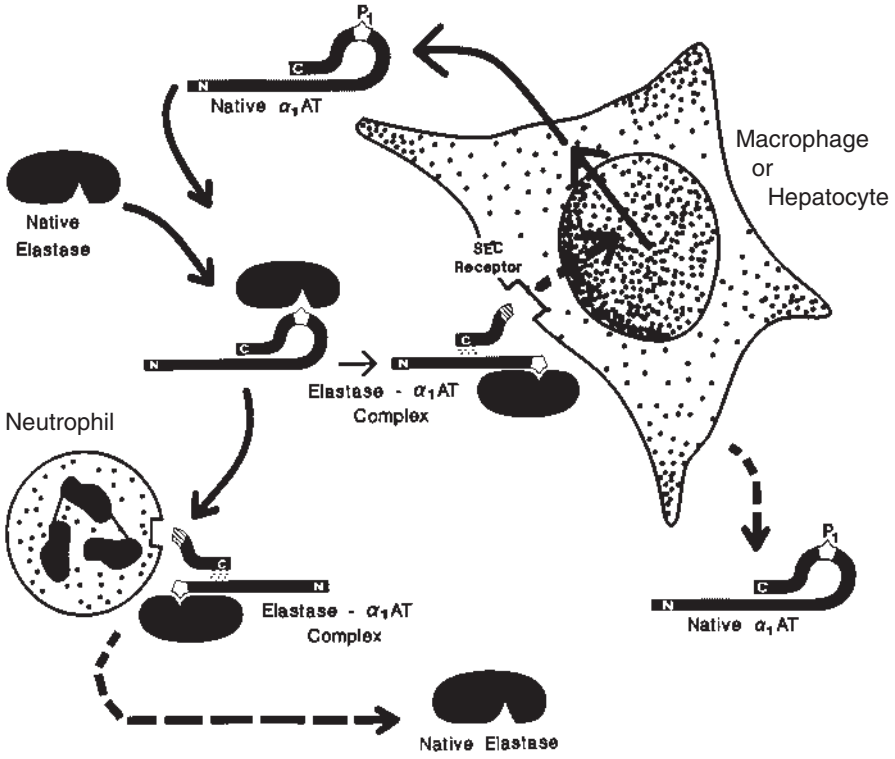

FIGURE 55.7-4 Feedback regulation of α_1-antitrypsin (AT) synthesis and neutrophil chemotactic activity mediated by the serpine-enzyme complex (SEC) receptor. Reproduced with permission from Perlmutter DH. α_1-Antitrypsin: structure, function, physiology. In: Mackiewicz A, Kusher I, Baumann H, editors. Acute phase proteins: molecular biology, biochemistry and clinical applications, Boca Raton (FL): CRC Press; 1993. p. 49–167.

surface receptor.[32,33,86,110,111] These receptor molecules are now referred to as serpin enzyme complex (SEC) receptors because they recognize the highly conserved domains of other SECs, such as antithrombin III–thrombin, α_1-antichymotrypsin–cathepsin G, and, to a lesser extent, C1 inhibitor–C1s and tissue plasminogen activator–plasminogen activator inhibitor I complexes, as well as α_1-AT–elastase complexes.[32,112] Substance P, several other tachykinins, bombesin, and the amyloid-β peptide bind to the SEC receptor through a similar pentapeptide sequence.[113] Recent studies indicate that the SEC receptor can mediate endocytosis of soluble amyloid-β peptide, but it does not recognize the aggregated form of amyloid-β peptide that is toxic to neurons and other cell types.[114] Thus, the SEC receptor may play a role in preventing amyloid-β peptide from accumulating into neurotoxic mature amyloid deposits associated with Alzheimer disease.

α_1-AT mRNA has been isolated from multiple tissues in transgenic mice,[106,115,116] but only in some cases have studies distinguished whether such α_1-AT mRNA is in ubiquitous tissue macrophages or other cell types. For instance, α_1-AT is synthesized in enterocytes and intestinal Paneth cells, as determined by studies in intestinal epithelial cell lines, ribonuclease protection assays of human intestinal RNA, and in situ hybridization analysis in cryostat sections of human intestinal mucosa.[21,117–119] Expression of α_1-AT in enterocytes increases markedly as they differentiate from crypt to villus, in response to IL-6 and during inflammation in vivo. α_1-AT is also synthesized by pulmonary epithelial cells.[120,121] Interestingly, synthesis of α_1-AT in pulmonary epithelial cells is less responsive to regulation by IL-6 than to a related cytokine, oncostatin M.[121]

Clearance and Distribution

The half-life of α_1-AT in plasma is approximately 5 days.[122–124] It is estimated that its daily production rate is 34 mg/kg of body weight, with 33% of the intravascular pool of α_1-AT being degraded daily. Several physiologic factors may affect the rate of its catabolism. First, desialylated α_1-AT is cleared from the circulation in minutes,[124,125] probably via hepatic asialoglycoprotein receptor–mediated endocytosis. Second, α_1-AT in complex with elastase or proteolytically modified is cleared more rapidly than native α_1-AT.[126] Because its ligand specificity is similar to that required for in vivo clearance of SECs, the SEC receptor may also be involved in the clearance and catabolism of α_1-AT–elastase complexes and other SECs.[33] The low-density protein receptor–related protein can also mediate clearance and catabolism of α_1-AT–elastase complexes.[127,128] Third, the rate of α_1-AT clearance may increase during the host response to inflammation.[129] There is a slight increase in the rate of clearance of radiolabeled α_1-ATZ compared with wild-type α_1-AT when infused into normal individuals, but this difference does not account for the decrease in serum levels of α_1-AT in deficient individuals.[123,125,130]

α_1-AT diffuses into most tissues and is found in most body fluids.[5] Its concentration in lavage fluid from the lower respiratory tract is approximately equivalent to its concentration in serum.[5] It is also found in feces, and increased fecal concentrations of α_1-AT correlate with inflammatory lesions of the bowel.[131] In each case, it has been assumed that the α_1-AT is derived from serum. Local sites of synthesis, such as macrophages and epithelial cells, may also make important contributions to the α_1-AT pool in these tissues and body fluids. In fact, it has been reported that fecal α_1-AT clearance is higher in patients with homozygous α_1-AT deficiency than in normal per-

sons.[132] Because the former have only 10 to 15% of the normal serum concentrations of α_1-AT, a local intestinal source for fecal α_1-AT is implicated. One possible explanation is that the bulk of α_1-AT in feces is derived from sloughed enterocytes. Increased fecal α_1-AT in those with homozygous α_1-AT deficiency would result from turnover or sloughing of enterocytes, with a greater amount of α_1-AT per cell owing to intracellular accumulation. Increased fecal α_1-AT in normal persons with inflammatory-related, protein-losing enteropathy would result from increased turnover or sloughing of enterocytes with a normal amount of α_1-AT per cell.

MECHANISM OF α_1-ANTITRYPSIN DEFICIENCY IN PIZZ INDIVIDUALS

The mutant α_1-ATZ molecule is characterized by a single-nucleotide substitution that results in an amino acid substitution of Lys for Glu 342.[133–135] There is a selective decrease in the secretion of α_1-AT, with the abnormal protein accumulating in the ER.[105,136] The defect is not specific for liver cells because it also affects extrahepatic sites of α_1-AT synthesis, such as macrophages[105] and transfected cell lines.[137–139] Site-directed mutagenesis studies have shown that this single amino acid substitution is sufficient to produce the cellular defect.[139] Once translocated into the lumen of the ER, the mutant α_1-AT protein is unable to traverse the remainder of the secretory pathway because it is abnormally folded.

Substitution of Glu 342 by Lys in the α_1-ATZ variant reduces the stability of the molecule in its monomeric form and increases the likelihood that it will form polymers by means of a "loop-sheet" insertion mechanism.[140] In this mechanism, the reactive center loop of one α_1-AT molecule inserts into a gap in the β-pleated A sheet of another α_1-AT molecule (see Figure 55.7-2). Lomas and colleagues were the first to notice that the site of the amino acid substitution in the α_1-ATZ variant was at the base of the reactive center loop, adjacent to the gap in the A sheet.[140] These investigators predicted that a change in the charge at this residue, as occurs with the substitution of Lys for Glu, would prevent the insertion of the reactive site loop into the gap in the A sheet during interaction with enzyme; therefore, the mutant α_1-ATZ would be susceptible to the insertion of the reactive center loop of adjacent molecules into the gap in its A sheet. This would, in turn, cause the mutant α_1-ATZ to be more susceptible to polymerization than the wild-type α_1-AT. In fact, their experiments showed that α_1-ATZ undergoes this form of polymerization to a certain extent spontaneously and to a greater extent during relatively minor perturbations, such as a rise in temperature. Presumably, an increase in body temperature during systemic inflammation would exacerbate this tendency in vivo. Polymers could also be detected by electron microscopy in the ER of hepatocytes in a liver biopsy specimen from a deficient individual.[140] Similar polymers have been found in the plasma of patients with the PIS_{Iiyama} and PIM_{Malton} α_1-AT variants.[141,142] The mutations in α_1-AT PIS_{Iiyama} (Ser 53 to Phe)[69] and PIM_{Malton} (Phe 52 deletion)[64] affect residues that provide a ridge for the sliding movement that opens the A sheet. Thus, these mutations would be expected to interfere with the insertion of the reactive center loop into the gap in the A sheet and, therefore, to leave the gap in the A sheet available for spontaneous loop-sheet polymerization. It is indeed interesting that hepatocytic α_1-AT globules have been observed in a few patients with these two variants. Recent observations suggest that the α_1-ATS variant also undergoes loop-sheet polymerization[143] and that this may account for its retention in the ER, albeit a milder degree of retention than that for α_1-ATZ.[144] Moreover, α_1-ATS can apparently form heteropolymers with α_1-ATZ,[145] providing a potential explanation for liver disease in patients who are compound heterozygotes for the α_1-ATS and Z alleles. In a recent study, Davis and colleagues have shown that dementia in two families is associated with mutations that cause polymerization of another member of the serpin family, neuroserpin.[146] The mutations, mechanism of polymerization, and morphology of the inclusion bodies in affected neurons are remarkably similar to those that occur in the classic form of α_1-AT deficiency

The precise mechanism by which the loop-sheet insertion develops is not yet completely understood and may be more complicated than previously thought.[141,147,148] Further studies to characterize the mechanism more precisely will undoubtedly be forthcoming.

A study by Yu and colleagues compared the folding kinetics of α_1-ATZ in transverse urea gradient gels.[149] This study shows, for the first time, that α_1-ATZ folds at an extremely slow rate, unlike the wild-type α_1-AT, which folds in minutes. This folding defect leads to the accumulation of an intermediate, which has a high tendency to polymerize, presumably by the loop-sheet insertion mechanism.

By themselves, however, these data do not prove that the polymerization of α_1-ATZ results in retention within the ER. In fact, many polypeptides must assemble into oligomeric or polymeric complexes to traverse the ER and reach their destination within the cell, at the surface of the plasma membrane, or into the extracellular fluid. If viral proteins, such as the vesicular stomatitis virus G protein or influenza virus hemagglutinin, and host proteins, such as the T-cell receptor and fibrinogen, do not assemble into oligomers, they are retained and ultimately degraded in the ER.[150]

The strongest evidence that polymerization results in the retention of α_1-ATZ in the ER has been provided by studies in which the fate of α_1-ATZ is examined after the introduction of additional mutations into this molecule. For instance, Kim and colleagues introduced a mutation into the α_1-AT molecule at amino acid 51, F51L.[151] This mutation is remote from the Z mutation, E342K, but it apparently impeded loop-sheet polymerization and prevented insertion of synthetic peptide into the gap in the A sheet, implying that the mutation led to the closing of this gap. The double-mutated F51L α_1-ATZ molecule was also less prone to polymerization and folded more efficiently in vitro than α_1-ATZ. Moreover, the introduction of the F51L mutation partially corrected the intracellular retention properties of α_1-ATZ in microinjected *Xenopus* oocytes[152] and in yeast.[153]

However, Lin and colleagues recently found that a novel, naturally occurring variant of α_1-AT, bearing the K342Q mutation that characterizes α_1-ATZ as well as carboxyl-terminal truncation, is retained in the ER for as long, or longer, than α_1-ATZ even though it does not polymerize.[154] These results could indicate that mechanisms other than polymerization determine whether mutant α_1-AT molecules are retained in the ER. An alternative possibility is that polymerization of α_1-ATZ is not the cause of ER retention but rather its result.

Despite what is stated in one review,[155] it is still not entirely clear what proportion of the newly synthesized mutant α_1-ATZ molecules is converted to the polymeric state in the ER. In one cell culture model system, Lin and colleagues found that 17.0 ± 0.9% of α_1-ATZ is in the insoluble fraction at steady state,[154] but comparable in vivo data are not yet available. It is also not known whether polymeric molecules are degraded in the ER less rapidly than their monomeric counterparts or whether polymeric molecules, when retained in the ER, are more hepatotoxic than their monomeric counterparts. Indeed, recent studies on the effect of temperature on α_1-ATZ have indicated the high degree of complexity involved in these issues. Although Lomas and colleagues showed that a rise in temperature to 42°C increases the polymerization of purified α_1-ATZ in vitro,[140] Burrows and colleagues found that a rise in temperature to 42°C resulted in increased secretion of α_1-ATZ and decreased intracellular degradation of α_1-ATZ in a model cell culture system.[156] In contrast, lowering the temperature to 27°C resulted in diminished intracellular degradation of α_1-ATZ, without any change in the small amount of α_1-ATZ that is secreted.[156] Consistent with the well-established role that temperature plays in most biochemical processes, these results suggest that changes in temperature have the potential to affect multiple steps in the pathways by which α_1-ATZ is translocated through the secretory and degradative compartments/systems, as well as affecting the relative proportions of α_1-ATZ in the monomeric and polymeric state. On the basis of these considerations, as well as long-standing clinical experience with α_1-AT–deficient children and other children with liver disease, and in the complete absence of any epidemiologic evidence, it seems unlikely that there is a simple relationship between febrile episodes and phenotypic expression of liver disease in α_1-AT–deficient patients.

To understand how polymerization of α_1-AT or alteration in folding of monomeric α_1-AT might result in retention within the ER, one needs to consider what is now known about the biology of protein secretion. Most newly synthesized secretory proteins are translocated into the lumen of the ER. Before being transported to their final destination, these nascent secretory polypeptide chains undergo a series of post-translational modifications, including glycosylation, formation of disulfide bonds, oligomerization, and folding. Moreover, transport through the secretory pathway involves interaction with resident ER proteins, termed molecular chaperones. These interactions facilitate disulfide bond formation, assembly, and folding.

Several families of ER chaperones have been identified. One has been referred to as the polypeptide chain–binding protein family and includes several heat shock/stress proteins (HSPs), GRP78/BiP and GRP94, protein disulfide isomerase, and Erp72.[157] Several calcium-binding phosphoproteins of the ER, most notably calnexin and calreticulin, have also been implicated as having molecular chaperone activity within the ER. Calnexin is an approximately 88 kD transmembrane ER-resident phosphoprotein originally discovered in association with class I major histocompatibility complex (MHC) molecules.[158,159] It is now known to facilitate the folding and assembly of many membrane and secretory glycoproteins. This chaperone activity involves a lectinlike mechanism in which calnexin binds the innermost glucose residue of the asparagine-linked oligosaccharide side chains present on most glycoproteins. The innermost glucose residue becomes accessible almost immediately after the secretory glycoprotein has undergone the initial stages of oligosaccharide side chain trimming in the lumen of the ER, including the removal of the two outermost glucose residues by the actions of glucosidases I and II (Figure 55.7-5). Once bound to calnexin, monoglucosylated glycoproteins are retained in the ER until properly folded.[160] Once folding is complete, the glycoprotein can dissociate from calnexin for vesicular transport out of the ER. Recent studies have indicated that a unique reglucosylating enzyme, uridine diphosphate–glucose:glycoprotein glucosyltransferase (UDGGT), can transfer glucose onto unfolded or denatured deglucosylated proteins in the ER.[161,162] In fact, the binding of glycoproteins to calnexin during folding in the ER is now thought to depend on a cycle of glucosidase II activity, producing the deglucosylated form of a protein, and reglucosylation by ER–luminal UDGGT, leading to regeneration of the monoglucosylated form. The glucosyltransferase acts preferentially on unfolded or denatured proteins. Thus, the repeated cycles of binding to and dissociation from calnexin are designed to maximize the possibility that a given unfolded or denatured protein will undergo proper folding for transport out of the ER.

It is now well established that the ER possesses a machinery whereby it can degrade any mutant or unassembled polypeptides that are unable to fold properly even after interaction with the ER chaperones. This machinery has come to be called the "ER degradation pathway" or the "quality control apparatus" of the ER.[163] Although the ER degradation pathway was originally thought to involve a distinct proteolytic system, it now appears to be mediated in large part from the cytoplasmic aspect of the ER by the proteasome.

Several studies have shown that α_1-ATZ is degraded in the ER and that the proteosome is a key component of the degradation pathway.[164–166] Degradation of α_1-ATZ is markedly reduced by specific proteosome inhibitors in yeast and mammalian cells.[165,166] In a mammalian cell–free system, degradation of α_1-ATZ is, at least in part, attributable to a pathway that involves interaction with the transmembrane ER chaperone calnexin, polyubiquitination of calnexin, and targeting of the α_1-ATZ–polyubiquitinated calnexin complex by the proteosome.[166] There is also evidence for the involve-

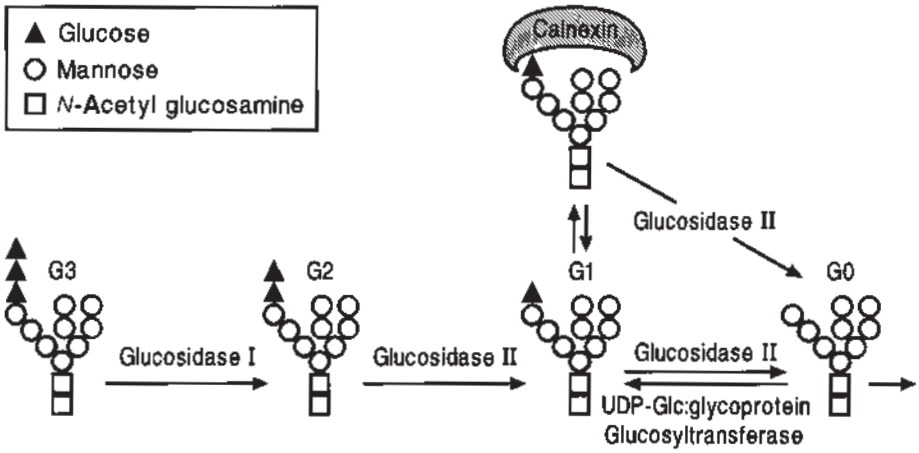

FIGURE 55.7-5 Model of glucose trimming and reglucosylation in relation to interaction with calnexin. Adapted from Hebert DN, Helenius A. Glucose trimming and reglucosylation determine glycoprotein association with calnexin in the endoplasmic reticulum. Cell 1995;81:425–33.

ment of ubiquitin-independent proteosomal and nonproteosomal pathways in degradation of α_1-ATZ in the mammalian cell–free system.[167]

As discussed below, autophagy may represent one nonproteosomal mechanism for degradation of α_1-ATZ.[168] Because this is based on the effect of chemical inhibitors of autophagy, which have other effects on cellular metabolism, definitive evidence for the role of autophagy in degradation of α_1-ATZ will require more detailed, probably genetic studies. Cabral and colleagues have recently provided evidence for a nonproteosomal degradation pathway that is sensitive to tyrosine phosphatase inhibitors.[169] In their studies, degradation of α_1-ATZ in a hepatoma cell line was not affected by proteosome inhibitors but was reduced by tyrosine phosphatase inhibitors. Although this finding was originally interpreted to suggest that there were cell type–specific differences in the role of proteosomal and nonproteosomal degradation mechanisms and that nonproteosomal degradation mechanisms were more important in hepatocytes, subsequent studies have shown that the proteosome still plays a major role in degradation of α_1-ATZ in other hepatoma cell lines.[170] This means it is more likely that nonproteosomal mechanisms, sensitive to tyrosine phosphatase inhibitors, are particularly important in specific cell lines rather than specific cell types. The relative importance of proteosomal and nonproteosomal mechanisms to the disposal of α_1-ATZ in vivo is still unknown. Despite what was stated in one review,[155] there are no data on the effect of age, inflammation, or other physiologic conditions on degradation of mutant α_1-ATZ.

The mechanism by which the proteosome gains access from the cytoplasm to α_1-ATZ on the luminal side of the ER membrane is also uncertain. Although retrograde translocation from the ER to the cytoplasm has been demonstrated for some luminal substrates of the proteosome, there is very limited evidence for retrograde translocation of α_1-ATZ. Werner and colleagues detected α_1-ATZ free in the cytosolic fraction of yeast when the proteosome was inhibited,[165] but only a small fraction of the total α_1-ATZ in the ER could be detected,[165] and there has been no other evidence for retrotranslocation. Recent studies have provided evidence for extraction of substrates through the ER membrane by the proteosome.[171] The AAA adenosine triphosphatase Cdc 48/p97 and its partners appear to play an important role in this process.[172] It is also possible that the proteasome gains access to α_1-ATZ and/or the α_1-ATZ–polyubiquitinated calnexin during the formation of autophagic vacuoles. Our recent studies have shown that retention of α_1-ATZ in the ER is associated with the induction of an autophagic response.[168] The autophagic response is thought to be a general mechanism by which intracellular organelles, or parts of organelles, are degraded. It is a highly evolutionarily conserved process that occurs in many cell types, especially during stress states, such as nutrient deprivation, and during the cellular remodeling that accompanies morphogenesis, differentiation, and senescence. Several studies have suggested that autophagic vacuoles are derived in part from subdomains of ER.[173] Autophagosomes initially form as invaginations from ribosome-free areas of the ER membrane. Together with constituents of the ER, autophagosomes engulf cytosolic constituents, including components of the ubiquitin system and the proteasome.[174,175] Thus, it is possible that degradation of α_1-ATZ is mediated by proteasomal machinery engulfed during formation of the autophagosome. Indeed, in our recent studies, an intense autophagic response was demonstrated in cell culture model systems with ER retention of mutant α_1-ATZ and in liver biopsy specimens from patients with α_1-AT deficiency.[168] Moreover, α_1-AT and calnexin were colocalized within autophagosomes as well as within the ER. Finally, degradation of α_1-ATZ in the cell culture model system is partially abrogated by inhibitors of autophagy, including wortmannin, 3-methyladenine, and LY294002. However, it is also possible that α_1-ATZ molecules taken up into autophagosomes are degraded by a nonproteasomal mechanism when the autophagosomes merge or fuse with the lyosomal pathway and that the autophagic and proteasomal pathways constitute completely independent mechanisms for degradation of α_1-ATZ.

A study by Van Leyen and colleagues suggested the possibility that a type of autophagic response termed "programmed organelle degradation" allows access of cytoplasmic proteases to both luminal and integral membrane proteins.[176] This process appears to involve the highly regulated recruitment of 15-lipoxygenase from the cyto-

plasm to the ER membrane, where it presumably oxygenates membrane phospholipids, in turn releasing proteins from the ER lumen and membrane. A mechanism like this could possibly account for the ER degradation pathway of some substrates.

PATHOGENESIS OF LIVER INJURY IN α_1-ANTITRYPSIN DEFICIENCY

There are several theories for the pathogenesis of liver injury in α_1-AT deficiency. According to the immune theory, liver damage results from an abnormal immune response to liver antigens.[177] This theory is based on the observation that peripheral blood lymphocytes from PIZZ infants are cytotoxic for isolated hepatocytes. However, this is probably a nonspecific effect of liver injury in that peripheral blood lymphocytes from PIMM infants with a similar degree of liver injury on the basis of idiopathic neonatal hepatitis syndrome are also cytotoxic for isolated hepatocytes. More recent studies have indicated an increase in the human leukocyte antigen (HLA)-DR3-DW25 haplotype in α_1-AT–deficient individuals with liver disease.[178] However, there is no difference in the expression of class II MHC antigen in the livers of these individuals compared with normal controls.[179] Moreover, an increase in the prevalence of a particular HLA haplotype in the affected population does not by itself imply altered immune function. In fact, because of the linkage dysequilibrium displayed by genes within the MHC, it is possible that increased susceptibility is caused by the products of unrelated but linked genes. For instance, the MHC contains genes for several HSPs,[180,181] which play an important role in the biogenesis and transport of other proteins through the secretory pathway.

The accumulation theory, in which liver damage is thought to be caused by accumulation of mutant α_1-AT molecules in the ER of liver cells, is the most widely accepted theory. Experimental results in transgenic mice are most consistent with this theory and completely exclude the possibility that liver damage is caused by "proteolytic attack" as a consequence of diminished serum α_1-AT concentrations.[26] Transgenic mice carrying the mutant Z allele of the human α_1-AT gene develop periodic acid–Schiff–positive diastase-resistant intrahepatic globules and liver injury early in life.[9,10] Because there are normal levels of α_1-AT and (presumably) other antielastases in these animals, as directed by endogenous murine genes, the liver injury cannot be attributed to proteolytic attack.

Some have argued that the histologic characteristics of the liver in the transgenic mouse model are not identical to those in humans. Detailed histologic characterization of the liver in one transgenic mouse model by Geller and colleagues has shown that there are focal areas of liver cell necrosis, microabscesses with an accumulation of neutrophils and regenerative activity in the form of multicellular liver plates, and focal nodule formation during the neonatal period.[182] Nodular clusters of altered hepatocytes that lack α_1-AT immunoreactivity are also seen during the neonatal period. With aging, there is a decrease in the number of hepatocytes containing α_1-ATZ globules; there is also an increase in the number of nodular aggregates of α_1-AT–negative hepatocytes and development of periosinusoidal fibrosis.[183] Within 6 weeks, there are dysplastic changes in these aggregates. Adenomas occur within 1 year, and invasive hepatocellular carcinoma is seen between 1 and 2 years of age.[183] However, the relationship between the α_1-ATZ globules and inflammation or dysplasia is not yet apparent from these animal studies. The histopathology of the α_1-ATZ transgenic mice is remarkably similar to that of hepatitis B virus surface antigen–transgenic mice; this similarity is particularly interesting because hepatitis B virus is retained in the ER, or in the ER-Golgi intermediate compartment of hepatocytes, often called "ground-glass hepatocytes."[184] It is still unclear why the liver injury in this transgenic mouse model is somewhat milder and less fibrogenic than that seen in children with liver disease associated with α_1-AT deficiency. It is possible that there are strain-specific factors that condition the response to injury in the mouse model. There are certainly host-specific factors that determine the amount of liver injury in α_1-AT deficiency (see below), and the degree of inflammation and fibrosis varies widely among our patients with liver disease from α_1-AT deficiency.

Data from individuals who have null alleles of α_1-AT and therefore negligible serum levels of α_1-AT have also been used as evidence against the "proteolytic attack" theory. These individuals do not develop liver injury, at least not enough to result in clinical detection. However, only a few individuals with null alleles have been reported; each has a different allele, and based on data in PIZZ individuals showing that only 10 to 15% of these individuals develop clinically significant liver injury, it might be necessary to evaluate 7 to 10 individuals with each null allele before detecting one with liver injury.

The recognition that several other naturally occurring variant alleles of α_1-AT associated with deficiency can undergo polymerization has provided some support for the accumulation theory. The most important of these variant alleles is the compound heterozygous α_1-ATSZ phenotype. Work by Lomas and colleagues has shown that α_1-ATS and α_1-ATZ may form heteropolymers.[145] We know from the nationwide study of α_1-AT deficiency in Sweden that the incidence of liver disease among individuals with the α_1-ATSZ phenotype is similar to that of individuals with the α_1-ATZ phenotype.[1,11] We also now know that the PIM_{Malton} allele undergoes polymerization, and liver injury has been reported in several patients with this allele.[64,68,141] However, there is a report of an individual with the PIS_{Iiyama} allele having hepatocyte α_1-AT globules but no liver injury.[69] Moreover, a recent report by Ray and Brown has indicated that $PIM_{Heerlen}$ and $PIM_{Procidia}$ undergo aggregation and that $PIM_{Mineral\ Springs}$ and $PINull_{Ludwigshafen}$ may undergo aggregation, but there are no reports of liver disease in individuals carrying these alleles.[55] However, only a few patients with M_{Malton}, S_{Iiyama}, $M_{Heerlen}$, $M_{Procida}$, $M_{Mineral\ Springs}$, and $Null_{Ludwigshafen}$ have been identified. It is also not clear how many of these patients have been thoroughly examined for liver disease. Again, on the basis of what we know about the α_1-ATZ and α_1-ATSZ phenotypes, at least

7 to 10 individuals with each of these alleles would need to be examined to detect one with liver injury.

It has been difficult to reconcile the accumulation theory with the observations of Sveger,[11] which show that only a subset of α_1-AT–deficient individuals develop significant liver damage. We have made the prediction that a subset of the deficient population is more susceptible to liver injury by virtue of one or more additional inherited traits or environmental factors that exaggerate the intracellular accumulation of the α_1-ATZ protein or that exaggerate the cellular pathophysiologic consequence of mutant α_1-AT accumulation (Figure 55.7-6). To address this prediction experimentally, the Perlmutter laboratory transduced skin fibroblasts from deficient individuals, with or without liver disease, with amphotropic recombinant retroviral particles designed for constitutive expression of the mutant α_1-ATZ gene.[185] Human skin fibroblasts do not express the endogenous α_1-AT gene but presumably express other genes involved in the postsynthetic processing of secretory proteins. The results show that expression of the human α_1-AT gene was conferred on each fibroblast cell line. Compared with the same cell line transduced with the wild-type α_1-AT gene, there was selective intracellular retention of the mutant α_1-ATZ protein in each case. However, there was a marked delay in degradation of the mutant α_1-ATZ protein after it accumulated in the fibroblasts from deficient individuals with liver disease (susceptible hosts) compared with those without liver disease (protected hosts) (Figure 55.7-7). Thus, these data provide evidence that other factors that affect the abnormal α_1-ATZ molecule, such as a lag in ER degradation, at least in part, determine susceptibility to liver disease.

The lag in ER degradation of α_1-ATZ in susceptible hosts may involve several distinct mechanisms. In one susceptible host, the retained α_1-ATZ interacts poorly with calnexin.[185] In the liver cells of this host, there is likely to be only a very little polyubiquitinated α_1-ATZ–calnexin complex that can be recognized for proteolysis by the proteasome. In several other susceptible hosts, the retained α_1-ATZ interacts well with calnexin but is degraded slowly (J. Teckman, D. Qu, D. H. Perlmutter, unpublished data, 1997). These hosts may have a defect in calnexin that prevents its ubiquitination or a defect in the ubiquitin system of the proteasome. Hosts with the latter defect would also be more likely to respond to a pharmacologic agent, such as interferon-γ,[186] that enhances the activity of the ubiquitin-dependent proteasomal system. This type of study, which involves complementation in human skin fibroblast cell lines, and recent studies involving yeast that have identified at least 30 putative recessive mutants and 7 complementation groups of strains defective in ER degradation of α_1-ATZ[187] are likely to lead to recognition of other mechanisms for excessive ER retention of α_1-ATZ.

There is still relatively limited information about the short- and long-term effects of ER retention of α_1-ATZ in model systems. In one report, the accumulation of α_1-ATZ in *Xenopus* oocytes was associated with the release of lysosomal enzymes.[188] Several recent studies have shown that ER retention of mutant α_1-ATZ provokes a rather specific cellular response with autophagy as a major feature. Autophagosomes develop in several different model cell culture systems genetically engineered to express α_1-ATZ, including human fibroblasts and murine hepatoma and rat hepatoma cell lines. Moreover, in a HeLa cell line engineered for inducible expression of α_1-ATZ, autophagosomes appear as a specific response to the expression of α_1-ATZ and its retention in the ER.[168] There is a marked increase in autophagosomes in hepatocytes in transgenic mouse models of α_1-AT deficiency and a disease-specific increase in autophagosomes in liver biopsies from patients with α_1-AT deficiency. Mutant α_1-ATZ molecules can be detected in autophagosomes by immune electron microscopy, often together with the ER molecular chaperone calnexin.

Taken together, these results have suggested that the autophagic response is induced to protect liver cells from the toxic effects of aggregated α_1-ATZ retained in the ER. We have also speculated about the role of autophagy in protecting liver cells from tumorigenesis. Several recent studies have shown that autophagic activity is decreased in tumors and that reconstitution of autophagic activity inhibits

tumorigenesis in vivo.[189,190] In our studies, autophagosomes are predominantly found in liver cells with dilated ER in both human and transgenic mouse liver.[168] Previous studies in transgenic mouse models of α_1-AT deficiency have shown that hepatocarcinogenesis evolves within nodular aggregates of hepatocytes that are negative for α_1-AT expression by immunofluorescent staining.[183]

It is not yet clear whether autophagy is substrate specific for α_1-ATZ or provides a more general response to aggregated proteins retained in the ER. No such cellular response has been described in studies of mutant proteins that aggregate in the cytoplasm or nucleus. Although there is some mention of autophagic vacuoles around the aggresomes that form when cystic fibrosis transmembrane regulator (CFTR) ΔF508 accumulates in the presence of proteosomal inhibitors,[191,192] the histologic pictures in cells expressing α_1-ATZ or CFTR ΔF508 are quite distinct.[168] Autophagy is not induced by tunicamycin or thapsigargin, agents that cause a generalized form of "ER stress" (N. Mitzushima, personal communication, 2002). Russell bodies, which have been described in cells retaining certain mutant immunoglobulin molecules in the ER,[193] do have many characteristics of autophagosomes. Autophagy has also been implicated in the cellular response to the mutant form of the ER membrane protein peripheral myelin protein 22, which causes a gain of function disease in Schwann cells in Charcot-Marie-Tooth disease and Dejerine-Sottas disease.[194]

Recently, we examined the autophagic response to ER retention of α_1-ATZ in vivo by testing the effect of fasting on the liver of the PiZ mouse model of α_1-AT deficiency.[195] Starvation is a well-defined physiologic stimulus of autophagy and a known environmental stressor of liver disease in children. The results show that there is a marked increase in fat accumulation and in α_1-AT–containing, ER-derived globules in the liver of the PiZ mouse induced by fasting. These changes were particularly exaggerated at 3 to 6 months of age. Three-month-old PiZ mice had a significantly decreased tolerance for fasting compared with nontransgenic C57 black mice (none of the PiZ mice tolerated a 72-hour fast even though 100% of C57BL mice survive the same duration of fasting). Although fasting induced a marked autophagic response in wild-type mice, the autophagic response was already activated in PiZ mice to levels that were more than 50% higher than those in the liver of fasted wild-type mice, and they did not increase further during fasting. These results indicate that autophagy is constitutively activated in α_1-AT deficiency and that the liver is unable to mount an increased autophagic response to physiologic stressors. From our search of the literature, the only other condition in which there is accumulation of autophagic vacuoles under homeostatic conditions is Danon disease.[196] In contrast to α_1-AT deficiency, however, autophagosomes accumulate in Danon disease because of a genetic defect in the terminal phases of autophagy, that is, the fusion of autophagic vacuoles with lysosomes and subsequent degradation within autolysosomes.[196,197]

In the course of our ultrastructural studies of the liver of the PiZ mouse and of patients with α_1-AT deficiency, we have recently been struck by the degree of mitochondrial autophagy that is induced.[198] A comparison of the liver from four α_1-AT–deficient patients with livers from eight patients with other liver diseases and four normal livers showed a marked significant increase in mitochondrial autophagy associated with α_1-AT deficiency. Even more interesting is the observation that many mitochondria that are not surrounded by autophagic vacuolar membranes are nevertheless damaged or are in various phases of degeneration in liver cells from α_1-AT–deficient hosts. This damage is characterized by the formation of multilamellar structures within the limiting membrane, condensation of the cristae and matrix, and, in some cases, dissolution of the internal structures, often leaving only electron-dense debris compressed into a thin rim at the periphery of the mitochondrion. Although this second type of damaged mitochondria appears distinct from the mitochondria that are degenerating within autophagosomes, these mitochondria are sometimes seen in close proximity to, or even fusing with, autophagic vacuoles or lysosomes.

Mitochondrial autophagy and injury are also marked in the liver of the PiZ transgenic mouse model of α_1-AT deficiency. Immunofluorescence analysis shows the presence of activated caspase 3 in the PiZ mouse liver.[198] Because cyclosporin A (CsA) has been shown to reduce mitochon-

drial injury[199] and inhibit starvation-induced autophagy,[200] we examined the effect of CsA on PiZ mice and found that it significantly reduces hepatic mitochondrial injury while eliminating activated caspase 3 and improving the animals' tolerance of starvation. These results provide evidence for the novel concept that mitochondrial damage and caspase activation play a role in the mechanism of liver cell injury in α_1-AT deficiency. Although this analysis suggests that there is mitochondrial injury that is separate from the autophagic process, the possibility that autophagy plays some role in all of the mitochondrial damage that is observed cannot be completely excluded. Thus, one model of mitochondrial damage in this deficiency holds that accumulation of α_1-ATZ in the ER is in itself responsible for mitochondrial dysfunction. Indeed, there is now ample evidence in the literature for functional interactions between mitochondria and closely apposed ER cisternae.[201,202] Recent studies show that specific signals are transmitted between these two intracellular compartments[203,204] and that mitochondrial dysfunction, including release of cytochrome *c* and caspase 3 activation, is associated with the ER dilatation and stress induced by brefeldin A, tunicamycin, and thapsigargin.[205,206] It is not yet known, however, whether mitochondrial dysfunction in the latter cases is due to ER dilatation and/or ER stress or to independent effects on mitochondria by these experimental drugs. A second possible explanation, not necessarily incompatible with the first, envisages mitochondrial dysfunction as a result of the autophagic response to ER retention of α_1-ATZ. In this scenario, mitochondria are recognized nonspecifically by the autophagic response, which is constitutively activated to somehow remove and degrade areas of the ER that are distended by aggregated mutant protein. Although our data indicate that CsA inhibits hepatic mitochondrial injury in vivo, this benefit could reflect the drug's known effects on the mitochondrial permeability transition,[199] on autophagy,[200] or on both.

The CsA findings are also noteworthy for their therapeutic implications. They indicate that CsA can prevent mitochondrial damage even under circumstances in which α_1-ATZ continues to accumulate in the ER. Thus, they provide proof in principle for mechanism-based therapeutic approaches to liver disease in α_1-AT deficiency—pharmacologic intervention directed as distal steps in the pathobiologic pathway that leads to liver injury, such as the "mitochondrial" step, without correction of the primary defect and/or the more proximal steps in the pathobiology of this liver disease.

Other cellular response pathways could potentially be activated by ER retention of mutant proteins. Work in several laboratories has shown that a novel structure called the aggresome is formed in cells when expression of misfolded membrane proteins (such as CFTRΔF508, other mutant membrane proteins, and mutant viral proteins) exceeds the capacity of the proteasome to degrade them.[191,192,207] The aggresome is a pericentriolar membrane-free cytoplasmic inclusion containing misfolded ubiquitinated protein ensheathed in a case of vimentin and perhaps other intermediate filaments. Recent studies indicate that retention of α_1-ATZ induces expansion of the ER, alteration in the structure of the ER and formation of autophagic vesicles but does not cause aggresome formation.[168]

The unfolded protein response is also induced by the accumulation of unfolded proteins in the ER. It results in the induction, or up-regulation, of a repertoire of genes that serve to protect the cell from damage by the denatured proteins.[208,209] This includes up-regulation of chaperones and enzymes in the phospholipid biosynthetic pathway to permit new ER membrane biogenesis and attenuation of the translation of most endogenous proteins, which could become denatured.

Two other signal transduction pathways activated by misfolded proteins in the ER have recently been characterized and may be relevant to α_1-AT deficiency. The ER overload pathway is a signaling pathway that appears to be distinct from the unfolded protein response and that involves activation of nuclear factor κB and release of active oxygen intermediates.[210] So far, this pathway has been described only in experimental conditions associated with ER overload of misfolded or unassembled membrane proteins. Recent studies in the Morimoto laboratory have shown that heat shock factor (HSF)2 may be activated by the accumulation of ubiquitinated proteins.[211] The downstream effect of HSF2 activation by ubiquitinated protein is induction of the classic heat shock response, including cytoplasmic and nuclear chaperones HSP90, HSP70, HSC70, HSP27, an ER chaperone GRP78/BiP, and mitochondrial chaperone HSP60.

It is not yet known whether one or all of these signaling pathways are induced by ER retention of α_1-ATZ or whether there is any alteration in their activation in the subgroup of α_1-AT–deficient patients who are susceptible to liver disease. Because these are considered response pathways that are designed to protect the cell, it is presumed that they must be overwhelmed by the concentration or intrinsic toxic potential of a particular mutant protein before cell injury occurs. However, the consequences of prolonged activation of these response pathways are entirely unknown and could potentially include cytotoxic and/or oncogenic effects.

LIVER DISEASE IN α_1-ANTITRYPSIN DEFICIENCY

Soon after homozygous PIZZ α_1-AT deficiency was described, an association with premature development of emphysema was discovered.[212] Eriksson noticed that some of the individuals with emphysema also had cirrhosis of the liver,[213] but an association between α_1-AT deficiency and liver disease was first clearly established in 1969 by Sharp and colleagues[214]; Sharp also noticed the distinctive histopathologic features of inclusion bodies in the ER of liver cells in these children.[215]

The most important study of liver disease in α_1-AT deficiency was conducted by Sveger, who prospectively screened 200,000 newborn infants in Sweden.[1] Sveger identified 127 deficient infants and has followed them since then. These infants were evaluated clinically at the

age of 6 months. Fourteen of the 127 PIZZ infants had prolonged obstructive jaundice (group I). By clinical and laboratory criteria, 9 of these infants had severe liver disease and 5 had mild liver disease. Eight other PIZZ infants (group II) had minimal abnormalities in serum bilirubin, serum transaminases, and hepatic size. Approximately 50% of the remaining infants (group III) had abnormal serum transaminases.

Sveger collated data regarding the clinical outcome for these infants at 18 years of age. Three children from the group with prolonged obstructive jaundice (group I) died from liver disease before reaching 8 years of age. One group I child died from an unrelated cause. More than 85% of the remaining PIZZ children have persistently normal serum transaminases and no evidence of liver dysfunction.

Other studies of the incidence, prevalence, or prognosis of liver disease in α_1-AT deficiency[216–226] cannot be compared with the Sveger study[1] in that these studies involve PIZZ populations in which there is a bias in ascertainment (ie, the studies include only children referred to a specialty clinic). One issue not addressed by the Sveger study is whether 18-year-old patients with α_1-AT deficiency have persistent subclinical histologic abnormalities, despite the lack of clinical or biochemical evidence of liver injury, and whether liver disease will eventually become clinically evident during adulthood.

Liver involvement is often first noticed at 1 to 2 months of age because of persistent jaundice. Conjugated bilirubin levels in the blood and serum transaminase levels are mildly to moderately elevated. Blood levels of alkaline phosphatase and γ-glutamyl transpeptidase may also be elevated. The liver may be enlarged. There is a tendency for some of the affected infants to be small for gestational age. Affected infants are usually admitted to the hospital with a diagnosis of neonatal hepatitis syndrome and are subjected to a detailed diagnostic evaluation.[214,215,227] In fact, homozygous PiZZ α_1-AT deficiency appears to be the most common metabolic disease causing neonatal hepatitis syndrome.[216,228]

Infants may also be initially evaluated for α_1-AT deficiency because of an episode of gastrointestinal bleeding, bleeding from the umbilical stump, and/or bruising.[229] Occasionally, the deficiency is identified because of hepatosplenomegaly, ascites, and liver synthetic dysfunction in early infancy; an even smaller number have severe fulminant liver failure in infancy.[230] A few infants are recognized initially because of a cholestatic clinical syndrome characterized by pruritus and hypercholesterolemia. The clinical picture in these infants resembles extrahepatic biliary atresia, but histologic examination shows a paucity of intrahepatic bile ducts. Despite what is stated in one review,[155] many infants with homozygous PIZZ α_1-AT deficiency are completely asymptomatic and often go undetected. Even when detected in the Swedish screening study, only approximately 50% of the asymptomatic infants had elevated transaminases.[1,231]

Liver disease associated with α_1-AT deficiency may also be first discovered in late childhood or early adolescence, when the affected individual has abdominal distention from hepatosplenomegaly and/or ascites or has upper intestinal bleeding caused by esophageal variceal hemorrhage. Some of these patients have a history of unexplained prolonged obstructive jaundice during the neonatal period. In others, there is no evidence of any previous liver injury, even when the neonatal history is carefully reviewed.

α_1-AT deficiency should be considered in the differential diagnosis of any adult who presents with chronic hepatitis, cirrhosis, portal hypertension, or hepatocellular carcinoma of unknown origin. An autopsy study in Sweden shows a much higher risk of cirrhosis in adults with α_1-AT deficiency than was previously suspected and shows that this deficiency has a strong association with primary liver cancer.[232]

It is still not clear which clinical manifestations or abnormal laboratory test results can be used to predict a poor prognosis for individuals with liver disease associated with α_1-AT deficiency. One study suggested that persistent hyperbilirubinemia, hard hepatomegaly, early development of splenomegaly, and progressive prolongation of prothrombin time were indicators of poor prognosis.[223] In another study, elevated transaminase levels, prolonged prothrombin time, and a lower trypsin inhibitor capacity correlated with worse prognosis.[227] However, in my experience, some children with liver disease associated with α_1-AT deficiency can lead relatively normal lives for years after the development of hepatosplenomegaly and mild prolongation of prothrombin time. Volpert and colleagues reviewed 44 patients with α_1-AT deficiency seen at St. Louis Children's Hospital since 1984 when a registry was established.[233] Seventeen of these patients had cirrhosis and/or portal hypertension. Nine of these have had a prolonged, relatively uneventful course for at least 4 years after diagnosis. Of these patients, two eventually underwent liver transplant, but seven have led relatively healthy lives for up to 22 years after diagnosis. These nine patients could be distinguished only from the remaining eight patients by overall life functioning and not by any single clinical or biochemical characteristic. Thus, the prediction of poor prognosis for liver disease associated with α_1-AT deficiency and the timing of liver transplant depend more on the overall functioning of the affected child than on the histology or laboratory data.

There is currently no evidence that the heterozygous α_1-AT MZ phenotype causes liver disease in children by itself. It is not clear whether heterozygous MZ adults are predisposed to liver injury. Early studies of liver biopsy collections suggested that there was a relationship between heterozygosity and development of liver disease.[234] A retrospective study of liver transplant recipients at the Mayo Clinic showed that they had a higher prevalence of heterozygosity for α_1-ATZ in a group of these patients without another explanation for liver disease.[235] However, these studies are biased in ascertainment and do not include concurrent prospective controls. A cross-sectional study of patients with α_1-AT deficiency in a referral-based Austrian university hospital who were re-examined with the most sophisticated and sensitive assays available suggests that liver disease in heterozygotes can be accounted for, to a

great extent, by infections with hepatitis B or C virus or by autoimmune disease.[236] Although there is an overall impression that heterozygotes for α_1-ATZ are susceptible to liver disease, the literature does not provide convincing evidence that liver injury can be explained by the α_1-AT MZ heterozygous state alone.

Liver disease has been described for several other allelic variants of α_1-AT. Children with compound heterozygosity type PISZ are affected by liver injury in a manner similar to that of PIZZ children.[1,11] There are several reports of liver disease in α_1-AT deficiency-type PIM_{Malton}.[64,68] This is a particularly interesting association because the abnormal PIM_{Malton} α_1-AT molecule has been shown to undergo polymerization and retention within the ER.[141] Liver disease has been detected in single patients with several other α_1-AT allelic variants, such as PIM_{Duarte},[66] PIW,[237] and PIFZ,[238] but it is not clear whether other causes of liver injury for which there are more sophisticated diagnostic assays (such as hepatitis C infection and autoimmune hepatitis) have been completely excluded in these cases.

The distinctive histologic feature of homozygous PIZZ α_1-AT deficiency—periodic acid–Schiff–positive diastase-resistant globules in the ER of hepatocytes—substantiates the diagnosis (Figure 55.7-8). According to some observers, these globules are not as easy to detect in the first few months of life.[239,240] The presence of these inclusions should not be interpreted as diagnostic of α_1-AT deficiency; similar structures are occasionally observed in PIMM individuals with other liver diseases.[241] The inclusions are eosinophilic, round to oval, and 1 to 40 μm in diameter. They are most prominent in periportal hepatocytes but may also be seen in Kupffer cells and cells of biliary ductular lineage.[242] There may be evidence of variable degrees of hepatocellular necrosis, inflammatory cell infiltration, periportal fibrosis, and/or cirrhosis. There is often evidence of bile duct epithelial cell destruction, and there is occasionally a paucity of intrahepatic bile ducts. Our recent study has shown that there may also be an intense autophagic reaction detected by electron microscopic examination of liver biopsies, with a full array of nascent and degradative-type autophagic vacuoles.[168]

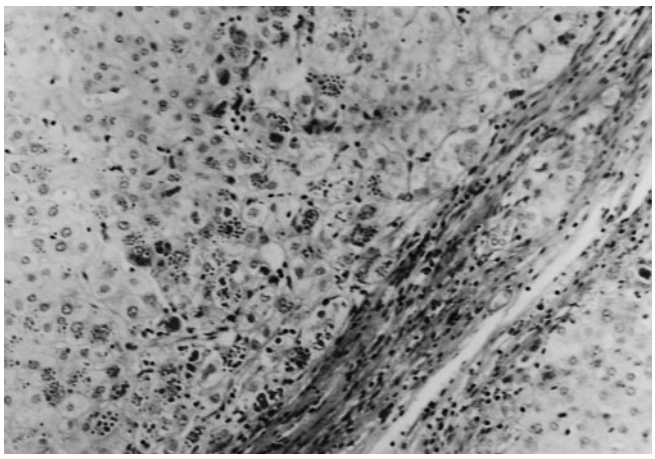

FIGURE 55.7-8 Hepatic histology in homozygous PIZZ α_1-antitrypsin (AT) deficiency. Micrograph of liver biopsy specimen in α_1-AT deficiency (periodic acid–Schiff [PAS]/diastase stain; ×40 original magnification), demonstrating the PAS+, diastase-resistant globules.

Diagnosis is established by a serum α_1-AT phenotype determination in isoelectric focusing or by agarose electrophoresis at acid pH (Figure 55.7-9). The phenotype should be determined in all cases of neonatal hepatitis or unexplained chronic liver disease in older children, adolescents, and adults. It is particularly important in the neonatal period because it may be very difficult to distinguish patients with α_1-AT deficiency from those with biliary atresia. Moreover, it is not uncommon for neonates with a PIZZ phenotype to have no biliary excretion on scintigraphic studies.[243] There is one report of α_1-AT deficiency and biliary atresia in a single patient.[244] We have had several patients with homozygous PIZZ α_1-AT deficiency and cholestasis and no biliary excretion of technetium-labeled mebrofenin, but with more prolonged observation in each of these cases, cholestasis remitted, so that it was then obvious that the patient did not have biliary atresia.

When used with isoelectric focusing, serum concentrations of α_1-AT may be helpful in distinguishing individuals who are homozygous for the Z allele from SZ compound heterozygotes, both of whom may develop liver disease. In some cases, phenotype determinations of parents and/or other relatives are also necessary to ensure the distinction between ZZ and SZ allotypes, a distinction that is important for genetic counseling. Serum concentrations of α_1-AT are occasionally misleading. For instance, concentrations may increase during the host response to inflammation, even in homozygous PIZZ individuals, giving a falsely reassuring impression.

LUNG DISEASE IN α_1-ANTITRYPSIN DEFICIENCY

The incidence and prevalence of emphysema in α_1-AT deficiency have not been studied prospectively. Autopsy studies suggest that 60 to 65% of people with homozygous PIZZ α_1-AT deficiency develop clinically significant lung injury. However, there are PIZZ smokers who do not have any symptoms of lung disease or evidence of pulmonary function abnormalities until the seventh or eighth decade of life.[245]

The typical person with lung disease is a male cigarette smoker. Onset of dyspnea is insidious in the third to fourth decade of life. About 50% of affected persons develop cough and recurrent lung infections. The disease progresses to a severe limitation of airflow. A reduction in the forced expiratory volume, increase in total lung capacity, and reduction in diffusing capacity occur. Chest radiography demonstrates hyperinflation with marked lucency at the lung bases.[246] Histopathologic studies demonstrate panacinar emphysema, which is more prominent in the lower lung.[246,247]

It is rare for emphysema to affect an α_1-AT–deficient patient during childhood. A number of patients have been described in the literature, but an alternative explanation can be offered in each of these cases. In the most convincing case, emphysema developed several years after a porta-

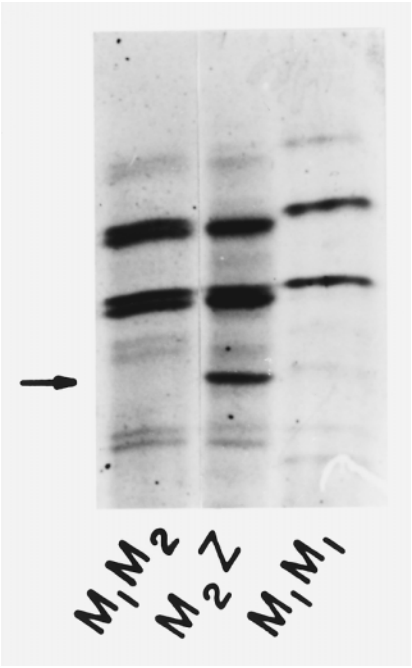

FIGURE 55.7-9 Isoelectric focusing of human serum samples for diagnosis of α_1-AT deficiency. Sera from a normal M_1M_2 individual, an M_2Z heterozygote, and a normal M_1M_1 individual were subjected to isoelectric focusing, with the anode at top and cathode at bottom. Migration of the Z allele is indicated by the arrow. The gel was provided by J. A. Pierce, St. Louis, MO. Reproduced with permission from Perlmutter DH. Alpha-1-antitrypsin deficiency. In: Snape WJ, editor. Consultations in gastroenterology. Philadelphia: WB Saunders; 1996. p. 793.

caval shunt procedure was done.[248] In three early cases, there were problems with the phenotypic diagnosis of α_1-AT deficiency.[249–251] In a more recent report, two patients had pulmonary abnormalities that could have been attributed to severe systemic illness associated with end-stage liver disease.[252] In a number of infants with α_1-AT deficiency, pulmonary function testing suggested a subtle degree of hyperinflation.[253] However, another study detected no significant difference between the pulmonary function of PIZZ children aged 13 to 17 years and that of an age-matched control group.[254] These data indicate that it is extremely rare for α_1-AT deficiency to cause emphysema in individuals less than 25 years of age.

The destructive effect of cigarette smoking on the outcome of lung disease in α_1-AT deficiency has been demonstrated in many studies. Actuarial studies suggest that cigarette smoking reduces median survival by over 20 years in deficient persons.[255] The rate of decline in forced expiratory volume is four times greater in α_1-AT–deficient persons who smoke than in α_1-AT–deficient persons who do not smoke.[256]

There is still very limited information about the incidence of liver disease in α_1-AT–deficient individuals with emphysema. In one study of 22 PIZZ patients with emphysema, there was an elevated transaminase level in 10 patients and cholestasis in 1 patient.[257] Liver biopsies were not done in this study, and such biopsies may be necessary to accurately determine the extent of liver injury in α_1-AT–deficient patients with emphysema.

TREATMENT

The most important principle in the treatment of α_1-AT deficiency is avoidance of cigarette smoking. Cigarette smoking markedly accelerates the destructive lung disease associated with α_1-AT deficiency, reduces the quality of life, and significantly shortens longevity.[255,256,258] These facts need to be presented to the families of affected pediatric patients in an unambiguous manner. Although it is not usually an issue that arises in the pediatric gastrointestinal and liver clinic, it may be necessary to carefully monitor the smoking habits of the family and, during interval visits, to re-emphasize the important effect of smoking on outcomes for deficient individuals.

There is no specific therapy for liver disease associated with α_1-AT deficiency. Therefore, clinical care largely involves supportive management of symptoms owing to liver dysfunction and prevention of complications. Although the use of ursodeoxycholic acid and colchicine has been mentioned in the literature, there is no evidence for biochemical or clinical efficacy for either drug.

Progressive liver dysfunction and liver failure in children have been treated by orthotopic liver transplant, with survival rates in one study approaching 90% at 1 year and 80% at 5 years.[259] A more recent study put 10-year actuarial survival at 68%.[260] Nevertheless, a number of PIZZ individuals with severe liver disease (even cirrhosis and/or portal hypertension) may have a relatively low rate of disease progression and may lead a relatively normal life for extended periods of time. With the availability of transplant techniques with living related donors, it may be possible to manage these patients expectantly for some time. Children with α_1-AT deficiency and mild liver dysfunction (elevated transminases and/or hepatomegaly) and without functional impairment may never need liver transplant surgery.

Most α_1-AT–deficient children with liver disease are not candidates for alternative surgical interventions. However, there are rare specific clinical situations in which a portacaval or splenorenal shunt might be considered (such as in a child with only mild liver synthetic dysfunction and mild parenchymal liver injury but severe portal hypertension). Several children with severe liver disease and α_1-AT deficiency have survived 10 to 15 years after shunt surgery before requiring orthotopic liver transplant.[261] Moreover, previous hepatobiliary surgery is not a statistically significant risk factor for poor outcome of subsequent orthotopic liver transplant.[262]

Trials of pharmacologic therapy for α_1-AT deficiency have been conducted. Patients have been given the synthetic androgens danazol or stanazolol because of the dramatic effects of the same agents in patients with hereditary angioedema,[263] which is a deficiency of the homologous serine proteinase inhibitor C1 inhibitor, and because danazol was initially found to increase serum levels of α_1-AT in PIZZ persons.[264] However, further evaluation has demonstrated that danazol increases serum levels of α_1-AT in only 50% of deficient persons, and the magnitude of the effect is small.[265] Moreover, it was not clear from any of the studies whether the effect of androgens occurred at the level of

synthesis and might also be associated with increased accumulation of α_1-ATZ in the ER, with potential hepatotoxic consequences.

Several studies have shown that a class of compounds called chemical chaperones can reverse the cellular mislocalization or misfolding of mutant plasma membrane, lysosomal, nuclear, and cytoplasmic proteins (including CFTRΔF508, prion proteins, mutant aquaporin molecules associated with nephrogenic diabetes insipidus, and mutant galactosidase A associated with Fabry disease).[266] These compounds include glycerol, trimethylamine oxide, deuterated water, and 4-phenylbutyric acid (PBA). Burrows and others recently found that glycerol and PBA mediate a marked increase in secretion of α_1-ATZ in a model cell culture system.[156] Moreover, oral administration of PBA was well tolerated by PiZ mice (transgenic for the human α_1-ATZ gene) and consistently mediated an increase in blood levels of human α_1-AT, reaching 20 to 50% of the levels present in PiM mice and normal humans. The synthesis or intracellular degradation of α_1-ATZ was not affected by PBA. The α_1-ATZ secreted in the presence of PBA was functionally active in that it could form an inhibitory complex with neutrophil elastase. Because PBA has been used safely for years in children with urea cycle disorders as an ammonia scavenger, and because clinical studies have suggested that only partial correction is needed for prevention of both liver and lung injury in α_1-AT deficiency, PBA constitutes a candidate for chemoprophylaxis of target organ injury in α_1-AT deficiency.

It also now appears that several iminosugar compounds may be potentially useful for chemoprophylaxis of liver and lung disease in α_1-AT deficiency. These compounds are designed to interfere with oligosaccharide side chain trimming of glycoproteins and are now being examimed as potential therapeutic agents for viral hepatitis and other types of infections.[267,268] We have examined several of these compounds initially to determine the effect of inhibiting glucose or mannose trimming from the carbohydrate side chain of mutant α_1-ATZ on its fate in the ER but found to our surprise that one glucosidase inhibitor, castanospermine, and two α-mannosidase I inhibitors, kifunensine and deoxymannojirimicin, actually mediate increased secretion of α_1-ATZ.[269] The α_1-ATZ that is secreted in the presence of these drugs is partially functionally active. Kifunensine and deoxymannojirimicin are less attractive candidates for chemoprophylactic trials because they delay degradation of α_1-ATZ in addition to increasing its secretion and therefore have the potential to exacerbate susceptibility to liver disease. However, CST has no effect on the degradation of α_1-ATZ and, therefore, may be targeted for development of a chemoprophylactic agent. The mechanism of action of castanospermine on α_1-ATZ secretion is unknown. An interesting hypothesis for the mechanism of action of kifunensine and deoxymannojirimicin has mutant α_1-ATZ interacting with ERGIC-53 for transport from the ER to the Golgi complex when mannose trimming is inhibited.

Novoradovskaya and others have suggested that inhibition of ER degradation of α_1-ATZ by proteasome inhibitor lactacystin and by protein synthesis inhibitor cycloheximide is associated with increased secretion of α_1-ATZ.[270] Burrows and others have been unable to confirm this result.[156] Moreover, there are now several lines of evidence indicating that there is no simple relationship between ER degradation of α_1-ATZ and its secretion such that perturbations that delay degradation are automatically accompanied by increased secretion. Some physiologic and pharmacologic perturbations are associated with delayed degradation without any change in secretion. Other perturbations increase secretion without any change in degradation. Increased temperature is associated with both delayed degradation and increased secretion.[156]

Some patients with α_1-AT deficiency and emphysema are currently receiving replacement therapy with purified or recombinant plasma α_1-AT either by intravenous or intratracheal aerosol administration.[271] This therapy is associated with an improvement in serum concentrations of α_1-AT and in neutrophil elastase inhibitory capacity in bronchoalveolar lavage fluid, without significant side effects. Although an initial study suggested that there is a slower decline in forced expiratory volume in patients on replacement therapy, this occurred only in a subgroup of patients, and the study was not randomized.[272]

Protein replacement therapy is designed only for individuals with established and progressive emphysema. It is not being considered for individuals with liver disease because there is no information to support the notion that deficient serum levels of α_1-AT are mechanistically related to liver injury.

A number of patients with severe emphysema from α_1-AT deficiency have undergone lung transplant in the past 10 years. The latest data from the St. Louis International Lung Transplant Registry show that 91 patients with emphysema and α_1-AT deficiency underwent single or bilateral lung transplant by 1993. Actuarial survival for patients in this category who underwent transplant between 1987 and 1994 is approximately 50% for 5 years. Lung function and exercise tolerance are significantly improved.[273]

Replacement of α_1-AT by somatic gene therapy has also been discussed in the literature.[271] This strategy is potentially less expensive than replacement therapy with purified protein and would alleviate the need for intravenous or inhalation therapy. Again, this form of therapy would be useful only in ameliorating emphysema because liver disease associated with α_1-AT deficiency is not caused by deficient levels of α_1-AT in the serum or tissue. Before clinical trials involving gene therapy are conducted, it would be helpful to know that replacement therapy with purified α_1-AT, as it is currently applied, is effective in ameliorating emphysema in this deficiency. Also, there are still major issues that need to be addressed before gene therapy becomes a realistic alternative.[274] Several novel types of gene therapy, such as repair of mRNA by trans-splicing ribozymes[275] and chimeric RNA/DNA oligonucleotides,[276] are theoretically attractive alternative strategies for liver disease in α_1-AT deficiency because they would prevent the synthesis of mutant α_1-ATZ protein and ER retention. In fact, a chimeric RNA/DNA oligonucleotide based on the sequence of coagulation fac-

tor IX in complex with lactose (so that it could be taken up by asialoglycoprotein receptor–mediated endocytosis) was delivered to hepatocytes with surprisingly high efficiency after intravenous administration.[276] However, efficiency has been much lower for other mutant proteins.

Recent studies have shown that transplanted hepatocytes can repopulate the diseased liver in several mouse models,[277,278] including a mouse model of a childhood metabolic liver disease termed hereditary tyrosinemia. Replication of the transplanted hepatocytes occurs only when there is injury and/or regeneration in the liver. The results provide evidence that it may be possible to use hepatocyte transplant techniques to treat hereditary tyrosinemia and perhaps other metabolic liver diseases in which the defect is cell autonomous. For instance, α_1-AT deficiency involves a cell-autonomous defect and would be an excellent candidate for this strategy.

Alternative strategies for at least partial correction of α_1-AT deficiency may result from a more detailed understanding of the fate of the α_1-ATZ molecule in the ER. First, delivery of synthetic peptides to the ER to insert into the gap in the A sheet or into a particular hydrophobic pocket of the α_1-AT molecule[279] and prevent polymerization of α_1-AT might result in the release of the mutant α_1-ATZ molecules into the extracellular fluid and might prevent its accumulation in the ER. Although it is not yet entirely clear, there is some evidence from studies on the assembly of class I MHC molecules that synthetic peptides may be delivered to the ER from the extracellular medium of cultured cells.[280] There is also evidence that certain molecules may be transported retrograde to the ER by receptor-mediated endocytosis.[281,282] Second, elucidation of the biochemical mechanism by which abnormally folded α_1-AT undergoes intracellular degradation might allow pharmacologic manipulation of this degradative system, such as enhancing proteasomal activity with interferon-γ in the subpopulation of PIZZ individuals predisposed to liver injury. Third, a competitive antagonist of binding or signal transduction by α_1-AT–proteinase complexes at the SEC receptor might prevent increases in intracellular accumulation of α_1-AT during augmentation of α_1-AT levels with protein replacement or gene replacement therapies.

Genetic Counseling

Restriction fragment length polymorphisms detected with synthetic oligonucleotide probes[283,284] and family studies[285] allow prenatal diagnosis of α_1-AT deficiency. Nevertheless, it is not clear how prenatal diagnosis for this deficiency should be used and how families should be counseled regarding the diagnosis. Data from the Sveger study indicate that 70 to 75% of persons with α_1-AT deficiency do not have evidence of liver disease at the age of 18 years and that nonsmoking PIZZ persons may not develop emphysema or even pulmonary function abnormalities until 60 to 70 years of age.[11] These data could support a counseling strategy in which amniocentesis and abortion are discouraged. The only other data on this subject suggest a 78% chance that a second PIZZ child will have serious liver disease if the older sibling had serious liver disease.[224] However, this study was retrospective and was influenced by bias in the ascertainment of patients. The issue will not be resolved until it is studied prospectively.[1,11]

Screening for α_1-Antitrypsin Deficiency

Several recent studies have suggested that population screening for α_1-AT deficiency would be efficacious. First, there is now evidence that knowledge of and counseling in the consequences of α_1-AT deficiency are associated with a reduced rate of smoking among affected adolescents.[286,287] Second, although there was some evidence for adverse psychological effects from knowledge of the deficiency by affected families,[288] more recent studies have indicated that there were no significant negative psychosocial consequences in early adulthood from neonatal screening for α_1-AT deficiency in Sweden.[289] These data should give new momentum to the reconsideration of screening programs for α_1-AT deficiency.

ACKNOWLEDGMENT

I am indebted to the family of Sean Welek and to the support of National Institutes of Health grants HL37784, DK52526 and DK61760.

8. *Zellweger Syndrome and Other Disorders of Peroxisomal Metabolism*

Richard I. Kelley, MD, PhD
Gerald V. Raymond, MD
Paul A. Watkins, MD, PhD

Zellweger syndrome and an expanding spectrum of related peroxisomal diseases have emerged in the last 20 years as major identifiable causes of liver disease in the pediatric population. Because of the wide range of associated nonhepatic abnormalities in these disorders and the often initially silent nature of the progressive liver disease, many patients with peroxisomal diseases come to the attention of the gastroenterologist from a number of different hospital clinics, where they may have been followed for many months or years. Thus, a thorough understanding of the full spectrum of clinical and metabolic characteristics of peroxisomal disorders is essential for practicing gastroenterologists.

The cerebrohepatorenal syndrome of Zellweger is by far the best known genetic disorder of peroxisomal metabolism. Although Zellweger syndrome was first described as an autosomal recessive, multiple anomaly syndrome in 1964,[1] the discovery in 1973 that hepatic and renal cells of patients with Zellweger syndrome were devoid of recognizable peroxisomes and had dysfunctional mitochondria refocused attention on Zellweger syndrome as a possible metabolic disorder.[2] As a result, Zellweger syndrome emerged as the prototypic "metabolic malformation syndrome" and spawned the development of a new field of biochemical genetics. Indeed, more than a dozen clinical disorders have been identified or redescribed as diseases of the peroxisome. In some, such as classic Zellweger syndrome and neonatal adrenoleukodystrophy (ALD), the entire peroxisome and most of its associated biochemical functions appear to be lost or severely deficient. In others, such as X-linked ALD and several disorders of bile acid biosynthesis, only a single peroxisomal protein appears to be deficient. The different patterns of biochemical abnormalities manifest by these diverse syndromes are now understood to be caused by, principally, several different defects of peroxisomal protein importation and a variety of single enzymatic deficiencies. Overall, the discovery and biochemical characterization of these peroxisomal experiments of nature have fundamentally changed our understanding of the role of the peroxisome in human metabolism. In this chapter, the principal metabolic functions of the peroxisomes and the major clinical disorders associated with an apparent primary deficiency of peroxisomal metabolism are reviewed. Guides to the diagnosis and treatment of the peroxisomal disorders are also presented.

STRUCTURE AND FUNCTION OF NORMAL PEROXISOMES

Tissue Distribution and Characteristics of Peroxisomes

Peroxisomes are ubiquitous subcellular organelles defined by de Duve as small (0.1–1.0 μm), dense, subcellular particles bounded by a single membrane and containing the enzymatic machinery for the evolution and consumption of hydrogen peroxide.[3] Similar peroxidative organelles in plants contain the important glyoxylate cycle and related carbohydrate pathways and are known as glyoxysomes. The term *microbodies* is commonly used to refer to both organelles.[4,5]

Although large (0.5–1.5 μm) and more conspicuous peroxisomes were first identified only in hepatocytes (Figure 55.8-1) and renal proximal tubule cells, essentially all mammalian cells except erythrocytes have since been found to contain peroxisomes. These organelles range in size from smaller (0.1–0.2 μm) microperoxisomes in the brain to the larger structures found in liver and kidney. Hepatocytes and renal tubule cells have the greatest abundance of peroxisomes, which may constitute as much as 1% of the cell mass, whereas the collective volume of peroxisomes in muscle, fibroblasts, and neuronal tissue is at least an order of magnitude less.[6,7] The number of peroxisomes per cell can range from fewer than 100 to more than 1,000. In most tissues, peroxisomes appear as round or ovoid organelles with a finely granular matrix, bounded by a single membrane and stainable by a catalase-detecting reaction with diaminobenzidine. Although by electron microscopy the single peroxisomal membrane appears trilaminar, it is notably thinner than the trilaminar single membrane of lysosomes and lacks the clear zone subjacent to the lysosomal membrane. The larger peroxisomes of some species include a dense, crystalline-like "nucleoid" core containing urate oxidase. Species that lack urate oxidase, such as humans and birds, also lack peroxisomal cores. An important characteristic of hepatic peroxisomes of some species, especially rats and mice, is proliferation induced by a variety of natural and xenobiotic compounds, such as *trans*–unsaturated fatty acids, clofibrate, and thyroxine.[8,9] The proliferative action of these compounds is mediated by peroxisome proliferator-activated receptors

(PPARs), which are closely related to steroid hormone receptors.[10–13] However, although peroxisomal proliferation is associated with hepatic neoplasia in rats,[14] there is little evidence for drug-mediated peroxisomal proliferation or hypolipidemic drug-mediated carcinogenesis in humans despite the presence of PPARs in human tissues.[13]

Peroxisomes appear to be independent organelles with a biogenesis separate from other subcellular organelles and compartments.[15,16] Extensive investigation of peroxisome biogenesis has refuted early hypotheses that these organelles arise from budding of the endoplasmic reticulum (ER). Gould and colleagues have proposed that there are two coexisting pathways of peroxisome biogenesis: one involving growth and division of preexisting peroxisomes and the other beginning with a preperoxisomal membrane vesicle.[16] Both models require uptake of lipid and membrane proteins as well as matrix proteins, followed by fission once a critical size is reached. Extensive genetic studies using yeast mutants, Chinese hamster ovary cell mutants, and skin fibroblasts from patients with peroxisomal biogenesis disorders have revealed the existence of at least 23 genes involved in peroxisome biogenesis.[15] The genes are referred to as *PEX* genes and their protein products as peroxins. Deficiency or mutation in 11 of the *PEX* genes is now known to result in human peroxisomal biogenesis disorders. Unlike mitochondria, there is no evidence for specific peroxisomal deoxyribonucleic acid (DNA) encoding the synthesis of peroxisomal proteins. All peroxins, as well as other membrane and matrix proteins, are encoded by nuclear genes and are synthesized on free polyribosomes.

Matrix proteins are targeted to peroxisomes primarily by one of two peptidyl targeting signals. The majority of matrix proteins have been found to contain peroxisome targeting signal (PTS) 1, a carboxy-terminal tripeptide with a suggested consensus of (S/A/C)-(K/R/H)-L-COOH.[17] Fewer matrix proteins are targeted to the organelle by PTS2, found near but not at the amino terminus, which has a consensus sequence of (R/K)-(L/V/I)-X_5-(Q/H)-(L/A).[16] The receptors for PTS1 and PTS2 proteins are encoded by the *PEX5* and *PEX7* genes, respectively.[18,19] The currently accepted model of peroxisomal matrix protein import involves numerous peroxins located in both the cytoplasm and the peroxisomal membrane.[16] After a newly synthesized matrix protein binds to its receptor in the cytoplasm, the complex is transported to the surface of the peroxisome, where it interacts with docking proteins and the import machinery. The matrix protein is imported into the peroxisome, and the receptor is returned to the cytoplasm via recycling factors. Although several peroxins have been implicated in the import of peroxisomal membrane proteins, this process remains less well characterized than matrix protein import.

Peroxisomes are mostly randomly distributed in hepatocytes but may occur closely juxtaposed to the ER, from which peroxisomes were once thought to arise by budding. In some cells, peroxisomes are seen surrounding glycogen or triglyceride deposits.[20] The close association of peroxisomes with ER is denoted structurally by a dense thickening (the "marginal plate") of the segment of the peroxisomal membrane paralleling the ER.[21,22] Moreover, in tissues with a high rate of fatty acid β-oxidation, there is a nonrandom

association of peroxisomes with mitochondria, usually separated by an intercalated bilayer of ER.[20] An extreme structural specialization of peroxisomes occurs in the cells of sebaceous glands, wherein the peroxisomal compartment exits as an extensive filamentous network believed to subserve the synthesis of the unusual waxes and etherlipids of sebum.[23] Coreless, filamentous tails and interperoxisomal connections have also been found by careful serial sectioning of rat liver[24] and may be common, if variable, features of the peroxisomal space.

Metabolic Pathways of the Peroxisome

Once thought to be vestigial, the vertebrate peroxisome is now known to contain a remarkable variety of highly specialized and essential enzymatic systems for the synthesis and catabolism of, largely, lipids and amino acids (Table 55.8-1).[5] From a clinical-biochemical standpoint, the most important of these functions are (1) β-oxidation of very-long-chain fatty acids (VLCFAs) and 2-methyl branched-chain fatty acids; (2) synthesis of sterols and bile acids; (3) synthesis of plasmalogens; (4) α-oxidation of phytanic acid, a 3-methyl branched-chain fatty acid; (5) oxidase-mediated metabolism of amino acids; and (6) catalatic and peroxidatic decomposition of hydrogen peroxide. In addition, peroxisomes appear to have a role in the synthesis of cholesterol and, in some species, in the synthesis of highly specialized biochemicals such as waxy esters and pheromones.[25] For some processes, such as β-oxidation of fatty acids, a complete pathway exists in the peroxisome, whereas for others, such as bile acid or plasmalogen synthesis, only a portion of the pathway is unique to the peroxisome.

Major Metabolic Functions of the Peroxisome

Peroxisomal Fatty Acid β-Oxidation. Although fatty acid β-oxidation was first recognized as a function of peroxisomes (more exactly, glyoxysomes) of germinating seedlings in 1969,[26] not until 1978 was a complete ensemble of β-oxidative enzymes functionally similar to those of mitochondria found in mammalian peroxisomes (Figure 55.8-2).[27] However, despite identical stereochemistry and evolutionary homology of most of the peroxisomal β-oxidation enzymes and their counterparts in mitochondria,[28] the rate-limiting enzymes and substrate specificities

Synthesis of ether lipids (eg, plasmalogens)
Synthesis of sterol precursors and bile acids
Synthesis of waxy esters
Amino acid transamination
Oxidation of D- and L-amino acids
Oxidation of L-α-hydroxy acids
Oxidative catabolism of polyamines
Catabolism of purines
Catalatic and peroxidatic decomposition of hydrogen peroxide

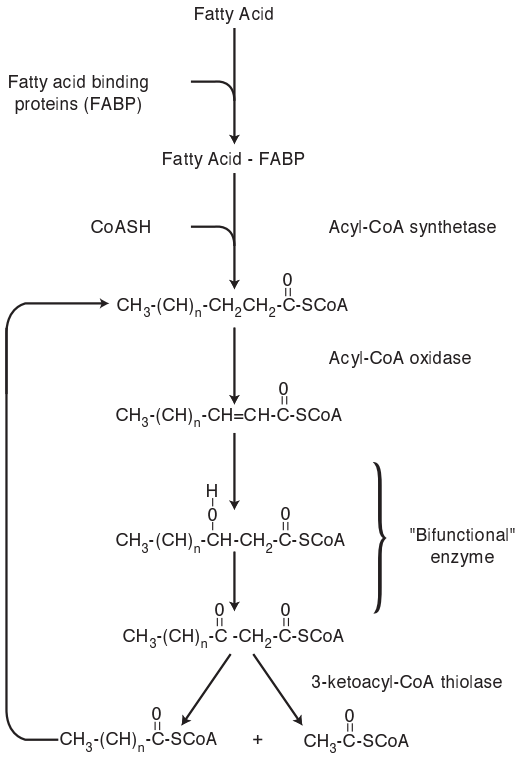

FIGURE 55.8-2 Peroxisomal pathway for β-oxidation of fatty acids. Medium-chain, long-chain, and very-long-chain fatty acids are shortened by two carbons for each cycle of β-oxidation down to an 8- or 6-carbon fatty acid. The acetate units and remnant fatty acids leave the peroxisome as carnitine esters via the action of acetylcarnitine and octanoylcarnitine transferases.

of β-oxidation in the two organelles are distinctly different. Recently, additional enzymes comprising a second, complete peroxisomal β-oxidation pathway have been identified in mammals.[29] Whereas the original peroxisomal β-oxidation pathway follows L-isomer enzymology and oxidizes straight-chain saturated fatty acids, the second, the D-specific peroxisomal pathway, catalyzes the oxidation of branched-chain fatty acids, including oxidation of the branched sterol side chain required for the synthesis of bile acids.[30] There is compelling evidence for interaction and crossover between the L- and D-specific pathways because the degradation of straight-chain VLCFAs requires enzymes from both pathways.[31]

There is considerable similarity between the enzymes and the enzymatic reactions of the two peroxisomal β-oxidation pathways. The first step in both pathways is carried out by an acyl coenzyme A (CoA) oxidase that consumes molecular oxygen and generates hydrogen peroxide. The straight-chain oxidase has broad specificity for all but short-chain (C_4–C_8) fatty acids.[32] In contrast, at least four separate acyl-CoA dehydrogenases—short-, medium-, long-, and very-long-chain acyl-CoA dehydrogenases—catalyze the degradation of straight-chain fatty acids in mitochondria. Deficiency of the straight-chain acyl-CoA oxidase in humans leads to the accumulation of VLCFAs and a distinct clinical disorder.[33,34] Known substrates for the branched-chain acyl-CoA oxidase are 2-methylacyl CoAs and include pristanic acid, a product of phytanic acid

oxidation,[35] and precursors of bile acids.[36] The second and third reactions of both peroxisomal pathways are carried out by monomeric, multifunctional proteins that contain both enoyl-CoA hydratase and 3-hydroxyacyl-CoA dehydrogenase activities.[37] In contrast, two separate proteins in mitochondria catalyze these steps. The originally identified "bifunctional enzyme," now known as either multifunctional enzyme (MFE) 1 or L-bifunctional protein (L-BP), is L-specific. However, human deficiency of the more recently described D-specific enzyme, referred to as either MFE2 or D-bifunctional protein (D-BP), causes a failure in the oxidation of VLCFAs and branched-chain fatty acids. MFE2 was found to be identical to 17β-hydroxysteroid dehydrogenase type 4 and has a domain at its carboxy terminus that resembles sterol carrier protein (SCP) 2, an important intracellular sterol and lipid-binding and transport protein.[38] The terminal β-oxidation reactions for both peroxisomal pathways are catalyzed by a 3-ketoacyl CoA thiolase, as in the mitochondrial β-oxidation system. The thiolase of the L-specific peroxisomal pathway is one of the few known PTS2-containing proteins. The thiolase of the D-specific pathway resides in the amino-terminal domain of SCPX, a 58 kD protein that is cleaved to form the two smaller functional proteins.[39]

Several other enzymes and proteins are involved in peroxisomal β-oxidation, and deficiencies of two of these are known to cause human disease. Clinically, the most important of these is the ALD protein, ALDP, a peroxisomal transmembrane transporter protein.[40] Mutations in the *ABCD1* gene that encodes ALDP lead to the accumulation of VLCFAs and the most common peroxisomal disease, X-linked ALD. Despite extensive investigation since the discovery of ALDP in 1993, the exact function of this protein remains unknown.

More recently, the importance of 2-methylacyl CoA racemase in peroxisomal β-oxidation of 2-methyl branched-chain compounds such as pristanic acid and bile acid precursors has been recognized. Only one of the two naturally occurring stereoisomers of pristanic acid or bile acid precursors, the *S*-conformers, are substrates for branched-chain acyl CoA oxidase.[41,42] Peroxisomal racemase converts compounds with an *R*-conformation at the 2-carbon to the corresponding *S*-conformer, allowing subsequent metabolism to occur. Four patients with deficiency of 2-methylacyl CoA racemase have now been identified.

From a physiologic standpoint, mitochondria are most important in the conversion of dietary fatty acids—palmitate, oleate, linoleate, and stearate—into acetyl CoA for energy metabolism, ketogenesis, and various synthetic pathways. Peroxisomes, on the other hand, appear to specialize in the β-oxidation of VLCFAs (more than 22 carbons),[43] certain unsaturated fatty acids,[44,45] dicarboxylic acids,[46] branched-chain fatty acids,[47] and a variety of xenobiotic acids, such as phenyl-substituted fatty acids.[48] The end products of β-oxidation—acetyl CoA in mitochondria versus acetylcarnitine and octanoylcarnitine in peroxisomes—as well as the fate of the extracted reducing equivalents—coupled to adenosine triphosphate (ATP) synthesis in mitochondria versus lost to hydrogen peroxide and its exergonic reactions in peroxisomes—also differ. Lastly, the total capacity of peroxisomal, but not mitochondrial, β-oxidation can be substantially amplified in some species by exposure to preferred substrates or drugs, such as clofibrate and related hypolipidemic drugs,[8,9] which also cause peroxisomal proliferation. The deficiency of this highly specialized system for β-oxidation is responsible for several of the clinically most important biochemical markers for peroxisomal disease, such as increased levels of VLCFAs.

Phytanic Acid Oxidation. Phytanic acid (3,7,11,15-tetramethylhexadecanoic acid) is a 3-methyl branched-chain fatty acid produced by oxidation of the free phytol

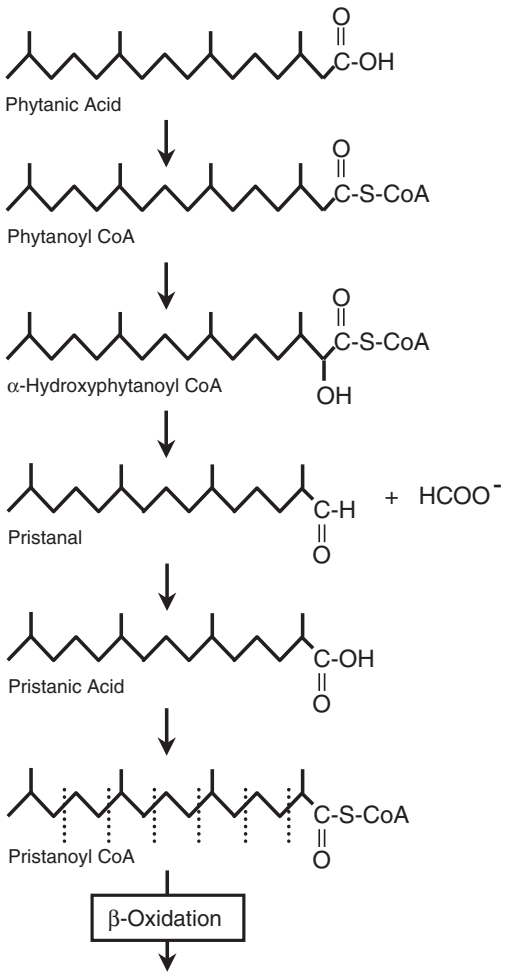

FIGURE 55.8-3 Sequence of α-oxidation of phytanic acid to pristanic acid and subsequent β-oxidation of pristanic acid to acetate and propionate units. α-Oxidation of phytanic acid, once thought to be coenzyme A (CoA) independent, requires activation of phytanate to a CoA intermediate, similar to β-oxidation in both mitochondria and peroxisomes. Pristanic acid, after reactivation to its CoA derivative, undergoes three cycles of β-oxidation in peroxisomes, alternately yielding propionyl CoA and acetyl CoA. The product of peroxisomal metabolism, 4,8-dimethylnonanoyl CoA, undergoes further degradation by mitochondrial β-oxidation. Not shown in this scheme is α-methylacyl CoA racemase, which is indispensible for converting any 2*R*-methylacyl CoAs to their 2*s* conformation.

chain of chlorophyll (Figure 55.8-3). Free phytol is concentrated in green vegetables, vegetable fats, and animal fats. However, phytanic acid formed by the action of phytol-metabolizing rumen bacteria and subsequently stored in animal and fish fats is the primary source of phytanic acid in human nutrition.[49,50] Once absorbed, dietary phytanic acid must undergo further α-oxidation in peroxisomes to remove the terminal carboxyl carbon to form pristanic acid (2,6,10,14-tetramethylpentadecanoic acid), a 2-methyl branched-chain fatty acid that is sequentially catabolized by the peroxisomal and mitochondrial β-oxidative systems.[35] Terminal Ω-oxidation activates a small portion of phytanic acid for β-oxidation from the omega end.[51]

Although it was originally thought that α-oxidation of phytanic acid began with a direct α-hydroxylation of the free acid by phytanic acid oxidase, more recent studies have established that a CoA derivative must be formed first.[52] Hydroxylation of the α-carbon by phytanoyl CoA α-hydroxylase (PAHX) yields L-2-hydroxyphytanoyl CoA, which is subsequently cleaved to formyl CoA and the aldehyde pristanal by 2-hydroxyphytanoyl CoA lyase.[53–56] Oxidation of pristanal to pristanic acid requires an aldehyde dehydrogenase, and early studies suggested that this dehydrogenase was identical to the microsomal enzyme defective in the mental retardation–ichthyosis disorder Sjögren-Larsson syndrome.[57] Most investigators now believe that a peroxisomal rather than a microsomal aldehyde dehydrogenase is responsible for the formation of pristanic acid, which, after activation to its CoA thioester, undergoes three rounds of peroxisomal β-oxidation (D-pathway) before transfer to mitochondria for further β-oxidation cycles.[35] As noted previously, pristanic acid β-oxidation requires the participation of α-methylacyl CoA racemase to convert R-pristanoyl CoA to S-pristanoyl CoA. Refsum disease has now been shown to be caused by mutations in PAHX.[58–60] Failure to import enzymes of both the α- and β-oxidation pathways in disorders of peroxisome biogenesis such as Zellweger syndrome results in the decreased ability to catabolize both phytanic acid and pristanic acid and the characteristic elevation of both phytol derivatives. Because phytanyl CoA α-hydroxylase is targeted to peroxisomes by PTS2, patients with rhizomelic chondrodysplasia punctata (RCDP) have impaired phytanic acid oxidation but normal pristanic acid oxidation.[61]

Cholesterol Biosynthesis. Hypocholesterolemia was one of the first relatively consistent biochemical abnormalities found in patients with Zellweger syndrome, suggesting that peroxisomes have a role in cholesterol biosynthesis. Sterols are synthesized by a complex series of reactions beginning with 3-hydroxy-3-methylglutaryl (HMG)-CoA and ending with the 30-carbon precursor of all other sterols, lanosterol (4,4,14-trimethylcholesta-8(9),24-dien-3β-ol). The first reaction in this complex biosynthetic pathway, the reduction of HMG-CoA to the 6-carbon acid alcohol mevalonic acid, is catalyzed by HMG-CoA reductase, which is generally accepted as the principal rate-determining step of cholesterol biosynthesis.[62] Cholesterol, a 27-carbon, monounsaturated sterol, is synthesized from lanosterol by a series of oxidations, reductions, and demethylations. Although all steps of cholesterol synthesis in mammals were once thought to take place in the ER, studies by Krisans and colleagues have established that the second enzyme of the pathway, mevalonate kinase, and at least two other enzymes required for the conversion of mevalonate phosphate to farnesyl pyrophosphate—mevalonate phosphate kinase and farnesyl diphosphate synthase—are exclusively or largely localized to peroxisomes.[63–65] SCP2, an apparent carrier protein for intracellular sterol transport, also appears to be targeted to and processed by peroxisomes.[66] In contrast, various subcellular localization studies have shown that synthesis of squalene, a nonsterol precursor of lanosterol, by squalene synthase occurs exclusively in the ER.[67] Peroxisomes also contain a form of HMG-CoA reductase that is structurally and functionally distinct from the HMG-CoA reductase in the ER.[68,69] Because the HMG-CoA reductase of the ER is clearly the apparent rate-limiting enzyme for cholesterol biosynthesis, the role of the peroxisomal isozyme is unknown at this time. In addition, although there is evidence from one laboratory that peroxisomes contain all of the enzymes necessary for the conversion of lanosterol to cholesterol,[70] the relative role of these and other peroxisomal enzymes in overall cholesterol biosynthesis and homeostasis is unclear. Nevertheless, observations that patients with Zellweger syndrome have markedly depressed serum cholesterol levels[71] and that Zellweger fibroblasts in vitro have depressed rates of cholesterol synthesis[72] suggest an important role for peroxisomes in cholesterol biosynthesis. However, not all laboratories have found that Zellweger fibroblasts have decreased rates of cholesterol synthesis. Also important to consider is that because the earlier enzymatic steps of cholesterol biosynthesis also participate in the synthesis of all isoprenoid compounds, peroxisomes must also have an important role in the synthesis of dolichols and coenzyme Q, among the many diverse products of isoprenoid biosynthesis.

Bile Acid Synthesis. Bile acids are synthesized from cholesterol by a complex series of cytochrome P-450–dependent ring hydroxylations of the cholesterol steroid nucleus, followed by a final β-oxidative cleavage of a propionate group from the C_{20}–C_{27} branched side chain of cholesterol (Figure 55.8-4). Normally, only the final end products of bile acid synthesis, cholic acid and chenodeoxycholic acid, are present in bile or other body fluids in any significant amount. However, in 1972, Eyssen and colleagues reported that the duodenal fluid of infants with a Zellweger-like syndrome contained unusually large amounts of the bile acid intermediates dihydroxycholestanoic acid (DHCA) and trihydroxycholestanoic acid (THCA).[73] Until then, DHCA and THCA had been known to be abundant acids only in the bile of certain primitive vertebrates, such as the alligator. In addition, significant levels of a previously unknown C_{29}-dicarboxylic bile acid were found in the blood of patients with Zellweger syndrome.[74] The finding of increased levels of DHCA and THCA in Zellweger syndrome and the discov-

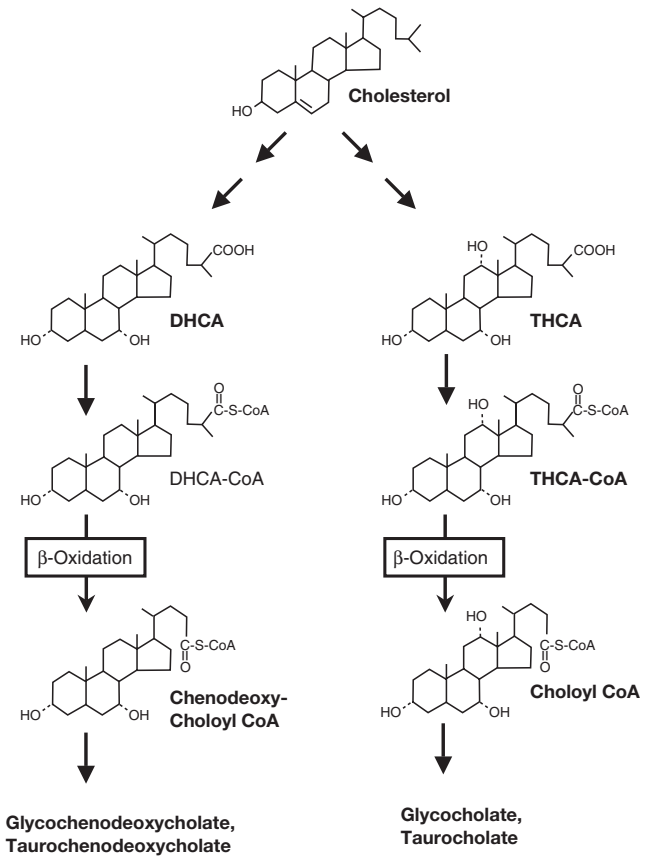

FIGURE 55.8-4 Conversion of cholesterol to bile acids via β-oxidation of the C_{22}–C_{27} side chain. After activation to their coenyzme A (CoA) derivatives, dihydroxycholestanoic acid (DHCA) and trihydroxycholestanoic acid (THCA) undergo one cycle of peroxisomal β-oxidation, yielding propionyl CoA and the CoA derivatives of chenodeoxycholic acid and cholic acid. DHCA-CoA and THCA-CoA can be conjugated to glycine or taurine by the peroxisomal enzyme bile acyl CoA:amino acid transferase. The levels of both DHCA and THCA are markedly increased in most patients with a peroxisome biogenesis disorder, such as Zellweger syndrome.

ery that hepatocytes of Zellweger syndrome are devoid of peroxisomes focused attention on the role of peroxisomes in the conversion of DHCA and THCA to their respective C_{24} bile acids, chenodeoxycholic acid and cholic acid.[36,74] Studies of the bile acids of patients with deficiency of the D-specific peroxisomal MFE2[30] also suggested involvement of peroxisomes in cholesterol side-chain cleavage.

Although bile acid ring hydroxylations take place primarily in the microsomal compartment, experimental evidence is compelling that cleavage of the cholesterol side chain, the final step in the synthesis of bile acids, occurs exclusively in the peroxisome. This conclusion has been reached both from careful subcellular fractionation studies in rat liver[36] and from the evidence that essentially all patients with Zellweger syndrome and related peroxisomal biogenesis disorders have increased levels of THCA, DHCA, and C_{29}-dicarboxylic bile acids.[75] The specific subcellular site of activation of DHCA and THCA to their CoA derivatives has not been resolved because enzymes capable of catalyzing this reaction are found both in microsomes and peroxisomes.[76,77] Naturally occurring THCA and DHCA are mixtures of *R*- and *S*-stereoisomers, but only the latter can be chain-shortened by the peroxisomal β-oxidation machinery.[41] Once inside peroxisomes, the CoA derivatives of R-THCA and R-DHCA must be converted to their respective *S*-conformers by peroxisomal α-methylacyl CoA racemase. S-C27-CoA derivatives undergo side-chain shortening via the D-specific peroxisomal β-oxidation pathway, converting DHCA-CoA and THCA-CoA to chenodeoxycholyl CoA and cholyl CoA, respectively.[29,78] These C_{24}-CoA compounds are substrates for the peroxisomal PTS1-containing enzyme, bile acyl CoA:amino acid *N*-acyltransferase, yielding glycine and taurine conjugates of the primary bile acids.[79] The mechanism by which these compounds exit the peroxisome is not understood. As discussed in Chapter 55.4, "Disorders of the Bile Acid Synthesis," in addition to peroxisomal diseases, abnormal bile acid synthesis is characteristic of a number of genetic defects of microsomal oxidases and dehydrogenases, most of which are associated with progressive congenital or postnatal liver disease.

Ether-Lipid Biosynthesis. In contrast to conventional phospholipids, which contain two fatty acyl groups ester-linked to a glycerophosphoryl backbone, plasmalogens are phospholipids with one acyl group *ester*-linked to the second carbon and an unusual, α-unsaturated long-chain alcohol *ether*-linked to the first carbon. Plasmalogens are major components of membrane structural phospholipids in all cells and constitute up to 90% of ethanolamine phospholipids in myelin.[80] Platelet activating factor (alkyl-, acetyl-glycerophosphorylcholine) also is an ether-lipid, the only one known to have a specific biochemical function.[81]

The first two steps of ether-lipid biosynthesis (Figure 55.8-5) have been shown to take place in the peroxisome.[82] Esterification of fatty acyl CoA to the sn-1 position of dihydroxyacetone phosphate (DHAP) is first catalyzed by DHAP acyltransferase,[83] a PTS1-containing protein. Subsequently, the PTS2 protein alkyl-DHAP synthase catalyzes the replacement of the sn-1 acyl group with a fatty alcohol.[83] The product of these initial reactions, 1-alkyl-glycerol-3-phosphate, is then transferred to the ER, where α,-β desaturation of the alcohol occurs and where enzymes for normal ester-lipid biosynthesis complete the formation of plasmalogens. There is also evidence that acyl CoA reductase, which catalyzes the synthesis of the long-chain alcohols incorporated into plasmalogens, is a peroxisomal enzyme and derives its reducing equivalents from reduced nicotinamide adenine dinucleotide phosphate generated through the action of a peroxisomal form of isocitrate dehydrogenase.[84]

Catabolism of Pipecolic Acid and Other Amino Acids. Pipecolic acid (2-piperidinecarboxylic acid), a cyclic imino acid and homolog of proline, is synthesized in animals via a minor pathway of lysine catabolism and then further oxidized sequentially to α-aminoadipic acid and glutaric acid (Figure 55.8-6).[85] The initial and probable rate-limiting step in the catabolism of L-pipecolic acid is catalyzed by a flavin adenine dinucleotide–dependent, L-pipecolic acid oxidase,[86] a PTS1 protein that has now been purified and

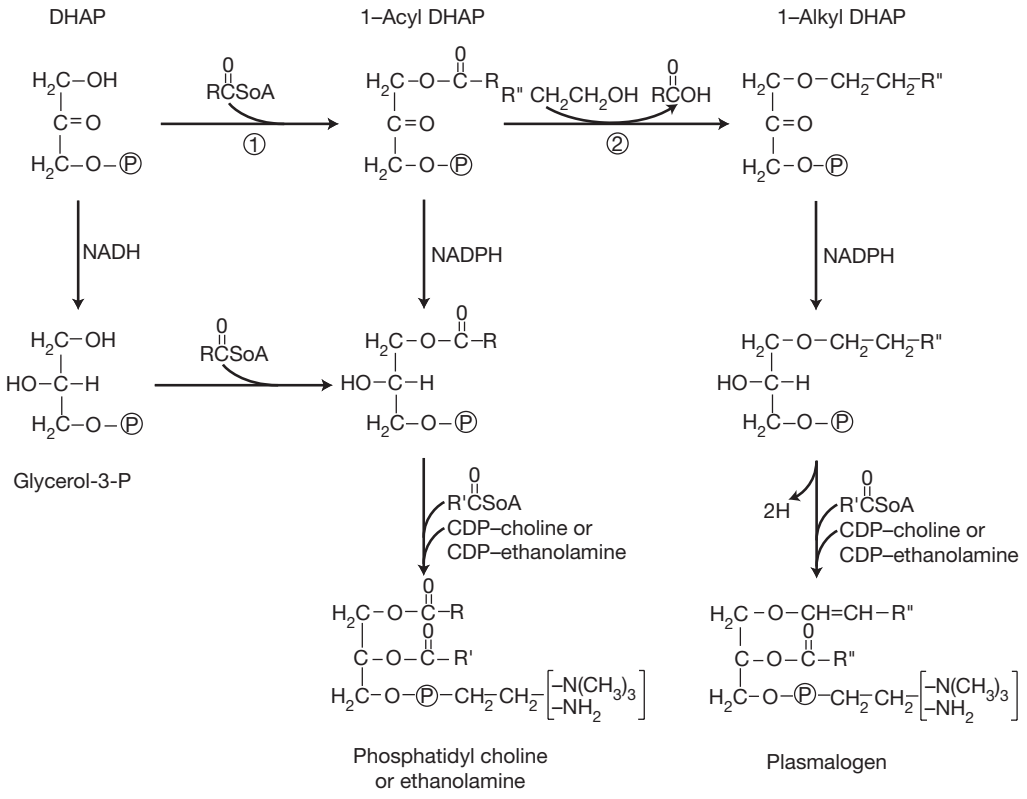

FIGURE 55.8-5 Pathway for biosynthesis of glycerol-ether lipids. Dihydroxyacetone phosphate (DHAP) acyltransferase and alkyl DHAP synthase, which catalyze the first two steps (labeled 1 and 2) in the synthesis of plasmalogens, are located in the peroxisome, whereas other reactions illustrated here take place in microsomes or mitochondria or both. CDP = cytidine diphosphate; CoA = coenzyme A; NADH = reduced nicotinamide adenine dinucleotide; NADPH = reduced nicotinamide adenine dinucleotide phosphate.

enzymatically and molecularly characterized.[87,88] Whereas both D and L forms of pipecolic acid occur in nature, only the L-isomer appears to be synthesized in animals, and only L-pipecolic acid accumulates to any significant degree in patients with peroxisomal biogenesis disorders.[89]

Although L-pipecolic acid has been shown experimentally to meet most criteria for an endogenously synthesized central nervous system (CNS) neurotransmitter and to have strong inhibitory effects on selected CNS neurons,[90] it is not clear what, if any, physiologic role pipecolic acid plays in the CNS. The rates of synthesis and oxidation of pipecolic acid, their tissue distribution, and even their subcellular localization appear to vary considerably among different vertebrate animals.[91] In most mammals, formation of pipecolic acid contributes to less than 1% of lysine degradation in the liver,[92] where the alternative saccharopine pathway of lysine metabolism (see Figure 55.8-6) appears to predominate. In contrast, conversion to L-pipecolic acid may be the major catabolic fate of L-lysine in rat brain.[93] More interesting is that whereas the peroxisome is the site of L-pipecolic acid oxidation to L-α-aminoadipic acid in humans and other primates,[94,95] only mitochondria appear to contain this activity in rabbits and rats.[95] Such differences in subcellular enzyme localization are unusual but not unprecedented and may reflect evolutionary flexibility of enzyme targeting mediated by cellular gene-splicing strategies. Interestingly, D-pipecolic acid, which is not abnormally elevated in Zellweger syndrome, appears to be oxidized only in peroxisomes in the rat and other animals.[96]

Metabolism of Hydrogen Peroxide. In mitochondria, the oxidation of a substrate by a nicotinamide adenine dinucleotide– or flavin adenine dinucleotide–dependent dehydrogenase is followed by transfer of the extracted electrons to the electron transport (respiratory) chain and then eventually to oxygen to form water. In contrast, reducing equivalents in the peroxisome are transferred directly to molecular oxygen through the action of one of the flavin-dependent peroxisomal oxidases to form hydrogen peroxide.[5] The large amounts of hydrogen peroxide generated by the many different peroxisomal oxidases would be cytotoxic without mechanisms for its safe decomposition within the peroxisome. Catalase, which is one of the most abundant proteins in liver,[97] serves this function and decomposes hydrogen peroxide by either a *catalatic* mechanism:

$$2\ H_2O_2 \rightarrow 2\ H_2O + O_2$$

or a *peroxidatic* process:

$$H_2O_2 + RH_2 \rightarrow R + 2\ H_2O$$

Most oxidase-generated hydrogen peroxide appears to be degraded in situ by the peroxidatic mechanism.[98] Although the absolute level of catalase activity in Zellweger syndrome cells is normal, most of the enzyme is found in the cytoplasmic compartment and not in the particulate (ie, peroxisome containing) fraction.[99]

The hydrogen peroxide–generating reactions of peroxisomal oxidases are highly exergonic and, unlike mitochondrial dehydrogenation reactions, are unconstrained by respiratory control and the synthesis of ATP. This exothermic nature of peroxisomal respiration may contribute to the heat-producing capacity of specialized tissues such as brown fat, in which cold adaptation causes a marked proliferation of peroxisomes.[100]

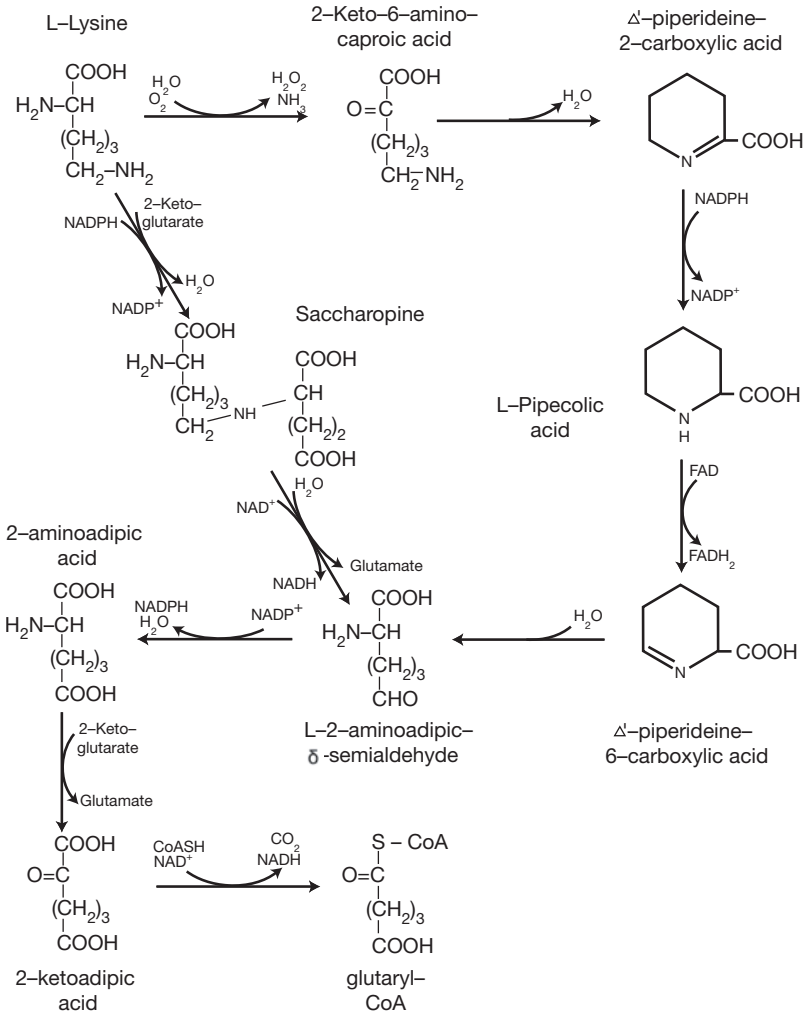

FIGURE 55.8-6 Biosynthesis of pipecolic acid and its relationship to the dual pathways for lysine catabolism to glutaryl coenzyme A (CoA). Glutaryl CoA is further catabolized both in peroxisomes and mitochondria. NADPH = reduced nicotinamide adenine dinucleotide phosphate.

PEROXISOMAL DISEASES

Disorders of Peroxisomal Biogenesis

The nomenclature of the three syndromes now classified as disorders of peroxisomal biogenesis—Zellweger syndrome, infantile Refsum disease, and neonatal ALD—reflects more the type of specialists who first described the patients than the characteristic biochemistry or pathology of these overlapping syndromes (Table 55.8-2). Indeed, evidence has appeared that, for example, patients with the clinical diagnosis of infantile Refsum disease have mutations in one of at least three different genes, all of which can also be associated with the other two clinical phenotypes of generalized peroxisomal disease.[101] Altogether, 11 different complementation groups for disorders of peroxisomal biogenesis have been defined,[16,102,103] and, among these, mutations in 10 different *PEX* genes affecting PTS1-mediated peroxisomal assembly and enzyme import have been associated with one or more of these clinical syndromes. Two of the original complementation groups, numbers 1 and 4, now associated with mutations in *PEX1* and *PEX6*, respectively, include patients of all three clinical phenotypes and account for more than 80% of patients with a disorder of peroxisomal biogenesis. Mutations in *PEX7*, which encodes the receptor for proteins containing the second peroxisomal enzyme import system PTS2, have been linked to the clinically quite different disorder RCDP.[61] These remarkable advances in our understanding of the molecular basis of peroxisomal diseases may eventually lead to a better understanding of the biochemical pathology and possibly even to therapy of these disorders. Despite our current understanding that Zellweger syndrome, infantile Refsum disease, and neonatal ALD can all be caused by different mutations in a single gene, and despite their often overlapping clinical and biochemical features, because much of the existing clinical literature views these three syndromes as separate clinical entities, they are discussed here individually.

Zellweger Syndrome. Zellweger syndrome was first delineated in 1967 as a multiple congenital anomaly syndrome by Passarge and McAdams, who suggested the descriptive term "cerebrohepatorenal" syndrome.[104] Subsequently, Opitz presented a comprehensive study of the pathology of Zellweger syndrome,[105] whereas later review articles discussed the complexity of the associated biochemical abnormalities.[71,75]

The majority of patients with Zellweger syndrome are identified as newborns or young infants, based on a relatively stereotypic phenotype (Table 55.8-3) and a variety of anatomic and histologic abnormalities (Table 55.8-4).

TABLE 55.8-2 CLASSIFICATION OF PEROXISOMAL DISEASES

DISORDERS OF PEROXISOMAL BIOGENESIS
Zellweger cerebrohepatorenal syndrome
Neonatal adrenoleukodystrophy
Infantile Refsum disease
Hyperpipecolic acidemia
Rhizomelic chondrodysplasia punctata
DEFICIENCY OF A SINGLE PEROXISOMAL ENZYME OR PROTEIN
Acyl CoA oxidase deficiency ("pseudo–neonatal adrenoleukodystrophy")
Peroxisomal multifunctional enzyme 2 deficiency
X-linked adrenoleukodystrophy
CADDS (contiguous *ABCD1 DXS1357E* deletion syndrome)
α-Methylacyl CoA racemase deficiency
Dihydroxyacetone phosphate acyltransferase deficiency
Alkyl-dihydroxyacetonephosphate synthase deficiency
Hyperoxaluria type I (alanine:glyoxylate aminotransferase deficiency)
Refsum disease (phytanyl CoA α-hydroxylase deficiency)
Glutaryl CoA oxidase deficiency
Acatalasemia

During infancy, the abnormalities that most suggest the diagnosis of Zellweger syndrome are the characteristic facial appearance (Figure 55.8-7), profound hypotonia, and absent neonatal reflexes. A typical infant with Zellweger syndrome has a high forehead with a widely open metopic suture, wide-spaced appearing and upslanting palpebral fissures, underdeveloped supraorbital ridges, triangular mouth, and apparently low-set, abnormally shaped ears. The appearance is sometimes reminiscent of Down syndrome. However, because most of the craniofacial and other dysmorphic characteristics of Zellweger syndrome are individually relatively nonspecific, the diagnosis of Zellweger syndrome is often missed at birth. Hepatocellular disease is usually less apparent during the first 3 months than later but may be evident as direct hyperbilirubinemia, hypertransaminasemia, coagulopathy, or hepatomegaly alone.[106,107] Other important and somewhat more specific clues to the diagnosis of Zellweger syndrome are glomerulocystic kidney disease,[108] abnormal calcification of the patella and other apophyseal cartilage (chondrodysplasia punctata),[109] cerebral dysgenesis,[110,111] and pigmentary retinopathy.[112] Structural abnormalities of the heart, mostly septal defects and conotruncal malformations, are also not uncommon. Seizures, which occur in over 70% of patients, are often difficult to treat. Indeed, a severe neonatal seizure disorder is one of the more common clinical problems that alone suggests the diagnosis of Zellweger syndrome. Because of the severity of the cerebral malformations, most infants with Zellweger syndrome achieve no developmental milestones and die within a few weeks or months of birth from seizures, apnea, aspiration, or pneumonia. Those patients who survive the first 6 months may show a slight degree of neurologic development and improved muscular tone but often eventually succumb to the complications of their severe neurologic disease. Rare patients in whom Zellweger syndrome has been diagnosed in the neonatal period have survived for more than 3 years.[113] Detailed compilations of the clinical characteristics of patients with Zellweger syndrome have been published by Heymans[114] and Wilson and colleagues.[115] Despite the tremendous expansion in our understanding of the biochemical and molecular bases of Zellweger syndrome and its related disorders, none of their malformative or degenerative characteristics has a clearly understood biochemical pathogenesis.

Although glomerulocystic disease of the kidney in Zellweger syndrome can be anatomically quite severe, renal glomerular or tubular insufficiency, apart from mild generalized aminoaciduria and proteinuria, is not common.[108] Similarly, the diagnostically important chondrodysplasia punctata affects mostly apophyseal cartilage, such as the patella, and does not itself cause dwarfing.[109] Other unexplained abnormalities with less obvious clinical consequences include islet cell hyperplasia, thymic hypoplasia, and siderosis.[104]

TABLE 55.8-3 MAJOR CLINICAL CHARACTERISTICS OF ZELLWEGER SYNDROME

Craniofacial	Midface hypoplasia resemblance to Down syndrome Hypertelorism, narrow papebral fissures Inner epicanthal folds, anteverted nares High narrow forehead, large fontanels, micrognathia
Skeletal	Clinodactyly, camptodactyly Equinovarus deformity, joint contractures
Neurologic	Severe hypotonia; absent Moro reflex, suck, grasp Complex seizure disorder (often neonatal) Profound psychomotor retardation Degenerative neurologic disease
Sensory	Optic atrophy, pigmentary retinopathy Cataracts, glaucoma, Brushfield spots Blindness (often congenital), nystagmus Sensorineural deafness
Hepatic	Hepatomegaly ± splenomegaly Prolonged or persistent jaundice Signs of portal hypertension Coagulopathy, biliary cirrhosis
Other	Cryptorchidism, hypospadias Patent ductus arteriosis, septal defects Single palmar creases

TABLE 55.8-4 ANATOMIC AND HISTOLOGIC ABNORMALITIES IN ZELLWEGER SYNDROME

Neurologic	Cerebral/cerebellar neuronal migration defects Microgyria, pachygyria, olivary dysplasia Septo-optic dysplasia, agenesis corpus callosum Dysmyelination, demyelination
Hepatic	Fibrosis progressing to cirrhosis Intrahepatic biliary dysgenesis and stasis Absent peroxisomes, abnormal mitochondria Iron storage (early); lipid storage (late)
Renal	Cortical glomerulocystic disease Hydronephrosis, persistent fetal lobulation
Skeletal	Chondrodysplasia punctata (nonrhizomelic) Osteoporosis, retarded skeletal maturation Bell-shaped chest (secondary to hypotonia)
Other	Pancreatic islet cell hyperplasia Thymic hypoplasia; Di George sequence

FIGURE 55.8-7 Facial appearance of two patients with Zellweger syndrome. *A*, At birth; *B*, at 3 years. Note in *B* the postural evidence of severe hypotonia.

The CNS disease of Zellweger syndrome is notable for the coexistence of congenital developmental abnormalities and acquired degenerative changes.[111,116–118] The most common CNS malformations are cerebral and cerebellar heterotopias, centrosylvian pachygyria and polymicrogyria, and olivary hypoplasia. Partial agenesis of the corpus callosum, hypoplasia of the cerebellar vermis, and septo-optic dysplasia are also common. Another unusual characteristic of patients with Zellweger syndrome is increased brain water and correspondingly increased brain weight. In addition to these abnormalities, most of which can be attributed to defective neuronal migration, myelin synthesis is qualitatively abnormal, and in longer-surviving individuals, a demyelinating process occurs.[116,118–120] When active demyelination is present (most commonly in the centrum semiovale, corpus callosum, occipital white matter, and cerebellum), macrophages with vacuolar lipid inclusions and "angulate" lysosomes are found. These storage macrophages are essentially the same as those found in the degenerating white matter of patients with X-linked ALD.[116,118,121] The recognition of an ALD-like white matter disease in Zellweger syndrome led to the discovery that patients with Zellweger syndrome, like those with X-linked ALD, have increased concentrations of VLCFAs, both in the CNS and systemically.[122–124]

Severe liver disease is almost universal in patients with Zellweger syndrome who survive the neonatal period.[106,107,125–128] Although the liver disease is often minimal during the first few months of life and may even appear to be absent, some combination of lobular disarray, focal hepatocytic necrosis, portal fibrosis or cirrhosis, intracellular and intracanalicular cholestasis, and increased iron storage can usually be found on biopsy. Foamy, lipid-filled hepatocytes, biliary dysgenesis, multinucleated giant cells, and focal areas of parenchymal collapse are also found, but less commonly (Figure 55.8-8). By electron microscopy and histochemistry (for the marker enzyme catalase), peroxisomes have been undetectable in the liver of almost all patients with classic Zellweger syndrome.[2,127] Abnormally shaped and dark-staining mitochondria with tubular cristae and paracrystalline inclusions, as well as scattered lipid-storage macrophages with angulate lysosomes, are also often found (Figure 55.8-9).[126] The chemical composition of the lamellar lipid material causing the distortion of lysosomes is not known but is suspected to consist of condensations of VLCFAs. Except for scattered cellular necrosis, the histology of individual hepatocytes is surprisingly normal, particularly in older infants, despite the progression of fibrosis and cirrhosis. By the age of 6 months, advanced cirrhosis and its many sequelae may dominate the clinical picture. Rapid progression from giant cell transformation without fibrosis to hepatocyte necrosis to cirrhosis in 3 to 4 months has been documented by serial biopsy in several patients. The cause of cirrhosis in Zellweger syndrome is not known, but increased levels of compounds such as hydrogen peroxide and unsaturated VLCFAs, which have aberrant metabolism in a peroxisome-deficient liver, have been proposed as hepatotoxins.

Another complication of liver disease in Zellweger syndrome and its related disorders is fat malabsorption and its multiple metabolic consequences, such as deficiencies of fat-soluble vitamins and nutritional failure to thrive. The cause of the malabsorption is often attributed to both the primary deficiency of bile acids and to the biliary abnormalities that follow the progressive cholestatic liver disease. These problems are not uncommon and, in milder forms of the disease, may even be the mode of presentation.[129,130]

Two biochemical abnormalities may have special importance in the evolution—and treatment—of the hepatic disease in Zellweger syndrome. First, the many abnormal species of bile acid that accumulate in the liver and other tissues of patients with Zellweger syndrome may cause injury to the liver. For this reason, there have

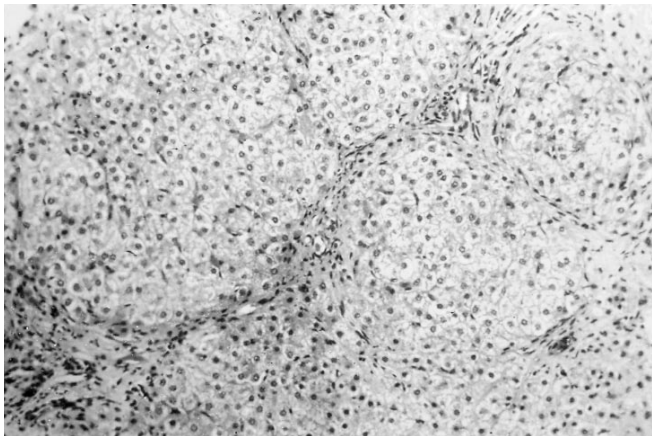

FIGURE 55.8-8 Liver histology in Zellweger syndrome showing lobular disorganization and early bridging fibrosis. Courtesy of H. Moser, MD.

been attempts to ameliorate possible bile acid toxicity by administration of bile acid supplements such as ursodeoxycholic acid, with some evidence of benefit.[131] Another more recently recognized abnormality is an almost universal severe deficiency of docosahexaenoic acid (DHA) and other related essential polyunsaturated fatty acids.[132,133] The cause of DHA deficiency in peroxisomal biogenesis disorders is reduced retroconversion of the precursor, $C_{24:6}$, to DHA via one cycle of peroxisomal β-oxidation.[134,135] Accordingly, many surviving patients with Zellweger syndrome and related disorders have been treated with supplements of DHA.[133] A third deficiency that may have a role in the degenerative pathology of Zellweger syndrome is the severely depressed level of plasmalogens, which, some have speculated, have important antioxidant properties in cell membranes.[136]

In addition to a variety of diagnostically useful anatomic and histologic abnormalities, several laboratory tests are now available for diagnosis of defective peroxisomal metabolism; these are listed in Table 55.8-5 and discussed in more detail in following sections. All of these peroxisomal abnormalities can usually be demonstrated in an infant with Zellweger syndrome, and their documentation in the proper clinical setting usually obviates the need to demonstrate absent peroxisomes by liver biopsy. Other less specific but relatively common biochemical abnormalities are also listed in Table 55.8-5. Once biochemical studies have established that a patient with a Zellweger phenotype has abnormalities in multiple peroxisomal biochemical pathways, complementation analysis and now mutational studies can be undertaken to identify the specific genetic lesion.

Infantile Refsum Disease. Infantile Refsum disease was first described in 1982 by Scotto and colleagues as a syndrome of developmental retardation, pigmentary retinopathy, sensorineural hearing loss, and mildly to moderately increased plasma levels of phytanic acid.[137] Although infantile Refsum disease differs clinically from Zellweger syndrome, early fibroblast complementation studies indicated

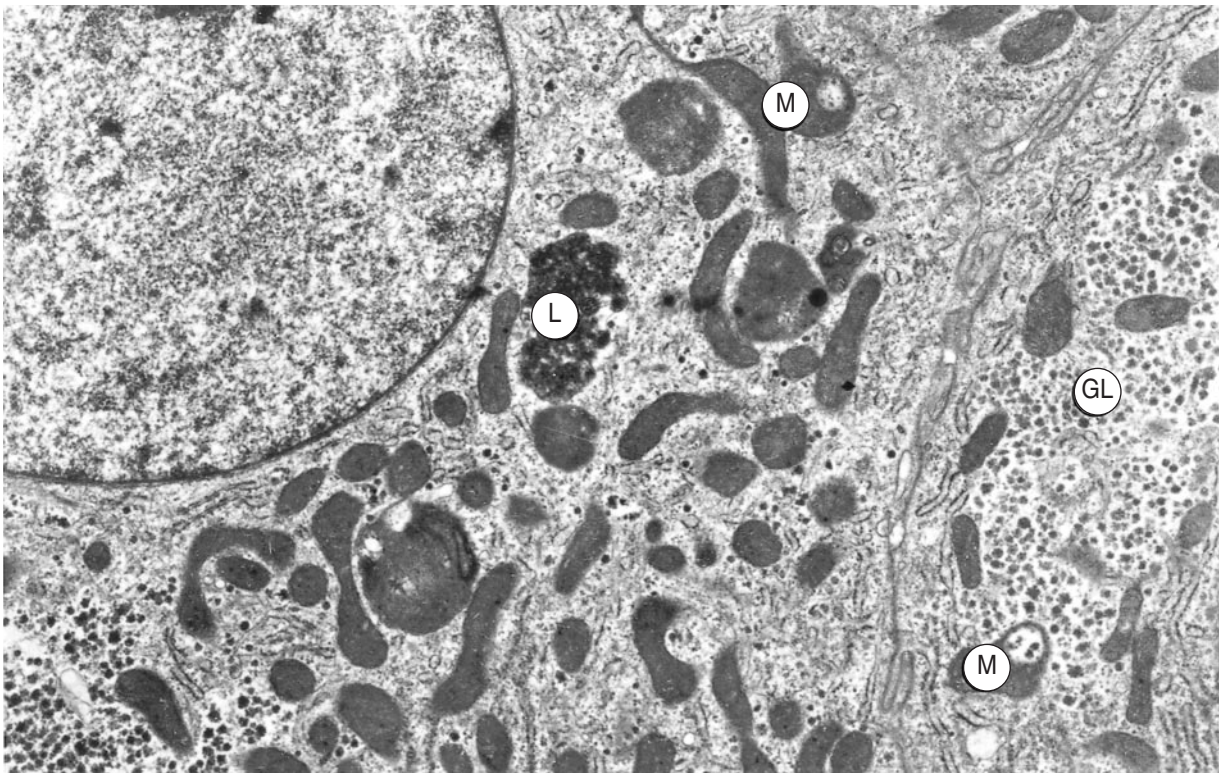

FIGURE 55.8-9 Liver ultrastructure in Zellweger syndrome. Mitochondria (M) with bizarre shapes and dense matrices are seen, together with normal lysosomes (L) and glycogen (GL). The mitochondrial abnormalities are most likely secondary phenomena because many patients with Zellweger syndrome have normal-appearing mitochondria. Courtesy of Sydney Goldfischer, MD.

TABLE 55.8-5 LABORATORY ABNORMALITES COMMON IN ZELLWEGER SYNDROME

ABNORMALITIES OF PEROXISOMAL METABOLISM
Increased levels of
Very-long-chain fatty acids (p, u, t)
Di- and trihydroxycholestanoic acids (p, u)
Pipecolic and hydroxypipecolic acids (p, u)
Phytanic and pristanic acids (p, t)
Dicarboxylic and epoxydicarboxylic acids (p, u)
Decreased levels of
Plasmalogens, platelet activating factor (p, t)
Phytanic acid β-oxidation (t)
Peroxisomal fatty acid β-oxidation (t)
Particulate catalase (t)
Normal bile acids (p, u)
Docosahexaenoic and related acids (p, t)
SECONDARY OR UNEXPLAINED BIOCHEMICAL ABNORMALITIES
Increased levels of
Serum transaminases, bilirubin
Serum iron and iron saturation (early months)
Cerebrospinal fluid protein (variable, late)
Threonine (p, u)
Urinary amino acids (generalized aminoaciduria)
4-Hydroxyphenyllactate (u)
Decreased levels of
Cholesterol (p)
Prothrombin, other coagulation factors (p)

p = plasma; t = tissues/fibroblasts; u = urine.

that infantile Refsum disease is actually a mild form of Zellweger syndrome,[102,103] as originally suggested by Poulos and colleagues[138] and now fully confirmed by mutational studies of the involved *PEX* genes.[101,139]

The first patients with infantile Refsum disease described in the literature lacked the characteristic facial appearance of Zellweger syndrome, except for mild craniofacial abnormalities such as epicanthal folds, anteverted nares, and midfacial hypoplasia. Unlike patients with classic Zellweger syndrome, who rarely achieve any psychomotor development, those with infantile Refsum disease have learned to walk and even have acquired some language.[139,140] Similarly, hypotonia is less severe in infantile Refsum disease, and a few patients have shown improving or normal muscle tone and brisk deep tendon reflexes beyond infancy. However, because pigmentary retinopathy, macular degeneration, and sensorineural hearing loss are progressive conditions, the majority of patients with infantile Refsum disease become blind and deaf because of their longer survival.

Liver disease is much less prominent in infantile Refsum disease than it is in Zellweger syndrome. Levels of serum transaminases and bilirubin are usually normal or only slightly increased, and hepatomegaly is less common. Nevertheless, major complications of hepatic disease, such as cerebral and gastrointestinal hemorrhages secondary to coagulopathy, have occurred.[140] Both intrinsic liver disease and malabsorption of vitamin K secondary to defective bile acid synthesis probably contribute to the coagulopathy. Associated vitamin A and vitamin E deficiencies are also common and may exacerbate visual and neurologic degeneration, as likely does the associated deficiency of DHA.[141] Histologically, the livers of patients with infantile Refsum disease do not have the lobular disorganization and biliary dysgenesis typical of Zellweger syndrome, but progressive fibrosis, apparently, is common. Morphologically recognizable peroxisomes are absent or at most represented by small numbers of catalase-positive microperoxisomes.[142] Hepatocytes and especially Kupffer cells often have inclusions of lipid vacuoles and leaflets similar to those of X-linked and neonatal ALD. In addition, unusual hepatocytic glycogen inclusions, only infrequently seen in Zellweger syndrome, appear to be relatively common in infantile Refsum disease. In one 12-year-old boy with infantile Refsum disease who came to autopsy, advanced micronodular cirrhosis was found.[143] Other important pathologic abnormalities in that patient included hypoplastic adrenal glands without degenerative changes, extensive infiltrates of lipid-storage macrophages in the lymph nodes, severe hypoplasia of the cerebellar granule layer, and severe degenerative changes in the retina and cochlea.

In addition to the full spectrum of peroxisomal biochemical abnormalities—increased levels of VLCFA, phytanic acid, pipecolic acid, and bile acid intermediates and depressed levels of DHA and erythrocyte plasmalogens—patients with infantile Refsum disease commonly have persistently low levels of serum cholesterol and both α- and β-lipoproteins.[140] Because plasmalogens and their precursors can be assimilated from the diet, erythrocyte plasmalogen levels, which are very low in infants with Zellweger syndrome, may increase and even normalize over a period of 6 to 12 months after birth. Nevertheless, when assayed in liver or fibroblasts, tissue levels and rates of synthesis of plasmalogens are consistently depressed.[140]

Neonatal Adrenoleukodystrophy. Between 1978 and 1982, several reports were published describing a total of 11 infants and young children of both sexes who suffered from a constellation of CNS, adrenal, and biochemical abnormalities almost identical to those of childhood (X-linked) ALD.[144,145] However, the apparent autosomal recessive inheritance of the disorder, its neonatal presentation, and a variety of associated systemic abnormalities uncharacteristic of X-linked ALD suggested that this new "neonatal" ALD was a genetically distinct disorder. The observation that some infants with neonatal ALD resembled patients with Zellweger syndrome then led to the discovery of multiple defects of peroxisomal metabolism and absent or severely diminished peroxisomes on liver biopsy in a number of these patients. Several review articles have described in detail the full spectrum of clinical and biochemical abnormalities in neonatal ALD.[145–147]

As in Zellweger syndrome, most infants with the neonatal ALD phenotype are severely hypotonic at birth and develop myoclonic seizures in the newborn period or the first few weeks of life. Dysmorphic features may be limited to midfacial hypoplasia, epicanthal folds, and simian creases or be absent altogether (Figure 55.8-10). Psychomotor development is globally retarded, and few patients achieve a mental age greater than 2 years. Growth is usually moderately retarded, although some patients have had normal linear growth. In addition, nystagmus, pigmentary retinopathy,

optic atrophy, limited vision, and deafness further handicap most of these children. After many months or years of slow psychomotor development, children with neonatal ALD may develop a leukodystrophy, a progressive demyelination process, and begin to lose skills and enter a phase lasting over several months or years, during which complete neurologic deterioration to a terminal vegetative state ensues. The onset of the destructive white matter loss cannot be predicted, and the course is extremely variable.

The diagnosis of neonatal ALD is sometimes unsuspected until autopsy, when the finding of demyelination and adrenal atrophy suggests the diagnosis of a form of ALD. However, in contrast to the postnatally acquired CNS defects of X-linked ALD, signs of prenatal CNS maldevelopment such as dysmyelination, polymicrogyria, and cerebral and cerebellar heterotopias, similar to those of Zellweger syndrome, are found at autopsy. In addition, infiltrates of macrophages filled with lamellar lipid inclusions are typically dispersed throughout the nervous system and the reticuloendothelial system. The principal difference between the CNS disease of neonatal ALD and that of patients classified as having Zellweger syndrome and infantile Refsum disease is the greater degree of demyelination in the children with neonatal ALD.

Unlike Zellweger syndrome, but more like infantile Refsum disease, most patients with neonatal ALD have hepatic disease that is clinically silent or very mild. Typically, only limited fibrosis or early cirrhosis is found by biopsy or at autopsy.[145,147] By electron microscopy, hepatic peroxisomes are severely reduced in both number and size but usually detectable, unlike in patients with Zellweger syndrome and most patients with infantile Refsum disease. Renal cysts and punctate cartilage calcification have been absent in neonatal ALD, an apparent distinction between neonatal ALD and Zellweger syndrome when the presence of demyelination and frank adrenal atrophy is used as a primary criterion for the diagnosis of neonatal ALD.[145,147]

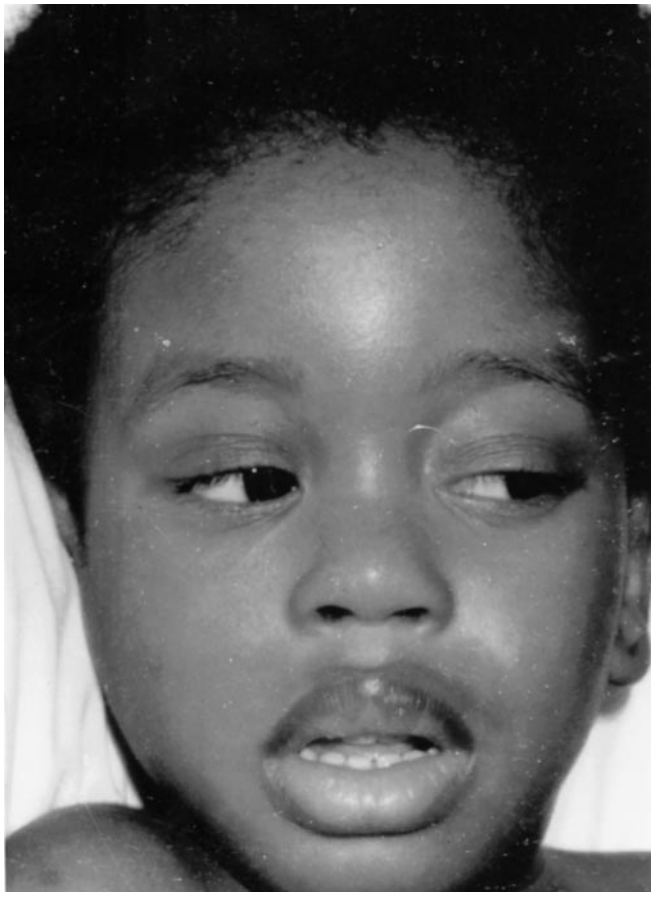

FIGURE 55.8-10 Facial appearance of a young child with neonatal adrenoleukodystrophy. Dysmorphic features are few but include a low nasal bridge and mild ptosis.

Most patients with neonatal ALD manifest all of the peroxisomal biochemical abnormalities characteristic of Zellweger syndrome, although the measured activity of some enzymes, such as phytanic acid oxidase and DHAP acyltransferase, may be somewhat higher than in Zellweger syndrome. Similarly, the plasma levels of VLCFA are often lower than in Zellweger syndrome and may be limited to increases of only saturated VLCFAs.[145,147]

Hyperpipecolic Acidemia. Three separate reports have described infants with progressive neurodegenerative disease and hyperpipecolic acidemia who, for a variety of reasons, were not considered to meet criteria for the diagnosis of Zellweger syndrome.[148–150] Although these patients are often grouped separately in reviews of peroxisomal disorders, studies of cultured fibroblasts or autopsy tissues from these patients later showed that all of them also had increased levels of VLCFA.[151] Accordingly, because of apparent deficiencies of at least two metabolically unrelated peroxisomal enzyme systems, these cases should be reclassified as examples of neonatal ALD or other disorders of peroxisomal biogenesis rather than cases of isolated hyperpipecolic acidemia. Although there are several as yet unreported patients who are suspected to have isolated hyperpipecolic acidemia (R. Kelley, unpublished observations, 1989) and who differ clinically from Zellweger syndrome, infantile Refsum disease, or neonatal ALD, none has yet been proven enzymatically to have a deficiency of either D-pipecolic acid oxidase or L-pipecolic acid oxidase, both of which appear to be peroxisomal enzymes in humans.[95] Isolated marked hyperpipecolic acidemia may be an unrelated, common autosomal recessive variant because it has been reported as an associated abnormality in isolated cases of autosomal recessive Joubert syndrome and Dyggve-Melchior-Clausen dwarfism.[152,153] Thus, it remains unknown whether isolated hyperpipecolic acidemia exists as a disease or only a biochemical curiosity of no clinical significance.

Diseases Caused by Deficiency of a Single Peroxisomal β-Oxidation Enzyme

X-Linked Adrenoleukodystrophy. The degradation of VLCFAs begins with their apparently specific transport into peroxisomes followed by activation to CoA thioesters by a specific very-long-chain fatty (VLCF)–acyl CoA synthetase (ligase). The VLCF–acyl CoA esters are then degraded by successive cycles of β-oxidative cleavage of 2-carbon acetyl CoA units mediated by three peroxisome-

specific enzymes: acyl CoA oxidase, MFE2, and 3-ketoacyl CoA thiolase (see Figure 55.8-2). The cause of reduced VLCFA oxidation in X-linked ALD was thought for many years to be caused by an isolated deficiency of peroxisomal VLCF–acyl CoA synthetase activity.[154,155] However, in 1993, the biochemical defect in X-linked ALD was shown to be caused by mutations in the *ABCD1* gene, which encodes ALDP.[40,156] ALDP is a peroxisomal membrane protein that is a member of the large family of ATP-binding cassette transmembrane transporter proteins, of which, for example, the cystic fibrosis protein (cystic fibrosis transmembrane receptor) is also a member.[157,158] This large class of membrane proteins transports substrates as diverse as chloride ions and entire proteins. Although ALDP has been studied intensely since its discovery, its exact role in the metabolism of VLCFAs remains unclear. Studies by Yamada and colleagues suggested that ALDP was important for the correct localization of the VLCF–acyl CoA synthetase within the peroxisome.[159] However, more recent work by Heinzer and colleagues has cast doubt on this hypothesis.[160]

X-linked ALD is the most common peroxisomal disorder and is unusual in its varying presentations from early childhood to late adult years.[161] When onset is between 5 and 10 years of age, X-linked ALD usually begins with a combination of behavioral, gait, and auditory disturbances and ends fatally after several years of devastating, global neurologic degeneration, with or without adrenal insufficiency. In adults, in whom a milder form of ALD is known as adrenomyeloneuropathy, peripheral nerve dysfunction and adrenal insufficiency predominate over relatively mild CNS disturbances. Occasionally, adults with isolated Addison disease or even clinically unaffected older adults with classic biochemical findings are discovered within pedigrees of cases of typical X-linked ALD or adrenomyeloneuropathy.

In contrast to the multiple congenital abnormalities characteristic of neonatal ALD, all of the neurologic and endocrinologic problems of X-linked ALD are acquired after birth. Nevertheless, diagnostic elevations of VLCFA in plasma and other tissues in X-linked ALD are present at birth.[161] Moreover, because of its mode of inheritance, X-linked ALD is also often manifest to a milder degree clinically and biochemically by carrier female patients.[162,163] Although X-linked ALD offers an excellent opportunity to understand the mechanism by which increased levels of VLCFA affect the CNS and steroid-secreting organs, very little is known at this time about the pathogenesis of VLCFA-associated CNS degeneration or endocrine dysfunction in either neonatal or X-linked ALD.

Individuals with X-ALD may come to the attention of the gastroenterologist when in childhood they present with cyclic vomiting, which is secondary to primary adrenal insufficiency. However, in the majority of individuals, there are no abnormalities of the liver or other gastrointestinal system abnormalities.

CADDS. Corzo and colleagues recently reported three boys with an apparently new syndrome characterized by neonatal hypotonia and cholestatic liver disease.[164] They were determined to have elevated VLCFA levels and were initially felt to have either Zellweger syndrome or one of the single enzyme defects in peroxisomal β-oxidation other than X-linked ALD. However, further study showed that they lacked immunoreactive ALDP. Mutation analysis identified deletions in the 5′ region of the *ABCD1* gene that extended through the promotor region and the neighboring gene, *DXS1357E*. The authors proposed the term CADDS for "contiguous *ABCD1 DXS1357E* deletion syndrome." The lack of ALDP in CADDS is noteworthy in that patients with childhood X-linked ALD typically present at 7 years of age but never < 3 years of age. In addition, liver disease is not found in patients with X-linked ALD. Liver biopsies of all three CADDS patients showed intracanalicular and ductal cholestasis. All three boys died in infancy (4–11 months), and causes of death included liver failure, gastrointestinal bleeding, and respiratory failure.

Acyl CoA Oxidase Deficiency (Pseudo–neonatal ALD). Two siblings who had severe hypotonia and myoclonic seizures in the first week of life but who lacked the dysmorphic appearance and other malformations characteristic of Zellweger syndrome were found by Poll-The and colleagues to have an apparently isolated deficiency of peroxisomal acyl CoA oxidase.[33] VLCFAs were markedly elevated in plasma and fibroblasts, but all other markers of peroxisomal dysfunction, including levels of bile acid intermediates, were normal. After a number of months of slow development, the children developed progressive sensorineural deafness, pigmentary retinopathy, and adrenal insufficiency and died in a vegetative state at age 4 years. There was no clinical or biochemical evidence of liver disease during life, and liver histology was notable only for somewhat increased peroxisomal size and lipoid deposits in hepatocytes. Cirrhosis or fibrosis, present in almost all patients with a disorder of PTS1-linked peroxisomal biogenesis, was not found. Isolated acyl CoA oxidase deficiency was documented by enzymatic assay of fibroblasts and immunologic methods[33] and, more recently, by DNA mutational analysis in the original and a second similar patient.[165] Additional patients with acyl CoA oxidase deficiency have been reported by Watkins and colleagues.[34]

Peroxisomal MFE2 Deficiency. More than 30 patients with a deficiency of peroxisomal MFE2 ("bifunctional enzyme") have now been described.[34,166,167] MFE2 is also known as D-BP. In contrast to the multisystem involvement of Zellweger syndrome, infants with MFE2 deficiency have a disorder dominated by their abnormal nervous system.[168] At birth, affected infants are severely hypotonic, macrocephalic, and neurologically depressed but usually lack hepatosplenomegaly, skeletal disease, or other important systemic abnormalities of Zellweger syndrome. However, neonatal seizures and severe psychomotor retardation are typical, and some of the infants have had dysmorphic facies reminiscent of Zellweger syndrome.[34] Although MFE2 deficiency is, in general, not a multisystem disorder like Zellweger syndrome, variable degrees of adrenal insufficiency, hepatic fibrosis, sensorineural hearing loss, pig-

mentary retinopathy, glomerulocystic kidney disease, and central white matter deterioration have been found. In contrast to Zellweger syndrome, however, hepatic peroxisomes are present. Despite the lesser systemic involvement, the severe CNS disease leads to the death of most MFE2-deficient patients in the first year.

Peroxisomal biochemical abnormalities in MFE2 deficiency are limited to increased tissue and plasma levels of VLCFAs and increased levels of bile acid intermediates, which MFE2 has a role in synthesizing. The absence of peroxisomal MFE2, but not peroxisomal oxidase or thiolase, was demonstrated by immunoblot analysis in the first patient identified.[166] Subsequently, more than 30 additional patients have been identified, mostly based on the clinical biochemical profile[166] and complementation analysis of cultured skin fibroblasts.[169] Of the three possible single enzyme defects of peroxisomal VLCFA β-oxidation, MFE2 deficiency is by far the most common.

Peroxisomal 3-Ketoacyl CoA Thiolase Deficiency (Pseudo–Zellweger Syndrome). Goldfischer and colleagues described a female infant who had Zellweger-like biochemical abnormalities but abundant hepatic peroxisomes and referred to this patient as having "pseudo–Zellweger syndrome."[170] As a result, a more detailed study of the enzymes of peroxisomal β-oxidation was undertaken by Schram and colleagues.[171] They reported that a single peroxisomal enzyme, 3-ketoacyl CoA thiolase, appeared to be deficient in liver tissue from this patient. Ferdinandusse and colleagues reinvestigated this case and determined that this patient with the only reported deficiency of peroxisomal 3-ketoacyl CoA thiolase actually had MFE2 deficiency.[172] The group of single peroxisomal β-oxidation enzyme deficiencies therefore appears to be limited to straight-chain acyl CoA oxidase, MFE2, and α-methylacyl CoA racemase (below) deficiency, and there is no longer evidence for the existence of peroxisomal 3-ketoacyl CoA thiolase deficiency as a distinct clinical entity.

2-Methylacyl CoA Racemase Deficiency. Ferdinandusse and colleagues reported three patients with elevations in pristanic acid and C_{27}-bile acid interediates, specifically DHCA and THCA, who were found to have a deficiency of 2-methylacyl CoA racemase.[173] This peroxisomal enzyme catalyzes the conversion of (2*R*)-methyl branched-chain fatty acyl CoAs to their (2*S*)-isomers. Only the *S*-conformers can undergo further β-oxidation. Two of the original patients had adult-onset neuropathy, but children with liver disease have also been reported. Setchell and colleagues described two sisters.[174] The proband was a 2-week-old girl with coagulopathy, vitamin D and E deficiencies, and mild cholestasis. A sibling who died at 5.5 months of age had had similar findings. Liver biopsy specimens showed neonatal hepatitis with giant cell transformation and hepatocyte necrosis, and peroxisomes were reduced in number. A high concentration of (25*R*)-THCA was found in the urine, bile, and serum and was similar to that seen in Zellweger syndrome. Serum phytanic acid was normal, whereas pristanic acid was markedly elevated. This patient was successfully treated with cholic acid therapy.

Other Peroxisomal Syndromes with Abnormal β-Oxidation. There are a number of other peroxisomal syndromes in which abnormal peroxisomal β-oxidation has been found, but not all are necessarily genetically distinct from the known peroxisomal disease complementation groups. Rather, they may differ only in the relative severity of the measured deficiencies. In our experience, there exist cases of peroxisomal disease featuring almost any combination of normal and abnormal levels of peroxisomal metabolites. Some of these, especially those with abnormal bile acid species, have been associated with progressive cholestatic liver disease. Similarly, several syndromes have been described in which phytanic acid oxidation and one or more peroxisomal functions are impaired.[175] Again, however, whether these represent genetically distinct syndromes or variants of other peroxisomal diseases is often unclear.

Pathophysiology of Zellweger Syndrome and Other Disorders with Abnormal Peroxisomal β-Oxidation. All of the primary defects of peroxisomal β-oxidation except X-linked ALD are associated with some degree of hypotonia, abnormal reflexes, seizures, and, in some instances, neuronal migration defects. This suggests that prenatal elevations of VLCFA-CoA esters, or possibly other acyl CoA substrates of the enzymes, may be involved in the congenital CNS abnormalities. However, there is not a clear understanding of how these compounds lead to abnormalities. It has been suggested that the increased levels of bile acid intermediates or the increased levels of unsaturated or 3-hydroxy-VLCF acyl CoA compounds may be contributing to maldevelopment. Such an association is also supported by the description of a patient with only impaired phytanic acid and bile acid metabolism who had the large fontanels and other craniofacial features of classic Zellweger syndrome.[47] Similarly, the abnormal CNS development of chondrodysplasia punctata may be dependent on deficient plasmalogen synthesis, which appears to be the biochemical common ground shared by Zellweger syndrome and various forms of RCDP, described below.

D-Specific Acyl CoA (Trihydroxycoprostanyl CoA) Oxidase Deficiency. The finding of increased levels of DHCA and THCA in peroxisomal MFE2 and thiolase deficiencies,[175] but not in peroxisomal acyl CoA oxidase deficiency, first suggested the existence of a specific oxidase for the initial hydroxylation step in the β-oxidative cleavage of the cholesterol side chain. This has now been confirmed enzymatically and by the description of patients who have normal VLCF acyl CoA oxidase activity but defective oxidation of trihydroxycholestanoyl CoA.[47,176] Interestingly, these infants resembled Zellweger syndrome physically and had progressive cholestatic liver disease. In addition, the patients had elevated levels of phytanic acid, presumably secondary to elevations of its metabolite, pristanoyl CoA, which, like VLCFA-CoA, is a substrate of the D-specific acyl CoA oxi-

dase. In contrast, in disorders of peroxisomal biogenesis and in adult Refsum disease, the elevation of phytanic acid occurs without bile acid abnormalities and is caused by a primary genetic (adult Refsum disease) or secondary (peroxisomal biogenesis disorder) deficiency of PAHX.[60]

Other Disorders of Peroxisomal Metabolism

Rhizomelic Chondrodysplasia Punctata. Although named for its severe rhizomelic dwarfism and diffuse epiphyseal and extraepiphyseal punctate calcification, RCDP is a complex, multiple congenital malformation syndrome with major nonskeletal abnormalities in the CNS (neuronal migration defect, seizures, deafness), eye (cataracts, blindness, corneal defects), and skin (ichthyosis).[177] Children with classic RCDP have severe growth retardation and profound mental deficiency, and most die before 1 year of age from respiratory insufficiency or complications of the CNS disease.

Recognizing that the punctate cartilage calcification of RCDP resembles that of Zellweger syndrome, Heymans and colleagues tested patients with RCDP for abnormalities of peroxisomal metabolism and discovered that both plasmalogen synthesis and phytanic acid oxidation were severely deficient.[178] By enzymatic assay, alkyl-DHAP synthase, the second enzyme of peroxisomal plasmalogen synthesis, and phytanic acid oxidase activity were depressed to less than 10% of normal activity. Plasma levels of phytanic acid in RCDP patients are usually higher than those of age-matched patients with Zellweger syndrome and may even reach the very high levels characteristic of adult Refsum disease in longer-surviving patients with RCDP.[179]

Because levels of intermediates of phytanic acid oxidation are not increased, the defective phytanic acid oxidation in RCDP is presumed to be limited to the initial α-hydroxylation step, as in adult Refsum disease. Plasma levels of pipecolic acid, VLCFAs, and bile acids are normal in RCDP, and liver disease and renal disease have also been absent.[179] Although one RCDP patient was reported to have reduced numbers of hepatic peroxisomes, others have had normally sized and abundant peroxisomes.[178] In addition to its multiple enzymatic deficiencies, the first clue that RCDP could be caused by a disorder of peroxisomal enzyme import distinct from that of the Zellweger syndrome group was the finding that fibroblasts of patients with RCDP contained a peroxisomal thiolase of a larger than normal molecular weight, indicating a failure of normal peroxisomal processing.[61,179] Molecular studies have now shown that, indeed, patients with RCDP have mutations in *PEX7*, a gene that codes for the PTS2 receptor.[61] Additional studies have shown that other PTS2-targeted enzymes, such as mevalonate kinase and phosphomevalonate kinase, are deficient in patients with RCDP.[180] Thus, RCDP is now classified with Zellweger and related peroxisomal syndromes as a disorder of peroxisomal biogenesis.

In recent years, several mild variants of RCDP have been found,[181,182] including children with normal stature who may have mild mental retardation and cataracts as only clinical problems. Others with the full RCDP biochemical phenotypes but normal stature have nevertheless had severe progressive neurologic disease.[181] Conversely, some patients with relatively typical adult Refsum disease and very high phytanic acid levels have been found to have milder but definite abnormalities in plasmalogen biosynthesis and, by complementation analysis, have been shown to have RCDP instead.[181] These milder forms of RCDP, wherein the major pathology may be caused by accumulation of phytanic acid, will likely be more treatable than classic RCDP using dietary restriction and direct elimination (plasmapheresis) of phytanic acid.[183] Although classic RCDP is clearly a disease affecting multiple peroxisomal enzymes, Barr and colleagues reported a patient with otherwise typical RCDP who had an isolated deficiency of DHAP acyltransferase.[184] This observation suggested that the clinical phenotype in classic RCDP is caused largely by defective plasmalogen biosynthesis. Other similar patients with isolated DHAP acyltransferase deficiency have been reported.[185,186] Rare cases of isolated DHAP synthase deficiency have also been reported.[187] Although abnormalities of plasmalogen synthesis and catalase distribution in a patient with the X-linked form of chondrodysplasia punctata, also known as Conradi-Hünermann syndrome, were reported by Emami,[188] these must be secondary abnormalities because the primary defect in Conradi-Hünermann syndrome was recently found to be a deficiency of 3β-hydroxysteroid-Δ8,Δ7-isomerase, a primary enzyme of cholesterol biosynthesis located in the microsomes.[189,190]

Heredopathia Atactica Polyneuritiformis: Adult Refsum Disease. In contrast to the early onset of infantile Refsum disease, adult Refsum disease (heredopathia atactica polyneuritiformis) is usually not evident clinically until the second or third decade. The major abnormalities in adult Refsum disease, all of which are acquired and progressive, include pigmentary retinopathy, sensorineural deafness, cerebellar ataxia, polyneuritis, ichthyosis, and cardiac conduction abnormalities.[191] Although clinical hepatic disease is absent, ultrastructural changes in the liver have been found to include excessive hepatocytic deposits of lipofuscin, vacuoles containing various types of lipoid accumulations, and an apparent deficiency of rough ER.[192] Vacuolization of renal tubular cells and structural abnormalities of their mitochondria have been reported and related to mild to moderate degrees of proximal renal tubular insufficiency in adult Refsum disease. Biochemically, Refsum disease is characterized by increased levels of free and esterified phytanic acid in the blood and tissues and a corresponding absence of phytanic acid β-oxidation activity as measured in fibroblasts and other solid tissues[193] and now known to be represented by a deficiency of phytanyl CoA α-hydroxylase.[60,194] All other peroxisomal functions appear to be normal. Because of the many years of accumulation of phytanic acid before diagnosis, levels of phytanic acid in plasma at the time of diagnosis of adult Refsum disease are often greater than 1,000 μg/mL compared with typical plasma levels of 10 to 200 μg/mL in Zellweger syndrome, infantile Refsum disease, or RCDP.[136,195] Refsum disease, which is one of the rarest inborn errors of metabolism, is inherited as an autosomal recessive genetic trait.

Stabilization and even partial reversal of the complications of adult Refsum disease can be achieved by restriction of dietary phytanic acid combined with direct elimination of accumulated phytanic acid by plasmapheresis, if necessary.[193] Although phytanic acid oxidase activity segregates with mitochondria in rats,[196] the localization is clearly peroxisomal in humans[60,194]; thus, adult Refsum disease is now securely classified as a peroxisomal disorder.

Primary Hyperoxaluria: Alanine:Glyoxylate Aminotransferase Deficiency. Primary (type I) hyperoxaluria is characterized by excessive oxalate synthesis, precipitation of calcium oxalate in the kidney, and progressive nephrocalcinosis.[197,198] Renal insufficiency usually develops during the first decade and may be followed by extrarenal calcification of the joints and, especially, myocardium. Except for some patients for whom pharmacologic doses of pyridoxine can substantially reduce the synthesis and excretion of oxalate, renal failure is inevitable. Although most of the oxalic acid in primary hyperoxaluria is produced by the liver, the liver is not subject to oxalate deposition or otherwise clinically diseased. Hepatic and peroxisomal ultrastructure is normal, apart from a mild to moderate increase in lipofuscin deposits.[199]

Danpure and colleagues have shown that type I hyperoxaluria is caused by deficient reclamation of glyoxylate, most of which is normally transaminated to glycine by alanine:glyoxylate aminotransferase (AGT).[200] A deficiency of this pyridoxine-dependent enzyme causes glyoxylate instead to be further oxidized to the metabolic end product oxalate. AGT has for many years been known to be located exclusively within the peroxisome,[201] and its deficiency appears to be the only peroxisomal defect in primary hyperoxaluria. In some cases of type I hyperoxaluria, an abnormality in the tripeptide peroxisomal targeting sequence causes AGT to relocate to the mitochondrial space.[202] Interestingly, hyperoxaluria does not occur in Zellweger syndrome, in which tissue levels, but not subcellular distribution, of AGT are normal.[203] Apparently, location of AGT in the cytoplasm does not impair its function as a transaminase. Because the AGT-deficient liver is the major source of oxalate and the kidney is the major target organ for the disease, combined kidney-liver transplant has become a standard of therapy for type I hyperoxaluria. As reviewed by Cochat and colleagues, patient survival after combined liver-kidney transplant at 5 and 10 years has been approximately 80% and 70%, respectively.[204] As anticipated, renal function in surviving transplant recipients has remained stable.

Acatalasemia. Catalase is present in all peroxisomes at high concentrations and serves the vital function of peroxidatic and catalatic disposal of hydrogen peroxide produced by the many peroxisomal oxidases.[5] Catalase is also present in the cytosol of erythrocytes, which lack recognizable peroxisomes. Acatalasemia is a rare, autosomal recessive disorder first identified in patients with progressive oral gangrene and characterized biochemically by a complete absence of enzymatically and, in some patients, immunologically detectable catalase in erythrocytes.[205] Because the only pathology associated with human acatalasemia is oral gangrene,[206] catalase in other tissues is presumed to be at least partially active. The pathogenesis of oral gangrene in this disorder is not fully understood, and only a minority of patients have any recognizable pathology. One theory holds that erythrocyte catalase detoxifies hydrogen peroxide produced by bacteria that invade superficial mucosal capillaries.[205] In the absence of catalase, tissue destruction by bacterial hydrogen peroxide proceeds unchecked and encourages further invasion of bacteria.

DIAGNOSIS OF PEROXISOMAL DISEASES

Clinical Problems Suggesting a Peroxisomal Disease

Even though children with Zellweger syndrome, infantile Refsum disease, or neonatal ALD are almost always considered abnormal at birth, the diagnosis of a peroxisomal disorder is often delayed for many months. For example, the not uncommon neonatal history of a difficult breech delivery, severe neonatal hypotonia, and abnormal neonatal reflexes characteristic of Zellweger syndrome is often misdiagnosed as perinatal asphyxia before the later development of liver disease, pigmentary retinopathy, or degenerative neurologic disease suggests a different diagnosis. The initial clinical impression of birth injury is often reinforced by the occurrence of myoclonic seizures during the newborn period. Alternatively, the finding of a combination of salt-and-pepper retinopathy and psychomotor retardation in some of the less severely affected children may lead to a mistaken diagnosis of congenital rubella or other prenatal infection. Cockayne syndrome, Leber congenital amaurosis, and Usher syndrome are other diagnoses commonly given to the more mildly affected patients with prominent pigmentary retinopathy and an extinguished electroretinogram. Similarly, Zellweger syndrome is occasionally misdiagnosed as Alagille syndrome (arteriohepatic dysplasia), another diagnosis that combines cholestatic liver disease with dysmorphic facial features. For such children, it is usually the appearance of an unexpected abnormality for the assigned diagnosis, such as pigmentary retinopathy or frank neurologic deterioration, that leads to the ultimate diagnosis of a peroxisomal disorder. Table 55.8-6 lists some of the diagnoses most commonly considered or given to patients with disorders of peroxisomal biogenesis. The clinician should consider the possibility of an underlying peroxisomal disorder when consulted about a patient with any of these diagnoses. Conversely, it is important to recognize that children with primary defects of bile acid biosynthesis (see Chapter 55.4, "Bile Acid Synthesis and Metabolism") may present as cholestatic liver disease and seizures and be initially considered for the diagnosis of Zellweger syndrome.

A number of clinical abnormalities that are especially important clues for the diagnosis of a peroxisomal disorder are summarized in Table 55.8-7.

Gastroenterologists are not uncommonly the first to suggest the diagnosis of a peroxisomal disease when consulted about a neurologically handicapped child who has

TABLE 55.8-6 DIFFERENTIAL DIAGNOSIS OF ZELLWEGER SYNDROME, INFANTILE REFSUM DISEASE, AND NEONATAL ADRENOLEUKODYSTROPHY

Down syndrome; other chromosomal disorders
Congenital hepatic fibrosis/polycystic kidneys

Cockayne syndrome
Septo-optic dysplasia (de Morsier syndrome)
Meckel syndrome (encephalosplanchnocystica)

TORCH = toxoplasmosis, other agents, rubella, cytomegalovirus, herpes simplex.

been found to have hepatomegaly, hepatic dysfunction, or simply persistently elevated serum transaminases. Gastrointestinal bleeding secondary to a coagulopathy, varices, or both is another common cause for involvement of the gastrointestinal specialist. However, more than once, evidence by liver biopsy of lipid inclusions in the Kupffer cells has been misdiagnosed as Niemann-Pick disease or another lysosomal lipidosis in a child with neonatal ALD or infantile Refsum disease who has marked VLCFA storage in macrophages. In these cases, careful electron microscopic examination of the storage material should differentiate the lipoid globules with associated birefringent lamellar lipid structures characteristic of the peroxisomal diseases from the lipid inclusions of the lysosomal sphingolipidoses. Other diverse routes have led to the diagnosis of a peroxisomal disease. The finding of either chondrodysplasia punctata (usually without rhizomelic shortening) or characteristic glomerular polycystic kidney disease in a neonate with typical neurologic signs is virtually diagnostic of Zellweger syndrome. In the older, more mildly affected child without clinically evident renal or skeletal lesions, neurosensory defects—optic atrophy, pigmentary retinopathy, abnormal electroretinogram, and deafness—are the most common problems that should lead to the consideration of a peroxisomal disease.

In general, a patient with any two of the major diagnostic criteria listed in Table 55.8-8 should lead the clinician to serious consideration of a disorder of peroxisomal biogenesis or one of the single enzyme defects of peroxisomal β-oxidation, which can closely mimic Zellweger syndrome, infantile Refsum disease, and neonatal ALD. The two newly described entities of CADDS and α-methylacyl CoA racemase deficiency may prove to be important causes of neonatal cholestatic jaundice, and appropriate investigations should be made.

Laboratory Evaluation of Patients with Peroxisomal Disorders

Although a definitive diagnosis of a generalized peroxisomal disorder at one time required demonstration of abnormal or absent peroxisomes by liver biopsy, now the diagnosis can virtually always be established with certainty by measurement of specific peroxisomal metabolites and enzymes in plasma, erythrocytes, fibroblasts, and other tissues, as outlined in Table 55.8-9. Nevertheless, whenever the diagnosis of a peroxisomal disease is entertained for a patient who is to have a liver biopsy, a portion of the biopsy specimen should be processed for study of peroxisomal ultrastructure and specific staining. Although for many of the peroxisomal disorders discussed in this chapter, the relevant genes have been cloned and causative mutations have been found, clinical findings and biochemical studies are still the mainstay of peroxisomal diagnosis and are likely to remain so for many years, especially for the peroxisomal biogenesis disorders, which have the most distinctive and usually unequivocally diagnostic biochemical abnormalities.[101,207]

TABLE 55.8–7 CLINICAL AND PATHOLOGIC CHARACTERISTICS OF THE PEROXISOMAL DISORDERS OF INFANCY AND EARLY CHILDHOOD

CHARACTERISTIC	ZELLWEGER SYNDROME	INFANTILE REFSUM DISEASE	NEONATAL ADRENOLEUKO-DYSTROPHY	ACYL COA OXIDASE DEFICIENCY	BIFUNCTIONAL ENZYME DEFICIENCY	3-KETOACYL COA THIOLASE DEFICIENCY	RHIZOMELIC CHONDRODYSPLASIA PUNCTATA

In general, the measurement of VLCFA levels in plasma, which is now available in several laboratories, is a good screening test for a disorder of peroxisomal biogenesis, X-linked ALD, or a single enzyme defect of peroxisomal β-oxidation.[101,207,208] The most important measurements in plasma are the absolute level of $C_{26:0}$ VLCFAs and the ratio of $C_{26:0}$ to $C_{22:0}$ VLCFAs, both of which are markedly elevated in Zellweger syndrome and related disorders. VLCFA abnormalities can even be detected in autopsy tissues preserved in formalin for many years. If RCDP or one of its variants is the diagnosis under consideration, then the measurement of plasmalogen levels in erythrocyte cell membranes, or, better, plasmalogen synthesis in cultured fibroblasts, and a plasma phytanic acid level are required. False-negative results are uncommon, and more detailed testing of plasma or fibroblasts is not usually required to diagnose Zellweger syndrome, neonatal ALD, infantile Refsum disease, RCDP, or X-linked ALD. There have been only a few cases of autopsy-confirmed neonatal ALD in which plasma levels of VLCFAs were only slightly increased, but subsequent studies in cultured fibroblasts were diagnostic of a multiple peroxisomal deficiency syndrome (R. Kelley and A. Moser, unpublished observations, 1987–1990). Also, it is important to recognize that tissue specimens obtained postmortem or from patients with severe hepatic disease or sepsis may have mild elevations of VLCFAs or pipecolic acid as secondary phenomena. As expected for a relatively newly delineated group of diseases, the clinical spectrum of peroxisomal diseases continues to widen, and new variants, particularly those with partial deficiencies, probably remain to be described.

When plasma levels of VLCFAs are increased in a patient suspected to have a peroxisomal biogenesis disorder, additional metabolite measurements are needed to help define the disorder. When all or most other basic peroxisomal metabolite measurements (pipecolic acid, plasmalogens, phytanic acid, bile acid intermediates) are abnormal, then Zellweger syndrome, infantile Refsum disease, or neonatal ALD is the diagnosis. On the other hand, if plasma levels of pipecolic acid and plasmalogen metabolism in fibroblasts are normal in a Zellweger-like patient or the nondysmorphic, severely hypotonic patient with elevated VLCFAs, then one of the isolated defects of peroxisomal β-oxidation is likely, that is, D-specific acyl CoA oxidase deficiency or MFE2 deficiency. The clinical distinction between X-linked ALD and one of the other isolated peroxisomal β-oxidation defects is usually not a question. However, the diagnosis of CADDS requires the demonstration of a lack of ALDP or a deletion in the appropriate region of the *ABCD1* gene. Despite the often severe adrenal atrophy present in patients with single β-oxidation enzyme defects, neonatal ALD, and infantile Refsum syndrome, adrenal insufficiency is usually not evident clinically but can sometimes be demonstrated by provocative tests of adrenal function.[145.147]

TABLE 55.8-8 MAJOR DIAGNOSTIC CRITERIA FOR A DISORDER OF PEROXISOMAL BIOGENESIS

Abnormal peroxisomal enzyme or metabolite level
Characteristic facial appearance
Evidence of cerebral dysgenesis
Hepatic fibrosis/cirrhosis, cholestasis, biliary dysgenesis
Polycystic (cortical) kidney disease
Abnormal electroretinogram, optic atrophy, pigmentary retinopathy
Sensorineural hearing loss
Punctate calcification of cartilage

TABLE 55.8-9 DIAGNOSTIC TESTS FOR PEROXISOMAL DISORDERS

Plasma	VLCFAs, phytanic acid, pipecolic acid, bile acid intermediates, essential fatty acids
Erythrocytes	Plasmalogens
Urine	Pipecolic acid; long-chain, odd-carbon, and epoxy dicarboxylic acids; bile acids
Fibroblasts, tissues	VLCFA levels, VLCFA β-oxidation, phytanic acid oxidation, plasmalogen levels and biosynthesis, DHAP acyl-transferase activity, alkyl-DHAP synthase activity, sedimentable catalase, peroxisomal size and abundance

DHAP = dihydroxyacetone phosphate; VLCFA = very-long-chain fatty acid.

Because renal tubular immaturity limits pipecolic acid reabsorption (via the iminoglycine transport system) in newborns, some infants with Zellweger syndrome may have normal or near-normal plasma pipecolic acid levels but diagnostically increased urinary pipecolic acid levels.[209] Conversely, after maturation of renal imino acid transport, previously diagnostic urinary levels of pipecolic acid may revert to normal at the same time that plasma levels become markedly increased. In addition, because red cell plasmalogens may with time normalize from dietary sources, specific assay of plasmalogen synthesis in cultured fibroblasts may be necessary in some cases.[101]

Except for X-linked ALD and the associated disorder CADDS, all of the other known peroxisomal disorders are inherited as autosomal recessive traits and therefore carry a 25% recurrence risk in future pregnancies. Prenatal diagnosis of peroxisomal diseases is possible both by traditional amniocyte culture and by chorionic villus biopsy technique. Measurement of VLCFAs, plasmalogen synthesis, and phytanic acid oxidase are commonly performed and reliable.[210–212] In addition, assay of VLCFA oxidation and measurement of particulate (ie, peroxisomal) catalase versus soluble catalase can be performed on amniocytes and cultured chorionic villus cells as backup tests.[210,211] Although there is less experience with prenatal diagnosis of the single enzyme defects of peroxisomal β-oxidation, they are detectable by measurement of peroxisomal β-oxidation rates in prenatally obtained specimens. The absence of a peroxisomal β-oxidation enzyme can also be detected in some cases by indirect immunofluorescence analysis or immunoblot analysis, whereas except for acyl CoA oxidase deficiency, direct enzymatic assay of tissues would be technically difficult because of the presence of much greater quantities of homologous mitochondrial enzyme. Of course, these analyses can be normal if a defect in a peroxisomal β-oxidation enzyme does not change the amount and electrophoretic character of the enzyme.

Finally, because prenatal diagnosis of most of the peroxisomal disorders involves the determination of metabolite and enzyme activity levels that are secondarily abnormal rather than the measurement of the primary genetic defect, it is important to measure more than one diagnostic metabolite or enzyme level and also to have evidence of the feasibility of a tissue biochemical diagnosis documented by prior studies of the proband's fibroblasts or other tissues. The recent finding of genetic mutations causing most of the more common peroxisomal disorders will eventually permit confirmation of a prenatal diagnosis by molecular methods in families with known mutation.

Treatment of Peroxisomal Disorders

General Measures: Zellweger Syndrome, Infantile Refsum Disease, and Neonatal ALD. Treatment of peroxisomal disorders is mostly supportive. For the more severe disorders of peroxisomal biogenesis, neurologic deficits appear to be dictated largely by primary brain malformations and, as such, are irreversible. Even if the postnatal demyelination and CNS degeneration that occur in the disorders of peroxisomal biogenesis could be prevented, it is unlikely that any of the classically affected patients would achieve even a marginal level of function. Supportive therapy for longer-surviving children with generalized peroxisomal deficiency syndromes should address at least five main areas: nutrition, seizures and other neurologic disabilities, progressive liver disease, adrenal insufficiency, and sensory or communication deficits.

Nutrition. Growth retardation in Zellweger syndrome, infantile Refsum disease, and neonatal ALD is common but not universal. Nutritional efforts to improve growth may be beneficial if significant malabsorption exists. Most often, however, even intensive nutritional therapy does little to ameliorate the growth retardation, which appears to be intrinsic in most cases and not caused by inadequate nutrition. Nevertheless, the absorption of fat and fat-soluble vitamins should be monitored. In the more severely affected children, swallowing dysfunction and gastroesophageal reflux are common problems that require medical attention, including nasogastric or gastrostomy feeding for many, if not most, patients.

Neurologic Problems. Seizures in this group of patients are typically myoclonic and may respond poorly to traditional one- or two-drug anticonvulsant therapy. However, there are no associated contraindications to medications, and any appropriate anticonvulsant may be used. Apnea, primary or secondary to seizures, is almost universal in Zellweger syndrome and is one of the more common causes of death.

Liver Disease. Liver disease is rapidly progressive in classic Zellweger syndrome but more variably progressive in patients with milder forms of the disorders. Early in the course of Zellweger syndrome, the only therapy needed for liver disease may be pharmacologic amounts of vitamin K to ameliorate (but not usually cure) a coagulopathy and special dietary measures to minimize the complications of fat malabsorption. Later, the expected complications of cirrhosis and end-stage liver disease—variceal bleeding, ascites, hemorrhoids, rarely hepatic encephalopathy, deteriorating seizure control, multiple hepatic synthetic deficiencies, and delayed drug metabolism—may emerge and require appropriate clinical management. Variceal bleeding in children with neonatal ALD and infantile Refsum disease has been treated by endoscopic sclerosing therapy.

Adrenal Insufficiency. In X-linked ALD, clinically significant adrenal insufficiency is common and requires appropriate adrenal steroid replacement therapy. Addison disease may be the only sign of X-linked ALD in the older child. It may appear at any age in individuals with the biochemical defect but is rarely seen in heterozygous women. It is rarely seen in Zellweger syndrome but may be seen in older individuals with peroxisome assembly disorders and does respond to appropriate replacement therapy.

Sensory Deficits. For patients with neonatal ALD or infantile Refsum disease phenotypes, who occasionally may achieve a developmental level of 2 or 3 years, visual and auditory deficiencies often become important management issues. The use of hearing aids may enable some patients to make surprising gains in communication skills and interactions with others. Even the use of sign language by severely hearing- and/or speech-impaired patients is known. Seemingly poor cognitive development in these children should not automatically be attributed to their congenital and acquired CNS defects if auditory and visual deficits remain unaided.

Other Peroxisomal Disorders. Because of its greater rarity, there is much less experience with the care of children with RCDP than the other disorders of peroxisomal biogenesis. Whereas liver disease is absent in RCDP, seizures, respiratory insufficiency, and recurrent pneumonia are common management problems. Despite excellent care, most RCDP patients die before 1 year of age from the complications of respiratory insufficiency. Growth retardation in long-term survivors is quite severe and, of course, not specifically treatable. Treatment of the single enzyme defects of peroxisomal β-oxidation varies. Patients with isolated defects of acyl CoA oxidase or MFE2 require therapy for the same range of neurologic and sensory deficits found in neonatal ALD, but significant liver disease has been absent in the few reported cases. However, as older, more mildly affected variants of these newer peroxisomal diseases are found, liver disease may yet emerge as a clinical problem.

Specific Metabolic Therapies. In part because of the often excellent response of patients with adult Refsum disease to dietary restriction of phytanic acid, a number of attempts have been made to treat patients with Zellweger syndrome or related peroxisomal diseases by correction of one or more of the characteristic biochemical abnormalities. Specifically, diets to limit the intake of pipecolic acid, phytanic acid, and VLCFAs have been given to several patients with Zellweger syndrome or infantile Refsum disease.[115,213,214] No therapy, however, has been clearly beneficial, despite sometimes substantial improvement in the

metabolite levels. In one patient with infantile Refsum disease treated with a low phytanic acid diet, phytanic acid levels normalized and VLCFA levels improved, but the abundance of hepatic lamellar lipid inclusions continued to increase.[213,214] Batyl alcohol, an octadecyl ether of glycerol that can be converted to plasmalogens in the microsomes, has also been given as a dietary supplement. Although red cell plasmalogen levels rose to normal on batyl alcohol supplements, there was no definite clinical improvement.[213,214] Other therapies without obvious benefit have included adrenal steroids and treatment with clofibrate, which in rats, but apparently not humans, increases peroxisomal numbers.[215] The deficient synthesis of DHA ($C_{22:6}$)[132] in peroxisomal biogenesis disorders can be ameliorated by dietary supplementation.[216,217] A more recent report of DHA treatment of children with peroxisomal biogenesis disorders showed remarkable improvement in clinical function and diverse biochemical abnormalities, including normalization of serum transaminases.[216] DHA supplementation was even associated with improved cerebral myelinization by magnetic resonance imaging.[218] Confirmation of efficacy of this as therapy awaits completion of an ongoing placebo-controlled study (G. V. Raymond and colleagues, unpublished data, 2003). Although the low levels of cholesterol and the antioxidant protection afforded by cholesterol may explain some of the evidence for hepatic fibrosis and cirrhosis, there is as yet no experience with prolonged cholesterol supplementation in children with Zellweger syndrome.

Another area of therapy for Zellweger syndrome and related disorders of peroxisomal biogenesis being explored has been the use of bile acid supplements. Anecdotally, liver function, seizure frequency, and growth all improved in a 6-month-old boy with Zellweger syndrome who was treated with a combination of cholic acid and chenodeoxycholic acid.[131] If, as speculated, the cholestatic liver disease characteristic of Zellweger syndrome is caused by the accumulation of abnormal bile acid species, then bile acid replacement therapy may indeed be beneficial. Despite the poor results of metabolic therapies for the peroxisomal disorders, there remains the possibility that extended trials of this nature may affect the course of sensory or other neurologic deterioration in some of the more mildly affected, longer-surviving patients if treatment is begun before degenerative neurologic changes have advanced.[219,220]

A mixture of triolein ($C_{18:1}$ triglyceride) and trierucin ($C_{22:1}$ triglyceride) ("Lorenzo's oil") has been used in X-linked ALD. There is very clear evidence of improvement of levels of VLCFAs in plasma. However, there is no clinical improvement in boys affected with cerebral disease or in men with adrenomyeloneuropathy.[221] Ongoing trials are presently evaluating this therapy as a preventive therapy.[222] A striking improvement in a case of X-linked ALD was achieved following bone marrow transplant.[223] Additional experience has allowed the development of guidelines for the appropriate selection of patients.[224] Whether bone marrow transplant will be a successful long-term therapy remains to be determined.

9. Lysosomal Acid Lipase Deficiencies: Wolman Disease and Cholesteryl Ester Storage Disease

Gregory A. Grabowski, MD
Kevin Bove, MD
Hong Du, PhD

HISTORICAL OVERVIEW

Abramov and colleagues described patients with severe malnutrition, hepatosplenomegaly, calcified adrenal glands, and death occurring within the first few months of life.[1] Additional patients in this family were described in 1961,[2] and the term Wolman disease was applied to such patients. These patients accumulated cholesteryl esters and triglycerides in many organs, most predominantly in the liver, spleen, adrenal glands, and lymph nodes. However, in 1946, Alexander described a patient with Niemann-Pick disease with a similar phenotype and calcification of the adrenal glands.[3] This is likely to be the earliest description of Wolman disease. During the period of 1963 to 1968, additional variants similar to but more mild than Wolman disease were described by Fredrickson, Schiff, Langeron, and Infante and their colleagues.[4–7] These individuals ranged in age from childhood to the fourth decade with hepatomegaly and increased levels of cholesteryl esters in the liver. The intestinal biopsy abnormalities in two such patients were described by Partin and Schubert; they coined the term cholesteryl ester storage disease (CESD).[8]

These two disorders represent a continuum of disease severity and are due to mutations in the locus for lysosomal acid lipase (LAL), an enzyme essential to the degradation of cholesteryl esters and triglycerides that arrive in the lysosome by receptor-mediated endocytosis. These allelic variants of LAL deficiency are termed Wolman disease and CESD. Because of the apparent rarity of the disorders, the full clinical spectra have yet to be fully described. These disorders represent a continuum of disease from the most severe variants, termed Wolman diseases, to progressively less severe involvement in CESD (Figure 55.9-1). The complete clinical spectrum, biochemistry, and pathophysiology have yet to be elucidated, although the availability of animal models should provide additional insight into the disease development and progression.[9,10] The work of Horton, Brown, and Goldstein and their colleagues has made clear the central role that LAL plays in intracellular cholesterol and lipid metabolism.[11–13] The disruption of intracellular lipid regulation leads to severe global metabolic derangements and lipodystrophy.[14]

CLINICAL/PATHOLOGIC PRESENTATION OF WOLMAN DISEASE AND CHOLESTERYL ESTER STORAGE DISEASE

Wolman Disease

The clinical course of Wolman disease has remarkable uniformity. Patients present within the first month of life with vomiting and diarrhea, hepatosplenomegaly, abdominal distention, and inanition with pyrexia and severe failure to thrive. This clinical course perpetuates itself in a downhill spiral to death by age 3 to 7 months.[15] An occasional patient survives beyond 1 year depending on the supportive medical interventions.

The first overt sign is protracted and persistent vomiting associated with abdominal distention. This occurs within

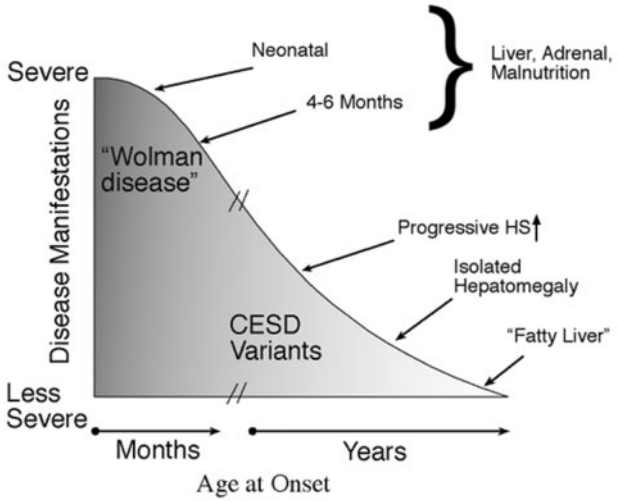

FIGURE 55.9-1 Schematic diagram of a continuum of lysosomal acid lipase deficiency states. Early-onset variants have manifestations in the first few days to weeks of postnatal life and by 4 to 6 months display characteristics of Wolman disease, including hepatosplenomegaly, adrenal enlargement and calcifications, and malnutrition. Variants with components of these signs occur from 1 to 12 years of age, and patients with cholesteryl ester storage disease (CESD), adrenal calcification, and pulmonary hypertension have been reported. At advanced ages, the only manifestation of poorly characterized "fatty liver" may represent late-onset CESD.

the first weeks of life and is accompanied by watery diarrhea, jaundice (occasionally), and low-grade fever. These are intractable to medical interventions or changes in diet and lead to severe weight loss, cachexia, and malnutrition.[1,16,17] Physical examination reveals hepatosplenomegaly with predominant liver enlargement. Enlargement of these organs can occur very soon after birth and has been noted as early as 4 days of age.[18] The first indication of Wolman disease is the abdominal radiograph showing massive enlargement and calcification of the adrenal glands.[16] The adrenal glands have punctate calcification throughout their parenchyma, are symmetrically and massively enlarged, and retain their normal shapes (Figure 55.9-2). Although not well delineated in published reports, these children also manifest adrenal cortical insufficiency (W. Krivit, personal communication, 2003).[18] Analyses of the abdomen by magnetic resonance imaging, computed tomography, or radiography also disclose massively enlarged liver and spleen with lymph node hypertrophy.[19] The latter can include the tonsils and adenoids that may be enlarged sufficiently to cause obstruction.

No specific signs or symptoms are referable to the central nervous system.[15] General deterioration is noted, with the progressive malnutrition and inanition that these children experience.[18,20] However, seizure, convulsions, and paralysis are reported occasionally in Wolman disease. These few central nervous system abnormalities are not primarily related to Wolman disease but rather are related to the malnutrition and specific nutritional deficiencies because of the severe malabsorption (see below).

No specific routine blood chemical abnormalities are present in Wolman disease patients. Anemia, abnormal liver function studies, or other chemical abnormalities referable to severe malnutrition can be present. Malabsorption of fats and other food stuffs has been documented. Specifically, triolein malabsorption is present.[20] This correlates with the infiltration of the jejunum with lipid-laden macrophages (see below). Indeed, intestinal damage may be so severe as to prevent enteral nutrition, and parenteral supplementation should be considered.[21] Because of the adrenal calcification, it is not surprising that patients have adrenocortical insufficiency and require supplementation.[16]

Wolman disease should be considered in the differential diagnosis of any child presenting with persistent vomiting or diarrhea, failure to thrive, hepatosplenomegaly, and malabsorption within the first month of life. The presence of enlarged calcified adrenal glands should be an immediate clue to the diagnosis of Wolman disease.

Cholesteryl Ester Storage Disease

In comparison with Wolman disease, CESD is a more variable and poorly delineated clinical syndrome. Although CESD is thought to be quite rare, this is an underestimate because of poor disease recognition. The clinical spectrum ranges from children diagnosed at age 3 to 4 years to adults in the fifth to sixth decade who present with variable manifestations but including isolated hepatomegaly.[22] The clinical course and progression of CESD in young children have been poorly documented. The relationship between apparent involvement early in life and the potential for significant progression to severe disease later in life remains to be elucidated. Importantly, the fulminant course is poorly documented and includes development of cirrhosis, pulmonary hypertension, onset of adrenal calcifications in adolescence, and failure to thrive.[23–25] In comparison, other patients may have a much more indolent course, with slow progression throughout their lifetimes. Except for mild hepatomegaly, these patients may go undiagnosed throughout their lives. The number of such patients and lack of follow-up information severely limit the ability of physicians to provide accurate information on disease progression to involved families.

Clearly, only the most severely involved patients are usually reported in the literature. This skews the perception of patients and physicians as to the degree of severity and progression of this disease. In particular, the presence of hepatic fibrosis may not be associated with progression to nodular cirrhosis, although both have been reported. Furthermore, the degree of variation within subpopulations

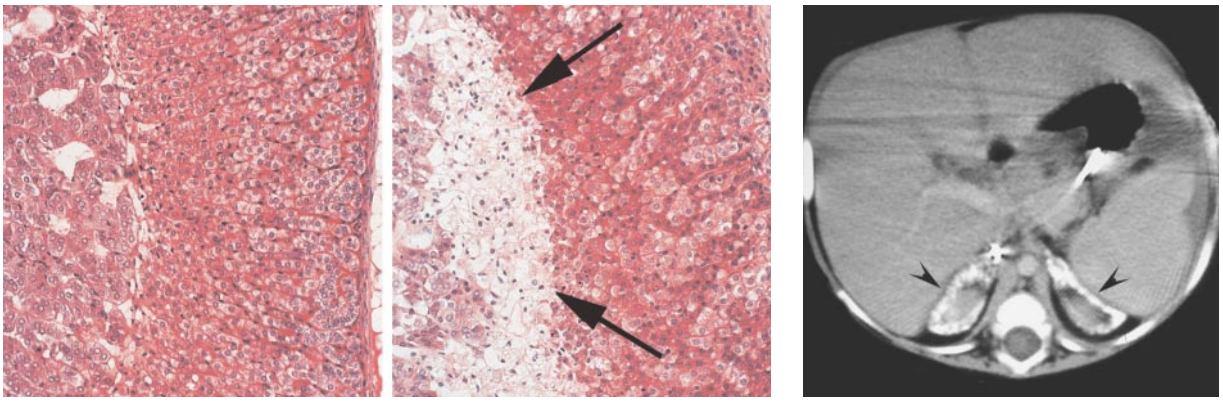

FIGURE 55.9-2 Histology and computed tomographic (CT) scan of abdomen. The zona reticularis of the lysosomal acid lipase (LAL)-deficient adrenal gland (*right*) becomes infiltrated with lipid-laden cells (*arrows*) containing birefringent material under polarized light. Normal adrenal gland is shown on the left. These are from the LAL-deficient mouse at age 4 months. The *arrows* show the calcific deposits in very enlarged adrenal glands in a human patient with Wolman's disease. The adrenal outlines are symmetric, as is the calcification. The CT scan is courtesy of William Krivit, MD, PhD.

may be significant and may or may not relate to the types of mutations that are present in these patients (see below).

Except for some hepatomegaly, there may be no specific abnormality leading the physician to the diagnosis. Specifically, malabsorption, malnutrition, and cachexia have not been reported as consistent components of CESD. Acute or chronic liver failure has occurred, as have progressive fibrosis and cirrhosis with varices.[23,24] Pulmonary hypertension has been described in one patient, but its relationship specifically to CESD is unknown.[24]

Hyperlipidemia may be the most consistent chemical abnormality in CESD patients. Some patients manifest a type IIb hyperlipoproteinemia profile, whereas others do not. Although CESD patients may have intestinal abnormalities on biopsy, abdominal pain and other indications of malabsorption, or cholelithiasis, have not been present in reported patients. Secondary abnormalities of the coagulation system may be noted and may depend on the degree of hepatic dysfunction.

Clearly, the literature is skewed toward reports of more severe CESD patients, and the disease may be much more common than such reports would suggest. The disease should be suspected in patients with uncharacterized vacuolization of the liver, hepatic steatosis involving Kupffer cells, and hepatomegaly, uncharacterized hyperlipidemia, or type II-b hyperlipidemia. Isolated hepatomegaly early in life or isolated hepatosplenomegaly may be the only finding in CESD, and the differential diagnosis of these findings should include CESD.

PATHOLOGY OF WOLMAN DISEASE AND CESD

Liver Pathology

The liver in Wolman disease is characteristically enlarged (> twofold) and progressively increases in size during the life span of the affected infant. Grossly, the liver is yellow in color and greasy in appearance. This is very similar to that in the LAL-deficient mouse.[9] Early in the disease course, the portal and lobular architecture is normal. Later, distortion of the portal spaces occurs with development of fibrosis and, occasionally, frank cirrhosis. Lymphoid infiltration without hepatitis also can be present. Progressive hepatic fibrosis is associated with marked accumulation of a mixture of triglyceride and cholesteryl esters in the lysosomes of hepatocytes, in Kupffer cells, and in portal area macrophages that develop in clusters. The lipid in macrophages tends to be more finely vacuolated than that in hepatocytes. Appropriate lipid stains performed on unfixed frozen sections demonstrate cholesterol and triglyceride in hepatocytes and an admixture of more complex, partly insoluble lipid in the macrophages. Ultrastructural study reveals lipid accumulation, mostly in lysosomes, and increased ceroid-lipofuchsin bodies. The latter are more evident in the macrophages than in hepatocytes.

In CESD, the liver has a gross appearance that is similar to that in Wolman disease (Figure 55.9-3), except that the liver may be more orange and less greasy. Biopsy specimens have a bright orange-yellow color and tend to float in formalin. The hepatocytes contain cytoplasmic vacuoles of variable size that can resemble nonalcoholic steatosis with septal fibrosis (Figure 55.9-4, A and B). The Kupffer cells and portal area macrophages have finely vacuolated cytoplasm and tend to occur in clusters, as in Wolman disease. Acid phosphatase activity is abnormally high in hepatocytes (Figure 55.9-4C). Lipid stains demonstrate a mixture of neutral lipid, cholesterol, cholesteryl esters, and ceroid (Figure 55.9-4D). The cholesteryl ester content of liver tissue is much higher in CESD than in Wolman disease. Because the lipid in tissues is extracted during processing into paraffin or plastic, cholesteryl ester crystals can be demonstrated only in unfixed frozen sections viewed in polarized light (Figure 55.9-4E). However, electron microscopy reveals a high content of cholesterol clefts (crystal-shaped voids) mixed with other lipids in membrane-bound vesicles (Figure 55.9-4F), presumably lysosomes where esterified lipid crystals had existed prior to processing. Septal fibrosis, periportal lymphocytic infiltration, and occasional plasma cells can develop. Portal fibrosis (see Figure 55.9-4B) and cirrhosis occur, but the fibrogenic mechanism is unknown, and progressive liver disease is not established as an inevitable outcome. Foamy macrophages, similar to the Kupffer cells, occur in the spleen, bone marrow, and lymph nodes.

Adrenal Glands

In Wolman disease, the adrenal glands are two to three times normal weight (~ 13–15 g) and have a yellow color. Characteristically, the zona reticularis has broad infiltration by large vacuolated cells that are scattered in haphazard clumps throughout this zone. Areas of necrosis and calcification occur. The adrenal glands have not been well studied in CESD. The adrenal gland in the LAL-deficient mice is very similar to that in Wolman disease, but the massive enlargement and necrosis with calcification are not present (see Figure 55.9-2).

Small Intestine

Intestinal malabsorption, a primary feature of Wolman disease but not of CESD, is associated with severe infiltration of

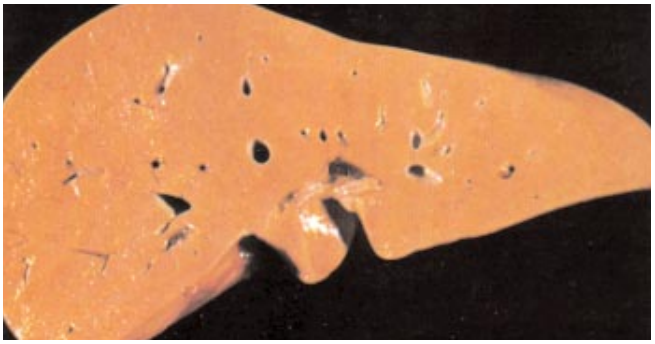

FIGURE 55.9-3 Cross-section of the liver in a patient with cholesteryl ester storage disease. The liver has an orange-yellow color that is immediately apparent on percutaneous or open liver biopsy. The color derives from the deposition of the major storage lipids and also carotene-like lipids (see CD-ROM for color image). Reproduced with permission from Dincsoy HP et al.[76]

the lamina propria by foamy lipid-laden macrophages, as well as accumulation of lipid in small intestinal epithelium. In contrast, Partin and Schubert reported that the proximal small intestinal epithelium of CESD is normal, the macrophages and the extracellular space of the lamina propria contain abundant lipids, including cholesteryl ester crystals, and macrophages at the tips of villi contain autofluorescent material, suggestive of ceroid-lipofuchsin.[8]

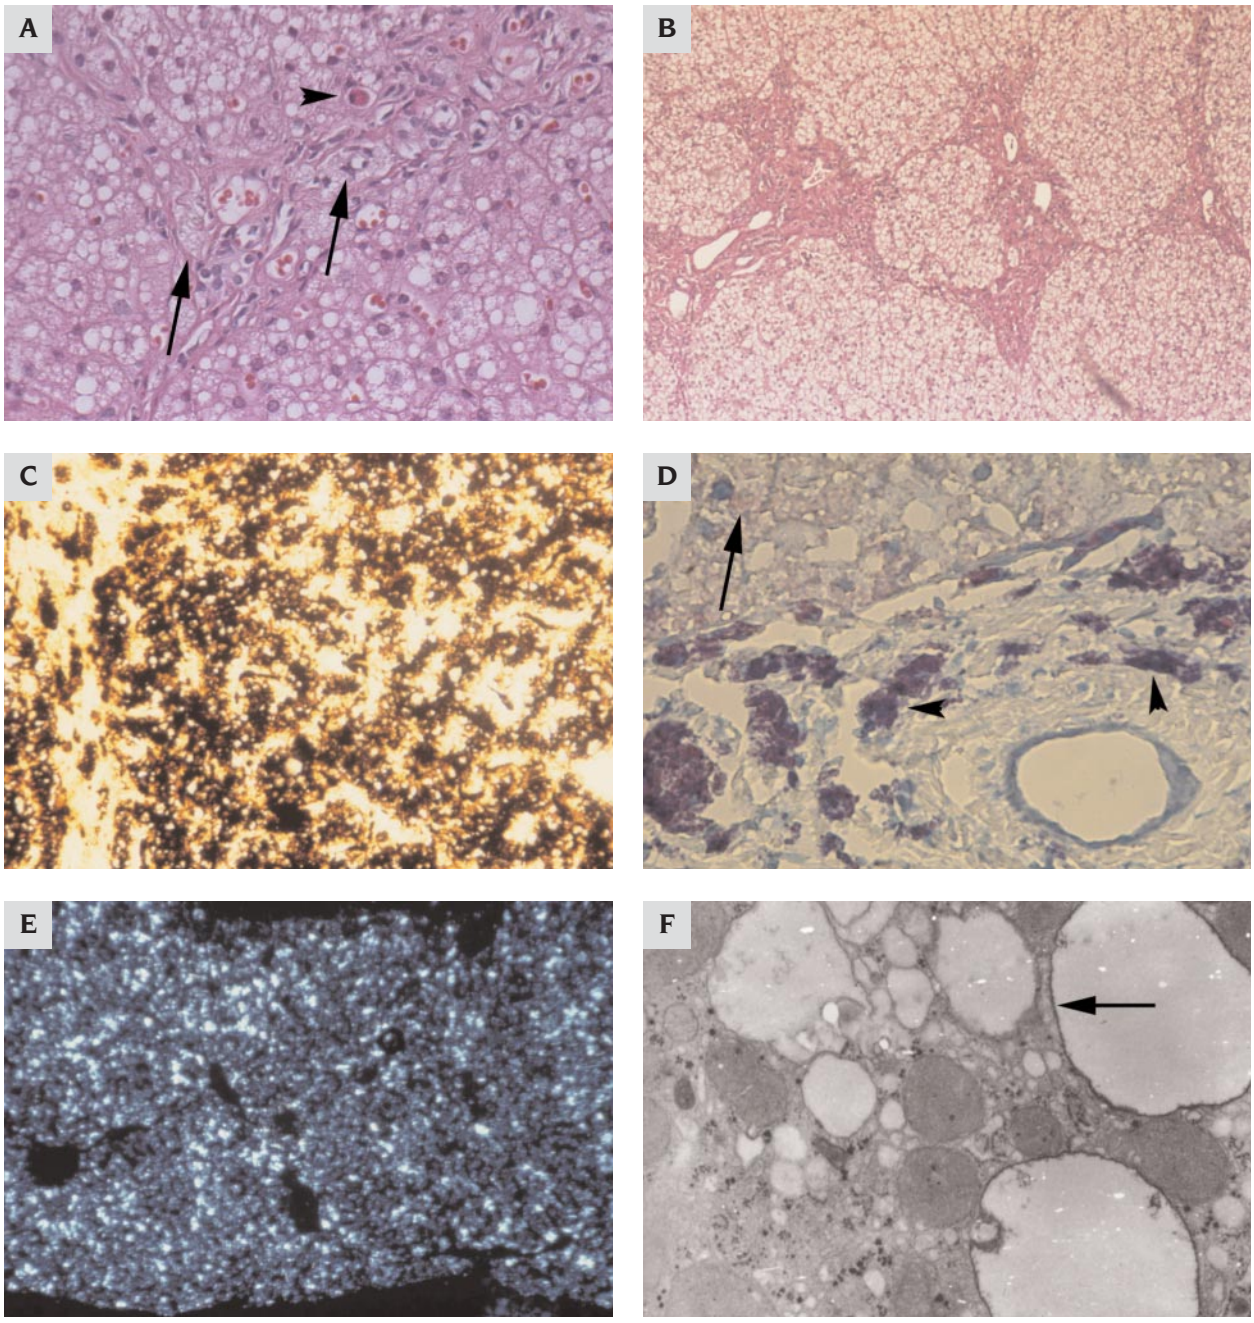

FIGURE 55.9-4 Histology and ultrastructure of the liver and small intestine in cholesteryl ester storage disease (CESD). *A*, Paraffin section of a liver biopsy in an adolescent with CESD. Hepatocyte cytoplasm is pale and vacuolated owing to lipid accumulation. Enlarged vacuolated cells in portal zone are macrophages (*arrows*). Occasional necrotic hepatocytes are present (*arrowhead*) (hematoxylin and eosin; x200 original magnification). *B*, Delicate septal fibrosis in liver from a child with CESD appears to originate in the portal zones without accompanying inflammation (hematoxylin and eosin; x200 original magnification). *C*, Acid phosphatase staining on unfixed cryostat section demonstrates massive increase of activity within hepatocytes in CESD (x200 original magnification). *D*, Nile blue sulfate lipid stain of unfixed cryostat section of liver in CESD demonstrates pale peach–colored neutral lipid in hepatocytes (*long arrow*) and dark blue-purple complex lipid mixture in portal area macrophages (*arrowheads*) (x200 original magnification) (see CD-ROM for color image). *E*, Unfixed unstained cryostat section of liver in CESD viewed in polarized light contains large numbers of anisotropic cholesteryl ester crystals. *F*, Liver cytoplasmic droplets in CESD have well-defined dense membranes (*arrow*), unlike usual hepatocyte lipid vesicles. This is consistent with the presumed lysosomal location of most of the lipid in CESD. Electron micrograph.

Liver, Adrenal Glands, Small Intestine, Spleen, and Other Tissues in Rodent Models of LAL Deficiency

Most published descriptions of Wolman disease are based on autopsy findings in infants, whereas most reports of CESD are based on clinical findings and study of biopsy tissue obtained during childhood and adulthood. The phenotypes are distinct in many ways, but overlapping phenotypes occur, and the concept of an incompletely defined spectrum is appealing (see Figure 55.9-1). The paucity of fully studied patients with Wolman disease or CESD limits the ability to define the morphology and natural history of these two closely related disorders. The two rodent models of LAL deficiency have provided insights into its pathogenesis and progression.[9,10] The most detailed descriptions are from the knockout mice with a complete deficiency of LAL in all tissues. These mice present with a phenotype that exhibits some of the manifestations of Wolman disease and CESD.[9,14] However, the calcification of the adrenal glands of Wolman disease and the hyperlipidemia of CESD are lacking. The mouse knockout model does not have progressive hepatic cirrhosis, although some fibrotic changes are present.

The mouse model provides insight into time-dependent changes in the hepatic disease. Specifically, the liver begins as a normal organ with relatively little change in hepatic weight or consistency in the first 2 to 4 weeks of life. During the second month, vacuolization and lipid storage of the hepatocytes become evident, as does the development of discrete areas of macrophages that are engorged with neutral lipids. Although the progression of hepatocellular storage may continue, the major pathologic abnormality from 2 to 8 months of life is the proliferation of Kupffer cells and portal macrophages that become engorged with cholesteryl esters and triglycerides. These cells can account for over 50% of the liver. The hepatomegaly is progressive and may reach 25% of body weight by 8 months of age, the life span of these mice. This progressive hepatomegaly is accompanied by macrophage storage cell infiltration in the spleen, small intestine, and lymph nodes throughout the body. Although the spleen has large numbers of storage cells, splenomegaly does not become as massive as that observed for the liver. Lymph nodes can be completely replaced by macrophage storage cells. Strikingly, macrophage infiltration of the villi of the jejunum is progressive (Figure 55.9-5). This extends progressively from the proximal to the distal small intestine so that the entire small intestine becomes infiltrated by these storage cells. The histopathology of the small intestine is nearly identical to that described by Partin and Schubert in the original human cases of CESD[8] and in the autopsy cases of Wolman disease.

Concomitant with the progression of hepatomegaly and storage cell infiltration throughout the body, LAL-deficient mice develop lipodystrophy leading to a complete loss of subcutaneous white fat and brown fat. By 6 months of age, essentially all white adipose tissue has disappeared: insulin resistance and low leptin levels develop simultaneously. The LAL-deficient mice are not hyperlipidemic, probably owing to malabsorption and massive redirection of lipids to liver Kupffer cells. This is reminiscent of the "triglyceride steal syndrome." The infiltration of the adrenal glands precisely mimics that in human Wolman disease, albeit without calcification. The zona reticularis is replaced progressively by storage cells (see Figure 55.9-5). The lungs have a few interstitial cells with vacuolization but no specific abnormalities. No gross behavioral or histologic abnormalities have been noted in the central nervous system.

This mouse model indicates that the complete absence of LAL leads to a macrophage and hepatocellular disease with macrophage proliferation and storage of cholesteryl esters and triglycerides as the primary pathologic abnormality. This leads to malabsorption and malnutrition, hepatic dysfunction, and infiltration of the adrenal cortex. The absence of significant fibrosis and/or cirrhosis in the mouse model suggests that either this is not a major or consistent component of the human disease or that mice simply do not survive long enough to develop reactions to the stored lipid in the macrophages.

In addition, mice do not develop the "premature arthrosclerosis" that has been described in human CESD. Thus, the mouse model more closely resembles the human Wolman disease model, with normal to subnormal plasma lipids. In the absence of hyperlipidemia, potentially caused by malabsorption, arteriosclerosis may not develop. If the LAL deficiency is placed against the background of an apolipoprotein E deficiency, a spontaneous atherogenic model in the mouse, doubly homozygous mice for apolipoprotein E and LAL deficiency have much more rapidly progressive lesions with apolipoprotein E deficiency alone.[26] Thus, the premature arteriosclerosis in the CESD may be accentuated by the presence of dietary or other genetic abnormalities in some patients, leading to hyperlipoproteinemia and progression of arteriosclerosis.

BIOCHEMICAL PATHOLOGY OF LAL DEFICIENCY

Lipoprotein and Lipid Abnormalities

Plasma triglyceride and cholesterol levels are usually normal in Wolman disease. Three cases showed elevated

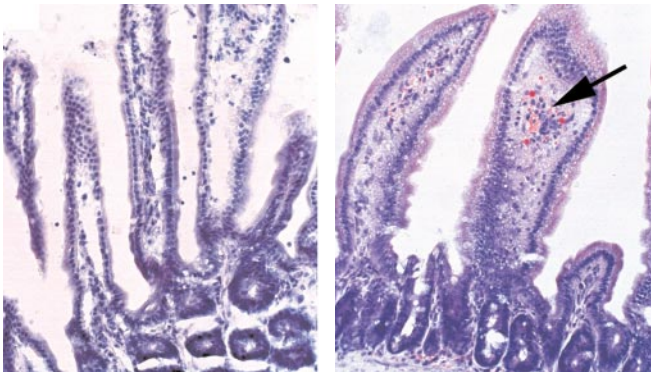

FIGURE 55.9-5 Small intestine in lysosomal acid lipase deficiency. The small intestinal villi become infiltrated with lipid-laden macrophages that contain cholesteryl esters and triglycerides. Normal and lysosomal acid lipase–deficient samples are on the left and right, respectively. The arrow shows oil red O–positive macrophages (see CD-ROM for color image).

triglycerides and very-low-density lipoprotein (LDL) cholesterol,[17,27] whereas plasma high-density lipoprotein (HDL) was decreased in others.[27–29] In comparison, CESD patients usually have hypercholesterolemia with increases of very LDL and LDL cholesterol levels. The plasma HDL in some CESD patients can be less than the 5th percentile (ie, < 20 mg/dL). In some other cases, the ratio of HDL_2-cholesterol to HDL_3 cholesterol was reversed (10:1) compared with the normal ratio (1:10).[30]

Patients with Wolman disease accumulate cholesteryl esters and triglycerides in the liver, spleen, small intestine, and adrenal glands. Compared with normal levels, the triglyceride concentrations can be 2- to 10-fold increased in the liver and 8- to 100-fold increased in the spleen. Quantitative analyses are not available for the patient's small intestine, but gross and histologic observations of the intestine from Wolman disease and CESD patients show accumulation of these lipids.[31] The mouse model of LAL deficiency showed total cholesterol increases of 43-fold in the liver, 27-fold in the spleen, and 2.5-fold in the small intestine by 8 months of age.[14]

All patients with Wolman disease have increased total cholesterol levels in the liver (~ 5- to 160-fold), spleen, small intestine, and adrenal glands (8-fold).[32] More than 98% of the accumulated total cholesterol are cholesteryl esters.[9] The fatty acid content of liver and spleen also can be increased, whereas the phospholipid and glycolipid contents are not, even at 8 months of age.[33,34]

In cases of CESD, triglyceride and cholesteryl esters were elevated in the liver. The cholesteryl ester storage in liver can be 120- to 350-fold higher than normal. Triglyceride levels have minor increases. Inconsistently elevated values were in spleen, small intestine, kidney, and lung. Analysis of acyl groups in the cholesteryl esters in the liver and small intestine of CESD patients revealed predominantly oleic and linoleic acids.[29,35–37]

INTRACELLULAR DERANGEMENTS IN LAL DEFICIENCY

LAL plays a central role in the modulation of cholesterol metabolism in all cells. The LDL receptor or other receptors on the plasma membranes of various cells can deliver LDL-bound cholesteryl esters and triglycerides to the lysosomes. Once delivered to the lysosome, the released cholesteryl esters and triglycerides are cleaved by LAL to free cholesterol and fatty acids. After LAL cleaves these lipids, they exit the lysosome and enter the cytosol. Normally, cholesterol will interact with the sterol response element binding protein system to modulate the intracellular production of cholesterol (Figure 55.9-6).[11] This system, elucidated by Goldstein and Brown over the past three decades, is a major component of modulation of neutral lipid metabolism in the body.[11] In LAL deficiency, cholesteryl esters and triglycerides cannot be cleaved; therefore, free cholesterol and fatty acids cannot leave the lysosome.[12,38] The cells detect an intracellular (cytosolic) cholesterol deficiency, and the cholesterol biosynthetic pathway is up-regulated to compensate. The increased production of cholesterol leads to enhanced esterification of cholesterol via the cytoplasmic enzyme acyl CoA:cholesterol acyltransferase and enhances the synthesis of very LDL to export the synthesized cholesterol. Similarly, the lack of fatty acid egress from the lysosome leads to up-regulation of a series of other biosynthetic fatty acid enzymes with enhanced fatty acid synthesis. The details of this fatty acid synthetic pathway are not fully elucidated, but the control of this pathway from lysosomally derived free fatty acids appears clear.[11]

The up-regulation of these systems in LAL deficiency has led to the use of statins for the treatment of hypercholesterolemia in CESD.[39] Apolipoprotein B synthesis and the plasma lipid abnormalities are partially corrected by statins, but this may be transient. Statins may be important for the therapy of CESD in the prevention of secondary disease but do not theoretically or practically have a major effect on the lipid accumulation in the lysosomes of various tissues, although re-esterification and the pathway should be diminished.

LAL PROPERTIES

LAL is a typical lysosomal hydrolase that is synthesized in the rough endoplasmic reticulum and is cotranslationally glycosylated as it emerges into the endoplasmic reticulum lumen.[38,40] Following clipping of the leader sequence, the enzyme is modified during transit through the Golgi apparatus but without further proteolytic modification. The oligosaccharides are remodeled to attach the mannose 6-phosphate targeting signal for lysosomal sorting. The newly synthesized LAL is delivered to the lysosome by the mannose 6-phosphate receptor system. LAL is not known to require cofactors for optimal hydrolysis, and it functions as a monomer. LAL has significant similarity to other acidic lipases, for example, hepatic or gastric lipases that cleave similar substrates in the hepatocyte cytosol or stomach, respectively. Because the isolation of LAL from natural tissues has been difficult, purified LAL has been characterized using recombinant expression systems.[41] The enzyme can be produced in large quantities from appropriately designed genetic sequences from humans using insect cells, Chinese hamster ovary cells, *Pichia pastoris* and *Pombe* yeasts, and other heterologous expression systems (G. A. Grabowski and H. Du, unpublished data, 2003).[42–44] As indicated above, LAL has significant homology to other acid lipases but is clearly distinct from hormone-sensitive lipase, pancreatic lysophospholipid lipase, lecithin cholesterol acyl transferase, lipoprotein lipase, hepatic lipase, and pancreatic lipase. A significant homology exists with a shared amino acid motif, –Gly-X-Ser-X-Gly, that is common to most lipases and is an essential pentapeptide in the active site.[43,45] This pentapeptide occurs twice in LAL, and serine 153 appears to be important to catalytic activity. Several other polymorphic variants of LAL have been described, and their physiologic significance and importance are under investigation.[46]

Recombinant heterologous expression and characterization of purified human LAL have proven that the triglyceridase and cholesteryl esterase activities are present in

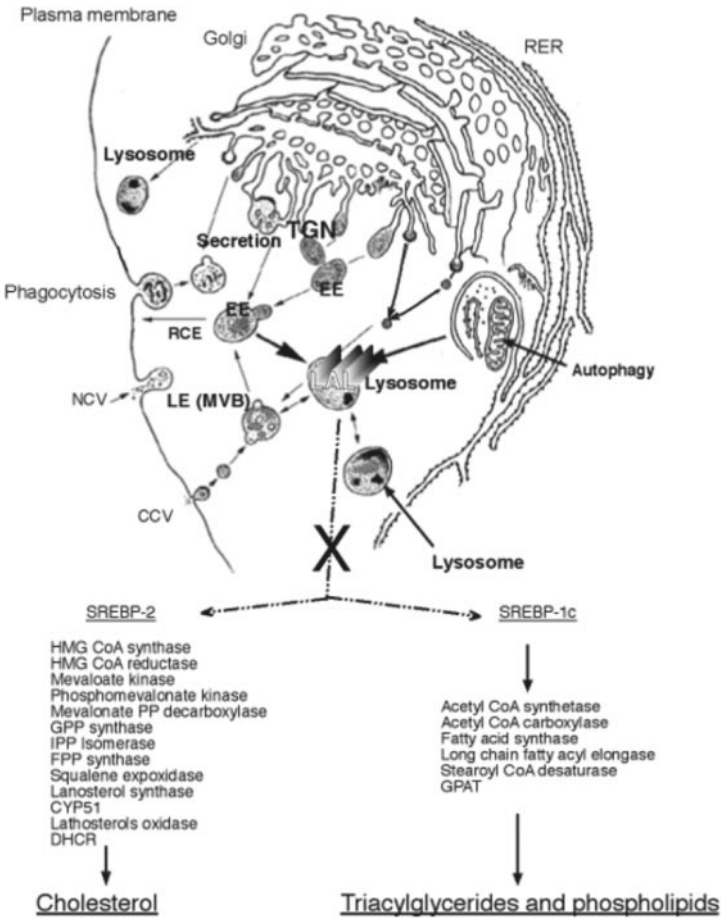

FIGURE 55.9-6 Schematic of the lysosomal acid lipase (LAL) system and its connection to cellular cholesterol and fatty acid metabolism. There are several types of lysosomes within cells that can contain different substrates and/or storage materials. Material can enter the lysosome from the surface, by autophagy of intracellular organelles, and after transit through the Golgi apparatus. LAL is synthesized in the rough endoplasmic reticulum (RER) and is post-translationally modified (oligosaccharides) and targeted to the lysosome following passage through the trans-Golgi network (TGN). CCV = clatherin CV; CV = coated vesicle; EE and LE = early and late endosomes, respectively; MVB = multivesicular body; NCV = nonclatherin CV; RCE = recycled coated endosome. The egress of cholesterol or fatty acids from the lysosome feeds back to the cytoplasmic, plasma membrane, ER-controlled SREBP systems for altering translation of specific enzymes leading to the synthesis of cholesterol and/or triacylglycerides and phospholipids.

the same polypeptide sequence.[44] This also is evident from the LAL knockout mouse. More importantly, serine 153 appears to be critical to the catalytic function for both substrates.[44] Thus, the deficiencies and abnormalities of LAL in Wolman disease and CESD must be explained by a single enzyme deficiency.

How can one explain the massive accumulation of cholesteryl esters and triglycerides in Wolman disease and just cholesteryl esters in the tissues from CESD patients? From mutagenesis data, the following appears clear: complete deficiency of LAL leads to Wolman disease with subsequent accumulation of cholesteryl esters and triglycerides. Diacylglycerides and monoacylglycerides also accumulate in smaller amounts because these are also LAL substrates. The catalytic activity of human LAL has a significant preference for tri-, di-, and monoacylglyceride substrates compared with cholesteryl esters.[44] The presence of apparently small amounts of normal LAL in tissues from CESD patients may provide an explanation for the variant phenotypes. A recurrent mutation in CESD leads to abnormal splicing and production of nearly normal amounts of a LAL messenger ribonucleic acid (RNA). But the mutation allows for only ~ 1 to 3% normal levels of LAL messenger RNA in the tissues of CESD patients.[30,47–49] This small amount of LAL RNA allows for the production of low levels of normal LAL that may be sufficient to nearly normalize the preferential acylglycerol substrate cleavage. However, this is insufficient to normalize metabolism of the less efficiently cleaved substrate, cholesteryl esters with their resultant accumulation in various cells. This indicates that large amounts of enzyme are not required for normalization and that low levels of LAL activity may be sufficient for prolonged survival with minor manifestations of disease.[50] LAL deficiency is very similar to other lysosomal hydrolase deficiency disorders in which small amounts of residual activity can normalize the flux of substrates through the lysosome. Higher thresholds of enzymatic activity are consistent with later-onset mild disease and, potentially, normalcy.

GENETICS AND MOLECULAR BIOLOGY

Wolman disease and CESD result from allelic mutations at the LAL locus on human chromosome 10q23.2–q23.3. The gene spans 45 kb, has 10 exons (Figure 55.9-7), and contains no unusual structures except for a large intron 3. The mutations found in Wolman disease and CESD are listed in Table 55.9-1 and represent patients from a variety of nationalities. A curious finding is the presence of mutations in intron 8 that result in abnormal splicing in either Wolman disease or CESD. This abnormal splice could eliminate intron 8 as owing to a splice junction abnormality. However, the location of the base change, either one or three bases following this donor slice, appears to affect the ability of the cell to produce normal LAL messenger RNA. The recurrent mutation in Wolman disease is a base substitution in exon 8 either one or three bases prior to the

intron 8 splice donor site. These appear to be incompatible with normal splicing and lead to a deletion of exon 8. The resultant truncated unstable protein in Wolman disease has no LAL activity and is rapidly degraded. In comparison, the substitution of a base at the +1 position downstream from the spliced donor site has been found in several CESD patients. This leads to ~ 5% of normal LAL messenger RNA splicing and the production of low levels of normal LAL protein from this mutant allele. Most (95%) of the mutant RNA produces a deletion of exon 8 and a truncated protein. The major difference, then, between Wolman disease and CESD is the absence or presence, respectively, of small amounts of normal LAL in cells and, as indicated above, the preferential cleavage of triglycerides compared with cholesteryl ester.

The most common mutation, a deletion of 254-277_1, Δ254-277_1 allele, was screened for in a randomly selected population in northwestern Germany.[15] In a cohort of 1,887 people aged 20 to 70 years, the frequency of Δ254-277_1 was 0.0019, giving an estimated homozygosity frequency of 1 in 300,000 or approximately 260 cases of CESD in Germany. If such calculations apply to the US population, there would be about 1,000 homozygotes for CESD. These calculations suggest that the frequency may be high enough to entertain screening of hyperlipidemic patients, particularly those with a type II-b profile, for CESD. The frequency of Wolman disease has been estimated at < 1 in 500,000 live births.[51]

Diagnosis

The diagnosis of Wolman disease should be considered in any infant with persistent vomiting and hepatomegaly in the first month of life, with progressive failure to thrive, and/or with hepatosplenomegaly and malabsorption. A radiograph of the abdomen may reveal adrenal calcifications (see Figure 55.9-2). The presence of adrenal calcifications can be observed in other conditions, but most occur later in life or are asymmetric. Thus, symmetric adrenal calcifications in the first few months of life may be pathognomonic of Wolman disease. Other lysosomal storage disease presenting this early in life with hepatosplenomegaly and severe failure to thrive includes the Niemann-Pick A variant with severe central nervous system involvement and inanition owing to sphingomyelinase deficiency. The severe variants of Gaucher disease type 2 have their onset in the similar time frame but with lesser degrees of hepatosplenomegaly, no malabsorption or diarrhea, and a predominant finding of rapidly developing neurologic signs with bulbar involvement. Suspect cases should have peripheral blood leukocyte LAL activities measured. The isolated deficiency of LAL is diagnostic. Contributing and supporting evidence for the diagnosis includes massive involvement of Kupffer cells on liver biopsy with or without some fibrosis and cholesterol crystals in the liver. Bone marrow biopsy may also show foam storage cells. Importantly, hypercholesterolemia and hypertriglyceridemia are not components of Wolman disease. Once the diagnosis is made by LAL enzyme assay, LAL mutations can be determined, and these may be used in further family studies or for prenatal diagnostic testing.

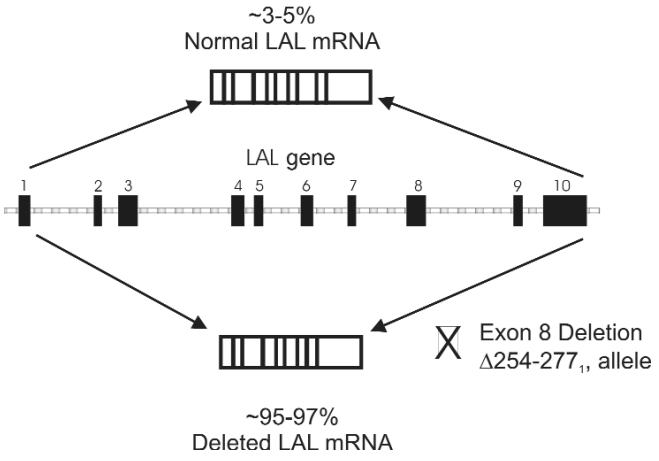

FIGURE 55.9-7 Schematic of the lysosomal acid lipase gene. The *LAL* is about 45 kb in size with 10 exons (*numbered rectangles*). Exons in the gene (*center*) are filled rectangles, and introns are represented by the thin horizontal rectangle. The spliced messenger ribonucleic acid (mRNA) is shown above and below to represent different mRNA products, resulting in a small amount of normal mRNA being formed. The majority of mutant mRNA leads to the splicing of exon 8 and a truncated translated protein.

CESD early in life must be considered in any child with hepatosplenomegaly and hyperlipidemia. CESD may be confused with glycogen storage disease (GSD) type IA or B because that disorder also presents with hepatomegaly and hypertriglyceridemia. Lactic acidosis can be a component of GSD IA or B but is not a component of CESD. Young children with CESD generally do not have failure to thrive but can have isolated hepatomegaly, prompting liver biopsy. The presence of engorged Kupffer cells with or without some fibrotic changes and cholesterol crystal deposition is highly suggestive. The CESD liver is distinguished from other lysosomal storage diseases, that is, Gaucher disease, Niemann-Pick A or B, and Pompe disease (GSD II), by its characteristic orange color and neutral lipid storage. GSD IA or B is not lysosomal, and glycogen storage predominates, not neutral fat. The diagnosis is made by isolated LAL deficiency in any nucleated cell. Peripheral white blood cells and cultured fibroblasts are the usual and most general sources for enzyme diagnosis. Thus, in the presence of hepatomegaly and hyperlipidemia, the diagnosis of CESD should be entertained in any child. On liver biopsy, the core may be orange in color, immediately suggesting the diagnosis.

In older children or adults, the findings are nonspecific. Mild hepatosplenomegaly or mild hepatomegaly with or without significant hyperlipidemia suggests the diagnosis of CESD. Characteristic liver biopsy findings and, occasionally, bone marrow biopsy findings should prompt LAL assays. The spectrum of the adult variants of CESD may be quite broad and include a large number of asymptomatic individuals. The diagnosis should be suspected in individuals with a type II-b hyperlipidemic pattern. LAL assays may obviate the need for liver biopsy for diagnosis. Mutation

CESD = cholesteryl ester storage disease; LAL = lysosomal acid lipase.
*The complementary deoxyribonucleic acid (cDNA) number is according to human LAL cDNA clone that was published by Anderson and Sando in 1991.[75]
†The amino acid (AA) number is from mature N-terminus, which is started from 22 aa from the first Met.

analysis in affected individuals may be helpful for family screening and additional diagnostic and correlative studies.

TREATMENT

Currently, there is no specific treatment for Wolman disease or CESD that is generally available. One patient with CESD had a liver transplant for chronic liver failure and was apparently well 2 years after the procedure,[52] but additional data have not been forthcoming. For Wolman disease, bone marrow or stem cell transplant has been attempted in several cases.[53,54] Because of the severity of the illness and the adrenal insufficiency, the mortality rate has been high. In one series, four of five patients succumbed to transplant complications. In the surviving patient, the bone marrow transplant appeared to be successful, with disappearance of storage macrophages in the liver, spleen, and, presumably, other tissues. The adrenal glands appear to atrophy following bone marrow transplant (W. Krivit, personal communication, 2003), and lifelong corticosteroid replacement therapy is necessary. Enzyme replacement and gene therapy studies have been conducted in the mouse knockout model with resolution of the hepatocellular and macrophage storage.[41,55] These remain investigational and provide proof of principle for the treatment of this disease. Currently, no clinical trials are ongoing for these modes of therapy. The approaches of enzyme replacement or gene therapy for enzyme replacement should be efficacious in both Wolman disease and CESD. Prenatal diagnosis is available for families who wish to exercise this option.

Supportive therapies for Wolman disease have been inadequate, and long-term therapies with intravenous alimentation have not been reported. Because enteral nutrition may be impossible owing to the severity of involvement of the gastrointestinal tract in Wolman disease, supportive parenteral nutrition may be the only option. In CESD, adjunctive therapy with statins or other suppressors of 3-hydroxy-3-methylglutaryl CoA reductase function has been useful in suppressing very LDL and LDL with subsequent lowering of plasma lipoprotein levels. This may lead to a decreased risk of heart disease. Statins have not been shown to prevent the development of progressive hepatocellular disease or adrenal insufficiency. Because of the intestinal involvement in CESD, studies for malabsorption should be undertaken, and supplementation with vitamins A, D, E, and K may be appropriate. Other supplements should be undertaken if malabsorption is present.

10. *Wilson Disease*

Ariel E. Feldstein, MD
Denesh K. Chitkara, MD
Randi Plescow, MD
Richard J. Grand, MD

Wilson disease is a rare autosomal recessive disorder of copper metabolism. S. A. Kinnear Wilson described the entity in 1912 and considered it to be a degenerative disorder of the central nervous system (CNS) associated with asymptomatic cirrhosis.[1] In 1921, Hall reported the hepatic symptoms and introduced the name "hepatolenticular degeneration."[2] It is generally accepted that the disorder is related to excessive accumulation of copper in the liver, CNS, kidneys, cornea, skeletal system, and other organs. The prevalence of the disorder is 1 in 30,000 persons worldwide, with a carrier frequency of 1 person in 90.[3] Wilson disease frequently presents in childhood, although the diagnosis may not be confirmed until adulthood. Early recognition of this disease and institution of appropriate therapy may be lifesaving.

PATHOPHYSIOLOGY

Wilson disease has been recognized as an entity for more than 80 years; the genetic defect has been identified, and the basic biochemical abnormalities are continuing to be elucidated. Wilson disease is a disorder of copper balance in which the biliary excretion of copper is inadequate, leading to excess accumulation in the other organs.[4] Copper is an essential trace element required in a number of enzyme systems. The main dietary sources of copper include liver, kidney, shellfish, chocolate, dried beans, peas, and unprocessed wheat. The average American diet includes 1.0 mg of copper per day.[5,6] Under normal circumstances, 50% of ingested copper is unabsorbed and lost in the feces[7] and 30% is lost through the skin.[8] A negligible amount normally is excreted in the urine. The remaining 20%, which is critically balanced for homeostasis, is normally excreted into the feces via bile.[4,5,9] Wilson disease is caused by the inability to excrete this remaining 0.2 mg of copper into bile; copper absorption from the gastrointestinal tract is normal. Studies measuring the peak copper concentration in blood after an oral dose of radiocopper have shown no difference between patients with Wilson disease and control patients.[7]

MOLECULAR GENETICS

Initial genetic linkage studies showed that the Wilson disease locus segregated with the red cell enzyme esterase D on chromosome 13.[10] Subsequent linkage analysis confined the disease locus proximally by the deoxyribonucleic acid (DNA) marker D13S31 and distally by the DNA marker D13S59.[11,12] Soon after it was confirmed that the Menkes disease gene (*MNK*) encoded a copper-binding P-type adenosine triphosphatase (ATPase) protein,[13–15] four independent groups identified the gene responsible for Wilson disease.[16–19] Three of these groups used the human Menkes disease gene as a probe,[16–18] whereas the fourth group used linkage disequilibrium and haplotype analysis.[19] The Wilson disease gene transcript encodes a transmembrane copper-transporting ATPase protein with a strong homology to the Menkes disease gene. The messenger ribonucleic acid for the Wilson disease gene is highly expressed in the liver, with limited expression in other tissues. The strong homology between the Wilson disease gene and the Menkes disease gene is interesting considering the different clinical manifestations of these two diseases. This can be better understood if both are considered to be disorders of ineffective intracellular transfer of copper.

The mechanism by which the Wilson protein, ATPase 7B, participates in copper metabolism is beginning to be understood (Figure 55.10-1). Dietary copper is absorbed in the upper intestine, where it binds to the proteins, albumin, copper histidine, and transcuprein.[20] Most of the copper is transported to the liver via the portal system and enters the hepatocyte, possibly by the cell surface transporter human copper transporter 1.[21] Once inside the hepatocyte, copper is transported by "copper chaperones," which traffic the metal within the cytoplasm. The identified copper chaperone in humans, known as human ATX homologue 1 (HAH1), functions as both a regulator of copper homeostasis and an antioxidant.[22,23] HAH1 transports copper to the Wilson ATPase 7B, which is located in the *trans*-Golgi network and, under basal conditions, also facilitates transfer of copper into ceruloplasmin.[24,25] However, an increase in cellular copper concentration has been shown to cause movement of the ATPase 7B protein to a cytoplasmic vesicle by a mechanism that appears to be reversible and independent of new protein synthesis.[24] This vesicle is hypothesized to be one of the mechanisms by which copper normally leaves the hepatocyte. Interestingly, ATPase 7B has also been found in the hepatocyte membrane and may represent a direct route to transport copper through the canalicular membrane.[25] Mutations in the ATPase 7B protein represent

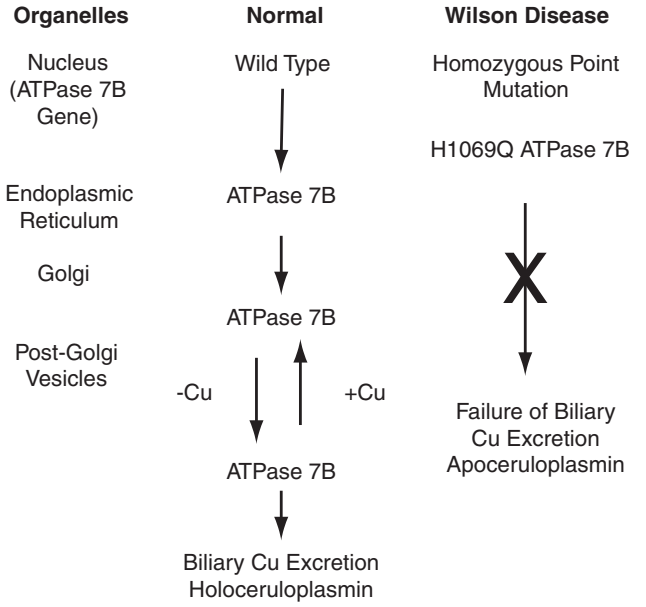

FIGURE 55.10-1 Molecular defect in Wilson disease. Under normal conditions, adenosine triphosphatase (ATPase) 7B is a transmembrane protein that traffics from the endoplasmic reticulum to the Golgi apparatus, where it is localized under basal conditions. ATPase 7B is responsible for the movement of copper into the Golgi, where ceruloplasmin probably acquires its copper. When copper is abundant, ATPase 7B traffics to a post-Golgi compartment, where it delivers copper to biliary excretory pathways that are thought to involve transfer to lysosomes and then to bile by a canalicular membrane transporter. In Wilson disease, the mutant protein fails to leave the endoplasmic reticulum and therefore is unable to transfer copper in the Golgi or facilitate copper excretion in bile. Reproduced with permission of Lippincott, Williams and Wilkins from Schilsky M. Inherited metabolic disease. Curr Opin Gastroenterol 1999;15:200–7.

the molecular basis of Wilson disease and are thought to cause a disruption in the transport of copper from the hepatocyte. Greater than 60 disease-specific mutations already have been identified[16,18,26] that make genetic screening of Wilson disease challenging. The most common mutation of the Wilson disease gene, His 1069 Glu (*H1069Q*), represents 30 to 60% of the Wilson disease alleles in North American, Austrian, Russian, and Swedish samples.[26,27] Two mutations not yet described in European samples have been found in Japanese children: 2874 del C in exon 13 and Arg 778 Leu in exon 8.[28]

The ability to study Wilson disease is enhanced with the recent identification of the Long-Evans cinnamon rat as an animal model.[29] This model has been used to demonstrate correction of the defect using complementation with a wild-type ATPase 7B complementary DNA incorporated into a recombinant adenovirus.[30] Under these conditions, ceruloplasmin synthesis was restored as well.

Much attention also has been given to the role that ceruloplasmin may play in the pathogenesis of disease. Ceruloplasmin is a blue-colored, α-globulin with a molecular mass of 132 kD. The gene for ceruloplasmin is on chromosome 3. It is produced exclusively in the liver, but its role in copper metabolism is unknown; it may function in iron transport.[20] Typically, patients with Wilson disease have low serum levels of ceruloplasmin. However, 5 to 25% of patients with Wilson disease have normal levels.[31] At times, this is secondary to an acute-phase response associated with active liver disease, but approximately 10% of patients have unexplainably normal values. Low values may be found in some heterozygotes who have no manifestations of the disease.[32]

The cause of the decreased and the occasional normal values of ceruloplasmin in Wilson disease is unknown, but available data do provide interesting clues. Both apoceruloplasmin and the number of atoms of copper per ceruloplasmin molecule are normal in Wilson disease, but the rate of holoceruloplasmin synthesis seems to be reduced.[3] Knowledge that Wilson disease results from a mutation of a copper transport protein is useful in explaining the variations observed in ceruloplasmin levels. Copper is incorporated during the biosynthesis of ceruloplasmin by transfer from the ATPase 7B located in the *trans*-Golgi network; ceruloplasmin is then secreted from the hepatocyte into the plasma.[33] Yet reduction of copper transport into excretory pathways still occurs, resulting in hepatic copper accumulation.[34] These mutations may also affect ATPase 7B interaction with copper chaperones or the excretion of copper across the canaliculus. In in vitro experiments, the *H1069Q* mutation appears to demonstrate an abnormal mechanism of protein folding that affects its ability to be expressed in the *trans*-Golgi network in the murine-mottled fibroblast cell line.[33]

The transfer of copper into the pathway for ceruloplasmin synthesis is altered by Wilson disease mutations, thereby causing decreased ceruloplasmin levels. Different mutations may alter copper transport to different degrees and at different cellular sites. Therefore, certain mutations may allow normal transport of copper for ceruloplasmin synthesis so that normal ceruloplasmin levels are maintained. Yet reduction of copper transport into excretory pathways still occurs, resulting in hepatic copper.

CLINICAL MANIFESTATIONS

The clinical manifestations of Wilson disease usually are related to hepatic or CNS involvement (Table 55.10-1). The presenting features are variable, and clinical disease is rarely present before patients reach 5 years of age. Most of the manifestations are related to deposition of copper in specific organs. In the series of Scheinberg and Sternlieb, the initial clinical manifestations were hepatic in 42% of patients, neurologic in 34%, psychiatric in 10%, hematologic or endocrinologic in 12%, and renal in 1% (Table 55.10-2). Approximately 25% of patients have more than one organ involved.[3] Of 50 cases reviewed by Walshe, 31 cases had hepatic and 17 had neurologic presentations.[35] In the pediatric age group, it is common for the hepatic manifestations to precede the neurologic manifestations by many years.

HEPATIC MANIFESTATIONS

Manifestations of liver disease are greatly varied. Wilson disease may present as acute self-limited hepatitis; full

recovery may appear to occur, in which case, the patient is thought to have had a viral hepatitis. Many months or years may elapse before the patient again has evidence of liver disease. Patients, especially younger ones, may come to medical attention because of fulminant hepatic failure with jaundice, hypoalbuminemia, coagulation defects, ascites, hepatic encephalopathy, and, frequently, hemolysis.[36–38] Large amounts of copper are released by the liver, resulting in high serum copper levels associated with hemolytic anemia. Without a family history of hepatic or neurologic conditions, or Wilson disease itself, it is difficult to distinguish fulminant Wilson disease from fulminant hepatic failure of another cause. Patients with fulminant Wilson disease have a particularly poor outcome even if the diagnosis of Wilson disease is made. Interestingly, in one series, 16 of 21 patients with fulminant Wilson disease were female.[39] This observation of a female predominance for fulminant Wilson disease has been confirmed by others and is hypothesized to be due to the influence of sex hormones. Children and adolescents may also present with clinical features of chronic liver failure and cirrhosis with ascites, edema, hypoalbuminemia, and evidence of portal hypertension. These patients may be jaundiced. In contrast to other causes of cirrhosis, few reported cases exist of hepatocellular carcinoma evolving from Wilson disease.[40] Young patients also may come to medical attention with a clinical and histologic picture similar to that of chronic hepatitis. The presenting symptoms and signs range from elevations in liver-derived serum enzymes to symptoms resulting from complications of portal hypertension or liver failure. In such patients, neurologic dysfunction and Kayser-Fleischer (KF) rings may not be found[31,41] and the serum ceruloplasmin level may be normal,[31] adding to the difficulty in diagnosis.

CNS Involvement

When Wilson initially described hepatolenticular degeneration, he thought that the CNS damage was limited to the basal ganglia, especially the putamen.[1] CNS involvement is now known to be more extensive, and a wide spectrum of neurologic findings ensues. Neurologic manifestations have been reported to occur as early as 6 years of age,[3] but more typically they begin in the second to third decade of life and are usually associated with the presence of KF rings. Reports of Wilson disease without KF rings illustrate that this diagnosis should be considered in patients who exhibit the typical neurologic manifestations without other signs of disease.[42] The onset of neurologic symptoms is gradual, and severity progresses without treatment. CNS damage in Wilson disease is limited almost exclusively to the motor system, with the sensory system being spared. Common first neurologic symptoms are tremor, incoordination, dystonia, and difficulty with fine motor tasks such as dressing and writing. Later, other manifestations such as mask-like facies, drooling, dysarthria, rigidity, and gait disturbances may become apparent. The patient often becomes highly frustrated because the intellect is unchanged. Older patients are frequently misdiagnosed as having a pure psychiatric disorder or neurologic disease, such as multiple sclerosis or a disorder of the basal ganglia.[43] In pediatric patients, the first neuropsychiatric symptom of Wilson disease may be deteriorating school performance.

Computed tomographic (CT) scan of the head may be helpful in making the diagnosis (Table 55.10-3). CT findings are more likely to be abnormal in patients with neurologic involvement but also may be abnormal in patients who are asymptomatic or have only hepatic involvement. In one study of 60 patients with Wilson disease, 73% had ventricular dilatation, 63% had cortical atrophy, 55% had brainstem atrophy, 45% had basal ganglia hypodensity, and 10% had posterior fossa atrophy; in 18%, the findings were normal.[44] Other studies have shown changes in the internal capsule, thalamus, and white matter.[44,45] The CT

abnormalities do not represent actual copper deposition because this would be expected to show as hyperdense areas. Rather, the changes are likely to result from the damage caused by copper deposition. The hypodense areas, along with areas of generalized atrophy, are fairly characteristic of Wilson disease.[44] The severity of the CT abnormalities does not correlate with clinical symptoms[46] and is also of little prognostic value because patients with extensive involvement often do well in response to therapy.[44] Magnetic resonance imaging (MRI) supports the abnormalities seen on CT scan and may be more sensitive in identifying abnormal regions.[43–47] The hypodense areas seen on CT scan appear as regions of increased intensity on MRI, suggesting that edema may produce the abnormality seen on CT scan.[48] In one report, high signal intensity was seen in the basal ganglia, with involvement in nearly all areas of gray and white matter with generalized atrophy. MRI has also identified abnormalities in the lentiform and dentate nuclei, substantia nigra, and vermis cerebelli.[49] Both positron emission tomography and MRI spectroscopy are beginning to be used to correlate the clinical manifestations with the gross findings in Wilson disease.[50]

Psychiatric Manifestations

Psychiatric manifestations may be dramatic in patients with Wilson disease. These include poor school performance, anxiety, depression, compulsive behavior, phobias, aggressive outbursts, neurosis, and even psychosis.[51,52] Affected patients frequently are labeled with erroneous psychiatric diagnoses before the correct diagnosis of Wilson disease is made. It is sometimes difficult to distinguish the behavioral symptoms resulting from excessive copper deposition from those secondary to the individual's reaction to having a chronic disease. This is particularly an issue in adolescent patients, and psychological intervention is often helpful.

Ophthalmologic Manifestations

Ophthalmologic manifestations of Wilson disease have received considerable attention because their presence may help lead to the diagnosis before any laboratory result is available. Kayser first described the "ring" in a patient thought to have multiple sclerosis,[53] and several years later, Fleischer reported an association of the ring with Wilson disease.[54] The KF ring may have a variable color, depending in part on the color of the iris. It has been described as a golden brown, brownish green, greenish yellow, bronze, or tannish green discoloration in the zone of Descemet membrane in the limbic region of the cornea (Figure 55.10-2). It can sometimes be seen with the naked eye, but a slit-lamp examination is mandatory. The rings consist of copper granules; however, they represent only a small fraction of the total corneal copper content. The bulk of copper deposition is in the stromal layer, but no color change is seen in any of the corneal layers except in Descemet membrane. Copper is initially taken up by the aqueous humor and diffuses into the cornea. Movement of water-soluble substances such as copper is a function of the evaporation of tears from the surface of the cornea. Evaporation is less at the superior poles and somewhat less at the inferior poles. Because the solvent flow is less in these areas, copper deposition is first seen there. Therefore, the rings first form superiorly and then inferiorly and finally extend laterally to complete the ring. Likewise, with treatment, the rings fade in the reverse order in which they appear.[55]

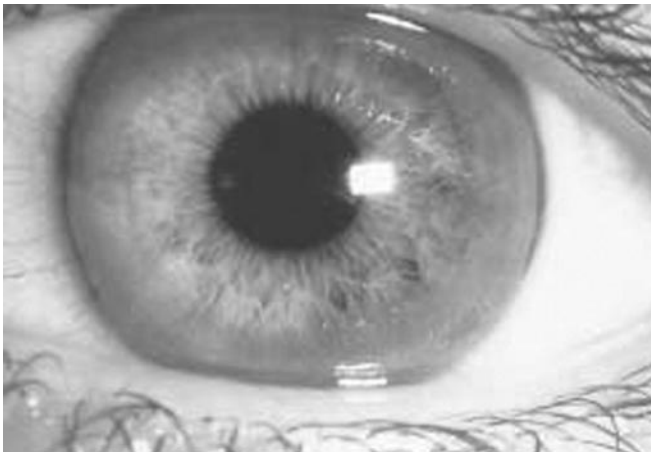

FIGURE 55.10-2 Appearance of the Kayser-Fleischer ring in a patient with Wilson disease. Note the deposition surrounding the limbus in this eye. With a darker iris, the ring may be observed only when using the slit lamp.

KF rings usually are present in patients with neurologic findings but frequently are present in those with only hepatic manifestations, as well as in some asymptomatic patients.[56] KF rings are not specific for Wilson disease. They have been seen in patients with chronic active hepatitis, primary biliary cirrhosis, and cryptogenic cirrhosis and in children with chronic intrahepatic cholestasis (Table 55.10-4).[55–61]

Sunflower cataracts are seen less frequently than KF rings and, when present, are accompanied by KF rings.[55] They can be seen with an ophthalmoscope as a greenish gray or golden disk in the anterior capsule of the lens, with spokes radiating toward the lens periphery.[61,62] Most of these cataracts resolve with therapy and will not affect vision.[55]

Cardiac Manifestations

Although Wilson disease is a multisystem disorder, few studies have evaluated the cardiac manifestations. One study of 53 patients showed electrocardiographic (ECG) abnormalities in 34%, including left ventricular hypertrophy, ST depression, T-wave inversion, premature ventricular contractions, sinoatrial block, and atrial fibrillation.[63] Thirteen percent of patients had arrhythmias, whereas 40 control patients of similar age all had normal ECG results. Of the patients with Wilson disease, 19% had mild asymp-

tomatic orthostatic hypotension. Response to a Valsalva maneuver (as a test for normal autonomic functioning) was abnormal in 6 of 18 patients with Wilson disease who were able to perform the maneuver.[63] Autopsy reports have shown cardiac hypertrophy, fibrosis, small vessel sclerosis, and myocardial inflammatory cell infiltrates, although gross abnormalities are not impressive. Pathologic findings did not correlate with myocardial copper content, which may be low or high. Several cases of sudden death are reported, presumably secondary to cardiac arrhythmia that may be related to Wilson disease.[64]

Renal Manifestations

Renal involvement is a widely recognized complication of Wilson disease. It is characterized by proximal tubular dysfunction as indicated by aminoaciduria, glycosuria, increased excretion of uric acid and calcium, and a decrease in filtration rate and effective renal blood flow.[65] There is an acidification defect that is likely a distal tubular dysfunction, in which patients are unable to acidify urine to a pH of less than 5.2 despite an acid load. Renal acidification defects can cause renal potassium wasting and recurrent hypokalemia.[66] Usually, however, patients are able to maintain normal or nearly normal plasma pH levels despite this renal tubular defect.[67–69] Renal stones are common and may predate the diagnosis of the disease. Hypercalciuria and inadequate acidification of urine may contribute to stone formation.[67] The histopathologic changes in renal biopsy specimens are not impressive. Membranoproliferative glomerulonephritis has been reported in association with Wilson disease but is more likely related to the presence of liver disease than Wilson disease itself.[70] Scheinberg and Sternlieb reported elevated copper concentrations in the kidney at autopsy in eight patients with untreated Wilson disease.[3] Rubeanic acid staining has demonstrated granules, presumed to be copper, within the tubular epithelium.[71] Renal function has been shown to improve with penicillamine therapy.[72]

Skeletal Manifestations

A variety of skeletal changes are observed in patients with Wilson disease. These include osteoporosis, rickets, osteomalacia, spontaneous fractures, osteochondritis dessicans, and osteoarthritis.[73] Bone demineralization is the most common abnormality seen. Renal defects causing hypercalciuria and hyperphosphaturia, with resultant hypocalcemia and hypophosphatemia, are the main cause of demineralization.[74,75] Other factors include dystonic contractures and immobilization. Chronic liver disease itself may cause skeletal abnormalities.[76] High levels of copper have been found in cartilage in some patients who underwent biopsy.[77] Pediatric patients rarely have significant skeletal changes on radiograph. Acute rhabdomyolysis has been reported as a presenting feature of Wilson disease.[78]

Other Manifestations

Hemolysis is a recognized complication of Wilson disease. It may precede other clinical manifestations of the disease and be short-lived or may progress to anemia and be the first recognized abnormality of the disease.[79] Hemolysis may occur secondary to an oxidative injury to red blood cell membranes from excess copper,[80] but the exact mechanism remains unknown.

As a consequence of hemolysis and cirrhosis, cholelithiasis may complicate Wilson disease. The stones are a mixed type, containing both cholesterol and pigment. Patients with Wilson disease should be examined for gallstones; likewise, in a child with gallstones, Wilson disease should be considered in the differential diagnosis.[81] Spontaneous splenic rupture has been reported as a presenting feature of Wilson disease.[82]

LIVER PATHOLOGY

The liver is the major organ for storage of copper. From more than 260 patients with Wilson disease analyzed by Scheinberg and Sternlieb, none of the liver specimens were normal; even a specimen from a 3.5-year-old boy was abnormal.[3] Cirrhosis has been seen in patients as young as 5 years of age.[83] Characteristic histologic findings are present but not pathognomonic. Fat deposition is one of the earliest changes seen in the liver biopsy specimen. Fine lipid droplets composed of triglycerides are dispersed throughout the cytoplasm.[3,84] As the disease progresses, these lipid droplets increase in size until hepatic steatosis is manifested. In early stages, electron microscopic study shows the mitochondria to be of varying shapes and sizes. The matrix density is increased, with vacuolated and crystalline inclusions. Inner and outer mitochondrial membranes, which are normally opposed, become separated, and the intercristal spaces expand. Peroxisomes, which are involved in cellular lipid metabolism, may become enlarged with a granular, flocculent matrix of varying density rather than with the homogeneous matrix seen in normal peroxisomes.[85] With progression of the hepatic lesion, there is collagen deposition and eventually development of fibrosis. Histologic features that are indistinguishable from those of autoimmune chronic hepatitis may develop, as well as hepatic necrosis (Figure 55.10-3).

If the diagnosis of Wilson disease is not made, and the patient survives, cirrhosis develops. Once cirrhosis is established, the fatty changes disappear, as do those changes seen in the mitochondria and peroxisomes. The electron microscopic findings are then relatively normal, except for excessive amorphous or globular copper-containing lipofuscin granules and lipid-containing lysosomes.[86]

A high copper content is found normally in the fetal and neonatal liver.[87] The cause is not known, but it is postulated that immaturity of bile excretion plays a role in this increased copper level.[88] Some of the copper binds to a sulfhydryl-rich protein, known as copper-associated or copper-binding protein, which is bound in hepatic lysosomes.[89] This lysosomal copper may be stained by orcein.[89] Between the third and sixth month postnatally, hepatic copper levels fall to within the normal adult range, and these orcein-positive granules are no longer seen in the normal liver. In children older than 6 months of age, orcein-positive granules indicative of elevated hepatic lysosomal copper are found only in abnormal conditions, including Wilson dis-
